Fig. 17 (a) Typically thin skin of patient with Ehlers–Danlos syndrome IV, showing prominent capillary and venous pattern with some venous varicosity. (b) Histological appearance of the thinned skin (R) shows collagen depletion and elastin proliferation compared with the control (L). (c, d) The facial phenotype is especially characteristic with large eyes, thin lips, and lobeless ears in the acrogeric arterial type. This is equally easily recognized in adults (1c) and babies (1d). (e) Hand radiographs often show a subtle acro-osteolysis (arrowed). (f, g) Transmission electron micrographs showing irregularity of a collagen fibril diameters in (f) skin and (g) arterial walls.

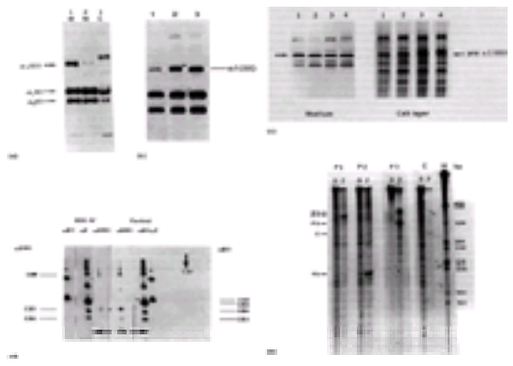

Fig. 18 (a) Typically poor secretion and intracellular retention of pepsinized collagen a1(III) chains in an Ehlers-Danlos syndrome IV mutant. Here the medium collagens (track 1) are diminished and an overmodified form is retained within the cell layer compared with the normal control in track 3. (b) Sometimes, instead of being poorly secreted (as in track 1) the mutant form is secreted as an a1(III) doublet (as in track 2) in which the secreted mutant product is starred; at other times (not shown) a normal and a shortened form of the protein are simultaneously secreted. (c) Overmodification of retained (cell layer) pro-a1(III) chains is variable (cell layer; tracks 2,3,4) according to the helical position of the mutation (the nearer the C terminus the greater the overmodification and the more retarded the band); the effect upon collagen secretion is remarkably similar (medium; tracks 2,3,4). (d) Two-dimensional electrophoresis of collagen a1(III) chains: in this instance there is an a1(III) CB5 doublet in the mutant (left hand) a1(III) track compared with the normal (right hand) sample; as expected, a1(I) and a2(I) tracks are identical. (e) Chemically cleaved cDNA/cDNA hybrids from positive mutant/wild-type standard (C) and three mutant/wild-type hybrids P1 –3. Under normal conditions the wild-type hybrids migrate at the top of the gel and are uncleaved. Those hybrids with mismatches will allow chemical cleavage at the point of incompatibility. In this instance, three different point mutations have been cleaved as has a small deletion (P3) of 27 bp, which produce two different-length cleavage fragments. The known positive control, glycine to aspartate 883, produces a faint but distinct cleaved fragment. The test mutant cleavages in P1 and P2 are at residue 910 in the case of P1, migrating later on the gel and smaller in the case of P2. Molecular-weight markers allow accurate estimations of fragment sizes.

Fig. 19 Diagrams of the distribution of currently known *COL3A1* mutations (Kuivaniemi *et al*. 1995; Pope *et al*. 1996): (a) point mutations; (b) splicing and deletion mutations.

Molecular analysis of the chondrodysplasias (see Table 1)

When this section was first drafted in 1991 very few *COL2A1* mutations had been identified and no other connective-tissue components had been implicated. Subsequent progress in the past 3 years has been exceptional: thus defects have been identified in other cartilage genes such as *COL5A2*, *–11A1*, and *–11A2* as well as potential defects in the *–9A1*, *–9A2*, and *–10A1* genes (see Table 1).

Several *COL2A1* mutations have been detected in disorders such as spondyloepiphyseal dysplasia, achondrogenesis, and familial osteoarthritis (Fig. 14). The patterns and mechanisms of mutation are again closely analogous to those that cause osteogenesis imperfecta and Ehlers–Danlos syndrome IV. Subsequently, mutations of other genes such as *COL9A1*, *–9A2*, *–11A1*, *–11A2*, *–5A2*, and other cartilage components have been observed in a variety of disorders.

Until 1991 only three mutations had been published (Fig. 14). The first was in a large family with an obviously abnormal type II collagen protein. Here Southern blotting of the proband's genomic DNA showed a 400-bp deletion in the 3.7-kb *Eco*R1 fragment next to the hypervariable region at the 3' end of *COL2A1* (Lee *et al*. 1988). This region coded for the last four exons (45–48) of the collagen II triple helix and all four exons (49–52) of the C-terminal propeptide. The investigators specifically used PCR amplification of this region. By consecutive amplification of exons 47–51, 47–52, 49–51, and 49–52 the deletion breakpoint was precisely located to exon 48. Sequencing confirmed a 390-bp deletion spanning the middle of intron 47 to the 5' splice-site of intron 48. This deleted all 108 bp of exon 48, consequently omitting 36 amino acids from the collagen II triple helix (residues 964–999). Such shortened molecules induce protein suicide just as in osteogenesis imperfecta and Ehlers–Danlos syndrome mutants (Prockop and Kivirriko 1984), and are abnormally retained intracellularly. As in the stoichiometry of collagen III homotrimers, only one-eighth of the collagen a1(II) chains can form normal, wild-type homotrimers that are correctly secreted. The remaining seven-eighths are intracellularly retained and/or degraded. Protein data from this patient are shown in Fig. 15.

The second early mutation lay very close to the first. Here the affected child was sporadic (Tiller *et al*. 1990). CNBr peptide mapping accurately mapped the mutation to the C-terminus and all peptides were consequently overmodified (Fig. 15(a)). The mutation lay between exons 45–52. (Fig. 15(b)). Amplification of exon 48 showed double fragments from the affected patient with normal/mutant heteroduplexes. Sequencing showed an intraexonic 45-bp (15 amino acid) duplication within exon 48. Anomalous homologous meiotic recombination had produced one allele with an extra 15 amino acids. In general the repeating GlyXY motif of collagen provides numerous potential sites for such recombinational asymmetry.

Subsequently, several other glycine substitutions have been identified and are irregularly distributed along the collagen II helix (see Fig. 14). For example, substitutions at positions 247, 274, 293, and 997 (all Gly–Ser) have all produced the clinical phenotype of spondyloepiphyseal dysplasia. In other examples, Arg75–Cys at position G^{+5}IVS20 causes skipping of exon 20, whilst more complex deletions/duplications, 964–999 and 970–984, respectively, also produce spondyloepiphyseal dysplasia. A Gly–Ser154 mutation has recently been observed in Strudwick-type spondyloepimetaphyseal dysplasia, which is more severe than spondyloepiphyseal dysplasia and also shows disproportionate, short stature. The three published examples included Gly–Val292, Gly–Cys709, and Gly–Cys302, respectively, all of which have abnormal collagen a1(II) a-chains and abnormal CNBr peptides similar to those of Fig. 13 and Fig. 15 (Tiller *et al*. 1995). Spondyloepiphyseal dysplasia has also been caused by *COL11A2* mutations. Tiller's patients were unusual in having *COL2A1* Gly–Cys substitutions. Transgenic mice heterozygous for *COL2A1* Gly85–Cys have a lethal chondrodysplasia (Garofalo *et al*. 1991).

Achondrogenesis

Achondrogenesis, hypochondrogenesis, and Kniest dysplasia form one disease spectrum. Clinical changes range from lethal, asphyxiating chondrodystrophy with very short limbs and multiple fractures (type IA achondrogenesis) to a milder disorder with disproportionate short stature, cleft palate, mid-facial hypoplasia, and a flattened nasal bridge (Kneist dysplasia). Infants with achondrogenesis usually die *in utero* or perinatally whilst Kniest dysplasia, although deforming, is more benign.

Experiments by Godfrey and Hollister (1988) accurately located (Fig. 13) a mutation to the C-terminus which was subsequently cloned and sequenced. The original strategy was to make cosmid libraries from the size-fractionated genome, that is DNA. The library was screened with a normal *Eco*R1, 3.7-kb genomic subclone within the mutated region. The proband was heterozygous for a *Hind*III *COL2A1* RFLP. Exons 51 and 52 were amplified with intron-specific primers (just as in the cases of spondyloepiphyseal dysplasia). Two unusual variations were detected. The first (in exon 51) was a neutral change of serine to glycine, caused by a *Pvu*II RFLP segregating in the patient's healthy relatives. The frequency in the normal population was 30 per cent. The second changed Gly–Ser (GGC–AGC) at position 943 of the collagen type II triple helix. It is therefore analogous to *COL1A1* osteogenesis imperfecta (lethal) mutations of Gly–Ser between positions 913 and 1003 (Byers

1989), all of which seriously impair the normal formation, secretion, and melting/denaturation profiles of the collagen type I helix. Very probably the collagen II helix was similarly disturbed. Subsequently a Gly–Glu at position 853 of collagen type II was described by Bogaert *et al*. (1992) in a patient with hypochondrogenesis. The field has now been advanced very rapidly by the combination of conventional protein analysis, peptide mapping, reverse-phase high-performance liquid chromatography, and genomic and cDNA PCR amplification (Tiller *et al*. 1993; Mortier *et al*. 1995; Tiller *et al*. 1995).

Since the first Gly–Ser *COL2A1* substitution (Vissing *et al*. 1989), numerous others have followed (see Fig. 14) including G310–D, G574–S, G691–R, G817–V, G891–A, and G943–S (two separate examples). Although without a consistent pattern, this implies much domain-related variability in the collagen II triple helix. The clinical phenotype of matrix cartilage disorganization correlates poorly with mutational position or type. Thus Gly–Ser574 is as damaging as two similar changes at positions 943. Contrastingly, serine substitutions of position 493 cause non-lethal and relatively mild spondyloepiphyseal dysplasia. Thus the phenotype/genotype correlations in achondrogenesis/spondyloepiphyseal dysplasia are more blurred than equivalent *COL1A1* mutations of osteogenesis imperfecta. In general, smaller substitutions such as Gly–Ser or Gly–Cys have clearer gradients of severity generally (worse at the C-terminus and mildest at the N-terminus).

In Kniest dysplasia there is a cluster of deletions close to the N-terminus (deletions of 94–108, 102–108, 124–141, 142–156, 274–279, and 361–378). The same phenotype is also caused by changes at positions 1007–1112 (at the other end of the molecule). On the other hand, Gly103–D is much more severe than its N-terminal location would suggest. Probably, shortening of the collagen triple helix is severely disruptive wherever it occurs and whilst deletions are rare in *COL1A1*, *–1A2*, and *–3A1* they are common in *COL2A1*.

The Stickler syndrome

Stickler syndrome is both clinically heterogeneous and distinctive (Fig. 12(a–c)). As originally described by Stickler it combines premature myopia with retinal detachment and early joint degeneration. Joint hypermobility is more variable. The severity of myopia varies and Stickler syndrome overlaps clinically with the Wagner syndrome, which has similar retinal, facial, and skeletal abnormalities. The Pierre-Robin anomaly with mandibular hypoplasia and cleft palate also overlaps with Stickler syndrome. Snead *et al*. (1994) have described two classes of vitreoretinal degeneration and recognize two specific phenotypes. One segregates with *COL2A1* whilst the other does not. Sometimes the latter is linked to *COL11A1* (see below).

Francomano *et al*. (1987, 1988) first showed linkage of the *COL2A1* gene to Stickler syndrome, which was also later confirmed by Knowlton *et al*. (1990). Allelic heterogeneity of Stickler syndrome was first described by Schwartz *et al*. (1989) and Fryer *et al*. (1990). Subsequently, progress has been rapid. British studies by Snead (1994) showed two sorts of vitreous morphology. One is always linked to the *COL2A1* gene whilst the other is unlinked and also heterogenous. The non-*COL2A1* phenotype includes mid-facial hypoplasia, tall or short stature, very high myopia, and marfanoid-like skeletal and facial features. Recent advances in the biology and biochemistry of vitreous composition clearly implicate protein and extracellular matrix components other than collagen II. The latter coassembles and coassociates with other collagens such as a1(II), a2(II) and a2(V) to form compound fibrils, whilst collagen VI and fibrillin 15 have also been deleted in the vitreous. Genes for all of these elements are therefore potential candidates for Stickler syndrome and related disorders. Gene linkage to either *COL11A1* or *–11A2* has been identified in certain families with Stickler syndrome, whilst *COL11A2* mutations have been described in both autosomal-dominant and -recessive osteochondrodystrophies with Stickler syndrome (Vikkula *et al*. 1995). The corresponding homozygous mutation caused severe spondyloepiphyseal dysplasia and sensorineural deafness without vitreous changes (otospondylomegaepiphyseal dysplasia syndrome). There was a homozygous glycine substitution of *COL11A2*. Although none of the *11A2* families had myopia or vitreoretinal degeneration, there was severe degenerative joint disease of the hips, knees, elbows and shoulders, and mid-facial hypoplasia with a depressed nasal bridge. *COL11A1* mutations in mice cause an autosomal-recessive chondrodystrophy with shortened snouts, cleft palate, protruding tongue, and shortened limbs. Airway obstruction, tracheomalacia, and hypoplastic lungs cause increased perinatal mortality from respiratory failure (Li *et al*. 1995). Homozygous stop-codon mutations in residue 570 of the mouse *COL11A1* gene have also been produced. The equivalent human heterozygotes show Stickler syndrome with vitreoretinal degeneration (Snead *et al*. 1994). In other Stickler families, stop-codon mutations are common. Thus, the first three-generation family with retinal and joint degeneration linked to *COL2A1* and every other published Stickler (*COL2A1*) mutant have stop-codon defects. These include several Arg–STOP abnormalities and others created by unexpected 1-bp deletions (Vikkula *et al*. 1994).

Mutations of other collagens that cause Stickler syndrome

In addition to collagen II a1(II), cartilage contains collagens a1(V), a2(V), a1(XI), and a2(XI) chains. All are interstitial collagens with similarly organized triple helices and variably large N- and C-terminuses. In both the vitreous and articular cartilage, certain components are interchangeable. For example, collagen Va2 chains can substitute for collagen XI a2 in collagen XI trimers. Thus collagens II, V, and XI are very important structural components of cartilage, which also contains collagen IX (coded by the *–9A1*, *–9A2*, and *–9A3* genes, respectively). Furthermore, hypertrophic cartilage is rich in collagen X. Latterly, mutations of such minority components have also been identified in diseases such as multiple epiphyseal dysplasia and Schmid metaphyseal dysplasia (see below).

Collagen XI mutations

There are now several convincing illustrations of the role of collagen XI in chondrodysplasia. Thus *COL11A2* has been linked to autosomal-dominant Stickler syndrome without ophthalmic changes (i.e., no myopia, retinal or vitreous pathology). The facial changes closely resemble those in Stickler's original descriptions but segregated irregularly with cleft palate and early arthropathy. The mutation changes GT to AG at the donor splice site causing an exon skip. A second homozygous Gly–Arg mutation in *COL11A2* was demonstrated by the same investigators in a more severe, autosomal-recessive chondrodysplasia characterized by severe degenerative joint disease (hips, knees, elbows, and shoulders), facial hypoplasia, and sensorineural hearing loss (Vikkula *et al*. 1995). Similarly, mouse homozygous knock-outs for *COL11A1* showed limb shortening, metaphyseal widening, and abnormal cartilage composition in the limbs, ribs, and trachea (Li *et al*. 1995). Perhaps collagen XI influences fibril formation, cartilage cohesion, and growth-plate organization.

Snead distinguishes Stickler syndrome type I from type II by the vitreoretinal phenotype. Type I Stickler syndrome always has an associated congenital vitreous abnormally with premature medium to high myopia (8–18 dioptres), whilst type II has a lesser non-congenital myopia that is of later onset. Stickler syndrome type I is always linked to *COL2A1* whilst the type II never is. Furthermore, Snead (1994) has recently identified linkage to the *COL11A1* gene in a family with Stickler syndrome type II. Here the clinical phenotype includes medium to low myopia, retinal detachment, variable joint laxity (regressing with age), minor skeletal disproportion, and cleft palate.

Collagen V, which substitutes for collagen XI in heterotypic fibrils of the vitreous, is also a strong candidate gene. Recently, a *COL11A2* mouse knock-out model has been described (Andrikopoulos *et al*. 1995). Affected homozygotes had severe kyphoscoliosis but without limb shortening. Both skin and cornea showed fibril disorganization. In this context, *COL11A2* has already been linked to variants of Ehlers–Danlos syndrome II (Burrows *et al*. 1995; Loughlin *et al*. 1995) and an exonic deletion of *COL11A2* has already been identified in a patient with Ehlers–Danlos syndrome II with corneal flattening (Nicholls *et al*. 1994). Other possible candidates include other cartilage-specific collagens such as the *– 5A1*, *–5A2*, *–9A1*, *–9A2*, and *–9A3* genes (although so far this has caused only Ehlers–Danlos syndrome-like disorders). Snead (1994) has recently suggest that Wagner and Stickler syndromes cannot be distinguished by the type or location of the *COL2A1* mutation. Instead he suggests that the vestigial vitreous of the Stickler syndrome type I-linked group is caused by dominant negative disruption of the collagen triple helix by either exonic deletions or nonsense Gly substitutions of *COL2A1*. The latter might be analogous to the collagen I-depleted bones in osteogenesis imperfecta and the collagen III-depleted arteries and skin of Ehlers–Danlos syndrome IV.

Other cartilage collagens and other extracellular matrix molecules

Collagen IX

Collagen IX is a fibril-associated (FACIT) collagen that decorates the surface of collagen II fibrils. Two mouse models have recently been created: one is a dominant-negative construct (Nakata *et al*. 1993) and the second a gene knock-out (Fassler *et al*. 1994). The latter produced vary mild disease whilst the former was severely crippling. In man the *COL–9A2* locus on chromosome 1p32 is linked to multiple epiphyseal dysplasia (Briggs *et al*. 1994). Probably the clinical phenotype is more easily recognized in man than mice. Multiple epiphyseal dysplasia is an autosomal-dominant disease in which mild short stature combines with early-onset osteoarthritis. It includes the Ribbing and Fairbank subtypes, the latter more severe than the former. Symptoms include pain and stiffness of large joints, with the onset varying between early childhood and mid-adolescence depending upon clinical severity. Pseudoachondroplasia, part of the same clinical spectrum and overlapping with multiple epiphyseal dysplasia, has much shorter hands and very stubby fingers. Cartilage biopsies show chondrocytes with unusual inclusions. Both mild and severe pseudoachondroplasia have now been linked to chromosome 19 and, subsequently, mutations of the *COMP5* gene have been identified at this locus (Briggs *et al*. 1995). Multiple epiphyseal dysplasia has also been linked to a second locus on chromosome 19 (Oehlmann *et al*. 1994).

Collagen X

Collagen X is a short-chain collagen with a helical centre and large, globular, non-collagenous regions at the N- and C-termini. It is expressed only in hypertrophic chondrocytes. The protein assembles into novel hexagonal structures and probably coassociates with collagen type II. Its actual function is unclear, though possibilities include a role in vascular invasion or matrix mineralization. Mice with dominant-negative (loss of function) mutations show defective compression of growth-plate cartilage. Contrastingly, mice homozygous for *COL10A1* knock-outs (Rosati *et al*. 1994) have virtually normal phenotypes. Presumably other collagens compensate for loss of function whilst disruption of function is very much more disturbing. Human *COL10A1* with Schmid-type metaphyseal chondrodysplastic mutants have been described both by Warman *et al*. (1993) and Wallis *et al*. (1994). The phenotype includes short stature, normal spines and hands, together with coxa vara and distorted distal femoral metaphyses. A 13-bp deletion disrupted the C-terminal propeptide. This closely resembles the *COL1A2* homozygote in severely deforming osteogenesis imperfecta. The *COL10A1* mutation is a frameshift causing rearrangement of the 60 terminal amino acids of the C-propeptide, which is also truncated by nine amino acids. Other *COL10A1* mutations have subsequently been located to the same region (Dharmavaram *et al*. 1994; McIntosh *et al*. 1994)

Osteoarthrosis (osteoarthritis)

In an American family, generalized osteoarthritis and a minor chondrodysplasia has been linked to *COL2A1*. Here, Knowlton *et al*. (1990) identified the mutant allele by segregation analysis with a 7-kb *Hind*III marker. The whole 28 kb of *COL2A1* was screened from exons 2B to 52, and an Arg(TGT)–Cys(TGC) mutation detected at position 519 of collagen type II (within the helix).

Although considered causative in this instance, such second-position (X or Y) helical changes are generally of doubtful structural significance in *COL1A1* and *–1A2*. In other collagens such as *COL4A5* there are exceptions to this rule. Allele-specific oligonucleotide hybridization with either the mutant or wild-type sequences showed assortment of the mutant sequence in family members with osteoarthritis whilst the wild-type allele was consistently transmitted to their normal relatives. Nevertheless, this may be a neutral polymorphism with an unidentified mutant sequence existing elsewhere such as exon 1, or the *COL2A1* promoter is not completely excluded. Alternatively, the change in the helical position of cysteine is pathogenetic and has produced unexpected conformational changes. More detailed mutational mapping in patients with osteoarthritis will clarify this matter. This study confirmed the pioneering studies of Palotie *et al*. (1989), who had shown linkage to *COL2A1* in a very large Finnish family with osteoarthritis. It also was consistent with the preliminary study of Hull and Pope (1989). Wordsworth *et al*. (1988) found only borderline evidence of association with *COL2A1* in a somewhat different osteoarthritis phenotype with prominent Heberden's nodes, with a non-statistically significant excess of certain haplotypes. Very probably, osteoarthritis is clinically heterogeneous so that collagen genes such as *COL2A1*, *–11A1*, *–11A2*, *–5A1*, *–5A2*, or even other constituents of extracellular matrix or bone/cartilage, are also candidates. For example, early onset of osteoarthritis with chondrocalcinosis has recently been linked to chromosome 8 (Baldwin *et al*. 1995).

*Type III collagen (*COL3A1*) mutations*

The clinical effects of type III collagen mutations closely mirror the distribution and functions of this protein. Thus, skin, blood vessels (especially arteries), pleuroperitoneum, ligaments, tendons, and the walls of gastrointestinal tracts are especially fragile and prone to damage. Often the clinical consequences can be life-threatening (Pope *et al*. 1988a, Pope *et al*. 1988b; Pope *et al*. 1996). All affect tissues in which collagen III is abundant: for example, it comprises 70 per cent of arterial collagen but rather less (35 per cent) of the cutaneous protein. Even though all such tissues are delicate, it is arterial fragility that is especially dangerous, and, unfortunately, small, medium or even larger arteries can suddenly burst at any time. In practice such catastrophes are most common in middle age, though not unknown even in adolescence. The collagen-depleted vessels are delicate and intolerant of sudden changes in arterial pressure; thus, isometric activities such as weightlifting and sprinting are potentially hazardous and should be forbidden. Pregnancy is also potentially hazardous. Rupture of the ascending or descending aorta with mediastinal bleeding can occur at any age, whilst medium-sized arteries, such as the renal, splenic, iliac, axillary, femoral, popliteal, and anterior and posterior tibial, are also fragile, especially after the age of 30 years (Fig. 16(a)). Unexpected or atypical abdominal pain should always be regarded with deep suspicion but cautiously investigated, preferably non-invasively. The internal carotid artery and intracranial arteries are commonly prone to dissection and ectasia, whilst multiple premature intracranial aneurysms are also recorded. Rupture of the internal carotid artery within the cavernous sinus is also a well-known feature (Fig. 16(b)) (Graf 1965; Pope *et al*. 1991). Cerebral aneurysms occasionally even occur in infancy and may be sporadic or familial (Pope *et al*. 1991). Easy bruising is especially common in childhood (Roberts *et al*. 1984). The external phenotype varies from classical, acrogeric Ehlers–Danlos syndrome IV with typical facial features and short stature to non-specific changes indistinguishable from benign hypermobile syndrome/Ehlers–Danlos syndrome III (Fig. 17). The latter can be very heterogeneous with various subtle subsets, one of which (with lumbosacral striae, mitral-valve prolapse, and aortic rupture) resembles the Marfan syndrome. Ehlers–Danlos syndrome III is distinguished by the normal lenses and bodily proportions in which the span equals the height, in contrast to Marfan syndrome where span exceeds height.

Typically, the cutaneous features of Ehlers–Danlos syndrome IV include thin, translucent skin with prominent capillaries, especially over the anterior upper chest, shoulders, and upper back (Fig. 17(a)). The unusually thinned skin of the hands and feet looks prematurely aged and resembles steroid atrophy. The face is often Madonna-like in younger women, showing large, attractive eyes, little subcutaneous fat, lobeless or small-lobed ears, and a thin, straight nose and lips (Pope *et al*. 1988; Pope *et al*. 1996) (Fig. 17(c,d)) Similar facial patterns can also occur rarely in Ehlers–Danlos syndrome I/II and merge with those of the normal population. Nevertheless, the special facial features when combined with short stature and slimness typify vascular Ehlers–Danlos syndrome IV. The facial features are often recognizable in family photographs, and are useful for family clinical analysis. Clubfoot deformities are common and, although improving in childhood, frequently persist into adult life. Subtle erosions (acro-osteolysis) of the finger tips are also common in acrogeric Ehlers–Danlos syndrome (Fig. 17(e)). Affected children occasionally present with congenital dislocations of the hip that can be confused with Ehlers–Danlos syndrome VII or the Larsen syndrome. Generalized laxity of joints is generally less impressive in Ehlers–Danlos syndrome IV. Low birth weight with small stature is common but non-specific. Histological examination of the skin typically shows dermal thinning, collagen depletion, and elastic proliferation (Fig. 17(b)), which also accompanies types I and II. Transmission electron microscopy shows an irregular distribution of collagen fibril diameters in skin and arterial samples (Fig. 17(e, f)), implying a role for type III collagen in the regulation of collagen fibril thickness. The latter also depends upon the relative proportions of collagen I, III and V and other unspecified components. In collagen III deficiency, collagen fibrils are irregular in size and shape, whilst in Ehlers–Danlos syndrome I/II, which is often caused by abnormalities of collagen V, cauliflower fibrils are common.

Biochemical and genetic changes

Collagen type III comprises only 15 per cent of total collagen protein synthesized by skin fibroblasts. It is measured chemically either as mercaptoethanol-treated procollagens or as unreduced or reduced a-chain monomers, which migrate separately from a1(I) collagen chains. Two-dimensional electrophoresis [similar to that of a1(I) and a2(I) collagens] is also an option, whilst the two most C-terminal peptides [a1(III)CB5 and CB9] comigrate. Mercaptoethanol-reduced monomers of CB5 + 9 cannot be separated, whilst if the disulphide bond of CB9 (which possesses a Cys residue) remains intact, CB9 runs as a dimer whilst CB5 is separated as a monomer. Unfortunately, the smaller peptides CB3, 4, 6, and 8 are less easily resolved. Vertebrate collagenase, which cuts collagen type III into N-terminal three-quarter and C-terminal one-quarter fragments, is also useful for molecular mapping. Because type III collagen is much less abundant than type I, peptide mapping of type III has lagged behind that of type I, in which protein mapping and subsequent gene amplification is relatively simple. To date, less than between one-third and one-half as many *COL3A1* mutants as *COL1A1*/*1A2* defects have been published.

In classical, acrogeric Ehlers–Danlos syndrome IV (Fig. 17(c,d)), little or no type III collagen is secreted. Instead, overmodified mutant protein is retained or degraded intracellularly. Occasionally, diminished or modified protein is secreted without intracellular retention (Fig. 18(a, c)). These mutations have mechanisms different from those that cause retained or secreted, overmodified type III collagen, which frequently have impaired helical winding, similar to certain osteogenesis imperfecta mutants. Exceptionally, in lethal Ehlers–Danlos syndrome IV, the secretion of type III collagen varies between 50 and 80 per cent of normal (Nicholls *et al*. 1988).

Peptide mapping of normal collagen III by one- or two-dimensional electrophoresis (Fig. 18(c,d)) is usually straightforward. Protein extracts can also be stained with silver or Coomassie blue. Very occasionally, type III collagen is normal in classical Ehlers–Danlos syndrome IV, although CB5 and 9 are normal (Pope *et al*. 1988a, Pope *et al*. 1988b; Pope *et al*. 1991). Perhaps the error is located in an N-terminal peptide such as CB3, or similar fragments such as CB1, 2 or 7, which are too small to be detected. Other possibilities are electrophoretically silent mutations or non-allelic phenocopies caused by other mutant genes. The degree of protein overmodification is both position- and residue-dependent. Just as for *COL1A1* and *COL1A2* mutants, abnormalities nearest to the C-terminus produce the most overmodified protein. 'Smiling' gels similar to those that can accurately locate abnormalities of a1(I), a2(I) or a1(II) should also discriminate between a1(III)CB5 and a1(III)CB9 mutations. A good example is the Ehlers–Danlos syndrome IV family with variable type III secretion mentioned earlier (Nicholls *et al*. 1988) which, when mapped by either one- and two-dimensional CNBr peptide gels produced a shortened form of a1(III)CB5. PCR showed an in-frame intraexonic deletion of 27 bp (caused by spliced mispairing) (Richards *et al*. 1991). Single-base substitutions, gene deletions, and splicing abnormalities are common, whilst other mechanisms such as base insertions are less frequent. Null alleles (many with premature chain termination) may also be expected. So far we have identified more than 20 glycine substitutions or exon skips (Fig. 19). Mutational position and type correlate reasonably well with clinical severity (Pope *et al*. 1996). Already several other

splice-junction mutations have been described.

With the methods outlined above the analysis of abnormalities in collagen III protein is simple. If the intracellularly retained protein is so very sparse it cannot be easily mapped (by immunoprecipitation, CNBr cleavage or proteinase digestion), then other approaches become necessary. Thus, specific cDNA or genomic fragments can be amplified by PCR with strategically placed primers, combined with mapping of S1 nuclease (Kuivaniemi *et al*. 1991) or RNAase A (Grange *et al*. 1988), or by the chemical cleavage of mismatched cytosines or guanosines by OsO_4 or hydroxylamine (Cotton *et al*. 1989). This strategy previously identified a 100-bp deletion (Cole *et al*. 1990) and we have also used it successfully. Since glycine (GGX) mutations are relatively common, cleavage with hydroxylamine is potentially more useful than with OsO_4, which is also technically more demanding. Cleavage accurately locates mismatches and requires direct or indirect sequencing to identify the actual mutant sequence. The method is particularly relevant for those patients with Ehlers–Danlos syndrome IV who have normal secretion and peptide maps of collagen III. We have previously identified several different Ehlers–Danlos syndrome mutants by this method (Fig. 18(e)). Alternatively, the whole cDNA can be amplified in several convenient portions and subsequently automatically sequenced (by machine), which theoretically shortens the process to as little as 7 days whilst conventional analysis takes at least 6 months. This includes 4 to 6 weeks each for primary cell culture and for protein mapping. The latter step can be omitted and cDNA or genomic mutational analysis and sequencing undertaken instead. Since each mutation is unique and common disorders such as cerebral or aortic aneurysms are also very varied, the analysis of individual mutations requires regional or nation-wide resources and may not be cost-effective in preventing cerebral aneurysms.

The current situation

In 1991, 15 *COL3A1* mutations had been identified (Kuivaniemi *et al*. 1991) but by 1995 nearly three times this number have now been recorded. Many of the 20 that we have sequenced lie within CNBr peptides 5 and 9. For technical reasons, mutations are more easily identified here but ascertainment (of the acrogeric clinical phenotype) also produces clustering. In contrast to osteogenesis imperfecta, in which the clinical gradient is well defined (least severe at the N-terminus and greatest at the C-terminus), *COL3A1* mutants are uniformly disastrous wherever they lie. A chemical gradation is still obvious, as C-terminal mutants are chemically more disruptive and may also induce more severe clinical phenotypes such as fragile arteries. Yet the nature of arterial rupture is such that even a single episode is potentially lethal. This contrasts totally with osteogenesis imperfecta in which the most severe clinical phenotype arises following the most numerous and continual fractures. The clustering of mutants with acrogeric Ehlers–Danlos syndrome IV who have a very high risk of arterial rupture has several unexpected exceptions, such as Gly–Glu625, which includes mild generalized joint laxity and late-onset osteogenesis imperfecta with Heberden's nodes but with apparently normal arteries. Originally we had included Gly–Asp883 with mild external features without arterial ruptures in this category; unfortunately, however, the affected father and daughter (aged 57 and 25 years respectively) recently both suddenly died of arterial rupture.

Mutations identified to date (Fig. 19)

Amongst the published defects (Kuivaniemi *et al*. 1991, 1995; Pope *et al*. 1996) are point mutations Gly619, Gly790, Gly883, Gly910, Gly1018, and several splice-junction mutations of exons 16, 20, 25, 27, 41, and 42 (Kontusaari *et al*. 1990; Kuivaniemi *et al*. 1990). All have changes at or near the crucial splice donor sites with complete exons always misspliced in-frame. The IVS20 mutation described by Kontusaari *et al*. (1990) is a typical example. Here the proband, a 34-year-old male, died of acute abdominal, retroperitoneal, and mediastinal haemorrhage. Other family members such as his brother and father had also died prematurely of arterial rupture.

We have recently observed several other unusual examples including two exon-24 skips caused by very similar splice-junction errors. In one affected father and daughter, the secretion of collagen III was reduced but a slightly shortened and an overmodified protein was secreted. The clinical phenotype included extreme fragility of medium-sized arteries. The proband eventually died from sudden aortic rupture but had previously undergone a mid-thigh amputation to control torrential bleeding from a routine operation to strip varicose veins. He also had suffered several previous pneumothoraxes. His affected daughter had survived avulsion of her common iliac artery and vein following a minor fall. The external clinical phenotype was non-specific but included large eyes and lobeless ears. Previously the proband had a provisional diagnosis of the Marfan syndrome but had a normal span/height ratio and no arachnodactyly or lens dislocations. In contrast, the second exon-24 skip showed a typical acrogeric facial phenotype but virtually normal patterns of type III collagen. Presumably the mutant splice-junction site was mostly ignored and normal collagen III mRNA spliced instead.

There was similar clinical variability in three different splice-junction skips at exon 37, of which two were acrogeric. Two had suffered fatal, late arterial rupture, one with several previous arterial tears that had been successfully repaired and the other with numerous simultaneous tears. So far, the youngest patient, although acrogeric, is free of arterial damage. Various other exon skips include missplicing of exon 43 in a two-generation family, two of whom had carotid–cavernous sinus aneurysms and various combinations of left renal and splenic aneurysms. Here the phenotype included large prominent eyes, slightly thin skin, and increased elastic proliferation on histological examination. Other mutants are detailed in Pope *et al*. (1996) and Fig. 19.

Mutation analysis

Our current strategy is to amplify *COL3A1* cDNA in four or five overlapping fragments. As we do not use genomic amplification (of the 52 exons), certain subtle in-house mutants may be missed. Stop-codon mutants are common in *COL2A1* and *COL7A1* mutants (see above and below). cDNA amplification of *COL3A1* mRNA is followed by density-gradient electrophoresis of the 3' coding sequences covering most of CB5 and 9. Originally, PCR products were then indirectly cloned and sequenced. Latterly, we use direct sequencing of double-stranded, PCR-amplified DNA (which is faster, easier, and more efficient). Early errors detected by others include deletions of exon 20 with a complicated mix of misspliced products such as exons 19, intron 20, and exon 19 in variable proportions (ranging from 24 to 132 nucleotides) (Tromp *et al*. 1989). Genomic clones showed a G–A splice-junction substitution in the first base of intron 20. Some variably spliced products deleted exon 20 (54 bp) but others included variably-sized intron sequences transcribed from the first, illegitimate, consensus splice-junction sequence.

Pepsin-resistant type III collagen secreted by cultured fibroblasts was decreased, whilst skin and arteries were deficient in type III collagen. The G–A mutation destroyed a *Bst*U1 site allowing the detection of affected family members. One of the proband's three children and his clinically normal sister were also mutants. Allele-specific oligonucleotides with either normal G or the mutant A sequence were also useful. Here, mutant DNA hybridizes to the mutant (A) oligonucleotide whilst wild-type sequences hybridize with the normal (G) in DNA dot-blots. Deletions of exons 16, 25, 27, 41, and 42 were mentioned in the first edition of this book, and more recently skipping of exons 7, 14, 24, 37, 43, and 45 has also been reported (Pope *et al*. 1996).

Gene deletions or insertions

Just as in osteogenesis imperfecta, there may be occasional large, and also smaller, deletions ranging from 27 to 7500 bp (7.5 kb) that are distinct from exon skips. Superti-Furga *et al*. (1988) have described two remarkable examples. One had rather mild Ehlers–Danlos syndrome IV and had successfully completed a normal pregnancy. Her fibroblasts produced low amounts of normal and shortened a1(III) homotrimers, whilst mixed heterotrimers were retained intracellularly. Southern blotting showed a 7.5-kb deletion extending from intron 33 to exon 48. This was an in-frame deletion between residues 586 and 999. A second, slightly smaller deletion induced more severe disease in an affected father and son. The father suffered a fatal intra-abdominal haemorrhage and the surviving son secreted two forms of type III procollagen/collagen, the mutant being shorter than usual. Typical clinical features of Ehlers–Danlos syndrome IV included thin skin, lobeless ears, and acrogeria. The protein deletion was estimated at 220 amino acids, based upon molecular weight. More detailed DNA analysis showed a 3.3-kb genomic deletion from exon 9 to 24 with a complex variable tandem repeat causing potential asymmetrical recombination at meiosis (Lee *et al*. 1991a). This is also a useful population and linkage marker with a three-allele deletion pattern (Superti-Furga *et al*. 1990). In both, the deletion breakpoints are now defined (Lee *et al*. 1991b; Vissing *et al*. 1991).

A third (2 kb) deletion was observed by McGookey *et al*. (1989) (Milewicz and Durie 1994). Here a female with sporadic Ehlers–Danlos syndrome (type unspecified) produced traces of procollagen type III, which, after pepsin isolation, ran as two closely apposed type III homotrimers. The cell-layer collagens were not described, although mixed heterotrimers were probably retained or degraded intracellularly. The proband's clinically normal father also secreted traces of the mutant homotrimer but nearly normal amounts of the wild-type protein. Genomic DNA probed with a *COL3A1* cDNA deleted a 5' *Hind*III fragment. The father's lymphocyte cDNA did not contain the deletion (as judged by Southern blotting). He was probably a mixed gonadal–somatic mosaic and the mutation had occurred after embryonic divergence of fibroblast and lymphocyte precursors. This was the first published example of gonadal mosaicism in Ehlers–Danlos syndrome IV. Just as in osteogenesis imperfecta, this mechanism is relatively common, especially in families with multiple affected siblings and clinically normal parents.

The mutation has subsequently been more fully characterized. Other smaller deletions have also been described. For example, as mentioned earlier (Richards *et al*. 1991), we have studied a three-generation Belgian family with variable production of collagen type III. Protein mapping showed a deletion in a1(III)CB5 (Fig. 18(d))

(Nicholls *et al*. 1988). This was caused by a novel, in-frame, 27-bp deletion within the 108-bp exon 37 close to the C-terminus, the so-called spliced, mispaired, homologous intronic sequences (Richards *et al*. 1991). Similar mechanisms also occur in globin and other genes (Richards *et al*. 1991). Although undetectable in whole a-chains, peptide mapping with CNBr was unambiguous.

Mutations such as point mutations, deletions or insertions are easily demonstrated by allele-specific amplification or hybridization. The strategy works well for carrier genomic sequences prepared from chorionic villus biopsies, amniocentesis or ordinary blood samples of appropriate family members.

Genetics of Ehlers–Danlos syndrome

Ehlers–Danlos syndrome is clinically heterogeneous and characterized especially by cutaneous fragility with variable permutations of skin thinning, ligamentous laxity, short stature, spinal deformity, vascular fragility or retinal detachment. By certain combinations of clinical and biochemical characteristics there are at least nine distinct genetic subsets, of which types IV, V, VI, and VII have specific biochemical abnormalities. Types I/II (see below) can also now be added, as mutations of collagen type V cause at least some of them. Collagen proteins are faulty in types I, II, III, IV, and VIIA and B, whilst types VI, VIIC, and IX are caused by enzyme mutations. Ehlers–Danlos syndrome type VII is caused by either structural or enzyme abnormalities. With rare exceptions the causes of Ehlers–Danlos syndrome types III and VIII are so far unknown, whilst the existence of Ehlers–Danlos syndrome V is controversial. Thus lysyloxidase deficiency is a strong candidate, usually causing either cutis laxa with bladder diverticula or Menkes syndrome. Collagen III mutations cause vascular Ehlers–Danlos syndrome and N-terminal collagen I mutations cause autosomal-dominant forms of Ehlers–Danlos syndrome VIIA and B. The latter patients differ from those with Ehlers–Danlos syndrome types I and II only in stature; they are usually petit(e) and in more severe cases have greater looseness of joints and ligaments, especially of fingers, shoulders, knees and hips, together with late scoliosis. Collagen V abnormalities (see below) cause at least some types of Ehlers–Danlos syndrome II, which is probably allelic with Ehlers–Danlos syndrome I. Other candidates for this phenotype include the *COL5A1*, *–11A1*, and *–11A2*. Cutaneous fragility is the norm in Ehlers–Danlos syndrome I but can be as marked in VIIA and B. (Fig. 20(a–f)) Compound heterozygosity for collagens I, III, V, and XI is also possible, as are double heterozygotes for collagen, elastin, fibrillin, lysyloxidase, lysylhydroxylase, and other components of the extracellular matrix.

Fig. 20 (a, b) Facial features of affected father and son with Ehlers–Danlos syndrome I, both showing typical facial scarring. (c) There is also often abnormal cutaneous extensibility or epicanthic folds. (d, e) Joint laxity is both widespread and commonplace. (f) Scarring of the shins and knees is also usual, closely resembling that of certain patients with Ehlers–Danlos syndrome VI (see Fig. 10(e)). (g) Cauliflower fibrils are typical (as viewed by transmission electron microscopy × 62 500).

Ehlers–Danlos syndrome VI is caused by specific enzymatic abnormalities, especially lysylhydroxylase deficiency (from homozygous or compound heterozygous gene mutation) causing Ehlers–Danlos syndrome VI. The latter differs from other subtypes of Ehlers–Danlos syndrome by its inheritance, which is either autosomal-recessive or compound. In contrast to other subtypes there is severe infantile or adolescent scoliosis and spectacular generalized joint laxity. The lysylhydroxylase gene lies on chromosome 1p36 (Hautala *et al*. 1992). Known mutations include homozygous termination-codon duplication rearrangements and both complex and single exon skips (Pousi *et al*. 1994; R. Myllyla and F. M. Pope, unpublished observations). Ehlers–Danlos syndrome type VIIC closely resembles types VIIA and B but produces much more disorganization of collagen fibril, as illustrated by hieroglyphic fibrils in transversely sectioned electron micrographs. Here the pNa1 and pNa2 propeptide extensions remain uncleaved so that the entire triple helix is faulty. All mutant molecules then misassemble to form flanged fibres that appear in transverse sections as hieroglyphs. In humans the clinical phenotype includes spectacular cutis laxa, joint laxity, and short stature in adults, differing only slightly from the types VIIA and B phenotypes in which either the pNa1 or the pNa2 chains are faulty. Here, family trimers incorporate either one or two abnormal chains. Lysyloxidase deficiency can potentially cause several osteogenesis imperfecta disorders, but it is unclear whether the families with X-linked Ehlers–Danlos syndrome V originally described by Beighton were lysyloxidase-deficient. Lysyloxidase deficiency also causes a syndrome of cutis laxa and extreme joint laxity, with bladder diverticula, a hydronephrosis, and chronic renal failure, which overlaps with both Ehlers–Danlos syndrome III and VI but is a much more severe and a separate disease. Deficiency of procollagen peptidase produces autosomal-recessive Ehlers–Danlos syndrome VIIC, as described above. Transmission electron microscopy shows angulated irregularities of collagen fibril shape in Ehlers–Danlos syndrome VII (most extremely in Ehlers–Danlos syndrome VIIC), with size irregularities in *COL3A1* deficiency (Ehlers–Danlos syndrome IV), some Ehlers–Danlos syndrome III, and hereditary aneurysms and spectacular disorganization (so-called cauliflower fibres in both Ehlers–Danlos syndrome I and II and occasionally pseudoxanthoma elasticum). There are animal models for *COL5A1* and *COL11A2* deficiency in which mutant mice show fibril irregularities in both homozygotes and heterozygotes. Cauliflower fibrils have not been observed, although there is an Ehlers–Danlos syndrome I/II rabbit model that has spectacular cauliflowers, fused fibres, and considerable bending and fraying of the affected structures (in skin at least) (Fig. 20(g)).

Collagen type V mutants

Three distinctive and separate pieces of evidence implicate collagen V (a1 and a2 chains) in the aetiology of Ehlers–Danlos syndrome I/II. Firstly, screening of numerous families with syndrome types I and II has shown occasional abnormalities of structural proteins (Nicholls *et al*. 1994). One patient had mixed clinical features of Ehlers–Danlos syndrome I/VII as judged by short stature, extensive skin fragility (of the forehead, knees and shins), and generalized joint laxity (Fig. 21(a,b)). Electron microscopy of the skin showed slight irregularity of fibril shape without cauliflower fibrils (Nicholls *et al*. 1994). Subsequently, an exonic deletion and genomic splice-junction mutation of *COL5A1* was detected. In a second patient with similar extreme clinical features but unexplained recurrent intraperitoneal bleeding, collagen V chains were both overmodified. By analogy with osteogenesis imperfecta either *COL5A1* or *–5A2* are implicated, but so far the mutation is unidentified. Two very large British families of Ehlers–Danlos syndrome II have also been linked to *COL5A1*. Thus Wordsworth and his colleagues (Loughlin *et al*. 1995) recently showed linkage in a large, four-generation, British family with syndrome type II and a lod score 11.9. We have studied a family with mixed syndrome I/II with a lod score of 4.6 (Burrows *et al*. 1996). Recently a translocation deletion causing both Ehlers-Danlos syndrome and hypomelanosis of Ito has been described (Torriello *et al*. 1996). Mouse mutants, heterozygous and homozygous for a *COL11A2* knock-out, demonstrate the equivalent phenotype consistent with human Ehlers–Danlos syndrome II. Thus heterozygotes had abnormal histological appearances of skin and mild ligamentous laxity, whilst homozygotes had much more extreme skin changes with severe spinal deformities. Electron microscopy showed misassembled fibres of skin and cornea (the fibres were both enlarged and irregular).

Fig. 21 (a, b) Face and feet of a patient with Ehlers–Danlos syndrome with collagen V mutation. The eyes have flattened corneas but the generalized physical

features strongly resembled those shown in Fig. 10 and Fig. 20 (i.e. were phenotypically similar to Ehlers–Danlos syndrome I, II, and VII).

Collagen type IV mutations

Understanding of the genetics and molecular mechanisms of Alport syndrome has also progressed very rapidly since 1991. Then, X-linked Alport syndrome with haematuria, thinning of the glomerular basement membrane, and deafness had been linked to Xq21.3–Xq22.2 and to the *COL4A5* gene (Hostikka *et al*. 1990), with a lod score of 9.1. There are six other types of Alport syndrome (McKusick *et al*. 1990): type I (classic juvenile with deafness), type II (X-linked juvenile with deafness), type III (X-linked adult with deafness), type IV (X-linked adult without deafness), type V (autosomal-dominant with deafness and thrombocytaemia), and type VI (autosomal juvenile with deafness). All share a symptom complex of deafness, haematuria, and thickening or splitting of the glomerular basement membrane through the lamina densa, but except for the type III disorder are caused by autosomal genes. Overall this is a common disease with an overall frequency of 1/5000.

By 1991 the first *COL4A5* mutation had been discovered by Southern blotting, which was used to study one family with a 15-kb genomic deletion of 5 including exons 5 to 10. The collagen a5(IV) protein was shortened by 240 amino acids. Soon after a second family was studied in which the third exon from the C-terminus contained a Cys–Ser mutation (Zhou *et al*. 1990). This probably impaired folding of the C-terminal globular domain, which is heavily reliant upon specific disulphide bridges. Consequently, normal helix formation and intermolecular assembly must be severely compromised. All families with X-linked Alport syndrome presumably have mutations of *COL4A5*, but, up to 1991, the mechanism of autosomal-dominant Alport syndrome was unclear. The other members of the type IV collagen gene family (*COL4A1–4A4*) are obviously strong candidates. Since then, more than 150, all mostly private, mutations have been described, including large deletions, insertions, glycine substitutions, and stop codons. Autosomal variants have been caused by both *COL4A3* and *COL4A4* mutations, and there are very probably *COL4A1* and *–4A2* mutants as well. The basement membrane components are at least tissue-specific.

Collagen type VII mutations

Collagen VII is a basement membrane-associated protein that forms distinctive, cross-striated fibrils, easily visible by transmission electron microscopy. The protein is found in stratified squamous epithelium and amnion, from which it is usually purified. The fibrils attach epidermal basement membrane to underlying dermal connective tissue, inserting both into the lamina densa and into the anchoring plaques of the underlying stroma, thereby anchoring the basement membrane to the underlying reticular dermis. Faults in the organization or composition of these structures severely disrupt the stable adhesion of epidermis to dermis. Such faulty tissue spontaneously splits at the level of the basement membrane/reticular dermis, with tense and painful, haemorrhagic, subepidermal blisters that eventually heal with scarring. There are both autosomal-dominant and -recessive forms. In the former (see below), painful blisters occur over extra-articular sites, such as the knees, elbows, knuckles, and lateral malleoli. In severe, autosomal-recessive dystrophic epidermolysis bullosa, blistering extends to the whole integument, including nails, trunk, and face, and also to buccal, oesophageal, and genitourinary mucous membranes (see below) (Fig. 22(a–d)).

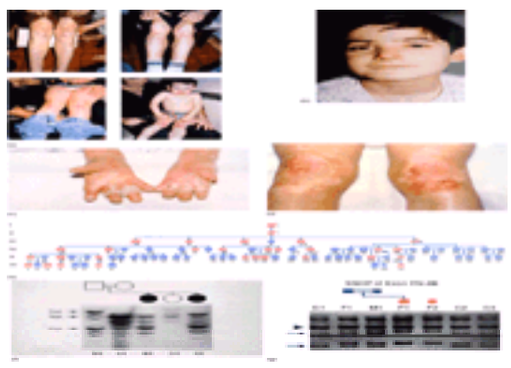

Fig. 22 (a) Montage of family with autosomal-dominant dystrophic epidermolysis bullosa (DEB) showing typical scarring and blistering of knees, shins, and the hands. (b, c, d) Severe recessive (R) DEB showing facial scars (b), mittening of the hands (c), and severe scarring of the knees (d). (e) Typical multigenerational pedigree of autosomal-dominant DEB. (f) Segregation of the variable random sequence D351100 with RDEB. The combination of parental alleles 4 and 6 carries both mutant genes. (g) Single-stranded confirmational analysis of exon FN4B of the *COL7A1* gene showing segregation of severe DEB with the abnormal component.

Collagen VII protein has C-terminal and N-terminal globular ends, of which the former is the larger. There is also a central interrupted triple helix. Individual molecules stack in antiparallel arrays. The C-terminus accounts for half the molecular weight of the entire protein. Western blots with various polyclonal and monoclonal antibodies to the globular and helical epitopes detect a 290-kDa protein with 140-kDa C-terminus.

Clinical phenotype

Epidermolysis bullosa dystrophica has autosomal-dominant (mild) (Fig. 22(a,e)) and -recessive (lethal) forms (Fig. 22(b–d)), both characterized by subepidermal blisters that split through the lamina of the basement membrane (Eady 1990). Skin sections stained with antitype VII antibodies stain the basement membrane either poorly or not at all. In some cases (e.g. the epidermolysis bullosa dystrophica inversa type), mutant type VII collagen protein is retained intracellularly. Such changes are analogous to those found in *COL1A1*, *–1A2*, *–2A1*, and *–3A1* mutants in diseases such as osteogenesis imperfecta, chondrodysplasia or vascular Ehlers–Danlos syndrome (see above), all of which also frequently impair helical stability or secretion of the mutant molecules. In the case of epidermolysis bullosa dystrophica and in contrast to such as Ehlers–Danlos syndrome and osteogenesis imperfecta, many are caused by stop-codon rather than helical glycine substitutions, or exon skips. Electron microscopy of the skin from such *COL7A1* mutations shows depleted or even no anchoring fibrils at all (largely dependent upon the type and clinical severity of the defect).

Since 1991 there has been impressive progress in exploring the molecular structure and analysis of *COL7A1*. Not only has the cDNA and genomic organization of the gene been completed (Parente *et al*. 1991; Christiano *et al*. 1992) but it has also been convincingly implicated in the causation of both subgroups of epidermolysis bullosa dystrophica. Thus the linkage of autosomal-dominant and -recessive dystrophic epidermolysis bullosa to *COL7A1* at 3p21 was rapidly followed by various mutations causing both dominant and recessive epidermolysis bullosa dystrophica (Fig. 22(f)). NC1, non-collagenous, helical, and NC2 mutations have all been described. They include exon skips, chain-termination codons, and helical glycine substitutions. Combinations include heterozygous dominant, homozygous recessive, and double heterozygous mutations (Hallopeau–Siemens inversa).

Gene structure and organization

Anchoring fibrils contain predominantly collagen VII protein (Lunstrum *et al*. 1986; Saiki *et al*. 1986;), although interactions with other matrix components such as collagen V and fibrillin are also possible. The collagen VII gene (*COL7A1*) is compact (32 kb) but complex, with 118 exons separated by rather small introns. The 9.2-kb mRNA encodes a 340-kDa protein (Parente *et al*. 1991; Christiano *et al*. 1992; Greenspan 1993). The NC1 domain is large, containing several distinct elements such as cartilage matrix protein 9, fibronectin III, and von Willebrand factor domains, and Cys/Pro sequences. Next is a triple helical collagenous domain and lastly the *C2*-coding region, the whole gene containing 118 separate exons (Christian *et al*. 1994a). Individual molecules stack antiparallel producing the typical cross-banded anchoring fibril joined at the epidermal end to the lamina densa and at the dermal end to so-called anchoring plaques.

Mutations of COL7A1

Since 1991 there has been very rapid progress both in the identification of the gene locus and in the analysis of mutants. This may be summarized as follows. Firstly, five independent studies have confirmed the linkage of *COL7A1* markers to all autosomal-dominant and -recessive variants of dystrophic epidermolysis bullosa. With regard to the dominant form, linkage was independently observed by American, British, and Dutch groups (Ryynanen *et al*. 1991, 1992; Al-Imara *et al*. 1992; Ryynanen *et al*. 1992; Gruis *et al*. 1992). The Americans tested both Finnish and American pedigrees whilst the British and Dutch looked at native families only.

Various markers close to the *COL7A1* locus at 3p21 were used initially, sometimes supplemented with intragenic *COL7A1* RFLP. Two different groups have studied linkage of *COL7A1* to severe autosomal-recessive disease (dysmorphic epidermolysis bullosa including so-called Hallopeau–Siemens (mitis) and inversa subtypes (Hovnanian *et al*. 1992). These were grouped together as generalized recessive dystrophic epidermolysis bullosa by the British investigators (Dunnill *et al*. 1994a). Fifty-two French and Turkish families with at least one living offspring were studied by Hovnanian *et al*. (1992), whilst Dunnill *et al*. (1994a) studied a mixed population of British, Italian, Irish, and South African families. Lod scores were 4.94 (British) and 3.97 (French). Both groups studied mutations on the assumption that N-terminal stop codons were likely (as proposed originally by Hovnanian). Four patients with heterozygous stop codons changing CpG sequences such as CGA(Arg)–UGA(STOP) were detected in the first eight exons of *COL7A1* to be tested by Hovnanian *et al*. (1992). Dunnill *et al*. (1994) also opted to screen the NC1 coding region in their British/Irish/Italian/South African patients. They found four stop-codon mutants, three of which were identically heterozygous but possessed different second mutations, whilst the fourth was homozygous for a different stop codon in the fibronectin III repeat at 4BN to the other three (Fig. 22(b–g)). The two homozygously affected children had mutilating epidermolysis bullosa and with C–U transition changing Arg to STOP. This abolished an Xho site for which both parents were obligate heterozygotes and which the children were homozygous. The carrier parents had clinically detectable, Hallopeau–Siemens epidermolysis bullosa inversa.

Two other mutations were also published at about this time. The first was a homozygous Met–Lys substitution in the non-collagenous NC2 domain producing relatively mild dystrophic epidermolysis bullosa mitis (Christiano *et al*. 1993). The second was a homozygous stop codon in the NC1 domain caused by a single base-pair insertion deletion (Hilal *et al*. 1993). This produced autosomal-recessive disease and severe mittening deformities of the hands and feet—the so-called Hallopeau-Siemens pattern. Subsequently, Dunnill *et al*. 1994*a*; *b*; 1995*a*; *b*; have described a nonsense mutation in the NC1 domain at position 578 in two unrelated individuals, one of whom had a second mutation deleting residue 789 and also creating a premature stop codon. In contrast to osteogenesis imperfecta/Ehlers–Danlos syndrome IV mutants, which show an increasing gradient of severity from N- to C-terminus, the pattern in severe recessive/compound epidermolysis bullosa dystrophica is the reverse. Thus, homozygous stop-codon mutants in the NC1 domain are very severe whilst the homozygous inversion of NC2 is much less so. Presumably, stop-codon homozygosity that produces no mutant products is less disruptive to the interactions of anchoring fibrils with other components and the clinical disorder much milder as a consequence. This has strong parallels with homozygous *COLX* mouse knock-outs in which the clinical phenotype is barely noticeable whilst single, dominant, *COLX* Gly mutations produce notable abnormalities in mice and men. In other words, loss of function can be much less damaging than altered function. Since dystrophic epidermolysis bullosa is relatively rare (with fewer than 100 families with dominant or recessive forms in the United Kingdom) (McGrath *et al*. 1993, 1995c), but with equal numbers of sporadic cases, the immediate future strategy will be to identify as many mutations as possible to optimize genetic counselling and prenatal diagnosis. Combined evidence from worldwide research should then provide a phenotype/genotype map similar to those already available for osteogenesis imperfecta, Ehlers–Danlos syndrome and the chondrodystrophies, before the development and exploration of animal models, then the development of gene therapy (a specific lesion of stratified squamous epithelium of this type should be one of the more easily soluble models for successful gene therapy) (Christiano *et al*. 1994b, Christiano *et al*. 1995, Christiano *et al*. 1996a, Christiano *et al*. 35 b).

In contrast to *COL7A1*, homozygous *COL1A1, COL1A2*, and *COL3A1* mutations are either extremely rare or missing. Possibly, in these instances, double stops would be genetically lethal as the affected proteins are more physically widespread and indispensable. Single stops of *COL2A1* frequently cause the Stickler syndrome. Overall, progress since 1994 has been very rapid, coinciding with technical improvements in PCR, heteroduplex analysis, and the demonstration of the full automated genomic sequence of *COL7A1*. The gene is compact but complex, though examination of the whole, 32-kb, 118-exon gene is now feasible. To date, many premature stop-codon mutants have been identified in autosomal-recessive, Hallopeau-Siemans epidermolysis bullosa and dystrophic epidermolysis bullosa mitis. Premature stops or glycine substitutions have been equally frequent in heterozygous dominant dystrophic epidermolysis bullosa. Other mechanisms of similar basement membrane non-connected genes include defects of laminin 3 and the bullous pemphigoid antigen BP 180 (McGrath *et al*. 1995a, McGrath *et al*. 1995b).

Marfan syndrome (Fig. 23)

The Marfan syndrome is characterized by long extremities, fingers and feet (arachnodactyly), tall stature, pectus deformities of the chest, facial and optical abnormalities such as dislocated lenses, high myopia, high-arched palate, and mandibular hypoplasia. There is also a distressingly common predisposition to sudden aortic rupture, particularly in middle adulthood (Fig. 23) (Marfan 1896). Mitral-valve prolapse, joint laxity, and cutaneous striations are also common. None of these individual physical features in themselves is specific. It is their subtle combination that makes the disorder so recognizable. Beighton *et al*. (1988) have clearly defined major and minor diagnostic criteria, various permutations of which allow a reasonably rational diagnosis to be made or suspected. Major criteria include disproportionately tall stature with arachnodactyly and skeleton deformity, lens dislocations, and aortic-valve disease and dilation.

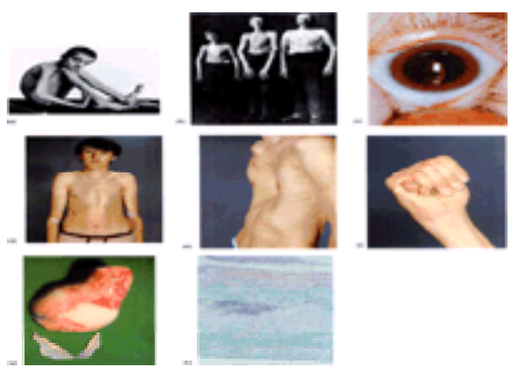

Fig. 23 Marfan syndrome phenotypes: (a) Marfan's original patient; (b) original family described by Weve (1931)—note chest deformities and elongated fingers and arms; (c) typical dislocated lens from individual with classical Marfan syndrome; (d, e) pectus excavatum and carinatum from two different patients with Marfan syndrome; (f) positive thumb sign (the grasped thumb protrudes beyond the width of the palm; (g) dilated aortic root from typical Marfan patients; (h) medial elastic degeneration of Marfan syndrome.

Although Marfan syndrome is one of the original 'inherited defects of connective tissue' (McKusick 1956; McKusick 1972), until quite recently its molecular genetics was obscure. Nevertheless, it is a clear autosomal-dominant (Weve 1931) (Fig. 23(b)) with complete penetrance and a prevalence of approx. 1/25 000.

Since mid-1991, complete molecular understanding of the disease has largely been achieved. Firstly, the abnormal gene was located by an international consortium whose combined evidence (Blanton *et al*. 1990) suggested chromosome 15 as the most likely gene locus. Next, specific gene linkage to *D15S45* was identified by Peltonen and her colleagues. Extended studies of 17 authentic families with classical Marfan syndrome by five different American and Northern European research groups quickly showed allelic homogeneity for the fibrillin 15 locus (Kainulainen *et al*. 1991). The only exception is a very large French family linked to 3p21 (Collod *et al*. 1995). Here the Marfan phenotype is disputed (Boileau *et al*. 1995; Dietz *et al*. 1995). Fibrillin 15 is a completely convincing candidate whose properties are consistent with known physical properties of Marfan syndrome. For example, the tissue distribution of fibrillin matches the known physical signs of the syndrome, such as the clinical and structural abnormalities of the aortic media, and faulty suspensory ligaments of the lens, skeleton and skin. Other preliminary evidence included poor immunofluorescent staining of the dermis and cultured skin fibroblasts from most Marfan patients (Godfrey *et al*. 1990).

Subcloning and sequencing of the human fibrillin 15 gene

Maslen *et al*. (1991) elucidated both the cDNA sequence structure and chromosomal location of a fibrillin on chromosome 15, whilst Lee *et al*. (1991*b*) also located a second fibrillin gene on chromosome 5, hinting at another on chromosome 2. Very quickly, Dietz *et al*. (1991) detected the first specific mutations in the Marfan syndrome. Soon after the Marfan-like syndrome, congenital contractural arachnodactyly, was linked to the fibrillin gene on chromosome 5 (Tsipouras *et al*. 1992). Congenital contractual arachnodactyly has many Marfan-like features but without vascular fragility. Fibrosis and contractures of certain ligamentous and cartilaginous structures such as the small flexor tendons of the hands or feet, with crumpling of the external ear, are prominent. Such clinical variability probably reflects the tissue distribution of particular fibrillin proteins.

Molecular structure of the fibrillin 11 gene

The two American groups who originally characterized the fibrillin 11 gene adopted slightly different approaches. Maslen *et al*. (1991) had screened a placental cDNA library with universal degenerate oligonucleotides of a 20-bp fibrillin peptide sequence. They located overlapping cDNA clones containing 6.9 kb of a predicted 10-kb

mRNA. Sequencing showed several novel features, including both 6- and 8-Cys motifs and an 184 amino-acid carboxyterminus. The overall 394 amino-acid sequence was homologous to various unexpected but well-known protein motifs, such as the 6-Cys repeat that strongly resembles vertebrate epidermal growth factor and also the *Drosophila* notch protein. The 8-Cys repeats resembled the binding protein for transforming growth factor-b $_1$, which is also homologous to epidermal growth factor. The epidermal growth factor-like repeats implied that the skeletal overgrowth of Marfan syndrome might somehow be mediated by abnormal stimulation of skeletal growth.

The second group (Lee *et al*. 1991b) used fibrillin-specific monoclonal antibodies to purify fibrillin peptide fragments from which sense and antisense oligonucleotide primers were designed. These were then used to select fibrillin cDNA sequences from amplified fibroblast or lymphocyte mRNA/cDNA libraries. When fibroblast cDNA was subtracted with lymphocyte cDNA a 1.6-kb fibroblast cDNA was identified. This was also fibrillin 15 and hybridized as expected to a 10-kb mRNA. Subsequent screening of genomic libraries produced two fibrillin genomic sequences located to chromosome 5q23–31 and 15q15–21. Both contained cysteine-rich, epidermal growth factor-like repeats and were used for linkage to Marfan syndrome and (later) congenital contractural arachnodactyly. Lee *et al*. (1991) also isolated a four-allele $(TA_4)_n$ repeat and a Taq RFLP on chromosome 15 and a seven-allele $(GT)_n$ on chromosome 5. These markers were extremely useful for testing linkage of fibrillin 15 to Marfan syndrome and fibrillin 5 to congenital contractual arachnodactyly.

Other important elements of fibrillin gene structure and organization

The complete genomic cDNA organization of the fibrillin 11 gene has a 11-kb coding region of 65 exons in a 110-kb genomic sequence (Pereira *et al*. 1993). There are numerous independent cassettes with distinctive C- and N-termini, 43 epidermal growth factor-like, calcium-binding motifs, four epidermal growth factor-like, non-calcium-binding regions, seven transforming growth factor-b $_1$-like binding regions and two hybrid motifs. The epidermal growth-factor regions form two subsets, mostly 8-Cys and others with 6-Cys repeats. Calcium binding depends heavily upon highly conserved cysteines at residues 6, 7, 8, 17, 19, and 20, whilst residues 8 to 19 form the b-hydroxylase consensus sequence. Similarly, residue 10 is a b-hydroxylated Asp whilst 15 is an aromatic Tyr (Dietz 1992; Dietz 1993a, Dietz 1993b). Calcium-binding cysteines of epidermal growth factor bridge between residues 6/8, 7/17, and 19/20, and as is evident below, mutations at any of these highly conserved sites are pathological. A quadruple-loop secondary structure results, forming a double 'S' shape upon which calcium binding depends. Various other residues are also strongly conserved, particularly the b-hydroxylase consensus sequence between residues 8 and 19. Yet other cassettes form transforming growth factor-b-like binding-protein domains (Lee *et al*. 1991; Corson *et al*. 1993; Pereira *et al*. 1993). These are interspersed with calcium-binding regions. Combinations of such domains somehow regulate interchain disulphide bonds, whilst the calcium-binding cysteines form intrachain disulphide bonds (Dietz *et al*. 1995). At intervals between the N- to the C-termini, transforming growth factor-b-like cassettes are occasionally coded by two exons but more usually, like the epidermal growth factor regions, by a single exon. The N- and C-termini are each coded by two exons. In all there are 58 cassettes coded by 61 exons whilst transforming growth factor-b domains are coded by cassettes 7, 14, 10, 33, 36, 44, and 50, with calcium regions of epidermal growth factor in between (Corson *et al*. 1993; Pereira *et al*. 1993, Nijbroek *et al*. 1995).

Fibrillin 5 and 15 (Fib1 and Fib2) gene markers in human diseases

Early mutational linkage studies (Dietz *et al*. 1991; Lee *et al*. 1991b; Maslen *et al*. 1991) used two separate but complementary approaches. Firstly, Ramirez's group (Lee *et al*. 1991) tested linkage of the fibrillin 15 gene to several plausible candidate diseases such as Marfan syndrome, familial aortic dissection, mitral-valve prolapse, annuloaortic ectasia, the marfanoid hypermobility syndrome, and congenital contractual arachnodactyly. Only Marfan syndrome linked to fibrillin 15. Next, the Saiki group (Dietz *et al*. 1991, Dietz *et al*. 1992; Maslen *et al*. 1991) used a fibrillin-specific PCR to search for mutations in Marfan syndrome. They also tested families with disorders such as mitral-valve prolapse, medial degeneration of the aorta, and idiopathic scoliosis, all of which were normal. Later fibrillin 15 was renamed fibrillin 1 and fibrillin 5 was renamed fibrillin 2.

Fibrillin-specific mutational analysis

Initial work concentrated on the mutational analysis in Marfan syndrome by PCR amplification of fibrillin 15 cDNA. This project eventually showed that Marfan syndrome, infantile Marfan syndrome, isolated ectopia lentis, and Marfan syndrome families with aortic dilatation were all allelic (and caused by fibrillin 15 mutations). Methods included combinations of cDNA, genomic mutational analysis, protein mapping of ^{35}S-labelled fibrillin proteins, and *in vitro* studies of fibrillin protein assembly using Western-blotted fibrillin and rotary-shadowing electron microscopy to study protein size, migration, and assembly.

Mutational analysis (Table 2)

Early studies

Dietz's originally amplified cDNA sequences corresponded to amino acids 388–408 and 831–849 synthesized from fibroblast mRNA. Later this protocol was extended to include all fragments of the partial 6.9-kb cDNA sequences. Differences in conformation caused by point mutations, exonic deletions or other abnormalities were then sought by single-stranded confirmational analysis followed by *M13* cloning and sequencing. Later (see below) the protocol was streamlined to include the last 3 to 4 kb of the fibrillin-15 cDNA sequence and double-stranded heteroduplex analysis in silver-stained MDE gels followed by direct rather than indirect sequencing.

Table 2 List of Marfan mutations as of early 1996 (after Nijbroek *et al*. 1995)

Mutations were originally found in two separate Marfan syndrome patients. The first had the severe infantile syndrome, severe joint laxity, scoliosis, high-grade myopia, mitral incompetence, and premature dissection of the ascending and descending aorta. The second was only slightly less severely affected. Both had a G–C transversions of nucleotide 716 in codon 239; Pro was substituted for Arg, therefore replacing a basic amino acid with a non-polar one, and impairing protein secondary structure. No similar mutation was detectable in 19 patients with sporadic Marfan syndrome or in 24 randomly affected family members chosen from various Marfan families, nor were any gross gene rearrangements found in 38 unrelated Marfan patients. By the combination of PCR single-stranded or heteroduplex DNA analysis the early mutational analysis was both cost-effective and relatively fast.

In 1991 much still remained to be done. Thus the missing 3.1 kb of the 10-kb mRNA had not been cloned and faster, better methods of mutational screening still needed to be developed. Obvious questions at the time included how often mutations were clustered and private, and whether mutational patterns such as point mutations, stop codons, and exonic and genomic deletions were usual. Rapid and reliable mutational analysis was urgently needed for accurate genetic counselling and prenatal diagnosis. Four years later (1995), by virtue of a large collaborative consortium, mainly of workers in the United States, Finland, and Western Europe, most of these questions now have satisfactory answers.

More recent analysis

The present situation is well summarized in papers by Sykes (1993), Hewett *et al*. (1994), Kainulainen *et al*. (1994), and Nijbroek *et al*. (1995). The latter lists 53 Marfan syndrome mutations, 15 of which are new. They were detected by genomic amplification combined with heteroduplex analysis. PCR primers were chosen for

immediate direct sequencing: 78 per cent were detected by heteroduplex analysis, with 13 novel polymorphisms, four of which were in coding regions. Eight were missense mutations, seven of which were located in the calcium-binding, epidermal growth-factor domain. Another was a missense change in a transforming growth factor-b binding protein-like region. Other mutations included one each in residues 2 and 5, another in the conserved Arg at residue 15, whilst a nearby conformational change in residue 16 substituted Arg for Pro. Contrastingly, in severe Marfan syndrome, there were substitutions in each of the disulphide bridges linking residues 7 to 17 and 19 to 20 with no less than five changes at Cys8 (in residues 129, 926, 1663, 2321, and 2307, each at homologous sites in different cassettes). Other mechanisms included small nucleotide deletions (1, 2, and 3 bp) and amino acid insertions. There were five premature stop-codon mutants, four caused by frame shifts and one by a nonsense mutation. Upstream premature terminations dependent upon 3' exons caused very shortened proteins unable to degrade. Other defects included null alleles with little or no expression of the mutant transcript and double heterozygosity of separate errors in severe infantile Marfan syndrome (Karttman *et al*. 1994). Here W217G and G2627 were derived from the paternal and maternal sides, respectively. The affected child produced no fibrillin microfibrils in culture, whilst fibrillin antibodies failed to stain skin sections.

Mutations that cause infantile Marfan syndrome mainly cluster in exons 24, 26, 27, and 31 between the third transforming growth factor-b $_1$binding-protein domain and the third next epidermal growth factor calcium-binding region (Corson *et al*. 1993; Kainulainen *et al*. 1994; Nijbroek *et al*. 1995). These adjacent domains structurally interact to form a single b-sheet. If intact, the N- and C-termini can somehow influence the behaviour of fibrillin 1 monomers. Nijbroek *et al*. (1995) suggest that the most structurally disruptive mutations are those that least perturb microfibrillar assembly; that is, no microfibrils are better than damaged ones. For example, severe disruption of disulphide bonds in transforming growth factor-b binding-protein regions 3 and 4 are associated with mild Marfan syndrome. Contrastingly, severe disease accompanies non-cysteine substitutions, in-frame deletions or insertions. There have also been two mutations causing truncated polypeptides (Milewicz and Durie 1994; Karttman *et al*. 1994). One is a 366-bp deletion with a shortened but not well-secreted protein (Kainulainen *et al*. 1992). Nijbroek *et al*. (1995) provided a good mutational map, which is shown in Table 2.

Other analytical strategies

Just as in the analysis of collagen I, II, and III mutants, molecular sequencing is often combined with protein studies. In the case of fibrillin, ^{35}S-labelled fibroblast cultures will effectively label profibrillin and fibrillin proteins, which are then visualized by polyacrylamide gel electrophoresis. Generally, three classes of Marfan syndrome mutants are detectable, including a general depression of fibrillin labelling (caused by degraded or null alleles) and shortened proteins such as the 366-bp deletion described by Kainulainen *et al*. (1992). Sometimes there are no visible changes, in some of which abnormal fibrillin 1 protein is masked by fibrillin 2, with which it comigrates. The protocols for pulse-chase analysis profiles have been clearly described by McGookey-Milewicz *et al*. (1992), Raghunath *et al*. (1993), Aoyama *et al*. (1994), and Nijbroek *et al*. (1995). Aoyama *et al*. (1994*a, b*) distinguish five distinct protein phenotypes according to the ratios of secreted (medium) and retained (cell layer) products. The least severe, group V, shows no difference from normal controls. Groups I to IV have variably reduced medium:cell-layer fibrillin ratios, which were lowered or almost equal in groups I and II, respectively. The secretion in the medium in groups III and IV was normal but here cell-layer fibrillins differed, being slightly reduced in group III but subsequently altered in group IV.

Lastly, fibrillin assembly can be observed by rotary-shadowing electron microscopy. This directly visualizes microfibril assembly in cultured dermal or other fibroblasts (Kielty *et al*. 1994, 1995). Interesting perturbations of microfibrillar periodicity and fragmentation have been demonstrated in several circumstances. The normal, 10 to 12 nm, beaded structures formed by trimeric filamentous association is clearly visible. Irregular periodicity, microfibrillar fraying, and missing transverse filaments or clustered beads have all been observed. Electron microscopy of fixed material can also be used for testing structure and function. Interpretation is rather subjective, and disordered patterns can sometimes be produced from normal cell lines and might vary with culture conditions, temperature, and length of incubation (Eladha *et al*. 1995).

Fibrillin 2 mutations

Similar approaches are also valid in clinical molecular analysis of fibrillin-2 mutants. This gene is located on chromosome 5 (Tsipouras *et al*. 1992). Congenital contractual arachnodactyly differs from Marfan syndrome in the presence of joint contractures and crumpled ears (Beale syndrome). Dolichostenomelia and scoliosis also are part of the syndrome whereas aortic rupture/dilatation and lens dislocations are absent.

For fibrillin 2 a combination of protein analysis from cultured fibroblasts and gene amplification works as well as for fibrillin 1. The tissue distribution of fibrillin 2 differs from that of fibrillin 1, being predominantly in the perichondrium, joint capsules, and vertebral columns whilst relatively sparse in the cardiovascular system and missing from the lens suspensory ligaments. Very probably the interactions of the two molecules differ subtly in producing varied clinical phenotypes of the two disorders.

Other genes and Marfan syndrome

Marfan syndrome is homogenous, caused only by mutations of the fibrillin-1 gene on chromosome 15, with two exceptions. The first is an intriguing family with an affected female who synthesized a double collagen a2(I) chain (Phillips *et al*. 1991). Arg(GGC) is changed to Gln(GAC) at position 618 (Phillips *et al*. 1991). This second-position mutation changes a charged Arg residue that is highly conserved in chick, bovine, and human material and also other similar human genes such as *COL1A1*, *–1A2*, *–3A1*, and *–5A2*. Charged amino acids are very highly conserved in collagen sequences and uncharged residues such as Gln may theoretically alter the intermolecular alignment of the a2(I) chain-containing fibrils. The substitution also accounts for the altered electrophoretic mobility of the mutant collagen a2 chain for several reasons. It is still unclear what relevance the mutation has to the Marfan syndrome. Although both the proband and her father carried the mutant *COL1A2* gene, only the proband had convincing clinical changes (without lens dislocation), but the father may have been a mixed somatic–gonadal mosaic. More significantly, no other Marfan syndrome has ever been linked to the *COL1A2* locus.

An unusual French family described by Collod *et al*. (1995) is also interesting. Here, linkage to chromosome 15 was excluded and the locus mapped to chromosome 3p24.2–p25. This is quite near the *COL7A1* locus at 3p21, which was later excluded as a candidate gene. The family contained over 170 affected individuals in at least four generations. Clinical features included small stature, widened arm span, arachnodactyly, scoliosis, pectus excavatum, valve prolapse, and aortic dilatation, dissection and rupture, together with myopia or ectopia lentis. The investigators were convinced that these fitted Marfan syndrome whilst other prominent researchers disagreed. Doubtless neither fibrillin 1 nor fibrillin 2 are the only causes of Marfan syndrome-like symptoms and signs. 'Splitters' have postulated intrafamilial genetic heterogeneity as the likely reason for the vascular pathology of the Marfan syndrome (Dietz *et al*. 1995). The original investigators, in contrast, are convinced that this is Marfan syndrome and that the Berlin nosology needs widening and modification (Collod *et al*. 1995).

Future directions and development

The information outlined above quite clearly illustrates the importance of 'the new genetics'.

Chondrodysplasias

Introduction

There are over 150 distinctive chondrodysplasias (Spranger 1992). They are inherited in autosomal-dominant, autosomal-recessive or X-linked recessive patterns from numerous different genes. The variability of clinical phenotype is exceptional, with almost bewildering numbers of variants. Understanding the mechanisms of mutations should illuminate fundamental questions regarding mechanisms of embryonic development, pattern formation (segmentation), determinants of bone, cartilage and limb shape or stability, and other important molecular interactions of skeletal components one with another. Until 1993, this field had lagged behind rather rapid advances in the unravelling of the molecular mechanisms of other matrix structures such as skin, ligaments, arteries, and bones. In the late 1980s this had begun to change with the initial identification of *COL2A1* mutations in certain chondrodysplasias, such as epiphyseal dysplasia or premature osteorarthrosis with associated vitreous or skeletal deformities. Examples of this group are achondrogenesis, Kniest syndrome, spondyloepiphyseal dysplasias, and the Stickler syndrome. There has been a recent information explosion regarding the mutational mechanisms of widely disparate disorders such as the Crouzon/Apert syndrome, Pfeiffer craniofacial abnormalities, thanatophoric dwarfism, achondroplasia and hypochondroplasia, as well as diastrophic dysplasia—all of which share similar mechanisms. Such abnormalities are caused not only by unexpected structural elements such as *COMP5*, but also by other substances that regulate, orchestrate, and determine skeletal patterning, shape, integrity, and development such as *HOX*, 'spiny hedgehog', fibroblast growth factor and its receptors (types 1–4), bone morphogenetic protein, GMP regulator proteins, growth hormone, parathyroid hormone-like protein, and modifying substances such as sulphate transporters and sulphatases of various kinds. In contrast, mutations of structural proteins such as those in collagens II, IXa1, IXa2, IXa3, X, and XIa1 or IXa2 are relatively rare. Hopefully, cataloguing of mutations in various types of collagen and matrix components will eventually clarify the biology of embryonic, limb, skeletal, and structural

development in very unexpected and enlightening ways.

Since the first version of this chapter was written in 1993, there have been unusually rapid and unforeseen advances in the molecular pathology and biology of these disorders. Skeletal maldevelopment is the result of many of them, although only relatively few are caused by errors in scaffolding components. Errors in the orchestration of connective tissue expression are very important indeed. Horton (1995) has recently tabulated in summary form most of the recent examples, which we have subsequently outlined below.

Hierarchical development of bone and skeleton

Skeletal development follows a orchestrated sequence and pattern that determines overall growth and morphology, and subtle variations in shape or location of particular components. These complicated symmetrical structures need regulating both in time and space. Final bone anatomy results from complex interactions of many different regulatory patterning or structural genes. Until very recently only some of the latter had been amenable to analysis.

Morphogenesis (the integrated determination of shape and pattern) results from a dynamic balance between cartilage or bone deposition and breakdown, so producing a constantly shifting balance between each of the individual constituents. There is also the continuous ebbing and flowing of bone and cartilage deposition and degradation, more particularly in those bones that grow by the balance of continual accretion and removal. Whilst individual bones enlarge they still maintain the shape of their original embryonic cartilaginous templates. There is a hierarchical organization of those factors that control this process. Such factors include the interaction genes and proteins that determine bone shape with factors that regulate bone growth, remodelling, modelling as well as certain crucial structural components including collagens II, IX, X, XI, BMP, and *COMP5* (Kingsley 1994; Erlebacher *et al*. 1995).

Skeletal patterning

Vertebrate skeletons have three major components, the head and neck (craniofacial region), the spine/pelvis (axial), and the limbs (appendicular skeleton). The craniofacial component derives from the embryonic branchial arches, which themselves arise from the neural crest. The axial skeleton (spine, ribs, and pelvis) originates from the sclerotomes whilst the lateral mesoderm dictates which elements eventually become the limbs. Except for the skull and pelvis, which are largely of membranous origin (and which develop directly from mesenchymal condensations), most of the remainder originates as cartilaginous templates that gradually transmute into bone. This sequence includes ordered mesenchymal condensation, chondrocytic differentiation, hypertrophic calcification, and apoptosis (Kraus *et al*. 1993). Vascularization is the trigger for the replacement of the cartilaginous protoskeleton with more mature, osteoblastic bony elements. Eventually, after epiphyseal closure, only traces of cartilage remain distally upon the articular surfaces, although hypertrophic metaphyseal cartilage precedes trabecular bone formation. Skeletal patterning is determined by certain segmentation genes, which turn out to be transcriptional regulators (the so-called homeobox genes). The homeobox genes are highly conserved, pattern-determining controllers acting very early in the embryos of segmented animals (including species as diverse as vertebrates and insects). The functions of particular subsets specifically vary with segmental positions (and are organized and expressed temporally in a head-to-tail distribution with subsets that specifically regulate the face, mid and peripheral elements). As might be expected, mutations of such neuroectodermal patterning genes seriously disrupt the correct sequences and patterns of, for example, branchial arch development and axial morphology. Typical vertebrate examples are mutations in the *HOXA2, HOXA13d*, and the *PAX* superfamily, all of which (see below) cause variants of craniofacial or skeletal patterning and development (Krumlauf 1994).

HOXA2 and *HOXA13d* mutants

HOXA2 acts before the appearance of the second branchial arch. Mutations in mice delete crucial elements of the second arch and instead replaces them with first-arch derivatives that are consequently duplicated (Gendron-McGuire *et al*. 1993). Examples include duplication of the middle-ear ossicles, duplication of the optic capsule, and bilateral clefting of the secondary palate. Such mutations disturb the execution of second-arch development even though the necessary precursors for their later appearance (that is, the neural-crest rhombomeres) are already safely in place (Rijli *et al*. 1993).

HOXA13d mutants

Similar inactivation of the *HOXA13d* gene transmutes the fourth into a third sacral vertebra with consequent limb abnormalities (Dolle *et al*. 1993); these include shrivelling of digits II and V in both the front and hind paws, and also the phalanges of digits III and IV, which are compressed whilst all the corresponding terminal phalanges are virtually normal. Sometimes extra rudimentary digits appear posteriorly (on the ulnar margins of the forelimbs). The affected animals are otherwise normal, in keeping with the late (temporal) activation of this rostrally located (sacral) member of the *HOX* family. Mutations impair the condensation of the cartilaginous precursors of digital bones so that final ossification is abnormal. The *HOX* family can be regarded as a series of morphogenetic clocks by means of which vertebrate development is controlled by the consecutive switching of the four members of the *HOX* gene cluster (*HOXA–D*). These are spatially disturbed in the same nose-to-tail order in which they both appear and function anatomically. Thus, the switching on of any 3' gene immediately precedes its next 5'-most adjacent associate. Mutations of these genes are highly homologous throughout many disparate animal species. Thus, errors of similar determining elements in flies produce spectacular disorganizations such as bithorax and antennopaedia in which segments are duplicated or legs appear where wings should normally be.

PAX mutations

Mutations at the *PAX* loci are homologous to one another (Tassabenji *et al*. 1993). This gene family participates not only in skeletal (embryonic) development but also in carcinogenesis. Mutations produce either gain or loss of function patterns. Thus *PAX3* (loss of function) causes disorders such as Waardenburg syndrome, craniofacial deafness with hand abnormalities or rhabodyomyosarcoma depending on whether this gene is amplified or duplicated. Similarly, *PAX6* gene loss-of-function mutations cause faulty eye development with aniridia and several *PAX* mutations perturb development of the central nervous system. *PAX3* mutations frequently disturb skeletal development, with characteristic facial malformations (broadened nasal bridge and misshapen orbits) combined with skeletal abnormalities such as contractures and hypoplasia of the upper limb bone. The craniofacial/deafness/hand syndrome MIM122880 is also a *PAX* mutant.

Other human homeobox mutants

Autosomal-dominant craniosynostosis (Boston type) is caused by mutations of the *MSX2* gene (Jabs *et al*. 1993) located on chromosome 5 (Warman *et al*. 1993). This is distinct from other craniosynostotic loci such as for Crouzon, Apert, and Jackson–Weiss syndromes, which are caused by mutations of the *FGFR1* or *–2* genes. As might be expected, *MSX2* is expressed precisely in the face, mandible and maxilla, especially in the cranial sutures. The responsible mutation changed histidine to proline at a site that is highly conserved in species as disparate as human, arthropods, sea urchins, and vertebrates. Only Boston-type craniosynostosis is caused by errors in these genes in contrast to others, such as Apert syndrome, in which the *FGFR* genes participate (see above).

Mechanism of action of the homeobox and segmentation genes

Skeletal symmetry largely depends upon certain crucial inductive interactions of one matrix gene with another. Thus limb-patterning signals emanate from the so-called zone of polarizing activity (*ZPA*) genes, which are specifically localized to the mesoderm of the posterior limbs. These entities are controlled by the apical ectodermal ridge of the developing limb. Transplantation of the ridge anteriorly induces a second, duplicated limb bud that is a mirror image of normal. Retinoic acid (vitamin A) has a similar effect. Thus a soluble inducing element spatially mediates *ZPA* activity by specifically inducing *FGFR4*. In turn this unleashes a cascade of regulatory substances that further influence patterns and development. Such inductive patterns execute the spatially and temporally expressed commands of the homeobox genes mentioned above. Thus the orchestration factor released by *ZPA* activity is mediated by the 'sonic' gene. In *HOX13D* mutants, 'sonic hedgehog' then switches on bone morphogenetic protein 2, which is a transforming growth factor-b protein that in turn itself tells cartilage when to appear and develop. 'Sonic hedgehog' factor (Riddle *et al*. 1993) is presumed to act either as a diffusable morphogen in a concentration gradient or by the initiation of cell–cell interactions by downstream elements in the hierarchy preceding the eventual appearance of more permanent scaffolding compounds. *ZPA* liberates a morphogen that also duplicates the action of retinoic acid, which in turn produces a specific signalling molecule. The signalling molecule resembles the segmental polarity regulators that are essential and common in developing embryos. These genes include those such as 'armadillo', 'engrailed', 'gooseberry' and 'wingless', all of which are crucial for the correct sequential development of *Drosophila* embryos. 'Hedgehog' is a classical concentration-dependent morphogen very similar to its equivalent *Drosophila* homologue. It is highly conserved in all animal species and is 78 per cent identical in chicks and flies, implying a very fundamental function in embryogenesis. Its name derives from a character in a computer game, whilst its expression is located to the posterior limb bud precisely congruent with the distribution of *ZPA*.

Local regulation of bone shape

The morphometry of prototype cartilage precursors themselves originates from more blurred mesenchymal condensations. Each step is controlled separately by one or more members of the gene hierarchy families mentioned above. Thus, mouse mutants, such as brachypodia and short-ear, can produce variously misshapen components or malformed skeletal elements. For example, short ear (sc) phenotype radically alters both sternal shape and the morphology of the external ear whilst 'brachypodia' (bp) specifically shortens appendicular long bones. Equally importantly, the equivalent embryonic precartilaginous structures are also similarly distorted. Furthermore, subcutaneous and bp are caused by specific inactivation of either bone morphogenetic protein 5 or GGF5. These are both members of the transforming growth factor-b superfamily that are expressed later than *HOX* patterning genes but before (earlier) than connective-tissue structural genes, which are later players in the hierarchy of development of gene expression. In skeletal development, such substances somehow orchestrate and timetable the development and three-dimensional patterning of precartilaginous mesenchyme. Similarly, the complexities of endochondral ossification necessitate the coordinated and orderly expression of epiphyseal, metaphyseal, and diaphyseal components essential for the synchronization of the cartilaginous epiphyseal plate/metaphysis/diaphysis, which enlarges progressively from infancy to adulthood in a similar manner to the circumferential seasonal accretion of tree rings.

Dysplasias, such as achondroplasia, hypochondroplasia, pseudoachondroplasia, and diastrophic dwarfism, that distort the appendicular skeleton are produced by disturbances of different elements in this complex process.

The functions of fibroblast growth factors (FGF) and their receptors

The *FGF* superfamily specifies proteins that bind to specific transmembrane FGF receptors (FGF1–4) (Grovl and Yaifin 1992). These regulate the proliferation or differentiation of certain mesenchymal and neuroectodermal cells, and are partially tissue-specific. Mutations of the *FGFR* genes produce very specific diseases such as achondroplasia (Lajeune *et al*. 1995), or Pfeiffer or Crouzon syndromes. They are transmembrane glycoproteins that bind fibroblast growth factors. The various homologues have common features such as intracellular tyrosine kinase and extracellular immunoglobulin domains and transmembrane bridges. The immunoglobulin domain that is variably spliced can generate various mutations or the FGFR3 receptors with differing affinity for FGF. The *FGFR3* gene that is expressed in cartilage rather than bone cause achondroplasia. Similarly, Crouzon and Pfeiffer syndromes are caused by mutations of *FGFR1* and *FGFR2* (Jabs *et al*. 1995). The various genes share both overlapping and common patterns of embryonic expression, and strongly influence both embryonic and fetal development. Thus, expression of *FGFR3* is detectable in the neurotubular epithelium, adult neuroglia, and cochlear ducts. On the other hand, *FGFR1* and *–2* occur in precartilaginous bone but also in resting cartilage during endochondral ossification (Peters *et al*. 1993).

Abnormalities of the *FGFR* genes

Recent advances in molecular pathology of certain apparently unrelated chondrodysplasias or craniofacial anomalies have all implicated the *FGFR1*, *–2* or *–3* genes in a manner that is both domain and position related. Thus, achondroplasia is caused by an *FGFR1* mutation, as are the Crouzon, Apert, Pfeiffer, and Jackson–Weiss syndromes. Very recently, both thanatophoric dwarfism and hypochondroplasia have also been shown to have *FGFR* mutants.

Achondroplasia (Fig. 24a–c)

The first mutation in achondroplasia was described by Shiang *et al*. (1994) in 15 out of 16 random achondroplastics, and by Rousseau *et al*. (1994) in 23 individuals. Remarkably the error lay in the transmembrane coding region, nearly always the same base of the same codon. The same single faulty codon was later detected in 153 out of 154 achondroplastics (Bellus *et al*. 1995). The mutation in codon 380 in the immunoglobulin repeat region is a G–A transversion, which in 150 individuals was at position 138. The remaining three had a G–C substitution at the same locus. The 154th case is so far unidentified. No G–T transversions have occurred and may either be genetic lethals or have a different clinical phenotype. So far, more than 99 per cent of achondroplastics have identical, single base-pair mutations. This is quite remarkable and has no precise parallels (so far) in any other genetic disease, but implies extreme chemical instability of this locus.

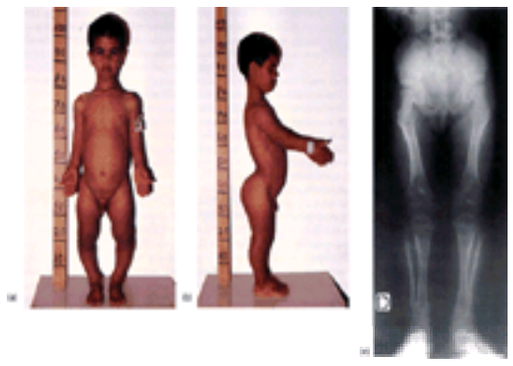

Fig. 24 Phenotypical (a) and (b), and radiographic features (c) of a typical patient with achondroplasia. The resemblance to Fig. 25 is obvious and both defects are caused by abnormalities of the same gene

Hypochondroplasia (MIM146000)

Hypochondroplasia, which is allelic to achondroplasia, is caused by mutations in the tyrosine kinase region of the *FGFR3* gene. Thanatophoric dysplasia is also caused by mutations at a different *FGFR3* locus. Although thanatophoric dysplasia (MIM187600) superficially resembles achondroplasia, there are variously distinctive clinical and morphological differences. Overall it is very much more disabling and severe, and also has associated severe defects in the central nervous system.

The mutation rate in achondroplasia is between 15 to 760 times higher than that of any other known CpG mutation. Other known examples such as globin, cystic fibrosis, haemophilia, and collagen mutations are much lower.

Other *FGFR3* mutations including thanatophoric dwarfism

Thanatophoric dysplasia has several subtly different phenotypes, all of which are severely deforming and genetically lethal. Recently the mutations that cause this disorder have been located to sequences between the Ig2 and Ig3, or between Ig3 and the transmembrane coding region of *FGFR* where the mutations also lie. There is also a second thanatophoric (type II) locus in the distal half of the tyrosine kinase extracellular coding domain. In contrast, many hypochondroplasia mutations lie within in the tyrosine kinase A domain, such as Arg540–Lys, which is a common error at this site. Similarly, Pfeiffer, Apert, Crouzon and Jackson–Weiss *FGFR3* mutants are positional homologues of equivalent *FGFR1* and *FGFR2* mutations.

Thanatophoric dysplasia (Fig. 25(a–e))

This is the most common, lethal, neonatal skeletal dysplasia with a frequency of 1/20 000 live births. Typical features include micromelia, macrocephaly with a frontal bossing, flattened vertebral bodies with disorganized cartilage growth plates, and markedly shortened ribs with abdominal distension. Affected babies usually die from respiratory failure caused by restrictive lung disease from the severe thoracic dysplasia. There are two radiographic subsets, thanatophoric dysplasia I with curved shortened femurs (telephone-receiver pattern) and clover-leaf skull, and thanatophoric dysplasia II with straight legs and severe clover-leafing of the skin. Achondroplastic homozygotes strongly resemble thanatophoric dysplasia I and II heterozygotes. These two disorders have long been considered as allelic. This conclusion is correct as both achondroplasia and thanatophoric dysplasia are caused by *FGFR* mutations (see above and below).

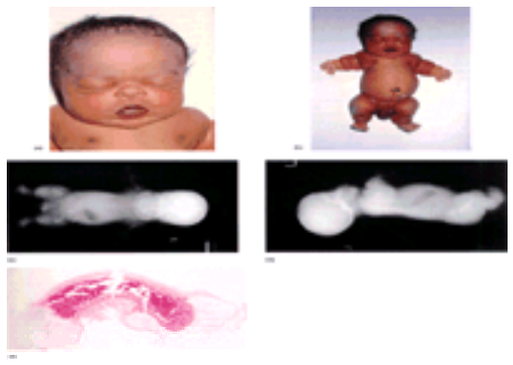

Fig. 25 (a, b) Facial and full-body phenotype of affected baby with thanatophoric dysplasia. (c, d) Babygram radiographs of the same child showing severe thoracic dysplasia, telephone-receiver femurs, and a dysplastic skeleton. (e) Histological appearance of section of femur showing a disturbed diaphysis and disorganized cartilage × 1.5.

Recently the two types of thanatophoric dysplasia have been distinguished by their molecular pathology. Firstly, Tavormina *et al*. (1994) suggested that the *FGFR3* gene functions either in growth-plate development or in calvarial bone fusion of the developing fetus. Those *FGFR* mutations such as Arg248–Cys and Lys650–Glu replace crucial residues and severely disrupt the secondary or tertiary structure and function of *FGRF3* protein as a result. Perhaps such errors severely impair intracellular signalling either by distorting protein structure or by preventing the dimerization of adjacent protein chains by a positive/negative effect. Such mechanisms are very much more disruptive than loss of function; thus simple deletion of one allele (lower dosage) has no clinical effects. The FGF signal-transduction pathway is complex, comprising at least nine ligands and four receptors, of which three are alternatively spliced.

FGFR1 and *FGFR2* mutations

The discovery of *FGFR3* mutations in achondroplasia is paralleled by the discovery of similar changes in the *FGFR2* gene in Crouzon syndrome (Reardon *et al*. 1994). The identification of *FGFR1* mutations in Crouzon, Apert, Pfeiffer, and Jackson–Weiss disorders rapidly followed. A little later, similar abnormalities were observed in thanatophoric dysplasia and hypochondroplasia. Such varied clinical phenotypes are dictated entirely by mutational position and type.

Craniosynostosis

The craniosynostoses include the Apert, Crouzon, Pfeiffer, and Jackson–Weiss syndromes. Common features include premature fusion of skull sutures producing skull distortion, widely spaced, bulbous eyes with hyperteleorism, and mid-facial folds (Muenke *et al*. 1994). The Pfeiffer, Crouzon, and Jackson–Weiss syndromes overlap, but the Pfeiffer syndrome is distinguished by severe hand and foot anomalies such as broadened thumbs, syndactyly, and shortened fingers and toes. Broadened big toes with tarsal and metatarsal syndactyly are also common in the Jackson–Weiss syndrome. Some Pfeiffer syndrome families are linked to chromosome 8 with *FGFR1* but others are not. In contrast both Crouzon and Jackson–Weiss syndromes were initially mapped to the distal long arm of chromosome 10 where *FGFR2* also lies. Subsequently, various *FGFR* abnormalities have been associated with these clinical phenotypes and mutations in three of the four known *FGFR* genes have been detected in the various Crouzon, Jackson–Weiss, and Pfeiffer families.

Examples

A highly specific Pro252–Arg substitution caused by an AC conversion in exon 5 was detected in the extracellular domain of five unrelated families with Pfeiffer syndrome. The Pfeiffer syndrome phenotype included premature skull fusion, widely spaced eyes, and mid-facial hypoplasia. Similarly, the Jackson–Weiss syndrome (MIM123150) combines skull and limb abnormalities with broadened toes and tarsal and metatarsal coalescence as mentioned earlier. Just as in Crouzon syndrome there are mutations in the IgIIIc region of *FGFR2*, whereas the original and subsequent Crouzon mutations included IgIII Tyr328–Cys and Ser347–Cys. The tissue expression and distribution of *FGF1, FGFR2*, and *FGFR3* proteins partially explains the clinical phenotypes of Crouzon and Jackson–Weiss syndromes. Thus, whilst *FGFR1* is expressed throughout active limb bud, *FGFR2* expression at the equivalent stage of embryogenesis is confined to limb-bud ectoderm. *FGFR1* mutants might therefore be expected to have more severe limb deformities. Those *FGFR2* mutations that cause Crouzon/Jackson–Weiss syndrome lie in exon 7, which codes for IgIII. These particular sequences are preferentially expressed in skull *FGFR* proteins and will therefore interfere with the timing of skull suture fusion. Contrastingly, the Pro252–Arg *FGFR1* mutation in Pfeiffer syndrome lies in an exon shared by several isoforms of *FGFR1* protein. The clinical phenotype is therefore less specific. Mutations are located to sequences normally very highly conserved in both man and chickens; so far the function of this domain, whilst important, is completely unknown.

Apert syndrome can also be allelic to Crouzon syndrome (Wilkie *et al*. 1995). Thus identical mutations of the *FGFR1* gene can cause either Pfeiffer or Crouzon phenotypes (Rutland *et al*. 1995). An example is Cys342–Arg previously described in Crouzon syndrome. A Tyr–Cys343 had also been described in Crouzon syndrome. Several Apert mutations mutate either Ser253–Trp or Pro253–Arg (Wilkie *et al*. 1995).

The mutational correlations can therefore be summarized as follows (Mulverhill 1995). *FGFR3* mutations were first demonstrated in achondroplasia (Shiang *et al*. 1994). Rousseau *et al*. (1994) then reported an achondroplasia mutation at nucleotide 1138 changing Gly380 to Arg. Very soon afterwards *FGFR2* mutants were detected in Crouzon syndrome followed by Jackson–Weiss mutants Arg344–Gly in exon 9 of *FGFR2*, which were two amino acids outside the loop-defining cysteine. Next, two *FGFR2* mutations in adjacent residues disrupting the peptide linkage between Ig loops II and III were detected in Pfeiffer syndrome. One form that exhibited mild syndactyly changed Ser252 to Trp whilst the other with more severe deformities and accompanied the Pro253–Arg mutation. Pfeiffer syndrome can be caused by mutations of either *FGFR1* and *FGFR2* genes (e.g., the *FGFR1* Pro252–Arg lies between Ig loops II and III with the *FGFR2* equivalent located to the second half of the IgIII loop). Similarly, Crouzon and Pfeiffer syndromes are allelic and may be caused by identical errors in *FGFR2* such as Cys342–Thy or Cys342–Arg. As Mulverhill (1995) comments, there are only limited numbers of clinical repertoires in response to widely variable molecular changes. Lastly, as mentioned earlier, thanatophoric dysplasia (both types I and II), achondroplasia, and hypochondroplasia are allelic but separately located to protein domains such as the tyrosine kinase and extracellular portions of the *FGFR1* protein. Presumably, epiphyseal growth is both dictated and regulated by particular fibroblast growth factors that in their turn define complex local paracrine/autocrine interactions between the varied mesenchymal components of bone and cartilage, which in turn themselves bind to particular fibroblast growth-factor receptors. These molecules are also influenced by other substances that consequently orchestrate overall skeletal growth. An example of the latter is parathyroid hormone-related protein. This is expressed throughout the epiphyseal plate even though its receptors are confined to the proliferative zone of hypertrophic cartilage where collagen X is also specifically expressed. Knock-out parathyroid hormone-related protein mice have prematurely ossified skeletons. Errors in other important factors such as the sulphatase genes (Hastbacka *et al*. 1995) result in diastrophic dwarfism, whilst faulty sulphate transport causes achondrogenesis (Superti Furga 1994). No doubt many other elements in the jigsaw await discovery.

2.3 Articular cartilage

Tim Hardingham

Introduction

Articular cartilage is a unique and long-time enigmatic tissue that is just beginning to reveal some of its secrets. Just a few millimetres thick, cartilage is ingeniously fashioned so as to withstand the considerable biomechanical forces created by walking, running, and jumping, extending over many decades (Muir and Hardingham 1986). Even during gentle walking, the force acting at the hip joint is equivalent to four times the body weight. Articular cartilage (Fig. 1) is unique in that it is a poorly cellular tissue with no basement membrane, no innervation, and no direct blood supply, relying on diffusion for its nutritive requirements. It is increasingly being realized that cartilage failure as seen in diseases such as osteoarthritis is far from being the passive degenerative condition long assumed, but represents an imbalance between dynamic reparative and catabolic processes, which in health proceed in a harmonized and strictly regulated manner (Hardingham 1990; Hardingham and Bayliss 1990).

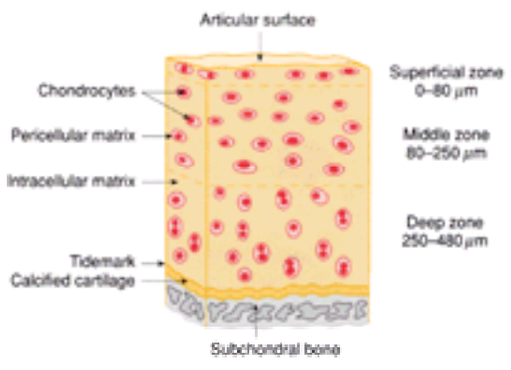

Fig. 1 Structure and organization of articular cartilage. Schematic drawing showing changes in organization from the articular surface to the subchondral bone.

The load-bearing properties of the tissue depend on the structure and matrix. The integrity of the matrix is maintained by the activity of the chondrocytes (Stockwell and Meachim 1979). The matrix contains more than 70 per cent water but, because of the high proteoglycan content, there is only free diffusion of small molecules. Solutes of large molecular weight are excluded from proteoglycan domains and, therefore, the mobility of molecules in the matrix depends on their size. The articular cartilage is bound to the underlying bone through a narrow calcified zone of cartilage. The junction between the calcified and non-calcified zone of cartilage forms the tidemark, which is named for its strong histological staining.

The articular surface is formed by a dense collagen layer of low proteoglycan content, but which is otherwise a part of the cartilage rather than a separate boundary layer. The articular joint and its component structures surrounding the synovial compartment are not bounded by any basement membrane. There are no epithelial or endothelial boundaries. All the structures are of mesodermal origin. The synovial membrane has a thickness of one or a few cells and forms the surface layer of the synovial tissue, but it is otherwise not distinct from it. The deeper synovial tissue is well supplied with blood vessels and contains many cells rich in fat deposits. The synovial tissue becomes a site of major inflammatory reaction in joint diseases such as rheumatoid arthritis.

In chronic rheumatoid arthritis it undergoes massive hyperplasia and forms a complex villous structure extending into the synovial space with a thickened lining cell layer and heavy lymphocytic infiltration with lymphoid follicles. The articular cartilage, synovium, and ligaments thus share a common compartment, with the synovial fluid linking them together. The tissues are therefore exposed to all the components that come into synovial fluid. Inflammatory events in the synovium that lead to the release of inflammatory mediators and cytokines will have consequences on ligaments and on articular cartilage.

The function of the articular joint is to give movement and mobility to the otherwise rigid bony skeleton (Mow and Lai 1980). The joint transmits force from one bone element to another. Bones are linked by ligaments and muscle/tendon elements. The articular cartilage provides two opposing smooth surfaces of extremely low friction for easy articulation, and a deformable and elastic tissue that helps distribute the load more evenly on to the underlying bone.

The different components in the joint thus have complimentary mechanical functions. All these connective tissues respond to the mechanical forces placed upon them and, in general, extra use leads to hypertrophy and mechanical strengthening. This is evident from experimental studies which showed that moderate running exercise in dogs resulted in an increase in articular cartilage thickness and proteoglycan content, and a rise in compressive stiffness (Kiviranta *et al*. 1992). This contrasted with excessively strenuous running exercise, which led to a fall in proteoglycan content, a loss of compressive stiffness, and some remodelling of the subchondral bone; but even severe exercise did not cause degeneration of the articular surface or lead to degenerative joint disease (Arokoski *et al*. 1993). High loading of a healthy joint is thus unlikely alone to initiate joint disease.

Unlike exercise, disuse of the joint leads to atrophy of the articular cartilage (Buckwalter 1995). Even temporary immobilization of a joint can result in a fall in the synthesis and content of proteoglycan; more prolonged disuse can result in the degeneration of articular cartilage and its eventual complete loss and replacement of the joint space with fibro-fatty tissue. The healthy maintenance of the different tissues thus depends on their regular mechanical loading in normal use and this reflects a property of the cells within the tissue that control the production and maintenance of the matrix. It is also clear that changes in the mechanical performance of any one joint tissue will have consequences on the loads experienced by other components causing further adaptive responses. This may be particularly prejudicial to articular cartilage integrity if it results in joint instability and greater impact loading. Therefore, the articular joint and its component tissues are far from being static structures and even in the mature animal they are in a constant dynamic state of adaptation and response. Many of the changes present in joints after many years of chronic joint disease may thus reflect adaptive responses to altered patterns of load distribution in the joint as well as direct effects of the disease processes

themselves.

Cartilage

Cartilage occurs in various forms in the body and with different functions. In embryological development it is the important forerunner of long bone development and it persists in the growth plate as the major site of long bone growth. Cartilage is also formed in the body whenever there is a recapitulation of bone development, such as in fracture healing. Cartilage occurs in other sites of the body: it supports the air passageways as bronchial rings, in the larynx it supports the vocal chords, and it occurs as nasal cartilage. It is also found in considerable amounts as intercostal cartilages and at other sites it is in various ways reinforced by other connective tissue components. The cartilage supporting the external ear contains elastin fibres, and fibrocartilage, such as that found in the menisci of the knee, contains extra type I collagen reinforcement. The intervertebral discs also contain a radially reinforced collagen structure surrounding inner regions more similar to hyaline cartilage that resist compressive loading. A thin hyaline cartilage layer also forms an articular surface at the end plate of the vertebrae where they contact the intervertebral discs. In all these forms, the basic features of cartilage are that the cells within it produce a large expanded proteoglycan-rich matrix, which together with the fibrillar network make a stiff but elastically deformable tissue that is able to withstand repetitive compressive loading.

Physical properties of articular cartilage

The physical properties of articular cartilage depend on the structure and organization of the macromolecules in the extracellular matrix (Hardingham 1990; Hardingham and Bayliss 1990). They largely can be understood in terms of the contribution made by fibrillar and non-fibrillar components (Fig. 2). The collagen fibrillar network is of fine fibres that have no preferred orientation in the mid-zone of the cartilage, although at the articular surface they are parallel to the surface and with one preferred orientation, and they are rather more perpendicular to the surface in deeper zones. The collagen provides an essential framework to the tissue that gives it shape and form. The triple helical collagen molecules are organized into fibrils with overlapping and cross-linking of adjacent molecules, and fibrils laterally associate into longer fibres. The structure of collagen gives it impressive tensile properties and this is utilized in cartilage in a special way to produce a tissue that is not only strong in tension but also resistant to compression. This is achieved by filling the interfibrillar matrix with a very high content of proteoglycan, primarily aggrecan. The aggrecan at high concentration draws water into the tissue as it creates a large osmotic swelling pressure (Fig. 2).

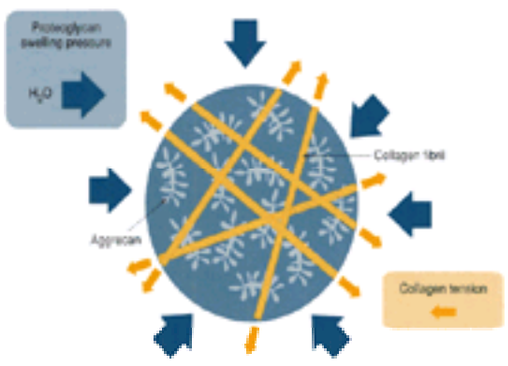

Fig. 2 The combined functions of collagen and proteoglycan in providing the compressive resilience of cartilage. The collagen fibres resist tension and provide the shape and form of the tissue. The proteoglycans (mainly aggrecan) are immobilized and create a large osmotic swelling pressure that extends the collagen network. The resulting tissue is tough, hard-wearing, and deforms elastically under load.

The osmotic pressure is caused by all the negatively charged anionic groups on aggrecan which carry with them mobile counter ions such as Na^+. This creates a large difference in the concentration of ions inside the cartilage compared with outside and also an imbalance amongst the freely diffusible anions and cations. Water is drawn into the tissue as a result of this osmotic imbalance and because aggrecan is too large and immobile to redistribute itself. The water thus swells and expands the aggrecan-rich environment. This places the collagen network under tension and an equilibrium is achieved when tension in the collagen network balances the swelling pressure, i.e. when no more water enters the tissue because the force is insufficient to stretch the collagen network any further. At this equilibrium, with the tissue swollen with water, it has good compressive resilience as any new load on the tissue now places the collagen network under further tension. Another feature of the composite collagen/aggrecan organization is now important, as not only is aggrecan greatly restricted in its ability to move within the matrix and the collagen/aggrecan network is stiff and resists deformation, but aggrecan offers great resistance to any fluid flow and redistribution of water. The tissue thus behaves largely as a stiff elastic polymer to sudden impact loading, but shows some slow inelastic deformation with sustained loads. However, removal of all loads leads to a redistribution of water and a return to the preloading equilibrium position. The articular cartilage thus forms a tough but compliant load-bearing surface and these characteristics depend on the integrity of the collagen network and the retention within it of a high concentration of aggrecan.

Collagens

The collagens are a family of secreted matrix proteins that contain elements of a unique triple-helical peptide structure with a repeating motif, with glycine as every third amino acid and a high frequency of proline, 40 to 50 per cent of which is hydroxylated. The presence of hydroxyproline is essential for the stability of the collagen triple helix and hydroxylation of proline is an early post-translational step in synthesis. The collagen gene family is now known to be quite large, but its members fall into two main groups, those that contain long, uninterrupted, triple-helical 'collagenous' domains that form the main fibrillar collagens, types I, II, III, V, and XI, and those that contain shorter, non-fibrillar-forming collagenous domains that form a variety of beaded filament and network structures (Vuorio and de Crombrugge 1990). A further subgroup has been identified as the fibril-associated collagens with interrupted triple-helical domains, such as type IX, XII, and XIV (Olsen 1995). All the fibrillar collagens pack into fibres with a characteristic overlap between adjacent triple helices that gives a staggered array, which facilitates the formation of a cohesive cross-linked fibre, and accounts for the 67 nm banding pattern visible in electron micrographs of collagen fibres.

The most common collagen in the body is the type I fibrillar collagen that occurs as the main structural element in bone, skin, ligaments, and tendons, often occurring together with type III collagen. In contrast, articular cartilage contains collagens of a more restricted distribution that are specifically associated with cartilage (see Table 1). The major collagen of cartilage is type II, which forms 80 to 90 per cent of the total content. It is a long-chain fibrillar collagen and forms the major fibre network of the tissue. Type II collagen differs from type I in containing three identical chains, whereas type I contains two a_1(I)-chains and one a_2(I)-chain. Type II also contains more hydroxylysine than type I and is generally more glycosylated, with a higher content of galactose–glucose disaccharides attached to the hydroxylysine residues. Type II collagen has a very limited distribution in other tissues; apart from in cartilage and the intervertebral discs, it only occurs in the vitreous chamber of the eye. It forms a long-chain, fibrillar, triple helix that is 285 nm long and has large N- and C-terminal propeptides that are removed enzymatically by specific N- and C-propeptidases prior to fibril formation. The fibres it forms are generally of a smaller diameter than those formed by type I collagen and they are cross-linked at specific segments of the N- and C-terminal regions. These bonds are of a stabilized Schiff base that forms a pyridinolone. It is therefore a permanent covalent linkage and mature collagen fibres cross-linked in this way can only be solubilized and resorbed by extensive proteolytic action to excise the cross-linked segments (Eyre and Wu 1995).

	Type	Molecular composition	Tissue distribution
Class I fibril forming	Type II	[α_1(II)$_3$]	Throughout tissue, major constituent
300 nm, triple helix	Type XI	[α_1(XI) α_2(XI) α_3(XI)]	Throughout tissue (possible core for type II fibrils)
Class II, short helix molecules	Type VI	[α_1(VI) α_2(VI) α_3(VI)]	Concentrated pericellularly
	Type IX	[α_1(IX) α_2(IX) α_3(IX)]	Linked to type II on the outside of fibrils, some pericellular enrichment
	Type X	[α_1(X)$_3$]	Deep calcified zone only (abundant in growth plate cartilage)

Table 1 Collagens found in articular cartilage (modified from Eyre *et al*. 1991)

Two more distinct collagens also occur in cartilage, these are types IX and XI (see Fig. 3). The latter is another long-chain fibrillar collagen comparable with type II. It can account for up to 10 per cent of the total collagen content of cartilage, but is typically about 3 per cent in adult articular cartilage. It is even more glycosylated than type II and is resistant to collagenase. There are two distinct type XI a-chains, but these show structural similarity to type V collagen a-chains, which are also expressed at a low level in cartilage and can be incorporated in hybrid type XI/V molecules. Type XI collagen in cartilage therefore contains a varying proportion of type V a-chains, which is reported to increase with development (Eyre and Wu 1995). Studies on the cross-links that join different peptides have shown that frequently type XI molecules are joined to each other, but some results show that linkages between type XI and type II chains are also present. Some of the collagen fibres in cartilage may therefore be cofibres of type II and type XI, and in these cases type XI may form the core elements, although analysis shows that some type XI collagen retains its N-propeptides in the tissue and this may be more compatible with a fibril surface role for these molecules.

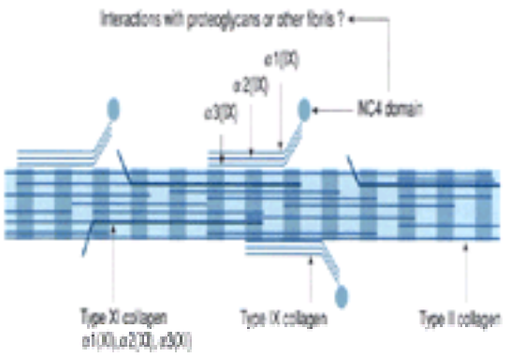

Fig. 3 Schematic showing collagen fibrils in cartilage formed from type II, type IX, and type XI collagen (from Jacenko and Olsen 1995).

Type IX collagen has a special structure with an interrupted collagenous sequence. It has three collagenous segments and four non-collagenous domains, and electron micrographs of the isolated molecule show it to be an elongated molecule with a kink towards one end. Type IX collagen contains three different a-chains and it has been shown that one of the a-chains (a_2 IX) has an attachment site for a chondroitin sulphate chain in the third non-collagenous domain. In fact the a_2-chain is slightly longer at this site than the a_1- or a_3-chains and this extension coincides with the kink in the electron micrograph image.

Localization of type IX collagen shows that it is found on the outside of type II fibrils and imaging has shown globular domains extending away from the surface of type II collagen fibrils at the end of short stalks, which would correspond with the fourth non-collagenous domain and the third collagenous segment lying at an angle with the axis of the first and second collagenous segments. Cross-links have been identified between the third non-collagenous domain and the N-terminal telopeptide region of type II collagen, and also between the second collagenous domain of type IX and the C-terminal region of type II collagen (Wu *et al*. 1992). The cross-linked fragments isolated show that type IX lies antiparallel to type II collagen in the fibres. Cross-links are also formed between type IX molecules. Type IX collagen therefore has the capacity to mediate covalent links between separate type II collagen fibrils. As stromelysin is able to cleave type IX collagen at the second non-collagenous domain and to cleave the telopeptides from type II collagen, it has the capacity to degrade these interfibrillar links (Eyre and Wu 1995). This would have major consequences on the collagen network and could provide a mechanism to facilitate matrix remodelling without great damage to major elements of the type II collagen fibrillar network. Linkage analysis has identified defects in the genes of the fibrillar cartilage collagens II, IX, and XI as being responsible for some inherited diseases affecting the joints, including early-onset osteoarthritis, Stickler's syndrome, and various chondrodysplasias (Jacenko and Olsen 1995).

As with type II collagen, type IX is also expressed in the eye. In studies on avian eyes, it has been shown that its expression used a different gene promoter from that used in cartilage and the protein expressed has an additional peptide within its sequence that enlarges the fourth non-collagenous domain (Nishimura *et al*. 1989). It has also been shown in chickens that the chondroitin sulphate chain synthesized on the third non-collagenous domain in the vitreous chamber is almost 10 times longer than that synthesized in cartilage (Yada *et al*. 1990). The structure of type IX is thus strongly influenced by the tissue in which it is being expressed.

Type VI collagen is found in a number of different tissues in the body. It contains three different a-chains and forms a short, triple-helical segment only 100 nm long. There are large, disulphide-bonded, non-helical extensions that are not removed as propeptides, and fibril formation appears to involve the packing of antiparallel molecules in tetrameric units that form microfibrillar structures lacking the characteristic 67 nm banding of the main fibriller collagens. Type VI collagen lacks the tight structure and extensive cross-linking of the fibrillar collagen and is easily extracted from the tissue in denaturing solvents. The distribution of type VI collagen in most tissues suggests a pericellular role, particularly associated with cell–matrix interactions. There is some evidence in cartilage that it is distributed principally in the pericellular region surrounding the chondrocyte, forming a lacuna bounded by a dense meshwork of fine collagen fibrils that forms a basket or chondron. Type VI collagen contains several peptide sequences (RGD) that form possible sites for binding to cell receptors. It also shows properties of interaction with hyaluronan. Type VI collagen may thus participate in cell–matrix organization in a number of different ways.

Type X collagen is a short-chain collagen consisting of three identical a-chains that form a triple-helical segment of 150 nm in length. It occurs primarily in calcifying cartilage produced by hypertrophic chondrocytes in the growth plate. It has been proposed that type X collagen may have some function associated with calcification, but transgenic mice deficient in type X collagen were found to develop normally and endochondral ossification was not greatly affected. It may therefore have more of a temporary structural role in the growth plate during the transition from cartilage to bone. It is also present in a limited amount in the calcified zone at the junction of articular cartilage with the bone and its expression in articular cartilage appears to be increased in osteoarthritis.

Proteoglycans

The major proteoglycan of cartilage is aggrecan, which is of high molecular mass. Aggrecan contains a large core protein (molecular mass: approximately 250 kDa) but most of its mass is provided by the polysaccharide chains attached to it (see Fig. 2). There are about 100 chondroitin sulphate chains (molecular mass: 10 to 25 kDa each) and up to 50 keratan sulphate chains (molecular mass: 15 kDa each) on each aggrecan molecule and also some *O*-linked oligosaccharides and a few *N*-linked oligosaccharides. Each aggrecan molecule thus has a total molecular mass of 1.5×10^6 to 2.5×10^6 kDa and contains about 10 per cent protein and 90 per cent carbohydrate. The carbohydrate chains are all synthesized on the aggrecan core protein during post-translational glycosylation within the chondrocyte prior to its secretion into the matrix (Hardingham 1986). Proteoglycans follow pathways of synthesis in common with other secreted glycoproteins and the site of major glycosaminoglycan synthesis lies in the vesicular compartments of the medial/trans-Golgi. The mechanisms of biosynthesis are highly efficient and the time taken for protein synthesis in the rough endoplasmic reticulum to glycosaminoglycan chain synthesis and secretion from the chondrocyte is about 20 to 30 min.

The protein core of aggrecan is a single polypeptide chain with several subdomains of different function (Fig. 4) (Hardingham *et al*. 1992; Hardingham and Fosang 1992). At the N-terminal of the protein core there are two globular domains, G1 and G2, separated by a short extended segment (21 nm long). The G1 domain provides the site for aggregation, and has specific properties of binding to hyaluronan and a separate globular link protein. Aggregates are composed of aggrecan molecules bound to hyaluronan via their G1 domains and each hyaluronan chain can have up to a hundred or more aggrecans bound to it. The interaction of link protein with the G1 domain stabilizes its binding to hyaluronan and essentially 'locks' the aggrecan into the aggregate form. The protein structures of the G1 domain and link protein are interesting as they are closely related to each other and contain two structural motifs, one is an immunoglobulin-fold and the other is a disulphide-bonded tandem-repeat structure.

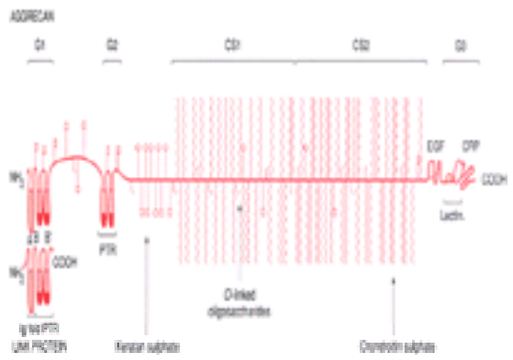

Fig. 4 The structure of the major cartilage proteoglycan, aggrecan. Aggrecan contains three disulphide-bonded globular domains, G1, G2, and G3, and has attached to it chondroitin sulphate, keratan sulphate, and *O*-, and *N*-linked oligosaccharides. Link protein is of similar structure to the G1 domain; both contain an immunoglobulin fold (Ig fold) and proteoglycan tandem repeat (PTR). Aggregation involves G1 binding to hyaluronan and this is stabilized by link protein, which binds to G1 and also to hyaluronan. G2 contains a PTR motif. G3 contains up to three protein motifs: an epidermal growth factor-like sequence (EGF), a mammalian type C lectin sequence (lectin), and a complement regulatory protein sequence (CRP) (see Hardingham and Fosang 1992).

The tandem-repeat structure forms the site for binding to hyaluronan and has specificity for a decasaccharide unit (hyaluronan HA10), whereas association between the G1 domain and link protein is by interaction of the immunoglobulin folds. The protein sequences of link protein are highly conserved amongst different species such that link protein from the cartilage of one species will bind and stabilize aggregate formation by aggrecan from another species. The formation of aggregates is an extracellular process. Aggrecan and link protein are synthesized and secreted together by chondrocytes, but hyaluronan is made separately at the chondrocyte cell surface. Aggregation can thus only occur after aggrecan has entered the matrix and it provides a mechanism for immobilizing it within the cartilage matrix.

The second globular domain also contains a sequence with homology to the tandem repeat found in the G1 domain and link protein, but it does not show any hyaluronan-binding activity (Fosang and Hardingham 1989). The main glycosaminoglycan attachment region of the proteoglycan is a long, extended protein sequence between the G2 domain and the C-terminal G3 domain. It is subdivided into three regions. Close to the G2 domain is a region rich in keratan sulphate which contains a repeating sequence that varies in number in different animal species. The remaining major chondroitin sulphate attachment sequence involves two further patterns of sequence repeats. The attachment of chondroitin sulphate at serine–glycine sequences is restricted in aggrecan to these particular regions. Keratan sulphate has a wider distribution than chondroitin sulphate as it also occurs in the chondroitin sulphate-rich region and close to the G1 and G2 domains, and at some sites chains are *N*-linked rather than *O*-linked.

The globular C-terminal G3 domain contains sequences related to other protein families. One part contains a sequence similar to a family of mammalian type C lectins, such as the asialoglycoprotein receptor. These bind oligosaccharide ligands on glycoproteins and the expressed recombinant G3 domain has some carbohydrate binding properties (Halberg *et al*. 1988). Two other sequences may be variably expressed in the human aggrecan gene: an epidermal growth factor-like repeat and a complement regulatory binding protein sequence (Baldwin *et al*. 1989). The incidence of these variations in aggrecan structure and their functional significance have yet to be determined. There are other proteoglycans structurally related to aggrecan in other tissues, which together form a family of hyaluronan-binding proteoglycans. These include versican in dermis, loose connective tissue, and smooth muscle, and neurocan and brevican in brain tissue. They all contain structurally related G1 and G3 domains although their glycosaminoglycan attachment regions are unrelated.

Aggrecan present in cartilage contains a heterogenous population of molecules differing in size and composition. This has two main causes: first, variations in glycosylation and chain synthesis during biosynthesis result in a polydisperse product with a considerable range of sizes, and second and more importantly, the aggrecan molecules in the cartilage matrix are subject to some proteolytic attack (Hardingham 1986). As the lifetime of each aggrecan in the matrix is quite long (months, or years in mature cartilage), the composition of molecules extracted at any one time represents a cross-section of the population from newly synthesized to the oldest molecules present. The proteolytic action results in a selective loss of C-terminal structures such as G3 and preferential retention of the N-terminal structures. This arises because the N-terminal G1 domain provides the binding to hyaluronan and the mechanism of anchoring aggrecan in the matrix, and it follows that cleavage of the molecule results in the shortened forms containing intact G1 domains being retained in the tissue, whereas the C-terminal fragments are able to diffuse out of the matrix and become lost from the tissue.

The average turnover time of aggrecan appears to become longer with age and its size distribution also becomes steadily biased towards a population containing more partially cleaved molecules. Even in young cartilage there appears to be only a proportion (perhaps 50 per cent) of aggrecan molecules with an intact G3 domain and this appears to be lower in mature tissue. There is also a marked accumulation in older tissue of fragments of low molecular weight comprising only the G1 domain.

In addition to aggrecan, articular cartilage contains two chondroitin sulphate/dermatan sulphate proteoglycans of low molecular weight, decorin and biglycan (Heinegard and Oldberg 1989; Hardingham and Venn 1993). These small proteoglycans account for only about 5 per cent of the total glycosaminoglycans in the tissue, but as they are of small size they are present in molar amounts comparable with aggrecan. In human cartilage decorin is reported to increase in abundance with age whereas biglycan decreases. Both decorin and biglycan are also broadly distributed in other connective tissues besides cartilage. They have similar-sized core proteins and are structurally related, but appear to have quite different properties and presumably different functions. Decorin and biglycan form part of a family of leucine-rich proteoglycans, which contain a common sequence repeat rich in leucine (Kobe and Deisenhofer 1994). Other members of this family include fibromodulin, which also occurs in cartilage, and lumican, a keratan sulphate proteoglycan, which is in the cornea. Whereas decorin and biglycan have chondroitin/dermatan sulphate chains attached towards the N-terminus (one chain for decorin, two for biglycan), fibromodulin has no chondroitin sulphate but has some sulphated tyrosines in the corresponding location, and also some molecules have keratan sulphate attached to *N*-linked oligosaccharide sites within the central leucine-rich repeats. Both decorin and fibromodulin have type II collagen-binding properties (Hedbom and Heinegard 1993) and *in vitro* they delay fibrillogenesis and cause the formation of thinner fibres. *In vivo* decorin has been localized at the d and e bands of type I collagen fibres, whereas fibromodulin binds to the a and c bands (Scott 1995) and these properties are functions of the protein cores. Biglycan in contrast does not have any collagen-binding properties and appears to be distributed close to a cell surface environment (Bianco *et al*. 1990). It may therefore be more important for cell–cell and cell–matrix interactions.

A further interesting property of decorin is its ability to bind transforming growth factor-b (Ruoslahti and Yamaguchi 1991). It may thus function as a matrix repository for this growth factor that might be released as a result of proteinase action fragmenting the decorin protein core. Transforming growth factor-b has also been shown to stimulate selectively the synthesis of decorin and biglycan and modulate the synthesis of the attached chondroitin sulphate/dermatan sulphate chains. The ability of decorin to bind transforming growth factor-b and thereby block this action may thus form part of a feedback control of decorin synthesis and control of other actions of this growth factor. The binding of transforming growth factor-b in the matrix could also provide a store of growth factor that might be released through the action of proteolytic enzymes that attack the matrix following inflammation or tissue injury.

Aggrecan turnover

Proteoglycans in the cartilage matrix are constantly turned over even in mature non-growing tissue. There is a constant slow rate of aggrecan degradation and loss, and its replacement by new synthesis. The mechanisms of turnover, involving biosynthesis by the chondrocytes and degradation in the extracellular matrix, must therefore be co-ordinated so that the tissue content of aggrecan is maintained at a constant level. The chondrocytes are responsible for controlling these events and appear to be sensitive to the aggrecan content of the matrix surrounding them, and some feedback mechanisms enables synthesis and degradation to be coregulated (Lohmander 1988; Morales and Hascall 1989; Caterson *et al*. 1990).

The normal turnover of aggrecan in healthy cartilage appears to involve their proteolytic cleavage in the region close to the G1 domain. This is a most important site of attack as it releases a large glycosaminoglycan-bearing fragment and separates it from its site for aggregation. This is thus an efficient mechanism for mobilizing aggrecan as it involves the minimum of enzyme action. It is important that turnover is an essentially conservative process as cleavage and release of only a small fraction of the tissue content is required at any one time so that the overall tissue content is conserved and the biomechanical properties are sustained.

Several studies of cartilage from different sources have thus established that a major product of normal turnover is a large aggrecan fragment that has lost its G1

domain and is thereby able to diffuse slowly out of the matrix. Investigation of the released fragments from *in vitro* experiments and those released from tissue *in vivo* into synovial fluid has identified cleavage within the interglobular domain at a single predominant site (Sandy *et al*. 1991; Lohmander *et al*. 1993), but attempts to identify the proteinase responsible from tissue extracts have been unsuccessful and in experiments *in vitro* most candidate enzymes cleave at other sites. Neutrophil collagenase, a metalloproteinase, is the only enzyme with any proven activity at this site, although it cleaves more readily at a site common to other metalloproteinases and is predominantly made by neutrophils (Fosang *et al*. 1994). However, some evidence suggests that it may be expressed together with other metalloproteinases by chondrocytes, but it remains to be shown if it is responsible for the action in the tissue. Matrix metalloproteinases are certainly involved at some stage of the degradative process, as specific metalloproteinase inhibitors are effective in reducing aggrecan loss from the cartilage stimulated by cytokines and retinoic acid (Buttle *et al*. 1993). Investigation of the actions of cytokines such as interleukin 1 or tumour necrosis factor-a have shown that they stimulate chondrocytes to degrade their matrix more rapidly and they also cause an inhibition of protein synthesis. They thus have a double action in depleting articular cartilage of its aggrecan content. In the presence of interleukin 1 or tumour necrosis factor-a, the aggrecan fragments released from cartilage are more extensively degraded than those released in normal turnover. The rate of aggrecan release is greatly increased and this results from a large increase in matrix proteolysis with cleavage at several additional sites within the chondroitin sulphate attachment region of aggrecan, which appears to be by the action of the same enzyme that cleaves within the interglobular domain (Ilic *et al*. 1992).

The neutral metalloproteinases are a family of enzymes that are likely to be involved in many aspects of extracellular matrix breakdown and turnover (see Table 2) (Woessner 1991; Murphy 1995). There are now more than 13 cloned enzymes, including collagenases, stromelysins, and gelatinases, which together have a range of complementary actions that enable them to attack and degrade all the major matrix macromolecules. The main matrix metalloproteinases are all secreted by cells in an inactive latent form that requires activation in the extracellular matrix. The process of activation involves a structural rearrangement and proteolytic cleavage with a reduction in molecular weight to give an active enzyme. Activation can be achieved *in vitro* with trypsin, which converts the proenzyme to active enzyme directly, or with APMA (aminophenyl mercuric acetate), which catalyses a protein rearrangement that leads to an autocatalytic cleavage and self-activation. The physiological mechanism of activation has not been fully established, but could involve one metalloproteinase activating others, as in the proposal that gelatinase is the major activator of procollagenase. Other types of proteinase such as plasminogen activator may also catalyse metalloproteinase activation. In addition to activation, control of enzyme activity is also provided by the natural enzyme inhibitors such as TIMP (tissue inhibitor of metalloproteinases), which binds to active enzyme and irreversibly inactivates it. There is normally an excess of TIMP in the extracellular matrix so that any activated enzyme is quickly inhibited. TIMP is produced by all cells that secrete the proenzymes. The extent of proteinase activity in the matrix is thus under tight control and can be regulated in several ways. First, the production of latent proenzymes is varied, second, the production and availability of various activators of the proenzymes can be varied, and third, the production of specific inhibitors can be varied. The metalloproteinases are also inhibited by the general proteinase inhibitors in serum, such as a $_2$-macroglobulin. There are thus mechanisms to prevent proteinases causing more widespread tissue damage should they escape from local control.

Enzyme	MMP family	Matrix substrates
Collagenase 1, 2, 3	MMP-1, -8, -13	Native collagen types I, II, III, VII, and X; also aggrecan and other non-collagenous proteins
Stromelysin 1	MMP-3	Aggrecan, link protein, fibronectin, laminin, gelatins, collagens III, IV, V, and IX, procollagen peptides
Gelatinases, 72 kDa, 92 kDa	MMP-2, -9	Gelatins, collagens IV, V, VII, and X, fibronectin, elastin
Range of activity		pH 5–9
Activation		Secreted latent enzymes require activation by other proteinases
Natural inhibitors		TIMP, TIMP-2, TIMP-3
Major plasma inhibitor		α_2-Macroglobulin
Chemical inhibitors		EDTA, 1,10 phenanthroline

TIMP, tissue inhibitor of metalloproteinase; EDTA, ethylenediamine tetraacetic acid.

Table 2 The neutral metalloproteinases

Growth plate

The cartilage forming the growth plate provides the site for the major longitudinal growth of the long bones of the skeleton (Iannotti 1990; Poole 1991). In macromolecular terms, it has all the attributes of cartilage, containing a dense network of predominantly type II collagen fibres and an aggrecan-rich matrix, but its cells are very different. The growth plate chondrocytes, which are produced by the continuous division of progenitor cells, progress through a rapid programme of differentiation, matrix expansion, hypertrophy, matrix calcification, and further differentiation, or cell death, which is quite unlike other chondrocytes. This process results in endochondral bone formation. As well as being responsible for long bone growth it is a process that also occurs in fracture healing and in osteophyte formation. It therefore has an important role in the growth of the skeleton and many inherited diseases affecting skeletal development are caused by mutations in genes that are active in the growth plate.

Cartilage formation begins during embryonic development as early as 6 weeks, with the condensation and differentiation of mesenchymal cells into chondrocytes to form the main elements of the skeleton. Soon after its formation, the central portion of each cartilage rudiment calcifies and is vascularized, which leads to the formation of a bony diaphysis capped at each end by a cartilaginous epiphysis. Later in development, a secondary centre of ossification develops in each epiphysis, which segregates the region of major cartilage growth from the cartilage that will be retained as the articular surface of the joint (Fig. 5). The transverse plate of cartilage which is sandwiched between the diaphysis and epiphysis remains as the site of growth throughout development, but finally calcifies and closes at skeletal maturity, typically between the ages of 14 and 18 years. The growth plate has a polarized and stratified structure (Fig. 5) that reflects the processes that occur within it. These primarily include a sequence of cell division, matrix expansion, cell hypertrophy, matrix calcification, vascularization, resorption, and replacement by bone and this continues throughout its life. It is thus a dynamic structure, which proliferates chondrocytes at its leading edge and deposits bone at its trailing edge.

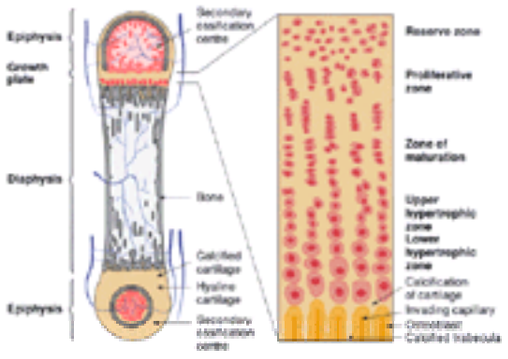

Fig. 5 The growth plate and cartilage development in a long bone at the late embryonic stage. The bone rudiment on the left shows the secondary centres of ossification that separate the growth plate cartilage from the articular cartilage. The expanded growth plate on the right shows the histologically distinct zones of the growth plate cartilage. Blood vessels penetrate the reserve zone of cartilage and the lower calcified zone, but the proliferative and hypertrophic zones are avascular. (Redrawn from Wallis 1993, with permission.)

The cartilage of the growth plate has three histologically and functionally distinct zones (Fig. 5) (Iannotti 1990; Poole 1991; Cancedda *et al*. 1995). At the leading edge of the growth plate is the reserve zone of cartilage. It contains a sparse population of chondrocytes that are only slowly dividing and they reside in a collagen-rich matrix. This is a stable non-dynamic structure that forms the interface between the growth plate and the bone of the epiphysis. Blood vessels penetrate the reserve zone, but do not enter the adjacent proliferative zone. The progenitor cells mark the boundary between the reserve zone and the proliferative zone. These are the stem cells that generate the continuous supply of cells for cartilage growth. Columns of chondrocytes extend away from the stem cells and they deposit and

expand the matrix surrounding them, thus providing the major mechanism to elongate the bone.

This highly active phase of chondrocyte maturation and matrix deposition is followed by cell hypertrophy. This is very evident histologically as the hypertrophic zone (Fig. 5), in which the cells become 5 to 10 times larger and the matrix is diminished prior to its calcification. The rate of cell division is again low in the hypertrophic zone and there is a much lower rate of synthesis of matrix macromolecules than in the proliferative zone. However, there is increased synthesis of some characteristic components of hypertrophic chondrocytes, such as alkaline phosphatase and type X collagen, and there is increased accumulation of intracellular calcium. Matrix vesicles, which are membrane-bound structures of 100 to 150 nm in diameter, are found in the interterritorial matrix of the hypertrophic zone. They are rich in calcium and their abundance increases towards the zone of calcification. It is undoubtedly the function of the chondrocytes in the hypertrophic zone to prepare the matrix for calcification, but the exact sequence of events and the mechanisms involved are a source of considerable debate. It is clear that hypertrophic chondrocytes accumulate calcium and produce matrix vesicles that are rich in calcium. They also produce alkaline phosphatase which can release inorganic phosphate, but what changes occur in the matrix to induce calcification are less clear. The unique expression of type X collagen in this region leads to the expectation that it may have a role in calcification; however, the development of transgenic mice that lack type X collagen but have apparently normal growth plate function suggested that it was not essential for calcification. The lowest calcified region of the hypertrophic zone forms the boundary for the penetration of blood vessels from the diaphyseal side of the growth plate and this forms an advancing front of cartilage matrix resorption and of new bone formation.

The fate of the chondrocytes in the calcified zone of the growth plate as the cartilage matrix is resorbed and bone takes its place is not completely clear (Cancedda *et al*. 1995). There is evidence of cell death amongst the hypertrophic chondrocytes in this region and in one model the resorption of the cartilage matrix and its replacement by bone could be caused by cells brought in by the blood vessels that penetrate into this region. However, there is also evidence that hypertrophic chondrocytes in culture can show some osteogenic potential and express matrix molecules, such as osteonectin, osteopontin, and switch from type II and type X collagen synthesis to type I, and deposit extracellular mineral. It therefore appears entirely feasible that some hypertrophic chondrocytes may survive and become osteoblasts and participate in the deposition of the growing bone. It may be that both these processes occur and that some hypertrophic chondrocytes undergo programmed cell death by apoptosis and are eliminated from the calcified zone as the matrix resorption and blood vessel invasion advances, whereas others may survive and proceed to participate in the generation of the new bone as osteoblasts. It may also be that the proportion of cells following either route varies from one site of endochondral ossification to another.

The chondrocytes in the growth plate are very sensitive to a range of growth factors including those of the insulin-like growth factor family, the transforming growth factor-b family (including bone morphogenic proteins), the fibroblast growth factor family, and vitamin D metabolites (Poole 1991; Cancedda *et al*. 1995). Some of these, such as the transforming growth factor-b family (and bone morphogenic proteins) are most active in promoting chondrocyte differentiation, whereas others, such as the fibroblast growth factors are most active in stimulating cell division, and these have little effect on fully differentiated cells. In contrast, the insulin-like growth factors are very effective in stimulating the synthesis of matrix macromolecules and also suppressing matrix degradation and they thus have a very positive anabolic effect. The effect of growth hormone on cartilage is mainly by stimulating the local production of insulin-like growth factors. The most rapid phase of growth is associated with sexual maturation at puberty and is driven by the hormonal changes and the accompanying increase in systemic growth factor production. Chondrocytes of the growth plate differ from other chondrocytes in that they are sensitive to vitamin D metabolites. These are essential for normal mineralization, and vitamin D deficiency, which causes rickets, is characterized by a slowing down of mineralization and an expansion of the hypertrophic zone of the growth plate. At the cellular level, the chondrocytes fail to accumulate calcium and there is poor production of matrix vesicles. The failure of calcification and bone formation causes the widening of the growth plate, which leads to instability and to deformed growth.

Investigation of many families that show inherited skeletal abnormalities, such as chondrodysplasias, has now identified a range of single gene defects that are responsible (Wallis 1993; Cancedda *et al*. 1995; Olsen 1995). Many of these are in the type II collagen gene in families with Kniest dysplasia, some forms of Stickler's syndrome, with spondyloepiphyseal dysplasia, and with hypochondrogenesis. Others have been identified in type IX collagen, type XI collagen, and in metaphyseal chondrodysplasia type Schmid in type X collagen. The sites of mutations involve substitutions, deletions, and frame shifts and each family group contains a different form. The range of phenotype is also very variable from mild to severe and there is no clear pattern of correlation between the site of the mutation, or its form, and the phenotype that results. Some forms of multiple epiphyseal dysplasia and pseudoachondrodysplasia have been linked to the cartilage oligomeric matrix protein gene; this produces a thrombospondin-like protein in cartilage matrix and its function is not yet understood. Some forms of hypochondrodysplasia are linked to polymorphisms in the insulin-like growth factor 1 gene. There are therefore a range of defects in genes that form part of the matrix or are involved in the processes that lead to the development of the matrix that can result in inherited skeletal abnormalities and with current techniques of molecular biology many more of these will be identified.

The basic process of chondrocyte differentiation, matrix expansion, matrix calcification, and its replacement by bone is not exclusive to the growth plate. A similar process occurs in fracture healing where the initial union in the fractured bone is made by chondrogenic development at the site of periosteal damage, which expands and forms the fracture callous, before it is eventually resorbed as cortical bone and healing becomes complete. The formation of osteophytes in synovial joints close to the articular surface also proceeds through an initial chondrophytic stage, often beginning at the site of the cartilage–bone junction. The differentiation of chondrocytes at this site forms a cartilage growth or chondrophyte, which then calcifies and becomes remodelled into a bony. It is only subsequently that the osteophyte fuses with the main cortical bone. Osteophytes therefore form not as direct outgrowths of the bone, but from separate, small, osteogenic centres that produce through a cartilage-mediated process, similar to that of the growth plate, a bony buttress joined with the main bone shaft.

Age-related change in articular cartilage

Age-related changes in articular cartilage are distinct from those characteristic of osteoarthritis, but give clues to the increasing susceptibility of cartilage to damage in old age. Age determines both the composition of the extracellular matrix as well as the distribution of chondrocytes and their response to external factors such as cytokines (see Table 3) (Hardingham and Bayliss 1990). Zonal changes in the distribution of chondrocytes are seen with ageing although the total number of chondrocytes shows little variation. Chondrocytes in the superficial cells mostly disappear with some increase in the cellular content of the deeper layers. Numerous changes in the extracellular matrix with ageing may compromise function. With old age there is a decrease in hydration of the matrix with a corresponding increase in compressive stiffness. This may have implications for the remarkable property of cartilage to undergo reversible deformation upon loading and may result in increased transmission of forces to subchondral structures. Loss of hydration is probably secondary to changes in the matrix components. Proteoglycan aggregation is adversely affected by proteolytic damage to link protein and a decrease in the available binding sites on hyaluronan; the latter is the result of binding of the free binding region domains that represent the limited digestion product of proteolysis of the glycosaminoglycan attachment region of core protein. Aggregation may also affect pore size distribution and solute permeability. Other changes observed include increasing proteoglycan heterogeneity with a general reduction in proteoglycan size accompanied by an increased ratio of keratan sulphate to chondroitin sulphate. Although the concentration of hyaluronan rises with age, this results from the gradual accumulation of partially degraded hyaluronan, rather than from a higher rate of synthesis. Age-related changes in the response of human cartilage to cytokines, especially to interleukin 1, have been documented with maturation, but little consistent change in response in old age has been noted. However, the reality is liable to be a complex interaction of endogenous anabolic and catabolic factors that are acting in articular cartilage in any age and considerable difficulties confront the investigator attempting to study their action *in vitro*.

Chondrocytes
Loss of most superficial chondrocytes, some increase in the number of deeper cells
Extracellular matrix
Decreased hydration with greater compressive stiffness of the matrix; increase in stable collagen cross-links
Proteoglycans
Aggrecan of smaller average size and higher keratan sulphate/chondroitin sulphate ratio, increased content of free hyaluronan binding region domain (G1); content of decorin may increase and biglycan decrease
Hyaluronan and link protein
Increased hyaluronan content, but hyaluronan chains of shorter length, increased proteolytic damage of link protein

Table 3 Age-related changes in articular cartilage following skeletal maturation

Cartilage response to cytokines and growth factors

Interleukin 1 (**IL-1**) and tumour necrosis factor-a (**TNF-a**) have generally been shown to have major effects on articular cartilage, including the inhibition of proteoglycan synthesis and the stimulation of matrix proteoglycan degradation (Fig. 6). Studies with human cartilage have not found a major effect on matrix degradation in most samples, which is in contrast to results obtained using immature bovine and other animal cartilage (Hardingham *et al*. 1992). Human cartilage studied *in vitro* has been found to respond in three ways: (i) no significant increase in the release of proteoglycan over several days in culture, (ii) a delayed response with increased release after about 6 days in culture, and (iii) acute activation of proteoglycan loss within 24 h. In the latter case, dramatic evidence of catabolism leading to 80 to 90 per cent depletion of proteoglycans within 3 to 4 days in culture has occurred in occasional specimens (about 5 per cent). However, the majority of cartilage explants show no significant increase in release. This probably corresponds to a low level of activation of the catabolic process, rather than no activation at all, because in human cartilage the dense collagenous network is probably less permeable to aggrecan fragments than in young animal cartilages and therefore requires more catabolism to give a significant increase in aggrecan release. Aggrecan biosynthesis is much more sensitive to cytokine action than aggrecan catabolism and the effects are much more consistent amongst cartilages from different animal sources. Recombinant human IL-1 demonstrates a dose-dependent reduction in proteoglycan synthesis in all animal and human cartilage samples tested; recombinant human TNF is also effective, but less potent. The sensitivity of human articular cartilage to IL-1 (and TNF-a), declines with age. The effects on aggrecan synthesis show that there is no lack of penetration of the cytokines to the chondrocytes in human cartilage, but that some steps in the response of the chondrocytes that lead to increased matrix degradation are less stimulated in uman cartilage than that from many animal sources. This might involve the production of less proenzyme, or of less activator of the proenzymes, or an increase in the inhibitors of the enzymes. Any of these effects may suppress the extent of proteolytic action and hence the rate of proteoglycan degradation and release from the matrix. It has been speculated that the effects of cytokines on human articular cartilage in joint disease may result primarily from shutting off aggrecan synthesis, rather than from any increase in matrix degradation.

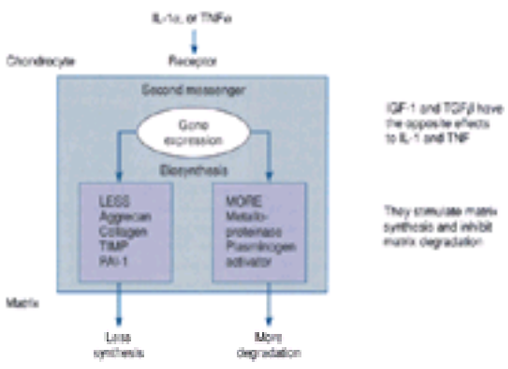

Fig. 6 Effects of cytokines and growth factors on articular chondrocytes.

Of the growth factors, insulin-like growth factor 1 is considered to be the major mediator of cartilage growth. As well as stimulating synthesis of proteoglycans, it may also reduce the rate of proteoglycan catabolism (Fig. 3), although human articular chondrocytes show a decrease in responsiveness to insulin-like growth factor 1 with increasing age. Other growth factors such as epidermal growth factor, fibroblast growth factor, and transforming growth factor beta (**TGF-b**) have been shown to potentiate the effect of insulin-like growth factor 1 on proteoglycan synthesis.

TGF-b has been shown to enhance the synthesis of small proteoglycans (decorin or biglycan) relative to the large aggregating proteoglycan. In explant cultures of cartilage from dogs that have undergone cruciate ligament transection, there was selectively more synthesis and a higher content of small proteoglycans, suggesting that TGF-b may be responsible in part for the increased activation of chondrocytes in experimental osteoarthritis (Venn *et al*. 1995).

In chronic rheumatoid arthritis TNF-a has been successfully identified as a therapeutic target (Elliot *et al*. 1994). Neutralizing, humanized, monoclonal antibody to TNF-a delivered to patients was effective in relieving clinical and laboratory parameters of disease activity, and the benefit was sustained over 1 to 3 months, after which there was a relapse. This suggested that TNF-a was an important cytokine in driving the chronic arthritic process and also that IL-1 production in the joint was largely caused by TNF-a, rather than vice versa. This form of treatment was also effective in animal models of arthritis in suppressing inflammatory cell infiltration into the joint and reducing joint swelling, but it is not yet clear how far it can protect from or reverse the damage to articular cartilage. IL-1 receptor antagonist is a natural inhibitor of IL-1 and forms part of a biological mechanism controlling IL-1 action. Blocking IL-1 action with injections of recombinant IL-1 receptor antagonist has also been investigated in experimental arthritis, but very high doses are required to achieve any effect (Lewthwaite *et al*. 1995). One way in which the action of TNF-a is controlled locally in tissues is by the release from the cell surface of the binding domains of TNF-a receptors. The released domains not only no longer function as receptors, but also act as soluble ligands that bind and inactivate the available TNF-a. The release of such receptors appears to be under the control of a cell surface metalloproteinase. The action of TNF-a and IL-1 on articular chondrocytes is thus likely to be controlled, not merely by their local abundance, but also by a network of interactions, involving changes in the expression of receptors, the release from cells of soluble receptors and IL-1 receptor antagonist, and also their actions are modulated by the competing effects of local and circulating growth factors.

Cartilage in experimental models of joint disease

The early events occurring in cartilage in the context of joint disease remain elusive in the human. In this regard, the availability of animal models of joint disease have proved useful in studying the sequence of response of cartilage to specific insults. Animal models of osteoarthritis have been the most extensively studied with respect to the effects on cartilage (for a comprehensive review see Pritzker 1994). The methods of inducing cartilage damage vary from surgical procedures such as section of the anterior cruciate ligament in the dog (the Pond–Nuki model) and partial meniscectomy in the rabbit, to chemical methods such as employing the metabolic poison iodoacetate. Genetic models of joint instability, such as the STR mouse are also used. Changes observed have to be seen in the context of the species used as well as the age and maturity of the animal, which remain important influences on cartilage behaviour and may account for apparently conflicting experimental results.

The Pond–Nuki model

In this model, the anterior cruciate ligament of the dog is sectioned causing instability and laxity in the operated joint, this alters the biomechanics of the joint and leads to the development of changes reminiscent of human osteoarthritis (Table 4) (McDevitt *et al*. 1977). These early events occur whilst the cartilage still appears macroscopically normal. Initial events after cruciate sectioning include increased hydration of the cartilage matrix, probably as a result of early disruption of the collagen network, seen especially in the superficial zones on electronmicroscopy. This is accompanied by a loss of tensile strength, which is detectable at 3 weeks postoperatively in the surface layers and progresses over 6 months to involve the deeper zones. Although there may be some evidence of cell death in the superficial cartilage, in general the chondrocytes show evidence of increased biosynthetic activity as part of a reparative process accompanied by some signs of cell division. The production of matrix components such as proteoglycan and collagen are increased, although because of increased turnover rates, the matrix content does not rise (Carney *et al*. 1992; Ratcliffe *et al*. 1992). However, under certain circumstances, it appears that the total proteoglycan content may rise and be accompanied by an increase in cartilage thickness (Brandt and Adams 1989). Although no changes in the ability of proteoglycans to aggregate has been detected, some minor changes in structure have been detected including lengthening of the chondroitin sulphate chains and the appearance of neoepitopes reflecting subtle changes in the pattern of sulphation (Caterson *et al*. 1990). Structural damage and fibrillation eventually occur and are mostly confined to the weight-bearing region of the tibial surface. Changes in articular cartilage are accompanied by alterations in subchondral bone including sclerosis and rapid osteophyte development. Initially appearing as ectopic, chondrogenic centres close to the cartilage–bone–synovial junction, these subsequently ossify before merging with the cortical matrix of the main bone shaft. Recent work examining the subchondral bone by computed tomographic microdensitometry has shown osteopenia, with an increase in the intertrabecular distance. It has been suggested that the characteristic osteosclerosis is in fact a relative appearance resulting from an absolute decrease in the underlying bony trabecular (Brandt 1991).

Increased hydration
Increased proteoglycan and collagen synthesis
Increased matrix turnover
Decrease in tensile strength of the superficial zone of cartilage
No depletion of proteoglycans or loss of aggregation
Altered proteoglycan structure with lengthened chondroitin sulphate chains and less keratan sulphate
Increased expression of chondroitin sulphate epitopes (3B3, 7D4)
Some mitotic activity of chondrocytes
Marginal osteophyte formation
Subchondral bone sclerosis
Capsular thickening

Table 4 Experimental osteoarthritis (Pond–Nuki): changes in the joint during the first 3 months following transection of the anterior cruciate ligament in the mature dog

There is some controversy surrounding the long-term fate of this model. Studies following animals for up to 2 years suggested that little progression occurred beyond the changes seen in the first few months following surgery. However, in longer-term experiments, it has been shown that cartilage may be maintained for up to 3 years before progressive loss occurs over the subsequent 9 months (Brandt *et al*. 1991).

Manipulation of the experimental method has made it possible to try and dissect out some of the multiple influences affecting the outcome of the reparative/degradative process following injury in articular cartilage and the results underline the fact that multiple factors determine response (Brandt 1991).

Differences in chondrocyte biosynthesis between control and operated joints seen in explant tissue disappear over the course of a few days (Venn *et al*. 1995). This suggests the action of local factors such as the effect of cytokines or growth factors, and the effect of altered biomechanical forces, which would not be present in culture. When the operated limb is immobilized in flexion following surgery, there is no stimulation of matrix production, appearance of fibrillation, or osteophyte formation. In fact there is a reduction of matrix synthesis similar to that seen with immobilization of normal joints. On the other hand, disruption of the normal proprioceptive control of joint forces, as happens with dogs who have undergone unilateral dorsal root ganglionectomy prior to cruciate transection, leads to rapid progression of cartilage breakdown. This occurred within weeks rather than the years required in neurologically intact animals. Some degree of synovial inflammation may be consistently seen in the Pond–Nuki model, although it appears that this is related to bleeding occurring perioperatively. When the synovitis is controlled by meticulous attention to haemastasis, little difference in the cartilage response is observed between those animals with synovitis and those without. Other external influences such as systemic medication may affect the response of cartilage to injury. Systemic salicylate therapy can accelerate the appearance of cartilage breakdown and may be due in part to inhibition of proteoglycan synthesis, which is independent of the effect on cyclo-oxygenase. These studies serve to underline that the response of cartilage to injury is complex and that outcome can be very heterogeneous depending on which external factors come into play.

Meniscectomy models

It is well known in humans that meniscectomy can precede the appearance of osteoarthritis in the affected limb after a variable period of time, usually many years. Similarly, meniscectomy performed in animal models, most commonly the rabbit, produces changes in articular cartilage that become more severe the more extensive the surgery. Meniscectomy alone induces a progressive but mild lesion, with eventually late compensation. However, section of the fibular collateral and sesamoid ligaments in addition to partial lateral meniscectomy leads to a lesion that progresses rapidly over 3 months, characterized by marked fibrillation, ulceration, increased mitosis with some cell death causing the formation of chondrocyte clusters, and loss of proteoglycan from the cartilage matrix (Colombo *et al*. 1983). Changes seen at the biochemical level with these models are similar to those seen with cruciate ligament transection, with increased hydration of the matrix, increased matrix turnover, and remodelling of bone.

Cartilage lesions resembling osteoarthritis can be induced by surgery to the hind knees of guinea pigs (Meacock *et al*. 1990). The rate of progression varies with the surgical procedure. Partial medial meniscectomy produces rapidly evolving lesions that are clearly evident after 1 week and are often severe by 3 weeks. Initial lesions occur on the medial tibial plateau and comprise focal loss of surface chondrocytes, with loss of proteoglycans. The cell and proteoglycan loss becomes progressively more extensive and is accompanied by surface fibrillation of the cartilage. By seven weeks, osteophyte formation can be observed and, by 20 weeks, involvement of the lateral tibial plateau is evident. Occasional subchondral cysts occur by 25 weeks. Evolution is slower following section of the lateral with or without the medial ligament and resembles the progression of spontaneous lesions (see below). Initial lesions, however, occur earlier than in unoperated animals (6 to 10 weeks in contrast with 12 weeks).

Chemical models

A single intra-articular injection of iodoacetate induces rapid changes in the articular cartilage of the affected joint that progresses over a matter of weeks. These changes include chondrocyte necrosis, proteoglycan depletion, cartilage fibrillation and subsequent loss down to bone, and the formation of osteophytes. As in the dog model, experiments that change the nature of the biomechanical forces acting across the joint affect the rate and extent of damage, with exercise exacerbating the lesions and immobilization having a protective effect, although this is reversed and leads to atrophy if immobilization is prolonged over an extended period (Williams and Brandt 1984).

Genetic models

There are several models of spontaneously occurring osteoarthritis in animals including various strains of mice (C57-black, STR-IN, and STR-ORT), Hartley albino guinea pigs, and hip dysplasia in beagle dogs. The STR mouse is particularly useful for experimental work as there is a 100 per cent incidence in males after 5 months of age, with females somewhat less affected. Changes seen in the joint are those of a mild generalized osteoarthritis, most prominent in the knee joints due to a distal shift of the patella leading to altered joint congruity (Walton and Elves 1979). The disease course follows the stages known from human pathology, with roughening of the cartilage surface, radial and horizontal cartilage fissures, and erosions down to bone accompanied by subchondral bone remodelling (Fig. 2), but the cellular and molecular changes they result from have not been characterized. Spontaneous cartilage degeneration develops in the femoral–tibial joint in male Hartley guinea pigs (Bendele *et al*. 1989). Lesions develop initially on the medial tibial plateau between 60 and 90 days, and by 1 year, bilateral fibrillation over 50 per cent of the medial tibial articular surface is consistently seen. The shoulder and elbow joints are affected less frequently. The early lesions of focal chondrocyte death and matrix degeneration become increasingly severe with age and lesions in some 9 or 12 month animals resemble those present in human osteoarthritis. Animals that are diet restricted, with a 29 per cent decrease in body weight, have a 56 per cent reduction in the severity of lesions, suggesting that body mass in guinea pigs, as in humans, is an important predisposing factor in the development of spontaneous osteoarthritis of the knee.

Markers of cartilage damage in joint disease

Recent advances in the understanding of the biochemistry and physiology of articular cartilage together with the advent of monoclonal antibodies have rendered it possible to measure matrix components in blood, synovial fluid, and urine. In the near future, it should be possible to define the role of measurement of these components as markers of cartilage metabolism in health and disease. To date, various epitopes have been identified in the extracellular matrix using both polyclonal and monoclonal antibodies or separation techniques such as high-pressure liquid chromatography.

Proteoglycan epitopes

Keratan sulphate

Unlike other carbohydrate constituents of proteoglycans, keratan sulphate is restricted to cartilage apart from a small amount found in the cornea. The monoclonal antibody 5D4, which recognizes a highly sulphated epitope present only at the non-reducing end of long keratan sulphate chains, forms the basis of a well-characterized assay (Thonar *et al*. 1992). Serum levels show no diurnal variation and, after skeletal maturity has been achieved, do not vary with age. With the injection of papain into a single joint or chymopapain into an intravertebral disc, the acute catabolism of cartilage is mirrored by a transient two- to eightfold rise in levels of keratan sulphate epitope. A good correlation exists between levels of keratan sulphate epitope and other proteoglycan epitopes found on the core protein.

Serum levels of keratan sulphate epitope have been found to be raised in patients with osteoarthritis and are stable with time, although the large overlap seen in the normal population does not recommend it as a diagnostic test (Sharif *et al*. 1995a). However, levels in synovial fluid are about 10 times serum levels and vary inversely with cartilage mass as measured radiographically (Campion *et al*. 1991).

Chondroitin sulphate epitopes

Recent studies have suggested that early changes in osteoarthritis may be accompanied by subtle changes in the structure of chondroitin sulphate chains. The monoclonal antibodies used recognize specific patterns of sulphation within the chains which are rare in normal cartilage, but which are expressed in osteoarthritic cartilage (Caterson *et al*. 1990). These chondroitin sulphate epitopes are also found in embryonic tissue and may represent the expression of a more primitive type of molecule during the attempted reparative processes. The abundance of these epitopes was investigated in patients following knee injury with cruciate ligament rupture or major meniscal damage (Hazell *et al*. 1995). Analysis of synovial fluids from the trauma joint compared with the contralateral uninjured joint showed that trauma caused an increase in the expression of chondroitin sulphate epitopes, which was greatest in the first few months after injury. In contrast there was a fall in the content of keratan sulphate epitopes. The aggrecan fragments released from cartilage in the injured joint were therefore of altered composition and contained chondroitin sulphate chains of higher epitope content and less keratan sulphate. This change may correlate with increased matrix synthesis and may form part of a reparative/remodelling response by the chondrocytes. The combination of a measure of chondroitin sulphate epitopes in synovial fluid to assess new aggrecan synthesis, and of keratan sulphate epitopes to reflect matrix aggrecan degradation, may provide a useful index of cartilage status during the early stages of joint disease. Studies of early lesions of spontaneous osteoarthritis in the guinea pig suggest that changes in the ratio of 6-sulphation and 4-sulphation of the disaccharides of chondroitin sulphate may be an important early event in osteoarthritis (Osborne *et al*. 1994). The initiation of lesions coincides with a decrease in chondroitin-4-sulphate to below 20 to 25 per cent. Non-load-bearing cartilage and cartilage that does not develop osteoarthritic changes have a relatively high content of the chondroitin-4-sulphate, which does not fall below 35 per cent. It is proposed that chondroitin-4-sulphate may have a more stabilizing influence on cartilage matrix during loading than chondroitin-6-sulphate.

Proteoglycan protein epitopes

Polyclonal antibodies that recognize protein epitopes on proteoglycans released into synovial fluid have been used to study the long-term progress of patients following acute knee injury. It has been shown that acute trauma gives rise to a release of cartilage proteoglycan fragments into the synovial fluid and that the level of the rise is related to the severity of the trauma in the initial phase (Lohmander *et al*. 1989). Levels were still significantly raised more than 1 year after injury compared with controls. Knee pain in the absence of acute trauma or abnormal arthroscopic appearance was not associated with increased levels and suggests a lack of cartilage involvement in these cases.

Studies in patients with rheumatoid arthritis have shown that higher synovial fluid levels of proteoglycan were found in patients with a poorer prognosis at the time when the cartilage height was still normal (Saxne *et al*. 1987; Saxne and Heinegard 1992). In addition, when samples were taken at times of increased disease activity, levels were remarkably constant and suggest a consistent response of cartilage to insult in the individual patient.

Hyaluronan

Various assays are available to measure levels of hyaluronan in tissue fluids. There is evidence relating levels of hyaluronan to disease activity and ongoing joint damage in rheumatoid arthritis (Paimela *et al*. 1991). Increased levels of serum hyaluronan have been found to predict progression of knee osteoarthritis (Sharif *et al*. 1995b). In this study, 94 patients with knee osteoarthritis were followed for 5 years. At entry, hyaluronan levels were significantly related to disease duration, minimum joint space, and previous surgery. Moreover, those with progressive joint disease had significantly higher baseline hyaluronan levels than those with stable disease.

Collagen

The potential exists to monitor the synthesis and degradation of type II collagen found in cartilage by measuring levels of type II procollagen or the urinary excretion of pyridinoline cross-links, respectively. Levels of pyridinoline cross-links have been found to be elevated in patients with rheumatoid arthritis and osteoarthritis, with higher levels in patients with rheumatoid arthritis and a correlation with inflammatory disease activity (Seibel *et al*. 1989). Carboxy-terminal type II collagen, a marker of collagen type II synthesis, is elevated over control levels in osteoarthritic synovial fluid and increases with disease progression. In addition, the levels correlate with body mass index as a measure of obesity in osteoarthritis. In traumatic arthritis synovial fluid, levels of carboxy-terminal type II collagen correlate with the severity of the cartilage lesion as assessed by arthroscopy (Shinmei *et al*. 1995).

Non-collagenous matrix molecules

More has become known about the structure and function of various non-collagenous matrix molecules, which are probably primarily involved in cell attachment and collagen fibre modulation (Heinegard and Oldberg 1989). Although many, such as fibronectin, are widely distributed throughout the connective tissue of the body, others, such as cartilage oligomeric protein and cartilage matrix protein, are more restricted to cartilage and could therefore be potential markers of altered cartilage metabolism. Cartilage matrix protein is not found in articular cartilage and levels could give an indication of the systemic component to raised levels of cartilage-derived molecules that are less specific in their distribution. Recently, a relationship has been found between serum levels of cartilage oligomeric protein and progression of knee osteoarthritis (Sharif *et al*. 1995a). Progression of disease was defined by a 2 mm or greater reduction in joint space or the necessity of knee surgery during a 5-year follow-up. During the first year, serum levels of cartilage oligomeric protein were significantly elevated in 20 of 57 patients who progressed compared with those that did not. Other studies monitoring bone sialoprotein in synovial fluid have suggested that its increased release in rheumatoid arthritis reflects the extent of tissue destruction (Saxne *et al*. 1995).

Patterns of change

The ability of individual markers to detect and monitor disease is likely to limited. More helpful is a number of assays used in combination that may reflect the molecular nature of the lesion and the sum of anabolic and catabolic events (Saxne and Heinegard 1995) (see Table 5).

Tissue component	Epitope assayed degradation	Remodelling/repair
Type II collagen	Pyridinoline	C-propeptide
Aggrecan	Keratan sulphate	3B3, 846 CS epitopes
Matrix protein	Cartilage oligomeric protein	
Proteases	Stromelysin/collagenase	TIMP
Cytokines	IL-1, TNF-α	TGF-β

IL-1, interleukin 1; TNF-α, tumour necrosis factor-α; CS, chondroitin sulphate.

Table 5 Potential markers for monitoring the health of articular cartilage

This approach has been adopted in a study of patients with rheumatoid arthritis with destructive hip disease (Mansson *et al*. 1995). Eighteen patients were studied from a prospective cohort of 180 with early rheumatoid arthritis. Nine of these were patients who had developed early erosive hip disease and nine were age- and sex-matched patients with arthritis that was more slowly progressive. Increased levels of cartilage oligomeric protein were found in all patients with progressive disease, whereas levels of the chondroitin sulfate epitope 846 were increased only in those with milder disease. The levels of type II collagen C-propeptide, a marker of collagen II synthesis, were elevated in both groups. These results suggest that elevated serum levels of cartilage oligomeric protein may indicate an adverse prognosis, whereas elevated 846 epitope may be more favourable. The elevation of type II collagen propeptide in both groups is indicative of a selective synthesis of

collagen compared with aggrecan, which may have implications for the quality of the repair process.

Further work is required before a panel of meaningful cartilage function tests are available. Interpretation of levels depends on the epitope recognized and the characteristics of the assay involved, an understanding of the kinetics and clearance of the epitope and its possible alteration by disease, and the effect of external factors on concentration in body fluids, such as the exclusion volume effect of hyaluronan in synovial fluid. The relevance of levels of the epitope then needs to be evaluated in long-term, prospective, clinical trials stratified for confounding variables such as drug therapy, age, disease duration, and disease severity. With this caveat aside, it should soon prove possible to develop a series of assays that accurately reflect the health of articular cartilage and its response to disease and therapy.

2.4 Bone in health and disease

Roger Smith

Bone is a metabolically active tissue that is formed, removed, and replaced throughout life (Evered and Harnett 1988; Martin *et al*. 1988; Tam *et al*. 1989; Manolagas and Jilka 1995). These processes depend on bone cells, whose activities are determined by many factors. They include genetic, mechanical, nutritional, and hormonal influences and a host of short-acting cellular messages, including growth factors, collectively termed cytokines (Russell 1990). This chapter deals with the normal physiology of bone (Vaughan 1981; Smith 1984; Avioli and Krane 1990; Coe and Favus 1991; Noda 1993; Brighton *et al*. 1994; Smith 1995), and outlines the changes in specific skeletal disorders.

Bone in health

Structure

Bone consists of cells and an extracellular mineralized matrix (35 per cent organic and 65 per cent inorganic). About 90 per cent of the organic component is type I collagen. The remainder includes many non-collagen products of the osteoblast, such as osteocalcin, osteonectin, and proteoglycans (Robey 1994; see below). The mineral is present mainly as a complex mixture of calcium and phosphate in the form of hydroxyapatite.

Two anatomical types of bone may be defined, trabecular (cancellous) and cortical. The proportion of these in bones normally differs: for instance the vertebral bodies are predominantly trabecular and the shafts of the long bones are cortical.

This distribution is relevant both to the functions of the bone and to skeletal disorders such as osteoporosis. In trabecular bone there are more metabolically active surfaces in a given volume than in cortical bone. The basic multicellular units (see below) act on the surfaces of trabecular bone and through resorbing channels (cutting cones) in cortical bones. The fine structure of bone is described by Boyde (1972).

Bone is often thought to be inert because of its structural rigidity and persistence after death, and also to be composed entirely of chalk because it contains 99 per cent of the body's calcium. Although both assumptions are superficially reasonable, neither is correct.

Bone cells

Conventional histological sections of bone demonstrate three types of bone cell, which are clearly different (Fig. 1 and Fig. 2): osteoblasts, which may be plump and apparently active, or flat and apparently inactive (otherwise called bone-lining cells); multinucleated osteoclasts, which most often occupy areas of resorption; and osteocytes within their lacunas in the mineralized bone, apparently in contact with other osteocytes and bone cells through their extensions in the canaliculi (Fig. 2 and Fig. 3). All these cells may be seen together in one microscopic field. They are often in close contact with cells of the bone marrow, which contains their precursors and also brings them into close relationship with the immune system. These cells and the mineralized organic matrix have almost infinite possibilities for exchange of information. It is the complexity of bone that provides both the challenge and the fascination for those interested in its disorders. Histological techniques have been developed to study the sequential events enacted by teams of bone cells in so-called basic multicellular units (Eriksen *et al*. 1989); the techniques of cell biology are used to study the origin and functions of different types of cells and the communications between them (Martin *et al*. 1988). These approaches provide different information: the histology tells us about the temporal events in bone as a tissue whereas the cell biology provides clues about the activities of the different cells, albeit in artificial culture systems.

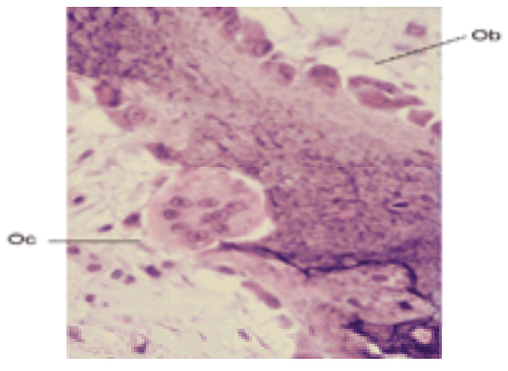

Fig. 1 A multinucleated osteoclast (centre: arrow, Oc) is present in a Howship's resorption lacuna along one edge of a bone trabecula; a row of plump mononuclear osteoblasts lie along the opposite edge (right: arrows, Ob). Haematoxylin and eosin, magnification × 4000.

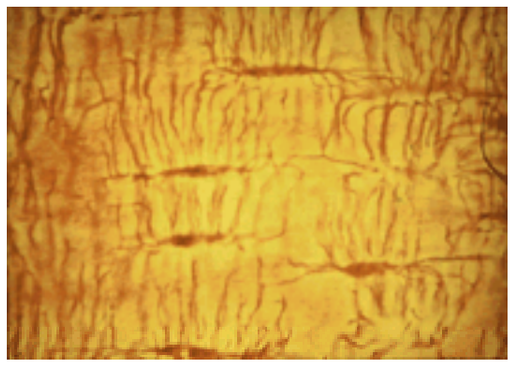

Fig. 2 A ground bone section showing osteocytes with numerous canaliculi, magnification × 400.

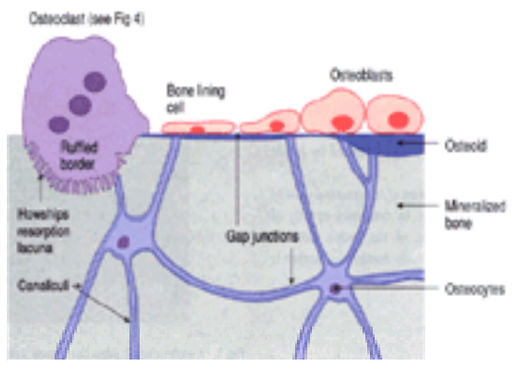

Fig. 3 A diagram of bone structure to show the relationship of different cell types.

The cells of bone occupy a central position in its physiology. Osteoblasts are one particular cell form derived from the mesenchymal stromal cell system; fibroblasts and adipocytes are others (Nijweide *et al*. 1988; Owen and Friedenstein 1988; Manolagas and Jilka 1995). Osteoclasts are haemopoietic in origin. The marrow contains precursor cells for the stromal and haematopoietic system; currently these are referred to as fibroblast colony forming units and granulocyte-macrophage colony forming units, respectively (see below). The osteocytes which are imbedded in the mineralized bone are derived from osteoblasts, as are also the bone-lining cells. All bone cells communicate with each other and control bone modelling during growth and remodelling throughout life. The constant processes of osteoclastic bone resorption and osteoblastic bone formation are closely linked and take place in basic multicellular units. The cellular cycle of such a unit (Fig. 4) begins with activation of multinucleate osteoclasts from their macrophage-like mononuclear precursors; osteoclasts produce resorption (Howship's) lacunas (Fig. 1) on the surface of trabecular bone, or cutting cones in cortical bone (Eriksen *et al*. 1989). These are similar processes. In cancellous (trabecular) bone, the basic multicellular unit may be looked upon as a cortical multicellular unit sectioned through the middle. Resorption is followed by a reversal phase, during which a cement line is deposited, and then the formation by osteoblasts of new bone matrix, which is subsequently mineralized. In the young adult, when the bone mass is constant, the amount of new bone formed equals that resorbed; in childhood more bone is formed than resorbed; and in later years there is an imbalance between these two processes in favour of resorption, leading to osteoporosis. The timescale of the remodelling cycle is approximately established, although estimates differ (Fig. 4).

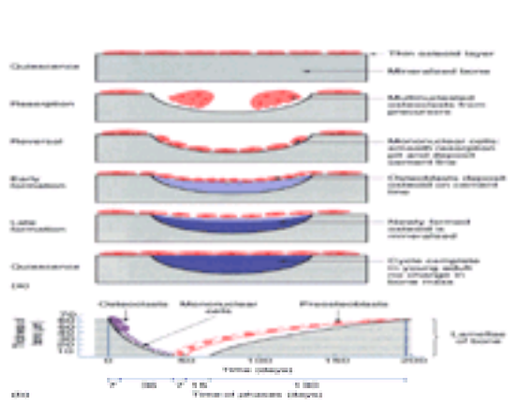

Fig. 4 (a) The remodelling events on the surface of bone during a bone multicellular-unit sequence (modified from Martin *et al*. (1988)). (b) The time sequences of these events from 20 young normal individuals (modified from Eriksen *et al*. (1989)).

Eriksen *et al*. (1989) give details of histomorphometrical findings in normal subjects and in those with metabolic bone disease. They point out that bone is one of the few tissues in which a time marker may be incorporated, and that histomorphometry can separate alteration in cellular activity from changes in cell number. The turnover of bone at the tissue level is determined by the activation frequency of basic multicellular units and the functional rates of individual cells. The mechanism of bone loss is different in different disorders. There are many unsolved mysteries about basic multicellular units. One is what factors lead to activation of the osteoclasts to initiate the resorbing cycle. Another is how cells communicate with each other (see below). However, it is becoming clear that many activities of the osteoclast depend on those of the osteoblast, which is a dominant cell in the skeletal scene.

Osteoblasts, osteocytes, and bone-lining cells

Osteoblasts (Fig. 1) have many important functions (Fig. 5). It is possible that the functions are divided between them. They respond to endocrine factors, both systemic and local (cytokines), and to mechanical stress. They synthesize the organic bone matrix (mainly collagen) and non-collagen proteins, and they control bone mineralization. Importantly, they also appear to direct the activity of other cell types, particularly the osteoclasts. In this respect they may also activate the bone-resorbing cycle.

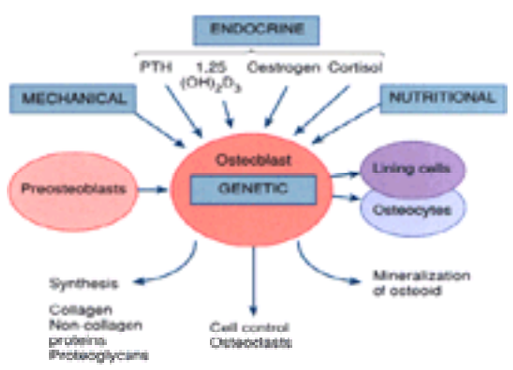

Fig. 5 The central position of the osteoblast in bone physiology. Broad arrows show the origin of osteoblasts from preosteoblasts, themselves derived from stromal

cell (fibroblast colony forming unit) lineage, and of the lining cells and osteocytes.

Osteocytes (Fig. 2) occupy lacunas within the mineralized bone. They communicate with each other by gap junctions via processes within the canaliculi and probably have an important function in the detection of, and response to, mechanical forces within mineralized bone. Bone-lining cells, a form of flattened, inactive osteoblast, cover endosteal surfaces and bone trabeculas, being separated from each other by gap junctions. They may also isolate bone fluid (if this exists) from the general extracellular-fluid compartment.

Osteoclasts

These multinucleated cells are derived from precursors in the haemopoietic system (granulocyte–macrophage colony forming units), but their immediate cell of origin is debated (Chambers 1988). They resorb bone by attaching themselves to its surfaces and forming a seal to isolate their area of activity (Baron *et al*. 1993) (Fig. 6). Within this sealed zone they produce a very acid environment, with the aid of a proton pump linked to the enzyme carbonic anhydrase II, within which digestion of whole bone by lysosomal enzymes occurs. Absence of carbonic anhydrase II is linked to a rare form of osteopetrosis (see below). Osteoclasts have receptors to calcitonin, which directly suppresses their activity, and also possibly to oestrogens (Glass and Broom 1993), but not, so far as is known, to any other hormone. However, they do respond to prostaglandins. The resorptive effects of parathyroid hormone and of 1,25-dihydroxycholecalciferol are probably mediated through the osteoblast.

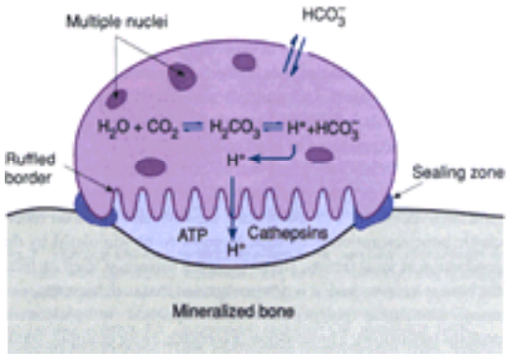

Fig. 6 A diagram of the main features and functions of the osteoclast.

Bone formation

The factors that control bone formation are complex and not fully understood, but must work largely through the osteoblast. Osteoprogenitor cells, the precursors of osteoblasts, are found in the periosteum and the endosteal surfaces close to the bone marrow. The local remodelling stimulus for new bone formation comes from some aspect of bone resorption, which could, for instance, be polypeptide growth factors or morphogenetic proteins liberated by this process (see below).

The activities of bone cells are influenced by cytokines. A cytokine may be defined as a peptide, produced by a cell, that acts as an autocrine, paracrine, or endocrine mediator. In this sense the definition includes a large number of substances of which many can be shown to have effects on bone and cartilage metabolism. Such effects have been demonstrated principally in experimental (and artificial) conditions and their physiological role is largely unknown. Many cytokines have alternative names and multiple actions, with synergism and antagonism; Table 1 provides examples of cytokines identified in bone matrix and produced by bone cells.

Effective on bone	In bone matrix/by bone cells
Interleukins (ILs)	IL-1, IL-6, IL-8
Tumour necrosis factors (TNFs)	TNF-α (cachectin)
	TNF-β (lymphotoxin)
Interferons	
Growth factors	Platelet-derived growth factors
	Insulin-like growth factors (somatomedins)
	Fibroblast growth factors
	Transforming growth factor-α and -β
	Epidermal growth factor
	Bone morphogenetic proteins (see Table 2)
Haemopoietic and colony stimulating factors (CSFs)	
Granulocyte (GCSF)	
Macrophage (MCSF)	MCSF
Granulocyte–macrophage (GMCSF)	GMCSF
Others	Parathyroid hormone-related peptides

Table 1 Cytokines, growth factors, and other mediators with effects on bone and those demonstrated in bone matrix and/or produced by bone cells

The local factors that control osteoblastic activity are probably of considerable importance (Canalis *et al*. 1989). Only some of these have been identified. The osteoblastic activity that follows on osteoclastic bone resorption is thought by some to be stimulated by the production of local factors, either from the osteoclast itself or from the bone it has resorbed. It is now recognized that such bone contains many stimulating polypeptides and important morphogenetic proteins (see below). The situation is complex, as for example, transforming growth factor-b appears to belong to a family of multifunctional regulatory peptides, and bone is probably its most abundant source. Not only do osteoblasts synthesize this factor but they also have high-affinity receptors for it, and are mitogenically stimulated by it. Growth factors may be defined as polypeptides with mitogenic activity, although they also affect the function of differentiated cells. They are produced by cells and, therefore, they may also be included under the general heading of cytokines. Important growth factors in bone matrix that have originated from cells within bone (Table 1) include platelet-derived growth factors, fibroblast growth factors, insulin-like growth factors (or somatomedins), transforming growth factors, and other osteoinductive factors (Canalis *et al*. 1989; Manolagas and Jilka 1995).

Bone resorption

Osteoclasts are controlled by systemic and local hormones but there is no direct evidence that they are influenced by mechanical stress. Calcitonin directly inhibits the osteoclast, temporarily abolishes the active, ruffled border, and suppresses the generation of new osteoclasts. Bone resorption is increased by parathyroid hormone and 1,25-dihydroxycholecalciferol. As the osteoclast does not contain receptors to either of these hormones it is proposed that the resorbing activity is mediated via the osteoblast. Again, the messages that the osteoblasts use to turn on the resorbing activity of the osteoclast are largely unknown. Amongst them are the prostaglandins. The number and activity of the osteoclasts is increased by a variety of cytokines produced by lymphocytes or monocytes (lymphokines and monokines, respectively) and by peptide growth factors (epidermal growth factor, transforming growth factors). They are also stimulated by a group of factors previously called osteoclast-activating factors (see below) (Table 2).

Systemic hormones	Cytokines
Activation	
Parathyroid hormone	Epidermal growth factor
1,25$(OH)_2$ vitamin D_3	Transforming growth factors-α and -β
Thyroxine	Prostaglandins
	Interleukin 3
Parathyroid hormone-related peptide	Granulocyte–macrophage colony-stimulating factor (and other colony-stimulating factors)
	Osteoclast-activating factors
Inhibition	
Calcitonin	Interferon-γ
	Transforming growth factor-β
	Interleukin 6

Table 2 Factors affecting bone resorption by direct or indirect effects on osteoclasts

Communication between bone cells

Many interactions between bone cells can be shown in experimental systems, but their relative importance *in vivo* is unknown.

Figure 7 attempts to bring together those influences on the osteoclast and osteoblast (and between them) that contribute to bone turnover. In addition to illustrating those factors already discussed, it shows the likely importance of colony-stimulating factors identified within the haemopoietic system, and the direct effect of the osteoblast in controlling the local production of collagenase in preparation for osteoclastic bone resorption. Manolagas and Jilka (1995) have recently updated this subject. They emphasize the importance of the close association of the haematopoietic system in the marrow and the bony tissue which surrounds it. The cells of both systems share progenitors, produce and respond to some of the same cytokines and colony-stimulating factors, and are critical for each other's function. The proposed relationship between these cells and the effect upon them of various cytokines is indicated in Fig. 8. It is suggested (Manolagas and Jilka 1995) that the differentiation pathway of osteoclasts is controlled by stromal osteoblastic cells utilizing cytokines such as interleukin 6 and interleukin 1; and further that the production of these and other cytokines by the osteoblast is stimulated also by interleukins, and additionally by systemic hormones such as 1,25-dihydroxycholecalciferol and parathyroid hormone.

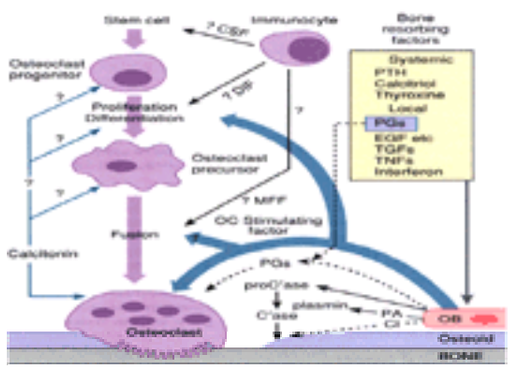

Fig. 7 Humoral and local factors regulating bone resorption (from Martin *et al*. (1988) with permission). Note how many of the arrows still have question marks. Stimulation represented by continuous arrows, inhibition by interrupted arrows. C'ase, collagenase; pro C'ase, procollagenase; CI, collagenase inhibitor; PA, plasminogen activator; OB, osteoblast; EGF, epidermal growth factor; TGFs, transforming growth factors; TNFs, tumour necrosis factors; MFF, macrophage fusion factor; DIF, differentiation-inducing factor; CSF, colony-stimulating factor.

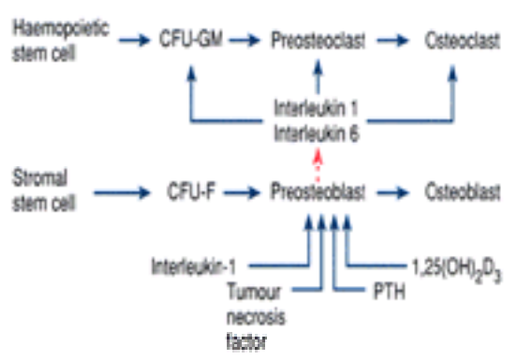

Fig. 8 The likely relationship between bone cells, their precursors, and cytokines. For CFU-GM (granulocyte–macrophage colony forming units) and CFU-F (fibroblast colony forming units) see text (modified from Manolagas and Jilka (1995)).

Bone mass

The eventual size and density of the skeleton and its development during the early years of life is influenced by important genetic factors. This genetic background is modified by mechanical stress, nutrition, the systemic effects of hormones, and by local factors produced by the bone cells themselves (Fig. 9). The relative contributions of these may vary with age (Fig. 10). Recent investigations suggest that the rate of bone loss as well as peak bone mass may be genetically determined, that adequate calcium intake conserves bone mass at all ages, and that mechanical loading of the skeleton is also important at any age.

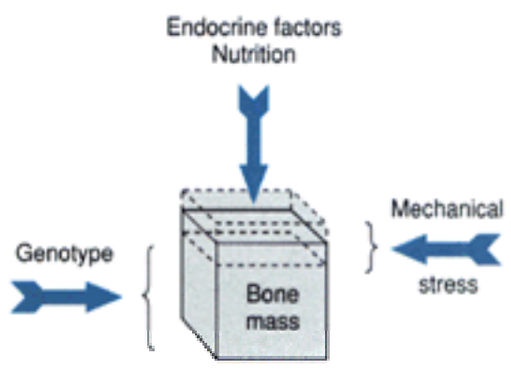

Fig. 9 A diagram of the main factors which influence bone mass (from Heaney (1986) with permission).

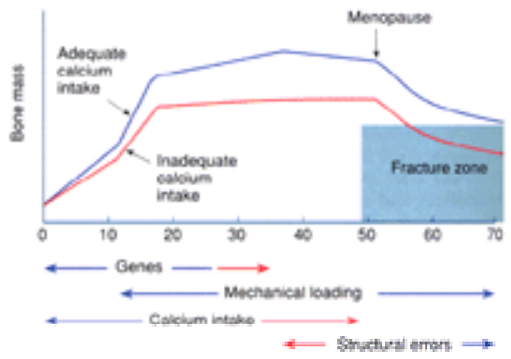

Fig. 10 The relative importance of factors contributing to bone mass with age (from Riggs and Melton (1988) with permission). The postmenopausal rate of bone loss is also influenced by genetic factors and calcium intake.

Genetic factors

Pocock *et al*. (1987) have confirmed the heritability of bone mass in monozygotic twins and Seeman *et al*. (1989) provide evidence that the bone mass of daughters of osteoporotic women is less than that of daughters of non-osteoporotic women. Recent Australian observations on mono- and dizygotic twins and postmenopausal women have shown that bone mass in the populations studied is partly related to particular polymorphisms in the vitamin D receptor gene (Morrison *et al*. 1994), although this has not been confirmed elsewhere (Hustmyer *et al*. 1994). In a disorder such a osteogenesis imperfecta, where there is clear evidence of gene mutations, the heritable component of bone mass is very important (see below). Work on this syndrome has illuminated important genetic mechanisms that account for apparently non-Mendelian forms of inheritance, particularly somatic and germ-line mosaicism (Hall 1988; Sykes 1990; Bernards and Gusella 1994).

Nutrition

It seems common sense that both the size and density of the skeleton should be related to nutrition, particularly of calcium, protein and energy, but this has been difficult to prove (Kanis and Passmore 1989; Nordin and Heaney 1990). Recent twin studies have demonstrated a significantly greater increase in radial and vertebral bone density in those prepubertal twins on calcium supplements (Johnston *et al*. 1992) and current evidence supports the notion that additional calcium is good for the skeleton at all ages (Heaney 1993).

Mechanical factors

The main function of the skeleton is mechanical and it has long been known that within the skeleton bone is laid down along the lines of stress. Thus, at any age, stress-induced changes in bone mineral density are site-specific (Heinonen *et al*. 1993). *In vitro* experiments show that osteoblasts in culture respond to mechanical stress by an increase in cAMP and phosphoinositol, partly mediated by prostaglandins (Sandy *et al*. 1989). Since the osteocyte may be the primary sensor of mechanical loading, attempts are being made in vivo to identify the candidate gene in this cellular response (Mason *et al*. 1995).

Systemic hormones

Sex hormones, testosterone and oestrogen, encourage new bone formation. Growth hormone is an important anabolic skeletal agent during the early years of life, both directly and through the local production of insulin-like growth factors. A number of hormones primarily thought of as resorptive may also have anabolic actions on the osteoblasts. These include parathyroid hormone, which has a long-term anabolic effect increasing the proliferation of osteoblast precursors, and 1,25-dihydroxycholecalciferol.

Bone matrix

The osteoblast synthesizes a large variety of substances that together form the organic bone matrix. These may be divided into collagen and non-collagen proteins, and the proteoglycans (Robey 1989; Robey 1994).

Collagen

Collagen is the major extracellular protein in the body and more than half is within the skeleton (Prockop and Kivirikko 1984). There are many different molecular types, with different functions and different genes (Burgeson 1988; Van der Rest and Garrone 1991; Hulmes 1992; Byers 1993; and Chapter 2.2) (Table 3). The main fibrillar collagens are type I, II, and III; type V and XI are minor fibrillar collagens; type IX, XII, and XIV collagens are associated with fibrils. Collagen in bone is type I. This is a heteropolymer composed of two a_1-chains and one a_2-chain. The general structure of an a chain is $(GlyXY)_{338}$. The a-chains are synthesized as precursors within the osteoblasts and undergo a number of synthetic steps that include posttranslational hydroxylation of proline and lysine residues; certain hydroxylysine residues are further modified into aldehydes and also glycosylated. After removal of their extensions the triple helical molecules form an exact structure with a quarter-stagger overlap, which is subsequently cross-linked (Fig. 11). In type I collagen the so-called hole zones within this structure provide a template for early mineralization. The arrangement of the collagen molecules differ according to their tissue function (Hulmes 1992). Mutations in the collagen genes and defects in posttranslational modification cause many inherited disorders of connective tissue, of which osteogenesis imperfecta is the main example. Recent work has demonstrated the causal importance of mutations in other collagens particularly those which cause chondrodysplasias (type II, IX, and X; see below).

Type	α-Chains	Most common molecular form	Tissue distribution
I	α1(I), α2(I)	$[\alpha 1(I)]_2\,\alpha 2(I)$	Most connective tissues, e.g. bone, tendon, skin, lung, cornea, sclera, vascular system
II	α1(II)	$[\alpha 1(II)]_3$	Cartilage, vitreous humour, embryonic cornea
III	α1(III)	$[\alpha 1(III)]_3$	Extensible connective tissues, e.g. skin, lung, vascular system
IV	α1(IV), α2(IV), α3(IV), α4(IV), α5(IV)	$[\alpha 1(IV)]_2\,\alpha 2(IV)$	Basement membranes
V	α1(V), α2(V), α3(V)	$[\alpha 1(V)]_2\,\alpha 2(V)$	Tissues containing collagen I, quantitatively minor component
VI	α1(VI), α2(VI), α3(VI)	$\alpha 1(VI)\,\alpha 2(VI)\,\alpha 3(VI)$	Most connective tissues, including cartilage
VII	α1(VII), α2(VII)	$[\alpha 1(VII)]_3$ $\alpha 2(VII)$?	Basement-membrane-associated anchoring fibrils
VIII	α1(VIII), α2(VIII)	$[\alpha 1(VIII)]_2\,\alpha 2(VIII)$?	Product of endothelial and various tumour cell lines
IX	α1(IX), α2(IX), α3(IX)	$\alpha 1(IX)\,\alpha 2(IX)\,\alpha 3(IX)$	Tissues containing collagen II, quantitatively minor component
X	α1(X)	$[\alpha 1(X)]_3$	Hypertrophic zone of cartilage
XI	α1(XI), α2(XI), α3(XI)*	$\alpha 1(XI)\,\alpha 2(XI)\,\alpha 3(XI)$	Tissues containing collagen II, quantitatively minor component
XII	α1(XII)	$[\alpha 1(XII)]_3$	Tissues containing collagen I, quantitatively minor component
XIII	α1(XIII)	$[\alpha 1(XIII)]_3$?	Quantitatively minor collagen, found e.g. in skin, intestine
XIV	α1(XIV)	$[\alpha 1(XIV)]_3$?	Tissues containing collagen I, quantitatively minor component

*Closely related to α1(I)

Table 3 The vertebrate collagens

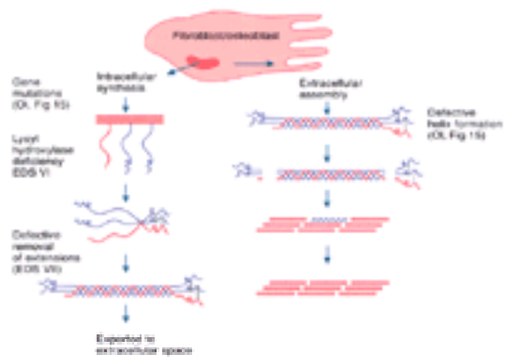

Fig. 11 Diagrammatic representation of the main synthetic pathways of collagen and the effects of some mutations. Type I collagen mutations which cause osteogenesis imperfecta are mirrored by similar mutations in type II collagen causing chondrodysplasias, and defects in minor collagens (type IX and X) (based on Prockop and Kivirikko (1984) with permission).

Non-collagen proteins

Many proteins may be extracted from bone, which differ according to the starting material and the methods used (Triffitt 1987; Termine 1988; Robey 1989; Robey 1994) (see Table 4). These include osteocalcin (Gla protein), sialoproteins, and various phosphoproteins such as osteonectin and osteopontin (Young *et al*. 1993). Within the group of non-collagen proteins it is convenient also to include the bone proteoglycans and, importantly, the bone morphogenetic proteins (Table 4 and Table 5). The complexity of non-collagen substances sequestered in bone matrix is emphasized by Hauschka *et al*. (1988) in their discussion of polypeptide growth factors. Osteoblasts are primarily responsible for the biosynthesis of all of these substances. However, other sources include substances selectively absorbed from the plasma, the products of monocytes, lymphocytes, and other cells within the bone marrow, the capillary network with its associated endothelial cells and basement membranes, and substances derived from the cartilage during endochondral ossification.

Names	Properties
Osteonectin (SPARC protein)	Gene on chromosome 5
	Binds to both collagen and hydroxyapatite
	Synthesized by many cells, including platelets
Sialoprotein I (osteopontin)	In many different bone cells; mRNA also in renal tubules, neuronal cells, etc.
Sialoprotein II (bone sialoprotein)	Gene on chromosome 4 (same as osteopontin)
	Fairly bone specific
Osteocalcin (bone Gla protein, BGP)	Gene on chromosome 1; found in young osteoblasts and odontoblasts
Matrix Gla protein (MGP)	Not unique to bone; mRNA earlier than that for BGP in development
Proteoglycan I (PG-I, biglycan)	Two separate species, but share single heterogeneous core protein
	Not unique to bone
Proteoglycan II (PG-II, decorin)	
Bone morphogenetic proteins (BMPs)	See Table 5
Insulin-like growth factors I and II	

Table 4 Major non-collagen protein products of bone cells

BMP	Chromosome	Comment[a]
1	8	Not a member of the TGF-β gene family
2	20p12	
3	4p14–q21	Dentinogenesis imperfecta type II
4	14	
5	6	
6	6	
7	20	

[a]BMP 2–7 are all members of the TGF-β gene family. There is evidence that BMP 2, 4, and 7 could be involved in the Holt–Oram syndrome. Any BMP genes could be candidate loci for FOP (Wozney 1993). TGF-β, transforming growth factor-β.

Table 5 The chromosomal localization of some bone morphogenetic proteins (BMPs)

The non-collagen proteins extracted from bone also depend on the type of bone and the methods used. Two-dimensional electrophoretic analysis may demonstrate more than 200 of them. Many of these bind calcium and many are phosphoproteins. A large number also originate outside bone. Many alternative names have been used for these substances. Robey (1989, 1994) in reviews of the structure and biochemistry of bone, points out that no unambiguous function has been determined for any bone matrix protein to date. Few, if any, are unique to bone, and bone matrix proteins can be expressed (at least transiently) in many tissues.

Osteonectin

This is the most abundant non-collagen protein produced by human osteoblasts (Young *et al*. 1993). It binds strongly to calcium ions, utilizing high and low affinity binding sites, hydroxyapatite, and native collagen. It is not limited to mineralizing tissue, being also found in human platelets. Although osteonectin mRNA is widely distributed in developing tissues, osteonectin is most abundant in bone.

Bone sialoproteins

Two types of these are now recognized. Their relative abundance varies with species studied. Thus sialoprotein I is a minor component of human bone, but a major contributor to total sialoprotein in rat bone. The protein contains a Arg–Gly–Asp cell-attachment sequence and is therefore called osteopontin. The major human bone sialoprotein is type II, similar to the substance originally described by Herring (for references see Termine (1988) and Robey (1989)).

Bone Gla-containing proteins

There are two of these, osteocalcin (bone Gla protein) and matrix Gla protein. The term Gla refers to the g-carboxylated glutamic acid residues, formed by vitamin K-modulated, posttranslational carboxylation of peptide-bound glutamic acid. These proteins have some sequence homology but are products of different genes. Matrix Gla protein is also a cartilage protein, and is found at an earlier developmental stage than osteocalcin. Despite extensive research on osteocalcin, its function is unknown. Warfarin-treated animals do not show abnormal mineralization. Biosynthesis of osteocalcin is regulated by 1,25-dihydroxycholecalciferol (and no other hormone), which enhances its nuclear transcription and eventually secretion from bone cells. Plasma osteocalcin has been linked to the rate of bone formation or, less specifically, bone turnover.

Bone proteoglycans

Proteoglycans from cartilage have been studied more extensively than those from bone (Hardingham 1981; Hardingham and Fosang 1992; Young *et al*. 1993). Bone matrix proteoglycans differ from them in their small overall size, relatively larger amounts of protein, and longer chondroitin sulphate chains. The two proteoglycans of

fetal bone (I and II) are different gene products. Small proteoglycans such as decorin and biglycan are thought to interact with growing collagen fibrils in a precise manner and to regulate their growth, maturation, and interactions.

Bone morphogenetic proteins

It has been known for many years that demineralized bone matrix contains substances capable of inducing ectopic bone formation. These substances are present in such small amounts that their extraction and isolation has presented great difficulties (Table 5). Wozney *et al*. (1988) reported the cloning and recombinant expression of several molecules that could induce cartilage but not bone; Sampath *et al*. (1987) isolated a 22-kDa protein from bone called osteogenin, capable of inducing new bone formation when implanted subcutaneously with the residue of extracted bone matrix. Bentz *et al*. (1989) isolated an osteo-inductive factor, which was active only together with transforming growth factor-b_1 and -b_2. Martin *et al*. (1989) emphasize the importance of the transforming growth factor-b supergene family in cartilage and bone formation. Subsequent work has shown that a large number of bone morphogenetic proteins exist, many of which belong to the transforming growth factor-b family (Tabas *et al*. 1991; Wozney 1993; Centrella *et al*. 1994) (Table 5). The bone morphogenetic proteins act as differentiation factors concerned with the induction and expression of multiple phenotypes derived from mesenchymal cells. Investigation of recombinant bone morphogenetic proteins has shown that individually and together they are involved in chondrogenesis and osteogenesis. Additionally members of the family are involved in the patterning and development of the human skeleton (Tickle 1994). It is becoming clear that recombinant bone morphogenetic proteins have great clinical potential in the repair of bony defects (Editorial 1992a).

Bone mineral and mineralization

Mineralization occurs against the background of the organic bone matrix. The ways in which mineralization happens continue to be debated (Boskey 1994) but there is good evidence that, in most mineralized tissues, calcifying vesicles derived from chondrocytes or osteoblasts provide a focus for mineralization (Robey 1989). These vesicles are particularly demonstrable in cartilage, but their function in the organized matrix of bone is controversial. The precipitation of calcium within these vesicles may be controlled by the action of a pyrophosphatase, which locally destroys pyrophosphate, itself an inhibitor of mineralization. Alkaline phosphatase is one such pyrophosphatase and is readily demonstrable both in osteoblasts and in mineralizing vesicles.

It is possible, for the purposes of clarity, to consider two types of mineralization—homogeneous nucleation, which occurs in the lumen of the matrix vesicles from amorphous calcium phosphate to form crystalline hydroxyapatite, and heterogeneous nucleation, which is collagen-mediated and may partly rely on absorbed non-collagen proteins as nucleators. After this first phase (mediated either by vesicles or collagen) there is a second phase of rapid spread of mineralization, initially in the hole zones and later the overlap regions of the collagen matrix.

Calcium and phosphorus balance

Calcium is essential for innumerable functions such as reproduction, neurotransmission, hormone action, cellular growth, and enzyme action. The central position of calcium as an ionic messenger continues to be explored. There have been considerable advances in our understanding of the messengers which control cellular processes by generating internal calcium signals. Chief amongst these is inositol triphosphate which is generated via G-protein and tyrosine kinase-linked receptors (Berridge 1993). Much has been written about external calcium balance and the main hormones that control it (MacIntyre 1986; Nordin 1990). Phosphate balance is less well understood. The circulating concentration of plasma calcium is determined by the amount of calcium absorbed by the intestine, the amount excreted by the kidney, and the exchange of mineral with the skeleton. The relative importance of these exchanges differs during growth and in different disorders. Total plasma calcium is closely maintained between 2.25 and 2.60 mmol/l, of which nearly half is in the ionized form (47 per cent ionized, 46 per cent protein bound, and the remainder complexed). The skeleton contains approximately 1 kg (25 000 mmol) of calcium. The main daily fluxes of calcium in the adult are shown in Fig. 12.

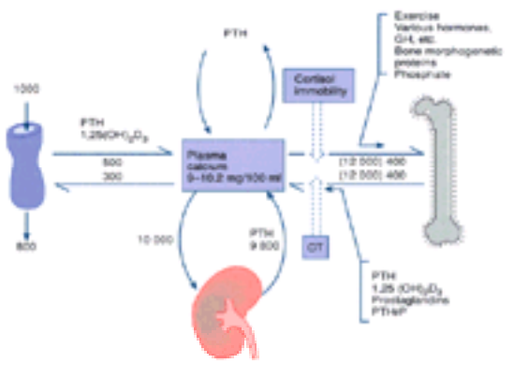

Fig. 12 Factors that control calcium balance; units are in mg per day (to convert to mmol divide by 40), and refer to an adult. The figures in parentheses are an estimate of exchange through the cellular barrier of bone. CT, calcitonin; GH, growth hormone; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related peptide.

Parathyroid hormone

The gene for parathyroid hormone is on chromosome 11. The hormone is synthesized as a large precursor for export (Kronenberg *et al*. 1986) and its secretion is stimulated by a reduction in the plasma concentration of ionized calcium and reduced by an increase in 1,25-dihydroxycholecalciferol. The way in which the parathyroid cells respond to very small changes in the extracellular concentration of calcium has been illuminated by the cloning and characterization of a calcium-sensing receptor from parathyroid-derived cells (Brown *et al*. 1993) (Fig. 13). Mutations within this receptor cause both hypercalcaemia and hypocalcaemia. An increase in parathyroid hormone secretion leads to an increase in calcium absorption through the gut, an increase in calcium reabsorption through the kidney, and an increase in bone resorption. Intestinal calcium absorption is mediated by 1,25-dihydroxycholecalciferol and 1a-hydroxylation is stimulated by parathyroid hormone, so that the effect of parathyroid hormone on intestinal calcium absorption is indirect and mediated by 1,25-dihydroxycholecalciferol. In contrast, the renal effect of parathyroid hormone on calcium reabsorption is direct. The cellular effects of parathyroid hormone are mediated through specific G-protein-coupled receptors in kidney and bone and appear to utilize more than one system (Caulfield and Rosenblatt 1990; Demay *et al*. 1993). Parathyroid hormone encourages osteoclastic bone resorption by its effect on the osteoblast as previously described.

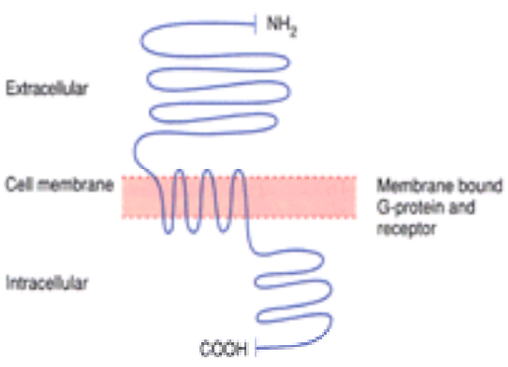

Fig. 13 A simplified diagram of the extracellular Ca^{2+}-sensing receptor from bovine parathyroid (redrawn from Brown *et al*. (1993)).

Vitamin D

Vitamin D (Fraser 1995) is synthesized either as vitamin D_3 (cholecalciferol) within the skin from its precursor 7-dehydrocholesterol under the influence of ultraviolet light (usually as sunlight), or taken in with food, either as vitamin D_3 or D_2 (ergocalciferol). It is subsequently transported to the liver by a binding protein where it undergoes 25-hydroxylation; 25-hydroxyvitamin D ($25(OH)D_3$) is then hydroxylated in the 1 position by the renal 1a-hydroxylase, 1,25-dihydroxycholecalciferol ($1,25(OH)_2D_3$) is the active metabolite of vitamin D, and it has widespread effects (Fig. 14). Its classic effects are on calcium metabolism, where it promotes the synthesis of a calcium-transporting protein within the cells of the small intestine. Its effects are mediated through a widely distributed vitamin D receptor which contains DNA and hormone-binding components. This receptor combines with retinoid X-receptors and vitamin D response elements to produce its effect on target tissues. It is now realized that 1,25-dihydroxycholecalciferol has many effects outside mineral metabolism, concerned with the immune system and the growth and differentiation of a wide variety of cells (Holick 1988; Reichel *et al*. 1989; De Luca *et al*. 1990). Measurement of plasma 25-OHD has proved to be a useful indicator of vitamin D status, and work on 1,25-dihydroxycholecalciferol and its receptors has illuminated the cause of the rarer forms of inherited rickets (see below). Although the kidney is the main sources of 1,25-dihydroxycholecalciferol, it is now clear that this metabolite can be synthesized by a variety of granulomata, providing a partial explanation for the hypercalcaemia of sarcoidosis and (occasionally) lymphomas (Cox and Haddad 1994).

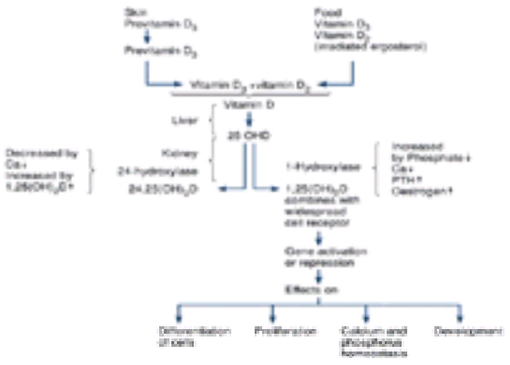

Fig. 14 The synthetic pathways and molecular and cellular effects of $1,25(OH)_2D$.

Calcitonin

Calcitonin (CT), a 32-amino-acid peptide, is one product of the CT gene which also encodes the calcitonin gene-related peptide (CGRP). Experimentally its secretion (by the C cells of the thyroid) is increased by an increase in plasma calcium. The main effect of administered calcitonin is to reduce bone resorption by direct and reversible suppression of the osteoclast (Azria 1989) via a receptor closely related to the parathyroid hormone receptor (Hruska *et al*. 1993). The physiological role of calcitonin is uncertain, although it is thought to protect the skeleton during physiological stresses such as growth and pregnancy.

Parathyroid hormone-related protein (PTHrP)

This hormone (Martin 1990) was discovered by studies on patients with non-metastatic hypercalcaemia of malignancy (see below). It has close sequence homology to parathyroid hormone at the amino-terminal end of the molecule and has very similar effects (Table 6). Its gene is located on the short arm of chromosome 12, which is thought to have arisen by a duplication of chromosome 11, which carries the human parathyroid hormone gene. It has been detected in a number of tumours, particularly of the lung. There is also evidence that it may have a role in fetal physiology, controlling the calcium gradient across the placenta and maintaining the relatively higher concentrations in the fetal circulation. The recent observation that targeted disruption of the PTHrP gene leads to a lethal dysplasia has widened our knowledge of its possible functions (Karaplis *et al*. 1994).

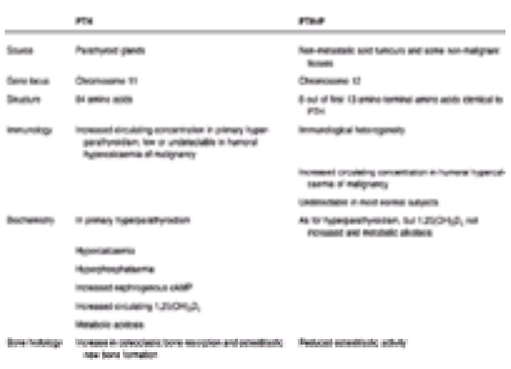

Table 6 Parathyroid hormone (PTH) and parathyroid-hormone related peptide (PTHrP) compared

Other hormones

Apart from the recognized calciotropic hormones, the skeleton is influenced by corticosteroids, the sex hormones, thyroxine, and growth hormone. The main effect of excess corticosteroids (either therapeutic or in Cushing's disease) is to suppress osteoblastic new bone formation. Both androgens and oestrogens promote and maintain skeletal mass. Osteoblasts have receptors for oestogen, although they are not abundant. Thyroxine increases bone turnover and increases resorption in excess of formation; thyrotoxicosis thus leads to bone loss. Excess growth hormone leads to gigantism and acromegaly (according to the age of onset), with enlargement of the bones. Absence of growth hormone will lead to proportional short stature; where there is a wider pituitary failure the reduction in gonadotrophins will cause bone loss.

Biochemical measures of bone turnover

Knowledge of bone physiology allows interpretation of biochemical measures of bone turnover. These include the plasma bone-derived alkaline phosphatase and osteocalcin, and urinary total hydroxyproline and cross-linked, collagen-derived peptides. The first two of these are closely related to osteoblast function, and the second two to bone resorption. As formation and resorption are closely coupled, such measurements are usually closely related to each other, and to overall bone turnover (Epstein 1988).

Plasma alkaline phosphatase (largely derived from osteoblasts) provides a crude but readily accessible index of bone formation, being increased during periods of rapid growth and particularly where bone turnover is greatly increased, as in Paget's disease. Where more skeletal specificity is required measurement of bone-derived alkaline phosphatase can be useful. Early measurements of serum osteocalcin (bone Gla protein) were widely variable and depended on the origin, sensitivity, and stability of the antibodies used. Total urinary hydroxyproline excretion is influenced by dietary collagen (gelatin) and reflects both resorption and new collagen synthesis. The recent development of methods for the measurement of urinary collagen-derived pyridinium cross-links promises to give a reliable indication of bone resorption, unrelated to new collagen formation and uninfluenced by diet (Black *et al*. 1988; Eyre 1992; Seibel *et al*. 1992). The nomenclature of these degradation products has become unnecessarily complex. The cross-links of collagen fibres are formed via aldehydes derived from lysyl and hydroxylysyl residues. When collagen is degraded fragments containing these cross-links, referred to as pyridium cross-links, are excreted in the urine. The cross-linked peptides are not further metabolized and the amount excreted is unaffected by dietary collagen (often in the form of gelatin). Pyridinoline (formed from hydroxylysyl cross-links) and

deoxypyridinoline (from lysyl cross-links) derived from bone collagen are excreted in the same ratio as they exist in bone. Pyridinoline also comes from other tissues, especially tendon and cartilage. Since bone is metabolically more active than cartilage the main source of urinary pyridium cross-linked, collagen-derived peptides is the skeleton. There is a diurnal variation in the amount excreted and according to the method used but significant increases are described in preadolescent growth and also in high turnover bone disease, particularly Paget's disease (Editorial 1992b).

New immunoassay methods are being developed which are likely to supersede the original HPLC (high-performance liquid chromatography) procedure. Methods which measure other aspects of collagen turnover, such as the circulating concentration of carboxyl- and amino-terminal fragments of the molecule, have yet to establish themselves in practice.

Bone in disease

The causes of many bone diseases may now be explained by our increased understanding of skeletal physiology. These diseases may be acquired or inherited, and provide examples of disorders of bone formation and resorption, of mineralization, of matrix synthesis, of enzyme function, and of abnormal cell biology. Many conditions previously thought of as skeletal curiosities are now known to have a biochemical basis (Whyte 1990; Royce and Steinmann 1993; Smith 1993). Some are dealt with in more detail elsewhere.

Osteoporosis

In osteoporosis, imbalance between resorption and formation leads to a reduction in the amount of bone per unit volume without a change in its composition (Riggs and Melton 1988; Smith 1990a; Riggs and Melton 1992; Dempster and Lindsay 1993). This reduction leads to microarchitectural deterioration, increased fragility and increased fracture risk. Although osteoporosis is most frequent with increasing years, especially in postmenopausal women, there are a number of other recognizable causes that reduce the density of the younger skeleton (Table 7). These include anorexia nervosa, and excessive exercise in females associated with premenopausal oestrogen lack (Johnston and Longcope 1990; Prior *et al*. 1990). The latter provides a striking example of the opposing effects of mechanical stress and hormone deficiency on the skeleton. A topical cause of osteoporosis is cardiac transplantation (Sambrook *et al*. 1994).

Common
Increasing age

Satellite travel
Unknown
Idiopathic osteoporosis
Juvenile
Pregnancy associated
In young people

Table 7 Causes of osteoporosis

Immobilization causes both osteoblastic failure and osteoclast excess. Cushing's syndrome and excessive therapeutic corticosteroids suppress osteoblastic activity.

The amount of bone in the adult depends on the peak bone mass and the subsequent rate of loss. As already stated, peak bone mass depends on genetic, nutritional, mechanical, and endocrine interactions. The rate of bone loss varies considerably between individuals and may also be genetically determined. It is also accelerated by certain so-called risk factors, such as immobility, excessive thinness, alcoholism, cigarette smoking, low calcium intake, prolonged periods of amenorrhoea, and early menopause. There is a relationship between reduced bone mass and fractures, but it is not a close one, as fractures depend as much on injury, including falls (especially in later life), as on loss of bone. How much excessive cytokine activity, especially of interleukin 6, contributes to postmenopausal bone loss is controversial (Manolagas and Jilka 1995). No differences have been found in circulating levels of this cytokine between normal and osteoporotic women (Khosla *et al*. 1994) but this is not unexpected since the action of interleukin 6 is likely to be very localized.

Osteomalacia and rickets

These conditions are distinguishable only by age. There is defective mineralization of the organic bone matrix due to vitamin D deficiency or a disturbance of its metabolism. The causes (Table 8) are best understood against the known metabolic pathways of vitamin D (Fig. 15). They include vitamin D deficiency, often in immigrants to the United Kingdom from the India subcontinent (Smith 1990b) where an increased utilization of vitamin D (related to chapatti consumption) combines with lack of sunlight and lack of vitamin D in the diet, malabsorption (particularly coeliac disease), and renal disease. The causes of rickets from renal glomerular failure (renal glomerular osteodystrophy) are quite different from those due to renal tubular disease (Fig. 16), and may be modified by aluminium intoxication in those on dialysis. The most frequent cause of renal tubular rickets is inherited hypophosphataemia, but there are many others (Thakker and O'Riordan 1988; Thakker 1992; Rowe 1994). Investigation of one of the rarer forms of rickets, so-called vitamin D-dependent rickets, has shown that it may be due to defective 1a-hydroxylation of 25(OH)D_3 (type I) or to end-organ resistance to 1,25-dihydroxycholecalciferol (type II). The molecular basis of the latter has been shown to be a number of mutations at either end of the 1,25-receptor (Fig. 17) (Editorial 1989; Ritchie *et al*. 1989; Thakker 1992; Hewison and O'Riordan 1994; Rut *et al*. 1994).

Parathyroid bone disease

Most patients with primary hyperparathyroidism do not have clinically manifest bone disease (osteitis fibrosa cystica), although in the majority the histological appearances are abnormal and improve after removal of the parathyroid tumour (Christiansen *et al*. 1990). Osteitis fibrosa cystica is characterized by an excess of fibrous tissue and osteoclasts within lesions that may become cystic (brown tumours). The most common cause of primary hyperparathyroidism is a parathyroid adenoma, and it is now recognized that a number of these are monoclonal in origin (Friedman *et al*. 1990) with a chromosomal situation similar to multiple endocrine neoplasia type II (Thakker *et al*. 1989). Parathyroid overactivity also occurs in multiple endocrine neoplasia type II associated with mutations in the RET proto-oncogene (Gardner *et al*. 1994).

Parathyroid overactivity can also result from prolonged hypocalcaemia (secondary hyperparathyroidism). Rarely, the parathyroids may become autonomous with hypercalcaemia (tertiary hyperparathyroidism). Finally familial hypocalciuric hypercalcaemia and familial hypocalcaemia can result from mutations in the parathyroid calcium-sensing receptor (Brown *et al*. 1993; Pollock *et al*. 1994). Parathyroid insufficiency can result from inadvertent surgical removal of the parathyroids or may be idiopathic. The condition of pseudohypoparathyroidism is characterized by the presence of short third and fourth metacarpals, ectopic calcification in the skin and in the basal ganglia, mental simplicity, and cataracts (Breslau 1989). It has now been shown that in a number of such patients there are mutations in the genes controlling the G-protein system that links parathyroid hormone to its effector tissue (Spiegel 1990; Gordeladze and Johansen 1994; Schwindinger *et al*. 1994; Wilson *et al*. 1994; Lefkowitz 1995). This provides an explanation of the resistance to parathyroid hormone in this condition (Fig. 18). Interestingly there are similar G-protein defects in polyostotic fibrous dysplasia (Levine 1991).

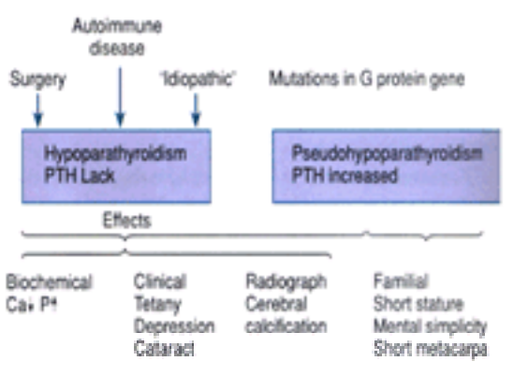

Fig. 18 The causes and effects of parathyroid hormone insufficiency or resistance. Mutations in the Ca $^{2+}$-sensing receptor may also mimic parathyroid resistance.

Paget's disease

In this disorder the main skeletal abnormality appears to be overactivity of large multinucleated osteoclasts. At first this leads to excessive bone resorption but, because of the linkage between osteoclastic and osteoblastic activity, excessive new bone formation follows. Normally this linkage is sufficiently close to prevent hypercalcaemia, however rapid the bone turnover, but this may occur if patients with Paget's disease are immobilized, in which case the osteoblasts become less active whilst resorption continues. It is currently considered that Paget's disease may be related to a viral infection of the osteoclasts (Gordon *et al*. 1994), possibly with the respiratory syncytial virus (Kahn 1990), but current attempts to identify the viral nucleic acid continues to give conflicting results (Smith 1992).

Disorders of bone matrix

Classically these disorders have not been regarded as metabolic disorders of bone but it is now clear that mutations, especially in the collagen genes, can produce a wide variety of skeletal disorders (Table 9 and Chapter 2.2).

Collagen I	Osteogenesis imperfecta
Collagen II	Achondrogenesis type II
	Hypochondrogenesis
	Spondyloepiphyseal dysplasia congenita and others
	Ocular Stickler's syndrome
Collagen IX	Multiple epiphyseal dysplasia
	Diastrophic dwarfism
Collagen X	Metaphyseal dysplasia (type Schmid)
FGF receptor 2	Crouzon's syndrome
FGF receptor 3	Achondroplasia
PTH/PTHrP receptor	Metaphyseal dysplasia (type Jansen)

For references see text and Spranger *et al.* (1994).
FGF, fibroblast growth factor; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related peptide.

Table 9 Gene mutations in the chrondrodysplasias

Osteogenesis imperfecta

Four clinical types are recognized, although many patients with this disorder cannot be accurately classified (Smith 1986; Cole 1988; Byers 1993). In the first, type I, the disorder is dominantly inherited and often appears to be due to a non-functional allele for type I collagen. The main result is that osteoblasts (and fibroblasts) make half as much type I collagen as they ought to, causing an inherited form of osteoporosis and affecting other tissues containing type I collagen (teeth, sclera, heart valves). Type II osteogenesis imperfecta is the lethal form of the disease, this is most often due to a single-base mutation in one of the type I collagen genes leading to an amino-acid substitution for one of the glycine residues normally present in every third position in the amino-acid chain. The importance of glycine is that it has no side-chain and can therefore fit into the interior of the helix (Sykes 1990). Replacement of such a 'core' glycine by an amino acid with a side-chain disturbs helix formation. The effect depends on the size of the side-chain and on the position of the replacement amino acid relative to the carboxyl-terminal end of the collagen molecule, where helix formation begins. The most lethal effects appear to be produced by large substitutions near to the carboxyl-terminal end of the molecule (Fig. 19).

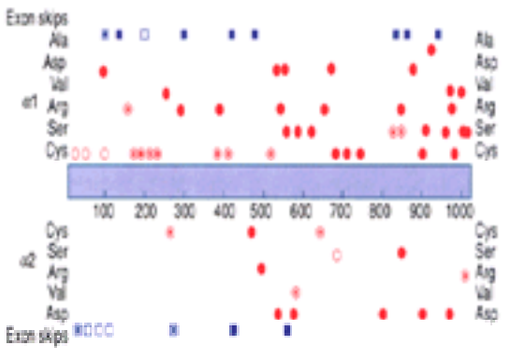

Fig. 19 Mutations in the collagen genes known to cause osteogenesis imperfecta (from Sykes (1990) with permission). Axial glycine (circles) and exon skip (squares) mutations in the genes for the a_1- (upper) and a_2- (lower) subunits of type I collagen. The scale indicates the osteogenesis imperfecta phenotype from lethal (solid) through severe (dot) to mild (open). Note that the collagen triple helix winds up from the carboxyl (right) to the amino (left) terminal and that the least severe phenotypes are often associated with mutations near the amino terminus. Ala, Asp, etc., refer to the amino acid replacing the axial glycine.

Type III osteogenesis imperfecta is a progressively disabling disease. Infants survive but the skeleton becomes more and more deformed. The chemistry of this condition is not so well known as in other forms but again it is probably frequently related to a disturbance of helix formation by glycine substitutions. Type IV is rare and is a dominantly inherited disease. Extensive linkage studies have demonstrated that dominantly inherited (type I and IV) osteogenesis imperfecta is linked to mutations in either the a_1- or a_2-chain of type I collagen (Sykes *et al*. 1990). A detailed study on the variable expression of the mutant osteogenesis imperfecta gene demonstrates the importance of somatic mosaicism (Wallis *et al*. 1990). The relationship between genotype and phenotype is still complex (Smith 1994).

Other forms of inherited disorders of connective tissue

These include Marfan's syndrome, Ehlers–Danlos syndrome, and the skeletal dysplasias. It is clear that in most cases Marfan's syndrome is due to mutations in the fibrillin genes (Pyeritz 1990; Francke and Furthmayr 1994; Pereira *et al*. 1994; Pyeritz 1993) on chromosome 15, although linkage to chromosome 3 has also been described (Collod *et al*. 1994). Since fibrillin is the major component of the suspensory ligament of the lens and of the elastin-associated microfibrillar system, mutations in its genes provide a neat explanation for the combination of lens dislocation and aortic dissection found in this disorder (Kielty *et al*. 1995).

There are many different types of the Ehlers–Danlos syndrome. The cause of the most common forms, types 1, 2, and 3, has yet to be elucidated. In type 4 the major complication is rupture of the middle-sized blood vessels resulting from a variety of mutations in the gene for type III collagen. In type 6 Ehlers–Danlos syndrome, whose main features are ocular fragility and scoliosis, there is evidence of hydroxylysine deficiency. Another type of Ehlers–Danlos syndrome (type VII, with excessive joint mobility) results from defective removal of the procollagen extensions from the precursor molecule due to mutations at the peptidase site.

Skeletal dysplasias

These conditions (Wynne-Davies *et al*. 1985) which include achondroplasia, spondyloepiphyseal dysplasia, and achondrogenesis, were long thought of as orthopaedic curiosities. However, numerous mutations have now been described. To begin with, exon deletions were described in the type II collagen gene in patients with spondyloepiphyseal dysplasia (Lee *et al*. 1989), and single-base mutations in the same gene in infants with achondrogenesis type II (Vissing *et al*. 1989). There was also evidence of genetic linkage of spondyloepiphyseal dysplasia congenita to type II collagen (Anderson *et al*. 1990). It is possible that mutations in type II collagen, which is the major collagen of cartilage, will be increasingly described as a cause of those disorders characterized by abnormal cartilage formation, although a number have been excluded (Spranger *et al*. 1994; Winterpacht *et al*. 1994). Indeed recent work (Table 9) has linked multiple epiphyseal dysplasia to mutations in type IX collagen (a minor fibre-associated collagen) (Briggs *et al*. 1994) and abnormal type IX collagen has been described in diastrophic dysplasia (Diab *et al*. 1994). Mutations in type X collagen have also been described in the Schmid type of metaphyseal dysplasia (type X collagen is specifically produced by hypertrophic chondrocytes) (McIntosh *et al*. 1994; Wallis *et al*. 1994). Unexpectedly, skeletal development is normal in type X collagen-null mice (Rosati *et al*. 1994). Most interesting of all mutations are those in the type 3 fibroblast growth-factor receptor (FGFR3) which have been identified as the cause of achondroplasia (Editorial 1994; Le Merrer *et al*. 1994; Rousseau *et al*. 1994; Shiang *et al*. 1994; Velinov *et al*. 1994). The reason why such mutations should lead to specific changes in the skeleton is not yet understood. Finally mutations in a similar receptor, FGFR2, appear to cause Crouzon's syndrome (Reardon *et al*. 1994). Another (activating) mutation, this time in the PTH/PTHrP receptor, has recently been identified as a cause of the Jansen type of metaphyseal dysplasia (Schipani *et al*. 1995).

Enzyme disorders

Some disorders that affect the skeleton result from abnormal enzyme function. These include hypophosphatasia, homocystinuria, and alkaptonuria.

Hypophosphatasia

In hypophosphatasia there are variable abnormalities in the skeleton associated with differing phenotypes. A common biochemical feature is an abnormally low plasma alkaline phosphatase associated with an excess of phosphoethanolamine in the urine. The disorder may be lethal, or it may cause hypercalcaemia in infants and early fusion of the cranial sutures (Whyte 1990). By contrast the disease can be mild in adults, although pathological fractures of the long bones may occur.

Various mutation in the gene for the tissue non-specific alkaline phosphatase have been described in some patients (Weiss *et al*. 1988; Henthorn and Whyte 1992; Orimo *et al*. 1994) but not in others. Family studies have now linked the defect to chromosome 1 (Greenberg *et al*. 1990).

Homocystinuria

This condition, which mimics Marfan's syndrome, is due to a defect in cystathionine synthase, a pyridoxine-dependent enzyme. Accumulation of homocysteine behind the metabolic block leads to homocystinuria. Skeletal features of this disease are very similar to those of Marfan's syndrome with arachnodactyly and scoliosis. There is also dislocation of the lenses.

Alkaptonuria

In this disorder there is a deficiency of homogentisic acid oxidase; the accumulation of homogentisic acid is associated with the features of ochronosis, with pigmentation of articular cartilage, early osteoarthritis, and calcification of the intervertebral discs.

Disorders of cell biology

In two rare conditions, osteopetrosis and myositis ossificans progressiva, there is evidence that the disorder is primarily due to abnormalities in the bone cells.

Osteopetrosis

There are a number of inherited disorders in which there is an excessive amount of bone within the skeleton. The most well recognized is marble bone disease (Albers–Schönberg disease). This condition may be severe and recessively inherited, occurring in infancy, or it may be mild with dominant inheritance. There are intermediate forms and a rare form due to deficiency of carbonic anhydrase II (Sly *et al*. 1983; Fathallah *et al*. 1994). In animals and in man, varying osteoclast defects are described and there is evidence that the infantile form may be cured by successful transplantation of normal osteoclasts (Fischer *et al*. 1986). Interestingly, osteopetrosis in the micro-ophthalmic *op*/*op* mouse is associated with a defect in the gene for macrophage colony-stimulating factor (Yoshida *et al*. 1990) and mice lacking the c-*fos* oncogene develop osteopetrosis, emphasizing the importance of this system in bone physiology (Wang *et al*. 1992). Jackson *et al*. (1994) suggest that osteoblasts may also be defective in mammalian osteopetrosis.

Fibrodysplasia (myositis) ossificans progressiva

In this disorder progressive ossification of the major striated muscles is associated with characteristic skeletal abnormalities from birth (Connor and Evans 1984; Cohen *et al*. 1993). The cause is unknown but it seems that the fibroblasts or mesenchymal cells within muscle behave as if they are osteoblasts to produce cartilage and true bone within muscles. This may be due to an inherited cellular abnormality; alternatively it could represent, for instance, an excess of one of the morphogenetic proteins (Smith and Triffitt 1986). The combination of skeletal abnormalities and ectopic ossification, which often occurs in a specific order, would seem to implicate proteins involved in skeletal patterning as well as bone morphogenesis (Storm *et al*. 1994).

The skeleton in malignant disease

The skeleton is often affected in malignant disease, which is the most frequent cause of hypercalcaemia in hospital patients. This hypercalcaemia results from excessive bone resorption and increased renal tubular reabsorption of calcium. The relative importance of these depends on the type and distribution of the cancer. Bone resorption in cancer is due to an increase in osteoclastic activity (either as a direct response to hormonal factors or indirectly via other cells), and to direct resorption of bone by the malignant cells themselves. The complexity of the mechanisms involved illustrates the multiple effects of cytokines and hormones on the skeleton (Mundy 1989; Orloff *et al*. 1989; Gutierrez *et al*. 1990; Martin 1990).

Neoplastic hypercalcaemia may occur in three clinical settings—haematological malignancy, solid tumour with metastases, and solid tumours without. In the first of these the hypercalcaemia is usually due to the release of osteoclast-activating factors by the malignant cells (occasionally, as in lymphoma, the plasma calcium is increased because of excessive formation of 1,25-dihydroxycholecalciferol by the lymphomatous tissue; Cox and Haddad 1994); in the case of myeloma this activating factor is a lymphokine called lymphotoxin. Osteoclast-activating factors have been divided into those from T cells, B cells, and monocytes.

In solid tumours with lytic metastases, predominantly from the breast, lung and kidney, a major contribution to hypercalcaemia is direct destruction of bone. However, where there are few or no detectable metastases, other mechanisms must be involved. Chief amongst these is the production of parathyroid hormone-related peptide by the tumour itself (Martin 1990). This hormone may also be relevant in metastatic and haematological malignancies. Parathyroid hormone-related peptide has been detected mainly in lung tumours, but also occurs in those from the breast (the mRNA for parathyroid hormone-related peptide is present in lactating mammary tissue) (Heath *et al*. 1990). The main biochemical effect of parathyroid hormone-related peptide is to produce changes similar to those of parathyroid hormone. These are hypercalcaemia and hypophosphataemia, which has led in the past to terms like 'pseudohyperparathyroidism' and 'ectopic parathyroid hormone syndrome'. It is now clear that the concentrations of parathyroid hormone are low, although nephrogenous cAMP is increased. Increases in circulating parathyroid hormone-like protein have been recorded in such patients (Budayr *et al*. 1989). Finally, although the increase in parathyroid hormone-related peptide provides a neat explanation for hypercalcaemia in the absence of metastases, it may be only part of the story because the peptide may act in concert with other factors locally on bone. These have already been dealt with and include transforming growth factors-a and -b, prostaglandins, and interleukins (Table 10).

Factor	Actions
Parathyroid hormone-related peptide (PTHrP)	See Table 6
Transforming growth factor-α (TGF-α)	Stimulates osteoclastic bone resorption
	Produced by some tumours as PTHrP
Tumour necrosis factor (TNF)	Powerful bone-resorbing cytokine; synthesized by normal activated macrophages
	Stimulates formation and activity of osteoclasts
	Probably produced by host cells under action of tumour-produced granulocyte-macrophage colony-stimulating factor
Interleukin 1	Effect similar to TNF; associated with solid tumours
	Acts synergistically on bone resorption with TNF, parathyroid hormone, PTHrP, and TGF-α
Prostaglandins	Unlikely as a mediator for the humoral hypercalcaemia of

Table 10 Factors involved in the humoral hypercalcaemia of malignancy

Conclusions

The skeleton fulfils many functions whose requirements are often in opposition. Bone is a very complex structure, which is continually being dismantled and replaced. This complexity leads to its fascination for investigators and provides many opportunities for a wide variety of bone diseases. Recent examples of rare diseases are provided by the discovery of mutations in the G-protein and Ca^{2+}-sensing receptor systems, in the minor collagens, and in the fibroblast growth factor receptors. Much more work is required before we fully understand the causes of the common polygenic disorders such as osteoporosis.

2.5 The physiology of the joint and its disturbance in inflammation

Paul Mapp, Cliff. R. Stevens and David R. Blake

No part of the physiology of bones abounds more in hypotheses and less in discoveries than the history of the synovial system. Many discussions and few facts; a long series of assumed principles; a brief assemblage of proofs; this is the analysis of all the hitherto known works on the subject. The notions already received throw but little light on those yet to be acquired.

Marie-Francois-Xavier Bichat (1771–1802).

This chapter covers selected aspects of the physiology of the joint in health and in disease. The normal synovium and synovial fluid will be described. Other areas of the joint such as the cartilage have been covered in previous chapters. Further, we will characterize the structural changes to the synovium and chemical changes in the fluid that occur in chronic inflammation and address the physiological implications of these changes. Finally we will evaluate possible mechanisms by which these changes may lead to joint damage.

The synovium

The normal human body contains 187 synovial joints. In this article the term synovium will be used to describe the connective tissue bounded by the fibrous joint capsule on one side and by the joint space on the other.

One of the most striking histological features of the normal synovium is a lack of cellularity, apart from a discontinuous layer of cells, the synovial intimal cells, on the internal surfaces of the joint. Although variously described as synoviocytes, lining cells, or surface cells, here they will be referred to as intimal cells.

Intimal cells have been described by many authors but a consensus has yet to be reached as to their cellular phenotype, relative proportions, and functions. They form a thin discontinuous layer lining the joint space and separating it from the fibro-fatty tissue and fibrous capsule that surrounds the whole joint. The intimal cells line all surfaces of the joint other than the cartilage and menisci. Synovial intimal cells in common with other connective tissues are derived in the embryo from the mesenchyme either directly or indirectly via the blastema (O'Rhailly and Gardner 1978). What are apparently intimal cells may also be generated under certain other circumstances in connective tissue, as in the case of a pseudoarthrosis, and as regenerated synovium covering the connective tissue of the joint capsule following synovectomy. Similar cells can be created in animal models when air is injected into loose connective tissue. The whole synovium is bathed in synovial fluid since there is no true basement membrane beneath the intimal cells. There is neither a continuous layer of cells nor any basement underneath them and, therefore, the term synovial membrane is strictly speaking a misnomer.

Histology and ultrastructure of the normal synovium

Cellular morphology

By routine light microscopy the intimal cell layer appears as a homogeneous population of varying thickness. In some areas the cells may lie three or four deep, whilst in others places there are gaps where no intimal cells are seen and the underlying stroma is apparently in direct contact with the joint fluid. The underlying tissue, however, may have markedly different appearances and this has led some authors to classify synovia on this basis. Divisions into areolar, fibrous, and fatty synovia have been applied to the synovium, although other researchers have recognized intermediate types, such as fibroareolar synovium. In general, the normal synovium appears as a quiescent connective tissue containing some macrophages and fibroblasts with a thin layer of cells opposing the joint space. The particular nature of the underlying connective tissue is unlikely to be of significance.

Ultrastructural examination of the synovium has yielded much data but little agreement with regard to the predominant intimal cell type or to their function. Intimal cells were first described by Barland *et al*. (1962) and divided into types A and B on a purely morphological basis. Other authors have made similar distinctions but have included an intermediate cell type, postulating that this is a precursor of the two intimal cell types. The type A cell is characterized morphologically by a prominent Golgi apparatus, numerous vesicles and vacuoles, and many filopodia and mitochondria. This description is typical of a tissue macrophage. Type B cells, in contrast, contain large amounts of endoplasmic reticulum and a few large vacuoles, correlating well with ultrastructural descriptions of fibroblasts at other sites. The weight of scientific evidence suggests that the type A cell is a bone marrow-derived macrophage and the type B cell is a mesenchymal fibroblast. The reader is particularly directed to the work of Edwards and Willoughby (1982) which demonstrates the arrival in the synovium of bone marrow-derived macrophages using intracellular granules as a genetic marker.

Vascular system

Capillaries occur within the synovium and also the underlying tissues (fat, skeletal muscle, etc.). The synovium is considerably more vascular than the structures supporting the joint, such as the capsule, ligaments, and tendons.

The first description of the vasculature within joints was by Hunter in 1743, who described the 'circulus articuli vasculosus'. He stated: 'All around the neck of the bone there is a greater number of arteries and veins which ramify into smaller branches and communicate with one another by frequent anastomoses like those of the mesentery. This might be called the circulus articuli vasculosus, the vascular border of the joint.'

At the margins of articular cartilage the synovium forms villi and folds, into which the plexus sends arcades of capillaries. The circulus articuli vasculosus anastomoses with deeper perichondrial vessels that communicate with the bone marrow vasculature. There are anastomosing plexuses in the deeper layers of areolar lining tissue, with decreasing vascular calibre towards the surface. A plexus of arterioles and venules also forms a quadrilateral array close to the surface of the synovium. This plexus yields capillary loops which pass through or immediately below the layer of synovial intimal cells. The surface of the tissue carries a much denser capillary bed than the deeper tissue layers. The dimensions of the mesh of the arteriolar/venous plexus are between 0.9 and 1.5 mm.

Arteriovenous anastomoses have been demonstrated to occur commonly in the joints of humans and animals. The pattern of the arteriovenous anastomoses suggests an important role in the regulation of the articular and, perhaps, the epiphysial blood flow, possibly by a shunt mechanism redistributing the blood flow between certain vascular beds. The arteriovenous anastomoses between muscle, capsule, and bone help to explain the production of endosseous blood stasis during rest or muscular

inactivity and suggests that the anastomoses are related to regional haemodynamic regulation.

The vascularity of normal synovium appears to depend considerably on the type of underlying tissue. Capillary density is greatest where the substructure is areolar or adipose tissue and is virtually zero over fibrous areas. Away from the margins of articular cartilage the synovium is flatter, and the synovial capillaries form a flat, loose, polyhedral network supplied by several articular arteries. The capillaries are sinuous, which may reduce wall stress during motion, and are occasionally so coiled as to resemble glomerular capillaries.

Morphometry of normal human knee synovia has provided data on the spatial distribution of these vessels. The density of the capillaries is 240/mm ^{2} of synovial lining and their modal depth is 35 μm from the intimal cell/joint space boundary. The mean intercapillary distance is 17 μm (Stevens *et al*. 1991); similar data have been obtained in rabbit synovia (Knight and Levick 1983). From these data the functionally optimal range of vascular parameters for the synovium can be extrapolated. The bulk of the constituents of the synovial fluid are derived from this blood supply.

Nerve supply

Joints are supplied by both primary and accessory nerves. Primary nerves are branches of peripheral nerves passing near to the joint, whilst accessory nerves are branches of intramuscular nerves crossing the joint capsule. Some joints, such as the knee and ankle, also receive a nerve supply from cutaneous nerves in the overlying skin. The nerves to any one particular joint always arise from more than one level in the spinal cord. About 50 per cent of the axons that comprise articular nerves are less than 5 μm in diameter, those that are less than 2 μm in diameter are unmyelinated. These fibres carry nociceptive information with a slow conduction velocity. The nerve supply to the synovium was, until relatively recently, thought to be sparse. However, it is now known that the synovium contains a good supply of unmyelinated nerve fibres (Mapp *et al*. 1990a) These are of two types: the postganglionic sympathetic adrenergic fibres located around the larger blood vessels are responsible for the control of articular blood flow; the unmyelinated C fibres, in contrast, are responsible for pain transmission. The latter group of fibres are not normally active and are thought only to fire during tissue damage, either mechanical or chemical.

The unmyelinated fibres arise from cell bodies which are located in the dorsal root ganglion, close to the spinal cord. In addition to its peripheral projection the cell body also has a central projection to the spinal cord. The fine diameter nerve fibres terminate in the superficial layers of the spinal cord, laminae I and II of the dorsal horn, from where they synapse with ascending fibres in the spinal cord. The cell bodies are the site of manufacture of neuropeptides which are transported both centrally and peripherally along the nerve axons. The functions of these peptides are not clearly understood in the central nervous system but some, for instance substance P, are thought to be involved in pain transmission. Peripherally, where the effects of these peptides are much easier to investigate, they are clearly involved in the inflammatory process, both its induction and modulation. They have the capacity individually or in synergism with other neuropeptides or mediators to modulate, mediate, or prime for an inflammatory response. In addition, they have an effect on vascular tone.

Having examined the structure of the synovium, we turn to the fluid that is derived from it and bathes the whole joint cavity.

Synovial fluid

The study of normal synovial fluid is difficult since the aspiratable volume of fluid is very small, in the range 0 to 4 ml. The fluid is regarded as an ultrafiltrate of the plasma, but in addition components secreted by the synovial cells are also present. The most important of these is hyaluronate. Hyaluronate is a linear repeating disaccharide, b-D-glucuronyl-b-D-*N*-acetyl-glucosamine, of high molecular mass (upwards of 10 000 kDa). Hyaluronate forms the central axis of the proteoglycan aggregates necessary for the functional integrity of articular cartilage and other extracellular matrices. It comprises the major macromolecular species of the synovial fluid and is responsible for the unique visco-elastic properties of the synovial fluid. More recently another component of human synovial fluid has been identified, lubricin, which as its name implies is thought to be involved in the lubrication of the joint (Swann *et al*. 1985). Lubricin is a protein with oligosaccharide side-chains and has a molecular mass of 166 kDa. *In vitro* its lubricating activity is concentration dependent, and at concentrations thought to be present in the joint it acts as a highly efficient lubricant. A similar molecule has been isolated from bovine synovial fluid. As well as acting as a lubricant, synovial fluid is also the source of nutrition for the articular cartilage.

The mechanism of formation of the synovial fluid is thought to be similar to that of interstitial fluid in any other body cavity. The flow across the capillary wall is driven by the difference between the pressure in the capillary and the joint fluid. This is opposed by both the osmotic and colloid pressure gradients, the Starling hypothesis (Starling 1896). Small physiological molecules of molecular mass less than 10 kDa are in full equilibrium with the plasma. A graphic plot of the diffusion coefficient of a molecule (which takes into account mass and size) against the synovial permeability yields a broadly linear curve. Larger molecules such as proteins have only restricted access to the normal synovial fluid. The total protein content of the synovial fluid is 13 mg/l (compared with the serum concentration of 65 to 80 mg/l); most of which is albumin. Proteins of higher molecular weight, such as fibrinogen, are excluded. Whilst proteins arrive in the joint at rates inversely proportional to their molecular size, their rates of egress are similar. This is a reflection of the fact that protein is cleared from the synovial fluid by bulk flow through the lymphatic system, which is not dependent on the size of the molecule.

Intra-articular pressure

The overall pressure within the normal joint is subatmospheric, pressures of –30 to –60 mmH_2O are typically recorded at rest and during movement. This is true both in relaxation and during weight bearing. The 'joint space' is therefore only an apparent space, since atmospheric pressure pressing on the soft tissues around the joint will cause the synovium to be in close apposition to the articular cartilage surface. This has the effect of optimizing the transfer of nutrients from the superficial blood vessels in the synovium to the avascular cartilage.

The intra-articular pressure is to be distinguished from the pressure that arises between the two cartilage surfaces when under load.

Inflammatory disease

Histology of the inflamed synovium

Examination of the synovium in chronic inflammation reveals a wide variety of morphological changes, many of which may alter the physiology of the joint. The intimal cell layer becomes thickened, both by an increase in cell number and an increase in cell size; hyperplasia and hypertrophy, respectively. The intimal cell layer is six to eight cells deep. Underlying the intimal layer, changes typical of chronic inflammation are seen. There is a large increase in the number of cells, comprising mainly macrophages and lymphocytes. The lymphocytes accumulate perivascularly around the postcapillary venules and may organize into foci resembling lymphoid follicles; plasma cells are seen at the margins of the follicles. Large numbers of macrophages are also seen scattered widely throughout the tissue, these are thought to be migrating to the intimal cell layer replacing the turnover in type A cells.

Vasculature

The dominating vascular feature of chronic inflammatory disease is a vasculitis localized to the venules and capillaries, although it has been demonstrated that arterioles also become involved to a lesser degree. Using vital microscopy to study the rheumatoid synovium it has been found that venular dilatation of varying calibre, resulting in uneven outline and slow, almost stagnated, corpuscular flow, is also a feature. In severe cases, focal and segmental venular-capillary necrosis and thrombosis are found in association with connective tissue necrosis. However, in less severe disease, vascular derangement is largely reversible and manifested by excessive venular-capillary dilatation, leakage, and occasionally by focal, partial, or temporary microvasculature obstruction.

Of particular relevance to the physiology of the joint are the changes seen in the synovial vasculature. Assuming that the data on capillary density and depth determined in normal joints represent the optimal situation, there is a significant reduction in vascularity in the functionally important superficial region of the synovium. The capillary density in rheumatoid arthitis is reduced to about one-third of the normal value, from 240/mm ^{2} to 80/mm^{2}; mean intercapillary distance is increased from 17 μm to 37 μm, reflecting not only an increase in spatial distribution of the vasculature but also a thickened synovial lining. The average capillary distance from the joint cavity is increased from 32.5 μm to 93.3 μm (Stevens *et al*. 1991). This apparent burial of the vasculature is due to the thickening of the synovial lining layer which would appear to proceed at a greater pace than angiogenesis (Fig. 1). In addition to these changes multilamination of the basement membranes (Matsubara *et al*. 1983) surrounding the blood vessel is also seen, due to stimulation of endothelial cells (by unknown mediators) to produce excessive cellular components of basement membrane; this represents a further barrier to nutrient exchange. This is compounded by the deposition of fibrin which is often seen

on the surface of the inflamed synovium.

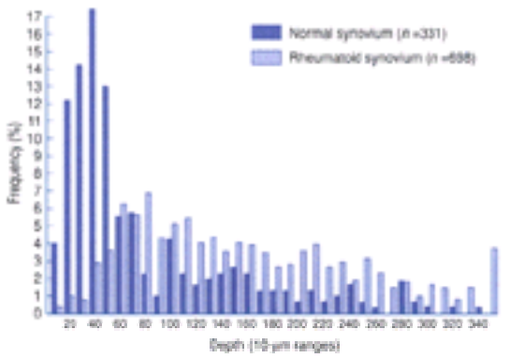

Fig. 1 Histogram showing the distribution of blood vessels in normal and rheumatoid synovia. The figures referred to relate to the distance of the vessels from the intimal cell surface.

The height of endothelium in small vessels is increased in chronic synovitis; an increase in the number of vessels with histochemical features of so-called high endothelial venules is seen in tissue from patients with rheumatoid arthritis. These vessels are thought to be the main site of lymphocyte traffic in lymph fluid and could represent a facilitated pathway for lymphocyte entry in pathological circumstances. One of the most frequent histological findings affecting small vessels in chronic inflammation is that of perivascular cuffing by lymphocytes.

Nerve supply

In common with the vasculature, the nerve supply which normally extends to the synovial/joint space interface, is buried deeper within the rheumatoid synovium. It is probable that this is due to proliferation of the synovium, but it may be due to release of factors which are inhibitory to nerve proliferation or the inactivation of peptides which promote neuronal outgrowth, such as protease nexin 1 (Meier *et al*. 1990). The blood vessels that are in the superficial layers of the synovium, up to 150 μm from the joint space, appear not to be innervated by postganglionic sympathetic nerve fibres. This would imply that there is poor control over the superficial vascular supply. Free nerve fibres, assumed to be sensory in nature, are also absent from this area.

However, nerves fibres, both free and perivascular, are present in the deeper inflamed tissues (Fig. 2). These fibres appear to contain reduced amounts of neuropeptide, as determined by immunocytochemistry. The probable explanation for this is that the stored peptide is being released into the joint cavity. The justification for this view, and its consequences, are discussed in a later section of this chapter.

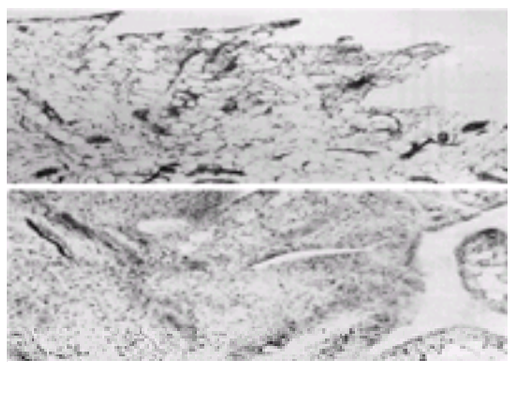

Fig. 2 Photomicrographs of normal (a) and rheumatoid (b) synovia. The specimens have been stained by immunocytochemistry to show all nerve fibres. Note the rich innervation of the normal specimen compared with the paucity of nerve fibres in the disease state.

In summary the inflamed joint shows the following characteristics:

1. infiltration with numerous inflammatory cells;
2. the intimal layer becomes hypertrophic and hyperplastic;
3. the vasculature is buried deeper within the synovium rendering the tissue relatively hypoxic;
4. the nervous supply is also buried deeper in the synovium, perhaps releasing cells from normal neuronal regulation;
5. the synovial fluid markedly increases in volume and changes in composition.

We now discuss how some of these basic changes induced by inflammation in turn influence the inflammatory process.

Ischaemia and hypoxia

The presence of a large cellular infiltrate in the inflamed synovium would lead one to think that there is an increased utilization of oxygen, often referred to as increased oxygen demand. This increased demand is not readily quantifiable. A working definition of ischaemia is that the steady-state rate of energy production, i.e. ATP synthesis, cannot be supported by the existing blood flow. Since the necessary levels of energy production cannot be maintained this stimulates anaerobic metabolism which in turn gives rise to lactic acid production and a fall in venous oxygen tension.

In order to determine whether the joint is ischaemic, attempts have been made to measure the blood flow in the synovium. Some studies, using the xenon-153 clearance technique have reported an increased perfusion in chronically inflamed synovia (Dick *et al*. 1970). The validity of such studies is in question because they fail to take account of the possibility of arteriovenous shunting, which would give rise to the impression of perfusion but would result in ischaemic, non-perfused synovial pockets. Other studies using iodine-123 or tritiated water appear to show that perfusion in chronic synovitis is markedly reduced (Simkin and Pizzorno 1979.) The stage of the disease at which the perfusion is measured may be the all important factor here. In the early stages of rheumatoid arthritis, the temperature of the joint is raised relative to normal whereas in late-stage disease the joint is cooler than normal. The implication of this is that in the early stages of the disease blood flow increases but in the later stages it is decreased, the most affected joints being the ones with the least blood flow. Microvessel plugging by inflammatory cells also serves to reroute blood from the peripheral capillary beds. This is associated to a varying degree with microthrombi and extravascular aggregates of platelets.

Synovial fluid oxygen tension is more easily quantifiable than synovial ischaemia. The oxygen tension (PO_2) within the inflamed joint cavity (Lund-Olsen 1970) has been shown to be lower (27 mmHg) than in traumatic effusions (63 mmHg) or osteoarthritic knee fluids (43 mmHg). These results are confirmed by independent studies. In addition to a low oxygen tension, many studies have shown alterations in rheumatoid synovial fluid physiology which would be anticipated in a hypoxic state: namely, a raised carbon dioxide tension (PCO_2 up to 150 mmHg), raised lactate (up to 10 mmol), lowered glucose, and acidosis (pH as low as 6.6). The most comprehensive study summarizing these changes is by Falchuk *et al*. (1970), who showed that joints with the lowest oxygen tension (as low as 9 mmHg) also exhibited large increases in carbon dioxide tension and lactate; the same joints showed severe microvascular obliteration in the synovial membrane.

In summary the inflamed joints are hypoxic because of increased metabolic demand of the inflamed synovium, and the inadequate oxygen delivery due to poor perfusion of the inflamed joint. It is important to note that physiological measurements in synovial fluid can vary with the patient's mobility. This is evident from a recent

study which showed that movement of an inflamed joint can induce significant further decrease in the oxygen tension from a resting baseline (Tsoulfa *et al*. 1989). This observation has particular relevance to the concept of joint 'ischaemia-reperfusion' injury (Blake *et al*. 1989).

Synovial metabolism

The oxygen consumption of the rheumatoid synovial membrane per gram of excised tissue is approximately 20 times that of normal (Page-Thomas and Dingle 1955; Dingle and Page-Thomas 1956). This work also demonstrated that the activity of the glycolytic (Embden–Meyerhof) pathway for ATP production was markedly increased in rheumatoid compared with normal synovium. The raised metabolic rate of the rheumatoid synovium concomitantly raises the demand for ATP. The intracellular production of this molecule can be achieved by either the aerobic or anaerobic oxidation of glucose via the tricarboxylic acid (**TCA**) cycle or the glycolytic pathway respectively. The oxygen-dependent TCA cycle is a much more efficient producer of ATP than the anaerobic system and so is generally favoured in normoxic tissues. The fact that the rheumatoid synovium favours the anaerobic glycolytic pathway indicates its hypoxic nature. In support of this, synovial intimal cells in rheumatoid arthritis contain significantly more glyceraldehyde-3-phosphate and lactate dehydrogenase activity than those of normal tissue. These are major enzymes of the glycolytic pathway. Their increase is more reasonably explained by a response to tissue hypoxia than by elevated metabolic activity, as mitochondrial oxidation in the synovium is not similarly enhanced.

The terminal end product of the anaerobic oxidation of glucose is lactate. The ratio of lactate to glucose, therefore, should give an indication of oxygen status in the synovium. This is indeed the case, it has been shown that lowered glucose and raised lactate levels correlate well with falls in oxygen tension and pH. Proton nuclear magnetic resonance (**NMR**) spectroscopy confirms the peculiar anaerobic environment in the inflamed joint. Comparison of paired synovial fluids and sera show that the concentrations of lactate, 3-D-hydroxybutarate and acetoacetate are all much higher in the synovial fluid than the serum pair. Additionally, high levels of ketone bodies are also found. The hypoxic conditions prevailing in the inflamed joint lead to an increase in fatty acid oxidation. However, the unavailability of NAD+ results in an inability of the citric acid cycle to oxidize fully acetyl coenzyme A. This process leads to a build-up of unoxidizable metabolites, ketone bodies, recently demonstrated by NMR spectroscopy and illustrated in Fig. 3.

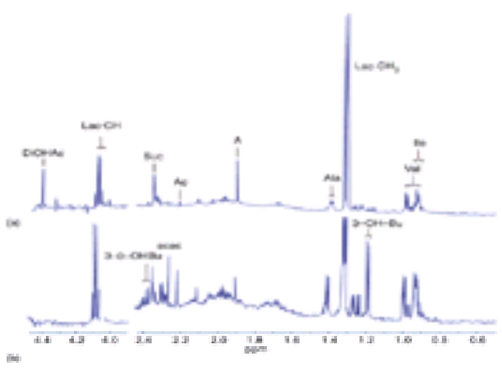

Fig. 3 600 MHz proton nuclear magnetic resonance spectra of low-molecular-mass, non-protein bound components of isolates from osteoarthritic (a) and rheumatoid (b) synovial fluids. DiOHAc, dihydroxyacetone; Lac, lactate; Suc, succinate; Ac, acetone; A, acetate; Ala, alanine; Val, valine; Ile, isoleucine; 3-D-OH Bu, 3-D-hydroxybutarate; Acac, acetoacetate. (Samples were run in a Varian 600 MHz machine operating at 600 MHz at ambient temperature.)

Acute exacerbation of chronic hypoxia

A distinguishing property of the joint is its ability to move. The inflamed joint of a mobile patient is unavoidably subjected to movement. This situation has profound significance in joint pathogenesis through the effects of hypoxic–reperfusion injury (Woodruff *et al*. 1986).

The environment for hypoxia and reperfusion in rheumatoid synovitis is created by the unique topography of the component parts of a joint which predisposes the synovium to pressure-induced fluctuations in blood supply. The synovium is the innermost confine of the joint space and its fluid. This moveable and compressible stroma is backed by the more rigid confines of the musculature and ligaments. It might be anticipated, therefore, that centripetal thickening and increasing fluid volume generates a pressurized system. This is indeed the case. We have confirmed (Blake *et al*. 1989) that the resting intra-articular pressure in chronically inflamed joints is slightly above atmospheric pressure (+5 to 10 mmHg) compared with that of normal joints which is subatmospheric (–5 mmHg). When normal joints (knee) are exercised, the pressure falls further, whereas in chronically inflamed joints intra-articular pressure rises, sometimes as high as 300 mmHg and always above the capillary perfusion pressure in inflammation of 30 to 60 mmHg; this is illustrated in Fig. 4. It is therefore suggested that in chronically inflamed joints, the intra-articular pressure rises during exercise above a critical level sufficient to occlude parts of the capillary bed, thus inducing acute ischaemia in an already hypoxic environment. Recent independent observations have supported the hypothesis of ischaemia induced by intra-articular pressure. James *et al*. (1990) have shown in patients with rheumatoid arthritis with knee effusions that intra-articular pressure elevations in the range encountered during daily activity can compromise blood flow. This effect is associated with increased synovial fluid lactate, elevated carbon dioxide tension and decreased pH. In rabbit knees intra-articular pressures as low as 19 mmHg cause synovial capillaries to assume a more flattened, elliptical profile (Levick 1990).

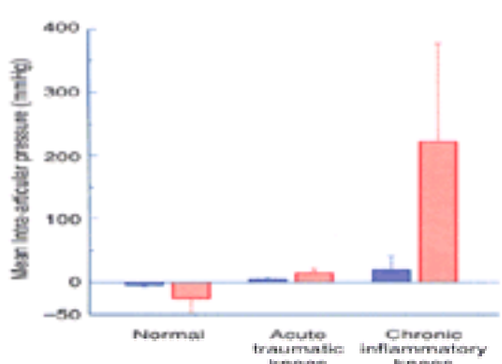

Fig. 4 Pressure changes on exercise. Solid bars, rest; hatched bars, exercise.

In mobile patients who may be subjecting their joints to pressure-induced ischaemia, subsequent rest allows reperfusion of blood and reoxygenation of the synovium, albeit to an inadequate degree. This eventuality, has pathological repercussions consequent on the generation of reactive oxygen metabolites which accompanies postischaemic reperfusion.

Biochemical consequences of synovial hypoxia

There are a number of biochemical consequences of hypoxia; calcium imbalance is arguably the most influential of these events. Intracellular homeostasis, with respect to Ca^{2+}, is dependent upon energy in the form of ATP. When ATP availability is compromised, as in the hypoxic synovium, cytosolic Ca^{2+} levels rise. Mitochondria are avid accumulators of Ca^{2+}, and when overloaded with Ca^{2+} their function is impaired (Nayler *et al*. 1979), resulting in the further depletion of ATP levels and the maintenance of a calcium influx. Many important cellular functions and control mechanisms are Ca^{2+} dependent. The consequences of hypoxia-derived Ca^{2+} imbalance must be considered as possible contributing factors in the pathogenesis of rheumatoid arthritis (Fig. 5). The mechanism for increased vascular permeability for instance, which is associated with inter-endothelial gap formation, is thought to involve changes in the actin cytoskeleton of the endothelial cell (Shasby *et al*. 1985). These changes can be elicited by calcium imbalance since actin binding proteins which regulate the endothelial cytoskeleton are calcium dependent (Hinshaw *et al*. 1988). The failure of cellular phosphorylation mechanisms also leads to accumulation of adenosine and of its breakdown products,

including hypoxanthine and xanthine which are the substrates for the xanthine oxidase enzyme system (see below). The outcome of these events in the hypoxic synovium confers the facility for the inappropriate generation of reactive oxygen metabolites upon reperfusion of blood. There is much evidence to show that postischaemic reperfusion of the synovium evokes the generation of reactive oxygen metabolites, despite the underlying hypoxic environment which is not conducive to most conventional radical generating systems. One proposed mechanism that can achieve this is dependent on the enzyme xanthine oxidase (McCord 1987), which is present within the capillaries of the synovium (Allen *et al*. 1987). The non-pathological dehydrogenase form of this enzyme oxidizes hypoxanthine and xanthine to uric acid using NAD+ as an electron acceptor. Under ischaemic conditions, however, this enzyme can be converted to an NAD+-independent form which catalyses the same reaction using molecular oxygen as an electron acceptor and resulting in superoxide anion generation. The inappropriate production of superoxide in a biological system can have catastrophic repercussions, particularly when the system facilitates the redox environment required for consequent hydroxyl radical (·OH) formation. The synovium is such a system, enabling the spontaneous or enzymatic conversion of superoxide to hydrogen peroxide, which can then fuel a Fenton-type reaction catalysed by decompartmentalized iron (Morris *et al*. 1986) forming the cytotoxic ·OH radical thus:

$$H_2O_2 + Fe^{2+} \rightarrow {\times}OH + OH^- + Fe^{3+}$$

Iron is decompartmentalized as a consequence of hypoxia and can be detected bound to citrate in the synovial fluid. In such a form it may promote hydroxyl radical formation.

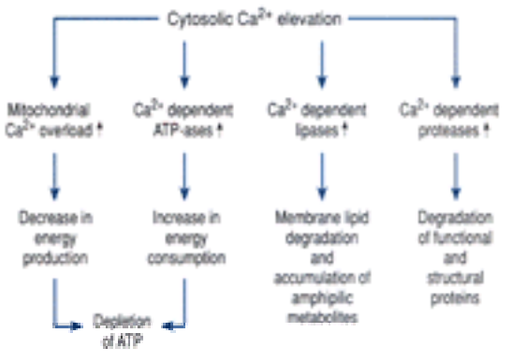

Fig. 5 Role of elevated cytosolic calcium in tissue injury.

Biological consequences of reactive oxygen metabolites

Biochemical analysis of synovial fluid reveals the effects of radical damage to endogenous biomolecules in rheumatoid arthritis.

Lipids

The cell membrane, composed primarily of polyunsaturated fatty acids, is a well-studied target for radical attack, and the resultant process of lipid peroxidation causes cell membrane damage. Polyunsaturated lipids undergoing the process of peroxidation give rise to the formation of lipid breakdown products such as lipid hydroperoxides, endoperoxides, aldehydes, and alkanes. These can be measured and correlate well with the clinical severity of the disease.

Proteins

Exposure of proteins to free radicals will lead to denaturation, cross-linking, aggregation, and fragmentation. There is much evidence of radical-mediated protein damage occurring in inflammatory synovitis. Immunoglobulin G (IgG) when exposed to free radicals *in vitro* develops a characteristic autofluorescence (excitation 360 nm, emission 454 nm) and forms both monomeric and aggregated complexes (Lunec *et al*. 1985). IgG with these characteristics is present in rheumatoid synovial fluid.

Additionally, the methionine residues on a_1-antitrypsin (the primary inhibitor of leucocyte elastase) are oxidized to sulphoxide adducts by free radicals, rendering the molecule biologically inactive. Such radical damaged a_1-antitrypsin is present in inflammatory synovial fluid.

Carbohydrates

Free radicals can also react with polysaccharides and induce fragmentation. The major macromolecule of the synovial fluid, which accounts for its viscosity, is the glycosaminoglycan hyaluronate. Loss of viscosity of the synovial fluid is thought to be due to the depolymerization of hyaluronate and an increase in the synovial concentration of dialysable hyaluronan fragments and saccharide monomers. The alternative explanation for the reduction in the molecular weight of hyaluronan is defective synthesis with premature termination of the polysaccharide chain. Pulse–chase labelling experiments have supported the view that the presence of short-chain molecules of hyaluronan in the synovial fluid is due to post-synthetic degradation rather than defective synthesis. As neither normal nor inflammatory synovial fluids contain any measurable hyaluronidase activity, it is inferred that the depolymerization of hyaluronan is the result of free radical attack. The degradation products have different biological properties from that of the native molecule. Low-molecular-mass fragments of hyaluronan are proangiogenic, whereas the high-molecular-mass hyaluronan has inhibitory effects on endothelial cell proliferation. Proliferation of both fibroblasts and mitogen-stimulated lymphocytes is similarly affected.

Effects on cells and cell viability

There are important effects of free radicals upon cells when considered as a whole. T lymphocytes in general have been shown to be susceptible to free radical attack. Free radicals are more toxic to T-cytotoxic/suppressor than to T-helper cells *in vitro* (Allan *et al*. 1986). These results support the speculation that free radical reactions, as well as inducing the denaturation of proteins, can prevent immune suppressor/cytotoxic cells from controlling autoimmune reactions with subsequent immunopathological consequences. As well as the cytotoxic aspects of free radical attack on whole cells, which occurs at high concentrations, the data (Murrell *et al*. 1990) also suggest that at low concentrations free radicals can stimulate proliferation of cells. Under *in vitro* conditions fibroblasts were stimulated to proliferate by low concentrations of free radicals (the fibroblasts themselves release their own free radicals), and fibroblasts were inhibited from proliferation but were still viable when the endogenous free radicals were inhibited.

Many other examples of oxidative damage to the joint have been reported. Apart from these damaging or cytotoxic properties of free radicals, they also have the capacity to interfere subtly with finely controlled physiological mechanisms. One example of this occurs in the control of vascular tone by vasoactive substances.

The activity of endothelium-derived relaxing factor (**EDRF**) has been ascribed to the nitrogen-centred radical nitric oxide, which is synthesized in endothelial cells by the Ca^{2+}- dependent enzymatic conversion of L-arginine. It activates the cytosolic guanylyl cyclase of the adjacent smooth muscle cells increasing the levels of cGMP and resulting in relaxation of the cells and hence vasodilation. Nitric oxide can interact with superoxide via peroxynitrite to produce the highly cytotoxic hydroxyl radical. *In vitro* this interaction abrogates the EDRF activity of nitric oxide. This is demonstrated by the ability of superoxide dismutase to enhance and prolong the relaxant effect of nitric oxide. Nitric oxide is unstable and rapidly degrades to nitrate and nitrite, which are relatively stable in biological fluids. In inflammatory joints the synovial fluid levels of nitrite exceed those of the paired serum samples, thus indicating local production. The implication of this is that nitric oxide is also produced locally in the synovium. Vascular tone is controlled by the opposing actions of relaxing and contracting factors released from the endothelium in response to neurogenic stimuli or platelet products. Superoxide has itself been implicated as an endothelium-derived contracting factor along with endothelin. An obvious vascular response to tissue ischaemia would be to lower its resistance to blood flow by vascular relaxation. This has been shown to be the case in some systems where hypoxia-induced release of prostacyclin (PGI_2) is sufficient to elicit endothelium-dependent dilation. Hypoxia also stimulates the release of EDRF from rabbit femoral artery and aorta. In the pulmonary circulation, however, it has been known for many years that hypoxia causes vascular constriction. The benefit of this is in rerouting the majority of the blood flow to the best oxygenated parts of the lung. Other pulmonary studies have shown that hypoxia blocks EDRF production and induces the

release of a constricting factor from the endothelium. These conflicting reports highlight the heterogeneity of endothelial cell responses to the same stimulus in different situations and environments, allowing the possibility of an apparently appropriate response to eventually become pathological.

Hypoxia has other quite pronounced effects on endothelial cells, for example on von Willebrand factor release (discussed later), reducing plasminogen activator activity, and increasing superoxide dismutase activity. The endothelium also produces other very powerful vasoactive substances which may be mediated by hypoxia. These include platelet-activating factor and the highly potent vasoconstrictor endothelin. In addition, endothelial cells play a pivotal role in the initiation, regulation, and maintenance of the inflammatory process via the induction of changes in their interactions with blood constituents. These factors, when considered in parallel with the susceptibility to perturbation by hypoxia of the endothelial cell, confer its prominent role in the pathogenesis of ischaemic states.

Leucocyte chemotaxis and adhesion

The initiating factors of inflammatory cell infiltration are adherence to endothelium and chemotaxis. Synovial inflammatory cell infiltration is a major characteristic of rheumatoid arthritis as is the expression of membrane-associated adhesion molecules. The contribution of hypoxia to this situation may have considerable significance, particularly where oxygen free radicals are a consequence. Superoxide, hydrogen peroxide, or both can generate a chemoattractant for neutrophils from extracellular fluid (Perez *et al*. 1980; Petrone *et al*. 1980). The identity of the neutrophil chemotactic factor(s) generated in ischaemia is unknown. However, possible candidates are cyclo-oxygenase and lipoxygenase metabolites of arachidonic acid, such as 12-hydroxyeicosatetraenoic acid which is found to be raised in hypoxic states and is a neutrophil chemoattractant. In support of this, cultured endothelial cells are capable of responding to hypoxia by producing a neutrophil chemoattractant which is suppressible by lipoxygenase inhibitors (Farber *et al*. 1987).

The adhesion component of leucocyte infiltration can be facilitated by oxygen radicals (Suzuki *et al*. 1989) and by hypoxia (Mullane and Pinto 1987) alone. Interestingly, the adhesion of neutrophils to ischaemic arterial vasculature is associated with a loss of endothelium-dependent vasorelaxant activity.

Microvascular barrier function

In any inflammatory condition the manifestation of the inflammatory response is controlled by the permeability of the microvascular blood/tissue barrier. Increased transvascular exchange of macromolecules, emigration of leucocytes, and oedema formation are indicative of modified barrier function and are characteristic of synovial inflammation. The dynamics of barrier function, particularly solute exchange, are modulated physiologically by a complex assortment of mediators. During hypoxia, however, homeostasis is disrupted by, as yet, poorly understood mechanisms involving mediators of altered barrier function, such as platelet activating factor, complement, leukotrienes, and prostaglandins. Increased permeability during ischaemia or hypoxia has been reported in many vascular systems *in vitro* and *in vivo*, for example heart (Armiger and Gavin 1975), lung (Lockhart and Saiag 1981), brain (Oleson 1986), and cultured bovine endothelium (Ogawa *et al*. 1990).

In addition to the effects of hypoxia alone, rheumatoid synovial microvascular function and permeability can be altered by the membrane damaging effects of oxygen free radicals. Measurement of von Willebrand factor illustrates this. von Willebrand factor, otherwise known as factor VIII-related antigen, is a large adhesive glycoprotein which is synthesized in endothelial cells and megakaryocytes and plays an important role in the adhesion of platelets to damaged vessel walls. Small subunits of von Willebrand factor are released constitutively by endothelial cells, accounting for normal circulating plasma levels. Larger multimers of von Willebrand factor are stored in specific organelles called Weibel–Palade bodies within endothelial cells. Interestingly, these bodies are common in the synovium and have been implicated as a marker of angiogenesis in rheumatoid arthritis (Kumar *et al*. 1985). A variety of physiological stimuli can induce acute release of these multimers from the Weibel–Palade bodies *in vitro* including hypoxia, by a Ca^{2+}-dependent process. Elevated levels of plasma von Willebrand factor have been observed in various disease states including rheumatoid arthritis (Woolf *et al*. 1987; Pottinger *et al*. 1989) where, in contrast to normal, levels increase with simple 'physiologic' exercise. This phenomenon has been taken to indicate vascular damage (Greaves *et al*. 1987).

The attempts of the joint to limit the hypoxic damage

The immediate local response to tissue hypoxia is elicited by the vasculature, utilizing vasoactive substances which serve to enhance perfusion. It is clear that the facility for this response is impaired in rheumatoid synovitis. A more long-term strategy for the re-establishment of adequate perfusion is neovascularization of hypoxic tissue. The facility for this, termed angiogenesis, most certainly exists in the rheumatoid synovium, to an extent which some believe to be pathological.

Under conditions of physiological stress, such as hypoxia, cell survival may become dependent on the expression of a specialized set of proteins, termed stress proteins.

Angiogenesis

The formation and growth of new blood vessels is under rigid control, so much so that in health angiogenesis only occurs in wound healing and during endometrial regeneration. Functional aberrations of the physiological regulation of new capillary growth, such as seen in ischaemia and reperfusion, are implicated in the pathogenesis (if not aetiology) of many neoplastic and non-neoplastic diseases.

The neovascularization of a wound progresses, logically, towards the centre where hypoxic macrophages are stimulated to produce angiogenic factors. The persistent synovitis characteristic of rheumatoid arthritis equates with persistent, though perhaps not fully effective, angiogenesis. The resulting fibroproliferative, inflammatory pannus invades and elicits the destruction of articular cartilage leading to joint deformation and loss of function. Clearly there is angiogenesis in the rheumatoid synovium, although morphometry suggests that this does not keep pace with synovial proliferation. This situation, as has been discussed earlier, promotes hypoxia in the peripheral region of the synovium which is rich in macrophages. The evidence that rheumatoid synovial tissue macrophages and hypoxic macrophages releases a substance capable of inducing angiogenesis invite the hypothesis that hypoxia drives synovial angiogenesis. The macrophage-derived angiogenic factor is thought to be tumour necrosis factor-a. This factor has been localized histochemically to the synovial lining cells in rheumatoid arthritis but no prominent staining is seen in osteoarthritis non-inflammatory samples.

Stress proteins

Often inaccurately given the general term 'heat-shock proteins', these ubiquitous intracellular molecules form two groups. True heat-shock proteins contain a specific consensus region within the promotor region of the gene while the second group, the glucose-regulated proteins, do not have this DNA sequence. Although the genes are normally quiescent or only partially active, stress protein mRNAs are actively transcribed following physiological stress, the proteins induced being dependent on the particular stressor; they are classified into families according to molecular weight. An excellent review of the subject is available (Lindquist 1986).

Rheumatological interest in the heat-shock proteins followed the implication of the 60 kDa family in the development of adjuvant-induced arthritis in rats (Van Eden *et al*. 1988). These observations have been extended to include other animal models of arthritis. Additionally, patients with rheumatoid arthritis have circulating isotype-restricted antibodies to stress proteins and these same proteins are abundantly present in inflamed but not normal synovia; the high levels of the stress-inducible 72 kDa protein give a good indication of the physiological trauma of synoviocytes within the inflamed joint (Winrow *et al*. 1990a).

No other information is available with respect to stress protein synthesis in joints. It has been shown *in vitro* that glucose-regulated proteins are synthesized during hypoxia and heat-stress proteins on reperfusion (Sciandra *et al*. 1984). Similarly, animal experiments show that *de novo* intracellular synthesis occurs during exercise. Measurement of the 78 kDa glucose-regulated proteins synthesized during glucose deprivation is difficult to quantify *in situ* since the available antisera which recognize this protein also bind with other members of the 70 kDa family. The usual method of cell radiolabelling is impractical *in vivo*.

Natural defence mechanisms exist to limit damage from reactive oxygen metabolites. The 32 kDa heat-shock protein, now characterized as the enzyme haem oxygenase, is specifically induced by hydrogen peroxide, by heavy metals including iron, and by its substrate haem. Interestingly, it is also induced by the antirheumatic compound auranofin. Haem oxygenase, in the presence of NADPH and oxygen, cleaves haem to form biliverdin which is then rapidly reduced to bilirubin, a radical scavenger. It has been suggested that increased production of this enzyme may be necessary to facilitate the turnover of haem-containing proteins, like the mitochondrial cytochromes which contribute to oxidative phosphorylation by respiration-linked electron transfer (Welch 1990). We have postulated that in the inflammatory joint, production of this enzyme would be beneficial, decreasing the levels of haem whilst additionally increasing the levels of the antioxidant bilirubin and thus limiting damage by the haem iron catalysed formation of hydroxyl radicals; the low oxygen tension within the joint may limit activation of this enzyme (Winrow *et al*. 1990b). Auranofin and thiol reactive agents may act by helping to stimulate production of the 32 kDa protein and thus affect vascular changes; it is known that

D-penicillamine suppresses neovascularization by generating low levels of hydrogen peroxide (Matsubara *et al*. 1989).

Reflex muscle inhibition

Exercise of the inflamed knee joints gives rise to elevated intra-articular pressures which is central to the mechanism of ischaemic reperfusion injury. However, this is not the case in all joints with effusions, there is a dramatic difference between a joint with an acute traumatic effusion and one with a chronic effusion. Measurement of the intra-articular pressure in the knee after quadriceps setting reveals that the patient with acute trauma is barely able to raise the intra-articular pressure at all (13 mmHg) whilst the patient with chronic inflammation is able to achieve pressures in excess of 250 mmHg. This phenomenon is explained by the fact that the patient with acute trauma has reflex muscular inhibition of the quadriceps whereas the patient with a chronic condition does not. This may be a defensive mechanism in the patient with acute trauma attempting to limit hypoxic–reperfusion injury. The mechanism behind this inhibition is not understood, neither the manner by which it is overcome in the chronic inflammatory condition. However, it is reasonable to speculate that the depletion of the sensory nerve fibres in chronic arthritis (see earlier) is the cause. The transition from the acute to the chronic condition obviously involves the nervous system but again how this is regulated is not known. The nervous system also has other influences on the chronic inflammatory condition, some of which are only now being elucidated.

Nervous system

A number of clinical observations point to a neurogenic mechanism operative in chronic arthritis. The clearest example of this is provided by the synovitis that often accompanies reflexed sympathetic dystophy. Sympathetic activity has also been implicated in the aetiology of the frozen shoulder (Maini *et al*. 1989). More controversial are the observations relating to hemiplegia and rheumatoid arthritis. In cases in which the rheumatoid arthritis develops after the hemiplegia the joints in the hemiplegic limbs are spared, but partially affected limbs are not always spared (Thompson and Bywaters 1962). In cases of patients paralysed by polio before the onset of the arthritis there is almost total sparing of the paralysed limbs. While it is tempting to consider this as clear evidence for a neural component in rheumatoid arthritis, other causal factors such a movement-induced hypoxic–reperfusion injury (see earlier) need to be considered.

In animal model systems the available evidence is clearer. Experimental evidence for a neurogenic effect in acute arthritis is provided by the fact that antidromic (reversed) stimulation of the articular C fibres results in vasodilation and plasma extravasation within the joint. The intra-articular injection of capsaicin, a compound known specifically to stimulate C fibres, gives similar results. Intra-articular infusion of 6-hydoxydopamine, a compound which stimulates post-ganglionic sympathetic nerves to release the contents of their peripheral terminals, can also produce a prolonged increase in synovial plasma extravasation. The acute vascular response to intra-articular injection of inflammatory compounds, such as carrageenan, can be significantly inhibited by prior joint denervation.

In chronic arthritis, substance P levels (see later) have been shown to be greater in those joints which develop more severe adjuvant arthritis (Levine *et al*. 1984), and injection of substance P into minimally involved joints increases the severity of the adjuvant disease in the injected joint. The destruction of the ankle joint in the same model is ameliorated by sciatic nerve section as compared with the contralateral non-operated side.

In human disease we have demonstrated that there is a change in the morphology of the nerve supply to the joint and have speculated on the release of neuropeptides in the inflamed joint.

Pain

One of the outstanding features of the inflamed joint is undoubtedly the pain which arises from it. As described earlier, the synovium contains unmyelinated C fibres which usually remain silent. However, in an inflammatory reaction the threshold of these fibres becomes lowered. This effect can be induced experimentally by agents such as prostaglandin E_1 and bradykinin (reviewed by Konttinen *et al*. 1994). Both substances are found in inflammatory joint fluid. Not only can the nociceptive fibres alter their threshold but they may alter their receptive field so as to widen it. Thus movement in the normal range which was once painless now becomes painful.

Neurogenic inflammation

In addition to a nociceptive function, it is now widely accepted that neuropeptides contained within these nerve fibres play a role in the inflammatory response. The activation of the sensory nerves results not only in an impulse transmission to the spinal cord but also a reversed (antidromic) transmission through the extensive branches in the peripheral C fibres. This is known as an axon reflex. This reversed transmission results in the release of neuropeptides, such as substance P, and stimulates an acute reaction—neurogenic inflammation (Foreman 1987). Radioimmunoassays point to the release of neuropeptides into the inflammatory joint fluid. There are numerous neuropeptides present in the synovium and a comprehensive description of all their actions is not possible. Here we have selected a few for closer examination.

Substance P

In 1931 von Euler and Gaddum extracted from equine brain and intestine a material which was hypotensive and smooth muscle stimulating (von Euler and Gaddum 1931). They designated this activity preparation P (for powderable) and in later publications referred to it as substance P. However, it was not until 1971 that the peptide was purified (Chang *et al*. 1971), sequenced, and synthesized.

Substance P is a small polypeptide of 11 amino acids and is one of a family of peptides, the tachkykinins, which share 4 common amino acids at the carboxyl terminal. Two precursor messenger RNAs have been isolated, one containing the substance P sequence (a-preprotachykinin) and the other containing substance P and the sequence for another tachykinin, neurokinin A. There appears, however, to be only one preprotachykinin gene, with alternative RNA splicing resulting in the production of the two messages.

Substance P in joints

C fibres containing substance P are mostly seen with their terminals at the boundary between the synovium and the joint space. The location of these fibres makes them ideally suited to play a part in monitoring the intra-articular environment or to act as sensory receptors. Since both the peptides associated with these nerves, substance P and calcitonin gene-related peptide, are found in the sensory nerves, a nociceptive role seems a likely hypothesis. Now that the presence of nerves containing substance P in human joints has been established, what evidence do we have that they contribute to arthritis?

In experimental animals antidromic stimulation of articular C fibres results in vasodilation and plasma extravasation within the joint. Intra-articular injection of capsaicin, the hot component of chili peppers which is known to stimulate C fibres, yields similar results. Direct intra-articular injection of substance P also produces vasodilation and plasma extravasation. This effect is probably mediated by the release of endothelial cell-derived relaxing factor (nitric oxide) The induction of an acute inflammatory response within the joint with an agent such as carrageenan may also be mediated by substance P. In knee perfusion experiments, pretreatment of the test knee with the substance P antagonist d-Pro^4, d-$Trp^{7,9,10}$ -SP (4 to 11) before challenge with carrageenan produced a 93 per cent reduction in the inflammatory response compared with knees treated with carrageenan alone (Lam and Ferrell 1989). Substance P levels have been shown to be greater in those joints that develop the most severe arthritis, and the injection of substance P into minimally involved joints increases the severity of the adjuvant disease in the injected joint. This and other work adds up to a substantial body of evidence that substance P can cause joint inflammation in animal models, is there evidence for an involvement in human disease?

Detection of substance P in synovial fluid

One obvious way to establish a link with chronic inflammation in human disease is to demonstrate the presence of the peptide in the inflammatory synovial fluid. This problem has been addressed by several investigators with differing results. The studies to date have utilized immunoassay methods and all have employed different polyclonal antisera, which makes comparison of results difficult. One initial report (Devillier *et al*. 1986) suggested that inflammatory fluids contained more tachykinin-like immunoreactivity than non-inflammatory fluids. Larsson *et al*. (1989) found no tachykinins (substance P or neurokinin A) in their inflammatory fluids but neurokinin A was present in the traumatic injury control group. In four types of arthritis (rheumatoid, osteoarthritis, Reiter's syndrome, and traumatic arthritis) the synovial fluid levels of substance P were higher than those seen in paired plasma samples (Marshall *et al*. 1990). Since the levels are higher in the synovial fluid than the plasma, the source of the substance P is probably intra-articular. The only known source are the C fibres, although there has been one report that a subpopulation of endothelial cells may also contain substance P (Loesch and Burnstock 1988). Whether these cells acquire substance P by uptake or by synthesis remains to be determined. The significance of absolute levels of substance P, or indeed any parameter measured in joint fluid, is difficult to assess since the dynamics of the system

in terms of production, degradation, and clearance rates are unknown. Furthermore, there is no method yet available to show whether the substance P detected is bioactive or simply a smaller non-active fragment, as the potency of the molecule might lead one to suspect.

These reservations are substantiated by recent data (Joyce 1993) demonstrating that authentic levels of substance P in joint fluids are less than 4.7 pg/ml, which was the detection limit of the assay. The study showed that the inhibition of degrading enzymes and correct extraction procedures were all important in obtaining reliable results.

In vitro investigations

The effects of substance P on a wide variety of cell types *in vitro* have been investigated. These data show release of inflammatory mediators from various cell types, including the degranulation of mast cells (Mazarek *et al*. 1981), the stimulation of prostaglandin E_2 and collagenase from synoviocytes (Lotz *et al*. 1987), secretion of prostaglandins and thromboxane from macrophages (Hartung and Tokya 1983; Hartung *et al*. 1986), and the modulation of immunoglobulin production from lymphoid tissue (Sanitz *et al*. 1986). Substance P is also reported to induce the release of interleukin 1 from cultured mouse macrophages (Kimball *et al*. 1985). Thus tachykinins may contribute to the maintenance of chronic arthritis. These activities of substance P require a dose of the peptide in the nanomolar range, which is consistent with published figures for the dissociation constant of substance P with its receptor (0.5 to 2.0 nmol). Other cells, such as neutrophils, only appear to be activated directly by much larger concentrations of the peptide (greater than 10 µmol) suggesting a lack of physiological relevance. However, lower concentrations of substance P, in the nanomolar range, appear to be able to prime neutrophils to respond to other mediators (Perianin *et al*. 1989). In particular, neutrophils have been shown to act in a synergistic manner with substance P to other chemotactic peptides, such as complement-derived C5a or bacterial fMLP. Low doses of substance P have also been shown to modulate the action of other peptides, such as calcitoin gene-relate peptide. Collectively these results suggest that in addition to a direct effect of substance P on several cell types a second modulatory mechanism is also operative. The nervous system may therefore be capable of priming cells to respond to lower doses of certain agents, than might otherwise be the case, leading to an apparent hypersensitivity. This mechanism may be particularly important in allergic responses, such as that seen in asthma.

Calcitonin gene-related peptide

Calcitonin gene-related peptide (**CGRP**) is a 37 amino acid peptide produced by alternative splicing of the primary transcript of the calcitonin gene. It is particularly abundant in the sensory nervous system, being present in approximately 50 per cent of primary sensory neurones. Behaviourial and electrophysiological studies have shown that CGRP may play a part in pain perception and reports have indicated that it can potentiate the hyperalgesia caused by intradermal injection of substance P. In addition to its presence in primary sensory nerves, CGRP has also been found in motor end plates and is stored and synthesized in motor neurones (Gibson *et al*. 1988). This is consistent with reports describing motor-related actions for this peptide, including a role as a muscle trophic factor. In both human and animal studies, CGRP has been shown to be a potent vasodilator, capable of inducing a protracted increase in microvascular blood flow when injected extravascularly. Although relatively inactive on its own, CGRP potentiates oedema induced by other mediators of increased microvascular permeability, including substance P.

The majority of substance P-containing nerve fibres also contain CGRP, and electron immunocytochemical studies have revealed that secretory granules in sensory nerves contain immunoreactivity for both peptides (Merighi *et al*. 1987). It is interesting to note that co-injection of CGRP with substance P into human skin converts the long-lasting vasodilation induced by CGRP into a transient response. Experiments in animals reveal that this phenomenon is dependent on the action of proteases from mast cells stimulated by substance P (Brain and Williams 1988). Thus if both CGRP and substance P are released simultaneously from nerve terminals, CGRP will exert a relaxant effect on vascular smooth muscle. The increased blood flow can then be controlled by proteolysis of CGRP by enzymes released from the mast cells in response to substance P. If this inactivation mechanism is overruled by an excess of CGRP, generated locally by depletion of substance P or by loss of mast cell proteases, protracted erythema, as occurs following local infection or injury, could result.

Since CGRP and substance P coexist, it might be expected that CGRP has a similar distribution to substance P in articular tissues. However, substance P-immunoreactive nerves are less abundant than CGRP neurones, while CGRP-immunoreactivity is found in motor nerves of muscles surrounding the motor nerves and long bones.

Neuropeptide Y

Neuropeptide Y is a 36 amino acid peptide. Neuropeptide Y is associated with catecholaminergic nerves because of its co-localization with tyrosine hydroxlase and dopamine b-hydroxylase in sympathetic peripheral ganglion cells. Potent vasoconstrictor effects on the vasculature and presynaptic inhibition of transmitters released from non-adrenergic, cholinergic nerves and non-adrenergic, non-cholinergic nerves are among the reported actions (Allen and Bloom 1986). Nerve fibres containing neuropeptide Y have been localized almost exclusively to blood vessels in synovial tissues and periosteum (Mapp *et al*. 1990b), unlike the peptides substance P and CGRP which also occur as free nerve fibres.

Degradation of peptides

The local activities of regulatory peptides depend on a combination of release and clearance from the vicinity of their receptors. Many peptides have a short half-lives, rapid clearance being due to membrane-bound peptidases. These enzymes have characteristic regional distributions, and their activities may vary during inflammation. Understanding the local topography of membrane-bound peptidases and their relation to the sites of release and action of those peptide that may act as substrates is therefore essential to understanding peptidergic regulatory systems in the normal and diseased synovium.

Neutral endopeptidase (NEP; EC 3.4.24.11) is responsible for the majority of the degradation of substance P in the human synovium. NEP is capable of the hydrolysis of many peptides including substance P (Skid *et al*. 1984) and CGRP (Katyama *et al*. 1991) This enzyme has been shown to be identical to the common acute lymphoblastic leukaemia antigen (CALLA) (Letarte *et al*. 1988) and is the CD10 determinant.

Its activity has been shown in the synovium of patients with chronic arthritis (Sreedharan *et al*. 1990). The activity of NEP was found to be higher in all patients with rheumatoid arthritis and some patients with degenerative joint disease, when compared with controls with traumatic arthritis. Our own data show the localization of this enzyme in human synovium; fibroblasts are its source, a restricted population of cells surrounding blood vessels being responsible for the majority of the activity (Mapp *et al*. 1992) (Fig. 6).

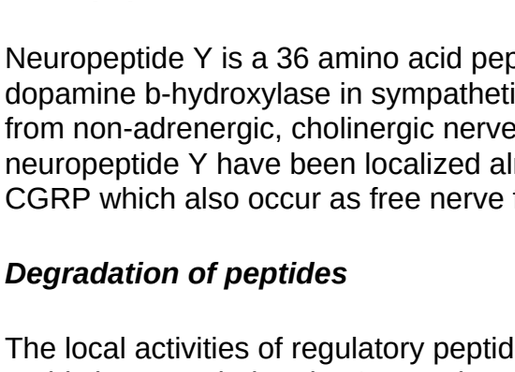

Fig. 6 Photomicrographs of rheumatoid synovia showing (a) the localization (black reaction product) of neutral endopeptidase, an enzyme that degrades neuropeptides, surrounding blood vessels and (b) at higher power, to a restricted population of cells surrounding those blood vessels.

These may represent a specialist subpopulation of fibroblasts. Since the function of NEP is probably the degradation of locally released regulatory peptides, its presence around the blood vessels makes it ideally located to inactivate vasoactive peptides, such as substance P, which are released from perivascular nerve fibres.

In addition to NEP, we (Walsh *et al*. 1993) have also localized several other peptide degrading enzymes to the synovium, including angiotensin converting enzyme,

dipeptidyl peptidase IV, and aminopeptidase M. Angiotensin converting enzyme is localized to the endothelia of all vessels, and aminopeptidase M to the lining layer of the synovium and scattered cells in the stroma. The localization of these peptidases in the human synovium suggests not only a role limiting the duration of action of regulatory peptides but also in localizing activities to the vicinity of their release. This functional compartmentalization of vascular and stromal regions in synovium is essential to the local regulatory function of peptides and is likely to influence reponses to exogenous peptides administered into non-physiological compartments during experimental investigations (Fig. 7).

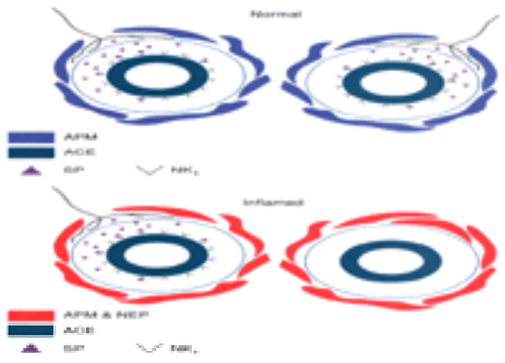

Fig. 7 Schematic diagram showing the distribution of enzymes in and around blood vessels, capable of degrading neuropeptides, in the normal and inflamed joint. Note how the neuropeptides are compartmentalized by the degrading enzymes. In disease nerve fibres may be absent and receptors downregulated. Additionally, degrading enzymes are induced. (Diagram by courtesy of Dr D.A. Walsh, London Hospital Medical College.)

Summary

In this chapter we have shown how we believe the altered states of the synovium and synovial fluid arise in terms of the physiology of the joint. This is not intended to be a comprehensive review, since we have not attempted to address the involvement of the many other important mediator systems, to which separate chapters are devoted. The mechanisms that we have described are surely going on in parallel with several others. The concepts that are advanced are widely accepted in other areas of biology but are not often applied to the field of rheumatology. As these ideas gain acceptance it is to be hoped that our understanding of the underlying causes of why the inflammation in a joint can be so extraordinarily persistent is enhanced and novel therapeutic strategies developed.

The researches of many commentators have already thrown much darkness on the subject, and it is probable that, if they continue, we shall soon know nothing at all about it.

Mark Twain.

2.6 Skeletal muscle damage

Joan M. Round and D. A. Jones

Weakness, feelings of fatigue, and myalgia are amongst the most common symptoms complained of by patients with a variety of rheumatic and autoimmune diseases. In evaluating these symptoms it is important to have an understanding of the underlying physiology of normal skeletal muscle and this requires a knowledge of muscle development, the structure of muscle fibres, the organization of fibres into muscles and muscle groups, and the interactions between muscles and motor nerves.

Structure: the contractile apparatus

The major proteins of the contractile apparatus are actin and myosin.

Actin is a protein of great antiquity that occurs in a very similar form in most animal and plant cells and is polymerized into what appear to be double helical strands (F actin). F actin, together with the proteins tropomyosin and troponin form the thin filaments of the contractile apparatus. Tropomyosin blocks myosin-binding sites until caused to move by calcium ions binding to troponin C (Fig. 1). Actin filaments join at one end to form the Z-line structure with a-actinin making the connections between actin filaments (Fig. 2).

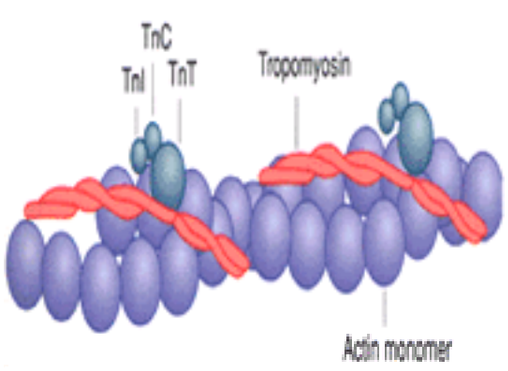

Fig. 1 Part of an actin filament together with tropomyosin and the troponin subunits.

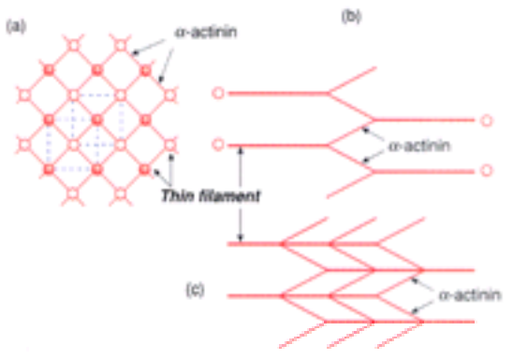

Fig. 2 Actin filaments joining to form the Z line. (a) View of the Z line along the axis of the thin filaments showing the square array. Solid symbols indicate thin filaments coming out of the page (or Z line), open symbols indicate thin filaments going into the page. (b) View from the side; note that only a-actinin connections in the plane of the page are shown, for every thin filament there will be another two connections in a plane at right angles to the page; (b) represents a simple Z-line structure found in fast muscle. (c) More complex Z line found in slow skeletal and cardiac muscle.

Myosin molecules consist of two identical heavy chains combined with four light chains. The myosin tail combines with other tails to bind the myosin molecules together to form a thick filament with the globular enzymic head regions, which combine with actin, projecting from the backbone of the filament (Fig. 3). Thick myosin filaments are arranged so that the thin actin filaments can slide between them. The unit from Z line to Z line is known as a sarcomere (Fig. 4).

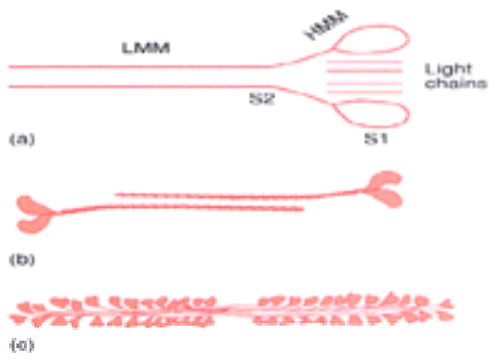

Fig. 3 Myosin structure and assembly into thick filaments. (a) Schematic arrangement of myosin subunits. (b) and (c) The basic double-headed myosin units aggregating to form a thick filament.LMM, light meromyosin; HMM, heavy meromyosin; S1, subunit 1; S2, subunit 2.

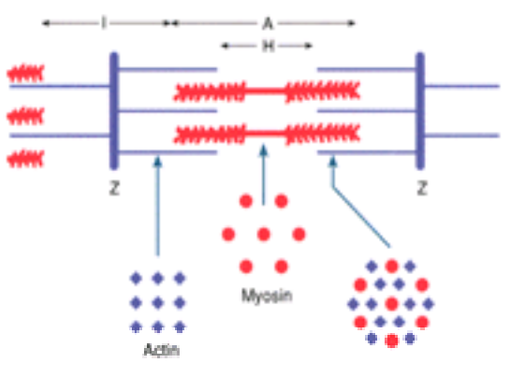

Fig. 4 The arrangement of thick and thin filaments to form a sarcomere. Below: cross-sections of the sarcomere.

A variety of structural proteins including C- and M-line proteins, titin, a-actin, desmin, and dystrophin are found associated with the structural apparatus and probably function to maintain sarcomere structure (Fig. 5).

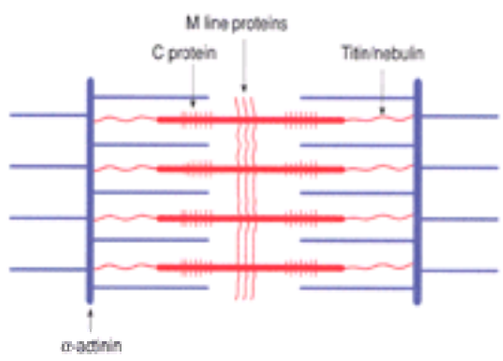

Fig. 5 Structural proteins in the sarcomere.

Bundles of 100 to 400 thick filaments form myofibrils (Fig. 6), which are separated from each other within the muscle fibre by sarcoplasmic reticulum, T tubules, and sometimes mitochondria (Fig. 7). Myofibrils vary in size but average around 1 μm in diameter. Myofibrillar protein constitutes about 80 per cent of the muscle fibre volume and it is primarily this protein which is lost when a muscle fibre atrophies.

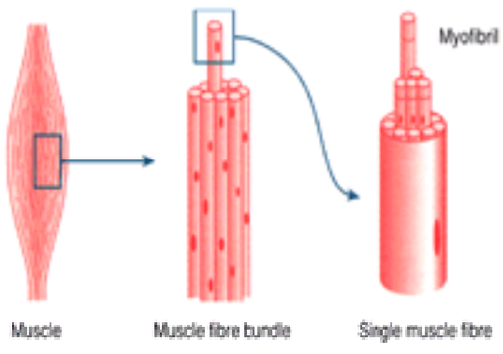

Fig. 6 Diagrammatic representation of the relationship between the muscle, muscle fibres, and myofibrils. In reality, the myofibrils are very much smaller in relation to the muscle fibre than shown here.

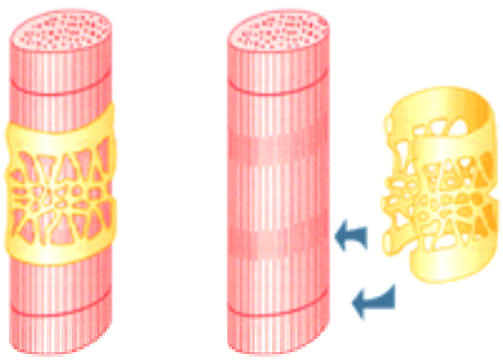

Fig. 7 The sarcoplasmic reticulum envelops a myofibril.

The muscle fibre is a multinucleate structure and, in healthy fibres, the nuclei are situated at the periphery of the cell just under the cell membrane. Muscle fibres grow by the addition of myofibrils, and there can be as few as 50 myofibrils in developing fetal muscle fibres while adult muscle fibres contain about 2000 myofibrils.

The membranous sarcoplasmic reticulum which encases the myofibrils acts as a store for the uptake and release of calcium. In mammalian skeletal muscle, the plasma membrane invaginates twice in every sarcomere forming a complex branching tubular network, the T tubules, which run through the whole fibre contacting every myofibril (Fig. 8). The lumen of the T tubule is continuous with the extracellular space and is separated from the interior of the sarcoplasmic reticulum even though the membranes of the T tubules and the sarcoplasmic reticulum are in close proximity at many points. The portions of the sarcoplasmic reticulum where the T tubules are in closest proximity are known as terminal cysternae (Fig. 9).

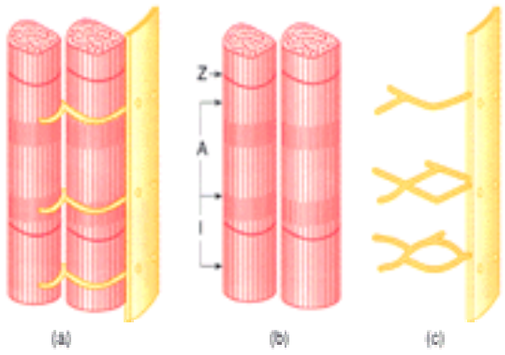

Fig. 8 The T tubules in relation to a sarcomere.

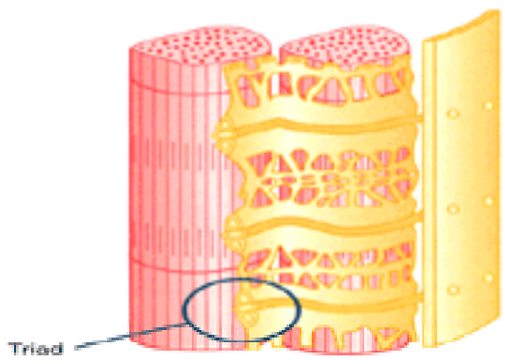

Fig. 9 T tubules, sarcoplasmic reticulum, and the myofibrils. Insert shows the structure of a triad.

Each muscle fibre is bounded by its sarcolemma, the innermost portion of which is the plasma membrane, which is the true boundary of the cell. This surface (plasma) membrane of skeletal muscle has all the properties of selective permeability and transport which are found in other excitable tissues, such as nerve, but it also has a number of distinctive features. Associated with the T-tubular membranes are modified calcium channels, known as DHP receptors as they bind dihydropyridines such as verapamil. These receptors are part of the link between the surface and the sarcoplasmic membranes that couples the passage of an action potential along the surface membrane to the release of calcium from the sarcoplasmic reticulum. The T-tubular membranes also contain a large number of chloride channels that act to stabilize the membrane potential. Where these channels are blocked or absent, as in myotonia congenita, the surface membrane is susceptible to repetitive bursts of firing in response to a single depolarization.

The surface membrane contains a variety of cytoskeletal proteins that may have the additional role of connecting the underlying sarcomere structure to the surface. One of these proteins, dystrophin, is of particular interest as its congenital absence or modification gives rise to the family of muscular dystrophies. How the absence of this one protein causes the fibre damage and degeneration seen in these conditions is not known and remains one of the major challenges in linking molecular genetics to cellular processes (McArdle *et al*. 1995).

Outside the plasma membrane lies the basement membrane, which is not a membrane in the usually accepted sense of the word as it does not have a lipid bilayer structure but consists of a loose glycoprotein and collagen network. The basement membrane is freely permeable and may enclose more than one fibre. Following muscle fibre damage the basement membrane forms a framework within which regeneration may occur.

At the end of a muscle fibre the outer membranes become irregular and indent to form a close link with the connective tissue. The connective tissue elements come together to form the tendons which join muscles to the bony skeleton (Fig. 10).

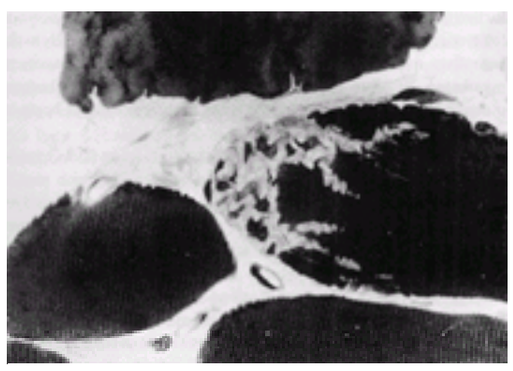

Fig. 10 Myotendinous junction. Low-power electron micrograph.

Situated between muscle fibres are fibroblasts which secrete collagen fibres to form a connective tissue matrix, the endomysium. Groups of 10 to 100 muscle fibres are bound together by a thicker layer of connective tissue, the perimysium, to form fascicles (Fig. 11). Fibroblasts and their major product, collagen, play an important role in maintaining muscle structure. Muscle fibres that suffer irreparable damaged are replaced by collagen fibres secreted by the ubiquitous fibroblasts; massive replacement of muscle tissue by connective tissue can be seen in biopsies from the muscles of patients with advanced muscular dystrophy or steroid-resistant autoimmune muscle disease (Fig. 12).

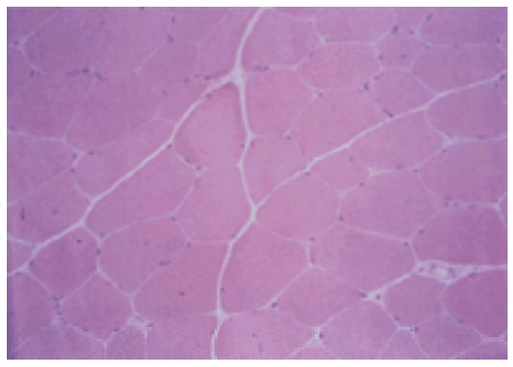

Fig. 11 Transverse section through a portion of human muscle showing delineation of the tissue into fascicles. Light microscopy, haematoxylin and eosin stain.

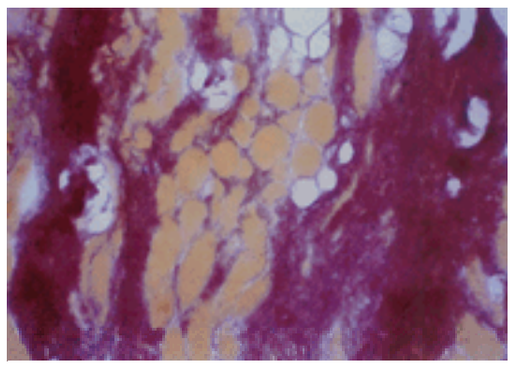

Fig. 12 Transverse section of quadriceps muscle from a 15-year-old boy with Duchenne muscular dystrophy showing replacement of muscle fibres by fibrous connective tissue. Van Geison stain; fibrous tissue stained red, muscle fibres stained yellow.

Small blood vessels and motor axons traverse the perimysial spaces to make contact with the muscle fibres. Muscle spindles, which detect change in muscle length, are also found in the perimysium enclosed in connective tissue envelopes (Fig. 13). Each muscle is covered by a thick outer connective tissue layer, the epimysium.

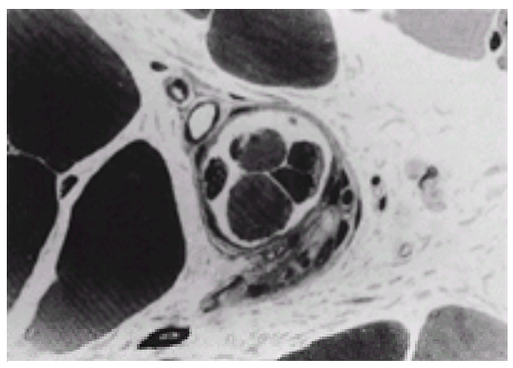

Fig. 13 Low-power electron micrograph of a muscle spindle. The intrafusal spindle fibres are contained within a connective tissue capsule, separating them from the extafusal fibres which make up the bulk of the muscle.

Embryonic origins and fetal development

Skeletal muscle is derived from the embryonic mesoderm. A myogenic fate is imposed on undifferentiated mesodermal cells by the action of a family of myogenic determining factors, the *myf* genes: *myf3* (*MyoD*), *myf4* (myogenin), *myf5*, and *myf6* (*MRF4*) (mouse genes in parentheses) (Buckingham 1992). These helix–loop–helix transcription factors continue to exert a controlling action on the genes encoding many muscle proteins and, together with thyroid hormone, they regulate the sequential development of muscle in the fetus. There is evidence that *myf* genes are also important in the adult in regulating gene expression in damaged and denervated muscle (Buckingham 1994).

At about the sixth week of gestation, mesodermal cells begin to divide and differentiate to form myoblasts. Some myoblasts remain as single cells with mitotic potential, but the majority aggregate and fuse to form primary myotubes attached at their ends to the tendons and the developing skeleton. Within a developing myotube a central chain of nuclei forms (Fig. 14), surrounded by basophilic cytoplasm rich in polyribosomes.

Fig. 14 Cultured myoblasts fuse to form myotubes. Note the chain of central nuclei.

Midway along the primary myotubes further myoblasts aggregate and fuse to form secondary myotubes. At first the primary and secondary myotubes share a common basement membrane (Fig. 15), but eventually the secondary myotubes develop a separate basement membrane, make contact with the tendon, and become independent of the primaries. In the human fetus the transition from myoblasts to primary myotube takes place at around the seventh to ninth week of gestation and by the end of this period the primordia of most muscle groups are well defined. At this time the synthesis of the contractile proteins, actin and myosin, occurs, the first signs of cross-striation are visible (Fig. 16), and contractile activity begins.

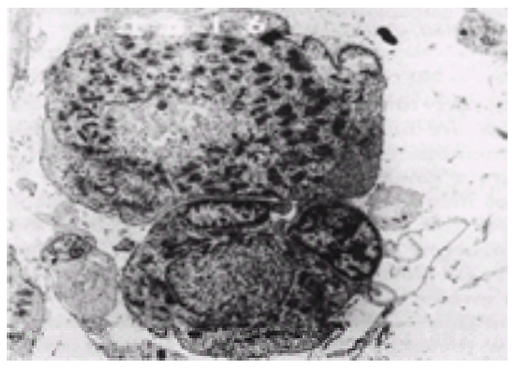

Fig. 15 Developing myotubes. Primary myotube with two attached myoblasts forming secondary myotubes. Electron micrograph of tissue at 9 weeks of gestation.

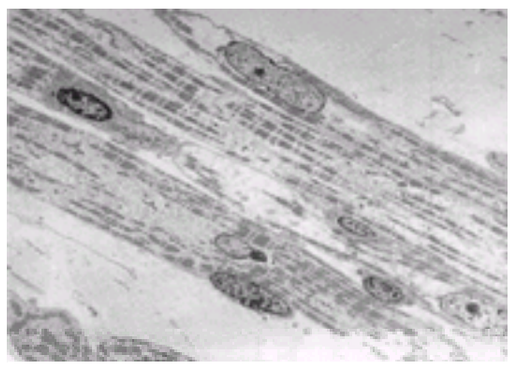

Fig. 16 Longitudinal section of developing myotubes showing the formation of myofibrils. Electron micrograph of tissue at 12 weeks of gestation.

From 11 weeks of gestation onwards there is a proliferation of myofibrils leading to hypertrophy of the muscle fibres, which also grow in length by the addition of sarcomeres at the ends. At 16 to 17 weeks a further population of myotubes becomes apparent and are known as the tertiary myotubes. These myotubes are small, adhere closely to the secondary myotubes, and are enclosed within the same basement membrane. By 18 to 23 weeks the tertiary myotubes have become independent and the nuclei of the more mature myotubes begin to move to the periphery of the fibre.

Under the influence of the *myf* genes the developing fibres express a number of different myosins which can be identified with monoclonal antibodies; these myosins include an embryonic form and an intermediate fast type that confers the properties of the type 2c fibres (often seen in regenerating adult muscle) when stained for myosin ATPase. The primary myotubes can be identified throughout embryonic development as they alone express adult slow myosin from about 9 weeks of gestation (Drager *et al*. 1987). At around 10 weeks the nervous system makes contact with the developing muscle fibres and, in response to the contractile activity imposed by the motor nerve, the fibres differentiate so that, eventually, fetal myosins are no longer expressed and about 50 per cent of fibres contain adult slow myosin and 50 per cent fast myosin. This process, which is apparent by about 32 weeks of gestation, is not fully completed in human muscle until a few months after birth.

Satellite cells

Integral to the growth of skeletal muscle and its recovery after damage are the satellite cells, first described by Mauro (1961).

During development of skeletal muscle some of the mesodermal cells fail to fuse but remain closely apposed to the walls of the developing myotubes. These undifferentiated myoblasts are eventually enclosed by the basement membrane of the mature muscle fibres but remain outside the sarcolemma and are known as satellite cells. Under the light microscope it is very difficult to distinguish muscle fibre nuclei from the 5 to 10 per cent of nuclei that belong to satellite cells, but with the electron microscope the position of the satellite cells beneath the basement membrane, but outside the plasma membrane, of the muscle can be seen (Fig. 17). If the muscle fibre suffers damage, the satellite cells are activated to divide, form new myonuclei, and begin the process of regeneration.

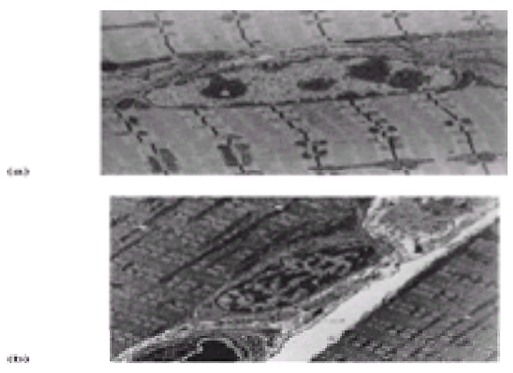

Fig. 17 Muscle fibre nucleus and satellite cell. (a) Muscle fibre nucleus lying just below the plasma membrane of the muscle cell. (b) Satellite cell lying outside the plasma membrane with a layer of cytoplasm around its nucleus.

Satellite cells isolated from both regenerating and non-regenerating muscle can be distinguished from embryonic myoblasts on the basis of their myosin heavy-chain expression, they also differ in their expression of desmin, an integral membrane protein, and enolase, a glycolytic enzyme. These differences suggest that mature satellite cells are a distinct class of myogenic cells. There is also some differentiation of function within the satellite cell population, some cells functioning as stem cells while others seem readily available to fuse and form new myotubes (Schultz and McCormick 1994).

In the new-born child about 30 per cent of nuclei are satellite cells, but this number decreases to between 5 and 10 per cent in mature muscle. Satellite cells are more plentiful in oxidative fibres in all mammals examined and more common in the region of the motor endplates (neuromuscular junctions) where the motor axon makes contact with the muscle fibre (Fig. 18).

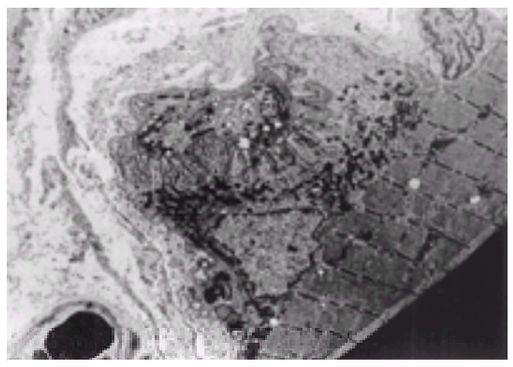

Fig. 18 Neuromuscular junction under low-power electron microscopy. There is only one neuromuscular junction per muscle fibre, the appearance is of very regular infoldings of the muscle plasma membrane.

Satellite cells are fusiform in shape, about 25 µm in length in most mammals, and using electron microscopy, it can be seen that there are multiple branches emanating from their poles. It appears that these branches are connected with the ability of satellite cells to migrate within the basement membrane (Schultz 1976). No evidence has been found that satellite cells communicate in any way with the fibres to which they are adjacent, they appear to be separate entities. Rare reports of cytoplasmic continuity appear to be associated with the proliferation of new myotubes rather than with communication between satellite cells and mature muscle fibres

Vital stains, and antibodies to membrane proteins are now available to aid recognition of satellite cells. Human satellite cells express the neural cell adhesion molecule (NCAM) cell-surface glycoprotein but not its embryonic form (ECAM) when muscle is growing. In regenerating muscle both NCAM and ECAM are expressed, while another marker of activation is upregulation of the *myf* genes. The use of tritiated thymidine and bromodeoxyuridine as nuclear labels in experimentally damaged animal preparations has enabled dividing satellite cells to be identified and, using this technique, the numbers of cells activated after a particular injury has been calculated (Schultz 1989).

In tissue culture, satellite cells respond to fibroblast growth factor, insulin-like growth factor 1, transforming growth factor, platelet-derived growth factor, adreonocorticotropin hormone, and melanocyte-stimulating hormone.

The response of satellite cells to these factors is variable among species and between different cultures of cells. Some of these factors, such as insulin-like growth factor 1 and fibroblast growth factor, are present in muscle *in vivo*, and receptors for insulin-like growth factor 1 have been demonstrated on satellite cells. It is probable that they play some role in satellite cell proliferation and fusion during growth.

To date the only known function of satellite cells in mature muscle is the production of new myonuclei and the initiation of new myotube formation, although recent work has suggested that, in early development, they may play a role in the production of the extracellular matrix proteins, fibronectin and laminin (Schultz and McCormick 1994).

The appearance of activated satellite cells is a good indication of perturbation occurring in a muscle, such as damage or the stimulus for growth. In rats the response to injury begins after several hours with the expression of myoD and myogenin. Proliferation of nuclei occurs after about 24 h and new myotubes begin to develop. Successive cycles of damage lead eventually to a reduction in the numbers of satellite cells and in the efficiency of the remaining population. This fact may provide an explanation for the decline in regenerative ability seen in the muscles of patients with advanced Duchenne muscular dystrophy (Webster and Blaud 1990) or chronic inflammatory muscle disease that is not responsive to steroids. The number of satellite cells which survives each cycle of damage also depends on the way in which the myofibres were killed; experiments with animals have shown that satellite cells do not survive ischaemic damage any better than other cells, and repair of the muscle fibres is initiated by satellite cells which migrate from adjacent undamaged areas of the muscle. Migration occurs extensively along the longitudinal axis of a muscle while only a small amount of transverse migration can occur. When muscle is injured its entire satellite cell population can potentially be recruited to aid in repair. Migration between muscles is very limited, so that the ability of a muscle to regenerate depends on its intrinsic satellite cell population.

The size of adult muscle

The number of fibres in each human muscle is probably set by 24 weeks of gestation. In the rat, fibre numbers do not change during life while the mean fibre cross-sectional area increases nearly 10-fold from the new-born to adult animal (Rowe and Goldspink 1969). There are considerable practical and ethical problems involved in making measurements of fibre size and number in children and adults, but the limited data available suggest that there is an increase in size without a change in fibre numbers (hypertrophy without hyperplasia) as the muscles grow in size and strength. The final cross-sectional areas of adult muscle fibre are reached shortly after puberty (Fig. 19). In an adult man about 40 to 45 per cent of the body weight is muscle and this figure is slightly lower for women. The mean cross-sectional area of fibres in a biopsy from the quadriceps muscle in a normal man is about 3500 to 7500 µm ^{2} and in the normal woman from 2000 to 5000 µm^{2}.

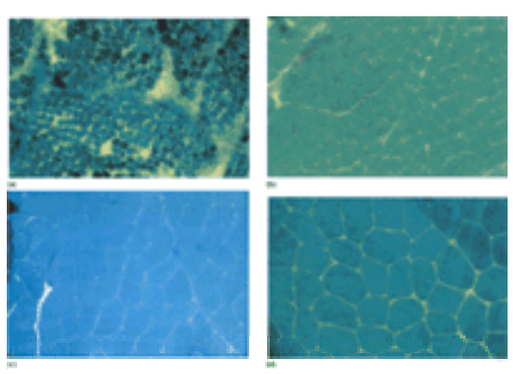

Fig. 19 Growth of muscle fibre size in the human quadriceps. (a) In a baby aged 8 months. (b) In a child of 5 years. (c) In a boy aged 14 years. (d) In an adult male. All at the same magnification.

Innervation of muscle fibres

In a mature muscle, one motor neurone will, through axonal branches, supply a number of fibres scattered throughout the muscle. In a healthy muscle the innervation is almost entirely random and adjacent fibres are likely to be supplied by branches from different motor neurones. All the muscle fibres supplied by one motor neurone form a motor unit (Fig. 20). The number of fibres constituting a motor unit varies from muscle to muscle and may be as few as 10 fibres in a small muscle of the hand to several thousand in a large muscle like the quadriceps. The finer the control of movement, the smaller are the motor units.

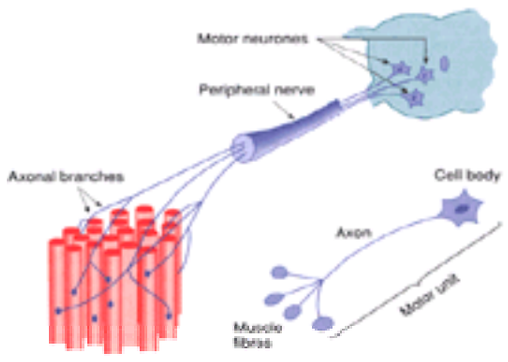

Fig. 20 The concept of the motor unit. A motor unit consists of the motor neurone and all the scattered muscle fibres which it innervates.

Loss of innervation by trauma or by death of the motor neurone, as in motor neurone disease, causes severe atrophy and ultimately necrosis of the deprived fibre if the muscle fibres are not reinnervated by another healthy axon.

Muscle fibre types

Muscle fibres fall into groups determined by their biochemical and physiological properties which are in turn determined by the type of motor neurone controlling the motor unit to which they belong. Various histochemical stains can be used on sections of unfixed frozen muscle to differentiate different fibre types, the most commonly used are the myosin ATPase stain with preincubation at either acid or alkaline pH and the NADH tetrazolium reductase or succinate dehydrogenase stains for mitochondrial activity. An indicator of glycolytic activity, such as myophosphorylase, is commonly assessed (Fig. 21). Three main fibre types can be identified. Type 1 (slow oxidative) fibres with low myosin ATPase activity at alkaline pH, high mitochondrial content, and relatively low glycolytic enzyme activity. Type 2 fibres (fast glycolytic) which stain darkly with myosin ATPase at pH 9.4 and have high glycolytic but lower mitochondrial content than type 1 fibres. The type 2 fibres can be subdivided into 2a and 2b, the former having a higher mitochondrial content and being more fatigue resistant. These two fibre subgroups can be differentiated by the myosin ATPase stain at pH 4.3 and 4.6 (Table 1).

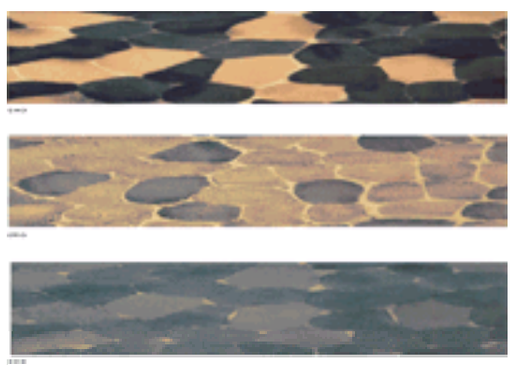

Fig. 21 Serial transverse sections of human quadriceps muscle stained with (a) ATPase at pH. 9.4, (b) NADH tetrazolium reductase for mitochondrial activity, and (c) for phosphorylase. Fibres high in phosphorylase are low in mitochondrial activity and stain darkly (type 2) with ATPase at pH 9.4.

	Muscle fibre type			
Stain	**1**	**2a**	**2b**	**2c**
ATPase (pH 9.4)	1+	3+	3+	3+
ATPase (pH 4.6)	3+	0	3+	3+
ATPase (pH 4.3)	3+	0	0	2+
NADH-TR	3+	2+	1+	2+
Phosphorylase	1+	3+	3+	3+

NADH-TR, NADH tetrazolium reductase is a stain for mitochondrial activity. Numbers indicate intensity of staining.

Table 1 Histochemical staining of human muscle fibre types

The broad classification of skeletal muscle fibres into three main types is adequate for most purposes when considering normal and pathological situations, but recent investigations show that there are complex combinations between the *myl* and other genes which control the expression of contractile proteins and, especially with the fast fibres, there can be variable amounts of mixed gene expression in single fibres.

Contractile properties

Fast muscles rapidly develop force and also relax more rapidly than do the slow muscles. The fast extensor digitorum longus muscle of a mouse, when stimulated at a frequency of 10 to 20 Hz, reacts quickly enough for the tension to fall back to the baseline before the next impulse, but in the slower soleus muscle the next impulse comes before relaxation is complete and the contraction is superimposed on the tension remaining from the previous stimulus. In this way the individual twitches are said to summate or fuse. When stimulated at a sufficiently high frequency the muscle will produce a smooth plateau of force. The frequency required to achieve this plateau is known as the fusion frequency and this frequency is higher for fast compared with slow muscles (Fig. 22).

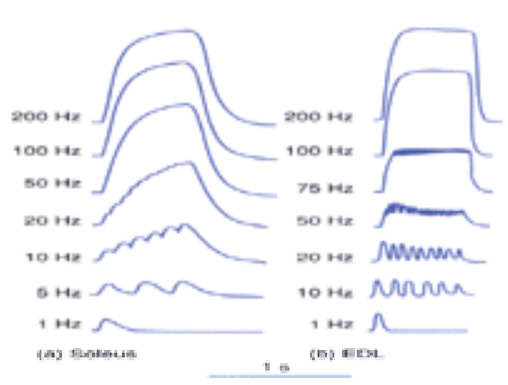

Fig. 22 Force generated during a 500-ms tetanus at different frequencies (isolated muscles, 25°C). (a) Mouse soleus; (b) mouse extensor digitorum longus.

As first recorded by Ranvier (1873), there is a clear connection between the appearance and the contractile properties of certain skeletal muscles, such as the red and white muscles of a chicken or the soleus and extensor digitorum longus in a mouse. These muscles are, however, somewhat unusual in consisting predominantly of one fibre type while the majority of skeletal muscles are a mixture of different types.

In animal preparations it is possible to characterize the functional properties of individual motor units in a muscle and, on the basis of size, speed, and fatiguability, they are found to fall between two extremes: large, fast, and fatiguable; or small, slow, and fatigue resistant (Fig. 23) (Table 2) (e.g. Burke *et al*. 1971) and all the evidence indicates that a similar type of organization applies to human muscle.

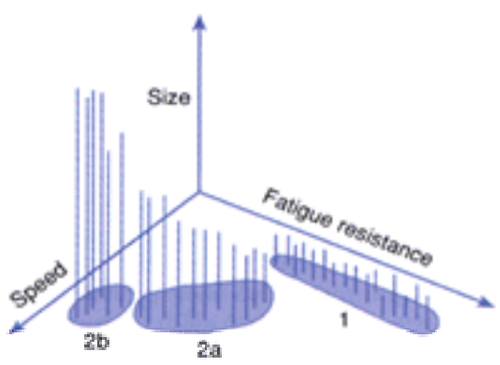

Fig. 23 Contractile properties of motor units. The size, speed, and fatigue resistance of different types of motor unit, as defined by their histochemical properties.

Type	Guinea pig and rabbit	Cat
1	**SO** Slow twitch Oxidative	**S** Slow twitch
2a	**FOG** Fast twitch Oxidative/glycolytic	**FR** Fast twitch Fatigue resistant
2b	**FG** Fast twitch Glycolytic	**FF** Fast twitch Fatiguable

After Burke *et al*. 1971; Peter *et al*. 1972.

Table 2 The relationships between histochemical fibre type classification and physiological properties; two ways are given of classifying the physiological properties

Examining the histochemical properties of the motor units shows that large units tend to be made up of type 2b fibres while the small slow units are predominantly composed of type 1 fibres. Type 2a motor units span a range of size and fatigue resistance which is reflected in the broad spectrum of their mitochondrial enzyme activities.

After severe traumatic damage, muscle fibres regenerating from active satellite cells within the basement membrane will express early myosins as they develop, the final myosin expression being determined through the neuromuscular junction by the motor nerve branch. If reinnervation follows the death of the motor neurone and loss of the muscle fibres constituting its motor unit, regenerating fibres may be innervated in a nonrandom fashion. This type of regeneration leads to muscle fibre grouping which can be detected with histochemical stains (Fig. 24(a)) and by giant action potentials on an electomyographaph (Fig. 24(b)).

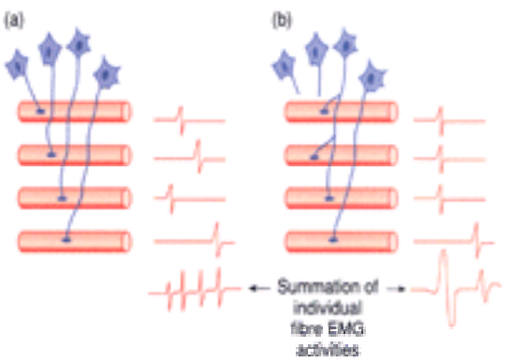

Fig. 24 (a) Normal muscle with fibres innervated by different motor neurones. The activity recorded is the summation of asynchronous activity in the fibres. (b) Muscle after denervation and reinnervation. A single motor neurone supplies a group of fibres giving a giant action potential.

Length–tension relationship

There are two components of the total force that can be measured: the passive tension which is due to stretching the connective tissue elements of the muscle and, possibly, the structural protein, titin; and the active tension which is superimposed on the passive tension when the muscle is stimulated (Fig. 25). In the discussion that follows we are concerned only with the active tension, the passive component being subtracted from the total force.

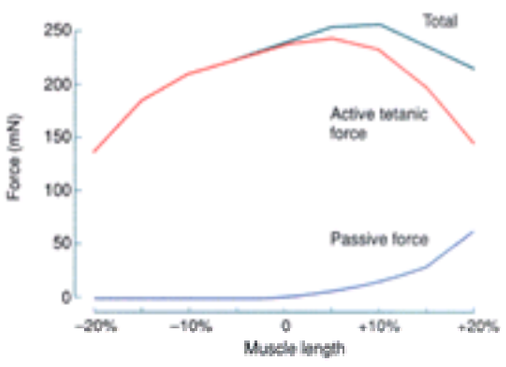

Fig. 25 The two components of force, passive and active tension. Total force is the sum of the two components. Mouse soleus muscle, 26°C, stimulated at 100 Hz.

The main feature of the length–tension relationship is that force declines on either side of an optimum length and, by extrapolating the line at longer lengths, a value can be predicted at which no tension would be generated. This value corresponds to the point where the thick and thin filaments no longer overlap.

Force–velocity characteristics

As the velocity of shortening increases so the force sustained by a muscle rapidly diminishes, eventually reaching a velocity at which force can no longer be sustained at all; this is the maximum velocity of unloaded shortening (v_{max}).

The force at zero velocity of shortening (isometric force) is often referred to as P_0. Muscles of different sizes and therefore different isometric strengths can be compared by expressing the force (P) at a particular velocity as a fraction of P_0.

Force during muscle stretch

In the body, muscles work in pairs, while one muscle shortens its antagonist is stretched, and many movements, such as walking down stairs or lowering weights, involve the extension of active muscles (Fig. 26(a)). The force generated during this type of movement is considerably greater than the isometric force (Fig. 26(b)) and varies with velocity. With increasing velocity of stretch, force begins to plateau, reaching a value of about 1.8 times the isometric force (Fig. 27).

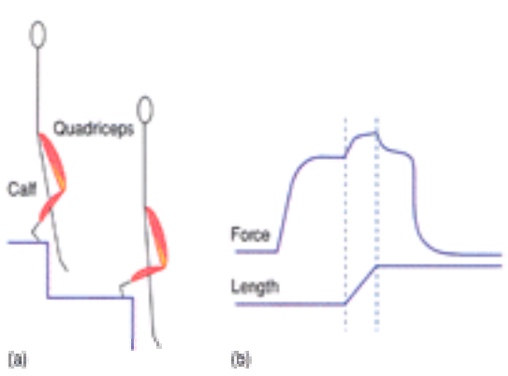

Fig. 26 Stretching muscles. (a) The quadriceps and calf muscles are stretched when lowering the body weight down a step. (b) Mouse soleus muscle stimulated to develop maximum isometric force and then stretched at a constant rate.

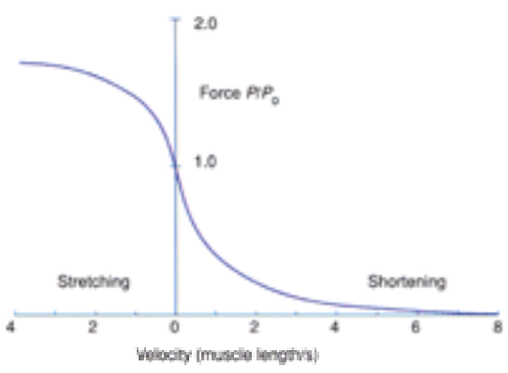

Fig. 27 Force of mouse soleus muscle during stretch and shortening at 26°C.

The overall shape of the curve shown in Fig. 27, with force increasing with stretch and decreasing with shortening, may have important consequences for the stability of sarcomeres acting in series. If one sarcomere is stronger than the next, it might be imagined that the stronger would pull out and extend the weaker, eventually destroying the fibre. However, this is not the case, as when the sarcomeres begin to move, the force generated by the stronger will fall as it shortens (moving down the right-hand portion of the curve in Fig. 27) while the force of the weaker sarcomere will increase as it is stretched (moving up the left-hand side of Fig. 27). Consequently, sarcomeres of unequal strength (due to differences in length, activation, or even damage) can coexist and function to transmit force along the length of the fibre. This holds true when the muscle is working on the left-hand side of the length/tension curve. When a muscle fibre is held at longer lengths, differences in sarcomere lengths along the length of the fibre may be such that this mechanism cannot stabilize the fibre, and shorter and stronger sarcomeres towards the ends of the fibre will pull out and possibly damage the longer weaker sarcomeres in the middle.

ATP splitting during contraction

During an isometric contraction there is no movement, no external work is done by the muscle, and all the energy liberated appears in the form of heat. During shortening, heat is still produced but the muscle also performs work which is the product of the force and distance moved. It was first observed by Fenn in 1923 that during shortening the total energy liberated, in the form of heat plus work, is greater than that occurring during an isometric contraction (Fenn effect) (Fenn 1923). However, heat production falls to low values when muscle is stretched, a fact first noticed by Fenn. More recently, Curtin and Davies (1973) showed that ATP splitting was likewise very low during stretching (Fig. 28).

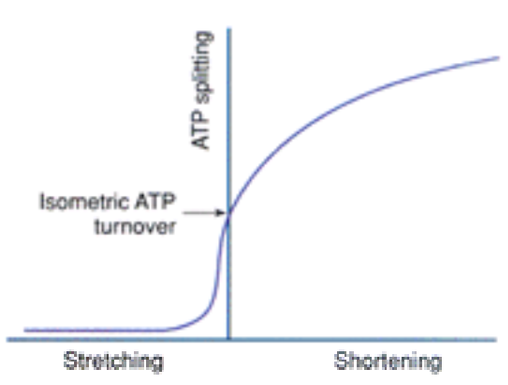

Fig. 28 ATP turnover in muscle allowed to shorten or while being stretched.

Ageing and muscle function

During and after the fifth decade there is a marked loss of muscle mass and a decrease in strength which is particularly notable in women when their hormonal

balance is changed after the menopause. The loss is less severe in men below the age of about 70 years. The more rapid loss of muscle mass in women is reflected in a similar change in bone, with women being much more susceptible to osteoporosis than men.

The loss of muscle in elderly individuals appears to be progressive and by the age of 90 years muscle mass can be reduced by 30 per cent. The loss of muscle bulk is reported to be greater than can be accounted for by atrophy of the muscle fibres, indicating that fibre numbers may be reduced (Grimby and Saltin 1983). It has been suggested that just as neuronal loss from the brain causes memory impairment in the elderly, so loss of motor neurones from the anterior horn causes a loss of motor units. In elderly rats there is a preferential loss of the fast motor units, suggesting that the fast motor neurones may be more susceptible to the processes of ageing. The consequence of this loss is that the slow motor units become larger as a result of reinnervation of the previously fast fibres by axon branches from slow motor neurones, and the slow fibres may become larger as a result of greater use (Kanda and Hashizume 1989). It is likely that a similar process occurs in ageing human muscle.

Histochemical examination of muscle specimens taken at autopsy from elderly subjects with no reported neurological symptoms frequently show areas of fibre type grouping that suggest some neurogenic disturbance has occurred (Fig. 29). These appearances could also be due to peripheral damage to motor nerves. It is of interest that the small muscles in the foot can show clear evidence of neuropathic change with increasing age, which is thought to be a consequence of wearing shoes. Increased collagen cross-linking and lipofuchsin deposits in the muscle are also common findings. Whatever its cause, the loss of muscle may eventually become disabling so that subjects cannot rise from a chair or visit the toilet unaided. A decrease in mobility is an important cause of loss of independence and postponing its onset will become increasingly important as the number of elderly people surviving in the population increases. There is no evidence that habitual exercise can help to prevent the changes associated with ageing although, by preserving cardiac and respiratory function, regular exercise will help the elderly make the best use of the muscle that remains.

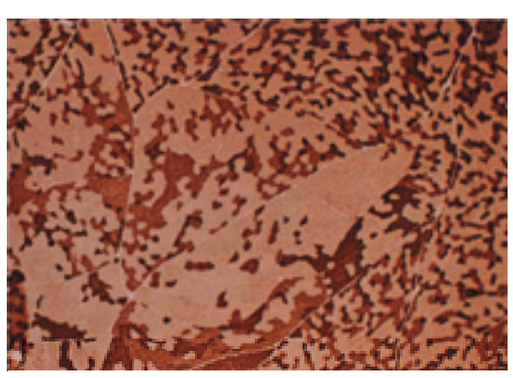

Fig. 29 Adductor pollicis muscle of the hand from an 80-year-old woman with no clinical or neurological signs. Transverse section of an autopsy sample, several fascicles consist largely of only type 1 fibres indicating reinnervation. ATPase stain at pH 9.4.

When examining muscle biopsy specimens from elderly patients with suspected muscle pathology, the fact that reduced fibre areas and some evidence of muscle fibre grouping are common findings in ageing muscle and do not point to any specific pathology should be borne in mind.

Methods of measuring damage

The most common presentation of muscle damage is weakness, sometimes accompanied by myalgia, often of specific muscle groups. If weakness is found it is valuable to quantify the degree in order to have a measure of severity and of progress and recovery with treatment. Simple functional tests such as the ability to rise from a chair or squatting position or stand on tiptoe are useful guides to strength but more objective measures are desirable. There are a variety of commercially available machines that allow measurements at different angles and speeds of contraction, but in clinical practice it is probably most useful to assess the isometric strength (isometric means the same length, i.e. with the muscle unable to move) in a relatively simple testing chair (e.g. Edwards *et al*. 1977; Fig. 30). These techniques are relatively easy to apply and reliable measurements can be made even on children after the age of 5 or 6 years.

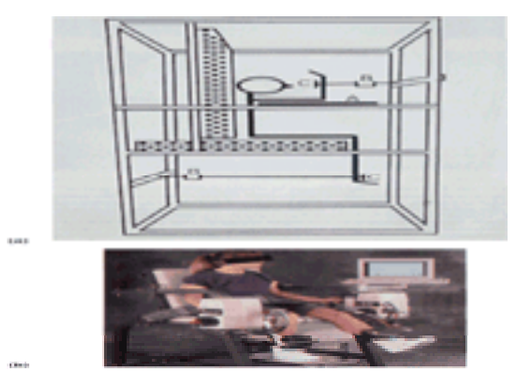

Fig. 30 (a) Diagrammatic representation of apparatus for measuring isometric strength of the quadriceps and elbow flexors. The subject is firmly held in the chair with a strap around the hips. (b) Cybex isokinetic strength testing chair.

Just as is the case with damaged cardiac muscle, damaged skeletal muscle fibres will leak soluble constituents into the circulation and the measurement of enzymes such as creatine kinase or lactate dehydrogenase in the blood can give valuable backup to clinical examination. Both creatine kinase and lactate dehydrogenase have specific muscle isoenzyme fractions which, if measured, allow effluxes from skeletal muscle to be distinguished from enzyme coming from cardiac muscle or other tissues. Myoglobin can also be used as a marker. It appears in the circulation somewhat sooner than creatine kinase but it is an expensive assay and provides little or no clinical advantage over the measurement of creatine kinase.

Histological examination of a muscle biopsy specimen from large muscle groups such as the quadriceps or gastrocnemius, obtained either by the percutaneous needle or choncotome technique, can often provide a diagnosis (Fig. 31). For smaller muscle groups it may be necessary to perform an open biopsy.

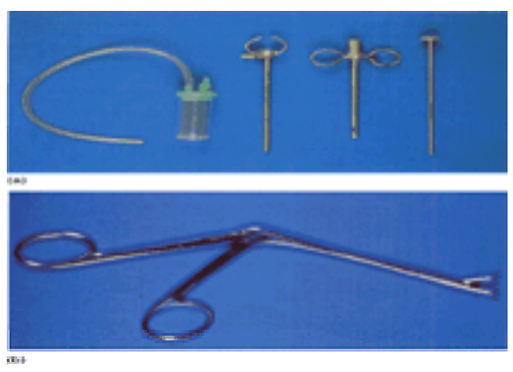

Fig. 31 (a) The University College Hospital (UCH) modification of Bergstrom's original percutaneous muscle biopsy needle. The cutting edge of the inner hollow cylinder is introduced within the outer pointed casing which contains a window at its lower end through which the muscle biopsy is taken. The sterile trap is attached

to a suction mechanism which assists in pulling the muscle tissue into the outer window. The central solid portion of the instrument is used only to remove the specimen after the needle has been withdrawn. (b) Conchotome forceps for percutaneous muscle biopsy.

Electromyograms from weak or myalgic muscle groups can also provide valuable information in confirming a diagnosis. Recording electomyogram activity from an affected muscle group is particularly useful in differentiating myopathic from neuropathic conditions. Polyphasic potentials tend to be seen in inflammatory myopathies while giant potentials are characteristic of neuropathies where muscle fibre grouping has occurred.

Mechanisms of damage

Damage to skeletal muscle can occur in healthy subjects after exercise or accident, as a secondary complication of disease, or as the result of pathology affecting either motor nerves or the muscle fibres themselves. For those whose primary interest is in rheumatic disease the two latter types of damage will be of greatest interest, but details of exercise-induced and ischaemic muscle damage will be helpful in later discussions of the muscle pathologies which occur in polymyositis, polyarteritis nodosa, systemic lupus erythematosus, and other related conditions.

Although the primary causes of muscle damage are varied, there is general agreement that the final stages of muscle cell death are brought about by a combination of relatively few pathways. These pathways are loss of ATP energy supply, loss of intracellular calcium homeostasis, and overactivity of reactions mediated by oxygen free radicals. Microscopically, these processes are revealed as muscle fibre necrosis with increases in lysosomal enzyme concentrations and invasion of the tissue with mononuclear cells.

A fall in intracellular ATP is associated with cell death, probably due to interference with the functions of the muscle cell membrane which leads to an efflux of soluble proteins from the muscle accompanied by an influx of calcium ions. Calcium accumulation will lead to mitochondrial overload and failure of oxidative metabolism which can further exacerbate the situation. Raised intracellular calcium will also stimulate calcium-activated proteases and phospholipases which cause further membrane disruption and a vicious circle of damage leading to final cell death. Abnormal mitochondrial function with poor metabolism of fatty acids can lead to the production of free radical species which will also damage cellular membranes by lipid peroxidation (Fig. 32).

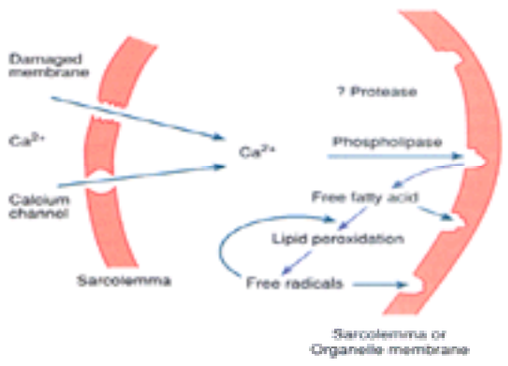

Fig. 32 Suggested mechanisms of muscle damage. Calcium entry may activate phospholipases and, possibly, protease enzymes. The free fatty acids liberated will, in turn, have a detergent effect on cell membranes and can be the substrate for free radical attack.

It is now important to examine the different ways in which this final common pathway of damage can be activated.

Damage due to physical trauma

Skeletal muscles are frequently subjected to physical trauma during everyday life and this risk is increased with participation in contact sports. There is little information about the extent of muscle fibre damage occurring as the result of bumps and bruises, but it is probable that most of the painful sensations experienced are due to inflammation of the skin, subcutaneous tissues, and the muscle fascia, with relatively little involvement of the muscle fibres.

After severe crush injuries or in cases where a patient has been found lying unconscious on a hard surface for some hours, severe muscle fibre necrosis (rhabdomyolysis) can occur with the release of intracellular proteins including myoglobin into the circulation, and a serious risk of subsequent acute renal failure due to precipitation of this muscle protein in the proximal renal tubules. Part of the mechanism which causes rhabdomyolysis in this situation may be that large areas of muscle are rendered ischaemic while the patient is lying for hours in one position and subsequently become reperfused (see below). The measurement of myoglobin in the laboratory is time consuming and expensive and the more commonly estimated soluble muscle protein is creatine kinase, although lactate dehydrogenase and aspartate transaminase are also indicators of muscle damage and are raised in parallel with creatine kinase.

Metabolic depletion

Large metabolic fluxes occur during intense exercise and it is natural to wonder whether excessive metabolic depletion leads to long-lasting changes in muscle which might be classified as damage.

Work with isolated muscle preparations subjected to prolonged damaging stimulation has shown that a build-up of calcium occurs within the muscle fibres, followed by an efflux of soluble enzymes and structural damage to the cells (Jones *et al*. 1984). The raised internal calcium leads to a stimulation of phospholipases which damage the cell membranes. The liberated free fatty acids are then oxidized leading to the production of free radicals, highly reactive species which can initiate a chain reaction leading to further membrane damage (Fig. 32).

Damage during fatiguing exercise

There is little evidence that conventional exercise testing such as work on a cycle ergometer or treadmill leads to significant muscle damage. Heavy exercise of this type maintained for several hours can lead to a rise of two or three times normal in circulating creatine kinase, reaching a peak about 24 h after exercise with a rapid return to normal within 48 h. In the late 1970s the possibility was explored that patients with various muscle disorders might have their condition exacerbated in response to a standard exercise protocol (Brooke *et al*. 1979) and, although some abnormalities were found, it was concluded that significant damage was not incurred in patients after this standard protocol. In healthy subjects, conventional hard work such as running uphill or working against a high load on a cycle ergometer, although metabolically depleting, produced very little muscle damage.

Damage due to eccentric exercise

Although a marked transient (two to three times the upper limit of normal) rise in plasma creatine kinase may occur after any heavy exercise, the most interesting and the most damaging exercise is that in which the muscle is extended while lowering the body weight; many movements, such as walking down stairs, lowering weights, when a person runs downhill, or in an experimental situation when a subject walks backwards down a treadmill, involve the extension of active muscles. This type of exercise is often termed 'eccentric' or plyometric.

The force generated during this type of movement is considerably greater than the isometric force and varies with velocity (see above). After this type of exercise the muscle is weak and some reduction in force can persist for 2 or 3 weeks in severely damaged muscle, subsequently there is a steady return to normal strength.

There are two major consequences of eccentric exercise which remain unexplained despite the considerable attention devoted to its investigation during the last 10 years. The first is the origin of the characteristic pain and tenderness experienced 1 or 2 days after an unaccustomed bout of heavy exercise which contains an eccentric component and with which most of us will be familiar. The second is the nature of the mechanism that causes the delayed rise in plasma creatine kinase which peaks at about 5 or 6 days after the exercise and subsequently falls to normal but precedes the muscle cell damage which is not apparent histologically until about 10 days after the exercise.

Muscle pain after eccentric (plyometric) exercise

During eccentric exercise the subject is aware of high forces generated in the muscle and tendons, but there is no burning sensation like that produced in muscles by metabolically demanding high-intensity isometric or concentric activity such as running up a long flight of stairs. After about 20 min of eccentric activity the subject usually notices a loss of force and increased tremor accompanied by an inability to fully flex or extend the affected limb. These sensations are generally described as unusual but not as painful. By 6 to 12 h after exercise, discomfort develops in the exercised muscles and typically the subject notices pain the morning after the exercise. The major sensation is not of continuous pain but of discomfort elicited by pressure on the affected muscle. Some degree of muscle oedema is also present. The degree of discomfort may be quantified by measuring the pressure required to elicit a painful response (Fig. 33).

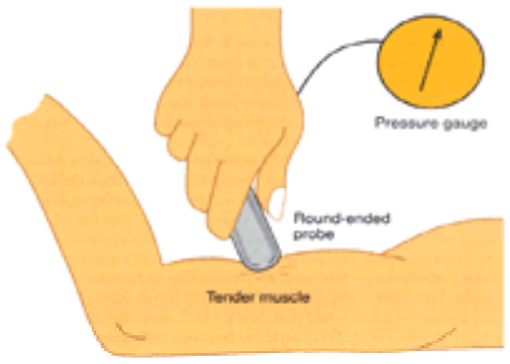

Fig. 33 Quantitative assessment of muscle tenderness. A round-ended probe attached to a pressure transducer is pressed into the muscle and the pressure recorded at which pain is first felt.

Associated with the tenderness is a feeling of muscle stiffness which limits the range of movement of the limb. Electromyography of the affected limb has not demonstrated any unusual electrical activity.

Damage after eccentric (plyometric) exercise

The most intriguing feature of muscle damage induced by eccentric exercise is the delay which occurs in many subjects between the end of the precipitating exercise and the evidence of damage in terms of both the leakage of soluble constituents from the muscle fibres and the necrosis and regeneration visible microscopically in a biopsy of tissue from the affected muscle.

A delay of some hours might be explicable in terms of slow diffusion of large proteins into the general circulation, as seen with the appearance of cardiac damage after infarction. However, following eccentric exercise there is usually a delay of about 2 days before any change is seen and the peak response is seen 4 to 6 days after the exercise (Fig. 34). Observations on patients undergoing orthopaedic surgery during which large amounts of muscle are either cut or at least roughly handled have shown relatively small increases in plasma creatine kinase, which reached peak levels 1 or 2 days after the operation (Fig. 35) (Jones *et al*. 1991), so there is a clear difference between the time course of damage caused by eccentric exercise and that provided by direct physical trauma to muscle fibres. The delay between exercise and damage could be explained if the exercise were to cause an initial change in the muscle which was amplified over the next few days until it resulted in muscle necrosis. There are a number of changes in the structure and contractile characteristics of the muscle which may be indicators of this initial damage. Immediately after the exercise, changes such as Z-line streaming (Fig. 36) and sarcomeres that have the appearance of being pulled apart can be seen in the ultrastructure of the muscle. These changes may be limited to isolated sarcomeres or wider areas of disruption may be seen (Friden *et al*. 1983). Immediately after eccentric exercise there is a loss of maximum voluntary isometric force which is not connected with pain or loss of central drive as similar force loss is seen with high frequencies of stimulation. The loss of strength and contractile properties persists for hours and sometimes for days (Newham *et al*. 1983a). Long-lasting alterations in function are generally ascribed to 'damage' rather than 'fatigue' since the latter carries with it the implication that recovery will occur within a period of minutes rather than hours. These long-lasting changes have been taken as evidence of 'microdamage' to the muscle fibres which, if of sufficient magnitude, could have a cumulative effect overwhelming the capacity for repair and leading to necrosis of a segment or the whole of the muscle fibre.

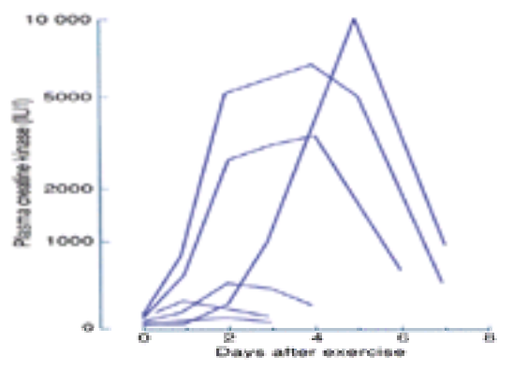

Fig. 34 Plasma creatine kinase levels following 30-min stepping exercise. Subjects stepped on and off a stool adjusted to just above knee height at a frequency of 15 cycles per minute using, every time, the same leg to step up and the opposite to step down.

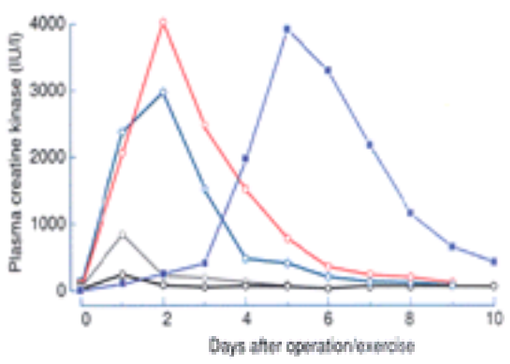

Fig. 35 Plasma creatine kinase (CK) measured in patients undergoing a range of orthopaedic operations. The values are compared with those obtained from one subject (■) who had undertaken eccentric exercise of the biceps.

Fig. 36 Electron micrograph of skeletal muscle after eccentric exercise to show Z-line streaming.

One of the first descriptions of Z-line streaming and sarcomere disruption as a consequence of eccentric exercise was made from observations on biopsies from the quadriceps muscles of subjects who had undertaken stepping exercise (Newham *et al*. 1983b). It was noted at the time, although not commented on, that there was no correlation between the extent of damage seen with electron microscopy and the subsequent creatine kinase release. In a further series of experiments using radioactive technetium pyrophosphate to identify damaged muscles, it was shown that as a result of stepping exercise the gluteus and one of the adductor muscles was affected, but not the quadriceps muscle (Newham *et al*. 1986).

Thus there is evidence of microscopic damage to the quadriceps which does not progress to full-scale degeneration of the muscle fibres (although it is still possible that gross muscle damage only ensues if some threshold is exceeded). The Z-line streaming and disruption of sarcomere structure probably includes damage to the sarcoplasmic reticulum and T-tubule systems and it is reasonable to assume that the immediate loss of force and change in the force/frequency relationship are reflections of the extent of this damage. Assuming that changes in contractile properties are indicators of 'microdamage', it has been noted that these changes do not correlate well with the extent of subsequent fibre degeneration, as indicated by creatine kinase release. This inconsistency is illustrated well by considering the effects of training. Figure 37 shows the loss of strength after a series of bouts of exercise at 2-week intervals (Newham *et al*. 1987). On each occasion the initial loss of force approached 50 per cent with recovery taking a little over a week and a very similar pattern of change was seen with the force/frequency relationship. Figure 38 shows the very different pattern of creatine kinase release from the exercised muscle between the first and the two subsequent bouts of exercise. After the first exercise session there was a large release of creatine kinase into the circulation with individual values ranging from 1570 to 10 904 IU/l (upper limit of normal 200 IU/l), reaching a peak at 5 days and returning to base levels within 10 days. Following the second and third exercise sessions there was no significant increase in circulating creatine kinase, indicating that the muscle had become resistant to the dramatic destructive process. This finding is in contrast to the changes that occurred in the contractile properties of the muscle with training and shows quite clearly that if microdamage is responsible for the changes in contractile properties it is unlikely to be a precursor of the delayed-onset muscle degeneration, especially as the extent of the initial force loss was so similar on the three successive occasions.

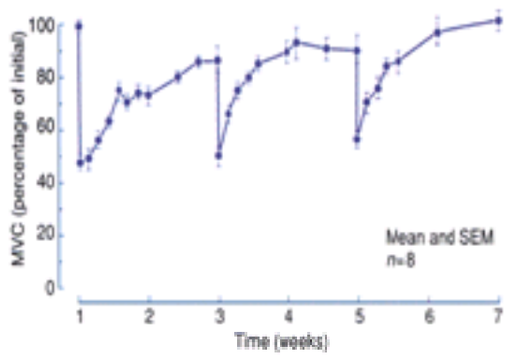

Fig. 37 Changes in strength with repeated exercise. Eight subjects exercised their forearm flexors with maximal eccentric contractions, repeating the exercise every 2 weeks. Maximum isometric strength was measured at regular intervals and the results are expressed as a percentage of the strength before the first period of exercise.

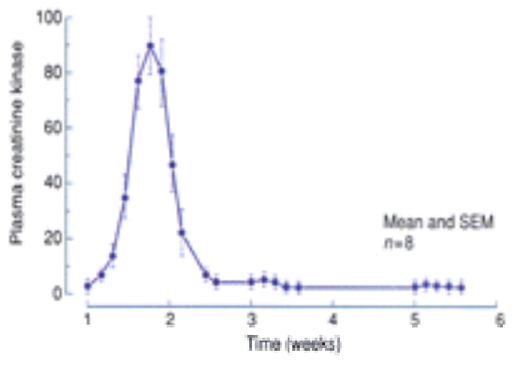

Fig. 38 Changes in creatine kinase (CK) response to repeated exercise. Plasma CK measurements were made on the subjects described in Fig. 37 and the results are expressed as a percentage of the highest value obtained for each individual.

Muscle biopsy after eccentric exercise

If a muscle biopsy is taken a few days after the peak of the creatine kinase rise, fibre necrosis and regeneration with invading mononuclear cells are seen, and in many cases the microscopic picture transiently resembles that seen in the muscle of patients suffering from inflammatory muscle disease (Round *et al*. 1987) (Fig. 39). Unlike the situation in inflammatory muscle disease where regeneration may be slow even after steroid therapy, further biopsies of this exercise-damaged muscle show that regeneration is virtually complete 3 to 4 weeks later (Fig. 39).

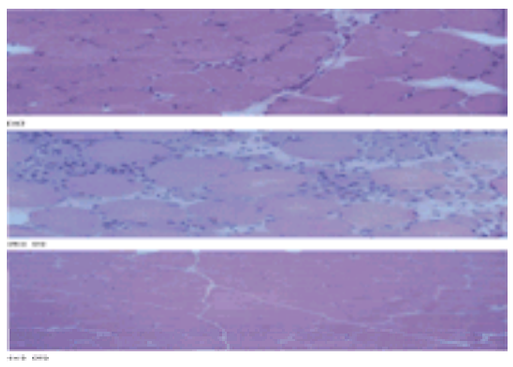

Fig. 39 Haematoxylin and eosin stains of transverse sections of: (a) biceps brachii, 10 days after eccentric exercise; (b) quadriceps muscle, 12 days and (c) 6 weeks after eccentric exercise.

Muscle damage after reperfusion of an ischaemic limb

The techniques of vascular surgery are now so well advanced that it is possible to salvage limbs which a few years ago would have been amputated. One of the side-effects of these advances has been the occurrence of occasional cases where, following successful revascularization, the patient experiences severe rhabdomyolysis often accompanied by acute renal failure. In this situation the huge rise in circulating creatine kinase and myoglobin is not seen to occur immediately after revascularization but 24 to 48 h later, suggesting that damage to the muscle has occurred not as a direct result of ischaemia but due to some subsequent damaging effect that occurred after oxygenated blood flow has been restored to the limb.

Muscle specimens taken immediately after surgery show very little evidence of fibre damage, but biopsies obtained several days later show the characteristic picture of fibre necrosis, regeneration, and infiltration of the tissue by mononuclear cells (Fig. 40). This chain of events, although occurring over a shorter time span, closely resembles that seen after damaging eccentric exercise. If adequate vascularization can be maintained postoperatively, recovery of the limb musculature is generally satisfactory although full strength may not always be restored (Adiseshiah *et al*. 1992).

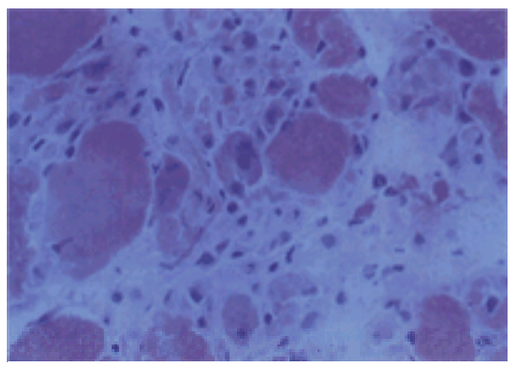

Fig. 40 Ischaemic muscle damage. Histological appearance of a biopsy from anterior tibialis muscle 10 days after surgical revascularization of the limb.

The mechanism of muscle damage following reperfusion is unclear but there are suggestions that processes mediated by free radicals are involved, radicals being generated when oxygenated blood returns to the metabolically depleted tissue. In a number of tissues the conversion of xanthine dehydrogenase to xanthine oxidase has been implicated in the process of reperfusion injury. A similar mechanism might be postulated for skeletal muscle but for the fact that xanthine oxidase is not found in skeletal muscle fibres (McArdle and Jackson 1994; McCord 1985). However, the enzyme is found in the capillary endothelium and it is possible that this endothelium is the site of primary damage in reperfusion injury. The rhabdomyolysis would then be a secondary phenomenon consequent upon the increased permeability of the damaged capillaries.

Muscle pathology in rheumatic disease

Weakness, particularly of proximal skeletal muscles, is frequently reported in patients with rheumatic disease. There are two major causes of such weakness. First, loss of muscle fibres by some destructive process leading to a biopsy picture of necrosis and regeneration, usually accompanied by invasion of the muscle by mononuclear cell infiltrates; such a picture is commonly seen in biopsies from patients with polymyositis and dermatomyositis. Second, atrophy of the muscle cells with loss of contractile material may occur due to disuse of the muscles through joint pain, as in rheumatoid arthritis, or to the prolonged negative nitrogen balance produced by the use of anti-inflammatory steroid therapy, a common finding in many patients who have received treatment for an autoimmune rheumatic disease. In the latter case it is the type 2 fibres which show the most severe atrophy. In some cases a mixed picture of both inflammation and atrophy is seen, as when polymyositis has been controlled by long-term steroid therapy but where the muscle tissue still shows focal inflammatory changes.

Where patients respond well to steroid therapy, muscle strength will show good recovery, but because of the nitrogen losses caused by the high steroid doses, recovery may take many months. Treatment in these cases must be aimed at balancing the therapeutic effects of the steroids against their catabolic side-effects, which may themselves influence the eventual degree of muscle regeneration (Edwards *et al*. 1979).

When examining muscle biopsy specimens it is important to differentiate between the atrophy which affects predominantly type 2 (fast) fibres, as seen for example in steroid myopathies (Fig. 41), and the scattered atrophic fibres of both types 1 and 2 which occur in certain acquired neuropathic disorders such as motor neurone disease, where the motor neurones are sequentially destroyed (Fig. 42). The cause of this relentless destruction is not known.

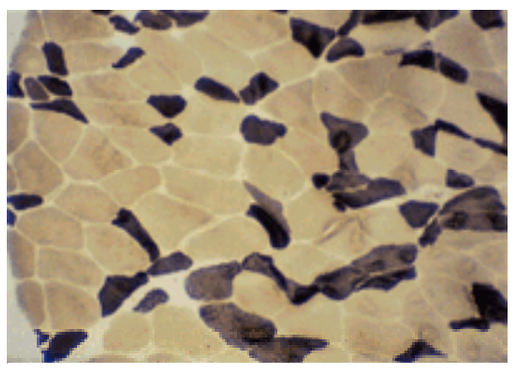

Fig. 41 Type 2 fibre atrophy in a 30-year-old woman on long-term steroid therapy. ATPase stain at pH 9.4

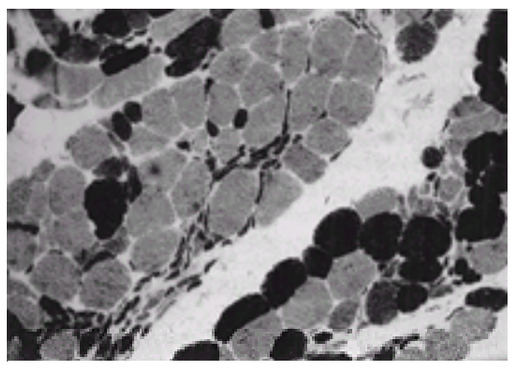

Fig. 42 Motor neurone disease. Transverse section quadriceps muscle from a 35-year-old man. Note the presence of atrophy in some type 1 and type 2 fibres, denoting loss of motor units. ATPase stain at pH 9.4.

The mechanism of muscle damage in rheumatic disease

Skeletal muscle damage is apparent in many autoimmune rheumatic diseases. There may be an apparently direct attack by the immune system on muscle fibres which have undergone some change in cell surface antigens, perhaps due to a virus infection, rendering them 'foreign' to the patient's immune system. It is notable that the expression of certain HLA determinants may predispose patients to such an abnormal responses after viral infections. Alternatively, muscle damage may be secondary to changes in the blood vessels and capillaries which are closely associated with muscle cells. Immune reactions against the endothelial cells of small blood vessels cause inflammation and necrosis. As a biproduct of this inflammatory process, muscle fibres may become damaged either by mechanisms mediated by free radicals or simply by a loss of blood supply, which reduces oxyen supply to the fibres. As discussed above, a loss of muscle energy will lead to fibre damage and necrotic changes followed by invasion of the tissue by mononuclear cells. The nature of these immune reactions is outside the range of this chapter; they are discussed elsewhere in this textbook.

In polymyositis and dermatomyositis there is widespread, patchy, muscle fibre breakdown accompanied by a lymphocytic invasion of the tissue, particularly in perivascular and perimysial areas (Fig. 43); subsequently, many macrophages are also seen associated with necrotic muscle fibres, and regenerating muscle cells are present (Fig. 44). In severe acute polymyositis, massive necrosis of muscle fibres with severe myoglobinuria and a consequent threat to renal function has been reported. The inflammatory appearances seen in a muscle biopsy usually improve with steroid therapy, but atrophy of type 2 fibres may delay the recovery of full muscle strength.

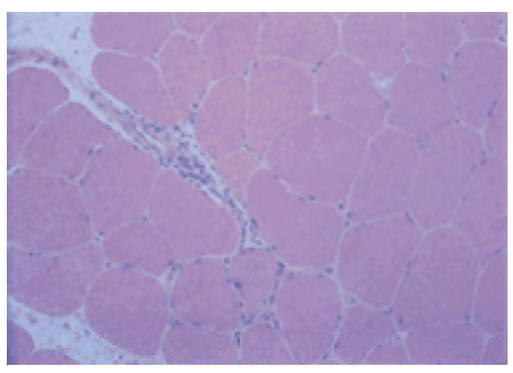

Fig. 43 Early polymyositis in a 38-year-old man. Inflammatory cells are seen in perimysial areas. Haematoxylin and eosin stain.

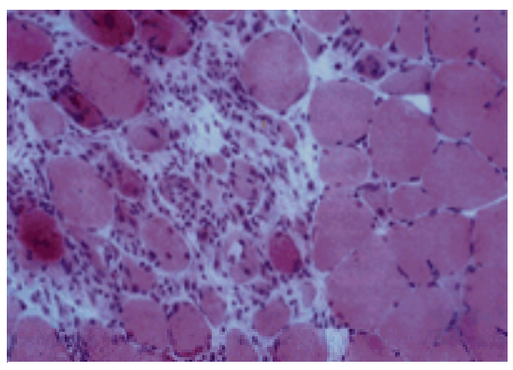

Fig. 44 Severe polymyositis in a 34-year-old woman. Necrotic and regenerating fibres are surrounded by inflammatory cells. One fascicle remains relatively normal showing the 'patchy' nature of the muscle damage. Haematoxylin and eosin stain.

In some cases the patient does not respond to steroids and the damage to muscle fibres becomes relentless, resembling that seen in muscular dystrophy with vacuolated fibres and replacement of contractile material with fibrous connective tissue and fat (Fig. 45). Some of these cases have been identified as inclusion body myositis. In this condition there is insidious muscle weakness accompanied by selective atrophy with an unusual distribution that affects, in particular, the quadriceps in the lower limbs, and forearm and finger flexors in the upper limbs. Most cases are sporadic but familial forms with variable genotypes also occur, in the latter cases inflammatory infiltrates of T cells and macrophages are not usually seen and the creatine kinase may be normal.

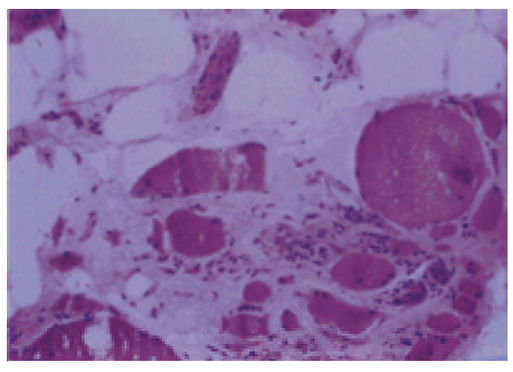

Fig. 45 Steroid-resistant inflammatory muscle disease. Much of the quadriceps muscle is replaced by fat and fibrous tissue. Haematoxylin and eosin stain.

Muscle biopsies reveal the presence of fibres containing characteristic rimmed vacuoles filled with hyaline eosinophilic inclusions. Recent immunohistochemical and electron microscopic studies have shown that these inclusions consist of cytoplasmic twisted tubulofilaments, b-amyloid, ubiquitin, and an array of other proteins including prion proteins similar to those seen in the cerebral plaques in Alzheimer's disease. The latter finding has led to the intriguing suggestion that the degenerative process in inclusion body myositis may have something in common with the degenerative brain changes in Alzheimer's disease (Askanas *et al*. 1993).

Inclusion body myositis is usually considered to be an autoimmune disease and prognosis in these cases is poor, but it is unclear whether the proposed autoimmune process leads to the formation of inclusion-containing vacuoles or the presence of vacuolar inclusions provokes the immune response. Genetic evidence for a possible immune origin in inclusion body myositis is the fact that 90 per cent of patients possess the DR3 allele of the MHC complex, usually on a haplotype marked by HLA B8 and have a deletion at the C4A (complement component) locus, or on a haplotype marked by HLA B18 BfF1 with a deletion of C4B. Both these extended haplotypes have been associated with other autoimmune diseases such as myasthenia gravis, systemic lupus erythematosus, and autoimmune thyroid disease (Garlepp and Mastaglia 1996). Despite this genetic evidence, the variable extent of inflammatory infiltrates and the poor response to steroids where inflammatory changes are seen, lead to the conclusion that the autoimmune status of this disease is far from proven. To date, the mechanisms by which amyloid, prion, and other proteins are produced in excess are not known. No genetic variations have been found in the genes encoding the production of these proteins in patients with inclusion body myositis. The existence of a 'master switch' gene that controls the production of all these proteins remains at present in the realms of speculation.

If multisystem vasculitis occurs in association with autoimmune rheumatic diseases, the skeletal muscles may be affected and fibre damage may subsequently occur. Inflammatory vascular changes are associated with myositis in polyarteritis nodosa (Fig. 46), Sjögren's syndrome, and rheumatoid arthritis. Although vasculitis can occur in rheumatoid arthritis, a more common cause of weakness is the disuse atrophy of both type 1 and type 2 fibres, associated with loss of mobility owing to joint pain. If there has been prolonged steroid therapy, atrophy of type 2 fibres predominates.

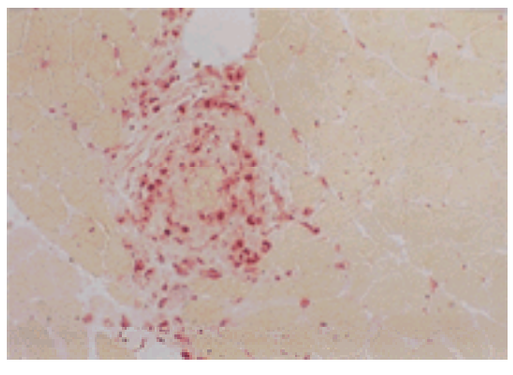

Fig. 46 Polyarteritis nodosa (PAN) inflammatory cells surround a blood vessel. Transverse section of quadriceps muscle. Acid phosphatase stain.

Muscle biopsy in systemic lupus erythematosus is seldom helpful as, although a broad spectrum of vascular abnormalities has been described (Weisman and Zvaifler 1980), the muscle usually appears relatively normal.

In scleroderma the disordered collagen metabolism leads to excess collagen deposits which produce swelling and partial obstruction of the capillaries and small blood vessels in the muscles, which in turn leads to ischaemic changes and necrosis of the muscle cells, sometimes with the presence of inflammatory infiltrates. If the ischaemic damage is widespread, interstitial and perivascular fibrosis is also seen.

Muscle pathology in patients with rare genetic defects

Malignant hyperpyrexia (hyperthermia)

There are some rare pathological conditions in which inherited metabolic defects can lead to severe damage after heavy exercise or unusual metabolic stress. One such condition is malignant hyperpyrexia in which skeletal muscle responds during anaesthesia to the muscle relaxant halothane with a prolonged contracture causing metabolic depletion of the muscle. The first signs of danger are muscle rigidity, a rise in the patient's temperature, and the release of potassium into the circulation which brings with it the risk of cardiac arrest. If the patient survives this acute emergency, the skeletal muscles subsequently undergo necrosis (rhabdomyolysis) with the release of massive amounts of myoglobin and other soluble proteins into the circulation, causing the risk of acute renal failure and another life-threatening crisis. Rapid treatment with dantrolene and cooling has proved effective in the therapy of this serious emergency. The gene defect in this condition has been identified in pigs but, to date, the human gene defect has not been characterized.

The glycogenoses

Other genetically determined conditions give rise to defects in muscle energy metabolism. These include defects in the enzymes of the glycolytic pathway, mitochondrial enzymes concerned with both pyruvate and fatty acid metabolism, and the cytochrome component of the electron transport chain. All of these pathways are important in the secondary supply of energy to the muscles as the primary reserves of phosphocreatine become depleted. In general, patients with metabolic defects are of normal or near normal strength when rested but are limited in their exercise endurance.

When a defect occurs in the glycolytic pathway as, for example, in myophosphorylase deficiency (McArdle's disease) or phosphofructokinase deficiency (Tauri's disease), if prolonged vigorous exercise is undertaken, the exercised muscle tends to go into a painful contracture (which is electrically silent, unlike muscle cramp in normal subjects which is electrically active). However, after a short period of rest, patients with myophosphorylase deficiency can often restart exercise for a short time as bloodborne glucose reaches the muscle cells (second wind phenomenon). This is not the case in phosphofructokinase deficiency, where the gene mutation affects an enzyme further up the glycolytic pathway. Patients vary in the severity of their symptoms, but if severely affected patients are forced to continue exercising, extensive rhabdomyolysis of the exercised muscle can occur. Fortunately these patients are generally well aware of their limitations and take care to reduce the exercise level before any crisis can develop.

Just as patients differ in the severity of their symptoms, they also differ in their ability to express myophosphorylase protein. Some patients produce mRNA but no protein, others produce no mRNA or protein, and one patient has been described who produced mRNA at normal levels but reduced enzyme protein. This molecular heterogenicity implies the involvement of multiple mutations. The muscle glycogen phosphorylase gene is approximately 14 kb in size and has been assigned to the long arm of chromosome 11 (Lebo *et al*. 1984). A C to T mutation in codon 50 has been identified on at least one allele in all patients studied. However, heterozygotes do occur although McArdle's disease is usually considered as an autosomal recessive condition, indicating that these heterozygotic patients must possess an additional mutation(s). Several new mutations have recently been characterized (Bartram *et al*. 1994), but there appears to be no obvious clinical correlation between the severity of the disease and the different mutation patterns, suggesting that other factors must be involved.

McArdle's disease is now categorized as type 5 in a group of inherited glycogenoses. Not all of these conditions affect skeletal muscle. A summary of those associated with muscle damage is given below.

Von Gierke's disease. Here there is a deficiency of the enzyme glucose-6-phosphatase leading to hepatomegaly, growth retardation, hypoglycaemia, and lactic acidosis. The liver, kidney, and skeletal muscles are affected.

Pompe's disease (acid maltase deficiency). The lysosomal enzymes a-1,4- and a-1,6-glucosidase are deficient. In children all tissues are affected with cardiomyopathy, severe weakness and large accumulations of glycogen in the muscle (Fig. 47). Death is usually within the first year of life. In adults the disease may present with a proximal myopathy of variable severity, and weakness of the respiratory muscles.

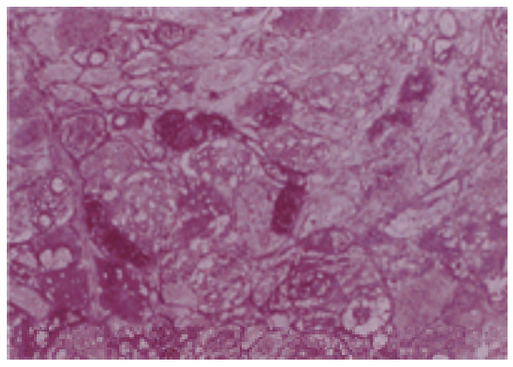

Fig. 47 Acid maltase deficiency. Severe vacuolar myopathy, the fibres are packed with glycogen. Periodic acid–Schiff stain.

Cori–Forbes disease (debrancher deficiency). The absence of debrancher enzyme leads to the production of limited dextrin as the myophosphorylase enzyme removes from glycogen the glycosyl units attached by 1,4-linkages but cannot attack any branch points. This abnormal glycogen accumulates in the muscle. Clinical symptoms vary from severe muscle weakness in childhood to asymptomatic adult forms.

McArdle's disease. In this condition the enzyme myophosphorylase is deficient. The disease is discussed above.

Tauri's disease. Here the enzyme phosphofructokinase is deficient in skeletal muscle and red cells. The clinical symptoms and exercise impairment are very similar to those of McArdle's disease. Because the deficiency is also present in the red cells, a haemolytic anaemia may occur, often detectable by a raised reticulocyte count in the peripheral blood.

Mitochondrial myopathies

Patients with defective mitochondrial function might be expected to have similar problems to those with defects in the glycolytic pathway, as they have severely limited exercise capacity and mild exercise is associated with breathlessness, acidosis, and a high level of blood lactate, such as would be seen in a normal subject exercising under hypoxic conditions. In practice they do not present with muscular damage following exercise. Although often severely limited in their exercise capacity, the normal glycolytic function in these patients must provide sufficient energy to prevent the development of muscle contractures. Histologically, these patients show abnormal 'ragged red' fibres in biopsy sections treated with trichrome stain (Fig. 48), the periphery of the fibres being packed with numerous red-staining mitochondria. Scattered necrotic fibres are also seen. Biochemical analysis of muscle biopsy specimens can be used to identify the location of the genetic defect in the electron transport chain.

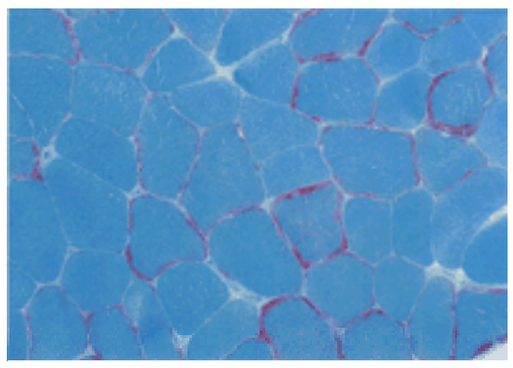

Fig. 48 'Ragged red fibres' in a transverse section of quadriceps muscle from a 19-year-old boy with a mitochondrial myopathy. Dark red staining at the periphery of the fibres is caused by aggregations of mitochondria. Trichrome stain.

Disorders of fat metabolism

These disorders should properly be classified under mitochondrial myopathies, as fat metabolism occurs within the mitochondria, but because defects in fatty acid metabolism do not have such a drastic effect on energy supply as defects in the electron transport chain, they are considered separately. Patients with disorders of fatty acid metabolism have symptoms of weakness, exercise intolerance, muscle stiffness, and pain (sometimes accompanied by myoglobinuria). Symptoms are most evident at times when free fatty acids are the main substrates for energy metabolism, such as during prolonged submaximal exercise, particularly in the fasting state. The b-oxidation of fatty acids depends on the transport of free fatty acids into the mitochondria by a shuttle mechanism which involves carnitine and the carnitine palmitoyl transferase (**CPT**) enzymes. Low plasma carnitine and deficiencies of CPT have been described. Patients lacking carnitine are weak, whereas those lacking the CPT enzymes are of fairly normal strength at rest but after fasting or exercise they may show evidence of muscle damage, with a raised creatine kinase and occasionally myoglobinuria. Carnitine is synthesized only in the liver and is taken up by muscle from plasma. Muscle biopsy may show large fat droplets in the muscle fibres. Treatment with oral carnitine has proved successful in children with a carnitine deficieny.

Patients with disorders of fatty acid metabolism often report episodes of muscle pain and myoglobinuria. While exercise, particularly in the fasting state, may sometimes be the precipitating factor, virus infections or alcohol are often implicated. It is unlikely that metabolic depletion is the cause of muscle damage in these patients and it is possible that high levels of free fatty acids may be the immediate cause. Exercise mobilizes free fatty acids from body fat depots and muscle triglycerides but, because fatty acid transport into the mitochondria is defective in these patients, the free fatty acids (mostly stearic and palmytic) accumulate within the muscle fibres and due to their detergent effect, damage the muscle fibre membranes.

2.7 Biomechanics of articulations and derangements in disease

Anthony Unsworth and Andrew A. Amis

Introduction

Synovial joints are nature's bearings which means that large loads can be transmitted through the joints while the frictional forces created by the accompanying motion are kept to a minimum. This is achieved by a combination of the properties of cartilage and synovial fluid which together maintain coefficients of friction which are less than 0.02. This, at first sight, is surprising since cartilage surfaces are rough compared with engineering bearings, the transmitted loads are high, and the large range of sliding speeds found in human joints means that a whole range of lubrication mechanisms need to be enlisted in order to maintain efficient articulation.

Typically, in the hip joint, loads of 3000 N are common, but an important feature of these loads is that they are 'dynamic' and hence only have a duration of the order of 0.1 s. However, a lower limb might undergo up to 200 million impacts of between 2000 and 5000 N in a lifetime and this sort of demand often leads to some degree of failure. Osteoarthritis is a common disease which bears many of the typical signs of mechanical failure of the material. The first sign of failure is the 'softening' of the cartilage which reflects the change in the way it responds to loads. Fibrillation, or a breakdown in collagen structures of the surface layer then leads to excessive wear of the cartilage which sometimes progresses to total exposure of the underlying bone.

It is clear that mechanical factors alone cannot fully explain the aetiology of osteoarthritis but in this chapter we will discuss the synovial joint as a bearing and describe the mechanical factors which may contribute to that failure. This includes the nature of the loading and how the cartilage responds by distributing it over the joint. The role of the menisci in the knee will be discussed and the consequences of damage to ligaments. The lubrication of joints and the mechanisms which have been identified as protecting joint surfaces from wear will lead on to a review of the breakdown of cartilage.

Mechanics of joints

The science of mechanics, whether applied to engineering artefacts or to human joints, is generally studied under one of three main categories: statics, kinematics, or dynamics, and these may be defined as:

1. statics is the study of forces without reference to motion;
2. kinematics is the study of motion without reference to forces;
3. dynamics is the study of forces and motion.

It is convenient to examine the biomechanics of articulations under these headings, each of which produce data relevant to different situations.

Static force analysis of joints

Statics is normally concerned with the study of the equilibrium of a body. For a human joint, the mechanical influences acting can be classified as either forces, which tend to cause a linear motion (or translation), or moments, which tend to cause rotational effects. These may be about an axis of flexion, for example. The general principle, arising directly from Newton's laws, is that for a static analysis, all forces and moments are assumed to be in equilibrium. If this were not the case, then the body being analysed would be subjected to a resultant load or moment which would cause it to accelerate. This would then mean that a dynamic analysis would be needed.

Static equilibrium uses the resolution of forces to account for linear translation effects, and the summation of the moments acting about a point in a body to balance rotations. Although the body is, of course, a three-dimensional structure, it is often acceptable to simplify a situation into two dimensions, in order to obtain an approximation for forces or moments acting on a joint. This applies to joints which have almost uniplanar motion, such as the interphalangeal joints of the fingers, where out of plane effects are small. In this case, the general situation where forces can act in three mutually perpendicular directions, and where moments can act to cause rotational effects about the three axes (i.e. involving six degrees of freedom), can be simplified to perhaps one equation that examines rotation about one axis, and then to two further components of force in order to calculate the joint load.

Before illustrating the equilibrium analysis of a simplified case, it should be noted that all such analyses involve several stages of work prior to the equilibrium analysis itself. This arises because it is not normally possible to perform invasive procedures, so assumptions must be made as to the state of load or position of internal structures.

The first step is to measure the external load acting on the body. This is sometimes simple, such as when a weight is being supported in the hand. Often, however, the biomechanical researcher must use a purpose-made load transducer, that can produce (usually) an electrical output for analysis. In the case of an interphalangeal joint, this may well be a relatively simple device such as a pinch strength meter, which gives a force-related output alone. Here, the analyst must assume that the force displayed acts along the axis of the finger tip pads. It is more complex if walking is involved, since the load can pass through a large area of foot to floor contact. Also, the loading may not be perpendicular to the floor, since there could be shearing actions (i.e. a tendency towards skidding), such as when the heel strikes the floor. In order to analyse complex situations, purpose-made load transducers are used. In the case of foot to floor contact, this is known generically as a 'force plate', which can give simultaneous output of all six degrees of freedom, i.e. three forces and three moments. Further, by using an array of force sensors (e.g. at each corner of a rectangular plate), it is possible to show the position and orientation of the resultant force, and thus the position where it acts on the sole of the foot. A further refinement to study pressures between the body and objects on which it acts uses sheets of electroconductive rubber with electrodes painted on to each surface. The resistance of this device changes as the rubber is compressed.

Having found the external loads, the researcher must turn to the internal loads. The majority of the loads acting on human joints arise as a reaction to the tensions in the muscles crossing the joints, and not (even in the lower limb) as a result of the weight of the body or other external loads being supported. This is because of leverage effects. The tendons generally pass much closer to the axis of a joint than does the line of action of an external load. This mechanical disadvantage may be considerable. At the elbow, for example, the moment arm of the biceps tendon may be 35 mm, while that of a load in the hand may be 350 mm, in which case the tendon tension must be ten times the external load, if that were the only muscle acting. Given that it is the muscles which cause most of the load, it is obviously of great importance to identify which of them are active, and to obtain data on their physical locations, especially their moment arms about axes of rotation, and the directions in which they act.

Muscle activity is discerned by electromyography, normally using skin-mounted electrodes. Data on muscles lying deep to the surface can be obtained by means of needle electrodes, but this is an invasive procedure. For analysis of a static situation there is much information published on electromyography (e.g. Basmajian 1967). For analysis of a moving subject, when different muscles will be switching on and off (e.g. when rising from a chair), it is necessary to use electromyography equipment, since the patterns of activity vary between subjects. This applies particularly to antagonistic actions which stabilize joints, causing great increases in the joint force.

The positions of the lines of action of muscles and tendons have usually been found by dissecting cadavers. If a range of joint positions is to be analysed, wires can be embedded in the tendons and three-dimensional data found by biplanar radiography (An *et al*. 1979), or by direct digitization of the structures *in vitro* at a range of joint positions (Amis *et al*. 1979). If the joint is surrounded by the fibre 'bellies' of muscles, such as at the hip, it is necessary to estimate the line of action within the muscle cross-section. In this case, the tissue can be frozen, sliced and the centroid of the cross-section found by digitizing a photograph. As medical imaging has advanced, it has become possible to obtain cross-sectional data by means of MRI scans of living subjects with physiological muscle tone. As the scanners and their software improve, so it is becoming possible to obtain multiple slices at a range of postures as a joint is flexed during a scanning procedure.

It is unusual for a joint to be acted on by a single muscle, and so the analyst must use the electromyography data to prepare a list of those that are active and then decide how they share the effort. There has been a range of optimization criteria put forward for this. One such technique is minimizing the energy expended during a movement. These assumptions are necessary in order to reduce the number of unknown variables and produce a solvable set of equations. Some workers have assigned the share of forces according to the physiological cross-sectional areas of the muscles (which allows for muscle fibre pennation geometry), and this may be appropriate for strenuous isometric actions, when the muscles are coming to the limit of stress that they can create (Amis *et al*. 1980b).

With all the muscle, geometrical, and external force data collected, the analyst can produce a mathematical model of the joint, placing all the lines of action of the forces with the correct sharing of the muscle tensions, and then examine the equilibrium of the joint:

Consider the finger tip pinch shown in Fig. 1:

For moment equilibrium about the axis of flexion,

$$\mathbf{70\ N \times 15\ mm = \mathit{T} \times 5\ mm,\ so\ \mathit{T} = 210\ N.}$$

For force equilibrium along the distal phalanx,

$$\mathbf{70\cos 65° + \mathit{T}\cos 50° = \mathit{F}_{axial},\ so\ \mathit{F}_{axial} = 165\ N.}$$

For force equilibrium across the distal phalanx,

$$\mathbf{\mathit{F}_{shear} + 70\sin 65° = \mathit{T}\sin 50°,\ so\ \mathit{F}_{shear} = 98\ N.}$$

By the theorem of Pythagoras, the (resultant force)$^2 = F^2_{axia} + F^2_{sheal}$, so the resultant force = 192 N and the angle of this force relative to the axis of the phalanx = $\tan^{-1}(F_{shear}/F_{axia}) = 31°$.

As noted above, it is the tendon tension, and not the external force, that causes the majority of the force transmitted across the joint itself.

Sometimes the analysis predicts a resultant joint force which is directed outside of the area of contact between the bones. This represents a potential instability, and ligament tensions may be invoked to regain equilibrium. For example, an analysis of pinching action showed that the axial force along the proximal phalanx, which would stabilize the metacarpopharyngeal joint, was overcome by the shearing action of the flexor tendon tensions when the metacarpopharyngeal joint was flexed. This would cause a palmar subluxation. Stability thus entailed tension in the collateral ligaments. In the rheumatoid hand, when the ligaments are slack because of loss of the joint surfaces, the shearing action causes palmar subluxation (Weightman and Amis 1982). This situation is at an extreme in the knee, where the tibiofemoral joint depends on the cruciate ligaments to resist the anterior–posterior actions of the muscles when walking (Morrison 1968).

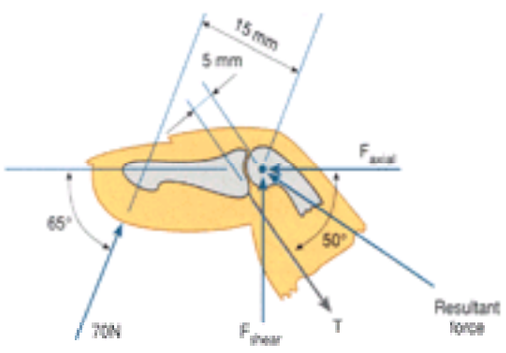

Fig. 1 Two-dimensional force analysis of finger tip pinch action. The flexor tendon tension *T* = 210 N, and the resultant joint force = 192 N at an angle of 31° to the axis of the distal phalanx.

Kinematics of joints

The most common aims of kinematic studies are to provide data on the patterns of movements of the body, or else to provide detailed information about the axes of rotation of individual joints, that can be used when making force analyses as described above.

The study of patterns of motion started approximately a century ago, when Braune and Fischer examined the limb movements when walking by means of stroboscopic pictures (Paul 1978). This is a method used more recently by Murray *et al*. (1964) where the flashes of light reflect from polished rods attached to the limbs. For three-dimensional analysis of movement, it is necessary to use multiple viewing directions. This produces large amounts of data (such as from high-speed cine-films) that must be synchronized, but allows details such as transverse rotations of the segments of the lower limb to be discerned (Levens *et al*. 1948) and a full three-dimensional force analysis to be carried out (Paul 1967: the hip; Morrison 1968: the knee). More recently, spatial data collection has used video cameras linked to computers, which allows reflective markers on joints to be tracked and their co-ordinates calculated automatically using the specialist software.

As well as photographic, non-contacting methods it is also possible to attach measuring instruments directly to the limb. Electrogoniometers can give outputs relating to rotations about more than one axis at a joint. For example, Kettlekamp *et al*. (1970) produced graphs of knee flexion–extension, abduction–adduction, and internal–external rotation during walking. Some studies of joint function have used such devices powered by batteries and combined with data loggers in order to obtain information on the numbers and magnitudes of joint movements in daily activities. The drawbacks of such devices are that they can inhibit subject actions and also move relative to the skeleton since they are usually held in place simply by tapes.

Detailed kinematic studies of individual joints often use multiple exposure radiographs or tracking of small lights or other markers. At any time, there will be an 'instant centre of rotation', about which all other points on a body are rotating. Since, by definition, these points are all on arcs of circles centred at the axis, it is a simple geometrical calculation to identify the axis from the paths of several points (Fig. 2). This methodolgy has shown that the complexity of the carpus, for example, can be reduced to a simple uniaxial rotation about the proximal pole of the capitate during wrist flexion–extension and abduction–adduction (Youm *et al*. 1978); a finding

which has been used to justify the design of simple spherical geometries for the articular surfaces of wrist prostheses.

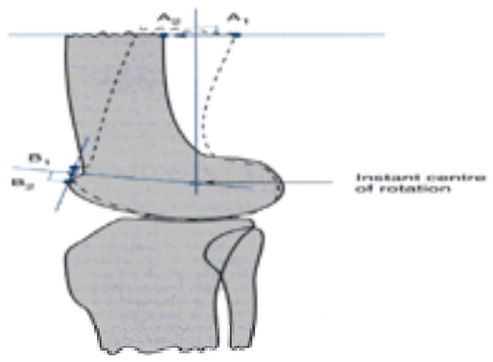

Fig. 2 Method to find 'instant centre of rotation' of a joint from double-exposure radiographs.

Dynamic analysis of joints

This approach is necessary when movements occur fast enough for inertial effects to cause significant errors if they are ignored. As the speed or direction of motion of limb segments changes, so their mass must be accelerated in order to cause the change in velocity, i.e. forces are required to overcome inertia. This applies to both linear translation and rotation. In the extreme, inertial effects limit the speed with which a joint can be moved, since active muscle tension capability diminishes as the speed of shortening increases (Elftman 1966), and large accelerations occur as the limb segment reaches the limits of motion. Amis *et al*. (1980*a*) showed that high-speed elbow flexion movements could cause accelerations of 20 *g*, while Paul (1974) reported accelerations of 4 *g* in the lower limb during walking.

In order to allow for the inertial effects of accelerations, data must be available on the masses, locations of the centre of mass and inertial properties of the limb segments. Fortunately, much of this is available in the literature (e.g. Contini and Drillis 1966). However, such data are based on a small number of cadavers, which may not have the same mass distribution as a particular experimental subject. It would be a major undertaking to attempt to gain such information from live subjects, and thus it is not normally attempted.

Joint forces during locomotion

The approaches to joint analysis described in the three sections above must all come together if a complex activity such as human locomotion is to be analysed, with simultaneous collection of spatial, electromyographic and force plate data. When the foot to floor forces are known, it is possible to work back into the body to estimate the joint forces. The external force action causes moments about the joints, which can have their equilibrium examined by means of 'static' methods that add in the inertial effects, which must themselves be calculated after analysing the accelerations of the limb segments. This is obviously a large undertaking, and while the data manipulation has been reduced by powerful computers, the data collection still requires a well set-up and calibrated gait analysis facility.

Typical force predictions for walking have been approximately three, four, and five times body weight for the ankle, knee and hip, respectively, with much higher loads anticipated in sporting activities.

Although it has been shown that such a gait analysis is the only way to find out the force distribution across a prosthetic knee when in use postoperatively, for example, (Johnson *et al*. 1980) the amount of work required has meant that such analyses have usually been done only as part of a specific research project, and not as part of the general aim to monitor progressive changes in motion or force patterns in patients.

Direct measurement of joint forces

It is obvious that the many stages and assumptions needed to perform a dynamic analysis leading to joint force predictions will lead to a large band of potential error in the results. It would, therefore, be very attractive to be able to measure the joint forces directly. Unfortunately, this is difficult to accomplish ethically, but there have been several reports of such measurements, all at the hip.

The method used has been to implant a hip prosthesis in which the neck of the femoral component has been instrumented by strain gauges that respond to the deflections caused by loads applied to the joint. The early work by Rydell (1966) was hampered by the need to use transcutaneous wires, but Bergmann *et al*. (1993) transmitted a signal containing all components of load on the joint from within a sealed cavity in the prosthesis. This has allowed the activities of patients to be followed for up to 2 years postoperatively, and thus to monitor a return to relatively normal gait. It is reassuring that this work has largely confirmed the earlier force plate predictions.

Lubrication of human joints

Having examined the loads passing through joints and seen how to measure these in clinical situations, we need to determine how the joints can respond to these with the minimum of damage. This leads us to look at the lubrication mechanisms in joints. Lubrication of human joints is important for two main reasons. A well lubricated joint has low friction and hence low energy loss, and if the lubrication mechanism actually separates the cartilage surfaces with a film of synovial fluid, then this will minimize wear and may help slow the process of osteoarthritic change (Unsworth 1984). There are a number of lubrication mechanisms which have been identified (Dowson 1967), some of which are better than others. Best of all is full-fluid-film lubrication. Here, the two surfaces which are loaded together, are completely separated by a film of lubricant, albeit a very thin film (about 0.5 m). This reduces both friction and wear. For the surfaces to be held apart by a film of fluid, the fluid must be pressurized in some way. One of the earliest mechanisms to be identified was 'hydrodynamic' lubrication (Reynolds 1886). Here the rolling and sliding motion between the surfaces generates pressure within the fluid. Thus motion and fluid viscosity are important. Another way is to pump the fluid between the surfaces using an external pump. This is called 'externally pressurized' or 'hydrostatic' lubrication.

If the load placed on the joint is not steady but varies, such as when we jump in the air and land on the ground, pressure can be generated by 'squeeze film' mechanisms. This can be explained by imagining two surfaces separated by a film of fluid suddenly being squeezed together. This puts a high pressure on the fluid which therefore resists the applied force. Obviously with time this fluid film disappears unless it is recharged by more fluid, but for dynamic loads as found in human joints, it is a most important mechanism (Unsworth *et al*. 1975).

If these pressures are very high compared with the elastic properties of the solid boundaries (about 2 MPa in the case of cartilage), then significant elastic deformation or 'squashing' of the surface will occur and this changes the geometry of the lubricating film. This in turn changes the pressures generated. When this happens, the mechanism is called 'elastohydrodynamic lubrication' (EHL or EHD lubrication). Under fluid-film conditions, and all the above mechanisms are classified as fluid-film lubrication, the coefficient of friction is of the order of 0.01 or lower. However, under some conditions a fluid film cannot be generated to separate the two surfaces. Here, intimate contact between the surfaces can be prevented by a boundary lubricant. A good boundary lubricant attaches itself to the solid surfaces by molecular forces and modifies the surfaces. This consequently reduces friction but not as much as fluid-film lubrication does (e.g. coefficient of friction in the range 0.1 to 0.5). The coefficient of friction is also independent of speed of sliding or load in boundary lubrication, whereas it is strongly dependent on both in fluid-film lubrication.

In reality many practical devices spend much of their working life running under a combination of fluid film and boundary lubrication known as 'mixed lubrication'. Here part of the load is carried by the fluid film and part by the solid to solid contact. Consequently coefficients of friction tend to be between 0.1 and 0.05.

Most surfaces, cartilage included, are rough on the microscopic scale (Jones and Walker 1968; Sayles *et al*. 1979) so separation of the surfaces only occurs when the fluid film is so thick that the roughnesses on the surfaces do not touch each other (Fig. 3). Thus for complete separation and hence fluid-film lubrication, the film

thickness must be greater than the combined roughnesses of the two surfaces.

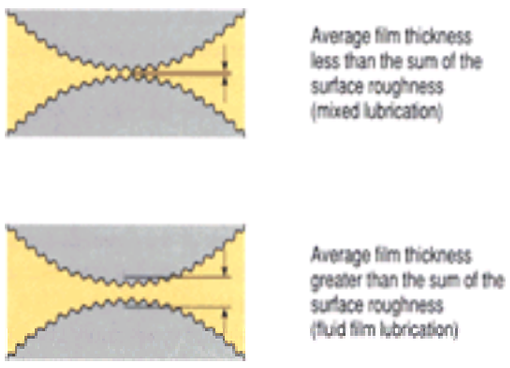

Fig. 3 Separation of surfaces.

A brief history of studies of human joint lubrication

The subject of human joint lubrication has only recently become clear in scientific terms, and therefore we will review briefly the history of the studies of human joint lubrication, followed by a summary of the current thoughts on the subject.

The early texts suggested that human joints were fluid-film lubricated (Reynolds 1886; MacConaill 1932). Comparisons of anatomical features of the hip and knee with features of engineering bearings led to the belief that hydrodynamic lubrication was the principal mechanism. In order to have hydrodynamic lubrication, an entraining velocity and a physical wedge of fluid between the cartilage surfaces are necessary. This, according to MacConaill, came from the shape of the articulating surfaces. He even claimed that the menisci of the knee act as 'tilting pads' to help optimize the load capacity of such joints. This was a reference to the work of Michell (1905). MacConaill also said that if these menisci were damaged, the resulting increase in friction was the cause of the higher incidence of osteoarthritis found to accompany this damage. This proved not to be the case, as Seedhom (1976) showed considerably increased contact stresses in knee articular cartilage following damage to menisci and this was more likely to be the cause of early osteoarthritic changes.

Jones (1934) was the first to measure the coefficient of friction in a joint. A horse's stifle joint produced a coefficient of friction of 0.27 when dry and 0.02 when lubricated with synovial fluid. These experiments were carried out under unphysiological conditions of high constant load and low sliding speed, therefore 2 years later, he used a proximal interphalangeal joint of the finger as the fulcrum of a pendulum (Jones 1936). His results were consistent with fluid-film lubrication.

Charnley (1959; Charnley 1960*a*; Charnley 1960*b*) repeated Jones's experiments using a similar apparatus but found that the friction was the same whether synovial fluid was present or not, and using a pendulum for human ankles found that the friction was independent of velocity of sliding and therefore boundary lubricated not fluid film. Charnley's measured values of friction were, however, very low for boundary lubrication (0.005 to 0.024).

Such low values of coefficient of friction at very low speeds of movement led McCutchen (1959) and Lewis and McCutchen (1959) to postulate a self-pressurizing hydrostatic lubrication mechanism which relied on pockets of liquid in the soft cartilage surface. Also, because cartilage was porous, they believed that as the surface was loaded, the cartilage matrix compressed, pushing pressurized synovial fluid from its pores into the interface of the joint. This they called 'weeping lubrication'. Evidence of the pockets of liquid was supported by Unsworth *et al*. (1975) but the 'weeping' mechanism was shown by Maroudas (1967) to be controversial. She showed that the permeability of cartilage was so low as to be unrealistic as a method of replenishing fluid films between cartilage surfaces within the time scale of normal gait. However, this permeability was important for nutrition (Maroudas 1968).

Dintenfass (1963) in his review of human joint lubrication favoured elastohydrodynamic lubrication as a mechanism. This was supported by Tanner (1966) and much later by Higginson and Unsworth (1981). However, squeeze film lubrication can act together with elastohydrodynamic lubrication, and Fein (1966–67) showed that in human joint applications this combination can be an important feature of effective lubrication.

The importance of the type of loading in joints can be seen from a series of experiments carried out by Linn (1967; Linn 1968) and Linn and Radin (1968). They used an 'arthrotripsometer' to measure the coefficient of friction in dog's ankle joints under constant load, which is unphysiological and predisposes against fluid films, and showed that mixed lubrication was present in the joints. In other words both hydrodynamic and boundary lubrication were acting together. The effects of boundary lubrication were examined by digesting synovial fluid with hyaluronidase and trypsin in turn. Trypsin did not alter the synovial fluid's viscosity but doubled friction, while hyaluronidase reduced viscosity but did not affect friction. Clearly this pointed to a protein component of synovial fluid acting as a boundary lubricant. However, it is important to emphasize that these tests were carried out with a constantly loaded ankle joint whereas in real life such joints are dynamically loaded (loads from almost zero to five times body weight every second). O'Kelly *et al*. (1978) and Roberts *et al*. (1982) repeated Linn and Radin's work but using the dynamic walking cycles of Paul (1967) and English and Kilvington (1979), respectively, and found fluid-film lubrication throughout. An obvious conclusion is that under physiological loads, (dynamic), fluid-film lubrication exists in human joints, while under static loads this reverts to 'mixed' lubrication, where boundary friction dominates. So what happens when we stand still under steady load for long periods? McCutchen (1959) showed that a type of self-acting hydrostatic lubrication (weeping lubrication) could force synovial fluid out of cartilage pores into the joint space to lubricate the joints by replenishing 'pools' of synovial fluid trapped in the surface roughnesses. The opposite of this was 'boosted lubrication' (Walker *et al*. 1968), a theory that fluid flowed from the trapped pools into the cartilage thereby concentrating the synovial fluid in the pools and increasing its viscosity to keep the surfaces apart. The same experimental evidence was often used by both sets of workers to justify the different conclusions. In the event Ling (1974) produced a theoretical model of elastic porous discs on impervious substrata and showed that weeping and boosted were not mutually exclusive.

The other important feature of human joints is their surface elasticity. Soft elastic layers are beneficial to lubrication and friction in pure-sliding (Bennett and Higginson 1970), especially in squeeze film situations (Gaman *et al*. 1974). A combination of elasticity and porosity was not significantly better than elasticity alone (Higginson and Norman 1974) since the permeability of cartilage was far too low to affect lubrication.

A combination of dynamic loading (physiological) and soft elastic surfaces had a very great effect (Unsworth *et al*. 1987). So much so that the friction in a Charnley hip prosthesis could be reduced by a factor of 10 by adding a soft elastic layer. Thus the important features of healthy behaviour of human joints are high viscosity synovial fluid (greater than 0.010 Pa s), dynamic loads, and a soft elastic surface (hardness 4 to 8 N/mm ^{2}).

Theoretical analyses

Using the experimental evidence already referred to, a number of analytical and numerical studies have been carried out to help understand the lubrication mechanisms. An elegant combined theoretical and numerical analysis of the movement of fluid in and out of cartilage concluded that 'The natural lubrication process is neither the weeping mechanism nor the boosted mechanism' (Mansour and Mow 1977). In any analysis, simplifying assumptions are necessary and several workers have followed the advice of Higginson and Norman (1974) and neglected cartilage permeability. This is extremely convenient since elastohydrodynamic lubrication of soft impermeable layers is quite well documented in rolling/sliding situations for cylindrical contacts (Hooke and O'Donoghue 1972). This is probably sufficient for knee or ankle analysis, though not for the hip. They give an equation for minimum fluid-film thickness of hmin – $U^{0.6}\,W^{-0.2}\,R$, where U = /ER and W = w/ER. R is the effective radius, the viscosity of the lubricant, U is the rolling/sliding speed, E is the equivalent elastic modulus, and w is the load/unit length on a cylindrical contact. For a typical knee in normal walking this gives a film thickness of 1.4×10^{-7} m. Since cartilage is rough (10^{-6} m) this film thickness is unlikely to separate the cartilage surfaces unless the soft compliant surfaces are more tolerant of surface roughnesses than are metals. Higginson and Unsworth (1981) show this to be the case and when account of this is taken, the film thickness is increased to about 6×10^{-7} m. This is still insufficient to separate the surfaces of cartilage. However, Dowson and Jin (1986) showed that using the ankle joint as a model the effect of high pressures generated on the roughnesses of the surfaces was to squash the high spots and produce a smoother surface. Adding squeeze film to the analysis increased film thicknesses to between 0.6 and 1.2 m, while the original surfaces had been smoothed to between 0.05 and 0.9 m depending on the wavelength of the surface roughness. Thus for the first time theory had supported experiments on human joints.

This theory relates only to line contacts and so hips are not truly represented. However, Dowson and Yao (1990) have analysed elliptical contacts and although the film thicknesses are smaller than for knees and ankles, Yao (1990) suggests that when combined with the microelastohydrodynamic lubrication of Dowson and Jin (1986) then fluid-film lubrication will be predicted theoretically.

The work of Dowson and Jin (1986) was taken further by Yao and Unsworth (1993) and while the basic mechanism of microelastohydrodynamic lubrication was still seen to be active, the predicted film thicknesses for realistic cartilage surfaces were seen to be very much smaller than the earlier predictions.

Summary of human joint lubrication

The important aspects of human joint lubrication are given in Fig. 4, which shows a hip joint at various stages in a walking cycle. During the lightly loaded swing phase, a relatively thick film of fluid can be entrained between the cartilage surfaces (Higginson and Unsworth 1981). When the heel strikes the ground, the load increases rapidly as the entraining velocity approaches zero. Here the thick film of fluid, generated during the swing phase, begins to squeeze out and the fluid-film thickness reduces. However, since the load is only applied for a short time (about 0.1 s, Fig. 4), the film does not reduce by too much at this stage. During the next phase of the walking cycle, the 'stance phase', the load reduces and the entraining velocity increases (both of which help to generate elastohydrodynamic lubrication), and so the fluid film separating the joint surfaces is maintained. Finally at 'toe off', the load is near to maximum and the entrainment velocity is low, so 'squeeze film' lubrication is called upon to maintain the fluid film and prevent surface to surface contact. With normal healthy tissue under physiological loads and motion, both theory and experiments show this to be true. During the time that the cartilage surfaces are completely separated by synovial fluid, little or no wear can take place. However, after resting, or standing motionless for long periods, we might expect our joints to squeeze all the fluid out from between the surfaces and therefore to have cartilage rubbing on cartilage (McCutchen 1959; Walker *et al*. 1968; Unsworth *et al*. 1975). When we start to move the joint again the potential for wear is high, except that a 'boundary lubricant' in the form of a protein (Swann *et al*. 1974) is present in the synovial fluid to keep friction low and help reduce wear. Once the motion has begun again, fluid-film lubrication takes over.

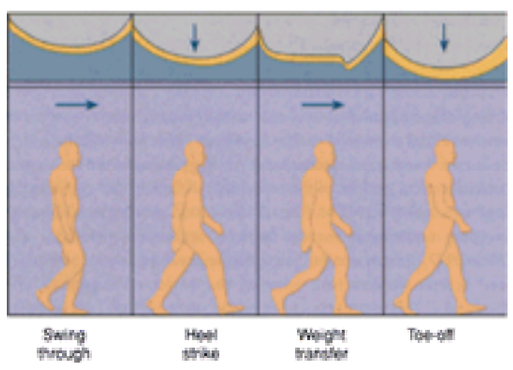

Fig. 4 A hip joint at various stages in a walking cycle.

Mechanical factors in the pathogensis of osteoarthrosis

Although the initiation and progression of articular cartilage breakdown is not well understood, the process seems likely to include both 'mechanical' and 'biochemical' factors, which may interact. From the viewpoint of the bioengineer, cartilage is seen as a bearing material which is subjected to repetitive impulsive loads and movements. For a normal engineering structure, such a situation would mean that it might be liable to accumulate microdamage that might eventually lead to fatigue failure. Such a mechanism is also attractive for explaining the breakdown of articular cartilage, since it is a tissue which has limited regenerative capability. With people typically taking 2 to 3 million steps per annum, this means that cartilage must probably resist in excess of a 100 million load cycles during a lifetime, which is effectively an infinite life in engineering design terms. In such a situation, a very small change in conditions can have a very large effect on the life of the structure. At 10^8 load cycles, a fatigue graph of cycles to failure versus stress is virtually flat even on a logarithmic scale, so a 5 per cent increase in stress can reduce the life to failure by a factor of 100.

Musculoskeletal tissues generally obey Wolff's law in that their form and structure are adapted to withstand the mechanical demands placed on them. Although this law was originally aimed at osseous tissue, it is accepted that articular cartilage also obeys it, and measurements have shown that the strength and stiffness of the articular surfaces increase as the stresses imposed locally increase. For example, Kempson *et al*. (1971) showed that the cartilage of the load-bearing area on the superior part of the femoral head had higher indentation stiffness than that from the inferior aspect, which was rarely loaded. This was later expanded to other joints of the lower limb by Swann and Seedhom (1985), who found a correlation between compressive modulus and predicted compressive stress in use. Kempson (1979) also found that there was a highly significant correlation with glycosaminoglycan content, and hypothesized that the loss of stiffness which follows early cartilage damage can be linked to loss of integrity of the collagenous framework that contains the glycosaminoglycans.

In an experiment on the cartilage of the femoral condyles, Kempson (1979) showed a significant loss of cartilage tensile strength with advancing age, and Weightman (1976*a*; Weightman 1976*b*) found a highly significant loss of cartilage fatigue strength with age. Thus, it seems that articular cartilage is more easily damaged with advancing age, and the exact mechanism for this is not known. However, since body weight does not fall greatly in most people with increasing age, the cartilage stresses will remain constant in normal activities, so one can foresee a convergence with the diminishing cartilage tensile and fatigue strengths which would lead to failure as a result of repetitive load cycles that eventually exceed a damage threshold. One hypothesis related to this is that an increase in stress can result from changes in the underlying bone, either a localized irregularity in the contour of the subchondral plate or a more general stiffening of the bone (Radin and Paul 1970). Repetitive loading experiments on rabbit joints (Radin *et al*. 1984) have shown that impacts caused trabecular microfractures, and that the healing response, associated with localized thickening of the damaged trabeculae, led to increased stiffness. These changes preceded cartilage damage. Trabecular hypertrophy is seen frequently as cartilage is lost from an osteoarthritic joint, and this is also part of a functional adaptation to the loss of the ability of the softened cartilage to support loads, which leads to localized areas of higher pressure. The growth of peripheral osteophytes is a further part of this adaptive process.

The studies above were careful to avoid testing damaged areas. With time, the early degenerative changes of softening and fibrillation (vertical fissures in the cartilage) seem to be found almost universally, but this is not the same as saying that fibrillation inevitably progresses to symptomatic osteoarthritis. In younger joints, fibrillation is found primarily in the non-loaded areas. This has been reported for the hip (Byers *et al*. 1970), the knee (Waugh *et al*. 1980) and the elbow (Goodfellow and Bullough 1967). These areas were found to be quite different from those which had 'progressive' lesions that led to full-thickness cartilage loss and which were associated with high stresses in use, such as the superior pole of the femoral head or the centre of the end-face of the radial head. It is interesting that there are differing frequencies with which the joints are affected by clinical degenerative changes. Beyond 70 years of age, most people have patellofemoral osteoarthritis, yet degeneration is rarely seen in the ankle. Part of the explanation comes from the pattern of movements, with 'linear' motion, such as in the ankle, appearing to be less damaging than a mixture of sliding and rotation, such as at the hip. This difference was emonstrated clearly by Goodfellow and Bullough (1967) between the humeroulnar and humeroradial articulations of the elbow. From a mechanical viewpoint, this appears to be related to the ability of the cartilage structure to adapt to resist the dominant loads. This can be visualized clearly through the demonstration of surface 'split lines', which display the orientation of the collagen fibres in the articular surfaces. They are able to align themselves with the sliding of a hinge joint, but cannot do so for a sliding and rotating joint, when the shear forces would be able to act across their orientation and hence to 'separate' the fibre bundles.

It is usually accepted that the areas of fibrillation, noted above, which are found in the majority of joints, do not lead directly to osteoarthritis. However, since these are areas of softening, it must be a possibility that cartilage damage could spread from them into the areas that usually carry significant forces. If there is a local area of cartilage softening, it will not carry its normal share of the joint force when the contact area covers it, thus, it is logical to expect elevated contact pressures in the adjacent cartilage. This phenomenon has been reported for chondromalacic lesions and for cartilage repairs that did not carry normal pressures when loaded (Shahgaldi *et al*. 1991). It is possible that large movements of joints that bring the loaded contact area over the softened zones at the normally unloaded aspect, can lead to expansion of the softened area until it is acted upon regularly, leading to breakdown in the heavily-loaded area. This is similar to the hypothesis of Swann and Seedhom (1985) that damage relates to occasional overload of cartilage that is not adapted to high stresses, and may be the cause of progression of patellar changes from localized degeneration of the extreme 'odd' medial articular facet, which only makes contact with the femur in full flexion (135°), across the full width of

the patella.

The discussion above has concentrated on 'primary' osteoarthritis, in which the cartilage changes have an insidious onset throughout a lifetime, and for which there is no obvious cause. There are, however, many cases where there is an obvious mechanical factor, often referred to as 'secondary' arthritis. The underlying principle is that there is a range of physiological stresses to which the articular surface is adapted, and that any sudden increase in loading, to a 'pathological' level, will initiate damage. This can arise from a wide range of orthopaedic problems, such as deformity of the joint surfaces due to malunion or malreduction of articular fractures, depression of the subchondral plate due to trabecular crushing, or to deformity of the limb due to angulation of an extra-articular fracture. There is also a spectrum of disturbances arising from abnormal growth, muscle actions, etc. A typical situation would be an inaccuracy of alignment following a femoral supracondylar fracture, which might leave a valgus angulation. In such a case, the line of action of the body weight would be shifted laterally at the knee, and this would cause elevated stresses on the lateral tibiofemoral articulation. This can then be the cause of a 'vicious circle', since lateral compartment cartilage loss will increase the valgus angulation on weight bearing, which will increase the stresses on the damaged articulation (that may now be devoid of cartilage). Total knee replacement can then act to restore the leg alignment, and balance the loads acting across the joint. Prior to the widespread acceptance of joint replacement, the procedure of choice was a realignment osteotomy, usually with a touch of overcorrection, that would allow the damaged area a respite, when reconstitution of a fibrocartilagenous surface and restoration of a healthy-looking joint space were sometimes observed (Maquet 1976). This approach is still used in young patients, for whom joint replacement is not advisable.

As well as bony damage, osteoarthritic changes can be initiated by soft tissue damage. At the knee, which has an inherently unstable articular geometry, the joint kinematics are controlled largely by the cruciate ligaments, which stabilize the tibiofemoral articulation against the anterior–posterior actions of the muscles. Rupture of the anterior cruciate ligament is common in sport, and this allows abnormal excursions of the femur across the tibial plateau. The resulting contact forces cause rapid articular damage in animals (Fig. 5), and this has been a widespread animal model for osteoarthritis (Muir and Carney 1987). The changes in humans are less drastic, and are often caused secondarily to meniscal damage. Loss of stability allows abnormal bone excursions, which then causes the menisci to be overridden by the femoral condyles, leading to damage. It is well known that the menisci transmit much of the knee joint force (Seedhom and Hargreaves 1979), so meniscal damage in a ligament-deficient knee combines abnormal motion with abnormal stresses, and can lead to degeneration. Meniscal damage alone has been suggested as a means of inducing arthritis experimentally (Shapiro and Glimcher 1980). With a slower rate of onset of cartilage damage, this was suggested as being more realistic than cruciate sectioning when inducing osteoarthritic changes experimentally.

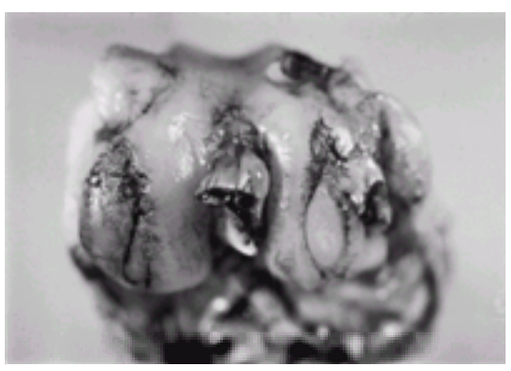

Fig. 5 Distal surfaces of rabbit femur, 6 months after division of the cranial cruciate ligament, showing areas of full-thickness cartilage erosion on the condyles. Cartilage damage has been highlighed by Indian ink staining (Meachim 1972).

Failure of lubrication mechanism

Another contributory factor to the development of osteoarthritis is a failure of the lubrication mechanism. This most likely acts in conjunction with one of the other failure mechanisms already discussed.

Under normal conditions, human joints function by having the two articular cartilage surfaces separated by a full film of synovial fluid. This does two things to help limit the damage to articular cartilage. First, by covering the rough surfaces of cartilage with a film of viscous fluid under pressure, the compressive stress transmitted to the cartilage is lower overall than if the two rough surfaces were in direct contact. We have seen that rough surfaces only contact at high spots, giving rise to very high stresses. The second method is by reducing the shear stress due to friction acting on the surfaces of the articular cartilage. Unsworth (1984) showed that these two factors could make all the difference to the failure of articular cartilage from fatigue stresses. In other words, if a full fluid-film mechanism exists between the cartilage surfaces, then they are likely to withstand a lifetime of use, whereas if the two surfaces rub directly on each other, premature failure is to be expected. The effects of this can be dramatic, reducing the life of 50-year-old cartilage to 4 years if lubrication fails (Unsworth 1984). This then raises another important feature of the way that the properties of synovial fluid and cartilage are affected by age, trauma, and disease. Anything that affects the joint's ability to produce a film of fluid can potentially cause damage to the cartilage surfaces and hence increase the effects of osteoarthritis.

Summary

It has been argued that cartilage is subjected to dynamic loading which can lead to a fatigue process causing damage to the surface layers of the joint. In addition, changes in the subchondral bone properties or in the stiffness of cartilage due to mechanical damage can also lead to accelerated mechanical failure of the articular surfaces. Changed kinematics in the joint, which for example might be due to the rupture of the anterior cruciate ligament of the knee, can also increase the resultant contact force and cause premature failure; as can damage to menisci or a failure of the lubrication mechanisms which normally promote fluid-film lubrication. All of these mechanisms effectively increase the resultant stress acting on the cartilage and this in turn will accelerate failure due to fatigue.

2.8 The neurophysiology of pain

Hans-Georg Schaible

General pain physiology (Table 1)

Table 1 Definitions (I)

Pain and nociception

Pain is the sensation which is evoked by potential or actual tissue-damaging stimuli (noxious stimuli) or by tissue injury. Pain has a sensory discriminative aspect consisting of the detection and identification of the noxious event. The affective (emotional) aspect of pain describes that a pain sensation is usually experienced as unpleasant. Furthermore noxious stimuli may elicit reactions of the motor system (e.g. withdrawal) and of the autonomic nervous system (e.g. changes in blood pressure, heart rate), and these reactions are defined as the motor aspect and the autonomic (vegetative) aspect of pain. Finally, pain sensations are compared and evaluated in regard to experiences of pain in the past and these mental processes form the cognitive aspect of pain. The occurrence of these components indicates that large parts of the central nervous system are involved in the responses to noxious stimuli (Perl 1984; Willis 1985; Besson and Chaouch 1987; Schmidt 1989; Willis and Coggeshall 1991).

The term nociception defines the neuronal events which occur in the peripheral and central nervous system when noxious stimuli are applied (Perl 1984; Willis 1985; Besson and Chaouch 1987; Schmidt 1989; Willis and Coggeshall 1991). Usually pain is a consequence of the activation of the nociceptive system but situations are known in which tissue damage and the resulting nociceptive processes do not evoke pain (e.g. during general anaesthesia) or in which pain occurs in the absence of noxious stimuli, i.e. without overt activation of the peripheral nociceptive system. It is of clinical importance that pain does not only depend on the processes of nociception but also on psychological and social factors.

The nociceptive system (Fig. 1)

A schematic illustration of the anatomy of the nociceptive system is shown in Fig. 1. The nociceptive system consists of neurones in the peripheral and central nervous system which are activated by the application of noxious stimuli to the innervated tissue. A proportion of neurones in the nociceptive system is specifically and exclusively activated by noxious stimuli (nociceptive specific neurones). In the central nervous system a large proportion of neurones shows convergence of non-nociceptive and nociceptive inputs, i.e. the neurones and pathways are not only involved in nociception but also in the processing of non-nociceptive sensory information (for references see Dubner and Bennett 1983; Perl 1984; Willis 1985; Besson and Chaouch 1987; Schmidt 1989; Willis and Coggeshall 1991 ; Mense 1993; Schaible and Grubb 1993; Wall and Melzack 1994).

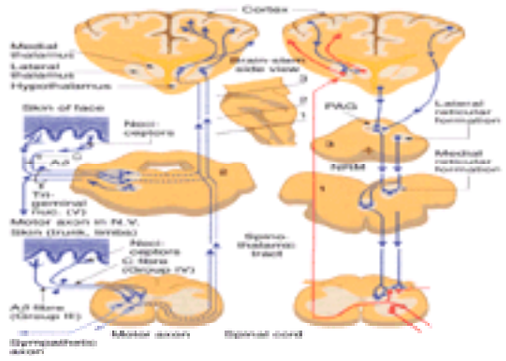

Fig. 1 The nociceptive system. The graph on the left shows a section through the spinal cord (bottom), of which the sensory neurones receive the afferent input from nociceptors supplying trunk and limbs. Sensory spinal cord neurones project to motor neurones and sympathetic neurones of the spinal cord (their axons leave the spinal cord in the ventral root) and to the brainstem and thalamus (top) via ascending tracts. The afferent input from the head is processed in the brainstem (above). Thalamic neurones project to the cerebral cortex. The graph on the right displays descending inhibitory systems which originate in the brainstem (two sections in the middle) and descend to the spinal cord. The brainstem is also influenced by pathways descending from the cortex. The central inset shows a side view of the brainstem with the three levels of the sections numbered 1–3. PAG, periaqueductal grey; NRM, nucleus raphe magnus. (Reproduced with permission from Schmidt 1989.)

Nociceptive afferent fibres of the peripheral nervous system (nociceptors) convey nociceptive sensory information from the innervated tissue to the spinal cord or to the brainstem. Functionally speaking, most of them are polymodal, i.e. they respond to mechanical, thermal, and chemical noxious stimuli. Nociceptive afferent units have unmyelinated axons with conduction velocities of less than 2.5 m/s (group IV or C fibres), a smaller proportion has thinly myelinated axons (group III or A d-fibres, conduction velocities 2.5–30 m/s). In contrast to non-nociceptive mechanoreceptors with thick myelinated axons (group II or A b-fibres, conduction velocities greater than 30 m/s), the sensory endings of nociceptive units are not encapsulated by or linked to specific corpuscular (receptive) structures but are free nerve endings. Numerous nociceptive afferent fibres not only have afferent sensory functions but also efferent functions by releasing peptides into the innervated tissue thereby exerting effects on the vasculature (Holzer 1988; see below). It should be noted, however, that not all slowly conducting afferent units with free nerve endings are nociceptors; some of them are involved in thermo- and mechanoreceptive functions.

The afferent sensory information is processed in the spinal cord (and in the brainstem for inputs from the head). Neurones encode the intensity and duration of noxious stimuli. Many spinal cord neurones show considerable convergence of inputs, i.e. they are activated from the skin and the deep tissue and/or viscera. Ascending axons convey sensory information to supraspinal targets such as the brainstem and the thalamus. The most important tracts are the spinoreticular and spinothalamic pathways, both of which ascend in the anterolateral quarter of the spinal cord. Interneuronal connections within the spinal cord constitute segmental pathways to the spinal cord output systems, the motor neurones in the ventral horn, and the sympathetic neurones in the lateral part of the grey matter. These pathways generate co-ordinated reflex responses which are, however, modified and controlled by descending systems from the supraspinal sites.

In the brainstem, several nuclei (e.g. the periaqueductal grey, PAG, the nucleus raphe magnus, NRM) are interconnected and form pathways which descend to the spinal cord. These pathways (mainly located in the dorsolateral funiculus) mediate a descending inhibition of neurones in the spinal cord, i.e. they partially suppress the processing of nociceptive information in spinal cord neurones (Fig. 1, right side). The brainstem nuclei are thought to be activated by nociceptive inputs via ascending tracts (thus forming a negative feed back system between spinal cord and brainstem) but they are also influenced from supraspinal sites (Gebhart 1986; Besson and Chaouch 1987; Willis 1988).

Activation of neurones in the thalamus and cortex is necessary to evoke the sensory, emotional, and cognitive components of the pain reaction (conscious sensation with unpleasant feeling, evaluation of the pain). Neurones in the ventrobasal complex of the lateral thalamus and in the cortical areas SI and SII are thought to be involved in the discriminative sensory aspects of pain since these neurones encode the parameters of a noxious stimulus such as intensity, localization, onset, and offset. Other neurones in the supraspinal structures such as neurones of the posterior thalamus and the intralaminar nuclei of the thalamus, and connections to the hypothalamus and the limbic system are thought to be involved in the generation of affective aspects of pain, in arousal reactions, and in pain memory (Perl 1984; Willis 1985 ; Guilbaud 1988; Kenshalo and Willis 1991).

The nervous system should not be understood just as a system of wires and switches which respond in a stereotyped manner to sensory stimuli. Considerable plasticity in the nociceptive system has been found in recent years (Dubner and Ruda 1992; Willis 1992; Coderre *et al*. 1993; McMahon *et al*. 1993; Schaible and Grubb 1993; Wall and Melzack 1994). Functional plasticity is an activity-dependent modification of neuronal processing and is observed during activation of the nervous system by long-lasting noxious stimuli such as inflammation. Structural plasticity describes anatomical changes in the nervous system such as sprouting of neurones, which is often seen after damage to the nervous system itself. Under both conditions a noxious stimulus will produce neuronal responses in the nervous system which are different to those seen in the nervous system under normal conditions. Changes in the nociceptive processing are thought to underly changes in the pain sensations such as allodynia and hyperalgesia (often present during inflammation, see below) or abnormal pain (often present after damage to the nervous system).

Neuronal basis of nociception in the joint

The anatomy of the innervation of joints

Articular nerves contain sensory afferent fibres and sympathetic efferent fibres. A proportion of about one-quarter of nerve fibres in the joint nerve consists of thick myelinated fibres (group II units) and thinly myelinated afferent fibres (group III units). Unmyelinated afferent fibres (group IV fibres) and the unmyelinated efferent units form the vast majority of all nerve fibres in the joint nerve. Non-nociceptive group II afferents (see below) are equipped with corpuscular endings of the Ruffini, Golgi, and Pacini type and these are located in the fibrous structures of the joint. By contrast afferent group III and IV fibres, many of which are nociceptive (see below), terminate as non-corpuscular or 'free nerve endings' in the fibrous capsule, the adipose tissue, the ligaments, the menisci, and the periosteum. The presence of non-corpuscular sensory nerve endings in the synovial layer (a major site of inflammatory foci in arthritic diseases) is still disputed since electron microscopy studies failed to identify nerve endings at these sites, whereas peptidergic structures in this layer have been assumed to represent afferent fibres (see Johansson *et al*. 1991; Schaible and Grubb 1993; Schmidt *et al*. 1994).

In their ultrastructure the non-corpuscular free nerve endings consist of a series of spindle-shaped thick segments connected by waist-like thin segments ('string-of-beads-appearance'). These beads and the end bulb contain mitochondria, glycogen particles, vesicles and 'bare' areas of axon sheaths which are not covered by Schwann cell processes. The beads are assumed to represent multiple receptive sites (Heppelmann *et al*. 1990). Proportions of the joint afferents (mainly unmyelinated fibres) are peptidergic, i.e. they express one or several neuropeptides such as substance P, neurokinin A, calcitonin gene-related peptide, and somatostatin, which are transported from the perikarya in the dorsal root ganglia to the peripheral endings in the tissue and also to the terminals in the spinal cord (Schaible and Grubb 1993; Schmidt *et al*. 1994). In the periphery, neuropeptides are thought to produce a neurogenic inflammation after their release upon stimulation of the afferent fibres since they lead to vasodilatation and plasma extravasation in the innervated tissue (Holzer 1988). Neuropeptides released in the terminals in the spinal cord modify the process of signal transmission (Duggan and Weihe 1991 ; Hökfelt *et al*. 1994; Urban 1994).

Nociception in the joint—peripheral mechanisms

Most joint afferents are mechanosensitive, i.e. they are activated by pressure applied to the joint and by movements of the joint. The receptive fields of the afferents are the areas that cause the fibre to fire on palpation. Figure 2 displays the receptive fields of two joint afferents in the capsule (the black spots). The receptive fields correspond to the location of the sensory endings of the afferent fibres in the tissue. According to their mechanosensitivity, afferent fibres are classified as non-nociceptive or nociceptive units. Non-nociceptive units are those which have sensory endings activated by innocuous mechanical stimuli, such as gentle pressure applied to the joint and movements in the working range of the joint. Most of them are group II and group III fibres and some are group IV units (see section I). Figure 2(a) shows a non-nociceptive group III unit which is activated by extension (ext.) and inward rotation (pronation, IR) in the working range of the joint (both are innocuous, normally not painful movements). Typically these units exhibit higher discharge rates during noxious movements such as noxious inward rotation (n.IR) but in the whole range of reactions these units do not clearly discriminate innocuous from noxious stimuli. The non-nociceptive units are considered to serve proprioceptive functions; their activation, however, does not necessarily cause conscious sensations which are related to the joint (the major sensation that is ascribed to the joint is pain).

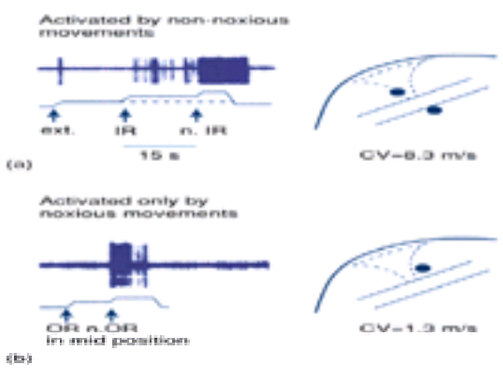

Fig. 2 (a) Response properties of a non-nociceptive unit with a low mechanical threshold in the innocuous range. The graph on the left shows the action potentials recorded from the axon during the application of the movements of the knee indicated by the traces underneath. Phasic response to extension of the knee, ext., and tonic response to inward rotation of the knee, IR, in extension (both movements in the working range of the knee joint); stronger response to noxious inward rotation of the knee, n.IR., in extension. The dots in the inset on the right show the location of two receptive fields of the unit in the capsule. (b) Nociceptive group IV unit with a high threshold. Same type of display as in (a). Strong response to noxious outward rotation, n.OR (and other noxious movements) but no response to outward rotation

in the working range, OR, in mid-position (and any other movement in the working range). The dot shows the location of the receptive field in the capsule. CV, conduction velocity of the axon.

By contrast, nociceptive units are those which have sensory endings that are only activated by noxious stimuli, such as strong pressure applied to the joint and movements exceeding the working range of the joint (thus these units are high-threshold units). Nociceptive afferents are group III and IV units. Figure 2(b) displays a nociceptive group IV unit which does not respond to innocuous movements such as outward rotation in the working range (OR) but responds to noxious outward rotation against the resistance of the tissue (n.OR). These units clearly signal noxious events. Most of them also respond to chemical stimulation, e.g. to algesic substances such as bradykinin. These afferents are polymodal nociceptors. In conscious humans, sensations of pain have been evoked when noxious mechanical, thermal, and chemical stimuli such as acids and hypertonic salt solutions were applied to the fibrous structures of the joint, the ligaments, and the fibrous capsule. By contrast, the application of mechanical and thermal stimuli to the cartilage did not evoke sensations and, interestingly, not much evidence was provided for sensations evoked by stimulation of the synovial layer (see Schaible and Grubb 1993). Muscle nerves contain nociceptive units which have response properties similar to those of joint afferents (Mense 1993).

A further group of afferents does not respond to innocuous or noxious mechanical stimuli; they are mechanoinsensitive afferents (Schaible and Schmidt 1988). These units do not have an apparent sensory function under normal conditions but they are important during inflammation of the joint (Schaible and Grubb 1993; see below).

Nociception in the joint—mechanisms in the central nervous system

In the spinal cord the nociceptive afferent input from joints is processed in neurones of the dorsal and ventral horn of the grey matter. With regard to the 'sensory channels' activated by joint input there are two subsets of neurones; one that has only afferent inputs from deep structures such as joint and muscle and another one which has additional cutaneous input. Thus the afferent input from the joint is further processed in spinal cord neurones which are not exclusively activated by joint afferents but also by afferents from other tissues. Since numerous afferent fibres project to one and the same spinal cord neurone (convergence) the receptive fields of the neurones are much larger than those of single afferent units. Figure 5(b) shows a spinal cord neurone which had a receptive field in the knee joint and the adjacent muscles.

Fig. 3 Overview of neuronal events in the course of an inflammation in the joint. The graph displays the spinal cord with the afferent input from the joint via sensory fibres and the motor and sympathetic output pathways. (Reproduced from Schaible and Grubb 1993, with permission.)

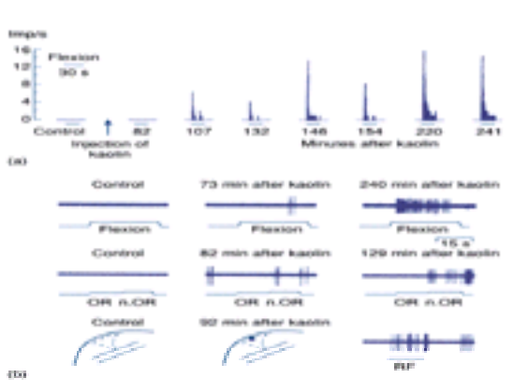

Fig. 4 (a). Sensitization of a nociceptive group III unit to mechanical stimulation of the joint during development of inflammation in the joint. The graph shows peristimulus time histograms indicating the number of action potentials elicted in this afferent fibre by flexion of the knee. No response to flexion of the normal joint. After the induction of inflammation by kaolin and carrageenan the previously high-threshold unit developed responses to flexion of the joint. (b). Sensitization of a mechanoinsensitive group IV unit during development of inflammation of the knee joint. No responses to mechanical stimulation before inflammation (control, traces on the left), i.e. no response to flexion, outward rotation, OR, noxious outward rotation, n.OR, and palpation of the joint (no receptive field identified). After induction of inflammation by kaolin and carrageenan there was induction of mechanosensitivity (traces in the middle and on the right). At this stage responses were elicted by movements and by palpation of the joint (with identification of the receptive field, dot). RF, pressure applied to the receptive field. (Modified from Schaible and Schmidt 1988.)

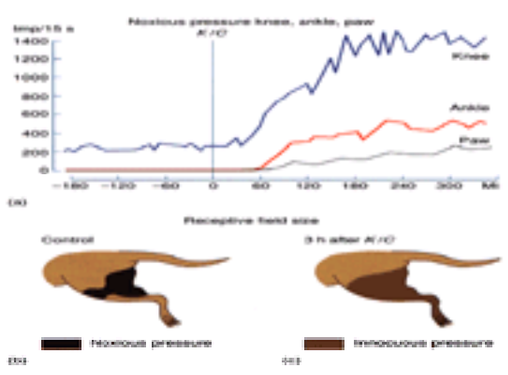

Fig. 5 Generation of hyperexcitability in a spinal cord neurone of the rat during development of inflammation in the knee joint. (a) Responses of the neurone (impulses/15 s) to noxious pressure applied to the knee, ankle, and paw before and after induction of inflammation in the knee joint (k/c). During development of inflammation in the knee the responses to noxious pressure applied to the knee were progressively enhanced and responses were also elicited by noxious pressure applied to the non-inflamed ankle and paw. (b) Receptive field of the neurone before inflammation. The neurone was only activated by noxious pressure applied to the knee and the adjacent muscles. (c) Expanded receptive field of the neurone 3 h after induction of inflammation. At this stage the neurone could be activated by gentle pressure applied to the whole leg. (Reproduced from Neugebauer *et al*. 1993 with permission.)

With regard to their activation threshold, the neurones with joint input have been classified as nociceptive specific and wide dynamic range. Nociceptive-specific

neurones with articular input respond only to noxious compression of the joint and other structures of the hind limb(s) and/or to noxious movements of the knee (movements against the resistance of the joint structures). Wide dynamic range neurones show substantial responses to innocuous pressure applied to the knee and other structures and to movements in the working range of the knee but show more pronounced responses to stimuli of noxious intensity. The convergence of nociceptive afferents to the spinal cord neurones provides some explanation for the diffuse and badly localized nature of joint pain.

The response characteristics of a spinal cord neurone do not only depend on its afferent inputs (non-nociceptive and/or nociceptive fibres). Numerous spinal cord neurones with joint input are tonically inhibited by descending inhibitory systems (see above). Indeed, the interruption of descending inhibitory influences leads to enhanced sensitivity and enlargements of receptive fields of many spinal cord neurones (Gebhart 1986; Willis 1988; Schaible and Grubb 1993). It is possible that intrinsic properties of the neurone (e.g. biophysical parameters) also contribute to its response behaviour.

A proportion of the nociceptive-specific and wide dynamic range neurones project to supraspinal sites (see Fig. 1). They activate supraspinal pathways and in awake humans and animals they evoke pain sensations (Willis 1985; Willis and Coggeshall 1991). Most nociceptive-specific and wide dynamic range neurones with joint input belong to intraspinal pathways mediating and controlling motor events. Reflexes evoked by joint afferents are important in eliciting protective muscle movements, i.e. movements counteracting hyperflexion, hyperextension, and hyperrotation. These noxious movements have marked effects on a-motor neurones which activate skeletal muscle fibres and initiate movements. Under normal (innocuous) conditions joint afferents only exert weak effects on the a-motor neurones. By contrast, the application of innocuous stimuli to the joint leads to considerable reflex discharges in g-motor neurones (g-motor neurones adjust the length of muscle spindles thereby optimizing the gain of the reflexes which control the length of the muscle, for details see Schmidt 1989). Through this pathway joint afferents may participate in the regulation of joint stiffness and joint stability during normal movement (Johansson *et al*. 1991).

The neurobiological response of the nociceptive system to joint inflammation

Studies using models of experimental inflammation (injection of crystals and/or carrageenan for induction of acute inflammation and injection of Freund's complete adjuvant (FCA) for induction of chronic inflammation) have provided evidence for complex changes in the peripheral and central nervous system during inflammatory diseases, indicating that the nervous system undergoes functional plasticity during inflammation (Fig. 3). Thus in the course of inflammatory lesions in the joint, the nociceptive system is not only activated but also modified to some extent. The changes observed are thought to be responsible for the allodynia (pain during application of innocuous stimulation such as gentle pressure and movements within the working range of the joint), hyperalgesia (enhanced pain during noxious stimulation), and persistent pain in the joint which are typical symptoms of joint inflammation. The activation of the nociceptive system may also have an influence on the inflammatory lesion due to the efferent function of the nervous system (Schaible and Grubb 1993).

As indicated in Fig. 3, there is an increased afferent inflow into the central nervous system by activation and sensitization of afferent fibres supplying the inflamed joint, thereby constituting the peripheral basis of pain in the inflamed joint (see below). Spinal cord neurones with input from the inflamed joint develop a state of hyperexcitability which significantly increases the gain of the processing of the afferent input. These changes in the spinal cord are thought to be produced by the increased or additional release of several transmitters/modulators and by the activation of receptors on postsynaptic neurones which are less or not activated under physiological conditions (see below). Changes in the release of transmitters and in the activation of postsynaptic receptors may be associated with an upregulation of the synthesis of transmitters in the long-term range. Output channels of the spinal cord (ascending axons, motoric and sympathetic pathways) are modified accordingly (see below).

Activation and sensitization of joint afferents—the peripheral neuronal basis of inflammatory pain in the joint

Numerous afferent units supplying an inflamed joint exhibit ongoing discharges and show increased responsiveness to mechanical stimuli applied to the joint, i.e. they are sensitized. Many non-nociceptive group III and IV afferents show increased responses to movements in the working range of the joints. This form of sensitization enhances the afferent input to the spinal cord quantitatively. Importantly, in most nociceptive group III and IV afferents the activation threshold is lowered: they start to respond to normally innocuous stimuli such as movements within the working range of the joint and gentle pressure applied to the joint. Figure 4(a) shows the sensitization of a high-threshold group III unit to mechanical stimuli. Before inflammation the unit responded only to noxious rotation of the joint (similar to the unit displayed in Fig. 2(b) but, during development of an acute inflammation, responses were also elicited by movements in the working range: after induction of inflammation this nociceptor started to respond to flexion in the working range of the joint (see Fig. 4(a). This form of sensitization represents a quantitative and a qualitative change since sensitized nociceptors transmit their message 'noxious movement' to the spinal cord in response to an ordinarily innocuous stimulus (Schaible and Grubb 1993; Schmidt *et al*. 1994) and thus the nociceptive system in the central nervous system is already activated by normally non-painful stimuli.

In addition to the sensitization of mechanosensitive non-nociceptive and nociceptive afferent fibres, a proportion of mechanoinsensitive afferent fibres are rendered mechanosensitive during inflammation. Figure 4(b) displays a unit which was not excited even by noxious stimulation before inflammation (traces on the left: no response to pressure applied to the joint, i.e. no identification of the receptive field, and no response to movements). During development of inflammation the fibre could be activated even by innocuous movements and gentle pressure (see action potentials in the traces on the right and the dot on the knee joint showing the location of the receptive field identified during inflammation). It was proposed that these units are 'silent nociceptors' which play a role particularly under inflammatory conditions (see above). By their activation these newly recruited nociceptive units increase the afferent drive of spinal neurones providing, by their recruitment, spatial and temporal facilitation in the spinal cord (Schaible and Grubb 1993).

Mechanisms underlying the activation and sensitization of joint afferents

The mechanosensitivity of joint afferents during inflammation may be altered by physical changes in joint tissues such as increase of the intra-articular pressure by an effusion, which is also accompanied by a decrease in joint compliance (see Fig. 3). The effect of this is that, during movements, articular pressure increases more in diseased joints than in normal joints for the same volume of fluid present. In addition to changes in the gross pathology of the joint in arthritis there are also changes in the microvasculature. Both factors could activate joint afferents but experimental evidence is sparse. Of great importance for the activation and sensitization of joint afferents is their chemosensitivity to inflammatory mediators which occur in inflamed tissue (Fig. 3). Inflammatory mediators do not only produce the inflammatory response (Moncada *et al*. 1979; Salmon and Higgs 1987; Sedgwick and Willoughby 1989) but also exert significant effects on afferent fibres (Mense 1993; Schaible and Grubb 1993; Schmidt *et al*. 1994). Whilst these extraneuronal changes represent stimuli to the receptive endings, there may be also (secondary) changes in the terminal sites themselves that contribute to the increased mechanosensitivity.

The application of inflammatory mediators to the joint has shown chemosensitivity of joint afferents for several inflammatory compounds, namely prostaglandins (in particular for PGE_2 and PGI_2), bradykinin, and serotonin. Chemosensitivity of joint afferents to other inflammatory mediators (e.g. leukotrienes) has not been experimentally tested. In significant proportions of afferent group III and IV fibres these inflammatory mediators induce patterns of firing which are similar to those seen under inflammatory conditions, i.e. excitation and/or induction of ongoing activity and an increase of the responses to mechanical stimuli (sensitization towards mechanical stimuli) and thus these mediators are thought to play an important role in the generation of inflammation-evoked activity.

In addition, individual mediators such as prostaglandins and bradykinin have been shown to interact. Both PGE_2 and PGI_2 enhance the excitatory effects of bradykinin in a proportion of neurones, and the combination of both mediators may sensitize afferent units more to mechanical stimuli than the individual mediators. The combined action of mediators may be more close to pathophysiological conditions in a joint than the action of just one mediator since several inflammatory mediators are present in inflammatory exudates at the same time. Interestingly, neuropeptides which are peripherally released from afferent fibres (producing neurogenic inflammation) failed to evoke marked effects in afferent units as far as this has been tested (Schaible and Grubb 1993; Schmidt *et al*. 1994).

Recordings from single units have shown two further important aspects of the chemosensitivity. First, each of the mediators tested excited and sensitized only proportions of the articular afferents; thus joint afferents are not homogeneous with regard to their chemosensitivity. Second, mediators excited and sensitized proportions of non-nociceptive, nociceptive, and initially mechanoinsensitive afferent units; thus there is no specific relationship between the mechanical threshold and the chemosensitivity of the afferent units. Inflammatory mediators usually do not, however, excite and sensitize non-nociceptive group II afferents (Schaible and Grubb 1993).

Activation of spinal cord neurones and generation of spinal hyperexcitability—a complex response of the central nervous system to peripheral inflammation

Figure 3 highlights the importance of the spinal cord as an integrative site for sensory and reflex functions. During the development of an acute inflammation in the joint, nociceptive-specific and wide dynamic range neurones in the spinal cord show enhanced responsiveness to noxious stimuli applied to the inflamed joint.

Nociceptive-specific neurones exhibit a reduction in their mechanical threshold such that the application of innocuous stimuli to the inflamed joint is sufficient to excite the neurones (Schaible and Grubb 1993). Figure 5 shows the changes of the response properties of a spinal cord neurone during development of inflammation in the knee joint of the rat. Before inflammation the neurone had a high-threshold receptive field in the knee and the deep tissue of the thigh and lower leg (black area in Fig. 5(b)), i.e. the neurone responded to noxious pressure on to the knee and the adjacent structures but not to noxious pressure applied to the ankle and paw (Fig. 5(a)). After induction of inflammation (k/c), the neurone showed increases of the responses to noxious pressure applied to the knee and it developed also responses to noxious pressure applied to ankle and paw (Fig. 5(a)), i.e. the neurone exhibited an expansion of the receptive field. At this stage innocuous pressure to all parts of the receptive field was sufficient to activate the neurone, i.e. the excitation threshold had changed from high to low (Fig. 5(b), stippled area).

The increased responses to stimuli applied to the inflamed joint are most likely induced by the increase of the afferent inflow due to activation and sensitization of afferent units (see Fig. 3 and above). The changes of the response properties of spinal cord neurones during inflammation do not, however, simply reflect the afferent impulses from the joint. The enhanced responses to mechanical stimuli applied to non-inflamed regions adjacent and remote from the joint and the expansion of the receptive fields (Fig. 5), as well as increased responses to electrical stimulation of peripheral nerves (not shown), indicate that the spinal cord neurones with articular input develop a state of hyperexcitability in which the responsiveness of the neurones to inputs from inflamed and non-inflamed areas is increased (the putative mechanisms of the spinal sensitivity changes are described in the next section). Numerous observations suggest that similar changes occur during chronic inflammation. It is thought that these neuronal changes underly the pain, allodynia, and hyperalgesia in the inflamed joint, adjacent and even remote non-inflamed tissue (Schaible and Grubb 1993).

Other mechanisms, however, have been found to counteract the increase in the excitability of spinal cord neurones to some extent, namely an increase in heterotopic inhibitory influences on spinal neurones with input from inflamed areas (i.e. the neurones may be inhibited by noxious stimuli applied to areas outside the receptive field of the neurone) and an increase in the effectiveness of the descending inhibition of spinal cord neurones (see Fig. 1).

Changes of the responsiveness of spinal cord neurones have effects on the motor system. In humans a painful joint always influences motor performance in that extensive movements are avoided and the limb is kept in a position where pain is minimized. In animals, there is an increase in the flexion reflex during long-lasting noxious stimulation of the knee, which is consistent with the nociceptive flexion reflex concept (stating that withdrawal is the adequate reaction to a noxious stimulus), but increases in inhibitory influences have also been demonstrated. Probably there is a new balance between excitatory and inhibitory drives from spinal and supraspinal neurones to motor neurones which makes one keep an injured or inflamed joints in mid-position where joint afferents are less active than at flexed and extended positions (Schaible and Grubb 1993).

Mechanisms underlying the synaptic activation of spinal cord neurones and the development of hyperexcitability (Table 2)

The communication between neurones is provided by chemical transmission in synapses. Upon activation (propagation of action potentials into the axonal terminal) the presynaptic neurone releases excitatory or inhibitory transmitters which cross the synpatic cleft, bind to receptors, and then open ion channels on the postsynaptic neurones (Fig. 6). The sum of all excitatory and inhibitory synaptic potentials evoked in the neurone determines whether the postsynaptic neurone will fire. Importantly, many neurones do not only contain a classical transmitter (small molecules such as L-glutamate or biogenic amines) but rather exhibit a coexistence of classical transmitters and one or several neuropeptides such as substance P and calcitonin gene-related peptide in their presynaptic endings. Postsynaptic neurones contain a variety of receptors for classical transmitters and neuropeptides (Duggan and Weihe 1991; Urban 1994).

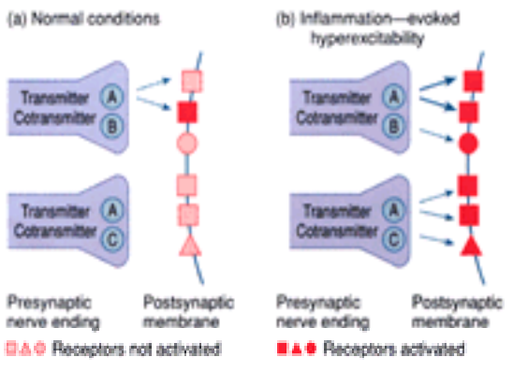

Fig. 6 Proposed mechanisms involved in the generation and maintenance of inflammation-evoked hyperexcitability of spinal cord neurones. The graphs in (a) and (b) show the membrane of a postsynaptic neurone with different receptors for transmitters. The ligands for these receptors, the transmitters, and cotransmitters, are stored in and released from the presynaptic nerve terminals connected to the postsynaptic neurone. (a) Synaptic function under normal conditions. Only the upper presynaptic ending is active and only one transmitter is released. In this situation many receptors are not activated. (b) Synaptic function during inflammation. Both presynaptic endings are activated and they release a number of transmitters which are bound to the receptors on the postsynaptic side.

γ-motor neurone	Nerve cell in the spinal cord which forms neuromuscular endings in the skeletal muscle. Activation of γ-motor neurones causes contraction of the muscle
Excitatory amino acids	Amino acids which cause depolarization (synaptic activation) of neurones. They serve as transmitters at synapses
γ-motor neurone	Nerve cell in the spinal cord of which the axon terminates on muscle spindles in the skeletal muscle. The activation of γ-motor neurones enhances the sensitivity of muscle spindles which measure the length of the skeletal muscle
Postganglionic sympathetic neurone	Efferent neurone of the sympathetic nervous system which is synaptically activated by preganglionic neurones in sympathetic ganglia. The postganglionic neurone mediates the effect of the sympathetic nervous system on the tissue
Postsynaptic receptor	Ligand-gated ion channel in postsynaptic membrane which is opened by a transmitter
Presynaptic ending	Presynaptic nerve terminal at which transmitter(s) is (are) released
Synapse	Microstructure by which nerve cells are connected. The presynaptic nerve terminal releases transmitter which diffuses to receptors on the membranes of the postsynaptic neurone and opens there ligand-gated ion channels
Transmitter	Endogenous compound that is released from a presynaptic ending and acts on a receptor in the postsynaptic membrane
Vasoconstrictor neurone	Neurone of the sympathetic nervous system which causes vasoconstriction of vessels

Table 2 Definitions (II)

Synaptic transmission is not only the basis of the normal communication between neurones; due to the complexity of the pre- and postsynaptic processes, changes in the synaptic transmission are also thought to be involved in the plasticity of the nervous system. Figure 6 illustrates some properties of the synaptic function proposed for the normal state and for the hyperexcitable state of spinal cord neurones, which is an example of the functional plasticity in the nociceptive system. Under normal conditions only a proportion of the afferent fibres are activated by innocuous and noxious stimuli and only some of several transmitters are released from presynaptic endings. Consequently only some receptors on the postsynaptic side are activated. During inflammation numerous afferent neurones are sensitized such that they are activated by innocuous and noxious stimuli (see above). Therefore more presynaptic endings in the spinal cord are active, and a 'cocktail' of transmitters and/or modulators is released which is quantitatively and qualitatively different to that released during noxious stimulation of normal tissue. Hence more and different receptors on the postsynaptic neurones are activated by the ligands. This results in a stronger activation on the postsynaptic neurone as shown in Fig. 5. In addition, sensitivity of postsynaptic neurones may be altered by intracellulalar processes which are induced by the synaptic activation (Schaible and Grubb 1993).

Excitatory amino acids such as L-glutamate are transmitters with a wide distribution in the central nervous system. Table 3 shows that L-glutamate acts on three classes of receptors at postsynaptic neurones (Monaghan *et al*. 1989; Headley and Grillner 1990; Urban 1994). Electrophysiological and behavioural experiments have shown that excitatory amino acids and their receptors are important in nociception (Headley and Grillner 1990; Schaible and Grubb 1993; Urban 1994). Figure 7(a) displays the involvement of non-NMDA and **NMDA** (*N*-methyl-D-aspartate) receptors in the synaptic activation of a spinal cord neurone which responds to innocuous and noxious pressure applied to the knee joint. The graph shows the action potentials of the spinal cord neurone which are elicited by application of innocuous and noxious pressure to the knee joint. Whilst the spinal ionophoretic administration of the antagonist, 6-cyano-7-nitroquinoxaline-2,3-dione (**CNQX**), at the non-NMDA receptor reduced the responses to innocuous and noxious pressure applied to the normal knee, the administration of the antagonist, ketamine, at the NMDA receptor, only reduced the responses to noxious pressure (Fig. 7(a)). Thus, under normal conditions, NMDA receptors seem to be mainly involved in the

nociceptive processing in these neurones but not in the processing of non-nociceptive inputs.

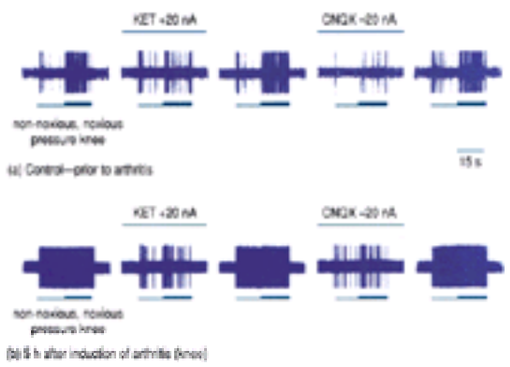

Fig. 7 Responses (action potentials) of a spinal cord neurone to innocuous and noxious pressure applied to the knee joint and reduction of the responses by antagonists at the NMDA receptor (ketamin) and at the non-NMDA receptor (CNQX, see text). In (a) the knee joint is normal and the NMDA antagonist reduces only the response to noxious pressure. In (b) the knee joint is inflamed (the mechanical stimuli evoke stronger responses) and in this situation the NMDA antagonist reduces the responses to innocuous and noxious pressure. CNQX reduces the responses to innocuous and noxious pressure under both conditions. The antagonists were administered ionophoretically to the neurone using multibarrel electrodes for simultaneous recording and drug application.

Receptor	Specific ligands	Functional properties
NMDA	N-methyl-D-aspartate	Ion channel for Na^+, K^+, Ca^{2+} only opened after strong depolarization
Non-NMDA	(RS)-2-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA); kainate	Ion channel for Na^+, K^+
Metabotropic	E.g. Trans-(+)-1-amino-(1S,3R)-cyclopentane-dicarboxylic acid (t-ACPD)	Coupled to G-proteins Activation of intracellular messenger systems

Table 3 Receptors for excitatory amino acids

The non-NMDA and NMDA receptors are not only involved in the synaptic transmission of nociceptive information; they are also involved in the generation of hyperexcitability (see Fig. 5). Increases in the responsiveness (hyperexcitability) of spinal cord neurones during inflammation and other noxious stimuli are prevented as long as either non-NMDA or NMDA receptors are blocked (see references in Neugebauer *et al*. 1993). Evidence has also been provided that blockade of the G-protein coupled metabotropic glutamate receptors prevents hyperexcitability (Neugebauer *et al*. 1994). Thus all three receptor types for excitatory amino acids must be activated to generate hyperexcitability of the neurone, and the changes of the responses displayed in Fig. 5 do not occur when the receptors for excitatory amino acids are blocked. Excitatory amino acids and their receptors are also involved in the maintenance of hyperexcitability. This is displayed in Fig. 7(b) which shows the same neurone as Fig. 7(a) but now the knee joint is inflamed and the neurone exhibits stronger responses to innocuous and noxious pressure applied to the knee. Both the increased responses to innocuous and noxious pressure applied to the inflamed knee are reduced by the antagonists at the NMDA and non-NMDA receptor (Neugebauer *et al*. 1993).

Some neuropeptides are also of particular interest for synaptic transmission in the spinal cord and its plasticity. They are contained in many afferent units and intrinsic neurones of the spinal cord (Holzer 1988; Duggan and Weihe 1991). The intraspinal release of the tachykinins, substance P and neurokinin A, and of calcitonin gene-related peptide can be evoked by application of noxious stimuli such as noxious pressure applied to the joint. During inflammation of the joint, innocuous stimulation of inflamed tissue may be sufficient to elicit release of the peptide, whilst such stimuli usually do not evoke release when the joint is in normal condition (Schaible and Grubb 1993; Schaible *et al*. 1994). Using antagonists it has been shown that substance P is involved in the synaptic transmission of nociceptive information (Henry 1994) and some evidence has been provided that substance P may also play a role in the generation and maintenance of hyperexcitability (see Neugebauer *et al*. 1995). Inhibitory neuropeptides may also play an important role. The synthesis of dynorphin, an endogenous agonist, at the k-opioid receptor has been found to be increased during long-lasting noxious stimulation such as inflammation. Inhibitory neuropeptides may set a new balance between excitatory drives and inhibitory mechanisms and thus control the degree of pain experienced (Dickenson 1994).

A number of issues have not yet been clarified; for example it is not known to what extent the changes in the central nervous system require the permanent drive from sensitized afferent fibres from the inflamed tissue and to what extent alterations in the central nervous system become independent of the afferent input. Furthermore it is not yet clear whether chronic pain lasting for weeks, months, and years involves the same mechanisms which are at work in acute and persisting acute pain.

Activation of neurones in the supraspinal nervous system during joint inflammation

Since spinal cord neurones change their response pattern during inflammation, neurones in the brainstem and the thalamus receive altered inputs via the ascending tracts. As a consequence, in the course of acute unilateral inflammation and of chronic polyarthritis, neurones in the ventrobasal thalamus and the cortical area SI display enhanced responses to mechanical stimulation of inflamed and non-inflamed areas and increases of their receptive fields (Guilbaud 1988). It is not known whether these alterations in the discharges are entirely due to the inflow from the spinal cord or whether intrinsic mechanisms in the thalamus and cortex contribute to the expression of these changes in response.

The contribution of the nervous system to the inflammatory process in the joint

As outlined above, the inflammatory process is mediated by a number of mediators which are released and/or synthesized in inflamed tissue. There is experimental and clinical evidence that the nervous system may also contribute to or influence the inflammatory process, by efferent functions of afferent fibres and by efferent sympathetic fibres.

Efferent functions of afferent fibres—mechanisms of neurogenic inflammation

The neuropeptides substance P and calcitonin gene-related peptide have been found to be released from afferent fibres supplying numerous organs including the joints upon activation. These peptides produce a neurogenic inflammation characterized by vasodilation and plasma extravasation (Holzer 1988). Other actions of neuropeptides include stimulation of white blood cells and synoviocytes to release and/or produce inflammatory compounds (Levine *et al*. 1987). There is experimental evidence that neuropeptides contribute to the development of the inflammation of the tissue since the expression of acute and chronic inflammatory lesions has been found to be attenuated after impairment of the function of afferent fibres (e.g. by pretreatment with the neurotoxin capsaicin which destroys or inactivates unmyelinated afferent fibres or by immunization against calcitonin gene-related peptide). A role in the contribution to the inflammatory lesion has been ascribed to substance P and calcitonin gene-related peptide. Observations in human joint diseases seem to support the experimental evidence, although the picture from clinical studies is not totally clear (Schaible and Grubb 1993). In this context, findings could be important which showed an upregulation of the synthesis of substance P and calcitonin gene-related peptide in the dorsal root ganglia in segments supplying inflamed tissue (Schaible and Grubb 1993). Neuropeptides, however, do not only support inflammatory reactions; they may also support wound healing (Holzer 1988).

Contribution of efferent sympathetic fibres to the expression of inflammatory disease

The joints are supplied by efferent sympathetic nerve fibres which exhibit ongoing and reflex discharges. From their efferent effects they are vasoconstrictor neurones. As other sympathetic subsystems, such as the cardiac postganglionic sympathetic neurones and the sympathetic adrenal system, the sympathetic efferents to the joint show reflex discharges when noxious stimuli are applied to the joint (Jänig 1985; Schaible and Grubb 1993). Some sympathetic subsystems (e.g. the cardiac system and the adrenal medulla) show more pronounced reflex responses to stimulation of the inflamed joint than to stimulation of the normal joint (Schaible and Grubb 1993).

In the polyarthritic rat, the sympathetic nervous system seems to contribute to the expression of the inflammatory lesions since the reduction of sympathetic activity and/or the blockade of the postsynaptic effects by antagonists at adrenergic receptors in the tissue partially reduced the severity of the lesions. In acute models of experimental inflammation the sympathetic nervous system has not been found to contribute to the expression of the inflammatory lesion (see Schaible and Grubb 1993).

Reduction of activity in afferent fibres and neurones of the central nervous system by antinociceptive compounds

With increasing knowledge of the nociceptive pathways and the reactions of the nervous system to inflammatory lesions in the periphery, the antinociceptive action of drugs can be better related to targets and neuronal events in the nervous system. The spectrum and sites of effects of antinociceptive drugs are more complex than previously thought.

Reduction of afferent discharges

Several classes of compounds have been found to reduce the inflammation-evoked activity in articular afferents. Non-steroidal anti-inflammatory drugs (**NSAIDs**) such as acetylsalicylic acid and indomethacin reduce ongoing and stimulus-evoked discharges. Since NSAIDs inhibit the synthesis of prostaglandins these findings show that elevated levels of prostaglandins are involved in the generation of inflammation-evoked discharges. Not all joint afferents, however, have been found to be sensitive to the effects of prostaglandins (see above). Whilst the reduction of activity in afferent fibres unequivocally shows the originally proposed peripheral action of NSAIDs, there is growing evidence that the antinociceptive action of NSAIDs is not only due to actions in the peripheral inflamed tissue, an additional action in the central nervous system is likely (McCormack and Brune 1991).

In behavioral experiments the application of bradykinin antagonists (of the B_1 and B_2 type) has been shown to reduce inflammation-evoked hyperalgesia suggesting an important role of endogenous bradykinin (Dray and Perkins 1993). A reduction of the sensitivity of joint afferents to mechanical and chemical stimuli has been described for capsaicin, a naturally occurring constituent of hot red peppers. The mechanisms underlying these desensitizing effects are not yet clear. Evidence is accumulating that opioids do not only have actions in the central nervous system (see below) but also in the peripheral nervous system. After peripheral administration of opioids a reduction of the afferent discharges, a reduction of nociceptive behaviours, and a reduction of the release of substance P from joint afferents have been shown. All three opioid receptor types, μ-, d-, and k-receptors, seem to contribute to these effects (Schaible and Grubb 1993). It remains to be determined whether bradykinin antagonists, capsaicin, or peripherally acting opioids can be successfully used for treatment of arthritic pain.

Reduction of activity in neurones of the central nervous system

The reduction of discharges in afferent fibres by peripherally acting compounds will reduce the activity in the central nervous system and thus a reduction of inflammation-evoked activity may be of peripheral origin. It should be noted, however, that it has not been shown to what extent the activity in the central nervous system is dependent on the afferent inputs under pathophysiological conditions (see above). Some potent analgesics such as opioids, e.g. morphine (acting on μ-receptors), have their main targets within the central nervous system. In spine cord transected animals a spinal site of the antinociceptive action of morphine has been demonstrated. It has also been suggested that morphine may increase the descending inhibition of spinal cord neurones by acting on brainstem nuclei (see Fig. 1). There is, however, still no agreement on the importance of the latter mechanism (Dickenson 1994). Both the analgesic effect of morphine and the tolerance for opioids have been found to be enhanced in polyarthritic rats (Kayser 1994).

As mentioned above, NSAIDs may also have additional targets in the central nervous system. It has yet to be shown whether actions of NSAIDs in the central nervous system are also due to the inhibition of prostaglandin synthesis or whether other mechanisms are involved. When the mechanisms of signal transmission in the central nervous system are better understood, a more specific blockade of receptors (e.g. receptors for excitatory amino acids and neuropeptides) may be applicable, provided that the overlap of transmitter/receptors at different sites and nerve functions does not create too many side-effects.

3.1 Cells and mediators

Mark J. Walport and Gordon W. Duff

Introduction

Inflammation is an essential protective process preserving the integrity of organisms against physical, chemical, and infective insults. Inflammation is associated with the production of disease when inappropriately triggered, acutely, as in an attack of gout, or chronically, when the normal mechanisms for the resolution of inflammation do not operate or the stimulus to inflammation cannot be removed.

This chapter will consider the basic physiology and pathophysiology of the innate mechanisms of immunity and their role in inflammation. Emphasis will be placed on the normal regulation of the pathways of inflammation and how these may be disturbed in disease. The major physiological activities of individual components of innate immunity are often redundant, for example there are many receptors capable of recognition of bacteria and immune complexes that co-operatively mediate phagocytosis. An accurate perspective of the function *in vivo* of a molecule or pathway of inflammation is sometimes gained by the analysis of individuals who show inherited total deficiency of a particular protein. Examples of such deficiency states will be considered throughout this chapter.

Variation in host response may play an important part in determining disease susceptibility. It may be that genetic susceptibility to many rheumatic diseases is determined in part by inherited polymorphisms in the function of the molecules and cells involved in inflammatory mechanisms. This will be illustrated by consideration of the role of inherited variations of the complement system in the induction of increased susceptibility to the development of systemic lupus erythematosus.

We will not attempt to provide a comprehensive review of the role of the innate system of immunity in the production of rheumatic disease, but will illustrate the main principles using selected examples. Particular issues that we will consider are: (i) what distinguishes acute from chronic inflammation; (ii) does genetic variation in the mechanisms of innate immunity influence the susceptibility to rheumatic disease; (iii) what are the factors determining the tissue specificity of inflammation in rheumatic diseases; (iv) what inflammatory pathways are implicated in the production of tissue injury; and (v) is there heterogeneity in inflammatory mechanisms between different diseases and between different individuals with the same disease?

Acute versus chronic inflammation

A critical question in understanding the pathogenesis of chronic inflammatory rheumatic diseases is what factors distinguish an acute attack of gout, followed by the restoration of normal joint function, from rheumatoid arthritis where there is prolonged influx of inflammatory cells and chronic synovial injury? There are likely to be many answers to this question, which may be classified under three headings: (i) persistence of the inflammatory stimulus; (ii) failure of normal homeostasis to switch off inflammation after the stimulus is gone; and (iii) escape of a clone of cells releasing proinflammatory stimuli.

There are many examples of the persistence of an inflammatory stimulus causing chronic disease in humans such as: (i) persistence of foreign antigen, due to replication of an infectious agent, for example the inflammatory consequences of bacterial endocarditis; (ii) persistence due to failure of clearance of a foreign substance, typified by asbestos-associated injury; and (iii) autoimmunity, where the antigen is indivisible from the host.

The hypothesis that defects in the homeostasis of inflammation cause chronic inflammation is less well explored, although the diseases associated with inherited immunodeficiency provide some dramatic support for this idea. Chronic granulomatous disease, for example, illustrates the consequences of the failure of electron transport to oxygen in phagocytic vacuoles, causing a precipitous drop in pH in this compartment. Granulomas ensue from the resulting failure to degrade engulfed micro-organisms and autologous debris. The strong association between inherited complement deficiency and systemic lupus erythematosus provides a further example of a host defect in innate immunity leading to chronic inflammation.

Autonomy of a clone of autologous cells leading to the production of inflammatory mediators is a further mechanism for induction of chronic inflammation. One example that illustrates this is the systemic effects of certain benign and malignant tumours, the 'paraneoplastic' syndromes (Butler *et al*. 1987; Sanchez-Guerrero *et al*. 1990). Clonal proliferation of T cells may produce dramatic inflammatory effects, for example some cases of the hypereosinophilic syndrome are associated with the presence of T-cell tumours (Catovsky *et al*. 1980; Fauci 1982; O'Shea *et al*. 1987). Another striking association is of clonal proliferations of large, granular, lymphocytic T cells with a Felty-like syndrome in rheumatoid arthritis (Dhodapkar *et al*. 1994). A third example is provided by the consequences of some 'benign' clonal proliferations of B lymphocytes. Essential mixed cryoglobulinaemia is a disease in which a B-lymphocyte clone produces an IgM rheumatoid factor that complexes with IgG *in vivo*, leading to the production of inflammation mediated by immune complexes and characterized by vasculitis, nephritis, Raynaud's phenomenon, and neuropathy (Brouet *et al*. 1974; Gorevic *et al*. 1980).

Genetics of inflammation

It is likely that inherited susceptibility to the majority of chronic inflammatory diseases is under polygenic control, and in most cases the relative contribution of genes and environment is unknown. The genetic contribution to the aetiology of rheumatic diseases may be considered under two overlapping headings, the genetics of the adaptive immune system and the genetics of innate immunity and of the control of inflammatory responsiveness. Important questions for those interested in the genetics of adaptive immunity are: (i) does the repertoire of immunoglobulin and T-cell receptors vary between different people; and (ii) what is the influence of the thymus and of products of the major histocompatibility complex (**MHC**) in selecting the T-cell receptor repertoire?

An understanding of the genetics of inflammation may have many important outcomes. This is illustrated by consideration of the pathogenesis of infectious disease, which may be influenced by variation in host responsiveness as much as by the particular organism, as follows.

1. Deficiency of a host defence pathway may lead to chronic infection and chronic inflammation, for example chronic infection with lymphochoriomeningitis virus in new-born mice.

2. An over-response to an infectious agent may lead to inflammatory injury of tissue, for example the granulomatous response in tuberculoid leprosy.

Similar heterogeneity of responsiveness, based on genetic polymorphisms, may determine the level of susceptibility to chronic inflammatory rheumatic disease following a particular environmental stimulus and also may influence the precise pattern of inflammatory damage. It is possible, for example, that microscopic polyarteritis nodosa (a leucocytoclastic vasculitis affecting small and medium arteries) and Churg–Strauss vasculitis (characterized by asthma, eosinophilia, and granulomas), both associated with the presence of antineutrophil cytoplasmic antibodies, are caused by the same agent, and that differences in the expression of the two diseases are due to different patterns of host response, which may be determined genetically. The opposite possibility is that they have entirely different causes and that the similarities between them are a result of the relatively limited pathways of expression of vascular inflammation. These possibilities cannot be distinguished on the basis of present evidence.

Cytokine genes

Inherited variation in the expression of cytokines may explain observed differences between individuals in the amplification and maturation of specific and/or innate immune responses. An example that illustrates this is the recent discovery of inherited polymorphisms around the human tumour necrosis factor (**TNF**) genes. Variation in mitogen-stimulated production of TNF-a (but not TNF-b) was correlated with HLA-DR type, suggesting that *TNF*-a genes in different MHC haplotypes may show differences in control mechanisms. Subjects with HLA-DR3 or -DR4 were high producers of TNF-a whereas HLA-DR2-positive individuals were low producers (Jacob *et al*. 1990). A correlation has been reported between the prevalence of lupus nephritis and the presence of HLA-DR2. These observations are compatible with the results of experiments in mice with systemic lupus erythematosus: NZW mice produced low levels of TNF-a and treatment of the (NZB × NZW) F_1 hybrid strain with TNF-a was associated with delay in onset of nephritis and prolonged survival (Jacob and McDevitt 1988).

In human inflammatory diseases, recent attention has focused mainly on the major proinflammatory loci such as the *TNF* gene on the short arm of human chromosome 6 and the interleukin (**IL**)-1 gene cluster on the long arm of human chromosome 2 (Duff 1994).

There is a cluster of lymphokine genes on chromosome 5 (Marsh *et al*. 1994) where several polymorphic variants have also been characterized, but less work has been done in populations of patients with inflammatory or immune diseases.

The increasing evidence that IL-1 and TNF act as important mediators of the inflammatory response led to the rapid characterization of their genes and then to the search for variant forms that may have functional differences making an individual more or less likely to develop a rheumatic disease, or influence the severity of the disease if not directly involved in its initiation. For example, the ability to predict rapid bone erosions in rheumatoid arthritis using markers in the *IL1* and/or *TNF* genes would be of clinical value in the management of new cases of rheumatoid arthritis.

TNF locus

These are three known *TNF* genes in close proximity within the class III region of the MHC. Across this region several DNA polymorphisms have been described in the normal human population. In the promoter region of the *TNF*-a gene (better known as *TNFA*), at 308 bp upstream of the transcription start site, there is an A–G change in nucleotides (Wilson *et al*. 1992) (Fig. 1). The carriage rate of the rarer allele (*TNFA2*) is 16 to 20 per cent in populations from England, Ireland, Germany, Holland, and The Gambia in Africa. The *TNFA2* allele is part of the extended MHC haplotype *A1, B8, DR3, DQ2* (Wilson *et al*. 1993). This particular haplotype of the MHC has been associated with several autoimmune diseases and is sometimes referred to as the 'autoimmune haplotype'. Diseases associated with this haplotype include: insulin-dependent diabetes; autoimmune thyroiditis; systemic lupus erythematosus; myasthenia gravis; and coeliac disease. It seems likely that in most cases *TNF* is not the primary disease locus and its higher frequency in these diseases results from linkage to other genes within the haplotype.

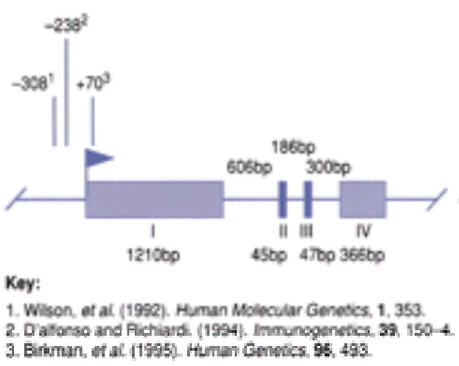

Fig. 1 Polymorphisms within the human *TNFA* locus (6p21).

The 308-bp change in *TNFA* is in the promoter region of the DNA that initiates gene transcription. This polymorphism, therefore, could change the function of the promoter, resulting in altered production of TNF-a. Assays of promoter function where the two allelic promoter fragments of *TNFA* were placed upstream of a bacterial reporter gene indicated that the rarer allele (*TNFA2*) was some six- to eight-fold more efficient at directing transcription than the common allele (*TNFA1*) (G. W. Duff, unpublished observation). However, to date there is little evidence that this results in a reproducible difference in the production of TNF-a protein, although this may be both cell-type and stimulus-specific and cannot at present be excluded.

Interest in *TNF* polymorphisms has extended into infectious diseases and a large study in The Gambia showed that homozygosity for *TNFA2* conferred an eight-fold increased risk of death or major sequelae from cerebral malaria (McGuire *et al*. 1994). Since death in malaria has previously been correlated with high blood levels of TNF-a, this finding suggests that the *TNFA2* allele may be a marker for an exaggerated TNF response that is pathogenic.

The IL1 *gene cluster*

There are three known *IL1* genes designated as *IL1A* (producing IL-1a), *IL1B* (producing IL-1b), and *IL1RN* (producing the IL-1 receptor antagonist). All three genes lie within approx. 500 kb of DNA on the long arm of chromosome 2 (Nicklin *et al*. 1994).

Several base-change and repeat-sequence polymorphisms have been described across this region (Fig. 2) and specific *IL1* cluster genotypes defined by these DNA markers have been found to be significantly over-represented in inflammatory diseases.

Fig. 2 (a) Polymorphisms within the human *IL1A* locus (2q13–14); (b) polymorphisms within the human *IL1B* locus (2q13–14); (c) polymorphisms within the human

IL1RN locus (2q13–14).

IL1A

Several polymorphisms have been described (see Fig. 2(a)). A base variation at position 889 produces two alleles, the rarer of which (*IL1A2*) was found to confer an approximate doubling of relative risk of juvenile chronic arthritis in Norwegian children (McDowell *et al*. 1995). This applied only to the early-onset, pauciarticular variety of juvenile chronic arthritis, and, within this population, *IL1A2* was more significantly over-represented in patients with higher erythrocyte sedimentation rates and those with chronic iridocyclitis, a sight-threatening ocular inflammation that occurs in early-onset, pauciarticular juvenile chronic arthritis.

Further studies involving larger numbers of patients and other ethnic groups need to be done to confirm this finding.

IL1B

A base change in the 5' flanking region (–511) and another within exon 5 (+3953) defines a genotype that occurs significantly more frequently in psoriatic skin disease (Di Giovine *et al*. 1996) (Fig. 2(b)). Studies of this genotype in psoriatic arthritis have not yet been completed, but of great interest is the additional finding that the rarer, +3953 *IL1B* allele is related to the production of IL-1b *in vitro*. Blood mononuclear cells from heterozygous individuals produce about twice as much IL-1b than cells from individuals who are homozygous for the common allele, while those who are homozygous for the rare allele produce approximately four times more IL-1b (Di Giovine *et al*. 1996).

This gene-dose effect on the production of IL-1b seems particularly relevant to the genetic association with psoriasis since IL-1 is thought to be a key mediator of skin inflammation and mice transgenic for an overactive *IL1* gene driven by a skin-specific promoter develop keratinocyte hyperplasia and dermal inflammation with many similarities to human psoriasis (Groves and Kupper 1994).

Preliminary studies in rheumatoid arthritis have suggested that the *IL-1* genotypes may also be relevant to the early occurrence of bone and cartilage erosion, a feature of the disease that is of major clinical significance.

***IL1RN* gene**

Several DNA variations occur within this gene but the most extensively studied marker in clinical populations has been a variable number of tandem repeats of an 86-bp sequence in intron 2 (Tarlow *et al*. 1993) (Fig. 2(c)). At least five alleles occur in most human populations, but the presence of four repeats (allele 1) and two repeats (allele 2) accounts for more than 95 per cent of individuals in all of the populations tested. The frequency of allele 2 (*IL1RN2*) is raised in a large number of inflammatory diseases including systemic lupus (Blakemore *et al*. 1994), ulcerative colitis (Mansfield *et al*. 1994), alopecia areata (Tarlow *et al*. 1994), lichen sclerosis (Clay *et al*. 1994), and some populations of patients with multiple sclerosis (Crusius *et al*. 1995).

A common theme in these studies has been that when patient populations were subdivided by clinical severity scores, the carriage rate of *IL1RN2* was greatest in the groups with the most severe clinical disease, and in some cases these individuals accounted for the disease association overall. This would suggest that the *IL1RN* genotype is a marker for the severity of inflammatory disease. There is some evidence that *IL1RN2* defines individuals with a lower rate of production of the IL-1 receptor antagonist, but this is not a consistent finding and cannot, at present, be accepted as the underlying biological mechanism of the association between the *IL1RN2* gene and disease.

From these and other studies it is becoming clearer that the genotype at the *IL1* region is likely to contribute to the risk of development of chronic diseases that have a prominent inflammatory component. Whether the specific DNA variants that are presently available for typing are themselves the source of differences of the production of IL-1 proteins or are physically linked to other functional polymorphisms in the same chromosomal region (not necessarily in a known *IL1* gene) remains an open question. However, logistic regression analysis indicates that where a composite *IL1* genotype is associated with disease (e.g. psoriasis), the individual markers within the genotype contribute independently of each other. This makes it unlikely that all the known disease associations with the *IL1*gene cluster occur because of a single, linked disease locus in the same region. It seems likely that composite genotypes of the *IL1* cluster and also of the *TNF* cluster will provide clinically useful, predictive information about disease phenotypes in a range of rheumatic diseases.

Cytokines are undoubtedly 'host defence' molecules and, like other molecules involved in innate or specific immunity, their genes show a relatively high degree of polymorphism. This is thought to be the result of selection of specific genotypes by the pressure of infectious diseases. Thus, while specific genotypes for cytokines confer fitness to survive certain infections, it would seem that they may also increase the risk of inappropriate inflammatory responses that can lead to chronic diseases.

Complement deficiency (reviewed in Lachmann and Walport 1987; Morgan and Walport 1991)

One of the clearest examples of an association between inherited variation in the function of host defences and autoimmune rheumatic disease is that between inherited complement deficiency and systemic lupus erythematosus. Only specific complement deficiencies have been associated with systemic lupus, particularly of the classical pathway proteins, C1q, C1r and C1s, C4, C2, and C3. Amongst these proteins there appears to be a hierarchy of association of both disease prevalence and severity with systemic lupus, according to the position of the protein in the activation pathway of complement (Fig. 3). C1q, C1r, and C1s (reviewed in Reid 1989; Bowness *et al*. 1994), and C4 deficiency (reviewed in Hauptmann *et al*. 1986) are associated with a very high prevalence of disease (more than 75 per cent), which tends to be severe. Deficiency of C2, the next protein in the pathway, is associated with a lower prevalence of disease, about 33 per cent, and disease tends to be of a similar severity to that seen amongst cohorts of patients with systemic lupus in the absence of complement deficiency (Ruddy 1986). C3 deficiency, reported in 24 individuals (Botto *et al*. 1993), has only been associated with lupus-like disease in three patients in two families. Such patients only account for a tiny minority of all patients with systemic lupus but may give a very important clue to one of the pathogenetic factors.

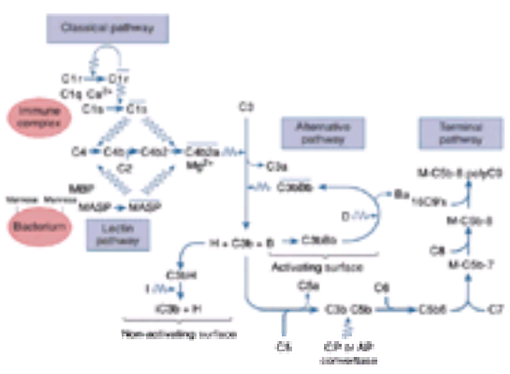

Fig. 3 Simplified diagram of the complement system. Complement may be activated by the classical pathway, the alternative pathway, or the newly characterized 'lectin' pathway, which is initiated by the binding of the collectin, mannose-binding protein, to bacterial surfaces rich in this carbohydrate. The 'amplification loop' of the alternative pathway on an activating surface can amplify C3 activation initiated by the other pathways, or by exogenous proteases from leucocytes, plasma (e.g. plasmin), or bacteria.

It may be that a more subtle inherited deficiency of complement is important as a disease susceptibility gene for the development of systemic lupus erythematosus in a majority of cases. Testing of this hypothesis followed two observations: (i) that there was an increased prevalence of the MHC antigens, HLA-DR3 and -DR2, amongst caucasoid patients with systemic lupus; and (ii) the discovery that C4A and C4B, the two isotypes of C4 encoded in tandem within the MHC, were both highly

polymorphic and that the polymorphism included null alleles (designated Q*0, quantity zero) at both loci. These findings led to examination of the possibility that the disease susceptibility locus within the MHC might be null alleles of one or both loci of C4.

Initial studies showed that there was indeed an increased prevalence of null alleles, mainly of C4A, amongst caucasoid patients with systemic lupus, but the analysis was confounded by strong linkage disequilibrium between C4A null alleles and HLA-DR3. This effectively prevented separation of the relative contribution of these two putative disease-susceptibility genes.

An approach that has been used in attempts to disentangle the relative contributions of HLA-DR3 and C4A Q*0 to disease susceptibility is the examination of the MHC associations with systemic lupus in different racial groups, in which haplotypes containing different combinations of the allotypic variants of the different MHC gene products are found. Using this approach, it has been found that the association of systemic lupus erythematosus with HLA-DR3 breaks down, but the association with C4A Q*0 is sustained. This finding is most striking in Japanese populations amongst whom HLA-DR3 is extremely rare.

The explanation for the association between complement deficiency and increased susceptibility to systemic lupus erythematosus is not certain. It has been known since work by Heidelberger in the 1940s that complement activation by immune complexes interferes with lattice formation and tends to maintain immune complexes in solution. When immune complexes are formed in the presence of complement, precipitation is inhibited, and this is particularly a property of the classical pathway of complement. In contrast, the alternative pathway of complement is implicated in solubilizing preformed immune complexes. The prevalence and severity of systemic lupus associated with inherited complement deficiency is highest for C1q, followed by C4 and then C2. This implies a physiological link between disease induction and an activity of the classical pathway of complement. Inhibition of immune precipitation may be the relevant activity and it has been proposed that complement deficiency leads to ineffective processing of immune complexes, followed by defective clearance of complexes by the mononuclear phagocytic system. This allows deposition of immune complexes in tissues causing inflammation. This inflammation leads in turn to release of autoantigens and the stimulation of a self-perpetuating autoantibody response. Some evidence in support of this hypothesis has come from studies of the mechanisms of immune-complex clearance in rabbits, monkeys, and man.

A second hypothesis associating complement deficiency with systemic lupus erythematosus flows from the role of the complement system in host defence against infectious disease. There is unequivocal evidence that deficiency of classical-pathway proteins is associated with increased susceptibility to infections by pyogenic bacteria, but no evidence for a role for such bacteria in the causation of systemic lupus. In contrast there is little evidence associating complement deficiency to increased susceptibility to virus infections. However, complement is effective in the lysis of certain retrovirally infected cells (though not those infected by the human immunodeficiency virus). There is enthusiasm for a possible role for retroviruses in the induction of systemic lupus, though little hard evidence. It may be postulated that complement deficiency could promote infection and the induction of systemic lupus by some, as yet unrecognized, viral agent.

What is the basis for tissue specificity in rheumatic disease?

The question of which factors determine the localization of inflammatory disease to joints remains unanswered. Possible explanations requiring consideration are that: (i) there are antigens present that are largely restricted to the complicated extracellular matrix of synovium, cartilage, and bone, which may behave as autoantigens or cross-react antigenically with foreign antigens; (ii) trapping of foreign antigens or infectious agents occurs as a result of an affinity to matrix or cellular components of joints or because of peculiarities of the vascular and lymphatic anatomy of joints; (iii) there are 'non-immunological' inflammatory responses to particular components of joints, for example the responses to calcium pyrophosphate and uric acid crystals; and (iv) the mechanical properties of joints, variable load bearing and repetitive movement, contribute to inflammation by mechanisms such as trauma and hypoxic reperfusion injury.

If the question 'why synovium' is difficult to answer, the answer to 'why particular synovial joints' is even more obscure, though there are a number of clues that might help. No very general explanation is likely to explain the distribution of inflammatory synovitis, since the pattern of joint involvement is so variable between different diseases. It is self-evident that joints are distinguished from many other structures in the body by their pattern of repetitive motion and structural loading. There are several pieces of evidence that mechanical factors play a part in joint inflammation: (i) rest is associated with amelioration of synovitis (Partridge and Duthie 1963); (ii) the presence of a hemiplegia may protect the paralysed side of the body from rheumatoid arthritis (Thompson and Bywaters 1962); (iii) mechanical damage to joints, for example cartilaginous injury in the knee, is associated with the onset later in life of osteoarthritis and crystal arthritis (Docherty *et al*. 1982).

The nature of the symmetrical involvement of joints in rheumatoid arthritis poses a further series of interesting scientific questions. One simple possibility is that symmetrically disposed joints share anatomical features that predispose to parallel mechanical injury or deposition of foreign antigen. A second intriguing possibility that is attracting much interest is that there may be reflex neuroendocrine stimuli that lead to symmetrical joint involvement.

What is special about inflammation within synovium?

The nature of the resident cells in an organ, the extracellular matrix, and its anatomical organization may determine the particular form of expression of an inflammatory response. The resident cells of joints include the cells comprising the synovium, chondrocytes, osteoblasts, and osteoclasts. The extracellular matrix is highly organized, comprising a network of collagens and proteoglycans.

The special effects of inflammation on the cells of any particular tissue depend, firstly, on the contribution of the resident cells themselves to the inflammatory process, and, secondly, on the consequences to that tissue of the loss of their specialized functions. In joints, inflammatory damage may lead to loss of lubrication, cartilage and bone, and secondary muscle wasting. The cells of the synovial membrane include monocytic phagocytes (A lining cells) and fibroblasts (B lining cells) (Henderson and Edwards 1987; Edwards 1994). Both types of cell are capable of elaborating cytokines such as IL-1 and TNF.

These factors amplify the inflammatory reaction by several mechanisms. They stimulate the local production of chemotactic peptides such as IL-8, and activate the endothelial lining cells of blood vessels—actions that increase the recruitment of blood leucocytes to the site of inflammation. Both IL-1 and TNF increase the activation of leucocytes (including an autocrine action on the macrophages responsible for their own production).

Such actions lead to production of proinflammatory prostanoids (prostaglandins and leukotrienes) through the mobilization of membrane phospholipids to generate arachidonic acid. Thus, indirectly, IL-1 and TNF contribute to local hyperaemia and increased vascular permeability leading to joint swelling. Through their induction of collagenases and proteoglycanases, and their effects on proteoglycan synthesis, the IL-1s have dramatic effects on the rate of turnover of extracellular matrix components. These actions are thought to be central to the destruction of cartilage and loss of bone density that accompany inflammation in a joint (Duff 1989a; Duff 1989b) (Fig. 4).

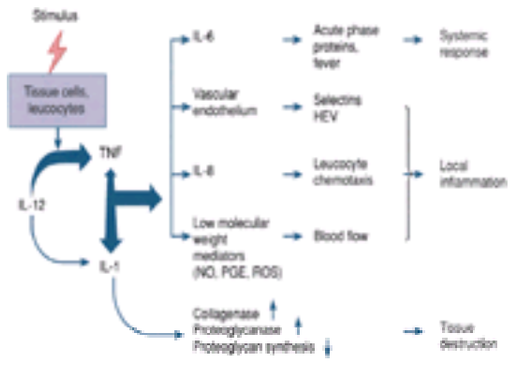

Fig. 4 Stimuli that can initiate inflammation include microbial products (e.g. bacterial lipopolysaccharides and exotoxins), irritant chemical agents (e.g. monosodium urate crystals), radiation (e.g. ultraviolet light on the skin), and endogenous molecules such as immune complexes and complement fragments. Polymorphonuclear and mononuclear phagocytes release IL-12 and this seems to be a very early event in the inflammatory response. Both IL-1b and TNF-a are inducible by IL-12 as well as being mutually inducible. In particular, TNF-a is a strong inducer of IL-1. These three cytokines trigger a proinflammatory cascade. By stimulating the production of other cytokines such as IL-6, a systemic acute-phase response ensues while local tissue inflammation progresses by the activation of vascular endothelium and the generation of high endothelial vessels (HEV). Selectin molecules expressed on endothelial cells mediate the early adherence of blood leucocytes, which then migrate into the surrounding tissue along a concentration gradient of chemokines (chemotactic cytokines, such as IL-8) and other chemotaxins towards the source of the inflammatory stimulus. Low molecular-weight mediators such as nitric oxide, prostaglandins, and reactive oxygen molecules (ROS) are also stimulated by the major

proinflammatory cytokines and cause vasodilation and local hyperaemia. Prolonged inflammation causes destruction of connective tissues, which can lead to resorption of nearby bone and cartilage. In synovial inflammation (for example in rheumatoid arthritis) IL-1b seems to be a particularly potent catabolic agent for connective tissues, inhibiting the synthesis of new extracellular matrix while accelerating the enzymatic destruction of existing components.

Many of the inflammatory diseases of synovium lead to synovial hyperplasia with pannus formation, and much of this hyperplasia appears to be due to immigration of cells of bone marrow origin with only a small contribution from division of resident cells (Henderson *et al*. 1988). The resident cells of cartilage and bone—chondrocytes, osteoblasts and osteoclasts—have the capacity both to synthesize and degrade their extracellular matrix. The balance between these activities may be tipped towards degradation by inflammatory stimuli.

One important characteristic of inflammation in synovial joints is the potential for the accumulation of inflammatory fluid, with consequences both for joint function and also as a modifier of the inflammatory response. Synovial cavities in their resting state contain only very small amounts of synovial fluid and are at atmospheric or subatmospheric pressure. The accumulation of synovial fluid following inflammation or injury is associated with a dramatic rise in intra-articular pressure, often seen clinically as the rupture of a Baker's cyst into the calf following flexion of the knee, a manoeuvre that causes a further rise in intra-articular pressure (Jayson and Dixon 1970). Such pressure changes are sufficient to overcome the capillary perfusion pressure and may render joints temporarily hypoxaemic, followed by a vascular hyperaemia on cessation of exercise (Blake *et al*. 1989). This may be associated with the generation of oxygen-derived free radicals, hypoxic reperfusion injury, and is discussed below in the context of injury caused by such radicals.

Angiogenesis (reviewed inRemmers *et al*. 1991; Folkman and Shing 1992)

An important feature of inflammatory arthritis is the formation of new blood vessels in the synovial membrane, which invade and destroy cartilage. Many peptides that can stimulate angiogenesis have been described. They include: (i) growth factors with activities on many cell types—including acidic and basic fibroblast growth factors, transforming growth factors-a and -b, and platelet-derived growth factors; (ii) growth factors with apparent specificity for endothelial cells—vascular endothelial growth factor, a family of related molecules; and (iii) cytokines and chemokines—including TNF-a and IL-8. There is evidence that several of these molecules collaborate to produce the angiogenesis that contributes to pannus formation. Both the resident synovial lining cells of the joint and invading inflammatory cells act as a source of angiogenic peptides (Fava *et al*. 1994; Koch *et al*. 1994). Angiogenesis is a potential therapeutic target and there is a report of an experimental inhibitor of angiogenesis suppressing collagen-induced arthritis in rats (Peacock *et al*. 1992).

Neuroendocrine influences

The endocrine, nervous, and immune systems are closely interwoven. Cells of each of these systems intercommunicate by the expression of molecules whose effects may be autocrine (i.e., on the same cell that secretes the molecule), paracrine (on other local cells) or endocrine (on other cells at a distance in the body). These molecules have been labelled as neurotransmitters in the nervous system, cytokines in the immune system, and hormones in the endocrine system. However, this terminology conceals the fact that there is enormous overlap in the activities of these cellular messengers. Lymphocytes bear receptors for 'neurotransmitters' and 'hormones'. Cytokines have wide-ranging effects within the nervous system. The chemical basis of these molecules is diverse. The recent discovery that nitric oxide, an inorganic gas and free radical, is a neurotransmitter and mediator of inflammation (reviewed in Moncada and Higgs 1993) has opened a whole new field of investigation. Dissection of the links between the nervous, endocrine, and immune systems in a meaningful fashion poses an enormous scientific challenge.

Endocrine influences (reviewed in Sternberg et al. 1992)

Three types of endocrine links with rheumatic disease may be distinguished, the first two physiological, the third pathological: (i) a role for sex hormones in explaining the predominantly female associations of most inflammatory rheumatic diseases (and also in the maintenance of bone density); (ii) the role of adrenal hormones as anti-inflammatory mediators; and (iii) specific associations between pathological endocrine over- or underactivity and rheumatic disease, for example hypothyroidism and Hoffman syndrome or acromegalic arthropathy. This third group of associations is not considered further in this chapter.

Sex hormones and arthritis

Sex steroids

There is a striking predominance of female sufferers from rheumatoid arthritis and systemic lupus erythematosus. The great majority of lupus patients are female, and symptoms tend to develop around puberty and improve after the menopause, which suggests an important role for sex hormones in the development of human systemic lupus. Furthermore, systemic lupus is sometimes exacerbated by oestrogen-containing oral contraceptives. Lahita and his colleagues (reviewed in Lahita 1993) have made a number of studies showing abnormalities of sex hormone metabolism in patients with systemic lupus. In particular they have observed that such patients are hyperoestrogenic and have decreased serum concentrations of testosterone. These findings are consistent with the observed effects of sex hormones on the lupus-like illness of (NZB × NZW) F_1 mice. Androgens protect these mice against disease whereas oestrogens accelerate its onset and severity. A small number of human kindreds have also been observed in which systemic lupus erythematosus is found in multiple male family members (Lahita *et al*. 1983). This may be the human counterpart of the BXSB mouse in which a Y-chromosome gene, whose effects are not mediated by sex hormone levels, confers disease susceptibility.

In rheumatoid arthritis, evidence for the involvement of sex hormones in explaining the enhanced predisposition of females to disease is: (i) an increased risk in nulliparous females; (ii) a protective effect of the oestrogen-containing oral contraceptive pill; (iii) improvement of established disease during pregnancy; and (iv) an increased susceptibility to the onset of disease during the first 3 months post partum (reviewed in Silman 1994).

Prolactin

A role has been postulated for prolactin in rheumatoid arthritis and other autoimmune diseases. Lymphocytes and monocytes bear high-affinity prolactin receptors (reviewed in Reber 1993). Hyperprolactinaemia in experimental animals is associated with worsening of systemic lupus (McMurray *et al*. 1994) and collagen-induced arthritis (Mattsson *et al*. 1992). There is evidence of excessive secretion of prolactin in patients with rheumatoid arthritis (Chikanza *et al*. 1993). Whether antagonism of prolactin will have any beneficial effects in rheumatoid arthritis in humans is not known.

Hypothalamic–pituitary–adrenal axis

The hypothalamic–pituitary axis plays a major part in the regulation of inflammation. A number of proinflammatory cytokines, produced at and released from sites of inflammation, such as TNF-a, IL-1b and IL-6, may stimulate, directly or indirectly, production of corticotrophin-releasing hormone by the hypothalamus. The corticotrophin-releasing hormone stimulates production of ACTH by the pituitary, which in turn stimulates production of glucocorticoids by the adrenal glands. Increased amounts of glucocorticoids down-regulate the inflammatory response. Defects in this homeostatic mechanism would be good candidates for increasing the severity of inflammatory responses.

There is substantial variability between different animal strains in their susceptibility to the development of experimental arthritis. The histocompatible Lewis and Fischer strains of rats show marked differences in susceptibility to the induction of several inflammatory diseases including adjuvant- and streptococcal cell wall-induced arthritis. Lewis rats are susceptible to disease induction; Fischer rats are resistant. The corticotrophin-releasing hormone response to stress is blunted in Lewis rats. A consequence of this is reduced glucocorticoid production following stress; that is, reduced expression of an endogenous anti-inflammatory molecule. Correction of this defect by infusion of corticosteroids can protect against the induction of inflammatory disease. In contrast, Fischer rats show a vigorous corticotrophin-releasing hormone response to stress. Antagonism of the corticotrophin-releasing hormone–ACTH–cortisol axis in Fischer rats by hypophysectomy or adrenalectomy increases their susceptibility to the induction of inflammatory disease.

There is preliminary evidence that the hypothalamic–pituitary axis may be defective in humans with rheumatoid arthritis. Although diurnal variation of cortisol in rheumatoid arthritis was within normal limits, it was inappropriately low for the amount of inflammation (Neeck *et al*. 1990). In keeping with this finding, the cortisol response to surgical stress was blunted in a group of patients with rheumatoid arthritis undergoing hip replacement compared with a group of osteoarthritic patients

undergoing the same operation (Chikanza *et al*. 1992).

The dominant effect on inflammation of corticotrophin-releasing hormone expressed in the hypothalamus appears to be inhibitory by downstream stimulation of glucocorticoid production by the adrenal glands. In contrast to its central action, peripheral expression of corticotrophin-releasing hormone is associated with proinflammatory effects (Karalis *et al*. 1991). Corticotrophin-releasing hormone can be produced by peripheral blood mononuclear cells and its expression is increased at sites of inflammation (Crofford *et al*. 1992; Crofford *et al*. 1993). Corticotrophin-releasing hormone receptors are present on a variety of cells of the immune system including lymphocytes and monocytes. In Lewis rats, which are susceptible to inflammatory disease and show reduced hypothalamic production of corticotrophin-releasing hormone, peripheral production was increased following stress and the hormone was expressed at sites of inflammation (Crofford *et al*. 1992).

Neural influences (reviewed in Basbaum and Levine 1991)

Synovium is richly innervated by neurones containing a large variety of neurotransmitters (reviewed in Kidd *et al*. 1990). There is a network of small, unmyelinated, afferent C-fibres containing many neuropeptides including substance P, neurokinin A, and calcitonin gene-related peptide. Efferent noradrenergic sympathetic fibres surrounding blood vessels contain neurotransmitters including neuropeptide Y. It was Bayliss in 1901 and Lewis in 1927 who observed that antidromic conduction in sensory neurones was responsible for the 'triple response' (redness, flare, and weal) seen after mechanical, thermal, or chemical injury to the skin.

This response has been shown to be largely mediated by the release of substance P, which causes vasodilatation and increased vascular permeability (reviewed in Holzer 1988; Garrett *et al*. 1992). An analogous response was described in synovium after antidromic stimulation of C-fibres, causing increased vascular permeability and exudation of protein across the synovial membrane.

Neuropeptides are analogous to cytokines in producing pleiotropic effects, and these are shown for substance P in Table 1. A teleological analysis of the inflammatory response provoked by nociceptive stimulation of C-fibres would argue that this would promote resolution of the injury responsible for the nociceptive stimulus. Inability, or failure, to remove the injurious stimulus could render the neural response maladaptive and augment chronic inflammation. A further neural consequence of injury to a joint is reflex inhibition of the surrounding musculature. This phenomenon promotes the periarticular muscular wasting that rapidly develops around an inflamed joint, an adaptive response promoting healing after acute injury, but maladaptive in the context of chronic inflammatory arthritis.

Target cell	Effect of substance P
Synoviocyte	Prostaglandin E_2 synthesis
	Collagenase synthesis
	Cell division
Neutrophil	Promotion of chemotaxis
	Degranulation
	Promotion of phagocytosis
Mast cell	Degranulation
Macrophage	Thromboxane-B_2 synthesis
T lymphocyte	Proliferation

Table 1 The pleiotropic effects of substance P

In addition to local neurogenic effects, the systemic level of activation of the sympathetic nervous system may influence the severity of arthritis (reviewed in Basbaum and Levine 1991 and Kidd *et al*. 1992. The spontaneously hypertensive rat has a high basal sympathetic drive. Experimental adjuvant arthritis in this strain was worse than in animals with normal sympathetic tone. As a corollary to these observations, adrenal medullectomy reduced the severity of adjuvant arthritis, with infusion of adrenaline restoring the normal severity of induced disease. These findings could help to explain a role for psychological and other stresses that cause an increase in sympathetic tone, inducing flares of inflammatory disease.

The field of neurogenic inflammation is still in its infancy despite the antiquity, in scientific terms, of the first observations. A reflex neurogenic hypothesis is attractive to explain the symmetry of joint involvement in rheumatoid arthritis. However, any hypothesis to explain symmetry in rheumatoid arthritis would have to cope with the asymmetry seen in other inflammatory arthritides such as reactive or psoriatic arthritis.

Nitric oxide (reviewed in Moncada and Higgs 1993; Stefanovic-Racic et al. 1993)

Nitric oxide was first identified as the molecular basis of endothelial-derived relaxing factor, a vasodilator synthesized by endothelial cells. It is a gas and a short-lived free radical, and has an enormous range of activities that may promote or inhibit inflammation under different circumstances. There are two classes of enzyme responsible for the synthesis of nitric oxide from the amino acid arginine, constitutive and inducible nitric oxide synthases. The latter enzyme is induced by several proinflammatory cytokines and is responsible for the local production of nitric oxide at sites of inflammation.

It has recently been discovered that cyclo-oxygenase also exists in constitutive and cytokine-inducible isoforms (**COX-1** and **COX-2**), see below. The discovery of cytokine-inducible enzymes that catalyse the formation of powerful mediators of inflammation adds to the pleiotropic mechanisms by which cytokines exert their effects on inflammation. To complicate matters further, it turns out that nitric oxide is an inducer of COX-2 (Salvemini *et al*. 1993), and the regulation of inducible nitric oxide synthetase and COX-2 at sites of inflammation is extremely complex (Vane *et al*. 1994).

There is good evidence for increased expression of nitric oxide in humans with inflammatory arthritis (Farrell *et al*. 1992; Kaure and Halliwell, 1994). Adjuvant arthritis in rats (Ialenti *et al*. 1993; Stefanovic-Racic *et al*. 1994) and arthritis and glomerulonephritis in MRL-lpr/lpr mice (Weinberg *et al*. 1994) could be suppressed by inhibition of nitric oxide synthesis using analogues of arginine. Nitric oxide production by osteoblasts was stimulated by combinations of cytokines and could be involved in the osteoporosis associated with inflammatory rheumatic disease (Ralston *et al*. 1994).

Humoral inflammation and rheumatic disease

There are several triggered enzyme cascades that play a major role in inflammation—the complement, coagulation and fibrinolysis, and kinin (contact activation) systems. These share many features in common and have interdependent activation pathways. Analysis of the activities of the triggered enzyme cascades can be subdivided into several major categories: (i) recognition of foreign molecules or of altered self; (ii) amplification of the recognition signal; (iii) localization of the amplified response; (iv) effector phase (Table 2); and (v) regulation. A detailed consideration of the physiology of each of these pathways is beyond the scope of this chapter and the reader is referred to the following reviews: complement (Walport and Lachmann 1993); coagulation and fibrinolysis (Hart and Fritzler 1989); contact activation (Bhoola *et al*. 1992).

System	Effect function
Complement	Opsonization
	Chemotaxis
	Lysis
	Priming and activation of leucocytes
	Anaphylatoxic activity
	Stimulation of lymphocytes
	Immune-complex lattice modification
Coagulation	Thrombosis
	Wound healing
	Cell proliferation
	Platelet activation
	Activation of fibrinolysis
Fibrinolysis	Fibrinolysis
	Complement activation
	Activation of extracellular proteinases
Kinin	Increased vascular permeability
	Pain production
	Smooth muscle contraction
	Complement activation
	Activation of fibrinolysis
	Stimulation of endothelium
	Activation of extracellular proteinases

Table 2 Humoral pathways of inflammation

The principles of inflammatory damage mediated by a triggered enzyme cascade can be illustrated briefly by consideration of the complement system. The effects of activation of this pathway result from ligation of receptors for split products of complement proteins on leucocytes and from insertion of the membrane-attack complex into cell membranes. Activation and cleavage of C3, C4, and C5 result in the production of anaphylatoxins, C3a and C5a, and of opsonins, C4b, C3b, iC3b, and C3dg (Fig. 3). Receptors for these products are present on most leucocytes. Ligation of anaphylatoxin receptors results in chemotaxis and cellular activation, including respiratory burst and degranulation; ligation of opsonic receptors leads to phagocytosis and cellular activation (also including respiratory burst and degranulation). In recent years it has been appreciated that insertion of the membrane-attack complex into nucleated cell membranes is frequently not accompanied by lysis but instead causes cellular activation, which includes mobilization of arachidonic acid to produce prostaglandins and leukotrienes, and stimulation of the release of cytokines.

There is good evidence implicating each of the triggered enzyme cascades as a contributor to synovial inflammatory injury. Fibrin is a prominent constituent of inflamed joints and the influx of monocytes into rheumatoid pannus, with their capacity to produce procoagulant, may be one important mechanism for activation of the coagulation system. Similarly, complement activation products, active tissue and plasma kallikrein, and evidence of fibrinolytic activity can all be assayed in effusions from inflamed joints. There is no definite evidence to allow assertion of the primacy of one triggered enzyme cascade over another in inducing inflammatory damage in joints. Although there is evidence for the presence of kinins in inflamed synovium, a patient with rheumatoid arthritis and Hageman factor (factor XII) deficiency has been described, a deficiency associated with a severely reduced capacity to produce kinins (Donaldson *et al*. 1972). Similarly, inherited complement deficiency is a strong predisposing factor for the development of systemic lupus erythematosus (Morgan and Walport 1991), although there is abundant evidence of a role for complement in producing inflammatory damage in systemic lupus.

Cellular inflammation and rheumatic disease

Endothelium (reviewed in Pober and Cotran 1990)

In the past it would have been considered eccentric to consider the endothelium first in a section on cellular contributors to inflammation. However, endothelium represents the cellular barrier between the blood circulation and the synovium, and has an extremely important role in controlling the delivery of blood to sites of inflammation and in regulating the traffic of cells and plasma proteins from the circulation (see Chapter 3.2 for a fuller discussion). The emigration of lymphocytes and leucocytes from blood vessels involves adhesion to endothelium followed by transmigration. Activation of both leucocytes and endothelium leads to the expression of adhesion molecules, which allow this process to occur. The importance of the adhesive process is illustrated by the consequences of hereditary deficiency of one of the families of adhesive molecules, the b_2-integrins, which leads to a severe immunodeficiency associated *inter alia* with failure of neutrophil adhesion and emigration from the circulation to sites of bacterial infection.

A second role for endothelium is in the regulation of blood flow, which can be both increased and decreased by molecules synthesized by endothelium. Tissue oxygenation, the immigration of inflammatory cells, and the exudation of plasma proteins are promoted by mediators, such as prostacyclin and endothelial-derived relaxing factor (which is nitric oxide), that increase local blood flow, and thrombin and histamine that cause shape changes in endothelial cells. Thrombosis, leading to the isolation of an inflammatory site, is mediated by factors, such as endothelin and platelet-derived growth factor, that cause contraction of vascular smooth muscle and by tissue factor expression, activating the triggered enzyme cascade of thrombosis, and leading to thrombin generation and fibrinogen cleavage.

Granulocytes (reviewed in Weiss 1989)

Neutrophils and their specialized relatives, eosinophils (reviewed in Gleich and Adolphson 1986; Spry 1988), basophils and mast cells (Crisp *et al*. 1984), collectively play a vital part in host defence against bacteria and parasites, and provide an important mechanism for the removal of autologous and exogenous debris from sites of inflammation. Their vital role in host defence is illustrated by the consequences of deficiencies of neutrophil activity. The resulting immunodeficiency state is characterized by recurrent infections with bacteria that are usually associated with the formation of pus, i.e., pyogenic bacteria, and these include Gram-positive cocci such as staphylococci and streptococci, and Gram-negative rods such as *Escherichia coli, Klebsiella*, and *Serratia*. Patients with neutropenia are also at risk of opportunistic infections with the fungal *Candida* and *Aspergillus* spp.

The interaction of neutrophils with the external milieu is mediated through the binding of extracellular ligands to specific cell-surface receptors. Neutrophil receptors may be classified into five major classes, according to their ligands and the nature of the evoked response (Table 3). Ligation of the majority of these receptors leads to priming and expression of neutrophil effector responses. Multivalent ligation and ligation of two different types of neutrophil surface receptors are often needed to evoke the full expression of neutrophil responses—respiratory burst and granule release. This can be viewed as a protective response to prevent inappropriate cell triggering.

Receptor	Ligand
Growth and differentiation	
Colony-stimulating factors (CSF)	Granulocyte–macrophage-CSF, granulocyte-CSF
Chemotaxis, priming, and activation	
C5a receptor	C5a
f-Met-Leu-Phe	Bacterial formylated
Leukotriene B_4	Leukotriene B_4
Cytokine receptors	Interleukin-1, interferon-γ, tumour necrosis factor-α and -β
Opsonic	
Fc receptors	Complexed IgG
CR1 and CR3	C3b, iC3b
Adhesion	
CR3	?
Laminin	Laminin

Table 3 Receptors on neutrophils

The cytoplasmic granules consist of an outer membrane surrounding the contents of densely packed proteins assembled in a mucopolysaccharide matrix. The granules are heterogeneous, with at least two, and probably several more, different types in neutrophils. They are packed with enzymes including elastase, cathepsin G, myeloperoxidase, collagenase, gelatinase and lysozyme, whose activities on the one hand directly promote bacterial killing by digestion of their cell walls, and on the other allow free migration of neutrophils outside blood vessels by digesting extracellular matrix proteins, leading to the formation of abscess cavities. Granules also contain peptides directly toxic to bacteria and parasites, such as eosinophil cationic protein (only eosinophils), defensins, and bactericidal/permeability-increasing protein; and molecules such as lactoferrin and vitamin B_{12}-binding protein that may act to starve bacteria of essential nutrients. The granules also act as a store of membrane receptors, such as the complement receptors, CR1 and CR3, whose expression can be rapidly up-regulated following neutrophil stimulation.

The 'professional' phagocytic cells, neutrophils, monocytes, macrophages and eosinophils, demonstrate an unusual process when they engulf microbes. They rapidly consume a large amount of oxygen. This 'extra respiration of phagocytosis' is not used for the normal purpose of generating energy by mitochondrial oxidative phosphorylation, for which the bulk of our inhaled oxygen is used. The oxygen consumption of the respiratory burst is required to produce the optimal conditions for the killing of most common bacterial and fungal pathogens as well as a variety of commensals. Cells deprived of oxygen engulf but fail to kill some microbes efficiently. The same is seen in the syndrome of chronic granulomatous disease, the hallmark of which is complete absence of this respiratory burst by cells that appear to be functionally normal in all other respects. There are three ways in which the respiratory burst may produce bacterial killing—free-radical production, myeloperoxidase-catalysed halogenation, and alkalinization of the phagocytic vacuole.

Apparently, whilst most of the receptors, the granule contents, and the respiratory burst of granulocytes are adapted to the recognition and destruction of microbes,

they also carry the potential to damage the host if triggered inappropriately or chronically. Most of the stimuli to chronic inflammation, outlined above, cause neutrophil migration and activation. Neutrophils are usually present at sites of rheumatic inflammation and their numbers often correlate with the severity of disease.

The formidable array of toxic contents of neutrophils, coupled with their short half-life of approx. 7 h and correspondingly high rate of production of about 1.63×10^{9} cells/kg per day, poses the question as to what happens to effete cells, especially at sites of inflammation? The traditional view was that neutrophils at sites of inflammation disintegrated, contributing all of their toxic contents to exacerbate the inflammatory process. Recent studies have shown that this view is largely erroneous and that neutrophils undergo a form of programmed cell death, known as apoptosis, in which the nucleus condenses and chromatin is cleaved in an ordered fashion. Apoptotic neutrophils display a change in surface phenotype that renders them susceptible to recognition and uptake by mononuclear phagocytic cells, where their contents may be harmlessly degraded. This mechanism of neutrophil death appears to operate within inflamed synovial cavities where monocytes that have phagocytosed neutrophils have been described for many years as Reiter's cells (Savill *et al*. 1989). Discovery of the physiological mechanism of disposal of granulocytes raises further hypotheses about mechanisms of inflammatory tissue damage. It is possible that defects in the process of apoptosis and the engulfing of apoptotic cells may contribute to inflammatory processes by increasing the available time for neutrophil-mediated injury or even, in some circumstances, allowing neutrophil disintegration.

Monocytes and macrophages

Many of the activities of monocytes and macrophages overlap with those of granulocytes. However, monocytes and macrophages are much longer-lived cells and they display a complex range of phenotypes depending on many factors, including their location, matrix attachment, and the soluble mediators to which they are exposed.

Recruitment of macrophages to sites of inflammation is a slower process than the accumulation of granulocytes, reflecting a smaller circulating precursor pool. However, as previously noted, the synovium also contains resident macrophages as type-A lining cells. The activation of monocytes/macrophages is complex and involves the induction of many different genes. The T-cell lymphokine, interferon-g, is a potent macrophage activator and differentiator. It 'primes' the macrophage to respond to other activating agents such as bacterial lipopolysaccharide and particles opsonized with IgG or C3, probably by increasing the number of surface receptors for these agents. Macrophage activation is associated with increased metabolic activity generating reactive oxygen radicals and an increase in phagocytic and cytolytic capacity. A range of proinflammatory cytokine genes is expressed, including those for IL-1a, IL-1b, TNF-a, IL-6, IL-8, and interferon-a. Activated macrophages release components of the complement pathway such as C2 and factor B, and, under the influence of interferons, they display on their surface increased numbers of class I and class II (interferon-g) MHC molecules.

Fibroblasts

The normal synovium contains mesodermal fibroblasts (type-B lining cells) and fibroblast-like cells are often prominent in the proliferating synovium during chronic synovitis. The extent to which these are derived from resident synovial cells or from adjacent connective tissue is unknown.

It seems likely that local signals for fibroblast proliferation would include messengers such as the fibroblast growth factors, platelet-derived growth factor, and transforming growth factor-b derived from platelets, macrophages, and other infiltrating inflammatory cells. Fibroblasts, themselves, can release proinflammatory prostanoids and cytokines such as IL-1, IL-6 and interferon-b (Meager 1990).

How do cells cause injury in joints? (see also Chapter 2.5)

Free radicals (reviewed in Merry *et al*. 1989; Greenwald 1991)

Oxygen-derived free radicals [including superoxide (O^{2-}), hydroxyl (OH), and hydrogen peroxide (H_2O_2)] may play direct and indirect roles in promoting inflammatory tissue injury. Their existence in biological fluids is transient and their activity in inflammation is largely inferred indirectly by the finding of evidence of molecular injury compatible with attack by free radicals. A low viscosity is an important characteristic that distinguishes an 'inflammatory' from a 'non-inflammatory' synovial effusion. The high viscosity of normal synovial fluid is due to hyaluronic acid, and degradation of the polymeric structure of hyaluronic acid is a characteristic of 'inflammatory' effusions. Both free radicals and the enzyme hyaluronidase can break down hyaluronic acid; however, there is no evidence for the existence of hyaluronidase in joint effusions *in vivo* and free radicals are the strongest candidates as mediators of the extracellular degradation of hyaluronic acid (McCord 1974; Greenwald and Moy 1980). There is similar evidence for a role of free radicals in causing lipid peroxidation, immunoglobulin aggregation, and collagen degradation.

Free radicals may contribute to inflammatory change in two important indirect ways. Neutrophil elastase is a broad-spectrum serine esterase enzyme capable of cleaving a range of molecules including elastin. However, it is effectively inactivated by a $_1$-proteinase inhibitor (previously known as a $_1$-antitrypsin). It has recently been appreciated that a methionine residue at the active centre of a $_1$-proteinase inhibitor is susceptible to oxidation by free radicals, leading to inactivation of enzyme inhibitory activity. Neutrophils may create a local 'zone of activity' for elastin by inactivation of a $_1$-proteinase inhibitor by oxygen-derived free radicals. A second way in which oxygen-derived free radicals may promote phagocyte-mediated injury is via the activation of latent metalloproteinase enzymes such as collagenase.

What is the source of free radicals in joints? The main cellular source in synovial effusions is phagocytic cells, both resident and immigrant. Stimulation of phagocytes, especially those partially activated by adherence to matrix proteins, by ligation of receptors, including those for Fc, C3b and iC3b, f-Met-Leu-Phe, and anaphylatoxins, may individually, or in combination, trigger oxidative metabolism and the production of a transient burst of free radicals. The chemistry of free radicals is complex and the chemical route of generation of biologically relevant oxygen radicals is not established beyond doubt. The chemical microenvironment within the synovium may be important. In particular, ferric iron (Fe^{2+}) may have a physiological role in catalysing the production of hydroxyl radicals from hydrogen peroxide, and supportive evidence for a role of iron in promoting inflammatory synovitis comes from observations of: (i) a protective role for iron chelators in animal models of inflammation (Andrews *et al*. 1987), though there are no similar data as yet from studies in humans; (ii) a correlation between the presence of free iron and rheumatoid synovial inflammation (Blake *et al*. 1984); and (iii) a flare of synovitis in a patient given an infusion of iron (Winyard *et al*. 1987).

A second potential source for oxygen-derived free radicals is from hypoxic reperfusion injury (McCord 1985). It was observed by Blake and his collaborators (Blake *et al*. 1989) that the increase in intrasynovial pressure related to exercise of knee joints containing effusions was associated with a reduction of synovial capillary blood flow, followed by reactive hyperaemia on cessation of exercise. A small increase was measured, after exercise, in oxidatively damaged lipids and IgG. The intracellular enzyme xanthine oxidase/dehydrogenase plays a major part in the generation of free radicals and this raises the speculation that allopurinol may be useful for more than the inhibition of uric acid production, a hypothesis that awaits full exploration (Puig *et al*. 1989). It is unclear to what extent this mechanism of generating oxygen radicals contributes to inflammation in joints, or whether it helps to explain the observation that inflammation tends to get better in a rested joint.

Enzymes

Tissue morphogenesis requires organized synthesis of complex matrices that are found in bone and cartilage. Growth of tissues and their remodelling after injury involves breakdown and dissociation of matrix proteins as well as synthesis of new protein. The tissues of joints and bones, therefore, are endowed with enzymes with the capacity to break down collagen as well as synthesize new collagen. Bone integrity is regulated by a delicate balance between osteoblasts and osteoclasts. Apparently any dysregulation of the balance between synthesis and breakdown of extracellular matrix may result in an increase or decrease of tissue mass. Osteoporosis following the menopause or glucocorticoid therapy is an example of such an imbalance leading to diffuse loss of bone.

Metalloproteinases and their inhibitors (reviewed in Weiss and Peppin 1986; Docherty and Murphy 1990; Sorsa et al. 1992)

Collagen, a major component of many tissues including joints, is resistant to the activity of most proteolytic enzymes because of its unusual amino acid sequence and triple helical structure, but sensitive to digestion by members of a family of matrix metalloproteinase enzymes, the collagenases and gelatinases, whose substrates are native and denatured collagen, respectively. A third member of the family, the stromelysins, cleaves proteoglycan core protein, laminin, fibronectin, and some collagen types. These enzymes are secreted in latent form by many cell types, including fibroblasts, bone cells, chondrocytes, macrophages, endothelium, and neutrophils. Their physiological activity is regulated in two ways, by activation from a latent to an active form and by inhibitors in the fluid phase, such as the tissue inhibitors of metalloproteinases, which prevent the geographical spread of enzyme activity and are synthesized and secreted by a similar range of cells.

By analogy with the other mediators of inflammation, the metalloproteinases may have deleterious effects if they are inappropriately secreted or activated, or

ineffectively inhibited. The chronic recruitment of inflammatory cells to joints, including fibroblasts, monocytes, and neutrophils, may lead to an increased tissue mass capable of secreting collagenases. Cytokine stimulation of each of these cell types promotes release of metalloproteinases. Oxidative metabolism and the activity of other protease enzymes may activate metalloproteinases, which in turn leads to collagen degradation and tissue injury.

A potential therapeutic role in inflammatory arthritis for inhibitors of matrix metalloproteinases has been proposed (reviewed in Vincenti *et al*. 1994). Experimental inhibitors of matrix metalloproteinases have proved effective in animal models of arthritis. However, it was found that a number of them inhibited the proteolytic processing of pro-TNF-a to mature, secreted TNF-a, a step presumably mediated by a zinc-dependent neutral protease (Gearing *et al*. 1994; McGeehan *et al*. 1994; Mohler *et al*. 1994). It has recently been found that one of the soluble TNF receptors, a fluid-phase inhibitor of TNF-a, is also cleaved from cell surfaces by a similar or identical metalloproteinase enzyme (Crow *et al*. 1995).

Other neutral proteinases

Many other proteinase enzymes are potential mediators of injury to joints, for example the neutral proteinases of neutrophils, cathepsin G and elastase. Elastase complexed with a_1-proteinase inhibitor has been identified in synovial effusions, providing evidence for the release of this enzyme from neutrophils. There is also evidence of oxidative injury to a_1-proteinase, which might prevent its efficient inhibition of neutrophil elastase. However, interesting experiments in beige mice genetically deficient in neutrophil elastase and cathepsin G did not show any reduction in the severity of the synovitis associated with antigen (bovine serum albumin)-induced arthritis (Pettipher *et al*. 1990). Whilst this experiment does not exclude a role for these enzymes in mediating tissue injury in synovial inflammation, it once again emphasizes the enormous redundancy of the mechanisms that potentially cause damage to joints.

Prostaglandins and leukotrienes (reviewed in Goetzl *et al*. 1995)

An important role for eicosanoids in the mediation of inflammatory damage in rheumatic disease is suggested by the clinical effectiveness of inhibitors of cyclo-oxygenase. Many of the cells present in inflamed joints mobilize membrane arachidonic acid and release the potent mediators, prostaglandin E_2, thromboxane A_2, prostacyclin, and leukotriene B_4 (Fig. 5). These mediators are particularly important in the generation of acute inflammation but some, such as prostaglandin I_2 (prostacyclin) and prostaglandin E_2, can also have suppressive effects on inflammation.

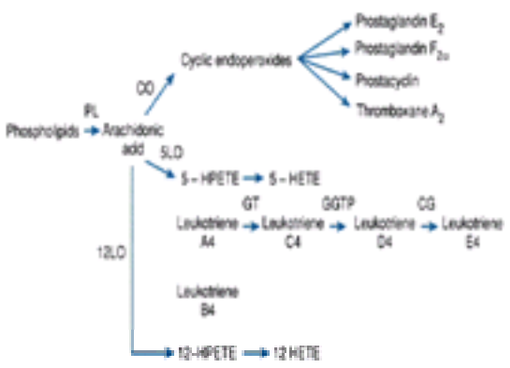

Fig. 5 Arachidonic acid metabolism: PL, phospholipases; CO, cyclo-oxygenase; 5LO, 5-lipoxygenase; 12LO, 12-lipoxygenase; H, hydrolase; GT, glutathione transferase; GGTP, g-glutamyl transpeptidase, CG, cysteinyl-glycinase.

Activation of phospholipase A_2 is an early event in the control of prostanoid production. This enzyme (stimulated by IL-1, TNF, and other factors) releases arachidonic acid from membrane phospholipids. Certain glucocorticoid-induced proteins (lipocortins) are thought to inhibit phospholipase A_2 as part of the anti-inflammatory action of steroids. Arachidonic acid is then metabolized further by one of the two major enzyme pathways, cyclo-oxygenase or lipoxygenase. The activity of the former results in prostaglandins while the latter produces the leukotrienes. Cyclo-oxygenase is a ubiquitous enzyme pathway in mammals but lipoxygenase activity is more or less restricted to monocytes, macrophages, neutrophils, eosinophils, and mast cells. Arachidonic acid is not the only substrate for these enzymes, and, for example, eicosapentaenoic acid can enter the lipoxygenase pathway, resulting in the production of pentaenoic leukotrienes, which are biologically less potent. This is probably the biochemical basis of the reported anti-inflammatory effects of diets rich in eicosapentaenoic acid (e.g. fish oil diet) (see also Chapter 1.3.6).

The proinflammatory effects of prostaglandins include vasodilation of the microcirculation (especially prostaglandins E_2 and I_2), amplification of oedema caused by other mediators (e.g. bradykinin, C5a), and increased nociception by sensitization of pain receptors. Leukotrienes can induce vascular permeability directly and leukotriene B_4 acts as a chemotaxin for neutrophils and increases their adhesion to endothelial cells. It has recently been found that a selective antagonist of the leukotriene-B_4 receptor inhibited the inflammation of collagen arthritis in mice (Griffiths *et al*. 1995). As noted above, prostaglandins have certain actions that may suppress chronic inflammation. For example, some leucocyte (macrophage and T lymphocyte) functions can be inhibited by prostaglandin E_2 and there are reports that prostaglandin E can inhibit cartilage degradation. Many of these effects may result from the inhibition, by prostaglandin (E_2), of the synthesis of IL-1 and TNF (Pettifer *et al*. 1992).

It has recently been appreciated that, as outlined above, there are two forms of cyclo-oxygenase: (i) COX-1, constitutively expressed in many tissues; and (ii) COX-2, inducible by proinflammatory cytokines and expressed relatively selectively at sites of inflammation, including rheumatoid synovium (Crofford *et al*. 1994). This discovery has substantial therapeutic implications, as selective inhibitors of COX-2 may have anti-inflammatory effects without producing gastrointestinal side-effects (Mitchell *et al*. 1993; Masferrer *et al*. 1994).

Cytokines (reviewed in Arai et al. 1990)

Cytokines can be defined as extracellular peptide mediators that regulate cellular growth differentiation and activation through specific receptor molecules on target cells. Within the immune system, cytokines that are produced by leucocytes and are active in inflammation or immune responses are designated as interleukins. There are now 17 interleukins, some of the features of which are shown in the Table 4, Table 5, Table 6, Table 7, Table 8, and Table 9. A related cytokine, TNF, is not classified as an interleukin for historical reasons but displays a very similar range of biological activities (Table 10) and has also been implicated in inflammatory diseases.

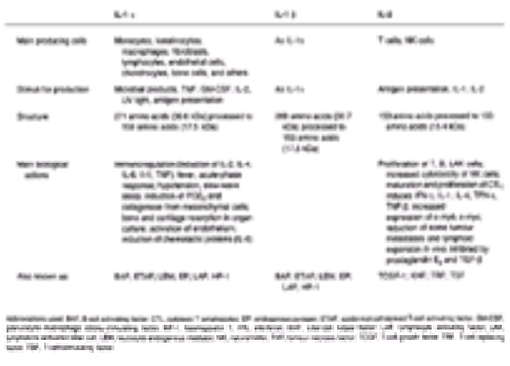

Table 4 Human interleukins (IL)

	IL-1	IL-4	IL-6
Main producing cells	Activated T cells	Activated T cells (T_H2)	Activated T cells (T_H2)
Stimulus for production	Antigen presentation	Antigen presentation	Antigen presentation
Structure	153 amino acids (14.6 kDa)	129 amino acids (15 kDa)	185 amino acids (153.2 kDa)
Main biological actions	Growth stimuli of all leucocyte lineages	T cells: TCGF activity (+++); thymocyte proliferation (antigen); $\downarrow$Ant activity B cells: BCGF (antigen) (+++); MHC class II (++); IgG, enhancer (+++); IgE enhancer (+++); IFN-γ inhibitor; (+++); IL-4R enhancer (+++) (all blocked by IFN-γ) Synergy with G-CSF, M-CSF, EPO, mast cell growth factor	Eosinophils, maturation, growth Synergy with IL-4 for IgG, IL-2 for CTL, genes and IL-2R
Also known as	Mob-CSF, MCSF-1 Pgl-CSF	TCGF-II, BCGF-I, BSF-1, BCDF-1, BCDF-γ, MCGF-II	BNF, BCDF-II, BCDF-α, EDF, HPF, BCDF

Abbreviations used: BCDF, B-cell differentiation factor; BCGF, B-cell growth factor; BCL, B-cell lymphoma; BSF, B-cell stimulating factor; CSF, colony-stimulating factor; CTL, cytotoxic T lymphocyte; EDF, eosinophil differentiation factor; EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; IFN, interferon; IGIF, interleukin factor; MCGF, mast-cell growth factor; M-CSF, macrophage colony-stimulating factor; TCGF, T-cell growth factor; TNF, T-cell replacing factor

Table 5 Human interleukins (IL)

	IL-4	IL-7
Main producing cells	Monocytes, macrophages, activated T cells, glioblastoma cells, fibroblasts, cardiac myxoma cells, cervical adenocarcinoma lines	Stromal adherent cell from bone marrow Physiological stimuli unknown
Stimuli for production	IL-1, TNF, PDGF, poly I:C autocrine in some lines	LPS is active
Structure	212 amino acids processed to 184 amino acids (20.7 kDa)	177 amino acids processed to 152 amino acids (17.4 kDa)
Main biological actions	Proliferation: plasmacytoma lines, hybridoma lines, haemopoietic cells (IL-3 and GM-CSF-like action) EBV-transformed cells, thymocytes (antigen) T cells: reduce IL-2R; with IL-2: CTL induction B cells: induction of immunoglobulin production (differentiation without growth) Antiviral: CTL induction of acute-phase proteins in liver cells, former in vivo	Long-term growth of pre-B cells and pro-B cells Mature T-cell activation in presence of lectin Early T-cell activation Induction of IL-2/IL-2R on some T-cell subsets
Also known as	BCDF, BSF-2, IFN-β_2, HPGF, HSF, CDF, LP-1	

Abbreviations used: BCDF, B-cell differentiation factor; BSF-2, B-cell stimulatory factor; CDF, cytotoxic cell-differentiation factor; CTL, cytotoxic T lymphocyte; EBV, Epstein-Barr virus; GM-CSF, granulocyte–macrophage colony-stimulating factor; HPGF, hybridoma/plasmacytoma growth factor; HSF, hepatocyte-stimulating factor; IFN, interferon; LP, lymphopenin; LPS, lipopolysaccharide; PDGF, platelet-derived growth factor; TNF, tumour necrosis factor.

Table 6 Human interleukins (IL)

	IL-4	IL-6	IL-10
Main producing cells	Monocytes, T cells (?), endothelial cells, dermal, fibroblast, epithelial lines, Kupffer cells	T cells	T_H2 cell lines, mast cell lines; B lymphomas
Stimuli for production	LPS, IL-1β, IL-1α TNF-α, IL-3 GM-CSF, ?lymphocyte activation	Antigen presentation	Antigen presentation
Structure	72 amino acids (8 kDa)	184 amino acid propeptide cleaved to 139 amino acids (19.1 kDa)	178 amino acids (18.7 kDa)
Main biological actions	Neutrophil activation: respiratory burst; release lysosomal enzymes Neutrophil chemotaxis: in vitro and in vivo T-cell and macrophage chemotaxis	Synergy with IL-3 on mast cell proliferation and activity Proliferation of megakaryoblastic leukaemia cells Enhancement of survival of T helper cell lines Proliferation of fetal thymocytes	Inhibits production of IFN-γ and IL-2; suppressor factor for T_H1 response
Also known as	MONCF, NAF, MDNAP, LYAAP, GCP, MIP-1	PAS, MFA, TCGF-II	CSIF

Abbreviations used: CSIF, cytokine synthesis inhibitory factor; ED, N-acetyladibin protein; EPO, erythropoietin; GCP, granulocyte chemotactic peptide; GM-CSF, granulocyte–macrophage colony-stimulating factor; MFA, mast-cell enhancing activity; MIP, macrophage-derived inflammatory protein; MONAP, monocyte-derived neutrophil activating peptide; NAF, neutrophil-activating factor; PBP, platelet-basic protein; TCGF, T-cell growth factor

Table 7 Human interleukins (IL)

	IL-11	IL-12	IL-13
Main producing cells	Bone marrow, stromal fibroblasts, trophoblasts	Monocytes/macrophages, B cells	Activated CD4 T cells
Structure	178 amino acids (23 kDa) monomer	219 amino acids (35 kDa) 328 amino acids (40 kDa) heterodimer	132 amino acids (10 kDa) monomer
Main biological actions	Synergism with IL-3 to expand megakaryocyte colonies Hepatic APP synthesis	Induction of T_H1 responses in TH0 cells IFN-γ induction in NK cells	B-cell proliferation and antibody class-switching to IgE Inhibition of proinflammatory cytokine production in macrophages/monocytes
Also known as	Adipogenesis inhibitory factor	Natural killer-cell stimulatory factor Cytotoxic lymphocyte maturation factor	

Abbreviations: APP, acute-phase protein; IFN, interferon; NK, natural killer.

Table 8 Human interleukins (IL)

	IL-15	IL-16	IL-18
Main producing cells	T cells, some malignant B cells	Fibroblasts, activated eosinophils	CD8 T cells, endothelial cells
Structure	4SB amino acids (52–64 kDa) monomer	70 kDa	192 kDa
Main biological actions	Inhibits Ig secretion and induces proliferation in B cells Induces Fas on B cells	Stimulates T- and B-cell proliferation Skeletal muscle hypertrophy Shares β- and γ-receptors with IL-2	Chemotaxis and activation of CD4 T cells, eosinophils and neutrophils IL-2 receptor induction in CD4 T cells
Also known as	High molecular-weight B-cell growth factor	IL-16	Lymphocyte chemoattractant factor

	IL-17
Main producing cells	CD4+ T cells
Structure	155 amino acids (17.3 kDa) predicted
Main biological actions	Stimulates T-cell proliferation IL-6 secretion and surface ICAM-1 in fibroblasts Activates NFkB

Abbreviations used: ICAM, intercellular adhesion molecule; NFKB, nuclear factor kappa B

Table 9 Human interleukins (IL)

	TNF-α	TNF-β
Also known as	Cachectin	Lymphotoxin
Molecular mass	Trimer of 3 × 17 kDa subunits	Subunit 18.5 kDa
Chromosomal location	Human chromosome 6 within MHC	Human chromosome 6 within MHC
Main cellular sources	Macrophages, T cells, NK cells, mast cells, fibroblasts	T cells, B cells
Main stimuli for production	Microbial products, LPS, viruses, IL-1, IL-2, antigen presentation	Mitogenic or antigenic activation
Receptors	55 kDa, 75 kDa	As TBF-1
Major effects	Induction of c-fos, c-myc, and c-ras in fibroblasts Induction of cytokines, IL-1, IL-6, IL-8, PDGF, IL-2 receptor, M-CSF, GM-CSF Increased expression of MHC molecules (especially class I) Inhibition of adipocyte lipoprotein lipase Autocrine macrophage activation Stimulation of neutrophil functions Activation of endothelial cells *In vivo* hypotension and fever Selective tumoricidal activity Catabolic effects on bone and cartilage Modification of liver acute-phase protein synthesis	

Abbreviations used: GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukin; LPS, lipopolysaccharide; M-CSF, macrophage colony-stimulating factor; NK, natural killer; PDGF, platelet-derived growth factor.

Table 10 Human tumour necrosis factors (TNF)

The findings that IL-1 and TNF have biological properties which include stimulation of inflammatory prostanoids, activation of vascular endothelial cells, induction of bone and cartilage metabolism, and activation of lymphocytes elucidate many aspects of inflammation in joint diseases, and also the associated destruction of osteoarticular tissues. Indeed, injection of IL-1 into animal joints produces an acute arthritis with leucocytes in synovial fluid and the breakdown of connective tissue proteoglycans. Since these cytokines are immunopotentiating and are themselves produced during immune responses, clearly they may contribute to the self-perpetuating mechanisms of disease chronicity (Symons *et al*. 1992).

The advent of specific immunoassays for IL-1a, IL-1b, TNF-a, IL-6, and other cytokines was followed by rapid progress in detecting these factors *in vivo* and relating them to different indices of disease activity. The best correlations with systemic inflammatory disease (erythrocyte sedimentation rate, peripheral blood platelet count, C-reactive protein) have been obtained with IL-1b, IL-6, and TNF-a. *In situ* hybridization studies have shown that the main source of IL-1b in the synovium of a rheumatoid joint appears to be the CD14+ tissue macrophage. What the stimulus or stimuli for macrophage activation might be in rheumatoid arthritis is unknown, but it is clear that the production of IL-1 by macrophages can be activated in an autocrine fashion by IL-1 itself, by TNF, other cytokines, immune complexes, and probably certain breakdown products of connective tissue. The initial triggering signal in rheumatoid arthritis remains unknown. The stimulation of IL-1 and TNF production by urate crystals is thought to be central in the development of inflammation in gout (Di Giovine *et al*. 1987; Di Giovine *et al*. 1991).

The biological activity of a cytokine *in vivo* is a net effect related both to its concentration and to the presence of specific inhibitory molecules. For example, in the cytokine system the shedding of cell-surface receptors has been found to be a fairly general phenomenon. Shed receptors retain affinity for their ligand, even in soluble form. In several cases, they have been shown to act as binding proteins that compete with the cell-surface receptor for any free ligand and act, therefore, as biological inhibitors (Symons *et al*. 1991). Some soluble receptors may be stimulatory rather than inhibitory. For example, the complex formed between IL-6 and its soluble receptor can stimulate the signalling component of the cell-surface IL-6 receptor. The soluble form of the IL-2 receptor (a-chain, tac protein) has been especially well studied in immune diseases. The level of soluble IL-2 receptor in body fluids has been found to reflect immune cell activation, and in many cases it correlates with clinical disease activity in autoimmune diseases and in other diseases with an immunopathological component (Symons *et al*. 1988). Apart from soluble receptors, there are examples of other cytokine inhibitory molecules. In particular, there is a third member of the *IL1* gene family that has the same affinity for the two IL-1 surface receptors but receptor occupancy does not transduce an activating signal. This molecule therefore acts as a receptor antagonist and is a potent biological inhibitor. It would seem that such molecules may have potential therapeutic applications (Meager 1990; Symons *et al*. 1992; Duff 1993).

Many of the local and systemic manifestations of the inflammatory response can be explained by the actions of the major monocyte-derived cytokines IL-1a, IL-1b, IL-6, IL-8, and TNF-a. The other interleukins (IL-2, IL-3, IL-4, IL-5, IL-9, IL-10) are mainly lymphocyte-derived and their predominant actions are in the pathways of clonal expansion and differentiation of different classes of lymphocyte (Callard 1990).

Cytokines and T-cell subsets

Helper T cells (Th–CD4+) can be divided into two major types with respect to function and the range of lymphokines they produce. Those that secrete IL-2, interferon-g, IL-3, granulocyte–macrophage-colony-stimulating factor (**GM-CSF**), and TNF-a and -b are known as Th1 cells. They are involved predominantly in the generation of cell-mediated immunity aimed at intracellular pathogens, and they generate the delayed-type hypersensitivity response of the kind seen in chronic inflammatory diseases such as rheumatoid arthritis.

The Th2 cell secretes B-cell growth and differentiation factors (IL-4, IL-5, IL-6, IL-10, IL-3, GM-CSF, TNF), leading to a predominantly humoral immune response that generates antibodies (e.g. allergic response with IgE production). These two major pathways of T-cell differentiation (and therefore types of immune responses) are mutually antagonistic (e.g. IL-4 inhibits Th1 development) so that one type predominates in response to an antigenic challenge (Fig. 6).

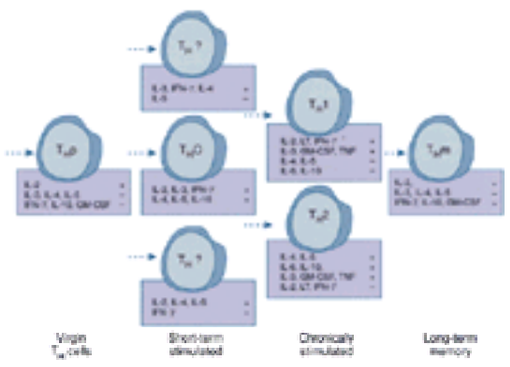

Fig. 6 Relation between the various cytokine secretion phenotypes. A scheme of the T helper (Th) cell functional subdivision is shown. Cytokines produced following activation are indicated in the box below each cell type. Resting cells ('virgin' T cells and 'memory' T cells) only express IL-2 protein; all intermediate differentiation/activation stages have definite patterns of cytokine production.

Since chronic inflammation in diseases such as rheumatoid arthritis has a predominantly cellular immune component, the prospect of suppressing this with Th2 lymphokines (such as IL-4, IL-10, and the related IL-13) has been suggested and clinical trials are in progress. It has been well established that IL-4, IL-10, and IL-13 suppress the production of IL-1 and TNF by stimulated blood monocytes *in vitro*. Whether this is a general phenomenon applicable to any cell type or is unique to blood mononuclear cells is not known.

Cytokine and cytokine receptor families

There are well over 100 characterized cytokines, but it is likely that more will be discovered. It is possible to define large families of similar molecules based on DNA and/or protein sequence homology. In many cases the biological roles of these homologies are not yet understood. A good example is the TNF group of ligands, which, in addition to TNF-a, TNF-b (lymphotoxin-a) and lymphotoxin-b, includes FAS ligand, CD27 ligand, CD30 ligand, CD40 ligand, and OX40 ligand. There are also several sequences with similarity to the known *IL1* genes.

Receptor molecules for cytokines are structurally dissimilar (Fig. 7(a)), but a major subgroup, the 'haematopoietin receptor family', can be distinguished on the basis of shared structural features (Fig. 7(b)). For several individual cytokine receptors, it is also possible to recognize homologous sequences that may represent an extended family of similar receptors. Good examples of this phenomenon are the IL-1 (Fig. 7(c)) and TNF (Fig. 7(d)) receptor families. These sequences have been discovered in vertebrates and in invertebrates (e.g. T cell in clinocephila) suggesting important and highly conserved functions. These observations highlight the limitations of our present understanding of the cytokine system.

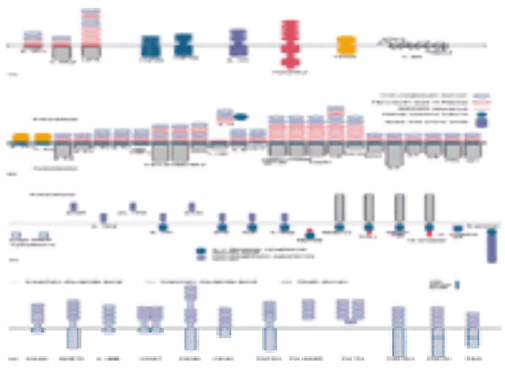

Fig. 7 (a) Cytokine receptor families. (b) The haematopoietin receptor family. (c) Type I IL-1 receptor gene family. (d) Tumour necrosis factor receptor family.

Cytokines in rheumatic diseases

There is little doubt that the pathology of all rheumatic diseases involves cytokine mediators, but the roles of the major proinflammatory cytokines IL-1 and TNF in rheumatoid arthritis has been the most intensively studied area to date.

Activity of proinflammatory cytokines in rheumatoid arthritis was first reported almost 30 years ago (Bodel and Hollingsworth 1969). Recognition of specific IL-1 activity dates back to the early 1980s, when interest was stimulated by reports of IL-1 in exudates in rheumatoid arthritis (Fontana *et al*. 1982; Wood *et al*. 1983), coinciding with the demonstration that IL-1 was produced by mononuclear cells *in vitro* when challenged with arthritogenic stimuli (Duff *et al*. 1983). *In vitro*, synovial cells from rheumatoid arthritic joints were found to release IL-1 (Duff *et al*. 1985) and the concentration of immunoreactive IL-1b in the blood of patients with rheumatoid arthritis was correlated with markers of disease activity (Eastgate *et al*. 1988). The main source of IL-1 in rheumatoid arthritis is probably the CD14+ synovial macrophage (Ogilvie *et al*. 1990; Wood *et al*. 1992). Several trials of anti-IL-1 therapy in rheumatoid arthritis (including small molecular-weight agents and recombinant IL-1 receptor antagonist) are in progress.

The other major cytokine implicated in rheumatoid arthritis is TNF-a, which, in addition to its own proinflammatory activities, is also a potent inducer of IL-1. The first reports implicating biologically active and immunoreactive TNF-a in rheumatoid arthritis are more recent than those for IL-1 (Di Giovine *et al*. 1986; Di Giovine *et al*. 1988a; Di Giovine *et al*. 1988b; Hopkins *et al*. 1988; Saxne *et al*. 1988).

The fact that the spontaneous production of IL-1 by explanted synovial cells from rheumatoid joints could be inhibited by an antibody to TNF-a (Brennan *et al*. 1989) was an important observation. It demonstrated that the suppression of a wider cytokine cascade could be achieved by the specific inhibition of a single cytokine. This work led to clinical trials of 'humanized' antibody to TNF-a in patients with rheumatoid arthritis. Excellent and sustained improvements in both laboratory markers of inflammation and the clinical condition of the patients were reported (Elliot *et al*. 1993) and have been confirmed independently with a different antibody by others (Rankin *et al*. 1995).

This, and similar work by many laboratories, represents a proof of the important principle that specific anticytokine inhibition is potentially a major new therapeutic strategy in rheumatoid arthritis. In the longer term it remains to be shown that efficacy extends to the prevention of erosive disease of cartilage and bone (the most important cause of disability in rheumatoid arthritis), but this seems a reasonable prediction given the activities of TNF, and particularly IL-1, in connective tissue catabolism. It will also be important to demonstrate long-term safety—especially in relation to infections and/or tumours—given the innate immunological activities of IL-1, TNF, and similar cytokines. However, it seems certain that a wide range of anticytokine therapies will enter clinical trials in rheumatic diseases, including biological agents (monoclonal antibodies, soluble receptor proteins, receptor antagonists, and 'anti-inflammatory cytokines' such as IL-10, IL-13), and also conventional, low molecular-weight pharmaceuticals aimed at suppressing the release of cytokines or their activities on target cells.

There are many other cytokines and growth factors that might potentially contribute to the pathology of rheumatic diseases but for which we have, at present, insufficient information. Of great interest is the relatively recent insight that many pathogenic viruses direct the production of factors that transactivate cytokine genes of host cells, while others seem to have captured mammalian cytokine genes (e.g. the Epstein–Barr virus and IL-10) or cytokine receptors (e.g. the poxvirus and IL-1, IL-6, TNF receptors). Such observations may be of relevance to explanations of polyarthritis during known viral infections and may also facilitate our understanding of some idiopathic inflammatory diseases.

Conclusion

The complexity of the mechanisms of inflammation is daunting and the cascade of interactions between the different effector pathways is almost impenetrable. Light is cast by analysis of the rare patient with an inherited deficiency of a single component of inflammation in whom the pathophysiological effects, or otherwise, provide genuine insight into the role of an inflammatory pathway *in vivo*. Our new capacity to delete genes from experimental animals by the method of homologous recombination will in the future allow the systematic analysis of the mechanisms of inflammation in animals deficient in specific pathways. Our present knowledge shows that the mechanisms of inflammation are highly redundant, and the notion that the pharmacological manipulation of a single pathway will have a major therapeutic effect is likely to be regularly frustrated.

3.2 Lymphocyte traffic in inflammation

Dorian O. Haskard

Introduction

Inflammation is traditionally divided into two patterns (Robbins *et al*. 1984). Whilst acute inflammation is dominated by a predominantly polymorphonuclear leucocyte infiltration of the tissues and by the exudation of fluid and plasma proteins, chronic inflammation is characterized by the presence of lymphocytes and monocyte/macrophages, and by the activation and proliferation of connective tissue. In some complex forms of inflammation such as rheumatoid synovitis, acute inflammation may be periodically superimposed upon a background of chronic inflammation. This chapter focuses on lymphocyte traffic to explain how an understanding of these inflammatory processes may be improved by analysing the mechanisms of leucocyte migration.

Until the second half of this century the origin and fate of lymphocytes was as much an enigma as was their function (Nature 1957). Lymphocytes could be found in large numbers in thoracic duct lymph and these were thought to be the products of recent cell division within lymph nodes. Moreover, lymphocytes that had been collected by thoracic duct drainage and then injected intravenously were found to disappear from the circulation within an hour, giving rise to the assumption that lymphocytes were short-lived non-dividing cells. The classical experiments of Sir James Gowans in the rat provided a completely altered view of lymphocyte physiology (Gowans and Knight 1964). Gowans showed that the reason why thoracic duct lymphocytes rapidly leave the circulation when injected intravenously is that they enter lymphatic tissues, through which they pass on a recirculation pathway back to blood (Fig. 1).

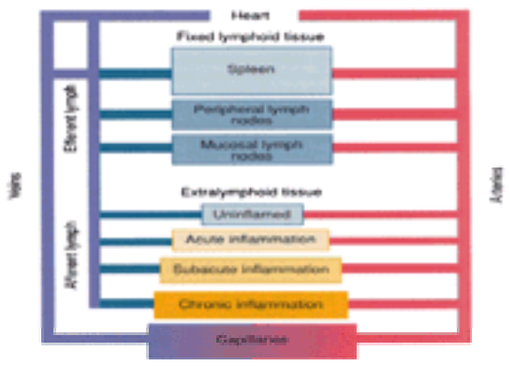

Fig. 1 The pathways of ongoing lymphocyte recirculation through spleen and lymph nodes, and the acquired pathway of recirculation through inflammatory tissues. Whilst passage from the blood into spleen and uninflamed extralymphoid tissue takes place through blood vessels with flat endothelium, passage into lymph nodes and some chronic inflammatory tissues takes place across blood vessels with 'high endothelial' morphology.

Besides recirculating through lymph nodes, lymphocytes also pass in large numbers through the spleen and bone marrow. Indeed it has been demonstrated in the rat that more lymphocytes circulate through the spleen than through all the lymph nodes put together (Pabst 1988).

The demonstration of lymphocyte recirculation implied that small lymphocytes have much longer lifespans than had previously been realized. Studies on the longevity of chromosomal alterations in patients with ankylosing spondylitis who had undergone spinal irradiation showed that a population of small lymphocytes recirculates for years (Buckton *et al*. 1967), although the median survival time for recirculating lymphocytes in man is probably more like 2 to 3 weeks.

The mean size of the recirculating lymphocyte pool in man has been estimated as 2.3×10^{10}, with approximately 50 per cent of recirculating cells being present in the blood (Scott *et al*. 1972). The mean blood transit of recirculating lymphocytes may be as fast as 30 min, resulting in an exchange rate between blood and lymphatic tissues of up to 48 times daily (Schick *et al*. 1975).

Lymphocyte recirculation is a vital element in the function of the immune system since it enables immunological memory to be shared effectively by many anatomically discrete lymphoid organs. Immobilized antigen is exposed to a wide range of lymphocytes of varying clonal specificity because of lymphocyte recirculation. Moreover, lymphocyte recirculation promotes interactions between different functional subsets of lymphocyte and accessory cell, and thus aids the modulation of ongoing immune reactions.

Lymphocyte migration in inflammation

In addition to the large-scale constitutive traffic of lymphocytes through lymphoid tissues, a small but significant steady-state migration of lymphocytes also occurs through most non-lymphoid tissues, as demonstrated histologically or by the migration of radiolabelled lymphocytes in animal models. Lymphocytes are found in afferent lymph draining uninflamed non-lymphoid tissues, although, with the exception of the liver and intestinal mucosa, the numbers of migrating lymphocytes are few compared with those found in efferent lymphatics from lymph nodes. Although modest in extent, the ongoing migration of lymphocytes through non-lymphoid tissues is probably important for routine immunosurveillance.

The presence of perivascular collections and diffuse infiltrates of lymphocytes is a hallmark of immune-mediated chronic inflammation in non-lymphoid tissues, as typified by the cutaneous delayed-type hypersensitivity response to tuberculin or by the rejection response to foreign grafts. Early studies using autoradiography demonstrated that mononuclear cells in chronic inflammatory tissues are mainly derived from the blood rather than from cells proliferating locally (Kosunen *et al.* 1963), and this view has subsequently been supported by immunocytochemical analysis of antigens related to activation and proliferation. For example, although

most rheumatoid synovial lymphocytes show evidence of partial activation (Burmester *et al*. 1984), only a small percentage are actually undergoing cell division (Bonvoisin *et al*. 1984).

Lymphocytes not only migrate in increased numbers into inflamed tissues, but an increase also occurs in the number of lymphocytes present in the afferent lymph draining sites of inflammation, indicating an induced peripheral pathway of recirculation (Hall and Morris 1963) (Fig. 1). Studies in which the peripheral lymph draining sites of chronic inflammation have been sampled by in-dwelling cannulas placed in afferent lymphatics have shown that the scale of lymphocyte migration through inflammatory tissue increases over days to weeks, eventually resembling that through lymph nodes (Smith *et al*. 1970). Peripheral recirculation of this magnitude may occur in some chronically inflamed synovial tissues, although this has never been demonstrated directly. The ability of chronic inflammatory tissues to support the large-scale traffic of lymphocytes has led to the speculation that fixed lymph nodes are an evolutionary development from chronic inflammatory tissues (Rannie *et al*. 1977). Conversely, chronically inflamed non-lymphoid tissues may acquire immunological functions that are normally confined to fixed lymphoid tissues, thereby devolving the immunological response to injury to the periphery (Janossy *et al*. 1981).

Factors promoting lymphocyte emigration and accumulation

From these considerations it will be appreciated that the lymphocytes in an inflammatory focus are in a dynamic state, governed by entry from the blood, retention in the tissues, programmed cell death, and migration into afferent lymph, with only a small proportion actually proliferating at the site of the lesion (Fig. 2).

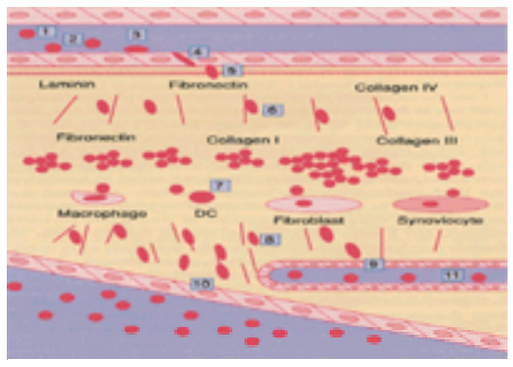

Fig. 2 Events in the migration of leucocytes from blood into and through inflammatory tissues: (1) circulating leucocytes; (2) rolling of resting unactivated leucocytes on endothelium; (3) contact with activating factors on the endothelial cell surface, resulting in up-regulation of leucocyte integrin function and firm adhesion of the leucocyte to the endothelial cell; (4) leucocyte transmigration between endothelial cells; (5) penetration of basement membrane; (6) adhesion and migration upon components of extracellular matrix (e.g. fibronectin, collagen); (7) contact interactions with resident cells; (8) programmed cell death or migration away from the inflammatory focus; (9) entry into afferent lymphatics; (10) entry into synovial fluid or other extracellular fluids; and (11) recirculation to lymph nodes and blood.

The role of vascular endothelium

Adhesion of leucocytes to the luminal surface of vascular endothelial cells is the first step in their migration from the blood into the tissues and is of critical importance in determining the number and type of leucocytes entering sites of inflammation. Interactions between leucocytes and endothelial cells therefore regulate the nature and progression of the inflammatory response.

Lymph nodes

Marchesi and Gowans (1964) observed that recirculating lymphocytes enter lymph nodes by passing through paracortical postcapillary venules, which are characterized by their plump, columnar endothelial cells. These vessels have subsequently been referred to as 'high endothelial venules' and have been found to have properties that are adapted to support lymphocyte adhesion and transmigration from the blood into the lymph node parenchyma (Yednock and Rosen 1989). The interaction between lymphocytes and high endothelial venules is specific, as neutrophils and monocytes do not migrate into the lymph node parenchyma under resting non-inflamed conditions.

Besides having an adhesive luminal surface that is suited to lymphocyte adhesion, the structure of high endothelial venules may provide a valve-like regulation of permeability to macromolecules, thereby minimizing the extravasation of plasma proteins during large-scale lymphocyte transmigration of endothelium. These venules are further characterized by the ability to synthesize and secrete sulphated glycoconjugates that are not normally synthesized by endothelial cells in uninflamed non-lymphoid tissues (Andrews *et al*. 1983). Recent work has identified some of these sulphated molecules as glycoforms of CD34 and GLYCAM-1 (see below) and shown that they act as ligands for the leucocyte adhesion molecule L-selectin (see below).

Spleen and bone marrow

There are normally no high endothelial venules in spleen and bone marrow, and lymphocytes migrate into these tissues across flat fenestrated endothelium (Goldschneider and McGregor 1968). In contrast to the effect on migration of lymphocytes into lymph nodes, lymphocyte entry into spleen and bone marrow is resistant to the digestion of the lymphocyte surface by trypsin, suggesting that different types of adhesion interactions are involved. In the case of the spleen, lymphocytes probably pass readily through fenestrated endothelium in the splenic marginal zones (Peters 1983) and retention in this organs is likely to be dependent largely upon adhesion to parenchymal cells.

Inflammation

Morphological changes in endothelial cells can be seen relatively early during cell-mediated immune reactions. Gell (1959) showed that endothelium took up intravenously injected carbon particles at an early stage during a cutaneous tuberculin reaction in guinea pigs and considered this to be evidence for endothelial cell activation. Likewise, endothelial cells appear activated in the early phase of graft rejection (Dvorak *et al*. 1979). Endothelial cells examined at the start of an immune response typically show an increase in size, abundant eosinophilic cytoplasm, enlarged nuclei, and prominent ribosomes and endoplasmic reticulum, suggestive of increased protein synthesis (Wiener *et al*. 1967). These morphological changes illustrate the fact that endothelial cells are far from inert during inflammation.

Although postcapillary venules in non-lymphoid tissues normally have a flattened endothelium, vessels can be found in established chronic inflammatory lesions that are similar or even identical histologically to the high endothelial venules of secondary lymphoid organs. Such vessels tend to develop in non-lymphoid tissues particularly in the vicinity of lymphocyte-rich inflammatory infiltrates and may occur as a consequence of lymphocyte traffic into the tissues (Freemont *et al*. 1983; Iguchi and Ziff 1986). Furthermore, high endothelial venule-like vessels in rheumatoid synovium can be shown *in vitro* to bind lymphocytes, and to have properties normally confined to high endothelial venules of peripheral lymph nodes, such as the synthesis of sulphated macromolecules, and expression of L-selectin ligands (see below) (Freemont 1987; Michie *et al*. 1993). The acquisition by chronic inflammatory tissue of high endothelial venule-associated mechanisms for the recruitment of lymphocytes may not only augment the scale of lymphocyte traffic, but may also allow the migration of lymphocyte subpopulations that do not normally enter non-lymphoid tissues in the absence of chronic inflammation.

The role of antigen

The large majority of lymphocytes entering inflammatory tissues are not clonally restricted to react with antigens responsible for the initiation or maintenance of the inflammatory response (Prendergast 1964). At the onset of immune-mediated inflammation the local activation of T lymphocytes sets up a cascade of events that results in the non-specific secondary recruitment of more lymphocytes and also other leucocyte types (Hanto *et al*. 1982). The degree to which inflammation can be induced and amplified by this means is shown by the ability to mount a delayed-type hypersensitivity response after passive transfer of a single T cell (Marchal *et al*. 1982). Any oligoclonality of antigen specificity detected in populations of lymphocytes isolated from inflamed tissues is likely, therefore, to be due predominantly to the selective retention, survival, and/or proliferation of cells activated within the tissues, rather than to the existence of a mechanism for the selective recruitment of

antigen-specific lymphocytes.

The influence of lymphocyte lineage

In the absence of inflammation, lymphocytes in human extracellular fluids are predominantly T cells rather than B cells (Manconi *et al*. 1978). Furthermore, the large majority of lymphocytes found in the tissues during a delayed-type hypersensitivity response are T cells with very few B cells (Poulter *et al*. 1982). Clearly, therefore, B cells migrate into non-lymphoid tissues less readily than T cells, at least during day-to-day constitutive traffic and in the first few days of chronic inflammation. Although both CD4+ and CD8+ T cells migrate into the skin during a delayed-type hypersensitivity response, there is an increase in the CD4/CD8 ratio in the tissue compared with peripheral blood, indicating the existence of T-cell subset selectivity in migration (Pitzalis *et al*. 1991).

A more complex picture is seen in chronic synovitis due to rheumatoid arthritis or to other causes. Here the tissue underlying the synovial lining contains perivascular aggregates of predominantly CD4+ T cells, B cells, and plasma cells (Kurosaka and Ziff 1983). Although it is difficult to distinguish the effects of preferential recruitment from preferential retention, mechanisms of lymphocyte migration must evolve in established chronic inflammation which facilitate the migration of B cells and other phenotypes of lymphocyte that do not migrate into the tissues within the limited time-frame of a cutaneous delayed-type hypersensitivity response. As discussed below, this might be because of changes in endothelial cell adhesion molecule expression or in the profile of tissue chemoattractants.

Natural killer cells and large granular lymphocytes constitute up to 30 per cent of CD2-positive lymphocytes circulating in peripheral blood and form a heterogeneous population of cells. There are few natural killer cells in thoracic duct lymph, suggesting that they are not recirculating cells (Fox *et al*. 1984). Natural killer cells tend to be found in rheumatoid synovial fluid but not synovial tissue, suggesting that they migrate rapidly into the joint cavity (Fox *et al*. 1984).

The effect of lymphocyte sensitization

The activation state of lymphocytes is one of the key factors determining their capacity to pass into inflamed non-lymphoid tissues. Lymphocytes that have recently undergone cell division in response to antigen within secondary lymphoid tissue enter efferent lymph and pass into peripheral blood but may not recirculate back through lymphoid tissue. True lymphoblasts are preferentially retained by extralymphoid tissues such as liver, lung, lamina propria, and skin (Rose *et al*. 1978; van Dinther-Jansson *et al*. 1983). Using isoforms of CD45 to distinguish unsensitized (CD45RA positive, 'naïve') from sensitized (CD45RO positive, 'memory') small lymphocytes, it is possible to show that the large majority of T cells found in inflammatory tissues in humans are memory cells (Pitzalis *et al*. 1987). In sheep, in which the traffic of lymphocytes can be studied using in-dwelling cannulas, most lymphocytes in afferent lymph are memory cells. On the other hand, lymphocytes that show little migration to inflammatory tissues are the predominant cells migrating through lymph nodes (Mackay *et al*. 1990).

The altered migration capacity of lymphocytes following sensitization is thought to be due largely to changes in the expression of adhesion molecules and responsiveness to chemoattractants that occur upon cell division. Compared with naïve lymphocytes, memory cells have an increased surface expression of a $^{L}b_{2}$, $a^{3}b_{1}$, $a^{4}b_{1}$, and $a^{5}b_{1}$ integrins, ICAM-1, and CD44 as well as the accessory activation molecules CD2 and CD58 (LFA-3) (Dougherty *et al*. 1988; Pitzalis *et al*. 1988; Sanders *et al*. 1988; Shimizu *et al*. 1990a). This increased adhesion molecule expression of recently activated lymphocytes contributes to their enhanced capacity to adhere to cultured endothelial cells and to transmigrate across endothelial cell monolayers (see below) (Pitzalis *et al*. 1988; Damle and Doyle 1990). Furthermore, memory lymphocytes have a lower threshold for further activation (Sanders *et al*. 1989; Merkenschlager *et al*. 1991) and increased effector function (Rodrigues *et al*. 1992).

Organ-selective migration

Lymphocyte traffic in animal models is not random, since lymphocytes show preferential routes of migration. For example, sheep lymphocytes collected from intestinal lymph or efferent lymph draining peripheral lymph nodes tend to recirculate selectively through intestinal and peripheral lymph nodes, respectively (Chin and Hay 1980; Mackay *et al*. 1992). Differences therefore exist amongst secondary lymphoid organs in the mechanisms by which recirculating lymphocytes are recruited across high endothelial venules into the lymphoid parenchyma. The molecular basis for the selective lymphocyte–endothelial cell interactions involved in homing to different lymphoid organs has been most extensively studied in mice (Berg *et al*. 1989).

There is an emerging picture that the cellular differentiation that occurs upon sensitization in lymph nodes not only enables lymphocytes to emigrate into inflamed tissues (see above) but also confers selective properties to migrate to particular tissues (Picker *et al*. 1990). Lymphocytes that home to skin have been found to express a carbohydrate antigen designated cutaneous lymphocyte antigen, which acts as a ligand for E-selectin (see below) (Picker *et al*. 1993a; Santamaria Babi *et al*. 1995). In contrast, the expression of $a^{4}b_{7}$ integrin (see below) is associated with the migration of lymphocytes to the gut (Hamann *et al*. 1994). Although it is likely that the exact lymphocyte–endothelial interactions that result in lymphocyte recruitment into synovium are distinct from those involved in adhesion of lymphocytes to endothelial cells in peripheral lymph nodes and mucosal tissues (Salmi *et al*. 1995), whether or not there is a particular subset of lymphocytes that selectively homes to inflamed synovium is still unclear.

Adhesion molecules

In the late nineteenth century Cohnheim (1889) postulated that a molecular change in the lining of the blood vessels in inflammation made the vessel wall more adhesive and allowed leucocytes to bind. In recent years monoclonal antibody and DNA technology has led to the identification of a number of leucocyte and endothelial cell adhesion molecules which participate in leucocyte diapedesis. Many of the same molecules are also concerned with the adhesion of leucocytes to cells other than endothelial cells and to components of extracellular matrix within the tissues (Springer 1990).

Selectins

The selectin family is a relatively recently described group of single-chain integral membrane glycoproteins that provide an adhesion mechanism for the tethering of circulating leucocytes to endothelial cells, platelets, or other leucocytes under conditions of flow (Bevilacqua and Nelson 1993). The primary structure of selectins is characterized by a terminal lectin-like domain, a proximal epidermal growth factor-like domain, and a variable number of short consensus repeats with homology to complement regulatory molecules such as decay accelerating factor, complement receptor 1 (CR1), and complement receptor 2 (CR2). The lectin domains of selectins are similar to mammalian asialoglycoprotein receptors and mannose-binding proteins, and have in common a functional dependence upon extracellular calcium ions (Drickamer 1988). There are three recognized molecules within the selectin family, each designated on the basis of the cell type on which the molecule was first characterized (Table 1). Thus L-selectin was first detected on leucocytes, P-selectin on platelets, and E-selectin on endothelial cells. Each of the three molecules is encoded by genes that lie within 300 kilobases of each other on chromosome 1, suggesting that they are derived from duplications and mutations of a single gene.

	L-selectin	P-selectin	E-selectin
Synonyms	CD62L, gp90[MEL]; Leu-8, TQ1, LECAM-1	CD62P, PADGEM, GMP-140	CD62E, ELAM-1
Molecular mass	75–100 kDa	140 kDa	110–115 kDa
Short consensus repeats	2	8–9	6
Distribution	Leucocytes	Endothelial cells, platelets	Endothelial cells
Regulation	Constitutive and shed upon activation	Rapid translocation to cell surface and transcriptional	Transcriptional
Cells bound	Endothelial cells, neutrophils	Leucocytes	Leucocytes
Carbohydrates	Sulphated sialylated and fucosylated carbohydrates	Sialyl Lewis x	Sialyl Lewis x, CLA
Counter-receptors	GLYCAM-1, CD34, ß-gp200, ?other	PSGL-1, ?other	PSGL-1, ESL-1, ?other

Table 1 Selectins

L-selectin

L-selectin is the smallest of the three selectins, consisting of an N-terminal lectin domain, an epidermal growth factor-like domain, two short consensus repeat sequences, a transmembrane domain, and a cytoplasmic domain. The cytoplasmic domain interacts with the cytoskeleton via a-actinin, and is necessary for L-selectin function (Pavalko *et al*. 1995). The molecular mass of L-selectin ranges from between 90 and 100 kDa (neutrophils) and between 74 and 90 kDa (lymphocytes) dependent upon differential post-translational modification. L-selectin was first identified by a monoclonal antibody (MEL-14), which inhibited adhesion of murine lymphocytes to the high endothelial venules of peripheral lymph nodes in an *in vitro* adhesion assay on frozen tissue sections (Gallatin *et al*. 1983). The MEL-14 antigen (mouse L-selectin) was then extensively characterized as a lymphocyte 'homing receptor', which mediates the primary adhesion of lymphocytes to the high endothelial venules of peripheral lymph nodes during recirculation. However, L-selectin was subsequently found to be expressed by most circulating leucocytes apart from a subset of memory T lymphocytes (Picker *et al*. 1993b), and this molecule is now considered to have an important role in the emigration of leucocytes into inflamed tissues as well as in lymphocyte recirculation. Apart from its role in supporting lymphocyte–endothelial cell adhesion, L-selectin also mediates the adhesion of neutrophils to other neutrophils, and may therefore play an important part in neutrophil intravascular aggregation during systemic vascular activation (Bargatze *et al*. 1994).

P-selectin

P-selectin is the largest of the three selectins, having eight or nine short consensus repeat sequences, depending upon alternative splicing of the gene. It was first characterized as a 140 kDa glycoprotein found in platelet a-granules and which appeared on the platelet surface after activation by thrombin. Subsequently, P-selectin was found to be synthesized also by endothelial cells and stored within intracellular granules known as Weibel–Palade bodies. As with platelets, P-selectin is rapidly translocated and expressed on the endothelial cell surface upon activation (see below). Additionally, recent evidence indicates that P-selectin expression by endothelial cells is cytokine-inducible (see below). P-selectin mediates leucocyte adhesion to platelets in addition to their adhesion to endothelial cells (E. Larsen *et al*. 1989).

E-selectin

The observation that neutrophils bind avidly to endothelial cells activated *in vitro* by interleukin-1 or tumour necrosis factor led to the generation of a monoclonal antibody which inhibited neutrophil adhesion to cytokine-stimulated endothelial cells (Bevilacqua *et al*. 1987). The molecule recognized by this monoclonal antibody was first designated endothelial leucocyte adhesion molecule-1 (ELAM-1), but is now known as E-selectin (CD62E). The crystal structure of E-selectin shows a rather linear molecule with little interaction between the epidermal growth factor-like domain and the lectin domain (Graves *et al*. 1994). Mutations that lead to loss of adhesive function are mainly clustered on the top face of the lectin domain close to the site of calcium binding, consistent with a primary role of calcium ions in selectin–ligand interactions. As discussed below, expression of the E-selectin gene is dependent upon endothelial activation by cytokines and other factors.

Selectin ligands

With the discovery of the primary sequences of the three selectins, it became clear that each of the extracellular N-terminal domains is similar to previously characterized C-type animal lectins. Consistent with this lectin structure, each of the three selectins has been found to bind carbohydrate determinants, expressed either on glycolipids or glycoproteins (Lasky 1992). Whilst it is now well established that selectins bind oligosaccharide motifs, the protein and/or lipid counter-receptors which present the oligosaccharides are less well defined. The regulation of expression of selectin ligands is complex since differential expression of glycosyl-transferases may result in potential protein- or lipid-counter-structures being appropriately glycosylated for selectin binding only in particular tissues or in response to specific cellular activation events (Kuijpers 1993).

Oligosaccharide ligands

Although there are differences between the selectins in their binding affinities for different carbohydrate structures, there is a considerable overlap in carbohydrate specificity. Thus each of the three selectins binds sialylated, fucosylated tetrasaccharide—sialyl-3-fucosyl- *N*-acetyllactosamine (**sialyl-Lewis x**). In the case of L-selectin, the oligosaccharide ligand also needs to be sulphated (Green *et al*. 1992; Hemmerich *et al*. 1995). The importance of sialyl-Lewis x for selectin binding is demonstrated by the recently described leucocyte adhesion deficiency type II in which an abnormality in fucosylation of glycoproteins leads to absence of sialyl-Lewis x expression by leucocytes and reduced selectin-mediated adhesion *in vivo* (Von Andrian *et al*. 1993). Affected individuals have a spectrum of clinical abnormalities which overlap with those of leucocyte adhesion deficiency type I (see below) (Etzioni *et al*. 1992).

Carbohydrate ligands for P- and E-selectin are found on neutrophils, eosinophils, natural killer cells, subsets of T lymphocytes, and activated B lymphocytes (Picker *et al*. 1991a; Shimizu *et al*. 1991; Damle *et al*. 1992a; Moore and Thompson 1992; Pinola *et al*. 1994; Postigo *et al*. 1994). In the case of CD45RO-positive memory T lymphocytes which enter skin, the carbohydrate which binds E-selectin is now thought to be the cutaneous lymphocyte antigen (see above), a complex carbohydrate related to sialyl-Lewis x (Berg *et al*. 1991). T lymphocytes isolated from either synovial tissue or synovial fluid have also been found to be capable of binding E-selectin *in vitro* (Postigo *et al*. 1992), although the carbohydrate ligand involved in this adhesion is not yet known. The relative contributions of P- and E-selectin to lymphocyte traffic are not yet established, since the T lymphocytes that bind P-selectin do not appear to be the same population as binds E-selectin (Rossiter *et al*. 1994).

Carbohydrate-bearing selectin counter-receptors

Most of the glyoproteins that have been so far characterized as presenting specific carbohydrate ligands to selectins are sialo-mucins, which have a serine-, threonine-, and proline-rich extracellular structure decorated with *O*-linked oligosaccharides which act as the selectin ligands. Glycoproteins in mouse lymph nodes which present sulphated carbohydrates to L-selectin include GLYCAM-1, CD34, and Sgp200 (Lasky 1992; Baumhueter *et al*. 1993; Hemmerich *et al*. 1995). Furthermore, L-selectin can bind *O*-linked oligosaccharides presented by MadCam-1 (see below) isolated from mucosal lymphoid tissue, suggesting that in mucosal lymphoid vessels L-selectin-mediated rolling on MadCam-1 may precede lymphocyte–Peyer's patch adhesion molecule-1(**LPAM-1**)-mediated firm adhesion (see below) (Berg *et al*. 1993). Although there is good evidence for inducible L-selectin-mediated adhesion on cultured endothelial cells *in vitro* (Spertini *et al*. 1991; Norgard-Sumnicht *et al*. 1993) and in non-lymphoid tissues in inflammation (Michie *et al*. 1993; Faveeuw *et al*. 1994; Lee and Sarvetnick 1994; Whyte *et al*. 1994), the ligands involved have not yet been characterized.

The principal counter-receptor for P-selectin is probably the recently described P-selectin binding glycoprotein-1 (**PSGL-1**). This is a 220 kDa sialylated homodimer with a disulphide bond situated extracellularly near the membrane (Sako *et al*. 1993). In addition to binding carbohydrates expressed by proteins, P-selectin may also bind myeloid cell sulphatides (Aruffo *et al*. 1991). Although PSGL-1 binds E-selectin, the affinity is weak and 50-fold lower than for P-selectin. A number of other candidate molecules have been proposed as counter-receptors for E-selectin, including L-selectin (Picker *et al*. 1991b), CD66 (Kuijpers *et al*. 1992), b_2-integrins (Asada *et al*. 1991), and a 150 kDa (reduced) glycoprotein on murine myeloid cells designated ESGL-1 (Steegmaler *et al*. 1995).

Whilst the lectin domain of selectins mediates adhesion by binding carbohydrate ligands, the epidermal growth factor-like domains and short consensus repeat sequences may also be important in determining the binding specificity of selectins. For example, the epidermal growth factor-like domain of P-selectin may be involved in protein–protein interactions between the selectin and the oligosaccharide-bearing protein counter-receptors (see below) (Kansas *et al*. 1994).

Integrins

The integrins constitute a large family of non-covalently linked ab-heterodimeric glycoproteins (subunits of 95 to 200 kDa) that are so named because of their integral function in connecting the intracellular cytoskeleton with the extracellular environment (Hynes 1992). One or more integrins is found on most animal cells, with the characteristics of the integrin(s) affecting the other types of cell and matrix components with which the cell can interact. The importance of this family of molecules is supported by their degree of conservation between species, with homologous heterodimers being found in the *Drosophila* fruit fly and in the *Xenopus* toad. A characteristic feature of integrins is their functional dependence upon divalent cations (Ca^{2+}, Mg^{2+}). Integrin a-subunits contain repeated segments which putatively act as cation binding sites and which are important not only for the association of a- and b-chains but also in influencing the affinity with which ligand can be bound (see below).

Classification of integrins

At least 15 human a-chains and 8 b-chains have been defined, with ab-associations grouping into subfamilies sharing a particular a- or b-chain (Fig. 3). The ligand specificity of individual integrins depends not only on the particular ab-association but also on the cell type in which the integrin is expressed and upon the state of cellular activation. In general there is considerable primary sequence similarity amongst the different a-chains and also amongst the different b-chains. It should be noted however that despite the similarity between extracellular regions of different integrins, there are substantial differences between the C-terminal cytoplasmic domains of different subunits. Integrins may therefore differ markedly in their signalling roles and relationships with the cytoskeletal proteins, and therefore perform distinct functions (Chan *et al*. 1992; Pasqualini and Hemler 1994).

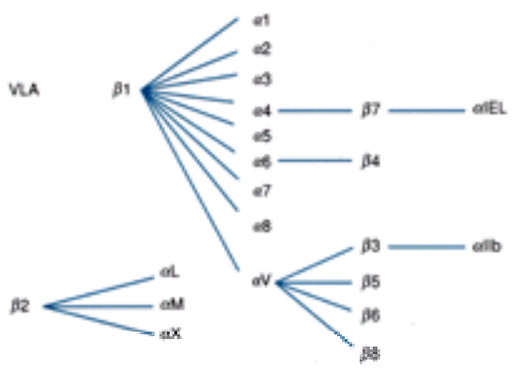

Fig. 3 The associations between integrin a- and b-subunits, resulting in integrin subfamilies.

It is convenient to classify the integrins involved in leucocyte traffic into the Leu-CAM (b_2), a^4, and VLA (b_1) sub-families (Table 2).

Integrin	Synonyms	Distribution		Ligands
		Leucocytes	Other	
$\alpha^L\beta_2$	LFA-1, CD11a/CD18	All		ICAM-1, -2, -3
$\alpha^M\beta_2$	Mac-1, CR3, CD11b/CD18	Prm, Eo, Bp, Mo, LGL		ICAM-1, iC3b, fibrinogen, factor X, β-glucan
$\alpha^X\beta_2$	p150,95, CR4, CD11c/CD18	Prm, Eo, Bp, Mo, LGL		Fibrinogen, iC3b, other
$\alpha_1\beta_1$	VLA-1, CD49a/CD29	Mo, late-activated T cells	EC, Fb	Collagens I and IV, laminin

(LFA-1, lymphocyte function associated antigen-1; LPAM-1, lymphocyte Peyer's patch adhesion molecule-1; VLA, very late activation antigen; Bp, basophil; Eo, eosinophil; EC, endothelial cell; Ep, epithelial cell; Fb, fibroblasts; LGL, large granular lymphocytes; Mo, monocytes; NK, natural killer cell; Prm, polymorphonuclear leucocytes; T, T cells; Pl, platelets; HML-1, human mucosal lymphocyte-1.

Table 2 Integrins involved in lymphocyte traffic

The Leu-CAM proteins (b_2-integrins)

The b_2(Leu-CAM)-integrins consist of a^Lb_2 (lymphocyte function associated antigen (**LFA**)-1, CD11a/CD18), a^Mb_2 (Mac-1, CD11b/CD18, CR3), and a^Xb_2 (p150,95, CD11c/CD18, CR4) (Larson and Springer 1990). The a-chains of b_2-integrins, as well as the a^1- and a^2-subunits (see below), are unusual in each having an inserted 'I domain'of 180 to 200 amino acids. The I domain is critically involved in the binding of metal ions (e.g. Mg^{2+}) and the mediation of the protein–protein interaction of the integrin with its ligand (Landis *et al*. 1994; Lee *et al*. 1995).

The expression of b_2-integrins is restricted to myeloid and lymphoid cells, with a $^Lb_2$ being found on all leucocytes and a $^Mb_2$ and a^Xb_2 on myeloid cells and relatively small lymphocyte subpopulations. a^Lb_2 is the b_2-integrin that is best established as being important for lymphocyte function. However, although a $^Mb_2$ is particularly involved in the extravasation of neutrophils and monocytes, a recent report suggests that this integrin also contributes to the emigration into inflamed tissues of some CD8+ T lymphocytes (Nielson *et al*. 1994).

Integrins of the b_2-subfamily are important for numerous aspects of leucocyte migration and function. Striking evidence for this can be found in the rare, hereditary, leucocyte adhesion deficiency type 1 in which leucocytes lack surface expression of all three b_2-integrins due to failure of synthesis of the b_2-subunit (Arnaout 1990). Infants with b_2-integrin deficiency are often noticed to have delayed separation of the umbilical cord, reflecting the role of phagocytes in this process. The clinical course of b_2-integrin deficiency is characterized by recurrent pyogenic infections, often leading to death from septicaemia in the first or second decade. Whilst these patients have strikingly high peripheral blood leucocyte counts (up to 150×10^9/l), infected tissue is characterized by a poverty of neutrophils, reflecting the failure of leucocytes to emigrate from the blood (Fig. 4).

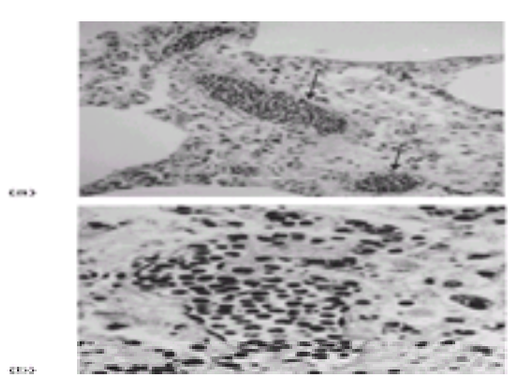

Fig. 4 Autopsy of infected lung tissue from a 19-year-old man with b_2-integrin deficiency, demonstrating the inability of neutrophils to extravasate into the tissues: (a) septal capillaries of the lung are filled with neutrophils (arrows) in contrast to the alveoli which contain macrophages and desquamated alveolar lining cells. Haematoxylin and eosin, magnification × 72; (b) the intravascular cells are mature and immature neutrophils. Haematoxylin and eosin, magnification × 220. (Davies *et al*. 1991, by courtesy of Blackwell Scientific Publications.)

a^4-integrins

In spite of the abnormalities of leucocyte migration in b_2-integrin deficiency, problematic viral infections are rare and patients are able to mount satisfactory humoral

and cell-mediated immune responses. Moreover, the chronically inflamed tissues contain some lymphocytes, monocytes, and eosinophils despite the marked reduction in neutrophils (Fig. 4). These observations, together with the finding that anti-b_2-integrin monoclonal antibodies failed to inhibit fully the adhesion of T lymphocytes to cytokine-stimulated endothelial cells *in vitro*, suggested the existence of an alternative mechanisms of integrin-mediated lymphocyte-endothelial cell adhesion (Haskard *et al*. 1986). b_2-integrin-independent leucocyte adhesion is now known to be mediated at least in part through integrins containing the a^4-subunit, which is expressed by lymphocytes, monocytes, eosinophils, basophils, and natural killer cells but only at very low levels on neutrophils (Lobb and Hemler 1994).

The a^4-subunit is unusual in having a cleavage site near the middle of the extracellular domain, leading to the generation of fragments of 70 and 80 kDa (Hemler *et al*. 1990). It can associate with either the b_1-subunit to form very late antigen-4 (**VLA-4**) (Hemler *et al*. 1990) or with the b_7-subunit to form lymphocyte–Peyer's patch adhesion molecule-1 (**LPAM-1**) (Holzmann and Weissman 1989). Interestingly, CD4+ memory T lymphocytes express either the b_1- or the b_7-subunit in conjunction with the a^4-subunit but not usually both, and which b-chain is used appears to depend on whether the lymphocyte was sensitized in peripheral (b_1) or mucosal (b_7) tissues (see above) (Schweighoffer *et al*. 1993; Erle *et al*. 1994). Both a^4-integrins bind VCAM-1 (see below), although VLA-4 on resting lymphocytes has a higher affinity than LPAM-1 for this molecule (Elices 1990; Ruegg *et al*. 1992). In contrast LPAM-1 but not VLA-4 binds MadCam-1 (see below) and is involved in selective lymphocyte traffic to mucosal tissues (Berlin *et al*. 1993). Both VLA-4 and LPAM-1 also bind the alternatively spliced form of fibronectin containing the CS-1 peptide sequence, which is therefore a possible alternative ligand to VCAM-1 on rheumatoid synovial endothelial cells (Elices 1994).

a^4-integrins are minimally expressed by neutrophils and, therefore, there is considerable interest in their role in supporting the selective traffic of mononuclear cells into chronic inflammatory tissues. Some evidence for this comes from the ability of antibodies against a^4-integrins to block the adhesion of lymphocytes to rheumatoid synovial endothelial cells in frozen-section adhesion assays (van Dinther-Janssen *et al*. 1991; Elices 1994).

VLA (very late antigen) proteins (b_1-integrins)

The b_1-integrin subunit has at least eight alternative partners in addition to the a^4-subunit, and collectively the integrins involving the b_1-integrin subunit are known as the very late antigen (**VLA**) subfamily, named after the detection of VLA-1 (a^1b_1) and VLA-2 (a^2b_1) on lymphocytes 2 to 4 weeks after the onset of T-cell proliferation *in vitro*, at a time that is late relative to the expression of other activation antigens (Hemler 1990). The VLA integrins are widely expressed on other cells besides leucocytes and, with the exception of VLA-4, are mainly concerned with adhesion to extracellular matrix components such as collagen (VLA-1, -2, -3), laminin (VLA-1, -2, -3, -6), and fibronectin (VLA-3,-4,-5). In the case of fibronectin, there are separate binding sites for VLA-4 and VLA-5, and the site utiliszd for lymphocyte adhesion may depend not only on the state of lymphocyte activation but also on differential alternative splicing of the fibronectin molecule (Guan and Hynes 1990).

Following stimulation of T-cell proliferation, there is a gradual increase over 3 to 4 weeks in expression of VLA-1 and VLA-2 and, to a lesser extent, VLA-3, -4, and -5. In contrast, the expression of VLA-6 on late-activated T cells is less than on resting cells. These alterations in VLA-integrin expression, together with variation in expression between lymphocyte subsets, leads to considerable heterogeneity between lymphocytes in their expression of receptors for the various components of extracellular matrix.

Control of leucocyte integrin function

A hallmark of integrins is their capacity to undergo rapid and reversible changes in affinity and avidity for their ligands. Changes in integrin affinity, which are thought to be related to conformational alterations in the ab-complex, are controlled in part from signals from within the cell ('inside-out signalling') and are dependent upon the cytoplasmic domains. Inside-out signalling to integrins occurs upon cross-linking a number of different surface proteins, including the T-cell receptor, CD7, CD28, CD31, and CD44 (Dustin and Springer 1989; Belitsos *et al*. 1990; Koopman *et al*. 1990; Shimizu *et al*. 1992; Tanaka *et al*. 1992), and probably also occurs in response to the action of chemoattractants on their G-protein-coupled receptors (see below). However, inside-out signalling is not the only mechanism whereby integrin affinity is increased, since affinity changes also occur upon contact of the integrin with its ligand ('ligand-induced adhesion') (Cabañas and Hogg 1993). This may be an important mechanism whereby adhesion can be strengthened for the ligand once initial contact has been made. Furthermore, changes in integrin conformation upon contact with ligand may signal changes in the affinity of the molecule for other ligands (Sanchez-Aparicio *et al*. 1994; Li *et al*. 1995), thus promoting a series of adhesion events that could guide a cell through a particular activity.

The ability of leucocytes to adhere through integrin-mediated mechanisms is also influenced by avidity changes due to clustering of the heterodimers at sites of cell contact. These are related to interactions between integrin a- and b-chain cytoplasmic domains and cytoskeletal proteins (Kupfer and Singer 1989; Peter and O'Toole 1995). Interactions between integrins and the cytoskeleton probably occur as secondary 'postreceptor' events, consequent to the initial adhesion interaction, as suggested by studies in which cross-linking of b_2-integrins leads to the polymerization of actin (Lofgren *et al*. 1993).

Integrins as costimulatory molecules

The ability of integrins to transduce signals into the cell is referred to as 'outside-in signalling', and is fundamental to their role in linking adhesion to the biology of the cell (Clark and Brugge 1995). Besides directly regulating cytoskeletal organization, outside-in signalling through integrins can provide important costimulatory signals which greatly influence lymphocyte responsiveness to other stimuli occurring in parallel. Thus surface integrins (e.g. a^Lb_2 and a^4b_1) can act as costimulatory molecules for lymphocyte proliferation upon binding to appropriate ligands (Shimizu *et al*. 1990b; Damle *et al*. 1992b). This costimulatory role of integrins may account for the prolonged immunosuppressive effects of administering antileucocyte integrin antibodies *in vivo* (see below).

Immunoglobulin-like molecules

The immunoglobulin (**Ig**) supergene family consists of a large number of molecules that are structurally related to antibodies (Williams and Barclay 1988). Within this family falls a subgroup of molecules (ICAM-1,-2,-3, VCAM-1, MadCAM-1) which act as adhesion ligands for integrins and which contain in their N-terminals variations of a conserved integrin-binding motif (Clements *et al*. 1994). Other important lymphocyte surface molecules that are contained within the immunoglobulin superfamily are HLA class I and II, CD4, CD8, CD2, CD31 (PECAM-1), and CD58 (LFA-3).

Intercellular adhesion molecule-1, -2, -3 (ICAM-1, -2, -3)

The finding that normal lymphocytes were able to adhere to lymphoid cells from a patient with b_2-integrin deficiency (see above) indicated that a ligand for LFA-1 (a^Lb_2) was present on the b_2- integrin deficient cells. By immunizing mice with b_2-integrin-deficient lymphocytes it was possible to raise a monoclonal antibody (RR1/1) that inhibited the LFA-1-dependent adhesion of normal cells (Rothlein *et al*. 1986). The antigen recognized by RR1/1 was designated intercellular adhesion molecule-1 (**ICAM-1**, CD54) and found to be a single-chain glycoprotein with a molecular mass from 88 to 110 kDa, depending upon tissue-specific glycosylation. ICAM-1 is a transmembrane protein with five C2-type immunoglobulin domains. The LFA-1 binding sites are localized on the two Ig domains nearest the N-terminal (Staunton *et al*. 1990). In contrast to their arrangement in antibodies, the Ig domains of ICAM-1 are unpaired and linear, with a potential bend between domains 2 and 3. In addition to acting as a ligand for LFA-1, ICAM-1 also binds Mac-1 (a^Mb_2) by a site on domain 3 (Diamond *et al*. 1991). The use of different binding sites on ICAM-1 by LFA-1 and Mac-1 suggests a mechanism for the strengthening of cellular adhesion to ICAM-1, which could be utilized by monocytes and other leucocytes which express both of these b_2-integrins (see above).

Most cells can express ICAM-1 if appropriately activated. Endothelial cells are unusual compared with other cell types in showing a relatively high level of constitutive ICAM-1 expression. The presence of ICAM-1 on extravascular cells in inflammation indicates that this molecule may be important not only for leucocyte–endothelial interactions but also for leucocyte migration and interaction with other cells within the tissues (see below).

Although ICAM-1 is constitutively expressed by endothelial cells, anti-ICAM-1 monoclonal antibodies were found not to be as effective as anti-LFA-1 monoclonal antibodies in inhibiting LFA-1-dependent lymphocyte adhesion, suggesting the existence of other LFA-1 ligands. Using a direct functional cDNA cloning strategy a novel LFA-1 ligand was isolated and designated ICAM-2 (Staunton *et al*. 1989). ICAM-2 (CD102) has a molecular mass of 55 kDa and can be considered as a truncated form of ICAM-1, consisting of two Ig-like domains which are 34 per cent similar to the two most N-terminal domains of ICAM-1. As might be expected from the lack of a third Ig domain, ICAM-2 is not thought to bind Mac-1. ICAM-2 has a high constitutive expression on endothelial cells, with a density 10-fold greater than that of the constitutive expression of ICAM-1 (De Fougerolles *et al*. 1991), and this may therefore be the more important LFA-1 ligand on endothelium in uninflamed tissues. However, ICAM-2 expression does not appear to be up-regulated by proinflammatory stimuli, and consequently ICAM-1 may be the predominant LFA-1 ligand

on endothelial cells in inflamed tissues.

Although it is likely that ICAM-1 and ICAM-2 are the only ligands on endothelial cells which can bind LFA-1, there is a third LFA-1 ligand in the form of ICAM-3 (De Fougerolles and Springer 1992). ICAM-3 (CD50, molecular mass 124 kDa) is a highly glycosylated protein with an extracellular portion of five Ig domains (Fawcett *et al*. 1992; Vazeux *et al*. 1992). It is highly expressed on most resting leucocytes and may be particularly important in initiating the interactions of lymphocytes with other leucocytes. Consistent with this, ICAM-3 has been found to be an active signalling molecule (Arroyo *et al*. 1994; Campanero *et al*. 1994).

Vascular cell adhesion molecule-1 (VCAM-1)

Vascular cell adhesion molecule-1 (**VCAM-1**, CD106) is a single chain glycoprotein (molecular mass 96 kDa) which is approximately 26 per cent similar to ICAM-1 (Osborn *et al*. 1989). It is encoded by a single gene on chromosome 1. Although the original form of VCAM-1 to be sequenced had six C2-type Ig domains, it is now clear that the predominant form on endothelial cells has an additional domain, which is very similar in primary structure to the N-terminal domain 1 and which is situated between domains three and four of the six domain form. Whereas VLA-4 binds domain 1 on both the six and seven domain forms, VLA-4 binding can additionally occur to the homologous fourth domain of the seven domain form, providing a mechanism for the strengthening of VLA-4-dependent adhesion. The crystal structure of the N-terminal two domains of VCAM-1 has recently been described (Jones *et al*. 1995). VCAM-1 is expressed by several cell types apart from endothelial cells, including germinal centre dendritic cells, interdigitating dendritic cells, Kupffer cells, renal proximal tubule cells, and type B synovial lining cells (Rice *et al*. 1991; Wilkinson *et al*. 1993).

Mucosal addressin cell adhesion molecule-1(MadCAM-1)

Mucosal addressin cell adhesion molecule-1 (**MadCAM-1**) is a 58 to 66 kDa glycoprotein which is expressed by endothelial cells in high endothelial venules of Peyer's patches and mesenteric lymph nodes and also on blood vessels in lamina propria of the small intestine and in some forms of extramucosal inflammation (Streeter *et al*. 1988; O'Neill *et al*. 1991; Hanninen *et al*. 1993). It is has three extracellular immunoglobulin domains which have structural similarities to ICAM-1, VCAM-1, and IgA1 (Briskin *et al*. 1993). The portion between the membrane proximal (IgA1-like) and intermediate (VCAM-1-like) Ig domains is occupied by a mucin region rich in *O*-linked sugars, which in mucosal lymphoid tissues are capable of binding L-selectin (Berg *et al*. 1993). MadCAM-1 acts as an endothelial ligand for the a^4b_7-integrin (Berlin *et al*. 1993).

Platelet–endothelial cell adhesion molecule-1(PECAM-1)

Platelet–endothelial cell adhesion molecule-1 (**PECAM-1**, CD31) is a six Ig domain glycoprotein which can self-associate in homotypic interactions between cells (Fawcett *et al*. 1995), or can bind heterophilically to the a^vb_3 -integrin on leucocytes (Piali *et al*. 1995). PECAM-1 is expressed by endothelial cells, platelets, neutrophils, monocytes, and a subset of T cells. On endothelial cells it is found at points of intercellular contact between endothelial cells, and may play a role in contact inhibition of endothelial cell migration and proliferation (Fawcett *et al*. 1995). PECAM-1 is also capable of transducing signals into cells and may be involved in modulating the function of surface integrins (Tanaka *et al*. 1992). Recent evidence points to a role of CD31 in leucocyte transmigration though endothelium into the tissues (see below).

CD44

CD44 (Pgp-1, HCAM, Hermes) is a highly polymorphic cell surface glycoprotein with similarity to cartilage link proteins. It has a wide cellular distribution which includes lymphoid and myeloid cells, endothelial cells, epithelial cells, and fibroblasts (Pals *et al*. 1989). Heterogeneity of CD44 is partly attributable to alternative splicing of 10 exons lying in tandem within the extracellular portion of the CD44 gene (Screaton *et al*. 1992), and partly to differential glycosylation (Jalkanen *et al*. 1988). Thus CD44 can be modified by *N*- and/or *O*-linked glysosylation and may also express chondroitin sulphate or heparan sulphate side-chains (Jackson *et al*. 1995). CD44 acts as a receptor for several extracellular matrix components including hyaluronan (Aruffo *et al*. 1990) and fibronectin (Carter and Wayner 1988). Furthermore, CD44 may support the adhesion of lymphocytes to synovial endothelial cells through binding an as yet unidentified ligand. Apart from acting as an adhesion molecule, CD44 is also a signalling molecule capable of mediating an up-regulation of LFA-1-dependent adhesion (Belitsos *et al*. 1990; Koopman *et al*. 1990), and also the costimulation of T-lymphocyte proliferation (Huet *et al*. 1989). Lastly, variants of CD44 that express proteoglycan side-chains may bind cytokines and growth factors to the cell surface (Tanaka *et al*. 1993; Bennett *et al*. 1995).

Vascular adhesion protein-1 (VAP-1)

Vascular adhesion protein-1 (**VAP-1**) is a newly described 90 kDa adhesion molecule for lymphocytes, recognized by a monoclonal antibody generated against stromal material from rheumatoid synovium (Salmi and Jalkanen 1992). In addition to being expressed by rheumatoid synovial endothelial cells, VAP-1 is also found on high endothelial venules of peripheral lymph nodes and on endothelium in mucosal and cutaneous inflammatory tissues (Salmi *et al*. 1993). The molecular nature of VAP-1 and the ligands it binds are not yet described.

Lymphocyte chemoattractants

The directional movement of leucocytes in response to a soluble stimulus is known as 'chemotaxis'. A large number of non-specific leucocyte chemotactic factors have been described, including activated complement components (e.g. C5a), lipid metabolites (e.g. leukotrienes, platelet activating factor), and bacterial-derived peptides (e.g. F–Met–-Leu–Phe). More recently a novel class of cytokines, known as chemokines, has been described, which differ from classical chemoattractants in having marked specificity of actions on leucocytes of particular lineage (Baggiolini *et al*. 1994). In the case of lymphocytes, additional chemotactic factors include interleukin-2 and interleukin-15 (Kornfield *et al*. 1985; Wilkinson and Newman 1994; Wilkinson and Liew 1995). Most chemoattractants act on leucocytes through a newly described family of surface receptors which span the membrane seven times ('serentine receptors') and which are coupled to G proteins (Murphy 1994).

Chemokines are 8 to10 kDa proteins that are released by leucocytes and tissue cells in response to proinflammatory stimuli, of which the best described are interleukin-1 and tumour necrosis factor. Members of the family have in common four conserved cysteine residues, with two subfamilies being distinguished by whether or not an amino acid separates the first and second cysteine (i.e. CXC or CC) (Table 3). CXC chemokines are mostly encoded by genes on human chromosome 4 (q12–21) and probably derive from a single ancestral gene. In contrast, CC chemokines are encoded by genes on human chromosome 17 (q11–32). Although IL-8 (Larsen *et al*. 1989) and particularly IP-10 (Taub *et al*. 1993) have chemotactic activity for lymphocytes, CXC chemokines are predominantly active specifically on neutrophils. Conversely, CC chemokines are chemotactic for lymphocytes, monocytes, basophils, and eosinophils but not neutrophils. CC chemokines that are chemoattractant for lymphocytes include RANTES (Schall *et al*. 1990), MIP-1a and -1b (Schall *et al*. 1993), and MCP-1, -2, and -3 (Carr *et al*. 1994; Taub *et al*. 1995). Variation between lymphocyte subpopulations in responsiveness to these chemokines is probably very important in determining the selective recruitment and distribution of lymphocyte subsets in the tissues. A critical feature of many chemokines is that they are heparin-binding proteins and have the ability to bind negatively-charged glycosaminoglycans on the surface of cells or incorporated in extracellular matrix. As discussed below, this property is thought to be fundamental to how chemokines stimulate leucocyte movement, since *in vivo* leucocytes may migrate along gradients of bound chemoattractants and adhesion molecules ('haptotaxis') rather than gradients of chemoattractants in solution.

Chemokine	Synonyms	Targets
C-X-C		
Interleukin-8	IL-8	Pmn, T
ENA-78		Pmn
Platelet factor 4	PF4	Pmn
Platelet basic protein	PBP	Pmn
β-Thromboglobulin	βTG	Pmn
Connective tissue activating peptide-III	CTAP-III	Pmn
Neutrophil activating protein-2	NAP-2	Pmn
GRO α, β and γ		Pmn, Mo
Interferon-inducible protein-10	IP-10	T
C-C		
Macrophage inflammatory protein-1α	MIP-1α	B, T, Bp, Eo, Mo
Macrophage inflammatory protein-1β	MIP-1β	T, ?other
Regulated on activation, normal T expressed and secreted	RANTES	T, Mo, Eo, Bp
Monocyte chemotactic protein-1	MCP-1	T, Mo, Bp
Monocyte chemotactic protein-2	MCP-2	T, Mo, Bp, Eo
Monocyte chemotactic protein-3	MCP-3	T, ?other

B, B lymphocyte; Bp, basophil; Eo, eosinophil; Mo, monocyte; Pmn, polymorphonuclear neutrophil; T, T lymphocyte.

Table 3 Chemokines

Control of leucocyte adhesion and migration

The balance in postcapillary venules between adhesion due to intercellular molecular bonds on the one hand and factors preventing adhesion (e.g. shear stress and surface charge) on the other, is normally set at an equilibrium which allows for the routine immunosurveillance of the tissues by a small number of migrating lymphocytes. During inflammation, lymphocyte adhesion and migration are enhanced by the locally regulated alteration in expression and/or function of a number of different adhesion molecules both on endothelial cells and on lymphocytes.

The adhesion cascade

The ultrastructural appearance of leucocyte emigration was well described by the early 1960s (Marchesi and Florey 1960). Leucocytes could be seen adherent to the luminal surface of the postcapillary venules and often appeared flattened with an increased area of membrane in contact with the endothelial cell surface. Migration through endothelium was associated with the development of pseudopodia which formed the leading edge of the leucocyte and which were seen to penetrate between adjacent endothelial cells.

Over the last few years there has been a considerable increase in understanding of the molecular and cellular mechanisms involved in leucocyte–endothelial cell interactions. The series of co-operative adhesive events which are now known to underlie the emigration of leucocytes into the tissues has become known as the 'adhesion cascade'. Although the events were first described for neutrophil–endothelial cell interactions, there is now evidence that similar rules apply for monocytes (Luskinskas *et al*. 1994) and for lymphocytes (Jones *et al*. 1994). The 'adhesion cascade' model now provides a framework with which to understand the specificity of leucocyte migration into different inflammatory tissues. Thus whether or not a leucocyte emigrates from the blood into the tissues is no longer seen as being due to a single receptor–ligand interaction but dependent on the leucocyte being able to participate in a series of potentially selective adhesion and activation events (Butcher 1991; Springer 1994). Although this model provides a reasonable paradigm with which to account for the complexity of cellular traffic in inflammation, the exact conditions of emigration may well vary with the leucocyte type, the tissue, and the precise type of inflammatory insult (Bullard *et al*. 1995; Ward 1995).

Leucocyte rolling

Atherton and Born (1972) showed by direct observation of the microvasculature *in vivo* that circulating leucocytes roll along the surface of endothelium before becoming firmly adherent to the vessel wall. As a result of rolling, the velocity with which leucocytes pass through venules drops from about 2000 to 3000 μm/s to approximately 10 to 25 μm/s.

Leucocyte rolling is now thought to be mediated largely by the interactions of selectins with their carbohydrate ligands, which have a high tensile strength but rapid on and off rates (Alon *et al*. 1995a). The involvement of selectins in leucocyte rolling has now been experimentally validated with models of neutrophil and lymphocyte interactions with endothelial cells or purified adhesion ligands under conditions of flow *in vitro* (Lawrence and Springer 1991; Abbassi *et al*. 1993; Lawrence and Springer 1993), and *in vivo* (Ley *et al*. 1991; Bargatze and Butcher 1993; Doré *et al*. 1993; Mayadas *et al*. 1993). In mice P-selectin and L-selectin dominate rolling at early and later time-points after endothelial cell activation (Ley *et al*. 1995), indicating some functional specialization amongst the three selectins. The relative contribution that each of the three selectins makes in humans to leucocyte rolling in different forms of inflammation and at different stages of the inflammatory response is still uncertain. Whilst the primary function of selectin–carbohydrate interactions is to support intercellular adhesion (see below), there is some evidence that these interactions may have cell-signalling effects, both in leucocytes and in endothelial cells (Lo *et al*. 1991; Kaplanski *et al*. 1994; Laudanna *et al*. 1994; Weyrich *et al*. 1995).

Firm adhesion of leucocytes to endothelial cells

Although early experiments studying neutrophil adhesion to endothelial cells under physiological shear stresses indicated a requirement for selectin-mediated adhesion prior to the involvement of integrins, reductions in shear rates in pathological situations may allow direct b_2-integrin-mediated attachment (Gaboury and Kubes 1994). Furthermore, it is now clear that monocytes and lymphocytes may use a^4-integrins with VCAM-1 or MAdCAM-1 for the initial attachment step (Jones *et al*. 1994; Alon *et al*. 1995b; Berlin *et al*. 1995; Luskinskas *et al*. 1995). Therefore mononuclear cells may be able adhere and emigrate in vessels in which selectin-mediated adhesion is not prominent.

During rolling the leucocyte is thought to be stimulated by local mediators that activate the adhesivity of integrins, resulting in firm integrin-mediated immobilization of the rolling cell and transmigration into the tissues. However, the precise stimuli which activate a rolling lymphocyte are not yet known but are probably associated with the endothelial surface, either in the form of integral membrane proteins, such as selectins (see above), or in the form of chemokines bound to glycosaminoglycans in the endothelial glycocalyx (Tanaka *et al*. 1993; Webb *et al*. 1993). Thus rolling leucocytes are thought to sample the endothelial surface for immobilized chemoattractants, and the subsequent activation of integrin function then leads to firm integrin-mediated adhesion to Ig-superfamily molecules such as ICAM-1 and -2 and VCAM-1.

Transmigration of leucocytes through endothelium

After adhering to the luminal surface of endothelium, leucocytes transmigrate between endothelial cells and through the endothelial basement membrane before gaining access to the tissues. Judging from work performed on rat lymph nodes, this process is very rapid, with emigrating lymphocytes passing through basement membrane within 10 min (Smith and Ford 1983). The adhesion interactions which result in leucocyte transmigration are not yet well defined but include mechanisms which facilitate de-adhesion from the luminal surface of endothelium, as well as mechanisms supporting the adhesion necessary for migration into the tissues.

In the case of granulocytes and monocytes there is good evidence that L-selectin is enzymatically cleaved from the cell surface between Lys-321 and Ser-322 as part of the sequence of events taking place on the endothelial cell surface (Kahn *et al*. 1994). This mechanism may facilitate de-adhesion from the endothelial lumenal surface and may also serve to avoid inappropriate adhesion in tissues containing carbohydrate ligands to which L-selectin could bind, as in the central nervous system (Huang *et al*. 1991). The precise events that lead to the rapid shedding of L-selectin may involve cross-linking L-selectin on the lympocyte surface (Palecanda *et al*. 1992). Although L-selectin is also cleaved from the surface of lymphocytes upon activation, *in vitro* studies indicate that this process is relatively slow, and may not occur during lymphocyte emigration through the vessel wall (Bührer *et al*. 1992).

The mechanisms which guide leucocytes through the vessel wall are still being established, but appear to involve two-way signalling interactions between leucocytes and endothelial cells (Huang *et al*. 1993; Pfau *et al*. 1995). The adhesion molecules involved in transmigration include similar integrin interactions with immunoglobulin-superfamily ligands to those supporting firm adhesion (Van Epps *et al*. 1989; Kavanaugh *et al*. 1991). A role for CD31 in leucocyte transmigration through endothelium has been suggested by studies both *in vitro* (Muller *et al*. 1993) and *in vivo* (Vaporciyan *et al*. 1993; Bogen *et al*. 1994). As discussed above, this could either involve CD31–CD31 homotypic interactions or binding of CD31 to other ligands such as a $_v b_3$ -integrin.

Endothelial cells may actively promote leucocyte transmigration, particularly after cytokine activation (Oppenheimer-Marks and Ziff 1988; Furie and McHugh 1989; Moser *et al*. 1989). This increased capacity of cytokine-activated endothelial cells to support leucocyte transmigration is probably related to the increased expression of adhesion ligands and chemokines (see below). A chemoattactant gradient appears essential for emigration, since inappropriate exposure of leucocytes to chemoattractants in the vascular compartment may prevent migration (Hechtman *et al*. 1991; Huber *et al*. 1991).

The mechanisms by which leucocytes penetrate the basal lamina, which is composed of types III, IV, and V collagen, heparan suphate, laminin, and fibronectin, are not well understood but probably involve the induced secretion or surface expression of degradative enzymes (Naparstek *et al*. 1984; Romanic and Madri 1994).

Endothelial activation

Functional changes in endothelium are of paramount importance for localizing inflammatory responses. Activation of endothelial cells not only leads to the controlled expression of adhesion ligands on the luminal surface, but also results in the generation of surface-bound and secreted factors capable of affecting leucocyte function and responsiveness to subsequent stimulation within the tissues. Endothelial activation may be classified according to the different phases of the inflammatory response, with each phase being associated with a particular profile of surface adhesion molecules, thereby contributing to the migration of the particular leucocyte subsets that characteristically infiltrate different types of inflammatory lesion.

Rapid activation

Stimulation of endothelial cells with agonists such as histamine, thrombin, C5a, or C5b to C9 terminal complement complexes elicits a rapid response, which includes the secretion of factors that regulate vascular tone (e.g. prostacyclin and nitric oxide), the surface expression of platelet-activating factor, and the translocation of Weibel–Palade bodies to the plasma membrane with the release of von Willebrand factor and the surface expression of P-selectin (Hattori *et al*. 1989a; Hattori *et al*. 1989b; Geng *et al*. 1990; Foreman *et al*. 1994). The rapid and transient expression of platelet-activating factor and P-selectin is thought to lead to the early phase of neutrophil adhesion to endothelial cells that occurs within minutes of the onset of an inflammatory reaction (Zimmerman *et al*. 1990).

Subacute activation

The effects of interleukin-1, tumour necrosis factor, and lipopolysaccharide

Injection of interleukin-1, tumour necrosis factor, or lipopolysaccharide *in vivo* stimulates a subacute inflammatory response associated with marked leucocyte emigration into the tissues (Cybulsky *et al*. 1988; Binns *et al*. 1992). To a large extent this is attributable to an orchestrated induction of endothelial function, which differs from the rapid reaction to the acute endothelial cell agonists described above in that it involves the transcription of a number of primary and secondary response genes, with subsequent *de novo* protein synthesis and surface expression (Pober and Cotran 1990). The transcriptional control of much of this response involves the translocation to the nucleus of the transcription factor NFkB, and is autoregulated by the synthesis of the inhibitory protein IkBa (Read *et al*. 1994).

The effects on endothelial cells of interleukin-1, tumour necrosis factor, or lipopolysaccharide are first detectable *in vitro* after 1 to 2 h and last for a variable time, depending upon the stimulus applied and the exact response measured. These factors stimulate the expression of a number of adhesion molecules involved in the rolling and firm adhesion stages of leucocyte–endothelial cell interaction, including E-selectin, P-selectin, ICAM-1, VCAM-1, and MadCAM-1, as well as the synthesis and secretion of cytokines such as interleukins-1and -6, colony stimulating factors (CSF) G-CSF, GM-CSF, and M-CSF, platelet-derived growth factor, and a number of chemokines such as interleukin-8 and monocyte chemotactic protein-1.

Effect of interferon-g and interleukin-4

Whilst interleukin-1 and tumour necrosis factor appear to be the dominant cytokines involved in the subacute phase of endothelial cell activation, their effects can be modulated by other cytokines, which in themselves have little or no direct action on the expression of endothelial cell activation determinants. In the context of immune-mediated inflammation, the effects of interleukin-1 and particularly tumour necrosis factor on the expression of ICAM-1 and VCAM-1 may be selectively up-regulated by the actions of interferon-g and interleukin-4 respectively, suggesting a possible differential control of endothelial cell activation during T-helper 1- and T-helper 2-type immune responses (Thornhill and Haskard 1990). Lymphokines may also have selective effects on chemokine synthesis, as shown by interferon-g inducing endothelial cell expression of monocyte chemotactic protein-1 but not interleukin-8 (Brown *et al*. 1994).

Chronic activation

Understanding the nature of endothelial cell activation in chronic inflammation has been hampered by the limitations of endothelial cell cultures, which are difficult to prolong beyond a few days. On the one hand it is likely that some endothelial cell responses are down-regulated as the inflammatory process becomes chronic, either through the endogenous control of transcriptional mechanisms (Read *et al*. 1994) or through the down-regulating actions of some cytokines and growth factors such as interleukin-4 and transforming growth factor-b (Thornhill and Haskard 1990; Gamble *et al*. 1993). On the other hand, additional adhesion molecules may be expressed at later times during the development of chronic inflammation, perhaps in connection with the acquisition of vessels with high endothelial venule-like morphology (see above). Although there is very little information on this point, Michie *et al*. (1993) have observed the expression of the peripheral lymph node addressin, a ligand for L-selectin, on endothelial cells in some forms of chronic inflammation, including rheumatoid synovitis.

Lymphocyte migration within the tissues

Once leucocytes have passed through endothelium they migrate within tissues by contact interactions with other cells and/or with components of the extracellular matrix such as fibronectin, collagen, and hyaluronate. Less is known about the molecular basis of these events than is the case for leucocyte interactions with endothelial cells, although it is likely that similar principles apply. Cytokines up-regulate the expression of ICAM-1 and VCAM-1 on synovial tissue fibroblasts, providing a mechanism for enhanced interactions of these cells with lymphocytes (En Chin *et al*. 1990; Marlor *et al*. 1992; Cicuttini *et al*. 1994; Shimada *et al*. 1994). Adhesion molecule expression by synovial fibroblasts may also be directly regulated by physical contact with T lymphocytes or monocytes (Bombara *et al*. 1993). As described above, adhesion molecules play a central role not only in the migration and arrest of lymphocytes within the tissues but also in determining their response to activating stimuli.

Identification and quantification of adhesion molecules *in situ*

Much of the new understanding of the mechanisms of intercellular adhesion has been gained from investigations at the cellular and molecular level *in vitro*. Evidence that the molecules identified as important for leucocyte function *in vitro* are relevant to the *in vivo* situation comes first from a large number of immunocytochemical studies of synovium (Table 4) and other tissues (Mason and Haskard 1994). An extension of the histological approach is to use the technique first devised by Stamper and Woodruff (1976) for studying the adhesion of lymphocytes to endothelial cells in frozen tissue sections. This technique has been used with inhibitory monoclonal antibodies to implicate the involvement of a number of adhesion molecules in lymphocyte adhesion to synovial endothelial cells *in situ*, including a^L-, a^M-, b_2- and b_1-integrin subunits, L-selectin, ICAM-1, VCAM-1, alternatively-spliced fibronectin, CD44, and VAP-1 (Jalkanen *et al*. 1987; van Dinther-Janssen *et al*. 1991; Salmi and Jalkanen 1992; Fischer *et al*. 1993; Elices 1994).

Table 4 Expression of adhesion molecules in arthritis

Owing to the constraints imposed by the availability of human tissue, there is also interest in measuring the soluble forms of the three selectins, ICAM-1, ICAM-3, and VCAM-1, as serum markers of cellular activation in tissues (Gearing and Newman 1993; Mason *et al*. 1993; Carson *et al*. 1994; Martin *et al*. 1995). In the case of E-selectin, synovial endothelial activation and E-selectin expression can also be quantified and imaged non-invasively using intravenously injected, radiolabelled,

monoclonal antibody (Keelan *et al*. 1994; Jamar *et al*. 1995; Chapman *et al*. 1996).

Therapeutic possibilities

A reduction in leucocyte traffic into tissues is to be expected as part of a general down-regulation of the inflammatory response. However, although the majority of antirheumatic drugs in routine use were originally introduced into clinical practice on an empirical basis, some agents may have direct actions that are relevant to cell migration (Chapman and Haskard 1995).

Experience with thoracic duct drainage and lymphocytephoresis gave some encouragement that direct manipulation of lymphocyte traffic might have therapeutic effects in immune-mediated inflammatory diseases (Paulus *et al*. 1979; Karsh *et al*. 1981; Wahl *et al*. 1983). The rapid development in understanding of mechanisms of leucocyte traffic described in this chapter has led to renewed interest in the possibility of inhibiting inflammatory processes by blocking white cell migration *in vivo*.

Studies in animal models of arthritis and other forms of inflammation have shown that monoclonal antibodies against a number of adhesion molecules can have marked suppressive effects on leucocyte traffic and upon the inflammatory process (reviewed in Mason and Haskard 1994). Whilst inhibiting selectins has effects that are limited to leucocyte–endothelial cell interactions, inhibiting integrin interactions may have quite widespread and lasting suppressive effects on the immune response, as shown in animal models of transplantation (Isobe *et al*. 1992; Orosz *et al*. 1993) and arthritis (Iigo *et al*. 1991; Jasin *et al*. 1992; Barbadillo *et al*. 1995) and more recently for anti-ICAM-1 monoclonal antibodies in patients with rheumatoid arthritis (Kavanaugh *et al*. 1994; Davis *et al*. 1995). Recent developments which should facilitate further understanding of the therapeutic potential of lymphocyte traffic as a target for therapy include the use of immunodeficient mice engrafted with human synovium (Rendt *et al*. 1993), and the use of murine models of arthritis in gene-targeted mice (Sligh *et al*. 1993; Wilson *et al*. 1993; Labow *et al*. 1994; Bullard *et al*. 1995; Subramaniam *et al*. 1995; Tedder *et al*. 1995).

3.3 Specific immune responses

B. P. Wordsworth, S. J. Bowman, and John I. Bell

A complex series of immunological events has evolved in man as a response to the threat posed by a plethora of potential pathogens. Many of these responses are of a non-specific nature (innate immunity), while others are targeted more specifically (adaptive immunity). Activation of the immune system typically leads to tissue inflammation, clearance of the invading organism, and healing of damaged tissues, often with fibrosis. In addition to infection by bacteria, viruses, and fungi, abnormal host cells such as tumours may serve as targets of the immune response. In the course of such reactions there may also be substantial damage to the host tissues and, in certain circumstances, the immune system may be directed aberrantly against components of the host tissues. At least some rheumatological disorders appear to belong to this group of 'autoimmune diseases' and, without doubt, immunological mechanisms are involved in their pathogenesis. A clearer knowledge of the basic physiology of these immunological responses may therefore improve our understanding of the pathogenesis of these conditions.

Innate immunity

There are many non-specific barriers to infection, including the skin, mucosal surfaces, and their secretions. In addition to the potential bactericidal effects of pH or proteolytic enzymes in some secretions, such as gastric digestive juices, tissue secretions may contain an enzyme, lysozyme, that disrupts the proteoglycan cell walls of many pathogens.

Several cell types, originating from bone marrow precursors, have the capacity to phagocytose organisms that penetrate these barriers. In the bloodstream these include neutrophil polymorphs and monocytes, both of which can migrate into the tissues in response to appropriate stimuli such as infection or inflammation. Some leucocytes have the capacity to recognize virus-infected cells; these natural killer cells can bind to such cells and kill them after activation by interferon produced by the host tissues. Furthermore, interferon induces resistance to viral replication in neighbouring cells and constitutes an important component of innate immunity to viral infection.

Clearance of pathogens may be enhanced greatly by the provision of opsonization, in which the target is coated by a variety of mediators that increase the efficiency of phagocytosis by macrophages and polymorphs. Examples of opsonins include complement components and acute-phase proteins (e.g. C-reactive protein) from the innate immune system and immunoglobulin antibodies from the adaptive immune system. Activation of the complement cascade (see Chapter 3.1) can lead to such diverse activities as opsonization (C3b), chemotaxis (C5a), and lysis of micro-organisms by the membrane attack complex. Many organisms activate complement through the 'alternat(iv)e pathway' which leads to their opsonization with C3b. This enhances phagocytosis because monocyte macrophages and polymorphs have specific receptors for C3b on their surface. Further activation of the complement cascade causes chemotaxis of phagocytes and other white cell types to the focus of inflammation by the accumulation of C5a. Cell surface determinants on some organisms allow their recognition by phagocytes without the need for complement, while others can be opsonized by acute-phase proteins (see Chapter 4.1). For instance, C-reactive protein is synthesized and rapidly released in many inflammatory disorders by the action of interleukin 6 on hepatocytes. C-reactive protein can bind to many organisms, activates complement *in situ* through the alternative pathway, and thereby facilitates phagocytosis through the C3b receptors on phagocytes. Consequently, hereditary deficiency of C3 may cause recurrent infections and septicaemia (Morgan and Walport 1991). During the process of acute inflammation that accompanies an immune response, there is an increase in blood supply to the affected areas and an increase in vascular permeability. Migration of leucocytes through the postcapillary venules is enhanced by the local accumulation of C5a in the tissue. Concurrently, a number of plasma enzyme systems are activated. These include the complement cascade, the kinin system (bradykinin release), the clotting system (through Hageman factor XII), the fibrinolytic system (through tissue plasminogen activator), and the release of histamine from mast cells, triggered by complement. Many of these chemicals are vasoactive and chemoattractant to neutrophils, and they lead to further increases in local tissue concentrations of other mediators of the immune response.

Adaptive immunity

Many components of the innate immune system can be activated non-specifically. However, not all pathogens stimulate such responses, because they lack the appropriate ligands for binding to phagocytes, complement, or acute-phase proteins and alternative mechanisms, involving lymphocytes, are required to initiate targeted responses. Recognition of antigens by two distinct lymphocyte lineages (B and T cells) is central to adaptive immunity. First, the production of antibodies by B lymphocytes provides considerable specificity and flexibility in adaptive interactions with antigens and can lead to activation of the immune system, including the complement cascade through the classical pathway. Second, T lymphocytes can recognize antigens directly through their cell-surface antigen receptors. Activated in this way they can either kill cells bearing non-self antigens (cytotoxic T cells) or provide 'help' to B cells to produce antibodies (helper/inducer T cells).

B lymphocytes are capable of producing antibodies that bind to the corresponding antigen with a high degree of specificity. Individual B cells are capable of synthesizing antibodies of only one specificity and carry membrane-bound copies of the antibody as cell surface receptors. Only when the appropriate antigen is encountered by the B-cell antigen receptor can that cell potentially proceed to activation and maturation towards an antibody-producing plasma cell. However, additional signals are required for this to occur, particularly from 'helper cells'. Antibodies provide a particularly flexible form of opsonin, with one end binding to specific antigenic determinants on specific microbial pathogens (Fab portion) and the other end (Fc portion) to complement or Fc receptors on the surface of some cell populations (Fig. 1).

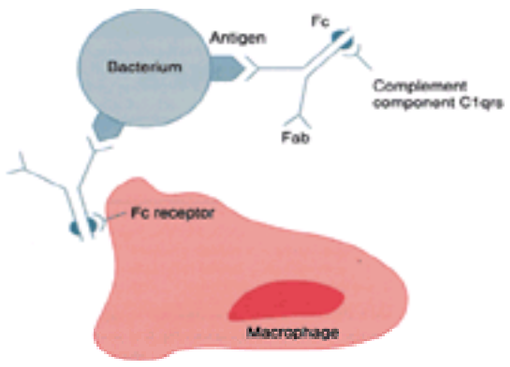

Fig. 1 Antibodies can activate complement or act as opsonins by binding through their Fc portions either to C1qrs or the Fc receptors on certain cells such as macrophages. The Fab portion recognizes specific antigenic determinants such as bacterial cell wall structures.

Specific immune responses

Immune activation is central to the pathogenesis of many of the inflammatory arthritides. In particular, rheumatoid arthritis and reactive arthritis are associated with many of the features that result from antigen-specific stimulation of the immune system. Many of the local features of these disorders within the joint can be attributed to lymphocyte activation, cytokine release, and activation of antigen-presenting cells or macrophages. Common to all these processes are the initial events associated with the recognition of peptide antigen in the context of major histocompatibility complex (**MHC**) molecules by T cells bearing the appropriate recognition elements. In the case of class-I-restricted MHC presentation this leads to the activation of cytoxic T-cell (CD8+) populations, and in the case of class II-restricted recognition, to the activation of helper T cells (CD4+). It is now widely believed that responses mediated by CD4 T cells can be separated into those mediated by a T_{H1} subset (enhanced cellular immunity) and a T_{H2} subset (facilitating B-cell humoral respones). The former responses result in the liberation of the cytokines interferon-a and interleukin 2 (**IL-2**), while the latter are mediated through the release of IL4 and IL-10 (reviewed in Paul and Seder 1994). Cascade events involving cell activation and cytokine release within the joint are undoubtedly extremely complex but include the activation of B cells and macrophages which in turn release other potent inflammatory mediators such as IL-1 and tumour necrosis factor.

The best opportunity for analysing these processes is to start with the simplest events surrounding antigen-specific, T-cell activation. There are three primary elements involved in initiating a specific immune response; these are an HLA class I or class II molecule, an antigen (in the form of peptide) that associates in the antigen-binding site of the HLA molecule, and the T-cell antigen receptor found on the surface of all T-cell populations (Fig. 2).

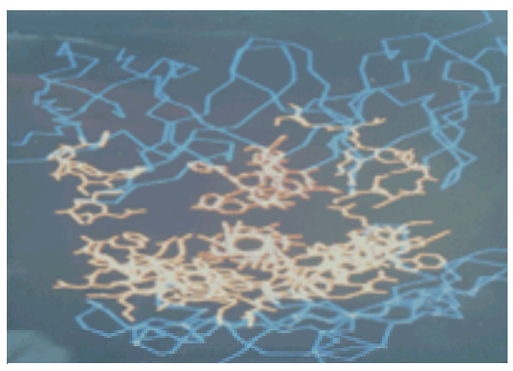

Fig. 2 Three-dimensional representation of the interaction between the MHC–peptide complex (below) and the T-cell receptor (TCR) above. The CDR1 and CDR2 of the TCR are shown in yellow and CDR3, which interacts most closely with the peptide antigen, in red. The a-helices of the MHC molecule interacting with CDR1 and CDR2 are shown in yellow and the peptide interacting with CDR3 is shown in red (Davis and Bjorkman 1988).

The interaction of these three molecules (often called the ternary complex) is assisted by the associated T-cell molecules CD4, CD8, and intercellular adhesion molecule 1, as well as by molecules such as lymphocyte function-associated antigens 1 and 2 present on the antigen-presenting receptor. This in turn leads to T-cell activation. Because of the central role of these elements of the ternary complex, this chapter concentrates on the molecular details of the components of this complex and discusses events leading to T-cell activation.

Major histocompatibility complex

Many of the genes implicated in susceptibility to autoimmune diseases, including many rheumatic conditions, map to the MHC at the centromeric end of the short arm of chromosome 6 (Stastny *et al*. 1983). Several genes in this region are essential to the mounting of normal cellular and humoral inflammatory responses and correspond to the immune response genes first described 30 years ago in the mouse. The HLA genes, for instance, are crucial to the determination of the host response not only to infections but also to transplanted tissues and they were first recognized as 'transplantation antigens'. Subsequently, much has been elucidated about their crucial role in the presentation of foreign antigens during immune responses. However, the HLA genes are but a small component of a region spanning over 3 million base pairs and containing over 100 genes. The MHC can be divided into three regions, classes I to III, each containing a series of homologous loci. (Fig. 3).

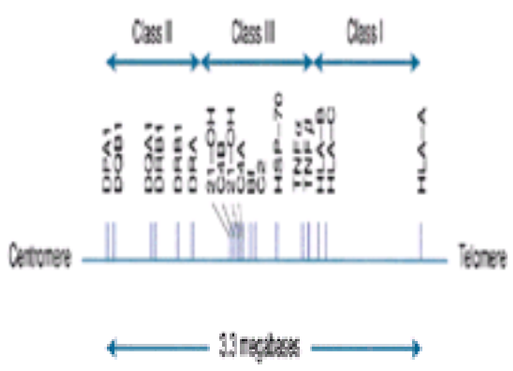

Fig. 3 The approximate genomic organization of the major histocompatibility complex on the short arm of chromosome 6.

Class I region

Encoded within this region are the polymorphic HLA-A, -B, and -C loci, encoding the corresponding 45-kDa heavy chains of HLA class I molecules, which are members of the immunoglobulin superfamily. At least 50 HLA-A, 90 HLA-B, and 30 HLA-C alleles have been identified (Bodmer *et al*. 1994), although new variants are continually being described. Each heavy chain has three extracellular domains (a_1, a_2, and a_3) a transmembrane portion, and a cytoplasmic tail. It associates with

a 12-kDa light chain (b_2-microglobulin) before expression on the surface of most nucleated cells. These molecules have long been recognized as transplantation antigens capable of triggering the rejection of tissue grafted from an HLA non-identical donor.

HLA class I molecules play an essential part in the presentation of peptide antigens to cytotoxic T cells in an HLA-restricted manner. The determination of the three-dimensional crystallographic structure of the class I molecules HLA-A2, -A68, and -B27 (Bjorkman *et al*. 1987; Garrett *et al*. 1989; Madden *et al*. 1991) has served to illustrate the probable mechanism of this process (Fig. 4). Antigens, typically peptides with eight or nine amino acids, are bound in a cleft on the surface of the HLA molecule (Jardetzky *et al*. 1991). The combined HLA–antigen complex can then interact with T lymphocytes bearing the appropriate antigen receptors to trigger an immune response. Something of the specificity of this system can be appreciated by considering T-cell clones raised against particular peptide antigens presented by target cells of known HLA type. The same clone will fail to recognize the same antigen if it is presented by target cells of a different HLA type. Likewise, even single amino acid substitutions in the peptide antigen may be sufficient to abolish recognition (Townsend and Bodmer 1989).

Fig. 4 Ribbon diagram of the HLA-A2 class I molecule, indicating the antigen-binding cleft. Polymorphic residues are concentrated around this structure pointing towards the peptide antigen from the floor and sides. The sites of interaction with the CD8 molecule and b_2-microglobulin are indicated.

Nucleotide sequencing of class I genes reveals that the polymorphism within these molecules lies largely in the a_1- and a_2-domains that form the sides and floor of the antigen-binding cleft (Fig. 4). Furthermore, the polymorphic residues are those that are orientated to be involved in interactions either with the peptide antigen or the T-cell receptor. Single amino acid substitutions may induce profound effects on both peptide binding and T-cell recognition. In general, class I molecules are concerned with the presentation of endogenously derived antigens to cytotoxic (CD8+) T cells and are therefore intimately concerned in the host response to tumour cells and virus-infected cells.

Class II region

Encoded within this region are the classical class II genes, HLA-DR, -DQ, and -DP as illustrated in Fig. 5. Class II HLA molecules are also members of the immunoglobulin superfamily and have considerable structural and functional homology with class I molecules, but a more limited tissue distribution. Each class II molecule is a transmembrane glycoprotein heterodimer, consisting of a non-covalently bound a- and b-chain. The amino acid sequences of these molecules share similarities with class I molecules, and the membrane distal portion of the a- and b-chains of class II molecules combine to form a similar antigen-binding cleft with a floor of eight antiparallel b-pleated sheets, and two antiparallel a-helices on either side (Brown *et al*. 1993). Class II molecules bind peptides of more variable lengths of around 14 amino acids, and this difference from class I molecules reflects a more open structure at both ends of the peptide-binding groove (Stern *et al*. 1994). Each a-chain is approximately 34 kDa and each b-chain approximately 29 kDa. Polymorphism of the various class II HLA molecules is contributed by both the a- and b-chains of DQ and DP, whereas the DR a-chain is non-polymorphic, and allelic variation is entirely confined to the DR b-chains, encoded at several distinct loci (Bell *et al*. 1989). In addition to the DRB1 locus on all haplotypes, there are supertypic specificities on many haplotypes (DR52 encoded at the DRB3 locus on DR3, -5, and -6 haplotypes; DR53 encoded at the DRB4 locus on DR4, -7, and -9 haplotypes; and DR51 encoded at the DRB5 locus on DR2 haplotypes). The DR and DQ loci exhibit extreme linkage disequilibrium but there is weaker linkage between DQ and DP. Consequently, particular DQ alleles are almost invariably associated with certain DR alleles within ethnic groups, although there may be differences in these linkage units between different races.

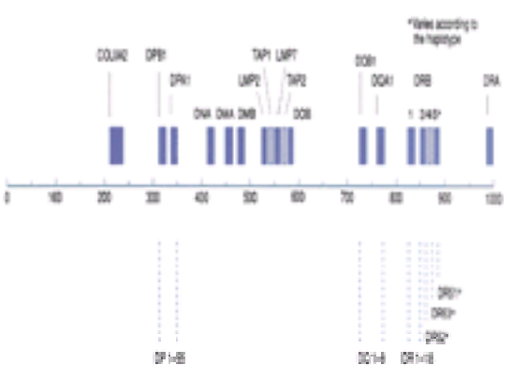

Fig. 5 The *HLA* class II region spanning approximately 800 kb which include several HLA loci as well as other loci encoding components of protesomes (LMP7, LMP2) and membrane transporters (TAP1, TAP2).

Class III region

This region, lying between the class I and class II region, encodes a number of the components of the classical complement cascade, including C2 and C4, as well as properdin factor B (Bf) of the alternate pathway. These genes are also polymorphic and may play important parts in immunological reactions during the host response, for instance in the clearance of immune complexes and pathogens. In addition, a number of other genes are found in this region, including those for 21-hydroxylase, the hsp70 heat-shock protein, and the genes encoding the cytokines tumour necrosis factor-a and -b (Spies *et al*. 1986; Sargent *et al*. 1989a). Since tumour necrosis factors are important cytokines involved in inflammatory processes (including the synovium in inflammatory arthritis), allelic variations of these genes may be involved in the predisposition to the autoimmune disease. Each of these exist as twin loci, not all of which are functional, highlighting the frequency of the gene duplication events that have given rise to many homologous loci throughout the MHC.

Definition of polymorphism of HLA molecules

Classically, serological reagents have been used to determine both HLA class I and class II specificities, either by the use of alloantisera or monoclonal antibodies raised against antigenic determinants on these molecules. Some of these may be 'public' specificities shared by a related series of molecules, while others may be more specific or 'private'. Biochemical methods have also been used to refine these definitions, but techniques such as two-dimensional gel electrophoresis or isoelectric focusing are too laborious for routine use. Initially, the mixed lymphocyte reaction has been used to refine HLA class II specificities in combination with homozygous-typing cell lines. Although this method consistently allows greater definition than do serological methods, it is also too labour intensive for routine use. In recent years direct analysis of the genomic DNA has provided a number of methods of typing for class II, and more recently class I alleles. The first of these involves analysis of the restriction fragment length polymorphisms associated with particular HLA types (Bell *et al*. 1987; MacMurray *et al*. 1987). A second method, based on nucleotide sequence analysis using sequence-specific oligonucleotides to probe HLA genes amplified to high copy number by the polymerase chain reaction, is both robust and highly sensitive and allowed a plethora of new alleles to be described (Vaughan *et al*. 1990; Wordsworth *et al*. 1990; Hill *et al*. 1991). A similar approach, also using the polymerase chain reaction, uses series of sequence-specific primers to determine the HLA class II genotype (Olerup and Zetterquist 1992).

HLA polymorphism in relation to disease

There is evidence of strong selection pressure for the maintenance of polymorphism within HLA class I and class II loci as a result of environmental factors. For example, a common class I allele in the Gambia (HLA-B53) is protective against the development of cerebral malaria. Similarly, a particular class II haplotype (DR13) protects those with malaria from severe anaemia (Hill 1991). A similar pattern is found in leprosy, in which the DR3 haplotype is associated with a strong cell-mediated response to *Mycobacterium leprae* characteristic of the tuberculoid form of this disease (Serjeantson 1983). Whether the existence of certain extended HLA haplotypes within some populations, such as A1, B8, DR3, DQ2 in north-west Europeans, can be explained in terms of protection against particular pathogens remains conjectural.

Recently described genes within the MHC

There are probably more than 120 genes within this region of the genome, most of which have not yet been characterized fully and some of which undoubtedly have important immunological functions (Sargent *et al*. 1989b). In particular, the region between the DQ and DP loci in the class II region contains further a and b class II genes (DM, DN, and DO loci) (Fig. 5). Other genes of interest in this region are those encoding for proteins involved in the class I MHC antigen-processing pathway. TAP1 and TAP2 (transporter associated with antigen processing) gene products transport peptides destined for presentation by class I molecules into the lumen of the endoplasmic reticulum. LMP2 and LMP7 (large multifunctional protease/low molecular mass polypeptide) genes encode components of a proteolytic enzyme complex known as a protesome, involved in processing complex antigens into peptides suitable for presentation by class I molecules (Monaco 1992). Since these genes are polymorphic (especially TAP2) they could contribute to disease susceptibility, although no such association has been proven to date (Monaco 1992; Trowsdale and Campbell 1992). Intriguingly, some defective antigen processing and presentation by HLA class I molecules map to the HLA class II region (see below).

Pulsed-field gel electrophoresis of the MHC has enabled a partial physical map of the region to be established. Physical mapping of the class II region has revealed that different haplotypes show variations in size. For instance, DR4 haplotypes contain an insertion of 110 kb of DNA between DR and DQ relative to most other haplotypes, while DR2 has a similar insert of 30 kb (Hardy *et al*. 1986). As both these haplotypes have been implicated in autoimmune diseases (rheumatoid arthritis with DR4 and multiple sclerosis with DR2), these inserts could be important if they contain expressed genes relevant to the disease susceptibility.

Recognition of antigens by the immune system

The mechanisms by which foreign and self antigens are recognized differ fundamentally between T and B lymphocytes. B cells carry surface immunoglobulin receptors capable of binding hydrophilic determinants on the surface of intact complex antigens. Binding of an antigen to this receptor may in principle lead to activation of the B cell and its differentiation to an antibody-producing plasma cell if the appropriate signals, such as interleukin 2, are also received from helper T lymphocytes. In contrast, T lymphocytes recognize antigenic determinants in the form of small peptides derived from more complex antigens. These peptides are typically processed fragments, which may come from parts of the intact antigen not normally exposed to immune surveillance by B cells. As these peptides are not necessarily on the surface of the molecule they may be hydrophilic or hydrophobic. The mounting of a primary antibody response is dependent on two separate systems of antigen recognition and, therefore, the chance of unwanted autoreactive antibody formation is minimized. However, it is not too difficult to envisage mechanisms by which this system could break down leading to the generation of humorally mediated autoimmunity (Fig. 6).

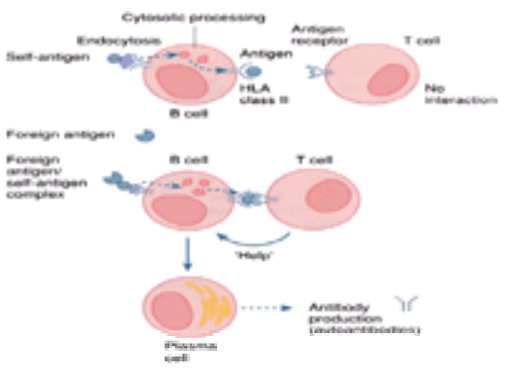

Fig. 6 One mechanism by which self-reactive antibodies might be presented. A self-antigen interacts with the surface immunoglobulin receptor of a B cell (top); as it does not receive T-cell help, it does not produce antibodies since the T-cell antigen receptor will not recognize self-antigens. However, if the self-antigen is complexed to a foreign antigen, as could happen with immunoglobulin bound to a foreign antigen, peptides from the latter could be expressed with HLA class II molecules in the B cell and elicit the necessary T-cell help to produce autoantibodies.

Processing and presentation of antigens to T lymphocytes

Antigenic peptides become associated with HLA class I and class II molecules before their presentation to lymphocytes, but the mechanisms involved are dependent on the nature of the antigen, the type of T cell involved, and the nature of the accessory molecules present on the cell surface (CD4 or CD8). Cytotoxic T lymphocytes (CD8+) generally interact with endogenously sythesized antigens bound to class I molecules. This system, common to all nucleated cells, is therefore particularly important in the immune surveillance of tumours and virus-infected cells. In contrast, helper T lymphocytes (CD4+) most commonly interact with antigens associated with HLA class II molecules, cell surface expression of which is restricted to specialized antigen-preserving cells (dendritic cells, macrophages, and B lymphocytes). However, in disease states, class II expression may be induced by the action of cytokines, such as g-interferon, on cell types including endothelium and fibroblasts that do not normally express these molecules. This may have implications for the pathogenesis of autoimmunity if it leads to the aberrant presentation of autoantigens in these tissues (Bottazzo *et al*. 1983). The processes of class I- and class II-mediated antigen presentation are not completely mutually exclusive; exogenous antigen may be presented by class I molecules, endogenous antigens by class II molecules, and some CD4+ cells are cytotoxic.

A consensus of the likely physiological process by which antigens and HLA molecules reach the cell surface has been derived from the study of certain mutant mouse and human cell lines (Monaco 1992; Neefjes *et al*. 1992). The presentation of antigens by HLA class I molecules requires the association of peptide with nascent class I heavy chains and b_2-microglobulin in the endoplasmic reticulum, and subsequent transport of the mature complex to the cell surface where it is exposed to T-cell surveillance. The peptide antigen itself is probably important in stabilizing with class I molecules. These peptide fragments may be available in the endoplasmic reticulum from *de novo* translation or else they may originate from the breakdown of proteins in the cytosol by proteases (Fig. 7). However, as these fragments lack hydrophobic leader-peptide sequences, they require active transmembrance transport into the endoplasmic reticulum if they are to associate with class I molecules.

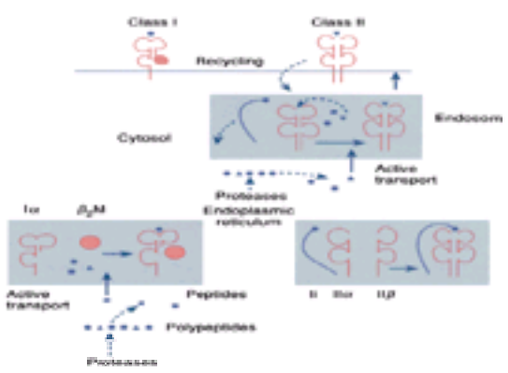

Fig. 7 Class I and class II pathways of antigen processing and presentation. The newly translated class I heavy chain (I) associated with b_2-microglobulin (b_2-m) and peptide in the endoplasmic reticulum. Peptides cannot associate with the class II molecules until the invariant chain (Ii) has been cleaved in the endosome. Active

transport of peptides from the cytosol occurs into both the endoplasmic reticulum and endosomes, and class II molecules may be recycled.

HLA class II molecules do not normally associate with endogenously synthesized peptides in the endoplasic reticulum but rather with a non-polymorphic protein known as invariant chain. This is thought to have both a signalling function, in directing the next stages of class II transport, and also to prevent endogenous peptides from binding to the class II peptide-binding groove. The invariant chain is removed by chemical cleavage in the post-Golgi system and replaced with peptide derived from endocytosed antigen that has been processed in the endosome. These complex processes involve multiple proteins, defects in any of which could potentially lead to defective antigen presentation and consequently to disease. Intriguingly, the TAP and LMP genes, whose products are involved in the class I processing pathway, are encoded within the MHC class II region (see above).

T-cell antigen receptor

The antigen receptor of circulating T lymphocytes consists of two immunoglobulin-like glycoproteins that associate as heterodimers on the cell surface in conjunction with five other invariant molecules referred to as the CD3 complex (reviewed by Moss *et al*. 1991). The cell surface heterodimers are of two major types, an a/b pair or a g/d pair. Each of these four chains is encoded as an immunoglobulin-like complex in the genome, with variable (V) diversity (D) joining (J) and constant (C) region elements which undergo germ-line rearrangement and, in association with N-region diversity, generate the extreme variation that is necessary to provide the range of antigen-presenting molecules on the T-cell surface. In peripheral blood the a/b T-cell receptor heterodimer is present on more than 95 per cent of circulating T cells. The rarer population of g/d T-cell receptors may also be involved in antigen-specific recognition, although their role is considerably less clear. They are commonly found in epithelial tissues and may have a 'sentinel' function. Recent evidence suggests that they may not require their ligand to be presented by MHC molecules and in this sense may have more in common with immunoglobulins (Davis and Chien 1995). The CD3 molecules are essential for the expression of the T-cell receptor heterodimer on the cell surface. They are also involved in transduction of signals to the T cell after the receptor interacts with peptide and MHC.

T-cell receptor genes

Germ-line organization of T-cell a, b, g, and d loci is similar to that of the immunoglobulin genes with a large number of gene segments comprising V, D, J, and C elements, which recombine resulting in a single VDJC transcript. Initial events result in the rearrangement of V, D, and J elements to produce a single exon. This exon and the exon encoding the C region are spliced together at the level of mRNA. A large number of individual V, D, and J elements for each of the major regions results in a very large amount of diversity in potential combinations. This diversity can be extended further by the use of N-region addition of nucleotides into the V, D, J and the JC junctions. In a, b, g, and d heterodimers there may be as many as 10^{15} possible combinations utilizing all the elements involved in the make-up of the receptor. There is no evidence that somatic hypermutation, as seen in immunoglobulin, occurs in these genes.

The V regions provide much of the diversity seen in a- and b-chains. Thirty-three distinct families exist for the a-chain and 25 for the b-chain. Each of these families may be subdivided further into subfamilies, representing both duplicated loci and allelic variation at the same locus. There are thought be 51 Vb (**TCRBV**) gene loci on chromosome 7, as well as a non-functional cluster on chromosome 9 (Robinson *et al*. 1993). There may be more than 100 different Va (**TCRAV**) chains in man. The g-chain has fewer V segments (14), although 4 are pseudogenes, and two clusters of J-C regions.

The d-chain lies within the a-chain complex and hence some V regions are utilized both by a- and d-chains. Multiple D elements can be used in a single transcript and extensive N-region diversity is seen in transcripts, considerably increasing the combinational diversity.

T-cell receptor repertoire

As T cells mature in the thymus, they undergo both positive and negative selection. As many as 95 per cent of T cells are deleted in the thymus, eliminating large populations of self-reactive receptors. In addition, particular receptors are positively selected in the thymus and directed to the periphery. MHC molecules are intimately involved in this positive and negative selection, and it forms one major mechanism of T-cell tolerance (Kappler and Roehm 1987). In the mouse, there is evidence of retrovirus-mediated negative selection of T-cell receptor TCRBV elements occurring intrathymically. This accounts for the profound effect on T-cell repertoire of the minor lymphocyte stimulating (**MLS**) antigen (see below). To date no equivalent process is recognized to exist in man. However, considerable diversity exists for both TCRAV and TCRBV usage in man. It is likely that both genetic (e.g. HLA type) and environmental factors contribute to this.

Allelic variation in the T-cell receptor

Despite the large range of allelic polymorphism in MHC molecules, less allelic variation has been documented in the V regions of the T-cell receptor. In part, this may be due to the difficulty in correlating polymorphism found in sequencing studies back to a single locus where multiple alleles may occur. In the absence of this formal genetic mapping, most sequence variation has been defined as a subfamily and more comprehensive studies are needed to define the extent of allelic variation. Several studies have suggested that susceptibility to some autoimmune disorders (e.g. multiple sclerosis) may be correlated with restriction fragment length polymorphisms within the germ line of the T-cell receptor complex (Oksenberg *et al*. 1989; Seboun *et al*. 1989). Major deletion/insertion polymorphisms within the TCRBV gene complex have also been described (Zhao *et al*. 1994). If this is true, allelic polymorphism may well have a role in determining an individual's susceptibility to autoimmunity (see below), and also may be important in dictating an immune response.

T-cell receptor/MHC interaction—a classical antigen recognition

Major interaction between the T-cell receptor and the MHC involves the recognition of polymorphic MHC determinants and peptides bound in the antigen-binding groove of MHC molecules by the T-cell heterodimer. Models for this classical interaction indicate that complementary-determining regions 1 and 2 of the T-cell receptor interact with the a-helices of the MHC molecule, while the highly polymorphic VDJ junctional regions interact with bound peptide (Davis and Bjorkman 1988; Stern *et al*. 1994). This is consistent with the extensive variation predicted from multiple peptides bound within a single antigen-binding site and relatively limited diversity seen within the a-helices.

Individual peptide–MHC combinations may be recognized by T-cell receptors that differ only slightly in their antigen-binding domains. This conservation of sequence suggests that genetically driven differences in T-cell repertoire may be important in determining susceptibility to autoimmune disorders where a single peptide antigen and major MHC restriction element are involved in the initiating stages.

A second form of interaction between T-cell receptor and MHC involves a class of molecules referred to as superantigens, which are encoded by either bacterial or viral pathogens and bind directly to V-region determinant and MHC elements. When expressed endogenously in the mouse by endogenous retroviruses (e.g. mouse mammary tumour virus) these MLS antigens can lead to the deletion of populations of T cells bearing particular receptor TCRVb chains (Dyson *et al*. 1991; Marrack *et al*. 1991). Similar molecules may also be expressed by environmental pathogens: the most common example of such exogenous superantigens are the b bacterial exotoxins such as staphylococcal enterotoxin and toxic shock syndrome toxin 1. These toxins can lead to the proliferation and activation of specific T-cell populations, events that may ultimately be responsible for some of the clinical features seen in these diseases.

T-cell receptor contributions to rheumatic disease

Differences between individuals in the receptor repertoire of T cells in peripheral blood may influence susceptibility to autoimmunity (see Chapter 3.1). This variation could be generated in two ways; first, as a result of germ-line polymorphism; second, as a consequence of selection processes dependent on the MHC in the thymus.

Polymorphism may exist at the level of germ-line sequences within T-cell receptor complexes. Of interest, one such polymorphism maps to the putative superantigen-binding site at residue 71 of the TCRVb chain. However, some evidence does exist from genetic studies that variation either within coding sequences or regulatory sequences may be present in T-cell receptor genomic DNA, and further, that these may contribute to particular autoimmune diseases, such as diabetes and multiple sclerosis. Studies of germ-line T-cell receptor polymorphisms in rheumatoid arthritis have produced interesting but as yet uncertain results (Funkhauser *et al*. 1992; McDermott *et al*. 1995).

The functional unit of the T-cell receptor on the cell surface has undergone extensive selection and modification during development in the thymus. This repertoire selection is both negative and positive in nature, and is in part determined by MHC products expressed within the thymus. The peripheral T-cell repertoire is more similar in identical twins than in unrelated individuals, suggesting that these variations may be one mechanism by which immune-response gene phenomena are determined (Loveridge *et al*. 1991). Analysis of the T-cell receptor repertoire in man has been possible only recently with the development of antibodies and polymerase chain reaction primers specific to individual V regions. Characterization of the repertoire in disease states has lagged even further behind. However, several studies have hinted that in autoimmune diseases, the lymphocytes infiltrating sites of tissue damage may show a biased T-cell receptor representation. This has been described in multiple sclerosis (Oksenberg *et al*. 1993) and also rheumatoid synovium (Howell *et al*. 1991; Paliard 1991). These studies all have methodological problems that make true quantification of V-region frequencies difficult, and hence their results can only be considered, at this time, speculative. In particular, the TCRBV14 predominance reported in rheumatoid joints has not been reproducible in other laboratories (Lunardi *et al*. 1992; Jenkins *et al*. 1993). For a detailed summary of the reported literature on T-cell receptors in rheumatoid arthritis to date see Struyk *et al*. (1995).

Expansion of discrete T-cell populations by superantigens

One appealing hypothesis has evolved that would help to explain the very strong associations between the presence of particular pathogens (e.g. salmonella, chlamydia) and HLA B27 in reactive arthritis. Putative superantigens from these organisms could in theory cause expansion of a particular population of T cells with the potential for autoreactivity. To date these organisms are not actually known to produce superantigens, but by inference from other bacteria and viruses, it seems quite likely that they may do so. Such expanded T-cell populations may be a subgroup with the potential to react with specific self-antigens, or alternatively, the superantigens may themselves alter the state of anergy of circulating T cells. Because of the established role of infectious pathogens in reactive arthritis, variations of repertoire may prove to be critically important in susceptibility. To date, little is known about the exact nature and alterations in peripheral T-cell repertoire to determine whether less variations might be important in dictating susceptibility to a range of inflammatory arthritides. It is likely, however, because of their critical role in the initial events in an antigen-driven immune response and because of their likely individual variation that important revelations may be forthcoming on the role of specific sequences in the initiation of the autoimmune process. Because of the interaction of the receptor with the peptide–MHC complex, such sequence conservation may be difficult to identify as it lies within the complementary-determining region 3 of the receptor. It is unlikely that V region-specific differences alone could account for the initiating events in disease and at present there is no evidence that the large V-region deletions mediated by endogenous superantigens in the mouse are present within the human. Identification of such effects may be difficult.

Both class I and class II MHC molecules have been implicated in susceptibility to certain rheumatic diseases. Characterization of the residues around the antigen-binding site suggests that the ability of individual MHC molecules to bind peptide may be central to the mechanism of susceptibility to these disorders. The following examples of MHC contributions to rheumatic disease share many similarities, but also indicate the complexities involved in assessing HLA-linked susceptibility. Not only may the primary susceptibility map either to the HLA class I or class II regions, but there may also be either primary or secondary effects arising from other loci that can influence susceptibility or the severity of these conditions.

HLA-B27 and the spondylarthritides

The spondylarthritides are characterized to varying degrees by inflammation of the spine and peripheral joints. They range from ankylosing spondylitis through the arthropathies associated with psoriasis and inflammatory bowel disease to Reiter's syndrome, in which there is clear evidence of an infective trigger. All of these conditions share similar patterns of joint involvement, are strongly associated with HLA-B27, and show at least circumstantial evidence of trigging by bacterial antigens.

Not only was the association between ankylosing spondylitis and HLA-B27 the first HLA association to be defined, but it remains to this day the strongest evidence linking susceptibility to a rheumatic disease with genes in the MHC. As at least 90 per cent of individuals with this condition are HLA-B27 positive, compared with only 7 per cent of the general population of the United Kingdom, the relative risk attributable to this antigen is approximately 120.

It is now known that there are at least 10 *HLA-B27* alleles, each differing by a limited number of amino acids around the antigen binding-site (Lopez de Castro 1995). Although the majority of these are associated with ankylosing spondylitis there is some evidence that HLA- *B*2703* in the Gambia and *HLA-B*2706* in Thailand may not be (reviewed in Khan 1995). In the United Kingdom both *HLA-B*2705* and *B*2702* are positively associated and in addition the class I allele *B*60* increases the risk threefold of ankylosing spondylitis in both B27-positive and B27-negative individuals (Brown *et al*. 1996).

Ankylosing spondylitis represents the tip of a clinical iceberg of spondylarthritides in which there are common clinical and histopathological features. Familial aggregation of these conditions is relatively common but does not necessarily breed true (i.e. some individuals in the family have ankylosing spondylitis while others have psoriasis or reactive arthritis). This can be explained by the association of each of these conditions with HLA-B27, although the strength of this association is variable. For example, HLA-B27 is only associated with those forms of enteropathic arthropathy in which sacroiliitis occurs, and even then only 50 per cent of the time, compared with over 90 per cent in ankylosing spondylitis. As triggering agents can be identified in a proportion (reactive arthritis following *Chlamydia trachomatis* infection of the genital tract or *Shigella flexneri* infection of the bowel), it is reasonable to infer that the arthropathy represents an unusual host immunological response to bacterial infection. Several ideas have been proposed to account for these observations (McMichael and Bell 1991), three of which are described below.

Linked gene

By this proposal, HLA-B27 itself is not directly involved in the disease process but is merely a marker for another closely linked gene. This could explain why the association with HLA-B27 is not absolute and why the association varies to some extent between racial groups. In some populations, such as black Africans, in which the frequency of HLA-B27 is very low (less than 1 per cent), the prevalence of ankylosing spondylitis is also low. However, the affected patients tend to be negative for HLA-B27.

There are, however, at least three major arguments against the linked gene hypothesis. First, the observation that the prevalence of the disease throughout the world generally mirrors the individual population frequencies of HLA-B27 suggests that HLA-B27 itself is involved directly. Second, the lack of families in which the disease can be seen cosegregating with a particular haplotype that is not HLA-B27 constitutes important evidence against the linked gene hypothesis. Third, additional evidence comes from the study of *HLA-B27*-transgenic rats. These animals spontaneously develop severe arthritis as well as other features sometimes associated with human spondylarthropathies, such as aortitis, uveitis, and psoriasis. The development of arthritis appears partly related to the number of copies of the *HLA-B27* gene incorporated into the genome of the transgenic animals (Hammer *et al*. 1990). In stark contrast, control animals transfected with *HLA-A2* do not develop arthritis, but the transgenic controls, for example with *HLA-A2*, are not perfect. Interestingly in this model, *HLA-B27*-transgenic rats reared in a germ-free state do not develop gut or joint abnormalities (Taurog *et al*. 1994), suggesting the involvement of both genetic (*HLA-B27*) and environmental factors, which may be of relevance to human ankylosing spondylitis.

Molecular mimicry

This theory gained considerable popularity in the late 1970s when it was demonstrated that antibodies raised against certain Gram-negative bacteria (*Klebsiella aeruginosa*) cross-reacted with HLA-B27-positive lymphocytes. Subsequently, faecal carriage of Klebsiella was shown in some studies, but not others, to relate to flares of the disease, in particular iridocyclitis and symptoms in peripheral joints. Circumstantial evidence to support this contention also came from the observation that serum IgA levels were elevated in active ankylosing spondylitis, indicating a mucosal response to bowel infection. More recently a molecular explanation for such a cross-reactive immune response has been suggested: an amino acid sequence from nitrogenase of *K. aeruginosa* shows marked homology with part of the HLA-B*2705 molecule, the most common variant of HLA-B27 in Caucasoids (Schwimmbeck *et al*. 1987). An epitope such as this could be the target for both pathogen and self-directed immune responses. Indeed, most of the amino acid substitutions corresponding to the HLA-B27 subtypes are clustered between positions 74 to 81 in the a-domain of the HLA heavy chain, precisely the region of proposed homology with Klebsiella nitrogenase.

The lesson from the reactive arthropathies is quite clearly that such organisms play a central part. Several reports have suggested the presence of bacterial antigens within the synovium of patients with both the postvenereal and postenteric form of reactive arthritis, although there is no evidence of the presence of intact, viable organisms within these joints (Howell *et al*. 1991; Hughes *et al*. 1991; Virtanen *et al*. 1991). Sensitization of the immune system to bacterial-derived antigens could in theory occur either within the joints or at a site distant from them, with subsequent traffic of activated T cells to the synovium. However, the precise mechanisms involved remain to be clarified.

Arthritogenic peptides

Arthritis can be induced in animals by a variety of materials under different sites of administration and adjuncts. Furthermore, adoptive transfer experiments have demonstrated that the disease can be transferred to other animals by T cells reactive to components of the inoculum (reviewed by van Eden 1991). Thus in adjutant arthritis, T cells recognizing the mycobacterial heat-shock protein hsp65 can pass on the disease to other animals not previously immunized. As heat-shock proteins are highly conserved between species and widely expressed in the tissue, cross-reactive immune responses could be responsible.

An immune response initially generated against a foreign immunogen may under certain circumstances by redirected against host self-antigens. For example, transgenic mice expressing the lymphocytic choriomeningitis virus (**LCV**) glycoprotein within the pancreas can develop diabetes mellitus in this way. The mice remain healthy until infected in later life by the LCV, whereupon an immune response directed against transgenic 'self' LCV glycoprotein in the pancreas leads to the development of tissue destruction and diabetes (Ohashi 1991).

Because it is now known that antigens are presented to the immune system in the form of short peptide fragments, it may be more appropriate to think in terms of 'arthritogenic peptides' as the triggering agents of these arthropathies rather than complex antigens or intact organisms. In animal models of immune-mediated disease, such as experimental autoimmune encephalomyelitis and collagen-induced arthritis, this approach has been extended to the investigation of the T-cell receptor usage in animals with these conditions. Thus TCRBV8 is commonly used by clones from defined mice strains with experimental autoimmune encephalomyelitis responding to particular myelin peptides (Urban *et al*. 1988) and anti-TCRVb8 and anti-TCRVb5 antibodies can ameliorate the disease in mice with collagen-induced arthritis (Chiocchia *et al*. 1991). Particular peptides may be common to a large number of different organisms and this could explain the wide variety of organisms that have been incriminated in the spondylarthritides. Although this type of response could account for some types of autoimmunity, it has not been described to date in man.

Definition of the genetic component of susceptibility to rheumatoid arthritis mapping to the MHC

Studies of identical and non-identical twins indicate that both genetic and non-genetic factors are involved in rheumatoid arthritis. At least 70 per cent of the identical twins of probands with rheumatoid arthritis do not develop the disease, clearly implicating non-genetic factors. However, concordance rates amongst non-identical twins (4 to 6 per cent) are approximately four to five times lower than for identical twins (15 to 30 per cent) (Lawrence 1970; Silman *et al*. 1993), from which a significant genetic contribution can also be inferred.

Most interest in the genetic contribution to rheumatoid arthritis has so far centred on the MHC. Studies of HLA haplotype sharing among affected siblings in families shows a significant trend for the sharing of at least one HLA haplotype by the affected siblings (Table 1). This observation links a gene (or genes) within the MHC to the development of rheumatoid arthritis (Payami *et al*. 1986). Further strong evidence of the importance of genes in this region comes from the study of outbred populations. Numerous studies in many racial groups have revealed associations with the HLA class II antigens DR4 (Wordsworth and Bell 1992). Furthermore, in some of these studies a weaker association with HLA-DR1 is evident, while in others there may be an association with HLA-DR1 or -DR10 (reviewed in Wordsworth *et al*. 1991). These data clearly implicate genes towards the centromeric end of the MHC in susceptibility to rheumatoid arthritis. However, they do not necessarily indicate a primary role for HLA-DR4 or -DR1 because these could equally well be genetic markers for another linked gene involved in the process of susceptibility.

	Shared haplotypes		
	2	1	0
Observed	112	147	52
Expected	78	156	78

Sharing ⩾ one haplotype χ^2=6.08; p<0.02.
The expected values are based on the prediction that 25 per cent would share two haplotypes, 50 per cent would share one, and 25 per cent would share no haplotypes. There is significant distortion of haplotypes shared by affected siblings, indicating that gene(s) within the MHC must be involved.

Table 1 Sharing of HLA haplotypes, identical by descent, between sibling pairs both of whom are affected by rheumatoid arthritis

Fine mapping of the precise susceptibility locus within the class II region has been achieved by the study of naturally occurring mutants that have given rise to a series of subtypes of HLA-DR, each producing a different predisposition to rheumatoid arthritis. Although the majority of HLA-DR specificities can be separated fairly easily on the basis of their associated DNA restriction fragment length polymorphisms, this is not true for the subtypes of HLA-DR4 (Nichlas *et al*. 1985). The sequence changes responsible for the different (formerly Dw-) subtypes of HLA-DR4 are restricted entirely to a few amino acids in the third allelic hypervariable region of the DR b-chain encoded at the DRB1 locus, which have probably arisen as a result of gene conversion events (Gregersen *et al*. 1986). In rheumatoid arthritis only subtypes *DRB1*0401* (Dw4), *DRB1*0404/8* (Dw14), and *DRB1*0405* (Dw15) are associated with predisposition to the disease, whereas *DRB1*0402* (Dw10) and *DRB1*0403/7* (Dw13) are not (Wordsworth *et al*. 1989; Gao *et al*. 1990; Nelson *et al*. 1991). The differential association of rheumatoid arthritis with particular subtypes of HLA-DR4 clearly pinpoints the DRB1 locus itself as the major determinant of susceptibility within the class II region, as the flanking DNA on all the DR4 haplotypes is the same.

Comparison of the amino acid sequences of the HLA-DR4 subtypes associated with rheumatoid arthritis and those unassociated with the disease reveals the presence of charged amino acids substitution within the third allelic hypervariable region of the DR b-chain (Table 2). These residues point into the antigen-binding site of the HLA-DR molecule (Fig. 8). They are therefore likely to have profound implications for peptide binding and interactions with T-cell receptors. Figure 9 shows an electron density of a peptide lying in the antigen-binding groove of an HLA-DR1 molecule (Brown *et al*. 1993). It is possible that the weaker associations between rheumatoid arthritis and HLA-DR1 and -DR10 may also be explicable on the basis of this third hypervariable region sequence. Both these molecules exhibit considerable similarities to the rheumatoid-associated HLA-DR4 subtypes, particularly in this region (Table 2).

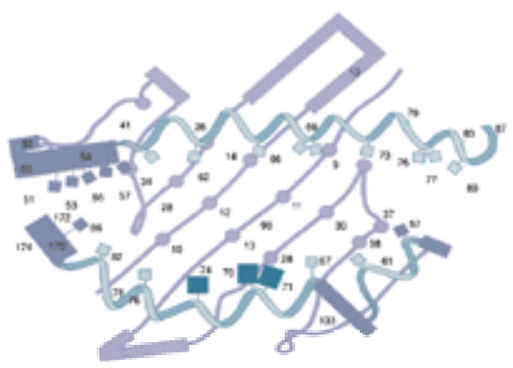

Fig. 8 Diagrammatic representation of the HLA-DR molecules, illustrating the binding site for antigens. Substitution of charged amino acids at positions pointing towards the binding site alter the susceptibility to rheumatoid arthritis. These positions (70, 71, 74) are shown as solid symbols on the DR b-chain a-helix. Relatively conservative substitutions at either end of the a-helix (positions 57, 86) do not affect susceptibility.

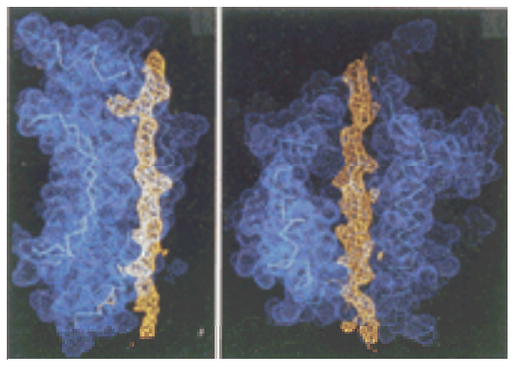

Fig. 9 Electron density map of a peptide lying within the antigen-binding groove of an HLA DR1 molecule (Brown *et al*. 1993).

Potential role of other MHC genes in autoimmune disorders

In many other HLA-associated autoimmune diseases there is evidence of a heterozygote effect or an additive effect from other HLA genes. Examples of these effects can be seen in insulin-dependent diabetes mellitus and coeliac disease. In the former, both HLA-DR3 and -DR4 are positively associated with susceptibility to diabetes but the DR3, DR4 heterozygote state greatly enhances this risk (Thomson 1988).

In northern Europeans, coeliac disease is typically associated with the extended HLA haplotype A1, B8, DR3, DQ2, but in some southern European populations an association with DR5/DR7 heterozygotes has been observed (Sollid *et al*. 1989). This observation has been interpreted as indicting that the primary restriction element in coeliac disease is DQ2, as the same DQ a-chain (*DQA1*0501*) and DQ b-chain (*DQB1*0201*) combinations can occur in both these situations (Fig. 10). In addition there appears to be a further effect in coeliac disease arising from another locus on the extended DR3 haplotype. Although DR3 and DQ2 occur on both the B8, DR3, DQ2 and B18, DR3, DQ2 extended haplotypes in the normal population of the United Kingdom, only the B8, DR3, DQ2 haplotype is found in patients with coeliac disease (Table 3). Therefore another gene in this haplotype must also be involved in determining susceptibility to this disease, although its identity is currently unknown (Rosenberg *et al*. 1989).

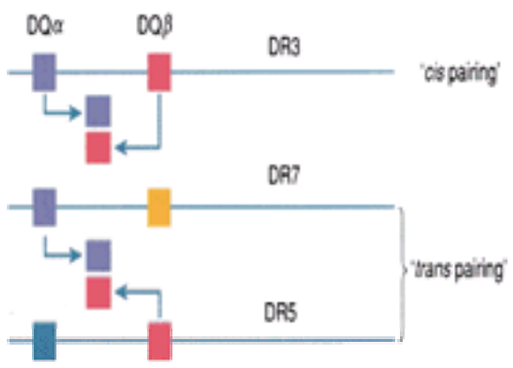

Fig. 10 The same DQ heterodimer may be assembled from the DQa and DQb paired in *cis* formation from a single DR3 haplotype or from the DQb of a DR7 haplotype paired in *trans* with the DQa from a DR5 haplotype.

	B8, DR3, DQ2	Non-B8, DR3, DQ2
DR3 coeliac patients (n=29)	29/29	0
DR3 healthy controls (n=23)	18/23	5/23

DR3-positive patients account for 90 per cent of all cases but DQ2 occurs in 95 per cent, pinpointing the latter as the primary susceptibility allele. However, a second locus on the B8, DR3, DQ2 extended haplotype must also be involved.

Table 3 The association of coeliac disease with an extended HLA-B8, DR3, DQ2 haplotype

Although rheumatoid arthritis is strongly associated with HLA-DR4, this is invariably linked to *DQB1*03* (both defined serologically) (Lanchbury *et al*. 1991). Several subtypes of *DQB1*03* have been defined, and it has been proposed that in rheumatoid arthritis, one of these subtypes, *DQB1*0301*, might predispose to more severe forms of the disease, such as Felty's syndrome. In this condition the association with HLA-DR4 is close to 95 per cent, and on these haplotypes there is an increase in the *DQB1*0301* subtype of *DQB1*03* at the expense of the *DQB1*0302* subtype. However, further analysis reveals that the primary association is with *DRB1*0401* (Lanchbury *et al*. 1991); the association with *DQB1*0301* is secondary, entirely explicable by the fact that *DRB1*0401* is more commonly linked to *DQB1*0301* than *DQB1*0302* (Table 4).

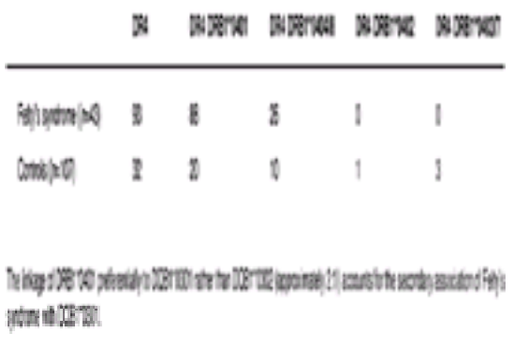

Table 4 The very strong association of DR4 and its Dw4 (*DRB1*0401*) subtype with susceptibility to Felty's syndrome

Nevertheless, in Felty's syndrome and seropositive erosive rheumatoid arthritis, there is evidence of more complex HLA-DR interactions. Several studies indicate that the HLA-DR association with rheumatoid arthritis is strongest with the most severe forms of the disease (Westedt *et al*. 1986). In the most severe forms of rheumatoid arthritis, HLA-DR4 homozygotes are also more common that would be expected by chance. Somewhat surprisingly, the majority of these DR4/DR4 homozygotes are actually *DRB1*0401/DRB1*0404/8* (Dw4/Dw14) compound heterozygotes (Table 5).

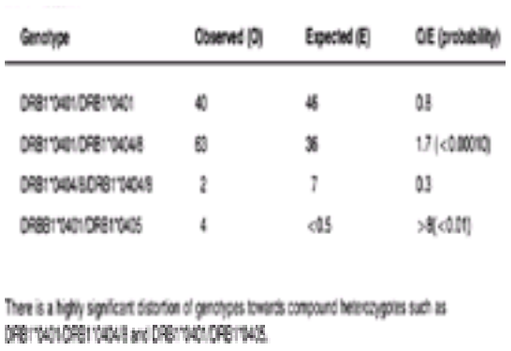

Table 5 A comparision of the subtype frequencies of HLA-DR4 in patients with severe rheumatoid arthritis or Felty's syndrome who are DR4/DR4 homozygotes

Overall these results can be interpreted in at least two ways. First there could be additional contributions from genes on particular HLA haplotypes carrying rheumatoid arthritis-associated HLA-DR alleles (particularly DR4 subtypes, DR1 and DR10). Second, these HLA-DR molecules themselves have the ability to bind and present a limited array of potentially arthritogenic peptides within the synovium to T cells. However, if this is the case, there is clearly potential synergy between these closely related alleles, in particular the compound heterozygotes, which needs further explanation. Perhaps these combinations allow more efficient binding and presentation of a range of peptides within the joint. Alternatively, the combination of two similar HLA-DR alleles may enhance the selection of a particular T-cell receptor repertoire during the thymic maturation of T lymphocytes (Wordsworth and Bell 1992).

Finally, other genes outside the MHC are undoubtedly important in determining susceptibility to rheumatoid arthritis. These could be interactive with HLA genes or provide independent susceptibility. An estimate of the importance of HLA genes in determining susceptibility can be gained from analysing haplotype sharing in sibling pairs both of whom are affected by rheumatoid arthritis. In a single-gene model of susceptibility, one would expect almost all affected siblings to share at least one HLA haplotype, but this is clearly not the case. Combined analysis of genes from over 300 families collected worldwide indicates that as many as 17 per cent of sibling pairs do not share HLA haplotypes (see Table 1). An estimate of the genetic contribution to rheumatoid arthritis arising from the MHC has been derived from a comparison of the recurrence risk in genetically identical monozygotic twins compared with HLA-identical siblings which suggests that no more than 30 per cent of the total is HLA linked (Deighton *et al*. 1989).

In insulin-dependent diabetes mellitus, another complex polygenic disorder, a genome-wide screen of a large number of families with affected sib pairs using 350 microsatellite marker loci has identified a number of susceptibility-associated loci outside the MHC (Davies *et al*. 1994). This approach is likely to yield similar findings in rheumatoid arthritis. A comprehensive understanding of the immunological responses underlying many of these disorders may require a fuller elucidation of these other genes involved in determining susceptibility.

3.4 Animal models of arthritis

W. B. van den Berg

Introduction

A major research goal in the field of arthritis is to unravel the pathogenesis of chronic arthritis and the concomitant joint destruction. A second, more practical goal, is to discover a treatment that selectively inhibits the progression of destructive arthritis yet leaves the host defence mechanisms virtually intact. This requires a critical understanding of the cells and mediators involved in the destruction and in the initiation, maintenance, and remission of the arthritic process. Studies in human arthritis are hampered by the fact that the precise time of onset is unknown, whereas lesional tissue is often obtained from endstage disease at the moment of joint replacement. The latter holds true in particular for cartilage specimens, since it is widely accepted that this tissue has a limited capacity for repair. In the past, synovial biopsies and synovial fluid were only taken from patients with an exacerbation of symptoms that necessitated arthroscopy or the withdrawal of an effusion, inherently representing extremes of the natural history of the disease. Moreover, specimens come from patients who have been receiving various drugs, and the shortage of control tissue is obvious. Numerous arthritis units have now started to run early arthritis clinics, in which early biopsies are taken more often and even the taking of small biopsies of articular cartilage surfaces from select areas have been considered. Another way to circumvent the problems is to resort to the use of experimental models of arthritis.

Although not ideal in the eyes of many in terms of precise mimicry of human arthritic disease, experimental models of arthritis do reflect key aspects of their human counterparts. Their time course, the easy access to tissue samples, and the facility for experimental therapeutic manipulation offer a useful approach to further understanding of the pathogenesis of arthritis. Models may also provide valuable insights into biological approaches to arthritis therapy, ranging from cytokines, cytokine inhibitors, and 'tolerizing' antigens to monoclonal antibodies against cellular receptors and vaccination directed against effector cells. Potential therapies need to be evaluated in the human diseases, indirectly approving the predictive value of findings in particular models. It is true that no single animal model of arthritis completely represents the human disease. In fact, the wide variety of agents that can induce an experimental arthritis with clinical and histopathological features close to those of the human arthritides supports the hypothesis that rheumatoid arthritis may have a variety of causes and that the characteristic features reflect common endpoints. Analysis of aspects peculiar to an individual model may be of limited value and the emphasis should be on general validity and common concepts in various models. In the following sections the models most widely used in the study of rheumatoid arthritis will be summarized and their value will be illustrated with some recent research findings. Since the questions to be answered in models must arise from elements of the human disease, current concepts will be briefly addressed first.

Concepts and features of rheumatoid arthritis

Rheumatoid arthritis is characterized by chronic inflammation in the joints and progressive destruction of bone and cartilage. Its pathogenesis is unknown, but the disease is often considered as an autoimmune process. The articular cartilage is an intriguing tissue, since it may function both as the trigger as well as the victim of this disease (van den Berg 1994). Two major events may underlie the chronic synovial inflammation: persistent stimulation of T cells by as yet unknown (auto-) antigens, or direct activation of the synovial cells by non-antigenic triggers. The latter may imply continuous stimulation by bacterial or viral triggers, but may also reflect deranged behaviour and tumour-like growth. Figure 1 depicts potential cascades in the synovial inflammation and concomitant cartilage destruction. It illustrates the various levels of potential therapeutic interference, ranging from antigen presentation to T cells, control by regulatory T cells, activation of synovial cells, and release of destructive mediators acting on the articular cartilage. It is, of course, attractive to target research in models at the level of the arthritogen, but, in the absence of an established antigen, to seek further understanding of effector mechanisms characteristic of joint inflammation and destruction seems at least as valuable. Recent research approaches in models are summarized in Table 1, which for obvious reasons cannot all be covered in detail. A recent overview by Wooley (1991) is recommended.

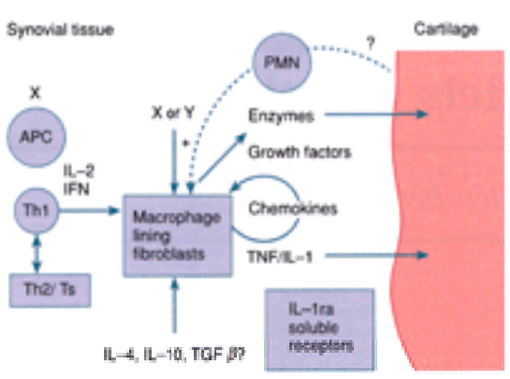

Fig. 1 Cytokine cascades in the arthritic joint.

Application of MHC blockade
Manipulation of defined T-cell subsets
Selective T-cell receptor usage/blockade
Potency/limits of T-cell vaccination
Regulatory role of heat-shock proteins
Control by bacterial flora
Preventive induction of tolerance
Immunomodulation in established arthritis?
Induction of bystander suppression
Neutralization of key cytokines
Up-regulation of cytokine inhibitors
Blockade of adhesion molecules
Identification of destructive cells/enzymes
Disease course in transgenic/knock-out mice

MHC, major histocompatibility complex.

Table 1 Recent approaches in arthritis models

Characteristic histopathological features in the rheumatoid arthritic joint include immune complexes in the articular cartilage layers and variable amounts of macrophages and T cells in the synovium, often accompanied by fibrosis and synovial hyperplasia. The antigens in the immune complexes in the cartilage are still poorly defined and, although candidates for a role in the synovitis, may even reflect an epiphenomenon of immune-complex deposition and retention in damaged areas. Considerable variation is found between patients and at various stages in one patient, making it difficult or even impossible to define critical correlations in animal models.

Models of arthritis

Historically, models of arthritis have been used to understand the stimuli provoking chronic arthritis and the mechanisms regulating chronicity and tissue destruction. When a model is established, the potential of a given stimulus is proven. The next step would be to obtain evidence that such reactions do occur in human arthritides, for instance T-cell reactivity against a cartilage antigen. If this is the case, it has still to be proved that this reactivity is of pathogenetic importance and not an epiphenomenon, for example by showing that antigen-specific immunomodulation really affects the course of the disease. Up to now such research has not yielded a clue about the definitive trigger of rheumatoid arthritis and continuing investigations can be divided into those that attempt further understanding of principles in established models and those that are still looking for new, putative triggers, and novel models and concepts.

In line with the historical concepts in rheumatoid arthritis the models most widely studied in the past decades are those of adjuvant arthritis, collagen-induced arthritis, antigen-induced arthritis, and streptococcal cell-wall arthritis. T cells play a dominant part in all of these models (Table 2). The second common principle is the presence of a chronic stimulus, either in the form of a persistent antigen or an autoantigen akin to joint structures. Persisting antigens are non-degradable bacterial cell walls in the synovial tissue, or antigen trapped in the collagenous reservoirs such as ligaments and articular cartilage (antigen-induced arthritis). Both conditions reflect escape from proper clearance by the phagocytic system. A second category of persistent stimuli is formed by autoantigens from the articular cartilage, such as collagen type II and proteoglycans. It cannot be excluded that other, yet unknown cartilage antigens may fulfil a similar role. In adjuvant and streptococcal cell-wall arthritides the cartilage could as well function as an autoantigen, related to structural mimicry between bacterial peptidoglycans and cartilage proteoglycans. However, ultimate proof that these cross-reactive responses really contribute to the arthritis has still to be provided. Of interest, destructive forms of rheumatoid arthritis tend to decline at the moment that the cartilage is fully destroyed. Moreover, total joint replacement often results in a complete remission of the arthritis in that particular joint, without the need for concomitant synovectomy. These are possible arguments for a direct role of cartilage antigens in the pathogenesis or an indirect role of cartilage components in the maintenance of the inflammatory process in the joint.

Model	Species	Immunization	Induction	Pers. Ag*	Auto Ag	T cells
Adjuvant arthritis	Rat	CFA		Bact?	?	+
Collagen-induced arthritis	Rat, mouse, primate	CII/CFA			Collagen II	+
Proteoglycan arthritis	BALB/c mouse	PG/CFA			Proteoglycan	+
Streptococcal cell-wall arthritis	Rat		i.p. SCW	SCW		+
Antigen-induced arthritis	Rabbit, rat, mouse	Ag/CFA	i.v. Ag	Antigen		+
CII-induced arthritis	Rat, mouse	CII			?	+
MRL/lpr/lpr	MRL mouse			Virus?		-

Ag, antigen; CFA, complete Freund's adjuvant; CII, collagen type II; PG, proteoglycan; SCW, streptococcal cell wall; i.p., intraperitoneal; i.v., intravenous.
*Relates to persistent antigen in the joints.

Table 2 Common models of arthritis

The third lesson from models is that microbial components, particularly cell-wall fragments from enteric organisms, are potential causative agents in humans. Apart from their ability to induce arthritis by direct localization to joint tissues, they may induce arthritis remotely as a result of molecular mimicry with joint structures. There is ample evidence from clinical observations that bacterial infections and development of arthritis may somehow be related.

It is almost a matter of choice whether persistent exogenous antigens or autoantigens should be considered as different entities or as reflecting integral parts of the body that need tight regulation of suppression and/or tolerance. Certainly, it is as yet unclear whether the regulation of these forms of immunity is the same.

In line with the increasing doubt in various research groups about the critical role of a T-cell-driven reaction to a defined (auto-) antigen, increasing attention is nowadays focused on less defined models, such as the spontaneous arthritis in MRL/lpr mice and the arthritis induced in susceptible strains with mineral oils. In addition, plain overexpression of cytokines [tumour necrosis factor (**TNF**)-a] or H_2-c-*fos* in transgenic animals provides further evidence that the expression of arthritis may occur in the absence of a clear involvement of T cells. In the following sections some of the commonly used models will be critically evaluated. Comparative information is given in Table 3 and Table 4. Technical details can be found in some overviews (Billingham 1983; Bliven and Otterness 1985; Greenwald and Diamond 1988; Hunneyball *et al*. 1989).

	AA	CIA	SCW-A	AIA
Main site of expression	Ankle	Peripheral	Ankle	Knee*
Bone marrow inflammation	++	-	+	-
Local plasma cells	-	±	-	++
Immune complexes in cartilage	-	++	-	++
Cartilage destruction	±	+++	+	++
Effect of NSAIDs†	+	++	+	-
Dominant feature	Periostitis	Destructive	Fibrosis	Destructive

*To be chosen by intra-articular injection; †effect on ongoing destruction.
AA, adjuvant arthritis; CIA, collagen-induced arthritis; SCW-A, streptococcal cell-wall arthritis; AIA, antigen-induced arthritis; NSAID, non-steroidal anti-inflammatory drug.

Table 3 Characteristic features of the arthritis models

Adjuvant arthritis
- Self-limiting arthritis
- Spontaneous tolerance
- Non-specific immunomodulation
- Dependence on bacterial flora

Collagen arthritis
- Self-limiting arthritis
- Genetic restriction
- Epitope-specific immunomodulation
- Sensitive to modulatory cytokines

Streptococcal arthritis
- Spontaneous resurrences
- Tumour-like synovial growth
- Cross-reactive flares*
- Dependence on bacterial flora

Antigen-induced arthritis
- Controlled onset, cartilage destruction
- Antigen retention in collagenous tissues
- Antigen-specific local hyperreactivity
- Chronicity by repeated flares

*Inducible in the unilateral model.

Table 4 Models used to study pathogenic mechanisms

Adjuvant arthritis

This is the first and most extensively studied model of polyarthritis, which was discovered some 40 years ago by Stoerk *et al*. (1954) as an experimental accident. Whilst trying to produce immunity to spleen extracts emulsified in Freund's adjuvant, an arthritis developed in the immunized rats. Pearson (1956) demonstrated that the arthritis was due simply to the bacterial component. The model has since been extensively used for the screening of drugs to be used in rheumatoid arthritis.

Nowadays the classical model is induced by intradermal injection of Freund's complete adjuvant containing heat-killed mycobacteria and the arthritis develops within 2 weeks in susceptible rat strains. In general, the model is induced in Lewis rats. The volume, type of oil, and composition of the suspension are critical variables that determine the incidence and severity of the arthritis. The active component in the bacteria is the cell-wall peptidoglycan and the disease can be induced with various bacteria.

The histopathological features of adjuvant arthritis mainly reflect a periarthritis, with marked periostitis instead of a synovitis, and massive inflammation in the bone marrow. Immune-complex deposition in the cartilage is not a characteristic feature and cartilage destruction is limited in the early disease (Fig. 2). The highly destructive attack on the cartilage seen in the autoimmune collagen type-II arthritis argues against cross-reactivity with cartilaginous autoantigens in adjuvant arthritis as the driving principle (van de Langerijt *et al*. 1994a).

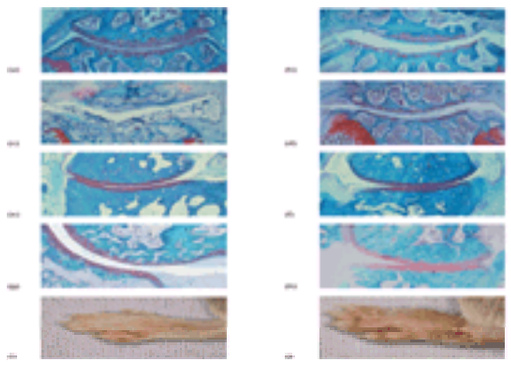

Fig. 2 Light-microscopic analysis of cartilage proteoglycan (PG) depletion in safranin O-stained knee (a–d) and ankle (e–h) joints. (a) Normal knee joint; (b) destructive collagen arthritis (CIA), day 14 after onset; (c) complete destruction in CIA, day 28; (d) antigen-induced arthritis, day 28, showing superficial loss of PG and bone erosion as well as outgrowth at the edges; (e) normal ankle; (f) adjuvant arthritis, day 17; (g) adjuvant arthritis, day 28; (h) streptococcal cell-wall, arthritis, day 17. Macroscopic appearance of collagen arthritis: (i) first onset in one toe; (j) full-blown expression.

Adjuvant arthritis is T-cell dependent and the strongest argument for an autoimmune process is the induction of arthritis by passive transfer of T cells from diseased animals. The joint inflammation may reflect the generation of a T-cell reaction to bacterial epitopes cross-reacting with endogenous bacterial fragments continuously present in synovial tissues or with cartilaginous antigens. It may also be based on non-specific immunomodulation, reflecting the adjuvant properties of the bacterium in oil preparations and the generation of a disregulated expression of autoimmunity to whatever autoimmune epitope is involved. The fact that non-antigenic adjuvants, such as the oil preparation avridin (CP 20961) and other mineral oils, can induce an arthritis indistinguishable from adjuvant arthritis may be in support of the latter hypothesis.

A bacterium-specific pathogenesis is likely since conventionally bred rats are generally resistant to adjuvant arthritis, whereas germ-free Fisher or Wistar rats are susceptible (van de Langerijt *et al*. 1994b). The germ-free rats are lacking early contact with bacteria and are therefore not 'tolerized'; colonization with bacteria before the induction of adjuvant arthritis prevented susceptibility (Kohashi *et al*. 1986). Susceptibility may also relate to an impaired steroid feedback response. Lewis rats are generally susceptible to numerous autoimmune processes and are low steroid responders to a large range of stimuli, whereas the non-susceptible Fisher rats are high responders. However, germ-free Fishers are also high steroid responders yet are susceptible to adjuvant arthritis, although the disease expression is less pronounced. This suggests that the regulation of the antibacterial T-cell responses is of prime importance and that steroid responsiveness of a rat strain or a particular individual is an element modulating the severity of the disease.

The most intriguing observation in the adjuvant arthritis model is the occurrence of spontaneous remission and the lack of susceptibility to reinduction. This resistance is antigen-specific. T-cell lines and clones were isolated that can induce disease, but when attenuated could also induce protective responses (Holoshitz *et al*. 1983). Attempts to repeat these studies were mainly unsuccessful, suggesting that the regulation is rather complex. Theoretically, it involves regulatory T cells that recognize antigen-specific receptors on the T cells driving the arthritis and are able to block the activity of those cells. The regulatory cells are not arthritogenic themselves. This principle, called T-cell vaccination, has raised a major interest in the further characterization of T-cell receptor usage in human arthritis, but so far this research has not yielded a defined receptor usage enabling therapeutic applications.

Treatment with antibodies against CD4, mainly present on T cells and macrophages, is of interest because, apart from the suppression of adjuvant arthritis, such treatment induced tolerance to the initiating arthritogen. Subsequently, it was found that rats undergoing anti-CD4 treatment before the induction of arthritis with either streptococci or non-antigenic adjuvants (mineral oils, CP20961) displayed a shared tolerance to the reinduction of both models, implying that there might be common bacterial epitopes in the regulation of adjuvant arthritides [for further details, see the review by Billingham (1994)].

The identification of epitopes on bacterial heat-shock proteins and the recognition of cross-reactive, highly conserved, endogenous heat-shock proteins in eukaryotes, has implicated these proteins as the target antigen in adjuvant arthritis (van Eden *et al*. 1989; van Eden 1991). However, subsequent research demonstrated a role for heat-shock proteins in other autoimmune models also, and a regulatory role in inflammation rather than as a critical antigen in arthritis seems more likely.

In industry, adjuvant arthritis is often the model of first choice for screening new therapeutic agents for anti-arthritic efficacy. This is mainly based on its ease of induction and the simple macroscopic observation of arthritis in the paws. The fact that non-steroidal anti-inflammatory drugs are effective inhibitors of cartilage and bone destruction in this model, in clear contrast to observations in human rheumatoid arthritis, puts some doubt on its applicability.

Collagen-induced arthritis

The model of collagen arthritis in rats was first described in 1977 by Trentham and colleagues, again as a coincidental finding in protocols to induce antibodies to purified collagen preparations (Trentham *et al*. 1977). The initial observation indicated that arthritis was confined to sensitization with native collagen type II, a major component of articular cartilage. Denatured collagen type II or other collagen types were not arthritogenic. Nowadays, data are accumulating that minor collagen types from articular cartilage may also function as arthritogens, for instance collagen type IX and XI (Holmdahl *et al*. 1993; Cremer *et al*. 1994).

The crucial element in the pathogenesis of this arthritis is the induction of immunity to foreign collagen type II, subsequently cross-reacting with homologous collagen type II. Plain immunization with homologous collagen type II can also be used, but then much stronger immunization regimens are needed to override natural tolerance. The disease can easily be induced in rats, with full-blown expression within 14 days, whereas expression in mice seems to follow tight genetic restriction (Wooley *et al*. 1981) Moreover, disease expression in mice is more gradual, starting after 3 to 4 weeks in some, whereas a 100 per cent incidence commonly takes 8 to 10 weeks. Of interest, collagen arthritis can also be induced in non-human primates. Most rhesus monkeys were susceptible (Bakker *et al*. 1991) and instead of the precipitation of a susceptibility gene, linkage studies on the major histocompatibility complex (**MHC**) revealed the presence of a gene regulating resistance.

Unlike adjuvant arthritis, collagen arthritis is not a systemic illness, but is localized to the peripheral joints and spares the spine. However, the ears may be affected, and this feature is mainly found at late stages in rats. This may suggest a role for this type of reactivity in polychondritis. In murine collagen-induced arthritis, marked disease was also found in knee joints, in addition to the paws, ankle, and wrist. Histopathology of collagen arthritis shows a distinct, acute synovitis with numerous

granulocytes, and bone erosions as well as periosteal new bone formation. Involvement of the bone marrow is limited. A characteristic feature is the direct attack by granulocytes at the cartilage surface. In contrast to findings in other models a complete loss of articular cartilage is often seen within 2 weeks (Fig. 2) and the arthritis results in ankylosis, with limited inflammation. The lack of sustaining antigen is probably the main reason for the remission of the arthritis. In addition, regulating T cells have been demonstrated in late-phase disease, which demonstrates that one should be careful with anti-T-cell therapy in human arthritis such treatment can either improve the condition or make it worse (Maeda *et al*. 1994).

The mechanism of collagen-induced arthritis is based on two principles: the presence of anticollagen antibodies and the generation of anticollagen type II T-cell immunity. Although antibodies alone are able to induce arthritis after passive administration to naive recipient animals, high concentrations are needed and, at best, a transient arthritis occurs. Passive transfer with bulk T cells or clones also produce mild or transient arthritis. Antibodies may be needed to bind to the cartilage surface and to release further collagen epitopes upon complement fixation and the attraction of leucocytes, including granulocytes and lymphocytes. A subsequent influx of anticollagen type II-specific T cells will than further drive the arthritic process.

It is convincingly demonstrated that the expression of collagen arthritis can be enhanced by extra anticollagen type II antibodies, non-specific inflammatory stimuli such as lipopolysaccharide or yeast particles (zymosan), or the simple addition of single inflammatory mediators such as interleukin (**IL**)-1, TNF-a, or transforming growth factor-b (**TGF-b**) (Hom *et al*. 1992; Thorbecke *et al*. 1992; Joosten *et al*. 1994). These observations suggest that slumbering autoimmune arthritis comes to full expression by a combination of potentiating elements. Recent studies not only implicate potentiating cytokines, but also the temporary control by modulators such as IL-4 and IL-10. This is further addressed under the heading 'Cytokines' below.

Much research has been focused on oral tolerance and intriguing progress has been made in identifying arthritogenic and tolerogenic epitopes on the collagen type II protein (Thompson *et al*. 1993; Myers *et al*. 1993a,b). Fragments containing tolerogenic epitopes may perhaps be safely applied to down-modulate anticollagen type II autoimmunity and to suppress established arthritis, without the risk of exacerbation. This collagen-induced arthritis model, using a defined autoantigen, is also suitable for analysing the restricted usage of T-cell receptors (**TCR**) and the possibility of suppressing arthritis by blocking a particular receptor. Treatment with antibodies against Vb8, a predominant TCR b-chain used in the immune response against collagen type II, prevented collagen arthritis (Moder *et al*. 1993) However, although specific TCR-Vb expression was noted in early synovial infiltrates at day 2 after the onset of collagen arthritis, this specificity was lost after only 1 week (Erlandsson *et al*. 1994). This particularly questions the usefulness of investigating TCR-Vb usage in the rheumatoid synovium.

Clear T-cell reactivity to collagen type II cannot easily be detected in patients with rheumatoid arthritis, casting some doubt on the relevance of this potential arthritogen in humans, but it is hoped that refined methods will provide further insight into relevant epitopes. A recent study of Trentham *et al*. (1993) indicated the usefulness of collagen type II in suppressing arthritis when given by the tolerizing oral route. Whether this really implies the possibility of antigen-specific down-modulation of collagen type II T-cell reactivity, indirectly proving the relevance of this response, or merely reflects non-specific 'bystander' suppression through the generation of suppressive cytokines (IL-10, TGF-b), remains to be seen. In fact, the anticollagen type II T-cell responses analysed so far were already low in patients before the treatment.

A worrying finding in terms of comparison with human arthritis is the highly destructive character of collagen arthritis and the marked sensitivity to non-steroidal anti-inflammatory drugs. Indomethacin is a very potent suppressor of both the inflammation and the joint destruction; steroids are also highly effective. This complicates experimental studies and stress can also profoundly disturb the expression of the arthritis. In contrast to the female preponderance in rheumatoid arthritis, male mice are more susceptible to collagen arthritis.

Proteoglycan arthritis

This is a rather new model and a logical extension of the collagen arthritis, since both collagen type II and proteoglycan are major components of articular cartilage. Yet again the discovery of the model was coincidental, following the immunization of mice to prepare antibodies. Repeated boosting was needed to induce consistent arthritis after 8 weeks, implicating poor antigenicity or tolerance. Importantly, arthritis was only noticed in inbred female BALB/c mice upon immunization with human fetal articular proteoglycan, stripped of chondroitin sulphate (Glant *et al*. 1987; Mickecz *et al*. 1990). The arthritogenic epitope resides in the core protein. The mechanism of induction of the arthritis is probably quite similar to that in collagen-induced arthritis: the induction of immunity to fetal human proteoglycan, subsequently cross-reacting with murine proteoglycans.

The proteoglycan model shows a polyarthritis, with severe cartilage erosion and marked ankylosis. In addition, involvement of the lumbar spine and disc regions was found, making it a model for spondylitis also. Like collagen arthritis, the most severe expression of proteoglycan arthritis is found in the presence of both antibodies and antiproteoglycan T-cell immunity. Of interest, antiproteoglycan antibodies on their own were capable of causing marked loss of proteoglycan from the cartilage in the absence of distinct synovitis.

Unfortunately, screening for the occurrence of such antiproteoglycan immunity in patients with rheumatoid arthritis did not yield unequivocal data in support of a role in human arthritis. It is to be expected that the further characterization of proteoglycan subtypes and epitopes may lead to better defined antigens, warranting thorough analysis of particular T-cell responses and antibodies in patients with arthritis.

Streptococcal cell-wall arthritis

This model was originally described by Cromartie *et al*. (1977). It was induced in Lewis rats by the systemic injection of cell-wall fragments of group A streptococci, which are highly resistant to biodegradation. Later on a similar disease was induced with cell-wall fragments from other bacteria, such as *Lactobacillus casei* or *Eubacterium aerofaciens*. The common principle resides in the poor degradability of the fragments, thereby creating a persistent stimulus. The lactobacillus and eubacterial models are of particular interest for the human disease, since these bacteria are part of the normal gastrointestinal flora (Stimpson *et al*. 1986; Hazenberg *et al*. 1992), which implies that an enormous load of potential arthritogenic stimuli is continuously present in the normal gastrointestinal tract.

Within 24 h of the administration of cell-wall fragments, acute inflammation develops in peripheral joints, coincident with the dissemination of cell-wall fragments in the blood vessels of the synovium and in the subchondral bone marrow. This acute, complement-dependent inflammation subsides over the next week and is followed within 2 weeks by a chronic, erosive polyarthritis, which involves mainly peripheral joints. In contrast with the acute phase, the chronic joint inflammation develops in only a limited number of rat strains, with the highest incidence in Lewis rats. The chronic phase often shows waxing and waning of arthritis, which brings it close to human rheumatoid arthritis. Mice strains studied so far are not susceptible to this form of arthritis. In general, female rats show a more severe arthritis than males.

Although macrophages become stimulated by the persistent bacterial fragments, cogent evidence now exists that the chronic phase is dependent on T cells. The chronic phase was not inducible in nude Lewis rats (no T cells) and cyclosporin A effectively inhibited this phase. In addition, chronic arthritis can be prevented with antibodies against the ab TCR (Yoshino *et al*. 1991). Moreover, streptococcal cell wall-specific T-cell responses were found in arthritis-susceptible Lewis rats, whereas resistant Fisher rats did not mount this immune reaction. Finally, germ-free Fishers rats were susceptible and did show streptococcal cell wall-specific T-cell reactivity. This set of data suggests that the chronic arthritis is driven by a streptococcal cell wall-specific T-cell reaction to persistent bacteria. Normal animals and most individuals are strongly tolerant of threatening arthritogenic reactions to bacterial cell walls, whereas Lewis rats and similar individuals display weak tolerance and are easily overloaded so as to lose tolerogenic control. Lewis rats display a disturbance in the hypothalamic–pituitary–adrenal axis, reflected in a low feedback response to endogenous corticosteroid (Sternberg *et al*. 1989). Such a defect is also noted in patients with rheumatoid arthritis, which is not attributable to chronic inflammation itself. As already discussed in the section on adjuvant arthritis, the defect in the hypothalamic–pituitary–adrenal axis is probably not a decisive but more a regulatory principle.

In addition to streptococcal cell wall-specific T-cell reactions, cross-reactive autoimmunity to cartilage proteoglycans may contribute to the chronic arthritis. However, it is unlikely that this is a major factor in its onset (van de Langerijt *et al*. 1994a). In fact, early histopathological appearances are those of a strong, mononuclear synovitis, with a sparse exudate in the joint space and limited loss of proteoglycan from the articular cartilage (Fig. 2). Only at later stages of the chronic arthritis were marked pannus formation and severe erosions of underlying cartilage and bone observed frequently.

In line with the involvement of growth factors and the tumour-like behaviour of synovial cells in patients with rheumatoid arthritis, similar characteristics have been found in synoviocytes from streptococcal cell-wall arthritic rats (Case *et al*. 1989). Probably due to the persistent bacterial stimuli, the cells do show continued proliferation *in vitro*, with apparent paracrine and autocrine regulation by growth factors (Lafyatis *et al*. 1989). This observation further delineates that macrophage–fibroblast activation may be a perpetuating principle, but it leaves unanswered why *in vivo* the observed T-cell dependence is still a critical, controlling

factor.

The model has rarely been used for drug studies, which is a pity. Cyclosporin shows efficacy and it has been claimed that non-steroidal anti-inflammatory drugs and steroids are suppressive as well. Gold and penicillamine were without effect, whereas methotrexate showed moderate activity. The main reason for limited studies in this model is the difficulty of preparing arthritogenic bacterial cell walls.

Antigen-induced arthritis

Since human rheumatoid arthritis is believed to be an immunologically mediated disease, albeit with an unknown inciting antigen, a model based on local antigenic challenge in a primed host appeared logical. Such a model was first developed by Dumonde and Glynn (1962) in rabbits. In principle it can be induced in any species, provided that proper immunity to a particular antigen can be mounted, and extensions have since been developed in mice, rats, and guinea-pigs. In contrast to the polyarthritis models described so far, this type of arthritis remains confined to the injected joint, enabling comparison with a contralateral joint of the same animal.

Commonly used antigens were ovalbumin, bovine serum albumin, and fibrin. Preimmunization is performed with antigen in complete Freund's adjuvant to induce strong humoral as well as cell-mediated immunity. Arthritis is usually induced 3 weeks later by a local injection in the knee joint of a large amount of antigen. Initially an Arthus type of reaction develops, followed by a T-cell-mediated chronic inflammation. In the rabbit, chronicity may last for years. The histopathological appearances are of a granulocyte-rich exudate in the joint space, thickening of the synovial lining layer, and, at later stages, a predominantly mononuclear infiltrate in the synovium, which includes numerous T cells and clusters of plasma cells. Interestingly, a large proportion (50 per cent) of these plasma cells are still making antibodies to the inciting antigen, providing evidence that the retained antigen might still be the driving force in the chronic arthritis. Intense immune-complex formation is seen in the superficial layers of the articular cartilage, which may contribute to the process of cartilage destruction. Early loss of proteoglycan, followed by pannus formation and cartilage and bone erosion, is a common finding. Of the models described so far these characteristics are the closest to those found in human rheumatoid arthritis.

Two important principles emerged from studies on antigen-induced arthritis: first, chronicity is only found in the presence of sufficient antigen retention in joint tissues, in combination with proper T-cell-mediated delayed hypersensitivity; second, joints contain numerous, avascular collagenous tissues such as cartilage, ligaments, and tendons, which allow for prolonged antigen retention by antibody-mediated trapping and charge-mediated binding (Cooke *et al*. 1972; van den Berg *et al*. 1984; Fig. 3). A key finding was the observation that antigen injected in the skin produced transient inflammation, whereas a similar dose in the joints caused chronic arthritis. The chronicity of arthritis in the standard model is probably related to the generation of local hyper-reactivity. Antigen trapped in the collagenous tissues will be released in tiny amounts to sustain low-grade chronic arthritis. As a consequence the local T-cell infiltrate will gain specificity, since retention of specific T cells is enhanced by homologous antigen. This means that small amounts of antigen are sufficient to sustain arthritis, whereas relatively large amounts are needed to induce it. This is a pivotal finding and forms the basis for exacerbations of arthritis described below (van den Berg *et al*. 1982).

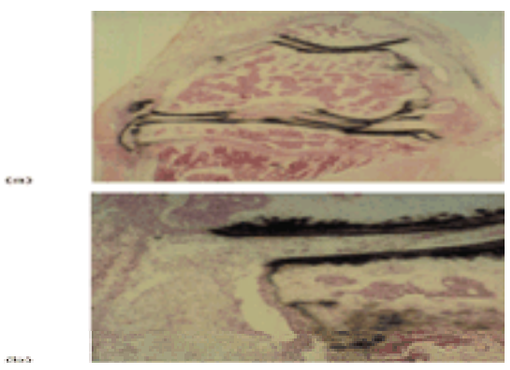

Fig. 3 Autoradiograph at day 2 after intra-articular injection of [^{125}I]-labelled bovine serum albumin (BSA) in BSA/Freund's complete adjuvant immunized mice: (a) whole knee joint, (b) detail of patella and femur; note the deep penetration of antigen in cartilaginous structures.

The finding in the mouse that cationic antigens are proper arthritogens in this model, owing to their ability to stick to the negatively charged collagenous structures of the joint, has led to a search for putative natural antigens with similar properties. Interestingly, cationic components of bacteria such as streptococci appeared to be stimuli in the model (Mertz *et al*. 1991), but subsequent searches for such T-cell reactivities in human rheumatoid arthritis were negative. However, similar reactivity was recently demonstrated in reactive arthritis (Probst *et al*. 1993), and antigen-induced arthritis, using a cationic antigen, probably makes a good model for reactive arthritis.

The model of antigen-induced arthritis is most suited to studies into the mechanism of cartilage destruction, which are facilitated by knowledge of the exact time of onset, the accessibility of the knee joint (as compared with ankles), and the presence of a contralateral control joint. Moreover, the model can be adequately used to test the feasibility of approaches to therapeutic immunomodulation. Comparison with autoimmune models may provide insight into similarities or dissimilarities in regulation of immunity to chosen protein antigens or cartilage autoantigens.

Antigen-induced arthritis is insensitive to non-steroidal anti-inflammatory drugs (de Vries and van den Berg 1989; Hunneyball *et al*. 1989), like the human condition. Steroids are highly effective, cytotoxic drugs are potent suppressants, and gold compounds were shown to be effective in the rabbit model.

Flares of arthritis

In comparison with the chronic process of human rheumatoid arthritis, a general shortcoming of most models is the relatively short duration of a severe and rapidly destructive inflammation. In that respect, models of repeated flares of arthritis, with slower development of lesions, provide a valuable extension. As stated earlier, an arthritic joint bearing a chronic T-cell infiltrate may display a state of local hyper-reactivity against the retained antigen, contributing to chronicity. However, it is intriguing that this is not restricted to retained antigen but also applies to new antigen entering the sensitized joint. In the model of bovine serum albumin-induced arthritis, flares of the smouldering arthritis are easily induced with as little as 10 ng of antigen. The flare is a T-cell-dependent process and can be completely blocked by *in vivo* antibody treatment against MHC (Ia) or CD4 (Lens *et al*. 1984). The flare can be induced by local rechallenge, but also by intravenous or even oral antigen administration. Higher dosages are, of course, needed for intravenous or oral challenges, and access to the joint is dependent on systemic antibodies and the physicochemical properties of the antigen. A model of repeated flares is probably more akin to the human state than is a model showing severe inflammation for some weeks, followed by rapid waning of arthritis. In a considerable proportion of patients with rheumatoid arthritis the disease course is characterized by exacerbations and remissions.

An important extension of this model was found by comparative dosing of IL-1 to naive joints and joints bearing a chronic infiltrate (van de Loo *et al*. 1992b). The infiltrated joint was much more sensitive to IL-1, and the reactivity seemed to reside in the macrophage infiltrate. Most importantly, the IL-1-induced flare was more highly destructive to the articular cartilage than the initial insult, and further understanding of the underlying mechanisms of such destruction is much needed.

In addition to models of flares of arthritis based on protein antigen, similar models have been developed in rats and mice using bacterial cell-wall constituents. In contrast to small protein antigens, which are only inflammatory in the context of an immune response, bacterial fragments may function as an antigen as well as a phlogistic irritant in their own right, and the ensuing reactions are a mixture of T-cell- and macrophage-driven processes. The generation of local hyper-reactivity requires large, persistent bacterial peptidoglycan–polysaccharide components, but the recurrence may happen with a variety of stimulants ranging from fragments, to lipopolysaccharide, to cytokines like IL-1 (Stimpson *et al*. 1987). The strongest flares occur in the presence of T-cell immunity and a correlation was found between the potential of fragments to induce an exacerbation and to elicit cell wall-specific T-cell proliferation *in vitro* (van den Broek *et al*. 1988; van den Broek *et al*. 1990; van den Berg *et al*. 1991). One other important aspect of these flares with cell-wall fragments resides in the presence of considerable cross-reactivity between cell walls from different bacterial origins. Flares can be induced with homologous as well as heterologous fragments (Esser *et al*. 1985) and this may even extend to cross-reactive autoantigens from the cartilage. Table 5 summarizes key aspects of such flares. These principles open up a wide range of putative stimuli involved in

exacerbations, simultaneously complicating the search for arthritogenic antigen in humans.

Local hyperreactivity in chronic infiltrate
Tiny dosages of homologous antigen sufficient
Contribution of cross-reactive antigens/irritants
Both T-cell and macrophage mediated
Hypersensitivity to TNF-α, IL-1, TGF-β

Table 5 Pathophysiology of flare reactions

Other models

In line with the trend of increasing concern about a particular T-cell-driven pathogenesis in rheumatoid arthritis, models not based on a specific antigenic trigger have received major attention in recent years. These include arthritis with various types of mineral oils, spontaneous models displaying arthritis amongst other changes, models based on superantigens or viral antigens exacerbating established models, and transgenic models based on overexpression of cytokines or mediators involved in cellular activation like c- *fos* or c-*jun*. These models reflect the hyper-reactivity of synovial cells or a general disturbance of the control of autoimmunity, either spontaneous or caused by compounds showing distinct adjuvant properties. In addition, interest has been raised in the **SCID** (severe combined immunodeficiency disease) mouse. This immunocompromised animal permits the *in vivo* study of the pathological potential of cells from animal models or patients with rheumatoid arthritis. For this purpose, cells or pieces of synovial tissue are transferred to the SCID mouse and pathological changes analysed (Williams *et al*. 1992b; Elkon and Ashany 1993). An interesting design is the combination of cells or tissue with cartilage as a target tissue, to obtain further insight into mechanisms of cartilage destruction. Detailed discussion of this model goes beyond the scope of this chapter. Some of the features of the other models will be addressed briefly.

Adjuvant oils can induce a symmetrical, destructive polyarthritis when injected intradermally in DA rats (Kleinau *et al*. 1991). Expression of the arthritis occurs between days 11 and 14, is found in 100 per cent of the rats, and lasts for 6 weeks. As in the classical adjuvant arthritis, readministration of oil to rats that had recovered from oil-induced arthritis fails to induce arthritis a second time. This points to an immunological background and indeed the arthritis could be transferred with concanavalin A-activated T cells from arthritic rats to irradiated recipients. A seemingly similar disease could be induced with adjuvant oil in certain strains of mice and was termed pristane arthritis (Wooley *et al*. 1989; Thompson and Elson 1993). The pristane disease, however, has proved difficult to characterize, due to late onset, variable penetrance, and difficulty of transfer. Moreover, in late disease numerous types of autoantibodies were noted, including rheumatoid factor, which may contribute to the expression of the arthritis and make this model less clearly T-cell driven. In clear contrast to findings in adjuvant and streptococcal cell-wall arthritides, pristane arthritis was suppressed in germ-free mice, implying involvement of bacterial flora and a bacterium-specific pathogenesis. Of interest, spontaneous arthritis may occur in DBA/1 mice, the strain that is highly susceptible to collagen-induced arthritis (Nordling *et al*. 1992). The spontaneous model seems to reflect aspects of the collagen arthritis since improvement could be achieved with anti-idiotypic antibodies to anticollagen antibodies. This is in sharp contrast with the adjuvant arthritis, which has been demonstrated to have a pathogenetic pathway different from that of collagen arthritis (Cremer *et al*. 1990; Holmdahl and Kvick 1992).

Spontaneous arthritis is also described in MRL–lpr/lpr mice (Hang *et al*. 1982; Koopman and Gay 1988). These animals develop a severe autoimmune disease, mainly characterized by massive lymphadenopathy, arteritis, immune complex-mediated glomerulonephritis, and chronic arthritis. The serological abnormalities in these animals include antibodies against native DNA, rheumatoid factors, and circulating immune complexes. This strain of mice may thus be regarded as a model of both systemic lupus erythematosus and rheumatoid arthritis. The presence of rheumatoid factors, which is lacking in most of the induced models, makes this model of potential interest. However, the incidence of arthritis is much lower than the incidence of the systemic lupus-like syndrome and is much more variable in presentation. Moreover, upon standard breeding it is often noted that the incidence of arthritis is further diminished, due to preferential survival and breeding potential of the more healthy individuals. The arthritis is characterized by synovial and mesenchymal cell hyperplasia, late T-cell infiltration, and cartilage destruction. The first signs are synovial cells with a transformed appearance and invasion of these cells into cartilage and bone, resulting in a rheumatoid arthritis-like pannus. Significant arthritis occurs only in aged mice, and signs are mild or absent before the age of 5 months. A viral cause has been suggested. Expression can be enhanced with an injection of Freund's complete antigen (Ratkay *et al*. 1993) or superantigen, the latter probably by induction of T-cell anergy (Mountz *et al*. 1994). In line with the autoimmune character, immunosuppressive drugs such as cyclophosphamide and leflunomide are effective in this model (Bartlett *et al*. 1988). In addition, chloroquine and gold were antiarthritic.

Transgenic mice expressing the human TNF transgene develop chronic polyarthritis with a 100 per cent incidence (Keffer *et al*. 1991). Hyperplasia of the synovium, inflammatory infiltrates in the joint space, pannus formation, and cartilage destruction were observed, and the expression could be completely blocked with anti-TNF-a antibodies. This model illustrates that systemic overexpression of TNF-a may lead to the precipitation of inflammatory processes in the joints.

The potential involvement of retroviral antigens in chronic arthritis was further underlined by the occurrence of arthritis after 2 to 3 months in mice transgenic for human T-cell leukaemia virus (Iwakura *et al*. 1991; Yamamoto *et al*. 1993). Recently, transgenic mice overexpressing c-*fos* were used in model studies. Overexpression of c-*fos* in synovial cells did not lead to arthritis. However, the eliciting of antigen-induced or collagen arthritides in these c- *fos* mice yielded more severe and more destructive arthritis. Remarkably, the cellular infiltrate in these mice contained hardly any lymphocytes, yet marked cartilage destruction was found, stressing the role of mesenchymal cells in that damage (Shiozawa *et al*. 1992). The expression of c-*fos* coincides with the enhanced expression of stromelysin and collagenase.

Involvement of cytokines

The synovial inflammation in patients with rheumatoid arthritis is characterized by an abundance of macrophage- and fibroblast-derived mediators and a relative lack of the T-cell factors IL-2 and interferon-g (Firestein 1991). It is encouraging to note that a considerable hierarchy exists in the plethora of cytokines and growth factors, putting major emphasis on cytokines TNF-a and IL-1. Characterization of the temporary involvement of these cytokines in the various models may shed some light on the (lack of) resemblance of the model arthritic processes to the human disease and may indirectly yield further understanding of the rheumatoid arthritic process. Before addressing the involvement of TNF/IL-1 it must be remembered that early studies into the synovial expression of IL-2 and interferon-g in proven, T-cell-driven experimental models of arthritis encountered major difficulties in the demonstration of these mediators. This should be taken as a warning that the relative absence of IL-2 and interferon-g in rheumatoid synovia must not be overinterpreted to mean exclusion of a T-cell-driven origin. Approaches to obtaining evidence of the involvement of TNF and IL-1 are the use of neutralizing antibodies, specific binding proteins or receptor antagonists in the various models (Henderson and Blake 1992).

Although adjuvant arthritis is still the model most widely used in drug discovery, information on TNF/IL-1 involvement is scant. Treatment with antibodies to the IL-1 receptor, starting directly after immunization, resulted in a marked reduction of arthritis. Such an early treatment may interfere with the generation of autoimmune responses in this model. (Schorlemmer *et al*. 1993). Anti-IL-1 treatment hardly affected late joint swelling and cell influx, but anti-TNF blocked the influx of lymphocytes and granulocytes in the arthritic joint and reduced swelling (Issekutz *et al*. 1994).

In murine collagen arthritis, anti-IL-1 and anti-TNF have been used before onset, shortly after onset, and in the established phase. TNF plays an important part in the onset of collagen-induced arthritis but is less dominant in late arthritis (Williams *et al*. 1992a; Wooley *et al*. 1993a). In contrast, IL-1 is a pivotal mediator in both early and established collagen-induced arthritis (Fig. 4). The elimination of IL-1 greatly suppressed the arthritis and yielded marked protection against cartilage destruction (van den Berg *et al*. 1994). The protection could be demonstrated using either neutralizing antibodies or IL-1 receptor antagonist, provided that large amounts (1 mg/day per mouse) of the antagonist were continuously supplied in osmotic minipumps. Given the poor pharmacokinetics and the need for sustained receptor

blocking, it must be stressed that any therapeutic application in patients with rheumatoid arthritis would need extremely high dosages.

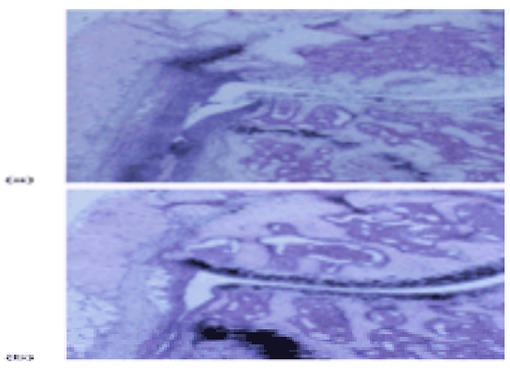

Fig. 4 Autoradiograph of a knee joint (patella/femur) at day 35 after induction of collagen arthritis: (a) arthritic control, (b) anti-IL-1ab treated (from day 28); note the restoration of ^{35}S incorporation in the chondrocytes.

In the flare model of streptococcal cell-wall arthritis in the rat both TNF-a and IL-1 appeared to be important (Schwab *et al*. 1991). A similar study in the mouse revealed a dominant role for TNF in the joint inflammation, but still a pivotal role for IL-1 in cartilage destruction. Flares induced with superantigen were IL-1/TNF independent (Schwab *et al*. 1993).

Finally, in antigen-induced arthritis in the rabbit and the mouse, elimination of both TNF-a and IL-1 was not very effective in suppressing joint inflammation, pointing to substantial 'overkill' by other mediators (Wooley *et al*. 1993b; Lewthwaite *et al*. 1994). However, elimination of IL-1 did yield protection against cartilage destruction (van de Loo *et al*. 1992a) and this was even more striking in the antigen-induced flare (van de Loo *et al*. 1995).

In summary, the dominance of IL-1 and TNF in joint inflammation in the different models is variable, implying that the stimulus, the type of process, and probably also the phase of the arthritis are important determinants. Given the apparent dominance of TNF-a in the cytokine cascade in rheumatoid synovial tissue, the model of streptococcal cell-wall arthritis is perhaps the closest to the human disease. However, all phases studied so far are rather more acute than the human disease and further study is needed in the late stages or repetitive flares of the models. Moreover, future studies are needed in arthritis models to dissect any critical dependence on the cytokine profiles of distinct T-cell or macrophage-driven processes. A consistent and important finding is the potential uncoupling of joint inflammation and cartilage destruction. Although IL-1 is not a dominant inflammatory cytokine in all models, it is certainly the pivotal cytokine in the inhibition of chondrocyte proteoglycan synthesis in all models studied so far and the blocking of IL-1 has a great impact on net cartilage destruction.

Apart from the cytokines TNF-a and IL-1, modulatory cytokines such as IL-4, IL-10, and TGF-b, and specific endogenous inhibitors like shed receptors or IL-1 receptor antagonist are of prime importance. Consistent findings have been made in collagen-induced arthritis and streptococcal cell-wall arthritis. Local TGF-b is a crucial proinflammatory mediator, yet becomes anti-inflammatory at later stages. TGF-b, when applied systemically, is generally anti-inflammatory (Santambrogio *et al*. 1993; Wahl *et al*. 1993; Wahl 1994). A similar dichotomy seems to hold for IL-4 and IL-10, which complicates any therapeutic application. These mediators may interfere at various levels of the arthritic process including skewing of T-helper cells, inhibition of macrophage cytokine production and direct action on chondrocytes (Fig. 1 and Fig. 5) The up-regulation of IL-1 receptor antagonist by IL-4 contributes to the suppression of streptococcal cell-wall arthritis (Allen *et al*. 1993). It is expected that the study of experimental arthritis in the recently developed cytokine 'knock-out' mice will further identify crucial roles of the various cytokines.

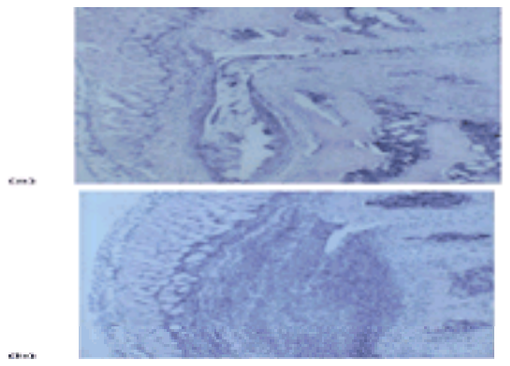

Fig. 5 Haematoxylin and eosin-stained section of a murine knee joint after triple injections of IL-1 (a) or IL-1 and transforming growth factor-b (b); note the markedly enhanced cell influx and fibrosis with the combination.

Uncoupling of cartilage destruction/joint inflammation

Apart from studies on the involvement of cytokines and on immunotherapeutic approaches, models of arthritis are valuable tools for further identifying subpopulations of infiltrating leucocytes or synovial cells involved in cartilage destruction (van Lent *et al*. 1994). The damage observed in the different models ranged from a selective loss of matrix in cartilage underlying pannus tissue to an overall loss of proteoglycans and, later on, of collagen, or even to the killing of numerous chondrocytes and the complete loss of the superficial and middle cartilage layer. This underlines that the arthritic processes can be more or less destructive, dependent on the underlying process. Large variation in progressive destruction is also noted in populations of patients with rheumatoid arthritis, which may indicate separate pathogenetic pathways. Enhanced degradation of matrix and inhibited synthesis of proteoglycans by the chondrocyte are general findings in all models.

In antigen-induced arthritis, clear uncoupling of joint swelling from cartilage destruction is a common observation. Non-steroidal anti-inflammatory drugs are effective in reducing the swelling but leave the destructive process untouched. It is even suggested that most non-steroidal anti-inflammatory drugs are harmful, by inhibition of prostaglandin production (Pettipher *et al*. 1989). Prostaglandin E_2 is a potent feedback regulator of IL-1 production and concentrations of this cytokine are higher in the presence of non-steroidal anti-inflammatory drugs with cyclo-oxygenase inhibitory activity.

The contribution of neutrophils to cartilage destruction is still unclear. Although the enzymes from neutrophils, such as elastase, can be highly destructive *in vitro*, neutrophils also contain TGF-b and IL-1 receptor antagonist and can be protective as well. Normally, neutrophils do not attach to the cartilage surface and released enzymes will be scavenged by enzyme inhibitors of the synovial fluid. Depletion of neutrophils in antigen-induced arthritis did not influence cartilage destruction and damage was similar in elastase-deficient mice (Schalkwijk *et al*. 1990). However, in the presence of dense immune complexes in the superficial cartilage layers, marked sticking of neutrophils is found in antigen- and in collagen-induced arthritis in particular. This attachment is potentiated by immobilization of the joint (Fig. 6). The ruffled cartilage surface under those conditions indicates direct destruction by the attached cells (van Lent *et al*. 1990).

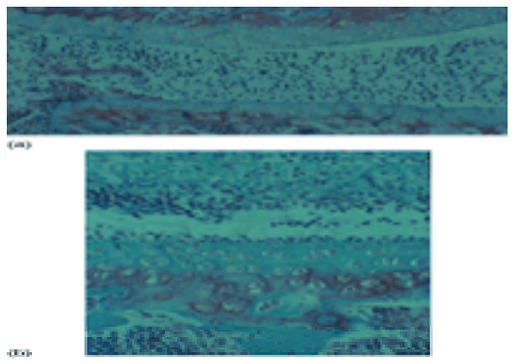

Fig. 6 Section of knee joint in antigen-induced arthritis (day 7) under normal conditions (a) or after joint immobilization (b); note the heavy sticking of granulocytes with immobilization.

Although neutrophils may be destructive under limited conditions, these cells are certainly not essential to the destruction and neither are lymphocytes. Observations in MRL lpr/lpr mice and the H_2-c-*fos* transgenic mice indicate that macrophage-rich infiltrates can be highly destructive without the presence of neutrophils and lymphocytes. Similarly, macrophage but not lymphocyte numbers in rheumatoid synovial tissue correlate with the radiological progression of joint destruction (Yanni *et al*. 1994). The critical enzymes involved in destruction in arthritis models and human rheumatoid arthritis are still far from understood. Detailed discussion of the various approaches to identify key enzymes in the models is beyond the scope of this chapter.

A general lesson that may be deduced from observations in most models is that continuing, irreversible destruction can occur under conditions that will be hardly considered as inflammatory. Symptomatic relief by anti-inflammatory therapy is promising but the main challenge remains to interrupt joint destruction. It is intriguing that combined, repeated injections of IL-1 and TGF-b give a much more profound synovitis than IL-1 alone, yet cartilage destruction is less (van Beuningen *et al*. 1994).

Final remarks

The various models have provided insight into aspects of chronic inflammation and joint destruction. Possibilities and impossibilities of targeted (immuno)therapy can be critically analysed in the models, which offers a framework for future application when the underlying process of human rheumatoid arthritis is unravelled. In recent years there has been a tendency for researchers to skip detailed analysis in complex models and to rely on models driven by T-cell clones and lines, or to jump directly to application in human rheumatoid arthritis. It is certain that the possibilities and/or limitations of, for instance, T-cell vaccination, TCR-Vb targeted therapy or immunomodulation in established disease still need evaluation in convincing animal models. Although cartilage autoantigens are attractive as putative arthritogens, final evidence for their role in human rheumatoid arthritis has yet to be provided, and future research is likely to focus on collagen type II and proteoglycan epitopes, and on novel cartilage antigens. An interesting approach is the use of non-arthritogenic antigens to provoke 'bystander' suppression to control arthritis of unknown aetiology. A still neglected area is the basis for preferential expression of the first inflammatory signs in either peripheral joints, whole paws, ankles or knees in the various models. This is of pathogenetic interest, since it is still not understood why the expression of human arthritides starts in particular joints and initially spares others.

A seemingly contradictory finding in all models is the relative abundance of periostitis in addition to synovitis, and the formation of osteophytes apart from bone and cartilage erosions. It is important that most studies are done in relatively young animals and that juvenile arthritis is also characterized by osteophytes. Moreover, periosteal lining layers and epiphyseal growth plates remain active until late in life in rodents, in contrast to the inactivity in those layers in aged humans.

Finally, the severity of the arthritis is often greater and the disease course commonly shorter in most models compared with rheumatoid arthritis. This complicates the screening of antiarthritic drugs, an issue that has not been addressed in great detail here. Reviews that selectively address drug therapy are recommended for further details (Bliven and Otterness 1985; Hunneyball *et al*. 1989). Suffice it to say that therapeutic studies on the late stages of chronic disease and on repeated flares are warranted.

A clear message from the animal models is that cartilage destruction is often dissimilar from joint inflammation. In some models, early anti-inflammatory treatment can completely prevent the onset of arthritis and under those conditions cartilage destruction is prevented too. However, in other models, cartilage destruction is still noted in the absence of marked inflammation, making it essential to define destructive pathways or mediators. It is promising that the model studies have yielded unequivocal evidence for a pivotal role of IL-1 in inhibiting proteoglycan synthesis by chondrocytes. However, the critical enzymes involved in cartilage degradation are still not fully elucidated. An intriguing approach is now offered by the analysis of enzyme-specific breakdown epitopes of proteoglycans and collagens in cartilage from human arthritides and various models, using recently developed monoclonal antibodies. Moreover, the development of arthritis in 'knock-out' mice, deficient in candidate enzymes, will provide evidence for their involvement. It is expected from the studies on current models that full protection against cartilage destruction will require a combination therapy of IL-1 blockade and neutralization of as yet unidentified, IL-1-independent enzymes.

3.5.1 Non-steroidal anti-inflammatory drugs

Peter Brooks

Introduction

Inflammation in the rheumatic diseases may be acute or chronic and involves a whole variety of cells and mediators interacting together to form a final common pathway to joint destruction (see previous chapters in this section). The cells involved in the inflammatory response include polymorphonuclear leucocytes, macrophages, and lymphocytes as well as the fibroblasts, platelets, and endothelial cells lining the blood vessels. Mediators of inflammation include the prostaglandins and leukotrienes, cytokines, platelet-activating factors, and kinins. In diseases such as osteoarthritis the inflammation may be mild but in the inflammatory arthropathies a number of different inflammatory pathways are activated, leading eventually to joint destruction. These are summarized in Fig. 1.

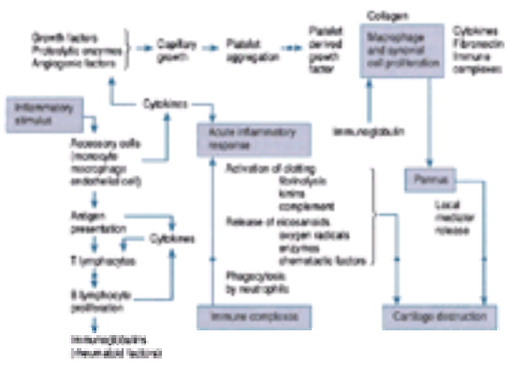

Fig. 1 Sites at which non-steroidal anti-inflammatory drugs may act on the inflammatory process. The inflammatory process comprises many detector, communication, and effector systems. These systems may be chemical or cellular, and there are clearly multiple interactions between them. · Possible action of NSAIDs. (Modified from Forrest and Brooks (1988) and reproduced with permission.)

The pharmacological agents used in the rheumatic diseases can interfere with various aspects of the inflammatory response. The mechanism of action, major adverse reactions, interactions, and the practicable prescribing of these agents will be discussed in the following chapters. The endpoint of inflammation in the rheumatic diseases is the destruction of cartilage, with its subsequent pain and loss of function. It would seem reasonable, therefore, to attempt to control inflammation as early as possible in an effort to reduce joint and cartilage damage to a minimum. A number of published studies support the view of Brook and Corbett (1977) that, if erosions are going to occur in rheumatoid arthritis, they do so within 2 years of disease onset. If we accept this premise, then it would seem important to use drugs which have antirheumatic activity at as early a stage as possible. In the past the traditional approach to the management of inflammatory arthritis has been to begin with the simple agents, such as analgesics and non-steroidal anti-inflammatory drugs (**NSAIDs**), and progress slowly towards the more potent agents. Even with this approach, the long-term outlook for rheumatoid arthritis is not good. Recently Scott *et al*. (1987) have shown that after 20 years of disease, over 50 per cent of patients are either severely disabled or dead. Significant functional disability also occurs in these patients and approximately half are work disabled 10 years after the onset of rheumatoid arthritis (Yelin *et al*. 1987). Wilske and Healey (1989) have suggested recently that the conservative 'pyramidal' approach to the management of rheumatoid arthritis, where NSAIDs are prescribed initially alone, be replaced by the more intensive and earlier use of corticosteroids, methotrexate, and other suppressive agents. The therapeutic goal in the management of inflammatory joint disease should be not just to suppress symptoms and signs of inflammation but also to try to normalize acute-phase reactants and attempt to slow and prevent bony erosion. If we are to do this, then the data support early treatment of rheumatoid arthritis with disease-modifying drugs as well as use of NSAIDs.

NSAIDs in the management of joint inflammation

NSAIDs make up one of the most commonly prescribed groups of drugs, with over 100 million prescriptions written worldwide in 1989. Over 20 per cent of patients admitted to hospitals in the United Kingdom and Australia are taking NSAIDs. There are over 50 different NSAIDs either marketed or on trial throughout the world, though most countries have between 7 and 17 available for use. Just how many NSAIDs are necessary for optimal management of patients with rheumatic disorders is not known. However, a study carried out in a number of private rheumatological practices in the United States found that 14 NSAIDs were required to control symptoms in 90 per cent of patients (Pincus and Callaghan 1989). Patients do seem to respond individually to NSAIDs, both in terms of pain relief and adverse reactions, but the extent of this variability and the reasons for it are still not clear (Brooks and Day 1991).

Mechanism of action

The major activities of NSAIDs are summarized as follows and include modulation of:

1. cyclo-oxygenase;
2. leukotriene synthesis;
3. superoxide production;
4. superoxide scavenging;
5. lysosomal enzyme release;
6. neutrophil aggregation and adhesion;
7. lymphocyte function;
8. rheumatoid factor production;
9. cartilage metabolism;
10. cell membrane activities, including:

a. enzymes (NADPH oxidase, phospholipase C),
b. transmembrane anion transport,
c. uptake of prostanoid precursor.

Prostaglandins, leukotrienes, and the cellular elements of acute and chronic inflammation might all be influenced by NSAIDs, as reviewed by Forrest and Brooks (1988). As our understanding of the way in which prostaglandins and other mediators influence the immune response increases, it is obvious that the NSAIDs do have some mild immunomodulatory activity. The differentiation between the varying classes of antirheumatic drugs into NSAIDs, slow-acting rheumatic drugs, and immunosuppressive drugs is thus becoming blurred.

The variability in patients' responses to NSAIDs is well recognized by rheumatologists (Brooks and Day 1991). The factors which might influence this variability are:

1. pharmacokinetics:
   a. absorption,
   b. protein binding,
   c. metabolism,
   d. renal clearance;
2. pharmacodynamics;
3. dosage selection and timing;
4. variability in disease state;
5. variation in adverse reaction profile.

From a practical point of view it is important that the prescriber of NSAIDs appreciates some of these variables and tries to find the most appropriate NSAID to use in a particular clinical situation.

Pharmacokinetics

The pharmacokinetics of a non-steroidal anti-inflammatory drug depend on its absorption and bioavailability, its distribution, and its half-life. Most NSAIDs are relatively lipid soluble, are weak acids, and almost all are completely absorbed from the gastrointestinal tract. The rate of absorption of NSAIDs is variable and is usually slower when they are taken with meals. Most NSAIDs are now provided as enteric-coated or sustained-release preparations and this can significantly alter the pharmacokinetics. NSAIDs are usually highly bound to plasma proteins and thus the amount of free drug (the active component) is relatively small. NSAID binding to plasma proteins might be reduced in various states such as renal and hepatic disease and in subjects with hypoalbuminanaemia. For most of the NSAIDs the unbound fraction is not altered by the plasma concentration. However, with naproxen, phenylbutazone, and salicylate, the unbound concentrations increase proportionally with dose. The binding of some other NSAIDs decreases in elderly patients and in patients with rheumatoid arthritis, emphasizing the importance of correlating unbound concentrations, rather than the total amount of drug in plasma, with clinical effect. NSAIDs are weak acids and, therefore, they tend to be trapped more effectively by cells in acid environments such as the inflamed joint, the stomach, and the renal medulla. This is of relevance since these are the sites of action and major adverse effects. Lipid solubility of NSAIDs allows them to pass easily through cell membranes, and cognitive changes, headache, and confusion are well reported as adverse effects (O'Brien and Bagby 1985). The half-life of elimination of a drug ($t_{1/2}$) is the time taken for the concentration of that drug to fall from any given concentration to 50 per cent of that concentration. NSAIDs have a wide range of plasma half-lives and can be divided into two broad categories on the basis of this variable—those with plasma half-lives of less than 6 h and those with half-lives in excess of 12 h (Day *et al*. 1988) (Table 1). NSAIDs with long half-lives show much smaller fluctuations between peak and trough concentrations, even on a once-daily dose regimen. Many of the shorter half-life NSAIDs have now been produced in slow or sustained release formulations, which tend to reduce the fluctuations between peak and trough levels and allow for once-daily dosing. As the major site of action of NSAIDs is the synovial membrane and synovial fluid, it is probably more important to consider synovial-fluid or tissue kinetics. These are obviously difficult studies to do but those that have been done show clearly that the concentrations in synovial fluid are much more stable and show fewer fluctuations than plasma concentrations, even for drugs with short half-lives. This is demonstrated in Fig. 2 where it can be seen that the peak concentrations in synovial fluid appear later and are lower than the peak concentrations in the plasma. This is one of the explanations for the fact that even NSAIDs with short half-lives often provide satisfactory pain relief on a twice-daily dosing regimen.

Short (<6 h)	$t_{1/2}$	Long	$t_{1/2}$
Aspirin	0.25	Azapropazone	15
Diclofenac	1.1	Diflunisal	13
Etodolac	3.0	Fenbufen	11
Fenoprofen	2.5	Nabumetone	26
Flufenamic acid	1.4	Naproxen	14
Flurbiprofen	3.8	Oxaprozin	58
Ibuprofen	2.1	Phenylbutazone	68
Indomethacin	4.6	Piroxicam	57
Ketoprofen	1.8	Salicylate	2–15
Pirprofen	3.8	Sulindac	14
Tiaprofenic acid	3	Tenoxicam	60
Tolmetin	1		

Table 1 Half-lives of NSAIDs

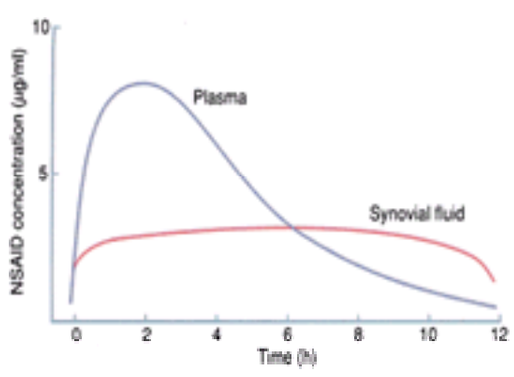

Fig. 2 Concentration in plasma and synovial fluid of a short half-life NSAID (ibuprofen) following chronic administration. The synovial fluid concentrations oscillate much less than the plasma concentrations (adapted from Day *et al*. 1988 and reproduced with permission).

The mechanism of clearance of NSAIDs is usually by hepatic metabolism with the production of inactive metabolites. Some NSAIDs, such as aspirin, nabumetone, fenbufen, and sulindac, are converted into active metabolites that produce the major anti-inflammatory pharmacological effect. Sulindac is particularly interesting because the active metabolite (sulphide) is produced in the large intestine and this process is reversible. Conversion of the active sulphide metabolite back to the inactive sulindac can occur in the kidney and has been suggested as an explanation for the reported renal-sparing effects of this drug. Some NSAIDs of the 2-arylpropionic acid class, including ibuprofen, ketoprofen, fenoprofen, naproxen, tiaprofenic acid, and flurbiprofen, exist as two optical isomers or enantiomers. Interestingly, it is only the *S*-enantiomer of these NSAIDs that inhibit cyclo-oxygenase and thus produces anti-inflammatory effects. All these compounds, except for naproxen, are produced as mixtures of the *R* and *S* forms with the inactive *R* being metabolically converted to the active *S*-enantiomer *in vivo*. Williams *et al*. (1986) have shown that the metabolism of the inactive isomer is also associated with uptake into triglycerides, which might remain in fat depots in the body for considerable periods of time.

Although only small amounts of NSAID are excreted unchanged from the urine, enal clearance does increase with increasing urinary pH, but this is only of clinical relevance for salicylate. The renal clearance of diflunisal, ketoprofen, fenoprofen, naproxen, and indomethacin is reduced in renal failure and by administration of probenecid. This is primarily due to the retention of acylglucuronide metabolites, which are then converted back to the original NSAID *in vivo*.

Side-effects of NSAIDs occur more frequently in the elderly and clearance of naproxen, ketoprofen, azapropazone, salicylate, and ibuprofen are reduced in elderly patients. In these patients it would seem sensible to commence treatment with lower than standard doses and only increase the dose in the face of an inadequate response and absence of side-effects.

Relationships between the plasma concentration of NSAID and clinical effects have been difficult to determine because of methodological problems. Linear relationships between dose and/or plasma concentration and anti-inflammatory effect have now been demonstrated for naproxen, carprofen, and ibuprofen in patients with rheumatoid arthritis. Correlations between plasma concentration and tinnitus, deafness, and gastrointestinal symptoms have also been demonstrated for some NSAIDs. Although the concept of responders and non-responders to an NSAID is generally accepted, many of the studies have flawed methods and the only study looking at reproducibility of the phenomenon has failed to demonstrate it (Preston *et al*. 1988). If responders and non-responders do exist, then it would seem an attractive hypothesis that the difference is pharmacokinetic in origin. However, it has been clearly shown that the pharmacokinetics of indomethacin and flurbiprofen do not differ between responders and non-responders and this does not seem to be the explanation for the phenomenon. Variability in pharmacokinetic parameters might play a role in individual patients; other factors that need to be considered in variability of response are listed above under mechanism of action. To these need be added genetic factors, age, gender, and the influence of a whole variety of environmental issues such as diet, smoking, and activity. Pharmacodynamic factors might also explain variability in response in that it has recently been shown that the cyclo-oxygenase enzyme system is made up of at least two components—so-called Cox-I and Cox-II. Cox-II is activated in inflammation and NSAIDs seem to have variable activities on the Cox I and II isoenzymes, thus adding to the complexity of variability of response to NSAIDs (Meade *et al*. 1993).

Adverse reactions

Adverse reactions to NSAIDs are common and have been extensively reviewed recently by O'Brien and Bagby (1985) and Simon (1995); the major side-effects are shown in Table 2. Adverse reactions to NSAIDs are the most commonly reported of any group of drugs to the Committee on Safety of Medicines in the United Kingdom. Gastrointestinal adverse events are the most frequent and usually mild (approximately 10 per cent of patients on NSAIDs) followed by renal events, skin rashes, and central nervous reactions. Although serious adverse events to NSAIDs might be extremely rare, they assume importance when up to 20 per cent of the population are ingesting these drugs on a regular basis. The real issue with serious adverse events to NSAIDs is just how frequently they occur.

Organ system	Reaction	Incidence
Gastrointestinal	Indigestion Erosions Peptic ulcer Small and large bowel ulceration	Common (>20%)
Hepatic	Hepatocellular Cholestasis	Rare (<5%)
Renal	Transient rise in serum creatinine Acute renal failure Interstitial nephritis Hyperkalaemia	
Haematological	Thrombocytopenia Neutropenia Aplasia Haemolytic anaemia	Rare
Cutaneous	Photosensitivity Erythema multiforme Toxic epidermal necrolysis	Uncommon (5–30%)
Respiratory	Bronchospasm	Rare
Central nervous system	Headache Dizziness Personality change Aseptic meningitis	Uncommon

Table 2 Adverse reactions to NSAIDs

Gastrointestinal effects (also see Chapter 1.3.6)

There has been a rapid rise in the incidence of death from gastrointestinal perforations and haemorrhage in association with increased ingestion of these drugs. The problems of risk assessment have been highlighted recently by Henry (1988) and Lichtenstein *et al*. (1995). Linkage of population databases has produced figures for relative risk of admission to hospital with upper gastrointestinal haemorrhage of approximately 1.5, with a much higher relative risk for fatal upper gastrointestinal haemorrhage in women over the age of 75 years. Controlled studies on the relationship between NSAID use and peptic ulcer complications (again summarized by Henry 1988), show odds ratios of between 1.8 and 3.8 for upper gastrointestinal haemorrhage and much higher odds ratios for ulcer complications. Until recently it has been assumed that all NSAIDs were similar in their ability to produce gastric ulceration. Recent studies, however, suggest that some NSAIDs (ibuprofen, naproxen, and diclofenac) are less frequently associated with gastric ulceration than others (Garcia-Rodriquez and Jick 1994 ; Langman *et al*. 1994).

Up to 50 per cent of patients with rheumatoid arthritis who have gastric ulcers might be asymptomatic and it is important to identify risk factors for development of peptic ulceration. The practical issues of management of NSAID-associated gastropathy are now becoming important with the advent of so-called 'gastroprotective' agents such as the prostaglandin analogues. Both peptic and duodenal ulcers will heal despite continuing use of NSAIDs, though they will heal more slowly. H_2-blockers will reduce the incidence of NSAID-associated duodenal ulcers, omeprazole will reduce the incidence of gastric ulcers, and the prostaglandin analogues will reduce the incidence of both gastric and duodenal ulcers. To date, no studies have demonstrated that use of these agents prophylactically in patients taking NSAIDs will reduce complications of peptic ulceration. This is an important issue to determine if these drugs are to be recommended widely on a prophylactic basis. Current recommendations are that prophylaxis be confined to those patients who are at particular risk of developing serious gastrointestinal side-effects, i.e. those over the age of 65 years, with a past history of peptic ulceration, on corticosteroids, or with severe rheumatoid or other system disease; the recommendations are based on risk factors demonstrated by Fries *et al*. (1989). It has been reported recently that NSAIDs also damage the small and large bowel, and oesophageal mucosal damage is also relatively frequent.

Hepatoxicity

Regular testing of liver function often shows transient elevation of liver enzymes in patients taking NSAIDs. This is reported more frequently with certain NSAIDs, such as sulindac or diclofenac. These abnormalities are usually mild and often disappear despite continuing drug therapy.

Renal effects

Many patients will have a transient rise in serum creatinine which will return to normal despite continuation of the NSAID. Prostaglandins are important modulators of renal flow, particularly in those patients with compromised renal function. It is in this group of patients that the severe problems of NSAID-associated renal dysfunction occur. Renal syndromes associated with NSAIDs include acute renal failure, interstitial nephritis, hyperkalaemia, and renal tubular damage. Patients particularly at risk from these problems include those with a past history of renal disease, those with volume depletion due to diuretic therapy or other factors such as surgery, and those with hepatocellular insufficiency. NSAIDs might also interfere with the control of hypertension in patients receiving antihypertensive agents as reviewed recently by Radack and Deck (1987). It is clear that NSAIDs interfere with blood pressure control on an individual basis, and patients with hypertension who are started on NSAIDs should have their blood pressure monitored carefully.

Haematological reactions

Iron-deficiency anaemia due to chronic blood loss is a common accompaniment of NSAID therapy, with unusual haematological adverse reactions including thrombocytopenia, agranulocytosis, aplastic anaemia, and haemotolyic anaemia. NSAIDs also affect platelet function, however all except aspirin do so in a reversible reaction, which means that platelet function is only disturbed while there are significant concentrations of NSAID in the bloodstream. This is important when calculating how long NSAIDs need to be withdrawn before interventions such as joint replacement or other surgery.

Skin

Cutaneous reactions to NSAIDs are relatively common. They are usually mild and have been reported most frequently with naproxen, sulindac, diclofenac, diflunisal, and piroxicam. The rare complications of Stevens–Johnson syndrome, which has a mortality rate of approximately 25 per cent, have also been reported with NSAIDs.

Respiratory

Bronchospasm might be precipitated in asthmatic patients after administration of NSAIDs. If asthmatics require NSAIDs, they should be monitored carefully under controlled conditions, particularly if they have a history of previous adverse reactions to such drugs.

Central nervous system

Central nervous side-effects, such as headache, are commonly described with NSAIDs such as indomethacin. Mild reactions have also been reported with a number of other NSAIDs. Ibuprofen has also been reported as producing an aseptic meningitis-like picture in patients with systemic lupus erythematosus.

Cartilage

A number of *in vitro* and animal studies have suggested that NSAIDs might interfere with cartilage integrity, leading to more rapid development of osteoarthritis. Evidence that this is an important issue in patients has not yet been obtained, as measurements of progression in osteoarthritis are still relatively crude. Whether NSAIDs do influence progression of arthritis, and in particular cartilage destruction, needs to be investigated.

Interactions

As NSAIDs are commonly taken by elderly people with other diseases, the potential for drug interaction is large. The common interactions of NSAIDs are shown in Table 3. Interactions can be seen as pharmacokinetic or pharmacodynamic, as described by Tonkin and Wing (1988). From a practical point of view, important interactions are those which might occur with oral anticoagulants, diuretics, and hypotensive agents. Although NSAIDs reduce the clearance of methotrexate, this is not a problem with the low doses used in the treatment of rheumatic arthritis.

Table 3 NSAID interactions

Practical prescribing

When prescribing NSAIDs, the most important thing is to find the right drug in terms of pain relief and lack of side-effects for each individual patient. It should only take 7 to 10 days at maximal recommended or tolerated dose to tell whether an NSAID is going to work. If pain relief does not occur and/or side-effects intervene, then that NSAID should be stopped and another one started. There does not seem to be any rationale for using combinations of NSAIDs. When using NSAIDs, the prescriber should be aware of potential drug interactions and adverse effects and should explain these appropriately to the patient.

NSAIDs can provide considerable symptom relief to patients with a variety of rheumatic diseases. Like all drugs they should be used judiciously for appropriate patients and clinical situations. Efficacy and adverse effects should be regularly reviewed. However, if these guidelines are followed, the majority of patients prescribed NSAIDs can be afforded symptom relief without adverse effects.

3.5.2 Antirheumatic drugs

A. M. Denman

Introduction

The last few years have seen a change in attitude to the treatment of rheumatoid arthritis. Rheumatologists now use disease-modifying drugs early in the natural history of the disease and are less inclined to await events before resorting to potent agents (Girgis *et al*. 1994). Fuller realization of the side-effects of non-steroidal anti-inflammatory drugs has also encouraged greater reliance on other antirheumatic drugs. Awareness of the devastating effects of progressive disease on joints and general health has stimulated a less restrained attitude to trials of drug combinations. The analysis of both formal drug trials and less structured usage has also become more sophisticated so that there is more reliance on established data and less on anecdotal experience. Patients and their doctors are now better able to select a proven 'best buy'. Many of the traditional debates on the mode of action of different antirheumatic drugs have now been superseded by the realization that these agents have multiple effects on inflammatory pathways, whether immune-mediated or otherwise. A more systematic analysis of conventional antirheumatic drugs has been prompted by the acceptance that scientifically more elegant ways of specifically interfering with these events will not speedily replace other forms of treatment. This applies especially to the management of systemic connective tissue diseases where rheumatologists still rely almost exclusively on non-specific immunosuppressive and anti-inflammatory drugs, namely steroids and cytotoxic drugs.

This change in attitude means that the order in which rheumatologists resort to different antirheumatic drugs has also changed; there is less frequent recourse to gold and penicillamine and a greater dependence on methotrexate. Choice is determined partly by precedent and partly by increasing insight into the manner in which drugs function.

Much information has accrued about the pharmacokinetics, and the *in vitro* and *in vivo* effects of antirheumatic drugs. This knowledge has been gained from experimental systems and clinical observation. However, many difficulties still face the rheumatologist concerned with the intelligent application of this knowledge or involved in the quest for more effective treatment. Since the aetiology and pathogenesis of the major rheumatic diseases is unknown, the best that can be achieved is selective inhibition of key inflammatory pathways.

Improved understanding of drug actions and more sophisticated clinical trials have made drug selection more rational. As a result, a limited number of antirheumatic drugs are used predominantly and many time-honoured forms of medication are becoming obsolescent. Unfortunately, drugs in current use are still unselective in their actions and therapeutic benefit is often offset by serious toxicity, scarcely surprising given the wide range of actions of these drugs. This intolerance also reflects the long periods of administration and, quite possibly, the abnormal susceptibility of these patients to side-effects.

The great variability in the natural history of rheumatic diseases compounds the difficulties. For example the prognosis in early rheumatoid arthritis is still so imprecise that it is impossible to say whether an individual patient will enjoy early remission or will suffer inexorable disease progression of such severity that vigorous early treatment is justified. The chronicity of most rheumatic diseases poses further dilemmas; 2 years is long enough to characterize the anti-inflammatory effects and short-term toxicity of a given drug in rheumatoid arthritis, but not to evaluate its long-term benefits and risks.

Ironically, the discipline of controlled trials has given important information about the relative value of different drugs in patient populations at the expense of studying individual variation. Pharmacokinetic and genetic factors ensure that drug efficacy and tolerance vary greatly in individual patients and assuredly these factors will assume greater importance in future studies.

The order in which the antirheumatic drugs is discussed reflects their current clinical importance.

Methotrexate

After an ephemeral appearance in rheumatological practice in the 1950s, methotrexate is now universally used to treat rheumatoid arthritis because of its rapid efficacy and low toxicity. The stage in the disease at which it should be introduced is still debated, but the trend is towards early treatment. This drug is also used in systemic connective tissue diseases including systemic lupus erythematosus and Wegener's granulomatosis (Sneller *et al*. 1995).

Pharmacology

Methotrexate is aminopterin, modified by the addition of a methyl group to position 10 of the 4-aminobenzoic acid portion. It is a folic acid antagonist and in high dosage inhibits thymidylate synthetase, thereby blocking DNA synthesis (Fig. 1). However, this is not necessarily its relevant action in the much lower doses employed in rheumatological practice. Its anti-inflammatory effects are probably more important, operating by the inhibition of aminoimidazocarboxamide transformylase and leukotriene B4 production (Furst 1994).

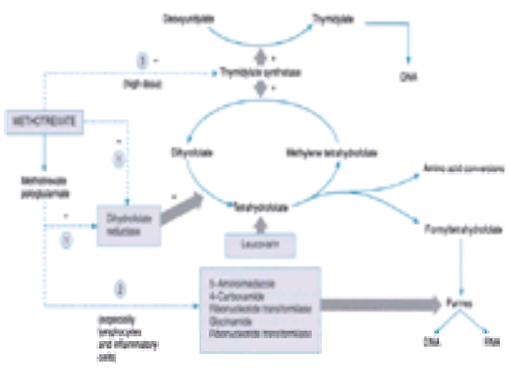

Fig. 1 Mechanism of action of methotrexate.

Since methotrexate structurally resembles pteroylglutamic (folic) acid, it is probably absorbed in the proximal jejunum. There is almost complete absorption, which is unaffected by food (Bannwarth *et al*. 1994). Bioavailability is high in doses in the range 5 to 10 mg/m ^{2} and with this dosage peak plasma concentrations are achieved as readily with oral as with parenteral administration. Subcutaneous injection is a more efficient way of sustaining high plasma levels than the intravenous route and has no disadvantages compared with intramuscular injection (Brooks *et al*. 1990). The drug is selectively concentrated in rheumatoid synovial effusions (Tishler *et al*. 1989).

Methotrexate is oxidized by aldehyde oxidase to its principal metabolite, 7-hydroxymethotrexate; both accumulate intracellularly in their polyglutamate form and have been detected in hepatocytes 1 year after drug administration. Methotrexate and its hydroxy metabolite are mainly excreted by the kidneys, but clearance of 7-hydroxymethotrexate is more prolonged. Thus methotrexate's effects are increased by impaired renal function.

Many drugs interact with methotrexate. While salicylates, most non-steroidal anti-inflammatory drugs, and sulphonamides have measurable effects on methotrexate phamacokinetics, these have not proved clinically relevant (Skeith *et al*. 1990) metabolism.

Therapeutically relevant effects (Table 1)

Table 1 Therapeutically relevant actions of methotrexate

Methotrexa. Nor has a combination of sulphonamides and methotrexate had the deleterious effects on bone marrow function predicted because of their theoretical synergistic effect on folatete affects *in vitro* and *in vivo* immune function and inflammatory reactions. Much of the experimental evidence is of dubious clinical relevance because of species differences and changes only noted with unrealistic drug doses. The most pertinent observations are those obtained by sequential observations in treated patients.

Methotrexate has proven anti-inflammatory effects. Granulocyte function is inhibited, judged by reduced chemotaxis, protease activity, leukotriene B4 production (Sperling *et al*. 1990), and superoxide radical generation (Al Balla *et al*. 1990). However, phospholipase A_2 activity is increased in peripheral blood cells of treated patients and particularly in platelets; there is some correlation with clinical efficacy (Michaels *et al*. 1994). There is also reduced granulocyte infiltration of psoriatic skin.

Methotrexate has some demonstrable immunosuppressive actions. Cell-mediated immunity is affected. A variable reduction in the numbers of circulating T cells has been reported (Wascher *et al*. 1994a); this variability is determined by drug dose and bioavailability. A reduction of blood g/ T cells has been noted in patients with juvenile chronic arthritis (Massa *et al*. 1993). However, the numbers of CD19+ T cells and activated CD25+ T cells are little changed (Lacki *et al*. 1994). Sequential synovial biopsies in treated patients showed a reduction in the numbers of infiltrating of CD4 T cells and HLA DR-positive cells (Balsa *et al*. 1993). Humoral immunity is also altered. Circulating B cell numbers are reduced (Wascher *et al*. 1994a). Rheumatoid factor titres are reduced (Spadaro *et al*. 1993) and IgA rheumatoid factor may be especially affected (Moore *et al*. 1994). Spontaneous production of rheumatoid factor by circulating B cells is also diminished (Alarcon *et al*. 1990). However,

these effects may be secondary to diminished disease activity.

Methotrexate has marginal effects on cytokine production. There is no correlation between clinical efficacy and changes in circulating cytokine levels (Kremer *et al*. 1995). Serum concentrations of interleukin 6 (**IL-6**) and tumour necrosis factor-a are unaffected by therapeutically effective doses in rheumatoid arthritis (Wascher *et al*. 1994b). It has rather unpredictable effects on the production of tumour necrosis factor-a and its soluble receptors (Barrera *et al*. 1994). It has some effects on cytokine production by peripheral blood cells and synovial cells *in vitro* including a reduction of IL-1 production, but there is no evidence that these effects are therapeutically relevant (Loetscher *et al*. 1994). Nevertheless, the expression of the gene encoding collagenase production is selectively depressed, an effect which has been attributed to an altered profile of cytokine production (Firestein *et al*. 1994).

Overall, there is little evidence that the demonstrable immunosuppressive effects of methotrexate are therapeutically relevant. Moreover, those effects which have been observed may be secondary to a reduction in disease activity through entirely different mechanisms. The most pertinent observation is that doses are commonly clinically effective which have no obvious effects on conventional markers of immune or inflammatory activity.

Clinical efficacy

Methotrexate is now an accepted drug for the treatment of rheumatoid arthritis in both hospital and community practice (Pincus *et al*. 1992). Joint inflammation is reduced and function improved in some 80 per cent of patients in the first 12 weeks of treatment and this improvement is maintained for up to 7 years in the majority of patients (Weinblatt *et al*. 1992). Controlled comparative trials have shown that methotrexate is as effective as sodium aurothiomalate and more effective than auranofin (Weinblatt *et al*. 1990). The drug is also perceived by patients to be highly effective (Tugwell *et al*. 1990). Controlled trials and assessment suggest that methotrexate may slow the appearance of radiologically detectable erosions, at least in the first 3 years of treatment (Jeurissen *et al*. 1991). There is now sufficient information about the long-term efficacy and safety of methotrexate to justify its early introduction in the treatment of rheumatoid arthritis (Furst 1994). Methotrexate may also be effective in counteracting some features of systemic lupus erythematosus and especially arthritis (Wilson and Abeles 1994), but the immunological abnormalities are not obviously affected. Controlled trials are still lacking.

Treatment regimens

Oral administration at weekly intervals is now standard treatment. There is no formally established dose schedule and clinical response and drug tolerance in individual patients are the best guidelines. The starting dose should be 5.0 mg with 2.5 mg increments at 2-monthly intervals to a maintenance dose which usually need not exceed 12.5 mg weekly. Rarely patients need higher doses of up to 20.0 mg weekly, in which circumstances closer monitoring is mandatory. A good response to higher intravenous doses has been reported in resistant disease (Gabriel *et al*. 1990). Higher doses are also not uncommonly necessary in paediatric practice. The clinical response is also the best guide to maintenance therapy. Furthermore, flares are difficult to predict from disease features in individual patients. Some patients with stable disease can be maintained on fortnightly doses (Kremer *et al*. 1995).

For use in paediatrics, see Chapter 5.6.3.

Adverse effects (Table 2)

Table 2 Adverse effects of methotrexate

With accepted dose regimens the incidence of adverse reactions necessitating drug withdrawal does not exceed 20 per cent in the first 5 years of treatment (Felson *et al*. 1990; Wolfe *et al*. 1990; Singh *et al*. 1991). Toxicity is more common in patients with impaired renal function (McKendry and Cyr 1989) and there are hints that toxicity has an immunogenetic basis (Tishler *et al*. 1988a).

Minor liver abnormalities are commonly revealed by serial blood tests and still more frequently by routine liver biopsies, but these changes are not an indication for stopping treatment and significant, irreversible damage is rare. Concomitant treatment with non-steroidal anti-inflammatory drugs increases the frequency of abnormal liver function tests, but these rarely prevent their continued, judicious use (Fries *et al*. 1993). Similarly, earlier strictures against the combined use of methotrexate and sulphonamides on pharmacokinetic grounds have been refuted (Haagsma *et al*. 1994; Nisar *et al*. 1994); clinically this combination is well tolerated. The rapid development of multiple subcutaneous nodules is a well-documented feature of patients receiving this agent (DiFrancesco *et al*. 1994).

Opportunistic infections have been reported in patients taking methotrexate. Infection by *Pneumocystis carinii* is a point of particular concern (Wollner *et al*. 1991). However, the patients were suffering from diseases associated with impaired immunity so that the contribution of methotrexate treatment is uncertain. The oncogenic risks of long-term treatment are unknown (Shiroky *et al*. 1991). Continued surveillance is essential as the numbers of patients exposed to this agent over a period of many years increases. Isolated reports of lymphomas in patients exposed to methotrexate in combination with other drugs emphasize this need (Ferraccioli *et al*. 1995).

Contrary to theoretical expectations, folic acid supplements do not reduce methotrexate's efficacy but do decrease the incidence of some adverse side-effects, notably gastrointestinal intolerance (Buckley *et al*. 1990; Morgan *et al*. 1990). It has not been established that folic acid administration prevents bone marrow suppression but serial measurements of red cell volume suggest this possibility (Weinblatt and Fraser 1989). It is now common practice to give a single oral dose of 10.0 mg of folic acid 24 h after methotrexate. In paediatric practice, a daily dose of 1.0 mg is often used to prevent nausea and the risk of bone marrow suppression.

Patient monitoring

A full blood count, serum creatinine level, chest radiograph, and liver function tests should be obtained before starting treatment. The latter should include at least serum concentrations of albumin, aspartate aminotransferase, and bilirubin. Antibodies to hepatitis B and C viruses should be sought if there is any clinical suspicion of infection by these agents. Liver biopsy is not indicated unless there is pre-existing liver disease (Kremer *et al*. 1994). Blood counts and liver function should be checked at monthly intervals for the first 3 months and an initial chest radiograph is mandatory. Thereafter 3-monthly checks are adequate in most patients. Routine liver biopsies are unnecessary and need only be performed if the cause of liver abnormalities in treated patients is in doubt. In patients with gradual increases in the blood levels of liver enzymes or alkaline phosphatase, it is usually possible to continue at a lower dose either immediately or after an intermission. Pneumonitis necessitates permanent drug withdrawal. Renal function should be monitored with particular care in patients with concomitant renal disease or who are receiving potentially nephrotoxic drugs (Seideman *et al*. 1993). In addition, impaired renal function increase the risk of toxicity (Rheumatoid Arthritis Clinical Trial Archive Group 1995).

Symptomatic discomfort such as mouth ulceration or diarrhoea may necessitate temporary withdrawal of treatment or a reduction in dose. Daily doses of folic acid (10.0 mg) may reduce the severity of symptoms. The major issue usually concerns deteriorating liver function.

Corticosteroids

The discovery of the dramatic anti-inflammatory effects of corticosteroids in the rheumatic diseases is part of medical history and has generated its own literature. The implications for current rheumatological practice are still debated. However, many pertinent questions remain unanswered.

Therapeutically relevant actions

The principal glucocorticoid hormone of the human adrenal cortex is cortisol (hydrocortisone), derived from cortisone. In common with other steroid hormones, cortisol has a basic structure of four carbon rings; the two hydroxyl groups, 11b and 17a, are important for glucocorticoid activity. Synthetic steroids are cortisol derivatives designed to increase glucocorticoid and reduce mineralocorticoid activity (Table 3). It is clearly desirable to modify the structure further so as to retain or increase the anti-inflammatory effects of these compounds at the expense of the therapeutically irrelevant or harmful actions of glucocorticoids. Deflazecort, an oxazoline analogue of prednisone, is one such compound (Gray *et al*. 1991).

Drug	Equivalent dose (mg)	Duration of action (h)
Cortisol	25	8–12
Cortisone	20	8–12
Prednisone	5	12–36
Methylprednisolone	4	12–36
Triamcinolone	4	12–36
Dexamethasone	0.75	36–72
Betamethasone	0.60	36–72

Table 3 Commonly used glucocorticoids

Free cortisol and its analogues diffuse into cells and bind to specific 95-kDa, phosphorylated protein receptors. The steroid–receptor complex moves to the nucleus where it binds reversibly to specific regulatory DNA sequences, thereby increasing or decreasing the transcription rate of adjacent genes. This in turn alters the rate of protein synthesis. In addition to these direct effects, cortisol increases the synthesis of lipocortin, which inhibits the proinflammatory enzyme phospholipase A_2 (George and Kirwan 1990). Recent evidence also suggests that steroids may interfere with cytokine-inducing transcription factors (Scheinman *et al*. 1995).

As a result, corticosteroids affect the synthesis of most major immunological and inflammatory mechanisms contributing to the pathogenesis of the rheumatic diseases (Table 4). Unfortunately, *in vitro* systems for studying these effects almost invariably discount the importance of *in vivo* regulatory pathways. Furthermore, the complexity of *in vivo* events makes it difficult to determine the relative importance of these effects. On current knowledge, it is best to attribute the therapeutic efficacy of corticosteroids to a combination of these effects.

Table 4 Therapeutically relevant actions of corticosteroids

Although synthetic steroids have enhanced glucocorticoid effects, it is difficult to see how further selectivity can be achieved by devising analogues with greater specificity in terms of target cells or therapeutically relevant actions. The only strategy currently available is to complement or replace corticosteroids with other immunosuppressive agents. Further progress depends on a better definition of the therapeutically relevant effects of corticosteroids and other immunosuppressive agents.

Indications for corticosteroid therapy

There are three main categories of rheumatic disorder in which systemic corticosteroid treatment is justified.

Systemic connective tissue diseases

The potential morbidity or mortality of many connective tissue diseases justifies corticosteroid treatment. Pertinent examples are systemic lupus erythematosus and dermatomyositis (see Section 5.7 and Section 5.9). However, the merits of other immunosuppressive drugs complicate therapeutic decisions even in these traditionally uncontroversial situations. Polyarteritis nodosa illustrates the currently contentious issues, since there is still a dearth of controlled trials indicating whether corticosteroids should complement treatment with cytotoxic drugs or be omitted entirely (see Section 5.11).

Polymyalgia rheumatica

Systemic corticosteroid treatment is still the only effective means of controlling this common disorder (see Chapter 5.11.5).

Rheumatoid arthritis

Corticosteroids now occupy an intermediate place between the euphoria which greeted their introduction and the opprobrium which followed the disclosure of gross hypercortisonism. The rehabilitation of systemic corticosteroid treatment has been aided by a truer definition of the hazards of continued treatment with non-steroidal anti-inflammatory drugs and dependence on more conservative dose regimens. Moreover, even after energetic treatment, the long-term outlook for severe rheumatoid arthritis is worse than was previously appreciated. The influence of judicious corticosteroid treatment on this progression is unknown and justifies the recent re-evaluation.

Corticosteroids are commonly used in patients over 60 years of age with rheumatoid arthritis in whom there is concern over the gastrointestinal side-effects of non-steroidal anti-inflammatory drugs and particularly the risk of haemorrhage (Schaardenburg *et al*. 1995).

Corticosteroids are also prescribed to induce a rapid remission while other drugs are taking effect. This may be given in conventional daily oral dosage, as a pulsed

oral high dose, by intramuscular injection (usually as triamcinolone acetonide), or as pulsed intravenous methylprednisolone. However, there is a risk of rebound disease activity once the steroids are withdrawn (Van Gestel *et al*. 1995).

Early corticosteroid treatment in rheumatoid arthritis has also been advocated on the grounds that this reduces the incidence of joint erosions in the first 2 years of disease activity (Kirwan *et al*. 1995). However, this is too short a period in which to judge the long-term benefits and hazards of this approach.

Adverse effects (Table 5)

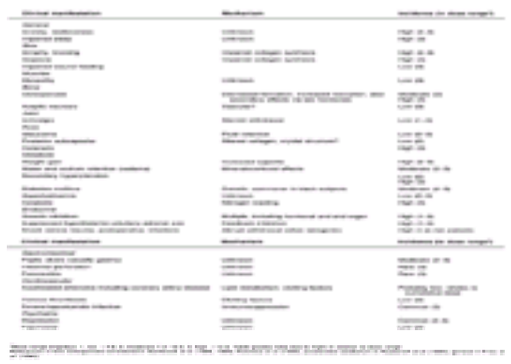

Table 5 Adverse effects of corticosteroids

The dose-related metabolic effects of systemic corticosteroid treatment have inevitable adverse consequences. The clinical manifestations depend on daily dose, duration of treatment, and genetic factors. Side-effects determined by hypersensitivity to corticosteroid analogues are rare.

Adverse effects can best be avoided by keeping maintenance doses as low as possible. Steroid treatment on alternate days is often tolerated by patients whose daily maintenance dose does not exceed 10 mg of prednisolone, but the only convincing reduction in side-effects achieved by this measure is a lower incidence of suppression of the hypothalamo–pituitary–adrenal axis.

Pulse treatment with high (1 g) or low (100 mg) doses of intravenous methylprednisolone or 1 g of oral prednisolone produce remissions of 4 to 6 weeks duration in rheumatoid arthritis. However, such approaches do not have proven short-term advantages over conventional treatment (Hansen *et al*. 1990) and there is little information about their ability to reduce the long-term adverse effects of maintenance corticosteroid treatment (Smith *et al*. 1990). Similarly, although pulse intravenous methylprednisolone is a helpful adjunct in rapidly controlling severe systemic lupus erythematosus, there is no evidence that the morbidity of maintenance corticosteroid treatment is diminished.

Sulphasalazine

Sulphasalazine was introduced in the 1930s as a rational means of treating diseases of possible infective aetiology (Svartz 1942), but it is now used pragmatically because of its established efficacy.

Pharmacology

Sulphasalazine (salicyl-azo-sulphapyridine, salazopyrine) is 5-aminosalicylic acid linked to sulphapyridine by a diazo bond. Less than 12 per cent of the intact drug is absorbed from the stomach and small intestine. It is split into its two components in the colon by bacterial action. Sulphapyridine is well absorbed and is acetylated in the liver, hydroxylated, or conjugated with glucuronic acid. The rate of acetylation is genetically determined but this does not influence efficacy or toxicity. The absorption of 5-aminosalicylic acid is poor.

Therapeutically relevant actions

Most investigational effort has centred on establishing a link between the proposed enteropathic aetiology of rheumatoid arthritis and the antibacterial effects of sulphasalazine or its moieties, but this issue is unresolved. The complete molecule and its components have different effects, which makes it difficult to identify the relevant actions. Both the parent drug and 5-aminosalicylic acid have anti-inflammatory actions by inhibiting random granulocyte mobility and chemotaxis *in vitro*; sulphapyridine has no such effects. In contrast, sulphasalazine and sulphapyridine but not 5-aminosalicylic acid inhibit *in vitro* activity of natural killer cells. Yet the parent molecule, but not its moieties, inhibits 15-hydroxydehydrogenase, thereby blocking prostaglandin inactivation by this enzyme (Porter and Capell 1990).

There are conflicting reports on the effects of sulphasalazine on immune responses. Sulphasalazine and its components have minor suppressive effects on *in vitro* lymphocyte responses to non-specific mitogens. Since the impaired *in vitro* reactivity of lymphocytes from some treated patients returns to normal with treatment, these effects might appear to have therapeutic relevance. However, the treatment dose of sulphasalazine does not affect serum concentrations of the soluble IL-2 receptor, indicating that the drug has little effect on lymphocyte activation *in vivo* (Crilly *et al*. 1993). Although the drug does not influence blood lymphocyte subpopulations, it reduces the numbers of CD3 and g/ T cells in the intestinal mucosa of treated patients (Kanerud *et al*. 1994).

Similarly, sulphasalazine suppresses B-cell activity *in vitro* (Imai *et al*. 1994), but earlier reports that it suppresses IgA production *in vivo* have not been substantiated (Jorgensen *et al*. 1993). The high incidence of IgA deficiency induced by this drug has led to speculation that immunoglobulin synthesis is more subtly affected in most recipients. Another possible effect of the drug on immunoglobulin synthesis has been proposed. There is evidence that sulphasalazine reverses the galactosylation defect in rheumatoid arthritis by suppressing autoantibodies which interfere with the enzyme galactosyltransferase in lymphocytes (Axford *et al*. 1992).

Therapeutic efficacy

Sulphasalazine reduces the intensity of rheumatoid synovitis, judged by accepted clinical and laboratory indices of disease activity. However, controlled trials show little functional improvement compared with placebo effects over a 2-year period of treatment (Capell *et al*. 1990) and 30 per cent at most benefit from long-term treatment (Porter *et al*. 1994). Hints that erosive changes may be blunted have not been confirmed.

Sulphasalazine has comparable anti-inflammatory effects in ankylosing spondylitis and its efficacy compared with placebo treatment has been confirmed in spondyloarthritis, particularly in association with psoriatic arthritis (Dougados *et al*. 1995).

Treatment regimens

The accepted regimen for instituting sulphasalazine treatment is to start with 500 mg daily, followed by weekly increases of 500 mg daily until a daily dose of 2 g is achieved after 4 weeks. Subsequent increases are dictated by tolerance and clinical response but there is no point in exceeding 40 mg/kg of body weight.

Since two-thirds of adverse effects occur within the first 3 months of treatment, clinical monitoring and blood counts are necessary at fortnightly intervals throughout this period. They should be continued at 3-monthly intervals thereafter unless there are grounds for concern. Immunoglobulins should be checked before starting treatment but need not subsequently be monitored routinely unless there is clinical suspicion of immunodeficiency.

Adverse effects (Table 6)

Reaction	Incidence (%)	Management
Discoloured urine	>50	Ignore
Oligospermia	70 (of males)	Reversible infertility Pretreatment counselling
Gastrointestinal (GI symptoms)	20	Symptomatic measures help, but 50% withdrawal
Increased mean corpuscular volume	72	No action needed
Macrocytosis	9	No action needed
Macrocytic anaemia	Rare	Rarely, headaches or haemolysis force withdrawal
Neutropenia	6	May tolerate lower dose, but 50% withdrawal
Rash (many forms from trivial to exfoliative)	5	High incidence in placebo-treated, but 50% withdrawal
Fever	2	Usually accompanies rash when significant
Stomatitis	2	Usually tolerated, may accompany severe rashes
Hepatitis	2	Withdrawal mandatory
Reduced immunoglobulin	10	Reversible
IgA deficiency	3	
Hypogammaglobulinaemia	1	

References in text.

Table 6 Adverse reactions to sulphasalazine therapy

Sulphasalazine is significantly toxic in at least 50 per cent of treated patients, forcing drug withdrawal in about 50 per cent of this number. Pre-existing sulphonamide hypersensitivity contraindicates treatment and deficiency of glucose 6-phosphate dehydrogenase enjoins extreme caution (Chalmers *et al*. 1990).

In general, these reactions are either toxic and largely dose related or attributable to hypersensitivity.

Toxicity

Orange-coloured urine is innocuous but gastrointestinal symptoms and dizziness are troublesome in up to 50 per cent of patients; symptomatic measures may avoid the need for dose reduction.

Reversible oligospermia with attendant infertility affects 70 per cent of treated males.

Red cell volumes rise in nearly 75 per cent of treated patients, amounting to frank macrocytosis in nearly 10 per cent (Farr *et al*. 1989). These changes are rarely attributable to overt folate deficiency.

Serum immunoglobulin concentrations are affected in some 10 per cent of patients; 3 per cent of treated patients develop selective IgA deficiency, 5 per cent low IgG levels, and 1 per cent panhypogammaglobulinaemia after 3 to 7 months of treatment. However, only the latter outcome is associated with a greatly increased risk of infection (Farr *et al*. 1991).

Hypersensitivity

The majority of hypersensitivity reactions can be countered by wariness and regular monitoring. Thus, while neutropenia is common and its onset often precipitous, fatal agranulocytosis is rare (Marabani *et al*. 1989). Similarly, biochemical tests often reveal evidence of asymptomatic hepatitis but clinically significant liver disease is unusual.

The overall rate of dropout for toxicity is some 20 per cent over 3 years (Felson *et al*. 1990). Concomitant steroid treatment reduces the incidence of adverse reactions (Gran and Myklebust 1993).

Immunosuppressive cytotoxic drugs

Cytotoxic drugs were introduced into rheumatological practice partly for their immunosuppressive actions and partly because of experimental evidence that they induce tolerance to specific antigens; it was reasoned that these agents would thereby restore tolerance to self-antigens in autoimmune diseases. They have indeed proved effective in rheumatoid arthritis and systemic connective tissue diseases either in isolation or as a means of reducing dependence on corticosteroids. However, it has not been established that their immunosuppressive properties account for the clinical improvement and non-specific anti-inflammatory actions may be more important. Certainly, there is no correlation between efficacy and measurable immunosuppression. The cytostatic and antiproliferative effects of cytotoxic drugs account for their therapeutic efficacy, but equally determine side-effects involving the inhibition of proliferating cells in bone marrow, gastrointestinal epithelium, and gonads. Cytotoxic drugs are also mutagenic, raising continued concern about their long-term oncogenic potential. Azathioprine is relatively safe and is still used extensively to treat rheumatoid arthritis and systemic connective tissue diseases. Alkylating agents are now reserved for life-threatening situations such as lupus nephritis and amyloidosis.

Azathioprine (Imuran)

Pharmacology

Azathioprine is a purine analogue which interferes with DNA synthesis. It is derived from 6-mercaptopurine by the addition of an imidazole group to the parent compound. The plasma half-life after oral administration is about 60 min. The drug is inactive until metabolized in liver and red cells by two pathways, one involving methylation of the sulphydryl group and later metabolites, the other oxidation of 6-mercaptopurine by xanthine oxidase.

Therapeutically relevant effects (Table 7)

Circulating lymphocyte count and subpopulation distribution	Slight non-selective fall
T cells	*In vivo* response to specific and non-specific stimuli not suppressed and may be enhanced Cytokine production unaffected Delayed hypersensitivity responses unaffected
B cells	*In vivo* response to non-specific stimulation not directly affected Minor fall in plasma immunoglobulin levels Little effect on primary and no effect on secondary antibody responses
Monocyte–macrophages	Arrival in inflammatory lesions depressed Cytokine production depressed
Natural killer cells	Circulating numbers and cytotoxicity depressed

Data relate to experiments in humans.

Table 7 In vivo immunosuppressive effects of azathioprine

The therapeutically relevant effects of azathioprine are those observed with conventional doses of 1.5 to 2.5 mg/kg of body weight. Azathioprine inhibits lymphocyte proliferation but does not affect resting lymphocytes. There is a modest, non-selective lymphopenia affecting T and B cells. Specific and non-specific *in vitro* responses of lymphocytes from treated patients are not significantly suppressed and cytokine production is also unaffected. Similarly, primary and secondary antibody responses to conventional antigens are resistant. In contrast to the unimpressive effects of azathioprine on classical immune responses, some activity of natural killer cells is inhibited (Cseuz and Panayi 1990). It is also likely that monocyte–macrophage accumulation in inflammatory lesions is blunted. Thus in the current state of knowledge, the clinical efficacy of azathioprine in inflammatory synovitis can reasonably be attributed to non-specific anti-inflammatory effects.

Therapeutic efficacy

Azathioprine is of proven benefit in rheumatoid arthritis and is as least as effective as gold and D-penicillamine. There is some indication that it limits the development of erosive changes; this protection may reflect the remarkably good, long-term tolerance of this drug enabling treatment to be continued for many years (De Silva and Hazleman 1981).

There are sufficient data from controlled studies to justify using azathioprine in patients with vasculitic diseases, polymyositis, or systemic lupus erythematosus whose disease is uncontrolled by tenable maintenance doses of corticosteroids. However, there is insufficient information about the relative benefits and disadvantages of this drug in comparison with other agents in well-documented, long-term studies. It is also unclear whether the outlook is improved by the early introduction of azathioprine or whether it should be reserved for patients with demonstrably steroid-resistant disease.

Treatment regimens

Azathioprine should not be used in a dose exceeding 2.5 mg/kg of body weight as there is no evidence that higher doses are more effective. If necessary, treatment can be continued indefinitely with appropriate monitoring.

Clinical wariness is essential in the early stages of treatment because of the risk of early intolerance masquerading as a disease flare. Monthly blood counts and liver function tests are essential. Temporary withdrawal is necessary if the neutrophil count falls below 2.5×10^{6}/l or the platelet count below 80×10^{9}/l. Treatment can usually be resumed in lower dosage once the count has recovered.

Adverse effects (Table 8)

Reaction	Incidence (%)	Management
Gastrointestinal		
Nausea	15	Many gastrointestinal symptoms controllable by drugs; often force withdrawal
Vomiting	10	
Abdominal pain	8	
Diarrhoea	5	
Mucosal ulcers	3	May remit on lower dose
Abnormal liver function	<1	May remit on lower dose
Skin		May remit on lower dose
Pruritis	2	
Rash	2	
Haematological		
Neutropenia	<1	Withdrawal; may tolerate lower dose
Thrombocytopenia	Rare	
Aplasia	Rare	Withdrawal
Acute hypersensitivity (Fever, rash, pain, often hepatotoxicity)	1	Can occur rapidly, may be confused with features of primary disease; withdrawal mandatory
Oncogenic	Slight increase	Counselling before starting treatment

Figures vary in different series. Those given are calculated on incidence in major published series.

Table 8 Adverse reactions to azathioprine

Adverse effects compel drug withdrawal in up to 30 per cent of patients in the first 6 months of treatment, but thereafter azathioprine is well tolerated (Singh I>et al. 1991). However, it is likely that this figure has subsequently been reduced owing to greater familiarity with this drug in rheumatological practice. This level of tolerance is impressive if one takes account of the disease severity and exposure to multiple drugs of patients receiving azathioprine and other cytotoxic drugs. Hypersensitivity reactions in the form of fevers, rash, and hepatotoxicity occur not uncommonly, often after only a few days of treatment (Jeurissen *et al*. 1990; Wijnands *et al*. 1990b). Gastrointestinal intolerance is common but can usually be overcome by appropriate symptomatic treatment.

Haematological problems are encountered more frequently in the elderly, in whom particular caution is essential because of the risk of marrow aplasia. Neutropenia and thrombocytopenia are usually ephemeral (Jeurissen *et al*. 1988). Macrocytosis is common and is not related to folate or vitamin B_{12} deficiency; it is not a reason for drug withdrawal.

Concern about the oncogenic potential of azathioprine has been largely assuaged in non-transplanted patients. Either no effect can be detected (Singh *et al*. 1989) or the incidence of lymphomas and related tumours is only marginally greater than that associated with rheumatoid arthritis itself (Silman *et al*. 1988).

Alkylating agents

The alkylating agents cyclophosphamide and chlorambucil (Fig. 2) have been used since the 1960s to treat immune disorders and in particular those which have proved resistant to other drugs. They have potent anti-inflammatory and immunosuppressive actions but also major adverse effects (Denman *et al*. 1992).

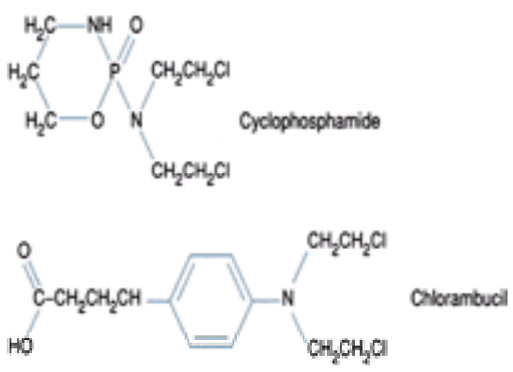

Fig. 2 Structure of alkylating agents.

Pharmacology

Alkylating agents bind covalently through their alkyl groups to other molecules, including phosphate, carboxyl, amino, sulphydryl, and imidazole groups. Binding to purine bases damages the DNA strand and interferes with mitosis and cell proliferation. The 7-nitrogen atom of guanine is particularly susceptible to covalent bonding and may be the most important target for these drugs. Damage to the DNA strand affects mitosis, thereby inhibiting cell division. However, these effects may be mutagenic rather than cytotoxic, creating long-term oncogenic risks (Lawley 1990). The damage to lymphocytes and other proinflammatory cells is immunosuppressive. In addition, the oxazaphosphorine cyclophosphamide is bifunctional (i.e. it has two active groups) so that covalent cross-linking of DNA prevents strand separation during mitosis.

Cyclophosphamide is absorbed rapidly but incompletely from the gut, with great individual variability. Maximum plasma concentrations of 1 to 2 µg/ml are reached some 2 h after an oral dose of 2 to 3 mg/kg. These levels reach 40 to 50 µg/ml after intravenous administration of larger doses (25 mg/kg). There is marked individual variation in plasma half-life irrespective of the means of administration.

Cyclophosphamide itself has neither alkylating nor cytotoxic activity but many of its metabolites possess these properties (Fig. 3). Less than 20 per cent is excreted unchanged by the kidney and the remainder is metabolized by liver microsomes. The initial oxidation product, 4-hydroxycyclophosphamide, is highly cytotoxic but also

unstable; it may also serve as a carrier molecule for transporting the final metabolite, phosphoramide mustard, across cell membranes. Renal excretion of the cytotoxic metabolites carboxyphosphamide and 4-ketocyclophosphamide accounts for some 65 per cent of the initial compound and is greatly slowed when renal function is impaired. Of clinical relevance, the intravenous administration of cyclophosphamide in high dose induces activating enzymes, which increase the rate of drug clearance and also peak plasma concentrations of its cytotoxic metabolites.

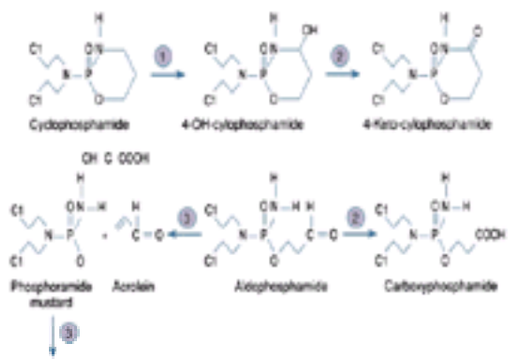

Fig. 3 Metabolic pathways of cyclophosphamide.

Therapeutically relevant effects (Table 9)

Blood lymphocytes	Non-selective lymphopenia, affecting all subpopulations; cytotoxic for resting lymphocytes and antiproliferative; marked fall after high oral dose, or pulse intravenous administration
T cells	*Suppresses:* *In vitro* activation and proliferation in response to specific and non-specific stimuli *In vitro* cytotoxicity Helper function for B cells Delayed hypersensitivity responses, if given in high or pulse dosage
B cells	Initially more sensitive than T cells *Suppresses:* *In vitro* immunoglobulin synthesis, spontaneous and induced Spontaneous *in vitro* IgM rheumatoid factor synthesis Serum immunoglobulin levels, especially with continued high dose, or pulse treatment Primary, but not secondary antibody responses to conventional antigens Autoantibody production
Monocyte–macrophages	Reduced proteolytic enzyme secretion Reduced cytokine production
Natural killer cells	Production and cytotoxicity variably affected, depending on dose

References in text, reviewed in Zeiniger *et al.* (1992).
(Only in vivo effects are considered; cyclophosphamide itself is inactive.
(Effects of chlorambucil and cyclophosphamide are similar but the latter is more effective, especially in high dose.

Table 9 Therapeutically relevant actions of alkylating agents

Alkylating agents have immunosuppressive effects of probable therapeutic importance. However, many reported observations are of dubious relevance because of species differences or contrived experimental design. For example, there is no convincing evidence that cyclophosphamide perturbs human immune responses by stimulating suppressor T-cell activity. Nor is there any data to suggest that it induces tolerance to autoantigens in a manner analogous to tolerance induced in animals to protein antigens by the correct timing of drug administration in relation to immunization.

Cyclophosphamide and chlorambucil reduce the numbers of circulating T and B lymphocytes in an essentially non-selective manner with some hint that CD4+ T cells are especially vulnerable. Primary antibody responses to test antigens are suppressed, but established antibody responses are unaffected by low-dose cyclophosphamide (0.5 to 1.0 mg/kg of body weight per day) and only slightly suppressed by higher doses given orally or as intravenous pulses. Autoantibody titres and polyclonal hypergammaglobulinaemia are reduced, but it is unclear whether these changes result from direct effects on B cells or a reduction in disease activity by other mechanisms. The activities of circulating T cells and other cells of treated patients, such as cytokine production and *in vitro* proliferation, are inconsistently affected.

Clinical efficacy

Recourse to alkylating agents is rarely justified in the treatment of rheumatoid arthritis. Their use is defensible in patients with severe systemic disease, but even in this context, there is still a lack of long-term trials comparing the benefits and risks of these drugs with those of other agents. Cyclophosphamide is of proven value in treating the nephritis and other systemic features of systemic lupus erythematosus, but the extent to which it should replace or supplement corticosteroids is controversial. Comparative data are also lacking on the relative efficacy of cyclophosphamide and newer immunosuppressive regimens. Uncontrolled experience suggests that it is more effective than corticosteroids in treating vasculitic disorders, but this has not been formally proven in comparison with other immunosuppressive agents.

Chlorambucil is established treatment for amyloidosis complicating juvenile chronic arthritis. It is now rarely necessary to use this agent in preference to azathioprine or cyclosporin to treat Behçet's syndrome and, in particular, uveitis complicating this disease.

Treatment regimens

Chlorambucil is usually given daily by mouth. The conventional starting dose is 0.1 mg/kg of body weight and subsequent doses should rarely exceed 0.2 mg/kg of body weight.

Cyclophosphamide is most commonly given orally in an initial daily dose range of 1.5 to 2.5 mg/kg of body weight. Higher, intermittent doses are often given intravenously for severe disease, but in this, as in so many situations, practice is dictated as much by local preferences as by the persuasiveness of collated data. However, there are claims that high-dose pulses of cyclophosphamide synchronized with plasma exchange can induce remissions in systemic lupus erythematosus (Euler *et al.* 1994). This is another situation in which there are unproven claims that earlier, more vigorous treatment is more effective than conventional protocols.

Clinical response and toxicity are the only guides to maintenance doses. Blood lymphocyte counts are a poor indication of efficacy or toxicity, while more sophisticated analyses of immune function have not yet proved of practical value.

Neutropenia and thrombocytopenia enforce the measures described for azathioprine treatment.

Adverse effects (Table 10)

Reaction	Incidence (%)	Management
Reproduction		
Male sterility	Virtually 100	Counselling patient or parents mandatory
Female sterility	Incomplete data, probably < 30	More data needed
Amenorrhoea	30	Hormone replacement for premature menopause unless contraindicated
Gastrointestinal		
Nausea	10	Usually responds to symptomatic measures
Vomiting	5	
Alopecia	< 1	Uncommon in dosage used in rheumatological practice
Bladder	<5	Uncommon in low oral or pulse intravenous treatment; mesna is good renal output
Infections	8	Rarely a reason for withdrawal
Haematological		
Macrocytosis	80	Not a reason for withdrawal
Neutropenia	5	Temporary withdrawal; risk of pancytopenia underestimated?
Thrombocytopenia	< 1 ?	
Pancytopenia	< 1 ?	
Lung	Rare	Withdrawal
Neoplasia	Probably justified risk/use	Keep cumulative dose to minimum
		Protect health workers exposed to drugs

References in text; see also discussion of risks of neoplasia (Fairweather *et al*. 1988), bladder complications (Stillwell *et al*. 1988), and infections (Dooley *et al*. 1990).

Table 10 Adverse actions of alkylating agents

A full explanation of the risks of treatment is even more essential before starting treatment with alkylating agents than with other antirheumatic drugs. Alkylating agents are inevitably mutagenic and clinically apparent toxicity underestimates the true extent of this process. Alopecia, stomatitis, and gastrointestinal intolerance are rarely a major problem in the doses used in rheumatological practice. Bone marrow suppression is common but almost always reversible if the drug dose is adjusted at the first sign of marrow toxicity. It is often possible to continue with a lower dose after a period of intermission. Patients with connective tissue diseases may be abnormally susceptible to bone marrow suppression (Thomas *et al*. 1983) so that especial wariness is essential. Marrow aplasia may ensue if warning evidence is ignored and may be slow to recover. Conversely, macrocytosis is very common and does not presage marrow toxicity; nor is it necessarily a marker of folate or vitamin B_{12} deficiency. It is also important to take account of low blood counts consequent on disease activity, which often improve with the response to drug treatment.

Intercurrent infections of unusual severity or by opportunistic infections are also encountered but these are not common in the dosage used in rheumatic disorders. Reversal of the immunosuppression accompanying disease may even reduce the risk of intercurrent infection.

Male sterility is almost inevitable after even low doses of alkylating agents. Amenorrhoea and sterility in females are less predictable but may still affect up to 30 per cent of those at risk (Schilsky *et al*. 1980), and serum gonadotrophin levels rise significantly after 2 months of treatment. Accurate long-term data on female fertility after treatment in childhood for rheumatic disorders are lacking.

Bladder toxicity is not usually encountered with pulsed intravenous cyclophosphamide which in general does not exceed a dose of 15 mg/kg of body weight per month. It is sufficient to ensure a good renal output thereby obviating the need for mesna. However, haematuria and aseptic cystitis are encountered in some 10 per cent of patients receiving oral cyclophosphamide for periods exceeding 12 months.

The oncogenic effects of alkylating agents are hard to assess. A long-term study has shown a small but definite increase in skin cancer and myeloproliferative diseases induced by these agents (Kinlen 1985). However, sporadic reports of unusual neoplastic diseases and bladder cancer induced by relatively short courses of cyclophosphamide suggest that the true incidence of cancer induced by alkylating agents may have been underestimated (Denman *et al*. 1992). This is especially likely to be true of bladder cancer in patients treated with long-term cyclophosphamide for lupus nephritis.

Cyclosporin

The immunosuppressive properties of cyclosporin were established in experimental and clinical transplantation. After a long period of uncontrolled observations in autoimmune diseases, its therapeutic efficacy has now been validated in controlled trials, especially in rheumatoid arthritis and uveitis. Much of the initial concern about its nephrotoxic hazards arose when high doses were employed in renal transplantation. These fears have been allayed by the low incidence of nephrotoxicity with the dose schedule used to treat autoimmune diseases; this nephrotoxicity is almost invariably reversible.

Pharmacology

Cyclosporin is a cyclic peptide derived from a fungus. Several of the amino acids are *N*-methylated and uncommon amino acids occupy the first two places in the sequence. It is usually given orally although it can also be administered by intramuscular or intravenous injection. The proven immunosuppressive dose range in clinical transplantation is 10 to 20 mg/kg of body weight per day, which produces plasma concentrations of 100 to 400 ng/ml with a half-life of 17 to 40 h. Cyclosporin is metabolized primarily in the liver and is excreted mainly via the gut; only a small fraction is recovered in the urine as the parent drug or its metabolites. The protein cyclophilin (molecular weight 17.8×10^3) is the major intracellular receptor for the agent and this binding is crucial for the drug's immunosuppressive effects. Cyclophilin consists of a single polypeptide chain with 165 residues whose structure and binding site for cyclosporin have been characterized (Braun *et al*. 1995). The complex formed between cyclosporin and cyclophilin interacts with the serine/threonine phosphatase calcineurin. This trimolecular complex interferes with factors governing the transcription of interleukin coding genes and other steps in the activation of lymphocytes and antigen-presenting cells. There is probably a family of cytophilins. A different cytophilin binds the immunosuppressive agent FK506.

Therapeutically relevant effects (Table 11)

Antigen-presenting cells (dendritic and macrophages)	*In vitro* depresses: Antigen presentation Class II molecule expression
T cells	*In vitro* depresses: Activation Proliferation Cytokine production (especially interleukin 2) Helper function and cytotoxicity *In vivo* restores: Impaired proliferative responses to *in vitro* mitogens Defective interleukin 2 receptor expression (secondary to disease activity) Impaired delayed hypersensitivity reactions No evidence that tolerance affected
B cells	*In vitro* depresses: Mitogen-induced immunoglobulin synthesis *In vivo*: Autoantibody production suppressed probably secondary to reduced disease activity

Table 11 Therapeutically relevant actions of cyclosporin A

Cyclosporin has many actions of which depressed T-cell activation is currently considered to be the most therapeutically relevant (Yocum *et al*. 1990; Yocum 1993). The problem is comparable with that posed by corticosteroids; it is not yet clear whether its efficacy in clinical immunosuppression results from a few crucially important actions or from a combination of these actions. Furthermore, the rapid relapses observed in many patients when the drug is withdrawn suggest that ephemeral anti-inflammatory effects are at least as important as T-cell suppression; the latter would be expected to be longer lasting, particularly if tolerance induction was involved. Clinical remission in rheumatoid arthritis is associated with improved *in vitro* lymphocyte responsiveness to standard antigens and reduced numbers of circulating cells expressing IL-2 receptors, findings which are as likely to reflect reduced disease activity as direct suppressive effects on T cells. Cyclosporin has little effect on conventional markers of the acute-phase response even when inflammatory activity is reduced, judged by clinical criteria.

Clinical efficacy

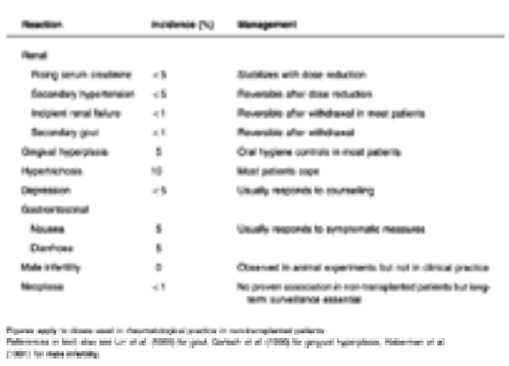
In controlled trials, cyclosporin has been shown to be effective in the treatment of severe rheumatoid arthritis in terms of reducing clinical markers of joint

inflammation. However, it has little effect on the acute-phase response and its ability to influence cartilage degradation is unproven (Dijkmans *et al*. 1993). A controlled trial has shown that cyclosporin in combination with methotrexate is more effective in the treatment of the disease than methotrexate alone (Tugwell *et al*. 1995). However, periods of follow-up have been short. So far the drug has mainly been reserved for patients whose disease has been resistant to other drug treatment. There are many uncontrolled reports of cyclosporin's efficacy in systemic autoimmune diseases. For example, anti-inflammatory activity has been shown in a short, 20-week trial of treatment in systemic lupus erythematosus (Tokuda *et al*. 1994). Its value in such situations in comparison with more conventional drug treatment has still to be established. Even in Behçet's uveitis where its short-term benefit has been proven in controlled trials, its long-term ability to suppress late disease features has not yet been demonstrated.

Treatment regimens

It is evident from controlled trials that a clinical response can be obtained and toxicity minimized if the dose of cyclosporin is kept in the range of 2.5 to 5.0 mg/kg of body weight. Renal function should be assessed before starting treatment. Blood pressure and serum creatinine should be checked at intervals of not more than 2 months. The drug should be stopped if a rising creatinine concentration or hypertension are noted, but it is often possible to resume treatment at a lower dose. For routine clinical purposes it is unnecessary to monitor blood levels of cyclosporin.

Adverse effects (Table 12)



Reaction	Incidence (%)	Management
Renal		
Rising serum creatinine	<5	Stabilizes with dose reduction
Secondary hypertension	<5	Reversible after dose reduction
Incipient renal failure	<1	Reversible after withdrawal in most patients
Secondary gout	<1	Reversible after withdrawal
Gingival hyperplasia	5	Oral hygiene controls in most patients
Hypertrichosis	10	Most patients cope
Depression	<5	Usually responds to counselling
Gastrointestinal		
Nausea	5	Usually responds to symptomatic measures
Diarrhoea	5	
Male infertility	0	Observed in animal experiments but not in clinical practice
Neoplasia	<1	No proven association in non-transplanted patients but long-term surveillance essential

Figures apply to doses used in rheumatological practice in non-transplanted patients
References in text, also see Lin et al. (2000) for gout, Gerlach et al. (1998) for gingival hyperplasia, Habermann et al. (1991) for male infertility

Table 12 Adverse actions of cyclosporin

Most of cyclosporin's adverse effects are symptomatically troublesome but do not threaten the function of vital systems. With low-dose treatment, serum creatinine concentrations do not rise significantly in the majority of patients (Landewe *et al*. 1994). Creatinine levels often stabilize with dose reduction thereby allowing treatment to be continued. Furthermore, they almost invariably return to normal once the drug has been withdrawn (Boers *et al*. 1990). The experience has been similar in large numbers of patients with psoriasis. Any associated hypertension also remits after drug withdrawal.

The impaired renal function is likely to result from reversible constriction of renal arterioles (Yougelman *et al*. 1991); this constriction may be in part secondary to selectively increased plasma concentrations of the thromboxane metabolite, 2,3-dinor thromboxane B_2 (Weinblatt *et al*. 1991). Glomerular filtration and urea excretion are also depressed (Laskow *et al*. 1990). There has also been great interest in renal interstitial fibrosis induced by cyclosporin, which may result from the enhanced transcription of procollagen coding genes (Nast *et al*. 1991). However, irreversible histological changes have been observed mainly in transplant recipients and are hard to interpret because of coexisting abnormalities associated with transplantation.

Chloroquine and hydroxychloroquine

Chloroquine and hydroxychloroquine have been used extensively to treat rheumatoid arthritis and systemic lupus erythematosus since 1943. These agents have demonstrable immunosuppressive effects *in vitro* of which the most impressive are depressed lymphocyte proliferation in response to stimulation by antigens or non-specific mitogens. This suppression is attributable to impaired antigen presentation by specialized cells, but has been analysed only in descriptive and not contemporary molecular terms. Since hydroxychloroquine is far less likely to cause retinal toxicity than chloroquine, it is more commonly used.

Pharmacology

Hydroxychloroquine and chloroquine are slowly absorbed from the upper gastrointestinal tract and a very high percentage of the drug (99.9 per cent) becomes tissue associated, with selective concentration in the liver, spleen, and heart.. These drugs bind especially avidly to melanin, a partial but incomplete explanation for their marked affinity for the iris, choroid, and skin. Drug concentration in blood white cells is also notably high. There is a delay of 3 to 4 months before steady-state plasma concentrations are reached and an equally slow fall when the drug is discontinued; excretion continues for months or even years (Tett *et al*. 1990).

Therapeutically relevant effects

Hydroxychloroquine is anti-inflammatory, primarily because it reduces the secretion of lysosomal enzymes by granulocytes and macrophages in response to stimuli such as immune complexes. It is also immunosuppressive *in vitro*, inhibiting T and B lymphocyte responses to non-specific mitogens (Van Loenen *et al*. 1990), but there is little evidence that it is immunosuppressive *in vivo* in conventional dosage. There is an intriguing suggestion that it increases pain thresholds through its effects on neurotransmitters (Middleton *et al*. 1995).

Therapeutic efficacy

Hydroxychloroquine and chloroquine measurably reduce disease activity in early rheumatoid arthritis (Tenorio and Orozco 1993; HERA Study Group 1995). However, it was not much more effective than the placebo in many reported trials (Nuver-Zwart *et al*. 1989). In terms of comparative efficacy, hydroxychloroquine is less effective than sulphasalazine judged objectively by clinicians or subjectively by patients. Any blunting of erosive changes is marginal (Van der Heijde *et al*. 1989).

Chloroquine and hydroxychloroquine are commonly used to treat systemic lupus erythematosus with the object of avoiding steroid treatment. There are uncontrolled claims that it suppresses fever, arthritis, and skin lesions, with an accompanying reduction in erythrocyte sedimentation rate and autoantibody titres. However, in a placebo-controlled trial only the joint manifestations responded (Williams *et al*. 1994). It is ineffective in combating more severe manifestations such as lupus nephritis. There is a suggestion that concomitant treatment with antimalarials may protect patients from the adverse effects of steroids on fat metabolism (Hodis *et al*. 1993).

Treatment regimens

Hydroxychloroquine is less likely than chloroquine to cause retinopathy and is therefore the more logical choice. There is good evidence that 200 mg daily is as effective as higher doses (Pavelka *et al*. 1989). Fear of ocular complications commonly restricts the duration of treatment, but the drug may be continued indefinitely with proper precautions (Carmichael 1992).

Adverse effects

Retinopathy is the complication of greatest concern because it may lead to progressive blindness. Corneal deposits disappear once the drug is stopped and are unrelated to retinal changes. A premaculopathy leads to the development of field loss to a red target between 4 and 9 degrees from fixation. The macular changes at this stage may be minimal and the visual fields may return to normal once the drug is stopped. If unchecked, the maculopathy will lead to a central, irreversible scotoma. However, this problem is hardly ever encountered in patients treated with hydroxychloroquine. It is particularly unlikely to cause ocular toxicity if the daily

dose does not exceed 6.5 mg/kg of lean body weight per day or a cumulative dose of 200 g. The eyes should be checked before starting treatment so as to establish a clinical baseline. The corrected visual acuity should be recorded, the fundi examined, and the central visual fields plotted. If any abnormalities are noted, the patient will require continued ophthalmological supervision. Patients should be warned that the drug may affect their vision and ideally they should be given a red Amsler chart with appropriate instruction on its use so that they can check their vision monthly. Any patient who notices any visual abnormality should stop the drug and obtain advice at once. An annual ophthalmological examination is not usually necessary. The prescribing physician should check vision with a red Amsler chart if any patient is unlikely to follow advice. The incidence of ocular problems necessitating drug withdrawal is now less than 1 per cent (Felson *et al*. 1990).

Gastrointestinal intolerance occurs in 10 per cent of patients and may be overlooked because of its insidious onset. It responds poorly to antacids and related drugs and is the commonest reason for premature withdrawal. Rashes appear in less than 1 per cent of patients; the drug does not cause increased photosensitivity (Seideman and Ros 1992). Hydroxychloroquine improves glucose tolerance and reduces serum cholesterol levels, changes with potential long-term but as yet uncalculated benefit (Wallace *et al*. 1990). Thrombocytopenia and other forms of bone marrow suppression are rare (Wijnands *et al*. 1990a). Toxicity overall does not exceed 20 per cent (Felson *et al*. 1990) but the drug is withdrawn in a far higher percentage of patients because of lack of efficacy (Wolfe *et al*. 1990).

D-Penicillamine

D-Penicillamine was introduced into rheumatological practice in the belief that it would dissociate immune complexes by its effects on interchain disulphide bonds in the immunoglobulin molecule. Much information has accrued about penicillamine's actions on immune and other systems but it is used in essentially pragmatic fashion.

Pharmacology

D-Penicillamine (D-(–)-2-amino-3-mercapto-3-methylbutyric acid) has an a-amine, a carboxyl, and a sulphydryl functional group, conferring great complexities in terms of the bioactivity of the drug and its metabolites. There are also pharmacokinetic complexities; peak plasma concentrations are reached irregularly between 1.5 and 4 h after oral dosage because of extensive interactions with dietary proteins and iron, antacids, and gut wall proteins which favour oxidation to poorly absorbed disulphides (Joyce 1990). The drug binds to skin, connective tissue, and albumin but uptake by cells is limited.

Little D-Penicillamine is cleared by the kidneys and most is biologically transformed to disulphides or inorganic sulphate with the formation of minor products. Disulphide formation results from oxidation by interaction with an oxidant such as oxygen or through thiol–disulphide exchange and is probably dependent on the catalytic action of trace amounts of transition metals such as copper. Disulphides are not excreted renally and accumulate during treatment; thus elimination is slow when the drug is withdrawn.

The methylation product *S*-methyl-D-Penicillamine is quantitatively a minor metabolite. However it is possible, although not yet demonstrated, that this product is further metabolized to a sulphoxide. Poor sulphoxidation has been linked to an increased risk of toxicity and so this proposed pathway is of practical interest (Madhok *et al*. 1990).

Therapeutically relevant actions (Table 13)

	In vitro	*In vivo*
Anti-inflammatory		
Neutrophils	Depressed: Chemotaxis, lysosomal enzymes, oxidative burst; myeloperoxidase inconsistently depressed	Inadequate information
Inflammatory mediators		Inconsistent effects on prostacyclin pathways
Immunosuppressive		
T cells	Depressed Mitogen-induced proliferation may be secondary to effects on macrophages or changes in T-cell membrane	Inconsistent
B cells	Depressed Mitogen-induced immunoglobulin synthesis, may be secondary to effects on macrophages	Inconsistent; *in vitro* IgM rheumatoid factor production suppressed, may be secondary to reduced disease activity
Natural killer cells	Cytotoxicity impaired	Little information
Monocyte–macrophages	Antigen presentation impaired	Antigen presentation impaired
Complement		May inhibit activation by immune complexes

Table 13 Therapeutic actions of D-Penicillamine

D-Penicillamine has several actions which could contribute to its therapeutic efficacy. These results are difficult to interpret since most of the data derive from *in vitro* experiments in which, hardly surprisingly, D-Penicillamine's many functional groups perturb assay systems unprotected by *in vivo* constraints. The effects are also dose dependent, particularly where these affect *in vitro* immune function. Furthermore, while the influence of drug metabolites on macrophages is often invoked to explain the drug's immunosuppressive effects, the data relate to immunological rather than pharmacological events. Reduced reactivity of T and B cells has been documented consistently in rheumatoid arthritis, but it is not known whether these are primary drug actions or secondary to reduced disease activity. It has been proposed that the drug impairs immunoregulation by the surface sulphydryl oxidation of the lymphocyte surface membrane (Brown-Galatola and Hall 1992).

Therapeutic efficacy

Many controlled trials have shown that D-Penicillamine is more effective than placebo in reducing the symptoms and signs of rheumatoid synovitis, with a corresponding reduction in laboratory measures of disease activity such as the erythrocyte sedimentation rate (Joyce 1990). There is some indication that D-Penicillamine is more effective than sulphasalazine in maintaining long-term remission in the small percentage of patients who continue to tolerate the drug (Carroll *et al*. 1989). There is a hint that many patients may remain in remission if treatment is stopped either as a therapeutic decision or because of the patient's failure to comply (Doyle *et al*. 1993). Serum concentrations of all immunoglobulin classes, IgM rheumatoid factor, and immune complexes also decline. Nodules and vasculitic features are not influenced by D-Penicillamine treatment. It is unlikely that erosive changes are retarded in the short or long term (Scott *et al*. 1990).

There is little evidence to show that penicillamine is effective in juvenile rheumatoid arthritis and any benefit in scleroderma is marginal.

Treatment regimens

The initial daily dose of D-Penicillamine is 125 mg, increasing to 600 mg over 6 months according to tolerance and clinical response. Little further benefit can be expected with daily doses exceeding 750 mg. The drug should be taken 1 h before meals to avoid interactions with food. Clinical monitoring, urinalysis, and blood counts must be repeated at monthly intervals.

Adverse effects (Table 14)

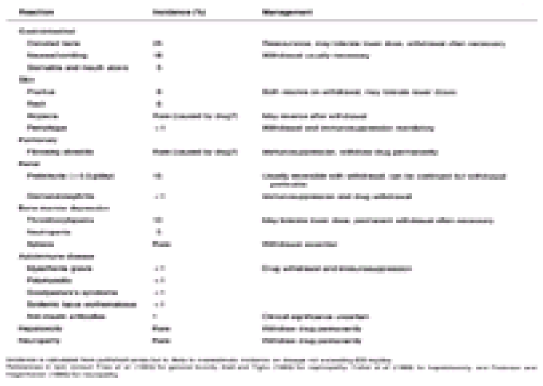


Table 14 Adverse reactions to D-Penicillamine

Adverse reactions to D-Penicillamine have been reported in some 50 per cent of patients with rheumatoid arthritis in the first 6 months of treatment; withdrawal was necessary in some 25 per cent of patients in these series in the first 5 years of treatment (Felson *et al*. 1990; Wolfe *et al*. 1990; Singh *et al*. 1991). Toxicity is associated with inheritance of a C4A null allele in the complement system, but this difference is insufficiently striking to be applicable clinically (Clarkson *et al*. 1992). Anti-Ro autoantibodies are also a possible pointer to adverse effects (Vlachoyiannopoulos *et al*. 1991). However, toxicity is dose dependent and is likely to have been greatly reduced with current prescribing practice. Proteinuria does not necessarily mean stopping treatment, but patients with this complication must be monitored carefully; the drug must be withdrawn in patients who develop nephrotic syndrome (De Silva and Eastmond 1992).

The pathological basis of this toxicity has not been elucidated. Clearly, the diversity of functional groups in the D-Penicillamine molecule gives great scope for the formation of immunogenic drug–protein complexes. Glomerular deposition of immune complexes probably accounts for the proteinuria. Similarly, thrombocytopenia is likely to follow a response to the drug acting as a hapten in combination with platelet membrane proteins. Antibody formation is probably the mechanism of penicillamine-induced myasthenia. Although myasthenia gravis is rare compared with other adverse reactions induced by D-Penicillamine, it is a particularly intriguing model because autoantibodies to the acetylcholine receptor in drug-induced and spontaneous myasthenia gravis have similar sequence and antigen-binding features (Tzartos *et al*. 1988; Morel *et al*. 1991), albeit against a different immunogenetic background. D-Penicillamine also induces the production of anti-insulin autoantibodies in some 40 per cent of treated patients with rheumatoid arthritis (Vardi *et al*. 1992), but their functional consequences are uncertain. Pemphigus has also been reported in treated patients and an autoimmune mechanism may be responsible (Bauer-Vinassac *et al*. 1992). Possibly, myasthenia and other autoimmune complications are induced by immunogenic drug–protein complexes; alternatively, the drug may induce mutations in the genes encoding variable sequences in T-cell antigen receptors or immunoglobulins.

Gold

Historically, gold was used to treat rheumatoid arthritis on the assumption that this antituberculous agent might benefit patients with a disease of presumed tuberculous aetiology. Relatively short-term trials in the 1960s showed that gold reduces disease activity and subsequently there has been much effort to lend scientific credibility to empirical usage. Gold is administered by intramuscular injection as the water-soluble thiolate, sodium aurothiomalate, or orally as the lipophilic monomeric phosphene, auranofin. However, intramuscular gold is being superseded by other drugs which are demonstrably more effective, easier to monitor, and less likely to produce severe, unforeseen toxicity. Oral gold is little used because of its gastrointestinal side-effects.

Pharmacology

Aurothiomalate is absorbed rapidly after intramuscular injection and peak plasma concentrations are reached after some 2 h (Champion *et al*. 1990). After standard weekly intramuscular doses of 50 mg of gold for 4 weeks, plasma concentrations rise to an average 300 µg/100 ml with a half-life of 3 to 5 days. With monthly maintenance doses of 50 mg, plasma levels fall to an average of 100 µg/100 ml with a half-life of 10 days. A high percentage of the injected gold is associated with cells in the circulation and in tissues so that only 40 per cent is excreted, of which 70 per cent is in the urine.

Some 25 per cent of orally administered gold is absorbed, most of the remainder being excreted in the faeces. The average plasma half-life is 15 days, with much individual variation. Although the elimination of orally administered gold is slow, it is more rapid than that of gold given by intramuscular injection.

Gold is selectively concentrated in macrophages in the synovial membrane and other tissues. This selectivity explains its widespread distribution in liver, spleen, kidney, and skin, and for its retention many years after treatment is discontinued. Only trace amounts are found in lymphocytes, granulocytes, or other cell types after *in vivo* or *in vitro* exposure. The association with phagolysosomes produces membrane-bound structures which can be readily detected in ultrastructural changes. This combination probably accounts for most of gold's anti-inflammatory and immunosuppressive effects. In addition, auranofin is taken up by polymorphonuclear granulocytes, resulting in the release of lysosomal enzymes and the inhibition of phagocytosis and the oxidative burst.

Therapeutically relevant effects (Table 15)

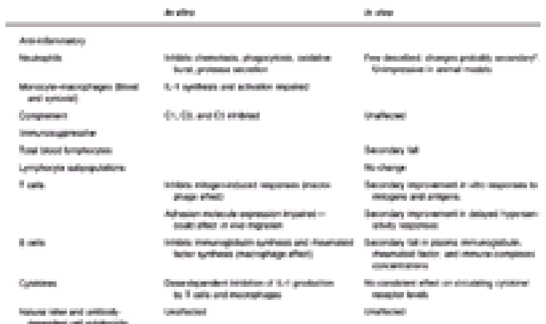

Table 15 Therapeutic actions of gold[a]

Gold suppresses non-specific inflammation in animal experiments. There is some evidence that it inhibits neutrophil accumulation by blocking the expression of the endothelial adhesion receptor ELAM-1 (Corkill *et al*. 1991). However it has little effect on immunologically induced models of chronic inflammation; nor does it alter the natural history of genetically determined, murine autoimmune disease.

Many non-specific *in vitro* immune responses are suppressed by gold. These include T-lymphocyte transformation and polyclonal immunoglobulin production by B cells in response to non-specific mitogens. This suppression can reasonably be attributed to gold's actions on monocyte–macrophages.

Gold salts also affect cytokine production. Gold sodium thiomalate and auranofin can stimulate or suppress the *in vitro* IL-1 production by monocyte–macrophages, the outcome depending on drug concentration and individual variation (Danis *et al*. 1990a). The pattern of *in vitro* IL-1 production by blood monocyte–macrophages from treated patients is highly variable, probably reflecting changes in disease activity rather than direct effects of the drug (Danis *et al*. 1990b). Monocyte accumulation in rheumatoid synovitis and cytokine production by these cells is also reduced by gold treatment (Yanni *et al*. 1994). It does not significantly affect circulating levels of soluble IL-2 receptors (Kirkham *et al*. 1993).

Delayed-type skin hypersensitivity reactions are consistently depressed in active rheumatoid arthritis, an abnormality corrected by chrysotherapy. However, this

improvement bears little relation to the clinical response (Smith *et al*. 1989). Like many antirheumatic drugs, gold reduces *in vitro* synthesis of rheumatoid factor by blood B cells from treated patients, but it is difficult to be sure if this is secondary to reduced disease activity or an independent mechanism. Gold is demonstrably anti-inflammatory through its effects on monocyte–macrophages but there is no predictable way of using this information for clinical monitoring.

Therapeutic efficacy

Sodium aurothiomalate reduces joint inflammation in rheumatoid arthritis, judged by controlled trials of up to 2-years duration. It is less certain that there is any longer-lasting benefit (Epstein *et al*. 1991); moreover, any retardation or reversal of joint destruction is modest at best. Since the natural history of rheumatoid arthritis is so variable, it is difficult to distinguish between an average, small effect on all patients with the disease and a major influence on a subset of patients which is masked when the overall benefits are analysed. Studies in the community have cast doubt on the benefit of long-term maintenance gold treatment (Epstein *et al*. 1991). Gold is of limited efficacy in psoriatic arthritis and is now rarely used in this condition.

Auranofin is of comparable efficacy to sodium aurothiomalate, judged by placebo-controlled trials of up to 2-years duration (Williams *et al*. 1988; Johnsen *et al*. 1989). The drug has also been shown to be modestly anti-inflammatory in juvenile chronic arthritis.

Dose regimens

Traditionally, sodium aurothiomalate is given in incremental weekly doses, starting at 2.5 to 5.0 mg and reaching a maximum of 50 mg. There is little evidence that the highest dose is mandatory, unless there is no clinical response to lower doses. Reduced doses are commonly tolerated by patients in whom higher doses have produced minor toxicity. Maintenance doses can be continued indefinitely in patients in remission who show no signs of intolerance.

Unfortunately, clinical response is the only satisfactory guide to dosimetry and duration of treatment. Relapses may occur when maintenance doses are discontinued and there is a suspicion, unsupported by formal evidence, that the drug may be less effective when reinstituted. Assays of drug concentrations in plasma or tissues are time-consuming and of no practical value.

Auranofin is given in a daily dose of 0.1 to 0.15 mg/kg of body weight and has been continued for up to 2 years in patients in whom it is effective and well tolerated.

Adverse effects (Table 16)

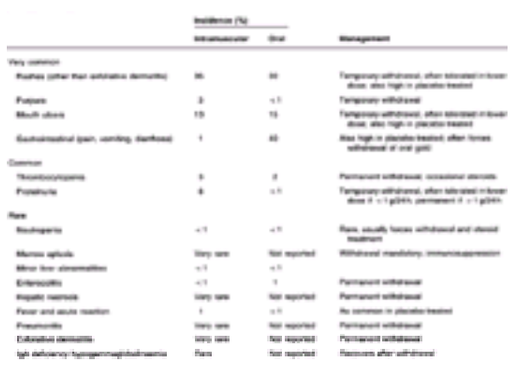

Table 16 Adverse reactions to gold therapy

Toxicity curtails sodium aurothiomalate treatment in a high percentage of patients, amounting to 30 to 45 per cent over 5 years in most reported series (Felson *et al*. 1990; Wolfe *et al*. 1990; Singh *et al*. 1991). The practical issues are to predict adverse reactions at an early stage, to decide which reactions enforce drug withdrawal, and to treat these when they occur. The theoretical problem is to elucidate the mechanisms which induce toxicity, with the possible practical benefit that patients at risk might be identified.

Over half the patients in placebo-controlled trials of auranofin develop gastrointestinal intolerance and about one-third develop rashes or stomatitis; these problems force drug withdrawal in about half the treated patients in the first 2 years of treatment (Williams *et al*. 1988; Johnsen *et al*. 1989) with a more variable cumulative drop out thereafter (Felson *et al*. 1990; Wolfe *et al*. 1990; Singh *et al*. 1991). However, many rashes which develop in patients on long-term treatment with gold are attributable to other causes and the drug is often withdrawn unnecessarily (Wilkinson *et al*. 1993).

Regular weekly clinical monitoring, blood counts, and urinalysis allow most reactions to be recognized at an early, reversible stage. Since hypersensitivity to gold is not dose-dependent, adverse reactions occur at all stages of treatment. Rashes, mouth ulcers, and proteinuria not exceeding 1.0 g/24 h necessitate temporary drug withdrawal, but treatment with lower weekly doses can often be attempted after some weeks. Bone marrow depression excludes further treatment with this agent. Marrow aplasia is rare and is the complication most likely to demand vigorous immunosuppressive treatment.

It is probable that gold toxicity is mediated by immune mechanisms. Animal experiments suggest that oxidized gold salts sensitize T lymphocytes, thereby provoking a cytotoxic reaction against gold–protein complexes (Schuhmann *et al*. 1990). Furthermore, T cells from patients with gold-induced dermatitis are specifically reactive with gold salts in proliferation assays (Verwilghen *et al*. 1992). Several studies implicate the inheritance of certain HLA coding genes in susceptibility to gold toxicity. The initial studies identified *HLA DR3* as the gene conferring an increased risk of proteinuria and thrombocytopenia; later reports suggest that this susceptibility is associated with the inheritance of an extended haplotype including the *DQA2.1* and *DQB2.1* genes on chromosome 6 (Singal *et al*. 1990; Sakkas *et al*. 1993). In contrast, the incidence of aphthous stomatitis and rashes during chrysotherapy is increased in patients inheriting the HLA-B35 antigen (Tishler *et al*. 1988b) and of enterocolitis in those with the HLA DRB1*0404 allele (Evron *et al*. 1995). These results suggest that susceptibility to gold toxicity is determined by interactions between T lymphocytes and immunogenic gold–peptide complexes presented by class II molecules. There is also a challenging contention that gold is more likely to induce remissions in patients who develop rashes (Caspi *et al*. 1989).

Thalidomide

Thalidomide (Fig. 4) has been used successfully in the treatment of lepromatous leprosy. By analogy it has also been used to treat many inflammatory rheumatic diseases in which immune complexes are thought to contribute to the immunopathological process. However, the disastrous teratogenic effects of thalidomide, which continue to be a problem in its unregulated use, and the neuropathy induced by high drug dosage deterred most rheumatologists from using this drug. However, its impressive ability to suppress orogenital ulceration in patients with Behçet's syndrome (Jenkins *et al*. 1984) led to renewed interest in the drug's therapeutic potential. Thalidomide is now regularly used in this context and also to treat similar symptoms in patients with AIDS. This interest was increased by the discovery that thalidomide is a potent inhibitor of the production of tumour necrosis factor-a by human monocytes (Sampaio *et al*. 1991). Subsequent studies have shown that it interferes with transcription of the gene encoding this cytokine.

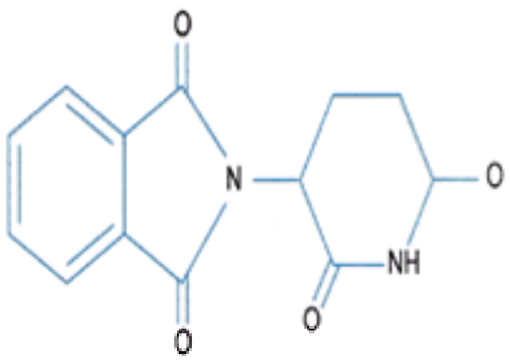

Fig. 4 Structure of thalidomide

Thalidomide may have wider immunosuppressive effects including the suppression of graft-versus-host disease in animal models and clinical practice (Heney *et al*. 1991). It now seems likely that the drug has immunoregulatory actions including the inhibition of interferon-g production by T lymphocytes because of its preferential stimulation of T_{H2} cells (McHugh *et al*. 1995).

The place of thalidomide in the treatment of other rheumatic diseases such as rheumatoid arthritis has not yet been established. When it is used, it is essential to ensure that the recipients are not at risk of pregnancy and that the drug is not taken inadvertently by pregnant women. Its use has to be carefully monitored because of its accumulation in target tissues and its slow removal from these tissues. The dose should be the minimum needed to control symptoms and should not ordinarily exceed 100 mg daily. Recurrent mouth ulcers can usually be controlled at a dose of 50 mg on alternate days.

Since thalidomide accumulates in target tissues and is slowly removed, it is essential to reduce toxicity by using low individual and cumulative doses. Drowsiness is encountered in 5 per cent of patients and its effects can be minimized by taking the drug at night. Neuropathy rarely develops in the doses employed in the treatment of rheumatic diseases. For practical purposes clinical monitoring suffices to prevent this complication, but some clinicians believe that baseline studies of nerve conduction are mandatory so that subsequent problems can be interpreted properly.

Interest in thalidomide analogues is likely to increase with the development of accurate assays for measuring plasma concentrations (Boughton *et al*. 1995) and better insight into the mechanism of thalidomide's teratogenic effects (Koch and Czejka 1986).

Antirheumatic drugs in pregnancy and lactation

There is justifiable concern about the safety of prescribing antirheumatic drugs during pregnancy and lactation and this subject is only now receiving detailed attention (Chapter 1.3.1.1 and Chapter 1.3.1.2). Most of the available data come from two sources, clinical observations and animal experiments. The interpretation of drug-induced teratogenesis in animals is complicated by species differences and dose effects. The metabolism and pharmacokinetics of cytotoxic drugs, for example, are not uniform in different species. There is also great variation in the efficiency with which potentially mutagenic DNA damage is repaired.

Until recently the clinical information was mainly anecdotal and did not evaluate other factors which may have been responsible for fetal abnormalities. However, controlled studies have now been published which take account of drug treatment, disease features, and other factors. Furthermore, there is increasing information about the genotoxic effects of antirheumatic drugs in children born to parents receiving these agents.

The available information is summarized in Table 17. It is now possible to give practical guidelines in different clinical situations. Theoretical concern over possible drug toxicity to the fetus in an established pregnancy should hardly ever be the sole grounds for termination. Techniques for monitoring fetal development provide additional safeguards. As far as possible antirheumatic drugs should be avoided or maintenance doses should be kept to the minimum during pregnancy; for example, a deterioration in lupus nephritis is a proven threat to fetal viability.

Table 17 Antirheumatic drugs in pregnancy and lactation

It is advisable to avoid starting or continuing treatment with potentially embryotoxic drugs in patients intending to become pregnant, even if in reality this decision is based on suspicion rather than firm evidence. Methotrexate and alkylating agents continue to arouse the most concern. Equally, it is important to control disease activity, particularly in systemic disorders, which pose known risks to the fetus. Higher corticosteroid doses are often the best interim solution.

Decisions about breast feeding should always be a compromise between maternal preference and medical prudence. Some drugs, notably alkylating agents, methotrexate, azathioprine, penicillamine, and maintenance corticosteroid doses above 10 mg per day contraindicate breast feeding; unavoidable treatment with other drugs is a possible reason for eschewing breast feeding but it should not be the sole grounds for influencing maternal choice.

Conclusions

There are still concerns about the long-term efficacy and safety of standard antirheumatic drugs. However, many agents have been shown to suppress inflammatory synovitis and systemic autoimmune diseases at least in the first few years of the disorder. There is also some evidence that some conventional drugs reduce joint destruction in rheumatoid arthritis. It seems likely that methotrexate, low-dose prednisolone, and cyclosporin are more effective and better tolerated than many time-honoured agents such as intramuscular gold and penicillamine. Increasing recourse to early treatment and drug combination has increased the need for accurate monitoring of drug efficacy and tolerance. Patient compliance is also an important consideration. There is still uncertainty about the mechanisms by which these agents exert their anti-inflammatory effects. One issue which will attract increasing attention in the coming years is the relative efficacy of conventional drug treatment and theoretically more selective immunosuppression with mainly biological agents. However, increasingly sophisticated analysis of the efficacy and problems of antirheumatic drugs has at least enabled rheumatologists to prescribe these potentially toxic agents with better understanding.

3.5.3 Therapeutic immunomodulation

A. M. Denman

Immunopathological basis

Immune reactions contribute to the chronic inflammation characteristic of chronic rheumatic diseases. In classic immune-mediated diseases the process is clearly initiated and maintained by an immune response to antigens. The stimulus may be an autoantigen, as in myasthenia gravis. Persistent exposure to exogenous antigens, such as drugs in drug-induced systemic lupus erythematosus or microbial antigens in untreated subacute bacterial endocarditis, also produces cumulative immune-mediated damage. It is also likely that atypical immune responses to microbial antigens in genetically predisposed individuals account for persistent inflammation in reactive arthritis. However, there are many situations in which immune reactions contribute to chronic inflammation but it is uncertain whether this is a primary or secondary event. For example, immune complex deposition in blood vessels is the main immunopathological event in systemic lupus erythematosus but the stimulus to this process is unknown. Similarly the T cells which infiltrate the rheumatoid synovial membrane undoubtedly contribute to inflammatory synovitis but it is still unproven that this process initiates the disease.

There has been major progress in elucidating the sequence of events which leads to immunopathologically mediated tissue damage. Thus details of the cytokine cascade which contributes to rheumatoid synovitis and joint erosion are largely understood. These advances have made it possible to introduce far more selective methods of immunotherapy. Whereas traditional methods of treatment were entirely pragmatic, at least the target for effective treatment can now be defined.

There are three approaches to practical immunotherapy in the rheumatic diseases. The first seeks to identify the initiating, immunologically mediated events and to block these specifically. Unfortunately there are few clinical situations in which this approach is relevant. A good experimental example is collagen-induced arthritis. Although the relevance of this model to rheumatoid arthritis is still debated, the goal of experimental immunotherapy in this model is clear, namely to block the inflammatory consequences of T-cell recognition. The second approach seeks to identify prominent immunopathological events and to block these irrespective of the process which led to their initiation. A pertinent example is rheumatoid synovitis where it is logical and feasible to interdict the T-cell component of this process or to inhibit proinflammatory cytokines such as tumour necrosis factor-a. Finally, it has become increasingly apparent that traditional antirheumatic drugs largely function through their effects on immunologically mediated events if one includes a broad range of anti-inflammatory processes in this definition. The rationale for using these drugs has often been empirical or even erroneous and only apparent in hindsight.

The immunological background

There are several stages at which immune-mediated inflammation can be blocked or blunted (Table 1; Fig. 1 and Fig. 2). These events are described in detail elsewhere in this book (see Chapter 3.1 and Chapter 3.2) and only points related to immunomanipulative strategies are considered here.

T cells
Tolerance induction by peptide administration
Tolerance induction by other methods of immunization
Receptor blocking by peptides
Antireceptor antibodies
Antireceptor immunoconjugates
Interdicting recirculation and proinflammatory traffic patterns
Antigen presentation
Peptide competition
Antireceptor antibodies
B cells and antibodies
Idiotype network manipulation
Antireceptor immunoconjugates
Intravenous immunoglobulin
Cytokine network
Cytokine administration (immunoregulatory)
Anticytokine antibodies and other agents
Anticytokine receptor antibodies and other agents
Genetic techniques — antisense oligonucleotides and gene transfection

Table 1 Strategies for selective immunosuppression

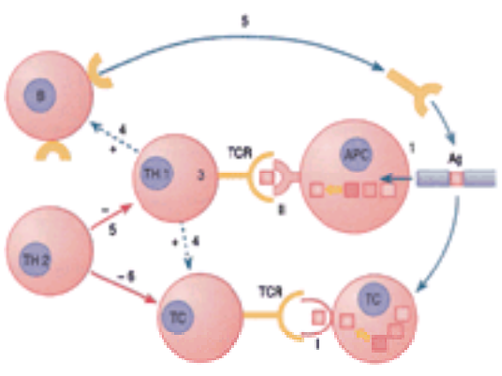

Fig. 1 Main events relevant to immunopathogenesis of rheumatic diseases. Antigen is degraded by antigen-presenting cells (APC) (1) and immunogenic peptides are presented by class II HLA molecules (II) (2). These peptide fragments are recognized by the antigen receptor of T cells (TCR) (3). T_{H1} lymphocytes are activated (+) to produce cytokines which induce a cytotoxic T-cell (T_C) response to target cells (TC) expressing the same immunogenic peptides and presented by class I HLA molecules (I) (4). T-helper cells also activate antibody-producing B cells (B) to secrete antibodies reactive with the immunizing antigen (5). Other T-cell populations of

the T_{H2} phenotype secrete cytokines which inhibit (–) many proinflammatory, antigen-driven immune responses.

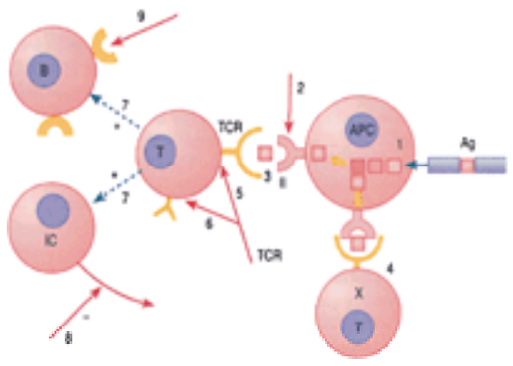

Fig. 2 Strategies for selective immunosuppression in the rheumatic diseases. Antigenic degradation into immunogenic peptides and their transport to surface class II HLA molecules may be inhibited (1). Class II molecules may be blocked (2) or their peptide-presenting groove occupied by competing peptides (3). The immunogenic response may be converted into a tolerizing event (4). Responding T cells may be inactivated by many potential monoclonal antibodies and other agents reacting with the T-cell receptor (TCR) (5) or other surface receptors essential for T-cell activation (6). Immunopotentiating cytokines may be inhibited (7) or proinflammatory cell populations (IC) may be inhibited by monoclonal antibodies and specific agents (8). Antibody-secreting B cells may be inhibited by anti-idiotypic antibodies (9).

T cells and antigen recognition

T cells recognize immunogenic peptides presented by class II histocompatibility (**HLA**) molecules that are expressed usually by specialized antigen-presenting cells but also by other cell types including B cells. The binding characteristics of the immunogenic peptides to the peptide-binding groove of the class II molecule is genetically determined and largely dictates the nature of the T-cell response. Peptide transport to the surface of specialized antigen-presenting cells is also genetically controlled. T-cell binding to peptides is specific and determined by the complementarity of the T-cell receptor. However, the rules governing T-cell binding by superantigens such as those displayed by many micro-organisms are less restrictive. T-cell interaction with antigen-presenting cells also depends on non-specific binding between ligands and their receptors expressed by both cell types. These interactions are essential for T-cell activation and also determine the outcome of the interaction between peptides and T cells. This may be activation, tolerance, or cell death (apoptosis). Interaction between the CD4 molecule and its ligands is the most crucial step in determining the outcome. It is also important in immunopathology that T cells traverse the endothelial cell barrier of small arterioles in order to reach inflammatory sites. This process also is dependent on receptors and ligands displayed by T cells and endothelial cells.

These interactions form the basis of many strategies for blocking T-cell activation and migration. The most specific interdiction involves the interaction between a given peptide and the relevant T-cell clone; the least specific depends on blocking an entire immunogenic step in the normal sequence of events.

Cytotoxic T cells

Cytotoxic T cells recognize peptides presented at the cell surface in association with class I HLA antigens. These peptides are derived from proteins that have been degraded in the cytosol and are then transported in the endoplasmic reticulum to the cell surface. The peptides bind to and take part in the assembly of glycoproteins of the class I molecule. The antigenic peptides are 8 to 20 amino acids in length and are presented to cytotoxlc T cells in the peptide-binding groove. Immunotherapeutic strategies are analogous to those employed to block T-cell recognition.

B cells and immune complex production

Normal antibody production may be qualitatively normal but quantitatively immunopathological if circulating immune complexes formed between antigens of any origin and antibodies are inadequately cleared or degraded and as a result are continually deposited in small blood vessels. A pertinent example is immune complex deposition in systemic lupus erythematosus, especially in individuals with inherited or acquired defects in the complement system. Therapeutic strategies then depend on partial suppression of antibody production, reducing antigen exposure, or correcting complement defects.

B cells and autoantibody production

It may seem self-evident that suppressing autoantibody production should be a prime object of immunosuppression. Yet two important points need to be considered. First, autoantibody production is not synonymous with abnormal B-cell behaviour, and second, autoantibodies do not invariably have immunopathological consequences.

Control of autoreactive B cells

Autoantibody production is part of the normal B-cell repertoire and autoantibodies are encoded by normal, non-mutated *VH* genes, suggesting that autoreactivity is an essential step in B-cell ontogeny. The emergence of pathogenic, autoreactive clones of B cells involves several stages. For example, systemic lupus erythematosus is likely to result from initial polyclonal B-cell proliferation followed by antigen selection of autoreactive clones. This process is aided by the failure of protective mechanisms that normally either eliminate or arrest the development of autoreactive B-cell clones.

The analysis of this regulation has been greatly assisted by transgenic experiments in which developing T cells are not exposed to selected antigens and are thereby not tolerized to these prenatally. Subsequent postnatal exposure leads to immune reactions which initiate autoimmune disease. It is evident that potentially autoreactive clones may be deleted or inactivated during tolerance induction or that loss of tolerance may be partial resulting in autoaggression restricted to certain organs. Paradoxically, experiments in which the T-cell repertoire has been selectively crippled ('knock-out' mice) show that genetically contrived immunodeficiency may lead to chronic inflammatory disease resembling human disorders. Thus increasing information about the maintenance of normal tolerance has mainly served to emphasize the complexity of restoring tolerance therapeutically.

Pathogenicity of autoantibodies

In many clinical states, autoantibodies lack pathogenetic significance and they may even be encountered in normal individuals. However, from experiments in which autoantibody-secreting B cells have been introduced into normal mice, it seems likely that autoantibodies can reproduce many of the immunopathological features of systemic lupus erythematosus and related diseases. Thus their inhibition may be a logical part of immunosuppressive strategies.

The idiotypic network

The specificity of antibodies for different antigens depends on their variable (V) region sequences. These regions are themselves novel sequences that stimulate an immune response by other lymphocyte clones. The immunogenic sequences are known as idiotypes and the set of idiotypes expressed by the complete molecule is termed its own idiotype. Idiotypes are called 'private' when they are unique to one antibody and 'public' when they are expressed by more than one antibody in the same or different individuals. Anti-idiotypic antibodies are generated as a physiological, regulatory response. They may also be created experimentally by active immunization or administered as passive immunotherapy.

The extent to which anti-idiotypic antibodies affect the antibody response partly depends on the location of the target idiotypes within the antibody molecule. Antibodies to idiotypes situated outside the antigen-combining site do not affect antigen binding by the target antibody. Antibodies to idiotypes near or contributing to

the antigen-binding site commonly interfere with antigen binding.

The same principles apply to novel sequences in the antigen receptors of T cells, which induce the production of anti-idiotypic antibodies by B cells and anti-idiotypic receptors on other T cells.

Thus, the idiotype network has long held a central place in ideas about the normal regulation of antibody production. This gave rise to the notion that autoantibody synthesis might reflect abnormal B-cell proliferation freed from the restraints of anti-idiotype regulation. This attractive idea has also stimulated schemes for the therapeutic manipulation of the network.

Cytokines

Cytokines may enhance or suppress immune responses depending on their local concentration, the nature of the target cells, and interaction with other cytokines. Cytokine production is genetically controlled and is likely to determine the duration and intensity of both normal and pathological immune responses. Cytokine production has been amply implicated in the rheumatic diseases by the direct assay of blood and inflammatory fluids and by demonstrating cytokine gene expression and protein production in lesions such as the rheumatoid synovial membrane. Since autoimmune disease may arise in experimental situations in which the control of cytokine gene expression has been artefactually disrupted, there is increasing speculation that abnormal cytokine production in disease may on occasion be the primary abnormality. These observations have stimulated a host of therapeutic ideas ranging from manipulation of cytokine-coding genes to the direct opposition of circulating cytokines with specific antibodies.

Non-selective immunomanipulation

Conventional agents

Non-specific immunosuppressive agents are still the mainstay of treating severe rheumatic disorders. Indeed the demonstrable efficacy of standard drugs such as prednisolone, methotrexate, and cyclosporin in rheumatoid arthritis has maintained interest in their mode of action. Furthermore, these drugs are simpler and cheaper to administer and monitor than many biological agents of current interest. Similarly, cyclophosphamide remains the drug of greatest proven value in controlling life-threatening features of systemic connective tissue diseases such as lupus nephritis. These agents have unpredictable effects on immune responses (Swanson and Schwartz 1967) with uncertain relevance to their clinical efficacy. Many antirheumatic drugs in standard use have been shown to affect immune-mediated inflammation. These drugs both benefit patients with rheumatic disorders and correct impaired immune responses, judged by *in vivo* and *in vitro* assays. As these effects occur simultaneously, some observers have concluded that the clinical improvement produced by cytotoxic drugs is mediated by therapeutic 'immunomodulation', but this point is far from established.

Unconventional agents

Most unconventional methods of non-specific immunosuppression are now of mainly historical interest. These were based on the premise that immunosuppression through lymphocyte depletion is the most logical means of controlling immune-mediated rheumatic diseases. Total lymphoid X-irradiation is a potent means of achieving a profound T- and B-cell lymphopenia and impressive remissions have been induced in severe rheumatoid arthritis and lupus nephritis (Strober *et al*. 1988). However, relapse is common in rheumatoid arthritis and there is a considerable incidence of illness and fatality mainly from unusually severe or opportunistic infections. While any benefit might reasonably be attributed to lymphocyte depletion, even this point has been disputed. There have been few comparative studies of the relative benefits of this approach and conventional treatment. It is probable that the side-effects of this treatment outweigh those of conventional cytotoxic drugs in patients with disease of similar severity. Thoracic duct drainage is in principle a more specific way of achieving profound depletion of the recirculating lymphocyte pool. While remissions have been recorded in severe rheumatoid arthritis resistant to other forms of treatment, this approach is no longer used. A more recent approach to the treatment of autoimmune connective tissue diseases is the extracorporeal inactivation of recirculating lymphocytes (Edelson 1991). Remissions have been claimed in open studies but controlled trials have not yet been reported. Selective removal of activated monocytes by leucapheresis has also been advocated as a means of reducing systemic inflammation (Hahn *et al*. 1993).

Strategies for selective immunosuppression

The detailed dissection of the normal immune system and its derangements in autoimmune diseases has stimulated a wealth of novel approaches for controlling immune-mediated inflammation. These are set out in Table 1. The practical problem now is to test the efficacy, safety, and relative merits of these strategies.

T-cell inactivation

Preoccupation with the proactive role of autoreactive T cells in many rheumatic disorders has stimulated interest in ways of suppressing or preferably tolerizing the abnormal clones.

Peptide administration

Impressive results have been achieved in experimental models of autoimmune diseases by administering peptides involved in the initiation of these diseases. Of obvious clinical relevance, some of these approaches suppress autoimmune disease which is already in progress. For example NOD mice with spontaneous diabetes have T-cell clones autoreactive with the 60-kDa heat-shock protein. The administration of a peptide, p277, derived from this protein both prevents and ameliorates ongoing diabetes in this model (Elias and Cohen 1994). There is particular interest in the prevention or suppression of disease by peptides given orally. Encouraging results have been achieved in the treatment of experimental allergic encephalomyelitis, collagen-induced arthritis, adjuvant arthritis, and spontaneous diabetes in NOD mice (Weiner *et al*. 1994). This principle was the basis for a trial of orally administered type II chicken collagen in patients with rheumatoid arthritis. Four out of the 28 patients remitted on this regimen (Trentham *et al*. 1993). Extended placebo-controlled trials of this principle are in progress.

Receptor competition

The factors which determine T-cell activation or tolerance after antigen exposure have been the subject of intensive investigation for many years. In addition to contact between antigenic peptides and the T-cell antigen receptor, activation requires a second signal initiated by interactions between surface receptors and their ligands. These receptors are readily accessible to experimental manipulation. One important interaction is between CD28 or CTLA-4 on T cells and B7 on antigen-presenting cells including activated B cells. T-cell activation is blocked by monoclonal antibodies to CD28 or CTLA-4. A protein constructed by genetic fusion of the extracellular domain of human CTLA-4 to an immunoglobulin C g_1-chain (termed CTLA4Ig) binds the B7 receptor and thereby blocks T-cell activation. Treatment with this novel protein inhibits the development or progression of lupus in NZB/NZW F_1 mice (Finck *et al*. 1994). Clinical trials based on this principle have not yet been reported.

Immunization by other routes

Several autoimmune diseases can be induced in experimental animals by immunization with antigens such as myelin basic protein or thyroglobulin. These disorders are mediated by T cells reactive with these autoantigens and can be transferred to other animals by autoreactive T cells or T-cell clones. On a similar theme, adjuvant arthritis is a chronic disorder of rats provoked by immunization with *Mycobacterium tuberculosis*. It is mediated by T cells reactive with a single nonapeptide epitope of the 65-kDa mycobacterial heat-shock protein. These T-cells cross-react with an autoantigen found in joints that may also prove to be a 65-kDa heat-shock protein (Karlsson-Parra *et al*. 1990).

The induction of these diseases can be prevented by vaccination with T-cell clones specifically reactive with the inducing antigen. Prerequisites for successful vaccination are attenuation of the clone by X-irradiation and its activation with the relevant antigen before vaccination. The efficacy of vaccination is greatly enhanced by the cross-linking of antigen receptors on the immunizing T cells through exposure to hydrostatic pressure or gluteraldehyde (Mor *et al*. 1990).

A novel approach has been described for achieving resistance to collagen-induced arthritis in rats and rhesus monkeys (t'Hart *et al*. 1993). The test animals inherit histocompatibility antigens which make them susceptible to this model autoimmune arthritis. Immunization with attenuated type II collagen in which arthritogenic

epitopes had been destroyed by heat inactivation conferred resistance to this disorder on subsequent challenge with the native collagen.

It is likely that several mechanisms account for the success of immunization strategies but that all of these involve anergy of potentially autoreactive T-cell clones. One intriguing possibility is that other T cells recognize idiotypic sequences in the antigen receptor of these clones and thereby inhibit their proliferation. However this strategy has not yet been applied clinically.

Monoclonal antibodies to T-cell receptors

The availability of monoclonal antibodies to T-cell receptors has prompted a spate of clinical trials. Antibodies to the CD4 receptor are of particular interest because success in experimental transplantation systems offers the prospect not simply of drug-dependent immunosuppression but of tolerizing autoreactive T-cell clones (Waldmann 1993). These hopes were increased by experience in controlling autoimmune disease in experimental models. Anti-CD4 monoclonal antibody suppresses murine lupus and the associated immunopathological abnormalities (Wofsy 1988; Ermak *et al*. 1989; Carteron *et al*. 1990). Furthermore, the disease can be suppressed without lymphocyte depletion since $F(ab)_2$ fragments of the antibody are equally effective (Carteron *et al*. 1989). In some such experiments the disease did not progress after treatment was stopped, raising the possibility that this agent had indeed induced tolerance to the inciting autoantigens. These observations led to the formulation of a strategy for treating autoimmune disease whereby the T cells mediating disease are first largely eliminated by a cytotoxic monoclonal antibody, and the remaining cells are than rendered tolerant to the inciting autoantigens by exposure to a second, non-cytotoxic monoclonal antibody.

Early impressions of anti-CD4 monoclonal antibody in rheumatoid arthritis were encouraging, with clinical improvement, minor toxicity, and a marked CD4-cell lymphopenia (Kyle *et al*. 1989). Most subsequent reports of uncontrolled trials have been similarly favourable and noted reduced joint inflammation, a decreased acute-phase response, and improved functional capacity. Different preparations of chimeric monoclonal antibody seem to have had similar effects. This amelioration of disease activity is accompanied by a CD4 lymphopenia whose intensity and duration are dose-dependent. There is an unpredictable effect on immune competence (Horneff *et al*. 1991a; Horneff *et al*. 1991b; Wendling *et al*. 1991; Wendling *et al*. 1992; Goldberg *et al*. 1991; Van der Lubbe *et al*. 1993). In addition, some patients have tolerated further courses of antibody with reported benefit (Reiter *et al*. 1991). The various hybrid antibodies are generally well tolerated; minor adverse reactions in the form of urticaria, transient hypotension, and fever have been attributed to cytokine activation, notably involving interleukin 6 (Moreland *et al*. 1993). An antibody response to the rodent hypervariable portion of the hybrid molecules which are administered has been noted in only a small percentage of the patients in these trials. This improvement probably does not simply depend on CD4 cell elimination since there is a poor correlation between circulating CD4 counts and clinical improvement (Choy *et al*. 1992; Van der Lubbe *et al*. 1994). An eventual reduction of cytokine production by circulating monocyte/macrophages has been noted (Horneff *et al*. 1993) but there is no correlation between circulating cytokine levels and clinical response.

Nevertheless the limited data from placebo-controlled trials do not as yet show any clear benefit in the treated patients (Choy *et al*. 1992). A recent trial of anti-CD4 monoclonal antibody showed no significant benefit even in early rheumatoid arthritis when agents of this kind might be expected to be most effective (Van der Lubbe *et al*. 1995). There is still uncertainty about the ability of patients to tolerate long-term or repeated courses of hybridized anti-CD4 monoclonal antibody. Despite earlier impressions, an immune response to rodent sequences or idiotypic human sequences is probably universal and may well compete for infused antibody even if the adverse effects can be combated. It also seems likely that the recirculating pool of CD4 cells is permanently depleted in some patients, particularly in those who have received potent immunosuppressive drugs (Horneff *et al*. 1992; Moreland *et al*. 1994). This raises the possibility of long-term opportunistic infections and other complications. The initial, often uncritical enthusiasm for this form of treatment has been tempered by the realization that more extensive controlled trials are needed (Burmester and Emmrich 1993). There is a still greater dearth of controlled trials of monoclonal antibodies against other T-cell surface molecules in rheumatoid arthritis.

Trials of monoclonal antibodies to T-cell surface molecules in systemic connective tissue diseases have been confined almost exclusively to anti-CD4 monoclonal antibody. The reports have involved few patients and are uncontrolled, so it is difficult to draw any conclusions about its efficacy. For example in one early report, systemic vasculitis was successfully treated by sequential administration of a monoclonal antibody that depleted CD4 cells and a non-cytotoxic anti-CD4 monoclonal antibody (Mathieson *et al*. 1990), with the intention of rendering the patient tolerant to the antigen putatively initiating the disease. Further exploitation of this idyllic principle is awaited.

Despite the theoretical advantages over previous methods of lymphocyte depletion, monoclonal antibodies against receptors expressed by all circulating T cells are still relatively non-specific. In principle, antibodies directed against the T-cell clones responsible for the autoimmune process would be the most specific form of immunosupression. Tolerizing antibody would be still more effective, thereby avoiding the need for continued treatment. This strategy depends on identifying the responsible clones by virtue of their unique antigen receptors. There is some information about the genes encoding T-cell receptors in model autoimmune diseases. Experimental allergic encephalomyelitis is a mixed inflammatory and degenerative disease of the central nervous system induced by an autoimmune attack by T cells immunized with basic myelin protein. The encephalitogenic T cells use a remarkably limited number of *V*-b genes to encode the receptor for the disease-inciting peptides. Monoclonal antibodies to these receptors prevent the induction of disease and partially suppress established disease (Kumar *et al*. 1989; Wraith *et al*. 1989). There is a similarly restricted usage of the same *V* genes in other models of organ-specific autoimmune disease, even though the T cells recognize different peptides. These observations suggest that the antigen receptors expressed by T cells responsible for autoimmune disease may have features in common (Adams *et al*. 1990; Heber-Katz 1990). Unfortunately there are two major practical problems in applying these principles to clinical practice. First, no consistent pattern of dominant T-cell clones has been identified in diseases such as rheumatoid synovitis. Some evidence of restricted T-cell receptor usage has emerged in individual patients and even in serial synovial biopsies from the same patient (Broker *et al*. 1993). However, the same dominant clone is not found in different patients so that it is as yet impossible to develop a specific reagent for general use. Second, non-specific anti-T-cell monoclonal antibodies have not induced lasting remissions so that it has been necessary to resort to repeated administration of these agents. In other words this treatment may suppress the relevant clones but there is no hint that it tolerizes them.

It would be less advantageous but still relatively helpful if diseases such as rheumatoid arthritis were mediated by T-cell clones reactive with superantigens. In these circumstances the antigen receptors would be encoded by a restricted family of *V* genes. Deleting this population of T cells would be less immunologically crippling than lymphopenia induced by entirely non-specific agents. However there is no good evidence that a mechanism of this nature is operating.

T-cell traffic

T cells accumulate at sites of inflammation by traversing the endothelial cells lining small arterioles. Recruitment by this route is largely governed by adhesion molecules and their ligands expressed on T-cell and endothelial cell surfaces. Experimental results show that it is possible to interdict this process with selective antibodies. Thus an antibody that prevents lymphocyte homing across high endothelial venules suppresses lymphadenopathy in MRL-1pr/1pr mice that develop spontaneous autoimmune disease (Mountz *et al*. 1988). Similarly, the transfer of spontaneous diabetes in mice by spleen cells can be prevented by a monoclonal antibody that interferes with macrophage adhesion in the recipient mice (Hutchings *et al*. 1990).

The interaction between the leucocyte function-associated antigen 1 and its receptor, intercellular adhesion molecule 1 (**ICAM-1**), is crucial to T-cell recruitment. One method of interdicting T-cell accumulation in rheumatoid synovitis depends on monoclonal antibodies to these adhesion molecules. Anti-ICAM-1 monoclonal antibody modifies T-cell recirculation and in an open trial produced clinical improvement in 9 of 23 treated patients (Kavanagh *et al*. 1994). The results of controlled trials are awaited.

Antigen presentation

Since T cells recognize peptide presented by class II molecules of antigen-presenting cells, several immunosuppressive strategies depend on blocking peptide presentation. Genetic susceptibility to autoimmune disease is strongly linked to the inheritance of certain class-II molecules. This linkage provides an additional rationale for this approach.

Peptide competition

In theory, autoimmune diseases could be blocked by substituting non-immunogenic peptides for the autoantigenic peptides which are presumed to break tolerance in T cells. These pathogenic peptides are probably presented in normal physiological fashion. Several technical advances have facilitated this approach. Oligopeptides can be synthesized and their binding properties to other molecules and biological structures screened on an almost industrial scale. Computer modelling has enabled their interactions with the peptide-binding groove of genetically different class I and II HLA molecules to be predicted with great accuracy. However there are still formidable problems. Some are readily foreseen, notably the difficulty in guiding immunotherapeutic peptides to the relevant receptors. Others are more unexpected.

Thus *in vitro* experiments have shown that different model peptides have a variable binding affinity for the class II molecule and that the resulting complex may be intrinsically unstable. Nevertheless, competition for antigen receptors on autoreactive T cells has been shown to operate successfully in experimental models of autoimmune disease (Fairchild *et al*. 1994).

Anti-MHC antibodies

Monoclonal antibodies to class II MHC gene products have been successfully used to treat many experimental models of autoimmune disease. Some of these models depend on immunization with tissue-specific antigens and include allergic encephalomyelitis, myasthenia gravis, autoimmune thyroiditis, and collagen-induced arthritis provoked in different species. Anti-MHC antibodies are mainly effective during the induction period. These antibodies also suppress spontaneously occurring autoimmune diseases, such as lupus in NZB/NZW mice and diabetes mellitus in BB rats (Vladutiu 1991). However, it is likely that anti-MHC antibodies do not simply block the target molecule but that they also initiate a sequence of secondary events. The overall result is a partial suppression of T-cell responses and, at least in experimental models, the activation of suppressor cell populations. Although at first sight this approach may appear to be rather non-specific, it is selectively immunosuppressive in both theory and practice. First, blocking the product of MHC alleles predisposing to autoimmune disease does not prevent the treated animal from expressing other MHC-encoded gene products that are perfectly able to engage a broad repertoire of microbial antigens. Second, microbial pathogens produce a range of antigenic determinants (epitopes) able to bind to other MHC products which T cells can recognize. Finally, class II antigens are abnormally expressed in target organs for autoimmune disease yet their local suppression does not affect systemic immune responses.

So far this principle has been little tested in clinical practice. An indirect trial of anti-class II antibodies has been conducted in rheumatoid arthritis on the basis that immunoglobulins with a high concentration of these antibodies can be obtained from the placenta and its blood supply; these antibodies may account for disease remission during pregnancy (Sany 1988). Clinical improvement has been claimed but more extensive trials are needed.

B-cell blockade

Idiotype network manipulation

The physiological importance of the network between idiotypes and anti-idiotype antibodies raised high hopes that these interactions would prove amenable to immunotherapeutic manipulation. The complexities of the idiotype network provide enormous scope for its therapeutic manipulation. For example, autoantibodies to the acetylcholine receptor contribute to the immunopathogenesis of myasthenia gravis. Antibodies to certain dextrans and to the acetylcholine receptor share idiotype determinants. Prior immunization with dextran reduces the antibody response to the acetylcholine receptor induced after subsequent challenge with this receptor (Tong and Dwyer 1990).

However, it was apparent from the outset that certain conditions would need to be met before this approach could become practicable. First, there must be common ('public') idiotypes associated with the disease to be treated. It is clearly easier to manipulate the idiotype network if certain idiotypes predominate in this condition. There are some indications that autoantibodies in patients with connective tissue diseases share common idiotypes. For example, the same idiotypes are expressed by a high proportion of anti-DNA autoantibodies in patients with systemic lupus erythematosus (Blank *et al*. 1990; Weisbart *et al*. 1990). Moreover the clones synthesizing this autoantibody appear to be stable during the course of the disease (Winkler *et al*. 1988). However, anti-DNA autoantibodies are synthesized by cells subject to considerable antigen-driven mutation so that there is the potential for considerable diversity in their variable sequence. Furthermore these idiotypes are not uniquely associated with anti-DNA autoantibodies. Similarly, while 60 per cent of monoclonal paraproteins with rheumatoid factor activity share the same idiotype determinants, there is far more idiotype diversity among rheumatoid factors synthesized by blood and synovial B cells in rheumatoid arthritis (Thompson *et al*. 1990). Thus, if selective suppression of the production of rheumatoid factor proved therapeutically desirable, it would be difficult to achieve by idiotype manipulation.

Second, the target idiotype for immunotherapy must be associated with the immunopathogenesis of the disease in question. It is not necessarily true that autoantibodies expressing a shared idiotype are pathogenic. On occasion this is clearly the case as, for example, with complement-fixing autoantibodies to formed blood elements. Occasionally the issue can be tested experimentally: for instance, it has been claimed that mice develop the immunopathological features of systemic lupus erythematosus when immunized with the idiotype 16/6 associated with anti-DNA autoantibodies (Mendlovic *et al*. 1990).

Third, the results must be therapeutically beneficial. In practice the outcome of perturbing autoantibody production in experimental systems is not easily predictable. Thus passively administered, monoclonal, anti-Sm antibodies increase or decrease the production of this autoantibody in mice with systemic lupus erythematosus, depending on the fine specificity of the administered antibody (Eisenberg *et al*. 1990).

Fourth, the benefit must be reasonably long lasting. Unfortunately, adaptive changes are likely to occur. Thus lymphomas treated with anti-idiotypes antibodies eventually escape elimination by changing their surface immunoglobulin (Rafield, *et al*. 1985). Autoantibody-synthesizing clones may behave similarly.

However, the greatest stumbling block has been the lack of practical methods for manipulating the idiotype network.

B-cell suppression

It has proved difficult to devise methods for directly inhibiting the proliferation or maturation of autoantibody-producing B cells. This is perhaps not surprising since B cells committed to conventional antibody synthesis are relatively resistant to conventional antiproliferative drugs. However, monoclonal antibodies to B-cell antigens have been used as antiproliferative agents in murine systemic lupus erythematosus (Asensi *et al*. 1989; Yakura *et al*. 1989). It is also noteworthy that anti-class II antibodies directly inhibit the spontaneous *in vitro* activation of human lupus B cells (Tanaka *et al*. 1989). The predominant attribution of autoantibody synthesis to the CD5+ subpopulation of B cells has formed the basis for a novel treatment with an immunoconjugate consisting of ricin linked to an anti-CD5 monoclonal antibody (Strand *et al*. 1993). Initial clinical improvement at least was noted in more than half the 79 patients with rheumatoid arthritis enrolled in the trial. It remains to be seen if consistent suppression of rheumatoid factor or other autoantibody production can be achieved in this fashion.

Intravenous immune gammaglobulin

There are suggestive anecdotal accounts but little controlled evidence to show that intravenous immunoglobulin benefits patients with autoimmune disorders. These include idiopathic thrombocytopenia, systemic lupus erythematosus, and rheumatoid arthritis. Many non-specific immunosuppressive effects may be operating but the most intriguing explanation is that pooled immunoglobulin from normal donors contains anti-idiotypic antibodies to idiotypes expressed by pathogenic autoantibodies (Dietrich *et al*. 1992). There is also good experimental evidence that genetically determined patterns of antibody response to micro-organisms influence autoantibody production. Polyreactive natural antibodies stimulated by infection may inhibit the production of pathogenic autoantibodies (Hentati *et al*. 1994). Thus some gammaglobulin preparations may fortuitously correct imbalances of this nature. The current impossibility of matching donor gammaglobulin preparations with postulated immunoregulatory defects in the recipient explains why this form of treatment is so hard to assess. So far, with the exception of dermatomyositis (Dalakas *et al*. 1994), there are few convincing controlled trials of this popular form of immunotherapy that have shown any benefit.

Plasma exchange was formerly a popular means of removing autoantibodies and immune complexes. Apart from its possible value as an emergency procedure in fulminating disease, it is now little used.

Cytokine manipulation

Cytokine production is a prominent feature in rheumatic diseases judged by circulating blood levels, high concentrations in inflammatory exudates, and local production in rheumatoid synovitis. Cytokines contribute to the acute-phase response characteristic of these disorders and also to joint damage in rheumatoid arthritis. There is growing evidence that cytokine production is genetically controlled and that the inherited pattern of cytokine generation influences the severity of immunopathological disorders. Detailed information about the structure and synthesis of cytokines and their receptors has led to the development of several strategies for manipulating the cytokine response in the rheumatic diseases. Many of these have already been introduced into clinical practice.

There are many possible strategies for manipulating the cytokine network for immunotherapeutic purposes. In general terms these involve administering cytokines or inhibiting cytokines or their receptors. However, the complexities of cytokine interactions mean that the administration of one cytokine may have a suppressive effect on other cytokines. Cytokine actions are pleomorphic so that inhibiting the production of a given cytokine or administering it therapeutically is likely to affect cells and systems other than the intended target. Cytokines are commonly interdependent thereby increasing the chances of unexpected actions. Transgenic models of

unopposed cytokine production have also shown that increased cytokine concentrations may directly or indirectly initiate autoimmune disorders. These considerations reinforce the need for caution over the long-term consequences of this form of treatment. The paradoxical findings in different situations also enjoin caution about superficial generalizations. Tumour necrosis factor-a (**TNF-a**) is clearly important in the pathogenesis of rheumatoid arthritis and its inhibition by monoclonal antibody is clinically beneficial. Yet spontaneous lupus nephritis in NZB × NZW F_1 mice is associated with genetically determined, low serum levels of TNF-a whose correction ameliorates the disease process (Gordon *et al*. 1989).

In the earliest attempts at cytokine therapy, patients were given interferon-g. This was a pragmatic venture since the biological effects of the interferons are unpredictable. Although interferon-g is produced by activated T lymphocytes of the kind contributing to rheumatoid synovitis, very low concentrations are encountered in rheumatoid synovitis (Firestein and Zvaifler 1990). Furthermore, blood T lymphocytes (Sadouk *et al*. 1990) and synovial macrophages (Bergroth *et al*. 1989) from patients with rheumatoid arthritis show impaired responses interferon-g. This reduction may result from the excessive production of other cytokines. Whether exogenous interferon-g can correct these defects is problematical and the therapeutic consequences are still more speculative. While one controlled trial showed some benefit in rheumatoid arthritis (Cannon *et al*. 1990), the results overall have been unimpressive and perhaps predictably so. More theoretically encouraging are cytokines whose effects are more likely to interdict other cytokines of proven immunopathogenetic relevance. For example, interleukin 10 (**IL-10**) inhibits the *in vitro* synthesis of IL-1 and TNF-a by rheumatoid synoviocytes (Katsikis *et al*. 1994) and also inhibits the induction of experimental allergic encephalomyelitis (Rott *et al*. 1994). This principle has not been tested in clinical practice but there is at least a stronger rationale than has been evident in earlier trials of cytokine manipulation.

The current phase of cytokine suppression is based on the inhibition of circulating cytokines by drugs or specific monoclonal antibodies. The proven importance of IL-1 in rheumatoid synovitis directed attention to this cytokine. Collagen-induced arthritis in mice is largely suppressed by treatment with a polyclonal anti-IL-1 antibody (Van den Berg *et al*. 1994). Tenidap has been introduced largely on the rationale that it inhibits the *in vitro* production of IL-1b and also of TNF-a and IL-6. However, it also inhibits cyclo-oxygenase production so that its anti-inflammatory effects are not entirely attributable to its effects on cytokine production. Clinical benefit has been noted in a double-blind, comparative trial of tenidap and the anti-inflammatory drug piroxicam (Littman *et al*. 1995). Tenidap was more effective than piroxicam in reducing blood levels of IL-6 and the intensity of the acute-phase response. The findings were similar in a 24-week comparative trial of tenidap and the anti-inflammatory drug diclofenac (Wylie *et al*. 1995). However, the high incidence of adverse effects and the limited duration of the reported trials makes it impossible to judge the potential of this agent on current evidence.

Arguably the most impressive results of selective cytokine inhibition have been achieved by treating rheumatoid arthritis with an anti-TNF-a monoclonal antibody. This agent also was found to be effective in earlier studies of experimental collagen-induced arthritis (Williams *et al*. 1992). Successful treatment in an open trial in 20 patients with rheumatoid arthritis (Elliott *et al*. 1993) was confirmed in a more extensive, placebo-controlled trial in 73 patients (Elliott *et al*. 1994). The clinical improvement was accompanied by a marked fall in blood C-reactive protein and IL-6 concentrations. In a similar double-blind, placebo-controlled study, a recombinant anti-TNF-a monoclonal antibody combining mouse hypervariable regions and a human IgG4 immunoglobulin reduced both joint activity and the acute-phase reaction (Rankin *et al*. 1995). However, there is as yet little information about the duration of remissions induced by this treatment, protection against joint erosion, or the patients' ability to tolerate further infusions. There is also some concern that long-term inhibition of TNF-a may make the recipients susceptible to intercurrent infections. It is still unclear how this agent achieves its anti-inflammatory effects since neutralizing the low circulating levels of this cytokine is surprisingly effective. *In vitro* and *in vivo* experiments suggest that this neutralization may have wider effects including the reversal of depressed cell-mediated immunity secondary to prolonged exposure to high TNF-a concentrations (Cope *et al*. 1994).

A potentially still more elegant method of inhibiting cytokine production depends on inhibiting the translation of messenger RNA (**mRNA**) by antisense oligonucleotides. In one experimental system an antisense nucleotide specific for IL-6 mRNA penetrated human articular cartilage *in vitro* and prevented the synthesis of this cytokine. This in turn blocked the inhibition of cartilage synthesis by IL-6 normally induced under the influence of IL-1 (Nietfeld *et al*. 1994). The success of this approach depends on the development of suitable delivery systems.

There is still only a fragmentary picture of experimental and clinical trials of methods for inhibiting cytokine receptors. Treatment with a soluble recombinant anti-IL-1 receptor antagonist reduces the intensity of collagen-induced arthritis in mice (Wooley *et al*. 1993a), but clinical trials have not yet been reported. IL-2 receptor blockade is effective in experimental autoimmune diabetes (Kelley *et al*. 1988) and there is preliminary evidence from a limited clinical trial that an intravenously administered IL-2 fusion toxin may be effective in rheumatoid arthritis (Sewell *et al*. 1993). On the same principle, a fusion protein in which the soluble TNF p55 receptor was linked to the Fc fragment of the IgG molecule efficiently blocked collagen-induced arthritis in mice (Wooley *et al*. 1993b); this agent has not yet been used in clinical practice. Similarly, a fusion protein consisting of human IL-2 and part of the diphtheria toxin selectively blocks the proliferation of activated T cells *in vitro*. In a clinical trial in psoriasis, which is T-cell dependent, this protein produced clinical improvement in four of the eight patients treated (Gottlieb *et al*. 1995).

The most fundamental way of correcting cytokine-mediated abnormalities is to devise methods of introducing genes whose transcribed proteins will block the excessive or unopposed production of proinflammatory or tissue-destructive cytokines. This could in principle be achieved locally, as in the rheumatoid synovial membrane, or systemically, in lymphoreticular tissues. Potentially therapeutic genes have been successfully transferred to the synovium. For example, a gene which encodes a protein antagonizing the IL-1 receptor was transfected to synovium and thereby protected the joint from IL-1 mediated destruction (Evans and Robbins 1994). The technology for gene transfer is well established. The main problems in the clinical application of these methods is to define cytokine expression and physiology in different diseases in precise detail. The potential hazards of gene transfer are still the subject of unproven speculation.

Dietary manipulation

There have now been intensive studies of the effects of dietary manipulation on experimental models of autoimmune disease and in clinical practice. This interest was largely stimulated by lay and medical disquiet over the failings and hazards of conventional antirheumatic drugs. It has now become a scientifically acceptable form of investigation which has revealed many interesting links between diet and inflammation (Darlington and Ramsay 1994).

In general terms there have been three main areas of study, namely the effects of dietary restriction, alterations in fat intake, and a search for dietary allergens of possible immunopathological relevance.

The most stringent form of dietary restriction is fasting and this regimen has anti-inflammatory effects in rheumatoid arthritis (Skoldstam and Magnusson 1991). In a controlled comparative trial, fasting followed by a gluten-free, lactovegetarian diet was effective for up to 1 year (Kjeldsen-Kragh *et al*. 1991) and the improvement was sustained for up to 2 years (Kjeldsen-Kragh *et al*. 1992). Interestingly, this improvement may have reflected not dietary factors but the patients attitude to treatment. The patients who responded to this form of treatment may have had confidence in a regimen under their control matched by scepticism about conventional drug treatment (Kjeldsen-Kragh *et al*. 1994a). A less draconian form of initial dietary restriction than fasting involves recourse to an elemental diet. This regimen has a beneficial effect on rheumatoid arthritis and the improvement is more likely to be attributable to protein and calorie deprivation than allergen exclusion (Kavanagh *et al*. 1995). Similar reservations were expressed after a comparable trial of this nature (Haugen *et al*. 1994a). Lactovegetarian diets also induce an improvement in rheumatoid synovitis and patients are more likely to comply with this form of diet than with more stringent ones. This diet probably has direct anti-inflammatory effects (Kjeldsen-Kragh *et al*. 1995). Gut flora is appreciably altered introducing intriguing possibilities about the cause of the clinical improvement (Peltonen *et al*. 1994). It is unlikely that the benefit can be attributed to changes in fatty acid composition (Haugen *et al*. 1994b).

The composition of dietary fat influences immune-mediated inflammation (Denman 1992). A low fat diet retards and a high fat diet accelerates genetically determined murine lupus. Furthermore, dietary fish-oil supplements also suppress disease features and increase longevity in this model. The high eicosapentaenoic acid content of fish oil is broken down into anti-inflammatory prostaglandins, possibly accounting for the protective effects.

The same dietary principles have been used to treat rheumatoid arthritis. Dietary enrichment with fish oils rich in -3 polyunsaturated acids significantly reduces joint inflammation judged by controlled trials (Nielson *et al*. 1992; Geusens *et al*. 1994; Kjeldsen-Kragh *et al*. 1994b). The likely mechanism is a relative increase in these acids in the phospholipid fraction of cell membranes at the expense of -6 polyunsaturated fatty acids. This substitution reduces the precursors of the proinflammatory 4 series leukotrienes and the 2 series prostaglandins (Tulleken *et al*. 1990). In addition to the inhibitory effects of these manoeuvres on conventional proinflammatory pathways, the production of IL-1, IL-6, and TNF-a is also inhibited (Watson *et al*. 1993).

There is little evidence that intolerance to dietary allergens contributes to disease activity in rheumatoid arthritis or systemic autoimmune diseases. This conclusion is supported by the failure to correlate changes in disease activity with the reintroduction of dietary items in patients on exclusion regimens. However, there is a suggestion that milk intolerance may be relevant in some patients and that an IgE-mediated component may contribute to the inflammation (Van de Laar and Van der Korst 1992; Van de Laar *et al*. 1992).

There is no doubt that dietary manipulation in the rheumatic diseases has achieved respectability. Treatment with fish oil or other sources of unsaturated fatty acids can be expected to achieve a 10 to15 per cent reduction in inflammatory activity in most patients. It is reasonable to encourage suitably motivated patients to pursue vegetarian diets, which generally prove nutritionally acceptable (Haugen *et al*. 1993) but nevertheless need careful supervision (Rauma *et al*. 1993).

Conclusions

Recent advances in understanding immunopathological mechanisms in the rheumatic diseases have stimulated a host of novel and ingenious methods of interdicting these pathways. Although many fundamental questions about the aetiology of most of these disorders are still unanswered, immunomanipulation is becoming increasingly rational and less pragmatic. Moreover, expectations raised by the success of these methods in experimental disease models have been gratifyingly realized in clinical studies. They usually work according to predictions, they produce at least a short-term remission, and their benefit has often been confirmed in controlled trials. Nevertheless many problems need to be settled before rheumatologists can at last move away from the hazards of traditional, non-specific immunosuppression. Not every speculation about the relative importance of different immune systems will necessarily be fulfilled. For example, the selective interdiction of CD4 T cells has not been shown to produce lasting benefit despite the central role attributed to these cells in many current ideas about the immunopathogenesis of rheumatoid synovitis. Enthusiasm over the successful suppression of rheumatoid synovitis by anticytokine monoclonal antibodies is yet to pass the real test, namely their ability to inhibit joint destruction. Only careful surveillance will test the long-term safety of even relatively selective immunomanipulation. This is especially true of the complex cytokine system whose members are interdependent and have pleomorphic effects. Simpler and cheaper drugs in routine clinical use may yet prove more cost-effective and not significantly less efficacious or more dangerous than scientifically more elegant methods.

4.1 Acute phase response

Rosamonde E. Banks, John T. Whicher, Douglas Thompson and Howard A. Bird

What is the acute phase response and how is it assessed?

The acute phase response

The acute phase response is the term generally used to describe the concerted series of diverse systemic and local events, which accompany inflammation resulting from tissue damage. Despite the term 'acute phase', the changes may be present in both acute and chronic inflammatory situations. These events are usually considered to be protective in nature, facilitating the inflammatory process and ultimately culminating in removal of tissue debris and foreign organisms, and tissue repair. They include fever, endocrine changes, leucocytosis, muscle proteolysis, and an increase in the synthesis of specific liver-derived proteins—the acute phase proteins. It is this latter event which is often used as an indicator of the presence and extent of the inflammatory process and indeed it is often used synonymously with the term 'acute phase response'. We will also follow this convention for the purposes of this chapter.

There are approximately 30 acute phase proteins. They fall into several different structural and functional categories of plasma proteins and fulfil various roles in inflammation such as inhibition of phagocyte-derived proteases, scavenging of cellular debris, and mediation and inhibition of the inflammatory process (Table 1) (reviewed by Laurell 1985; Kushner and Mackiewicz 1987; Whicher *et al*. 1989; Schultz and Arnold 1990; Mackiewicz *et al*. 1993; Steel and Whitehead 1994). The increase in serum concentration of these proteins (which by definition must be by at least 25 per cent in the first 7 days following tissue damage (Kushner 1982) probably serves to maintain their circulating and tissue levels, which may otherwise become depleted as a result of their consumption at the site of inflammation.

Table 1 The positive acute phase proteins and their proposed functions (adapted from Whicher *et al*. 1989)

The increased synthesis of the acute phase proteins by the liver has been ascribed to several cytokines, including interleukin 1 (IL-1), tumour necrosis factor-a (TNF-a) and particularly interleukin 6 (IL-6). These cytokines are predominantly derived from activated macrophages at the site of injury although they can be produced by many other cell types such as fibroblasts and endothelial cells, and they have also been implicated in mediating other aspects of the acute response such as fever (see Chapter 3.1). From extensive experimental work, principally involving cultured hepatoma cell lines, it is apparent that the regulation of the acute phase proteins is complex and that subsets of acute phase proteins are induced by different cytokines (reviewed by Baumann and Gauldie 1994). The IL-1 group of cytokines, IL-1a and b and TNF-a and b, induce the production of so-called type-1 acute phase proteins which include a $_1$-acid glycoprotein, serum amyloid A protein, C-reactive protein, and complement component C3, whereas the IL-6 family of cytokines (IL-6, IL-11, leukaemia inhibitory factor, oncostatin M, and ciliary neurotrophic factor) induce the synthesis of type-2, IL-6 specific, acute phase proteins, fibrinogen, a $_1$-antitrypsin, a$_1$-antichymotrypsin, haptoglobin, haemopexin, and caeruloplasmin. In most cases IL-1 or TNF have no effect on the production of type-2 acute phase proteins but the IL-6 group of cytokines can induce type-1 acute phase proteins and synergistically enhance the IL-1 and TNF-mediated production of the type-1 acute phase proteins. However to a certain extent these actions depend on the species and hepatocytes being examined. In addition, two groups of factors modulate cytokine-induced acute phase protein synthesis, namely the glucocorticoids and the growth factors such as insulin, insulin-like growth factor, hepatic growth factor, fibroblast growth factor and transforming growth factor-b (Baumann *et al*. 1987; Thompson *et al*. 1991). The net result achieved is dependent on the overall interactions (Fig. 1).

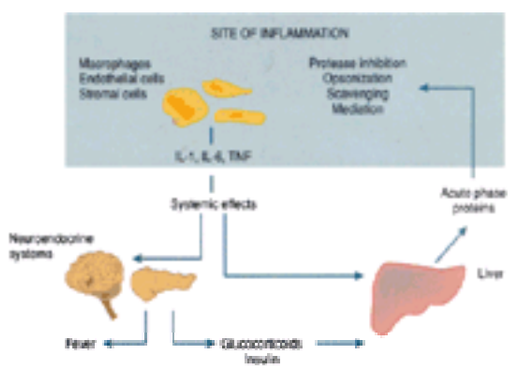

Fig. 1 The regulation of the acute phase protein response. The systemic acute phase protein response is mediated by cytokines such as IL-6, IL-1, and TNF-a released by activated macrophages, endothelial cells and stromal cells at the site of inflammation. The systemic effects of these cytokines include muscle proteolysis, fever, and the production of acute phase proteins, which exert a range of function at the site of inflammation. The synthesis of acute phase proteins can also be

modulated by hormones such as the glucocorticoids and insulin.

Most of the changes in acute phase protein production are thought to be mediated at the transcriptional level, however post-transcriptional modulation such as increases in stability of mRNA for positive acute phase proteins and altered glycosylation and hence possibly bioactivity/stability may also contribute to their regulation (reviewed by Steel and Whitehead 1994). Although the liver is generally accepted as being the site of acute phase protein synthesis, it is now recognized that extrahepatic tissues also have this capability. It has been shown for example, that cells of the monocyte–macrophage lineage can produce several complement components and a_1-antitrypsin. The significance of this and the extent to which it normally occurs in vivo, particularly at the site of inflammation, is not known.

A small group of proteins including albumin, transthyretin, retinol-binding protein and transferrin decrease in serum concentration during inflammation. These are often referred to as the 'negative acute phase proteins'. This decrease has been attributed to increased catabolism and vascular permeability although recent studies indicate that cytokines are capable of decreasing transcription of at least some of the negative acute phase protein genes (reviewed by Mackiewicz *et al*. 1993; Steel and Whitehead 1994).

Kinetics of the acute phase response in disease

The rate and extent of the increase in plasma concentration of any acute phase protein depends on factors such as molecular size, volume of distribution, rate and sensitivity to induction, and the rate of catabolism. Considerable incremental and kinetic differences are therefore seen between the various proteins. In acute inflammation, the overall pattern of the response is relatively constant, provided that the magnitude of the response is sufficient to elicit a detectable change in all the proteins. The properties of the major acute phase proteins and typical magnitudes and time courses of response are shown in Table 2. It is important to appreciate the differences in kinetics of these changes, for example while some proteins are elevated within 6 to 8 h of stimulus, there is no apparent change in others for appreciably longer. These relative changes in the acute phase proteins are exemplified in Fig. 2 which shows the changes in positive acute phase proteins in vivo following administration of IL-6.

Protein	Response time (h)	Molecular weight	Adult reference ranges
Group II: <1 × increase			
Caeruloplasmin	48–72	132 000	0.20–0.60 g/l (30–600 units)
Complement components C3	48–72	180 000	0.75–1.65 g/l (30–600 units)
C4	48–72	206 000	0.20–0.60 g/l (30–600 units)
Group II: 2–4 × increase			
α_1-Acid glycoprotein	24	41 000	0.5–1.2 g/l (male); 0.4–1.0 g/l (female); 5 to 10 years of age
α_1-Antitrypsin	10	54 000	1.3–2.1 g/l (30–600 units)
α_1-Antichymotrypsin	10	68 000	0.3–0.6 g/l
Haptoglobin	24	86 000	0.3–2.0 g/l (male); 0.4–1.6 g/l (female)
Fibrinogen	24	340 000	2.0–4.0 g/l
Group III: up to 1000 × increase			
C-reactive protein	8–10	110 000	0.008–0.3 mg/l
Serum amyloid A	8–10	180 000	

Adapted from Kushner and Mackiewicz (1987).
The normal ranges are those published by the Protein Reference Unit (1983) with the exception of fibrinogen (Blann and Lowe 1993) and C-reactive protein (Cross et al 1979). Levels of many of these proteins are affected by factors such as age and pregnancy (Kluft and Ramsoek 1979; Altman et al 1986).

Table 2 Properties of the major acute phase proteins

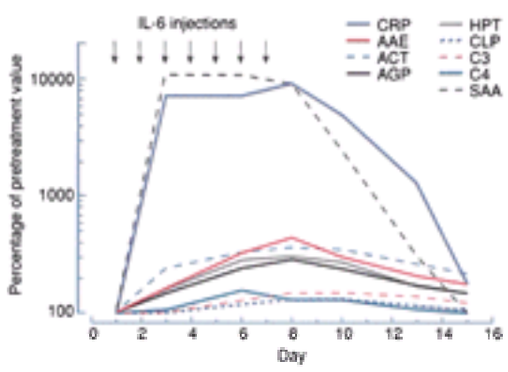

Fig. 2 Profile of the relative changes in the positive acute phase proteins following IL-6 treatment in a patient with cancer. IL-6 was administered subcutaneously once daily for 7 days (arrows) at a dose of 10 µg/kg per day (reproduced from Banks *et al*. 1995, with permission).

Generally the magnitude of the response is related quantitatively to the activity or extent of inflammation in the acute situation. In bacterial infection, an extremely large response is seen, probably as a result of systemic endotoxin-induced release of cytokines such as IL-1, IL-6, and TNF from macrophages. However, particularly in chronic inflammation, differential increases in catabolic rate may also result in altered 'profiles' for several proteins. For example when vasculitis is present, concentrations of a_1-antitrypsin are inappropriately low when compared with a group of other acute phase proteins, owing to its consumption by leucocyte enzymes. Similarly if intravascular coagulation is a complication, levels of fibrinogen may be lower than would otherwise be expected and haptoglobin is lower if haemolysis is occurring. Such differences in themselves may be useful in drawing attention to possible complications which may be present with the inflammatory process, but would contraindicate the effective use of that particular protein as an inflammatory marker in that particular situation. Often in chronic inflammation the magnitude of the overall response is lower than expected for the degree of inflammatory activity, possibly as a result of down-regulation. As will be discussed later in this chapter, some diseases show little or no acute phase response even though acute inflammation is clinically apparent.

Laboratory measurements of the acute phase response (see Chapter 4.2)

The main parameters usually measured to assess the acute phase response are the erythrocyte sedimentation rate (ESR), plasma viscosity, and the plasma concentrations of the acute phase proteins. General guidelines as to the relative merits of these tests have been drawn up by the International Committee for Standardization in Haematology (ICSH 1988). In view of the role of cytokines in the control of the acute phase response, it may be relevant in the future to include plasma levels of cytokines as an additional parameter to be used. Many cytokines can now be assayed either by bioassay or by immunoassay, but problems exist such as lack of sensitivity, poor inter-laboratory reproducibility, and unknown effects of inhibitors. However the use of cytokine assays in the clinical situation is likely to increase in the future with further research. This area has already been covered in Chapter 3.1 and will not be discussed further here.

Erythrocyte sedimentation rate (ESR) and plasma viscosity

The ESR is the oldest and probably still the most widely used index of the acute phase response (reviewed by Zlonis 1993). It is a laboratory measurement of the rate of sedimentation of erythrocytes which is dependent on their degree of aggregation and the packed cell volume (PCV). Aggregation is strongly influenced by the concentration of large asymmetric plasma proteins such as fibrinogen, a_2-macroglobulin, and immunoglobulins. The ESR is therefore a composite measurement reflecting changes in several proteins.

There are several disadvantages to this assay. It is influenced by red cell number and characteristics, abnormal immunoglobulins or complexes such as occur in myeloma or cryoglobulinaemia, age and sex, smoking, menstrual cycle, drugs, and dietary lipids therefore resulting in a circadian rhythm. In addition the ESR in the acute phase is mainly influenced by fibrinogen, an acute phase protein which is slow to increase and persists long after the inflammation subsides because of its long half-life. Its reliance on fibrinogen levels means that the ESR is often insensitive and relates poorly to the time-course of the inflammation, and is influenced by complications which result in the consumption of fibrinogen, such as the presence of intravascular coagulation. Due to the relative instability of red blood cells in terms

of their deformability and aggregation, stored samples cannot be used. Standardization and quality control are difficult although recent recommendations may improve this (ICSH 1993).

Plasma viscosity is increasingly being used in place of the ESR and has several advantages as a routine measurement (Lowe 1994). It is dependent on the concentrations of the same group of large-molecular-weight proteins but shows less interindividual variation than the ESR. This is at least partly because the plasma viscosity, unlike the ESR, is affected minimally by age, sex or pregnancy, and it is not affected by anaemia or red cell morphology. In addition it is a more rapid test to perform, easier to standardize and stored samples are suitable for use.

Despite the above reservations about the ESR and plasma viscosity, these are technically simple and inexpensive assays to perform and may provide a better screening test for the detection of many diseases than the measurement of a single acute phase protein. For example the ESR integrates the effects of anaemia, immune response and acute phase response. These tests thus still play an important role in the detection and monitoring of chronic inflammation where the hyperproteinaemia is more complex than in the acute situation, involving changes in other pathologically important proteins such as immunoglobulins.

Acute phase proteins

Individual acute phase proteins are usually assayed using specific antisera, the precise immunochemical technique being dependent on the particular laboratory. The techniques most often used are radial immunodiffusion (RID), enzyme-linked immunosorbent assay (ELISA), radioimmunoassay (RIA), and nephelometry. Proposed functions of the acute phase proteins have been given in Table 1 and the properties of the major acute phase proteins together with their reference ranges are shown in Table 2. However it must be emphasized that reference ranges vary between laboratories and clinicians should consult their own laboratories for appropriate figures. The relative merits of the major acute phase proteins as markers of inflammation are discussed below. Detailed reviews have been published by Laurell (1985) and Thompson *et al*. (1992).

C-reactive protein (CRP)

C-reactive protein is a non-glycosylated protein composed of five identical 21 kDa non-covalently bound globular subunits, a member of the pentraxin family. It is the most useful index of the acute phase response being specific, sensitive, and rising rapidly within 6 to10 h following the inflammatory event. This time lag represents the time for complete synthesis of the molecule as no hepatic store exists. Levels reach a peak by about 48 h and, because of its short half-life of approximately 19 h in man (Vigushin *et al*. 1993), decline rapidly following the decrease in inflammatory activity. It has been shown in humans that the catabolism of CRP is independent of its plasma concentration and is not affected by the presence of inflammatory illnesses such as rheumatoid arthritis, systemic lupus erythematosus or infections (Vigushin *et al*. 1993). This, coupled with the fact that there is no significant tissue sequestration of CRP, indicates that the circulating concentration is determined solely by the its rate of synthesis and hence inflammatory stimulus. However the normal range for CRP is very wide from 0.068 to 8.0 mg/l with a median value of 0.58 mg/l (Claus *et al*. 1976), and with many routine assay methods only having a lower limit of detection of between 5 and 10 mg/l, it is apparent that CRP concentrations in some individuals could increase more than a hundredfold and still remain within normal limits. It is therefore an unsuitable protein for detecting very mild inflammation unless sensitive assays are used, serial determinations are made and the normal values are known for the individual. Typically, mild infections are associated with CRP levels of between 10 and 40 mg/l (Peltola 1982), acute inflammation and moderate bacterial infection with levels of between 40 and 200 mg/l, and severe bacterial infection can produce levels in excess of 300 mg/l (Morley and Kushner 1982). For detecting or monitoring chronic inflammation, an additional slower reacting acute phase protein such as a_1-antichymotrypsin or a_1-acid glycoprotein or the ESR should also be measured as CRP may be transiently normal during brief remission periods. A World Health Organization (WHO) international standard is available.

Serum amyloid A protein (SAA)

SAA proteins are a family of at least three different apolipoproteins with similar kinetics to C-reactive protein but possibly greater sensitivity (reviewed by Malle *et al*. 1993). It is elevated even in relatively mild conditions such as the common cold. Higher levels of SAA have been reported in diseases which carry an increased risk of amyloidosis such as rheumatoid arthritis and systemic juvenile rheumatoid arthritis (De Beer *et al*. 1982) but as SAA is not routinely measured at present, for a variety of reasons including scarcity of suitable antisera and lack of an appropriate standard, it will not be covered further here.

a_1-Antichymotrypsin (ACT)

a_1-Antichymotrypsin is a glycoprotein consisting of a single polypeptide chain, with oligosaccharide chains accounting for approximately 23 per cent of its molecular weight. Measurement of a_1-antichymotrypsin is often available routinely and normal levels lie in the range of 0.3 to 0.6 g/l. It increases almost as rapidly as C-reactive protein and SAA following tissue injury, although normally only increasing two- to fourfold. It remains elevated for longer than C-reactive protein, is easy to measure, and does not suffer from genetic variation or differential catabolism. There is however an inter-laboratory standardization problem as values obtained are dependent on the antibody and standard used. At present relatively little is known about its levels in different inflammatory states.

Haptoglobin

Haptoglobin is a member of a family of polymers of a-b-chains with the a-chain having two main genetic variants. It is much slower in response but can be measured routinely. It is generally unsuitable as an acute phase response indicator however, because of its consumption associated with haemolysis, and genetic variations giving rise to phenotypic reference anges.

a_1-Antitrypsin (AAT)

The glycoprotein a_1-antitrypsin (a_1-proteinase inhibitor) can be routinely assayed and standardized with WHO preparations. It is generally unsuitable as an indicator of the acute phase response as genetic variants give rise to decreased serum levels. Approximately 15 per cent of the Caucasian population are heterozygous and have lower normal levels than the 1.1 to 2.1 g/l found in the normal homozygous MM phenotype. In addition levels increase in pregnancy or with oestrogen treatment, and may be inappropriately lowered in vasculitis because of its consumption.

Fibrinogen

Fibrinogen is composed of three pairs of non-identical polypeptide chains, two of which are glycosylated. Fibrinogen is slow to exhibit changes in concentration during inflammation and is relatively insensitive. Additionally, it is difficult to assay because gel-based techniques such as radial immunodiffusion (RID) are unsuitable as fibrinogen has a tendency to precipitate, particularly after storage.

a_1-Acid glycoprotein (AGP)

a_1-Acid glycoprotein (orosomucoid), as its name suggests, is glycosylated with polysaccharide chains accounting for 45 per cent of the molecule. Genetic variants exist although these have no effect on normal serum ranges. Levels of a_1-acid glycoprotein are not measured routinely being less sensitive than C-reactive protein or a_1-antichymotrypsin. In addition, concentrations may be decreased in pregnancy or during oestrogen treatment and a disproportionate increase in a_1-acid glycoprotein levels may occur in chronic renal disease, resulting from a reduction in the glomerular filtration rate.

C3, C4, and caeruloplasmin

Complement components C3 and C4, and the copper-binding glycoprotein caeruloplasmin are very insensitive and too slow to increase to be of use as markers of the acute phase response, although low C3 or C4 concentrations indicating their consumption may be of use for monitoring of immunologically-based diseases.

Clinical use of the acute phase response

Although the presence of an acute phase response is associated unequivocally with inflammation, the reverse is not always true. Inflammation occurring with mild chronic tissue damage, localized disease, recurrent attacks, or certain diseases including ulcerative colitis and systemic lupus erythematosus is often found

associated with a normal ESR or CRP level. The acute phase response by nature is a non-specific response in terms of the disease and therefore must be used in conjunction with other more specific tests for diagnostic purposes as it can be elevated in many pathological conditions and indeed some acute phase proteins such as a_1-antitrypsin and caeruloplasmin also exhibit elevated levels in physiological circumstances such as pregnancy (Laurell and Rannevik 1979). Although the magnitude of the acute phase response is related generally to the mass or activity of inflammation, this is not always the case. As previously indicated, an extremely large acute phase response is seen in bacterial infections for example, presumably as a result of the systemic endotoxin-induced release of IL-1, IL-6, and TNF from macrophages.

However, together with other clinical and laboratory measurements, the assessment of the acute phase response is generally used in three main ways to assist the rheumatologist.

1. detection of organic disease;
2. assessment of extent or activity of the disease, monitoring of therapy, and indication of prognosis;
3. detection of intercurrent infection.

There is no acute phase response in patients with soft tissue rheumatism or osteoporosis. The use of the acute phase response is given below for each of the main disease groups within the arthritides.

Crystal deposition diseases

The acute phase response may be only mild or absent in crystal deposition diseases unless accompanied by superimposed infection in the joints. In gout however, an acute phase response is often seen and C-reactive protein levels may reach in excess of 100 mg/1, even in the absence of intercurrent infection (Roseff *et al*. 1987).

Osteoarthritis

Primary generalized or nodal osteoarthritis is not associated with an acute phase response, the ESR being normal or only mildly elevated in the majority of cases (reviewed by Altman and Gray 1985). This may be partly age-related. No difference is seen between erosive and non-erosive osteoarthritis and there is no practical value in attempting to determine the severity of episodes of inflammation by the measurement of the acute phase response. Plasma viscosity however has been reported to be slightly elevated in more than 80 per cent of patients examined with non-erosive osteoarthritis (Sitton *et al*. 1987).

Polymyalgia rheumatica and giant cell arteritis

Most studies report a raised ESR in 95 to 100 per cent of patients with polymyalgia rheumatica/giant cell arteritis at presentation (reviewed by Kyle 1991), and indeed an ESR of greater than 50 mm/h is now included as one of five diagnostic criteria to be used in the classification of giant cell arteritis (Hunder *et al*. 1990). This marked acute phase response is of use clinically to differentiate between polymyalgia rheumatica and other causes of myalgia such as depression, myositis and thyroid disease, due to the lack of other abnormal biochemical findings in polymyaglia rheumatica. However there are reports of patients with biopsy-proven giant cell arteritis in whom the ESR is normal (reviewed by Kyle 1991) and it has been suggested that at least in some cases this may be because of prior use of steroids (Wise *et al*. 1991). A significant correlation between plasma viscosity and ESR has been reported (Esselinckx *et al*. 1977), but in 30 out of the 112 paired readings, one parameter was abnormal in the presence of a normal value for the other. Acute phase proteins such as CRP, a_1-acid glycoprotein, a_1-antichymotrypsin, and haptoglobin are also elevated in the majority of untreated patients with polymyaglia rheumatica or giant cell arteritis (CRP may be in excess of 100 mg/1). However the elevation of a_1-acid glycoprotein by corticosteroids and the consumption of haptoglobin limit their potential usefulness in monitoring disease activity, and a_1-antichymotrypsin does not decrease with clinical remission although lower concentrations during follow-up may be indicative of a reduced risk of subsequent relapse (Pountain *et al*. 1994). There is some controversy as to whether CRP or the ESR is the better index of disease activity and both may remain normal during clinical relapse on treatment (Mallya *et al*. 1985; Kyle *et al*. 1989; Berlit 1992; Pountain *et al*. 1994). If clinical suspicion of the disease is strong yet the chosen parameter is not abnormal, it may be appropriate to measure the other. Measurement of either CRP or the ESR may be used together with clinical assessment to monitor the initial effectiveness of steroid therapy, thus minimizing the risk of arteritis, with the change in CRP more rapidly reflecting the clinical improvement and in most cases reaching normal levels within 7 to 14 days of the start of steroid administration. Neither CRP nor ESR levels can be used to predict a relapse however.

Autoimmune rheumatic disorders

The acute phase response is often moderate or absent in these disorders, even when clinically active, and if marked may suggest alternative pathology. However in systemic lupus erythematosus the ESR is elevated in nearly all patients, often falling with a decline in disease activity, although it is of little use clinically. The use of CRP levels to discriminate between intercurrent infection (with or without fever) and disease exacerbation is controversial. Most studies report generally higher CRP levels in patients with infection compared with active disease (reviewed by Pepys *et al*. 1982). It has been proposed that a serum CRP level of greater than 60 mg/1 is strongly indicative of infection, with CRP levels of less than 30 mg/1 making it unlikely that severe infection is present (Pepys *et al*. 1982). However the discriminatory power of CRP levels is not absolute and must be viewed with caution as levels in excess of 60 mg/1 have been reported in patients with systemic lupus erythematosus in the absence of infection, and patients with this disease and intercurrent infection may have normal or only moderately elevated levels of CRP (Pepys *et al*. 1982; Mackiewicz *et al*. 1987a). Recently it has been proposed that the discriminatory ability of CRP levels is only of value in the absence of serositis (Ter Borg *et al*. 1990). In addition, patients with Jaccoud's arthropathy or polyarthritis appear to have higher CRP concentrations (Spronk *et al*. 1992).

The reason for the relative lack of acute phase response in many of the autoimmune rheumatic disorders even in the presence of active inflammation is not clear, but the finding of identical clearance rates for CRP in patients with systemic lupus erythematosus compared with healthy controls make it unlikely that altered clearance mechanisms account for the apparent lack of response (Vigushin *et al*. 1993). It is also unlikely to be due to a straightforward lack of hepatic responsiveness as these patients can present such a response in the case of bacterial infection. However, with the complex regulation of the acute phase response by a network of cytokine interactions, it is possible that the response may be impaired by certain combinations of cytokines which are present in this disease, either at the level of the hepatocyte or because of cytokine inhibitors (reviewed by Gordon and Emery 1993). This is discussed further in Chapter 3.1.

Seronegative spondylarthritides

Ankylosing spondylitis is variably associated with a raised ESR, plasma viscosity and CRP. Reports regarding correlation with disease activity are conflicting, possibly due at least in part to differences in study design and definitions of active disease. Generally CRP levels are between 10 and 30 mg/1 although levels in excess of 100 mg/1 have been reported in active disease. CRP or plasma viscosity have been advocated as being more sensitive markers of active disease than the ESR (Dixon *et al*. 1981) and significantly elevated CRP levels have been found in patients with active disease compared with inactive disease (Nashel *et al*. 1986). However Cowling *et al*. (1980) found CRP and ESR correlated well, both with each other and with disease activity. In subsequent studies, although the ESR was found to correlate with levels of CRP and other acute phase proteins, none of these parameters correlated with disease activity (Laurent and Panayi 1983; Sheehan *et al*. 1986). More recently Reynolds *et al*. (1991) have shown a significant correlation between disease activity and CRP levels only in HLA-B27 positive patients.

CRP levels in patients with Behçet's syndrome do not usually exceed 20 mg/1. Most patients with psoriatic arthritis have an increased plasma viscosity compared with controls (Sitton *et al*. 1987). Both psoriatic arthritis and Reiter's syndrome are associated generally with normal or only mildly elevated levels of CRP (Sitton *et al*. 1987), although levels as high as 40 mg/1 have been reported in patients with active Reiter's syndrome (Nashel *et al*. 1986). The few reports concerning the use of CRP or ESR to monitor disease activity in these illnesses are contradictory and hence no conclusion can be drawn.

Rheumatoid arthritis

Rheumatoid arthritis is associated generally with a marked acute phase response although fever is usually absent. Plasma viscosity, ESR and CRP levels are nearly always elevated and in many cases, although not all, reflect disease activity (reviewed by Van Leeuwen and Van Rijswijk 1994). CRP levels are generally in the range of 30 to 40 mg/1 in patients with moderate disease activity, and may reach in excess of 100 mg/1 in severe disease, although in a small group of patients CRP levels lie within the normal range despite clinical evidence of active disease. CRP concentrations in excess of 150 mg/1 may be indicative of an intercurrent bacterial infection. The question of which of these parameters is the best index of disease activity is open to debate (McKenna 1988). a_1-Antichymotrypsin has also been reported to reflect disease activity in rheumatoid arthritis, being elevated even in those patients in whom CRP levels are normal despite clinical evidence of active

disease (Chard *et al*. 1988), and merits further investigation.

Studies examining the prognostic implications of the acute phase response in rheumatoid arthritis have recently been reviewed (McKenna 1988, Van Leeuwen and Van Rijswijk 1994). In general it appears that isolated measurements of the acute response are of little use in predicting outcome of the disease. However, persistently higher ESR and CRP measurements have been associated with a higher rate of radiological progression (Amos *et al*. 1977; Dawes *et al*. 1986). More recently, time-integrated values of CRP and ESR have been found to be correlated significantly with radiological progression both in patients with early disease and in those with long-standing disease (Hassell *et al*. 1993; Van Leeuwen *et al*. 1993; Van Leeuwen *et al*. 1994). However with the considerable interindividual variation in CRP values found, it would be inappropriate to attempt to use a single cut-off value for prognostic purposes but rather the longitudinal findings need to be interpreted for each individual patient (reviewed by Van Leeuwen and Van Rijswijk 1994).

Following an examination of the literature, the American College of Rheumatology have recommended that the ESR or CRP should be one of the core set of disease activity measures in clinical trials (Felson *et al*. 1993). The slow-acting disease-modifying drugs such as gold, sulphasalazine, D-penicillamine, and hydroxychloroquine are usually associated with a decline in the acute phase protein response (reviewed by Kvien and Husby 1992; Menkes 1993). An exception is cyclosporin which has no effect on the ESR. A recent European collaborative study found ESR to be a more useful measure of disease activity than CRP, with CRP presenting standardization problems between countries and laboratories (Scott *et al*. 1992). Although a vast majority of studies have failed to find any effect of non-steroidal anti-inflammatory drugs on the acute phase response, a study which differentiated between clinical 'responders' and 'non-responders' in their analysis, did suggest a decline in ESR and CRP levels in the 'responders', correlating with improvement in clinical variables (Cush *et al*. 1990). However the finding that CRP decreases even in some clinical 'non-responders' suggests that this decline in acute phase protein response may not be secondary to a suppression of joint inflammation and cytokine production by the drugs, but rather to some other mechanism. Obviously under these circumstances, the use of the acute phase reactants to monitor drug efficacy would be inappropriate.

Conflicting reports exist regarding a possible association between a $_1$-antitrypsin phenotype and rheumatoid arthritis but the evidence overall does not currently support any such association (Kahl *et al*. 1989).

Potential future developments

Glycosylation of acute phase proteins

Many serum glycoproteins exhibit microheterogeneity due to variations in their *N*-linked heteroglycan sidechains. Such variation is often assessed using crossed immunoaffinity electrophoresis, on the basis of the degree of reactivity with the lectin concanavalin A, which reacts with biantennary glycans. In patients with active polymyalgia rheumatica the glycan microheterogeneity of a $_1$-antichymotrypsin is altered, with a decrease in concanavalin A reactivity (Hachulla *et al*. 1990). This was reported to allow a discrimination between active and inactive disease with a sensitivity of 97 per cent and a specificity of 91 per cent. This decrease in concanavalin A reactivity has been confirmed (Pawlowski *et al*. 1990) both for a$_1$-antichymotrypsin and a$_1$-acid glycoprotein in patients with active polymyalgia rheumatica or polymyalgia rheumatica/giant cell arteritis and allows the differentiation of these illnesses from polymyositis. Although only studied in five patients, the concanavalin A reactivity was shown to increase towards normal following steroid therapy.

A decrease in concanavalin A reactivity of a $_1$-acid glycoprotein has been observed in patients with ankylosing spondylitis (Mackiewicz *et al*. 1989a) and in patients with active rheumatoid arthritis (Mackiewicz *et al*. 1987b) compared with healthy controls. However more recently it has been suggested that the microheterogeneity of a$_1$-acid glycoprotein in rheumatoid arthritis is dependent on disease duration, with increased and decreased concanavalin A reactivity being characteristic of early and established disease respectively, emulating the change in reactivity seen in the transition between acute and chronic bacterial infection (Hrycaj *et al*. 1993). Although not significantly different between patients with systemic lupus erythematosus of varying activity and healthy controls, the glycosylation pattern of a $_1$-acid glycoprotein has also been reported to be a much more sensitive indicator of intercurrent infection than CRP, with an increase in concanavalin A reactivity in infected patients (Mackiewicz *et al*. 1987a).

Such findings warrant further clinical studies. The exact significance of such changes is not yet known although recent studies using primary human hepatocyte cultures indicate that such changes may reflect cytokine-induced alterations in intrahepatocellular processes (Mackiewicz *et al*. 1989b; Pos *et al*. 1989). The lack of correlation in the various reports between changes in level of acute phase proteins and their glycosylation patterns indicates that the regulatory mechanisms responsible for these two events are probably different.

Drug management

Little is known about the mode of action of most of the disease-modifying drugs currently available. All were introduced for other indications or for reasons now clearly felt to lack relevance to our current understanding of the pathogenesis of rheumatoid arthritis. Already we are seeing the introduction and evaluation of new families of drugs specifically designed for this task, including specific blockers of certain cytokines which may work relatively early in pathogenesis as well as collagenase inhibitors which, by preventing final joint degradation, may act at a later stage. Close monitoring of acute phase reactants in parallel with drug administration, together with clinical and radiological assessment, is likely to be invaluable in unravelling the many different sites at which the rheumatoid process may be manipulated pharmacologically.

4.2 Haematology

Charles Richardson, Bridget Griffiths, and Paul Emery

The anaemia of chronic disease

Introduction

The anaemia of chronic disease develops as a consequence of chronic activation of the immune system (hence the alternative name of the anaemia of chronic inflammation). It is associated with autoimmune rheumatic diseases, chronic bacterial infections and malignancy. The aetiology of the anaemia of chronic disease is multifactorial but is characterized by the suppression of erythropoiesis, a blunting of erythropoietin production in response to anaemia and abnormal utilization of iron stores. The availability of recombinant erythropoietin provides an effective but expensive treatment for the anaemia of chronic disease without resorting to blood transfusion.

The anaemia of chronic disease is exemplified by the anaemia which develops in rheumatoid arthritis within 1 to 2 months of the onset of systemic disease. It is seen only after the onset of systemic symptoms but represents the most common extra-articular manifestation of the disease and is an important clinical problem. Rheumatoid arthritis has therefore been chosen as the model condition to describe the features of the anaemia of chronic disease. However, these features apply equally well to other chronic inflammatory disorders.

The severity of the anaemia in rheumatoid arthritis fluctuates with the disease course and correlates with the magnitude of the acute phase response. The prevalence is dependent on the definition used, although it has been estimated that 60 per cent of inpatients and 25 per cent of outpatients with rheumatoid arthritis are clinically anaemic, with 5 per cent of these being severely so.

The causes of the anaemia in rheumatoid arthritis are multiple (Table 1), although the most important cause is the anaemia of chronic disease itself (Baer *et al*. 1990; Vreugdenhill *et al*. 1990). The pro-inflammatory cytokines are central to the pathogenesis of the anaemia of chronic disease and their role is discussed further below. In practice the problem most commonly faced is how to differentiate the anaemia of chronic disease from iron deficiency. There are many shared features and the two conditions often coexist. The anaemia of chronic disease is a diagnosis in its own right, with characteristic abnormalities in the biochemical indices of iron metabolism in the presence of an appropriate clinical setting. It does not require further investigation whilst iron deficiency may well do so. To understand the investigations performed to distinguish between the anaemia of chronic disease and iron deficiency a knowledge of normal iron metabolism is required.

Major causes	
	The anaemia of chronic disease
	Iron deficiency anaemia
	Bone marrow suppression secondary to disease modifying drugs
Other significant causes	
	Vitamin B_{12} or folate deficiency
	Haemolysis
	Hypersplenism secondary to Felty's syndrome
	Chronic renal failure
Causes of the rapid development of anaemia	
	Bleeding, usually gastrointestinal
	Septicaemia
	Haemolysis
	Sudden increase in disease activity*

*Abnormal but can occur. It is difficult to distinguish from other causes

Table 1 The causes of anaemia in rheumatoid arthritis

Normal iron metabolism

The body iron content of normal adult males and females is 50 and 35 mg/kg of body weight, respectively. Most of the body's iron is incorporated into the haem proteins, haemoglobin and myoglobin (70 per cent). The remainder is in the storage forms ferritin and haemosiderin (30 per cent). Only a minute portion (0.1 per cent) is present in the plasma, where it is carried by the transport protein transferrin. It is worth noting that it is only this 0.1 per cent that is available for routine measurement of iron status (Fairbanks and Beutler 1983; Lee 1993).

Iron balance

In normal subjects the amount of iron present remains within narrow limits. The physiological control of body iron stores is unique in that it is mediated by control of absorption. Iron is not excreted in the usual sense, the amount lost in urine and sweat being negligible. The average daily loss of iron in adult men and non-menstruating women is 1 mg. The normal Western diet contains 10 to 30 mg per day, therefore only 5 to 10 per cent needs to be absorbed to maintain balance. The non-absorbed iron is bound to the iron-binding protein, ferritin, in the epithelial cells of the small intestine and is lost subsequently into the gut when the cells are

desquamated. The amount of iron binding to ferritin provides the physiological control of iron absorption. The system is saturated easily, and during oral iron therapy there may be passive entry of iron into the plasma. Iron entering the plasma is bound to the transport protein, transferrin. The rate of iron absorption is determined by (i) the total body iron stores and (ii) the rate of erythropoiesis. It is enhanced during iron deficiency and periods of increased erythropoiesis.

There are two pathways for iron absorption in the upper small intestine, one for iron attached to haem and another for ferrous ions. Dietary iron must be converted to one of these two forms before absorption is possible. Haem iron is derived predominantly from haemoglobin and myoglobin in food of animal origin. Haem is released from its apoprotein in the acid environment of the stomach. Non-haem iron occurs mainly in the ferric state loosely bound to phytates, oxalates, sugars, citrate, lactate, and amino acids. The pathways of iron absorption and metabolism are illustrated in Fig. 1.

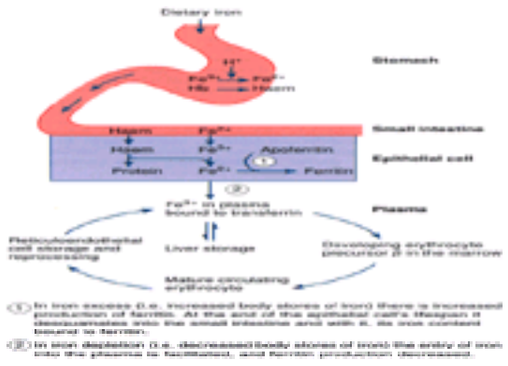

Fig. 1 The normal metabolism of iron.

The iron cycle

Iron metabolism is dominated by its role in haemoglobin synthesis. There is a continuous cycle of iron between erythrocytes, reticuloendothelial cells and the plasma (Fig. 1). The transport of iron in the plasma bound to transferrin is central to this cycling. Iron moves from the plasma to erythrocyte precursors, the mature erythrocytes enter the circulation and at the end of their lifespan are phagocytosed by macrophages and their iron extracted for reuse.

Plasma transport

Iron is transported in the plasma bound to transferrin, a b-globulin, synthesized primarily by the liver. Transferrin is distributed equally between the plasma and extravascular sites, with a half-life of approximately 10 days. Each transferrin molecule is able to bind two molecules of ferric iron.

Transferrin is measured indirectly by the total iron-binding capacity of plasma. In the normal subject the serum iron is approximately 18 mmol and the total iron binding capacity 56 mmol, indicating that only about 30 per cent of the transferrin binding sites are occupied. The rate of synthesis of transferrin is increased in iron deficiency and decreased in chronic disease. Therefore the total iron-binding capacity is increased in iron deficiency and decreased in chronic disease.

Transferrin delivers iron to the developing erythrocytes by binding to transferrin receptors found in greatest concentration on the normoblast. After binding, the entire transferrin–transferrin receptor complex forms a coated vesicle and undergoes endocytosis. The contents of the endosome are acidified with release of the iron present. Normoblast maturation is accompanied by shedding of the receptors into the plasma at a concentration that correlates with the rate of erythropoiesis. In addition it has been reported that an increase in the transferrin receptor concentration level is another indicator of tissue iron deficiency.

Ferritin is found in the plasma in small amounts (12 to 300 mg/l) and does not play an important role in iron transport (its role as a storage protein is discussed below). In a normal individual the concentration of ferritin correlates with the amount of iron stored. This may not be the case in inflammatory disease because ferritin is an acute phase respondent and its plasma concentration increases during periods of active inflammation.

Metabolism within normoblasts and macrophages

In a normal subject about 85 per cent of iron entering normoblasts is incorporated into haemoglobin, the remainder is stored within the iron storage protein ferritin.

There are two distinct populations of macrophage with respect to iron handling. The first type phagocytoses erythrocytes and stores iron, but does not return it to the circulation (e.g. the alveolar macrophage). By contrast other macrophages (e.g. the reticuloendothelial macrophages found in the liver and spleen) provide a storage pool for iron. The latter can either rapidly process iron and return it to the circulation or store it in the iron storage compounds ferritin and haemosiderin.

Iron-free ferritin (apoferritin) consists of a sphere with a central hollow cavity made from a number of subunits. Iron is deposited in the cavity in the form of a polymer of ferric hydroxide and phosphate. Under normal conditions about 2000 or less iron atoms are deposited, although in theory 4300 are possible. The synthesis of ferritin is stimulated by the exposure of cells to iron. At times of deficiency iron can be mobilized from ferritin and made available for erythropoiesis. Haemosiderin is an insoluble polymer of ferritin. It represents a more stable form of iron, but it is less readily available for utilization.

Iron is required in many other tissues besides erythrocytes for the synthesis of iron-containing enzymes. The most important tissue consumer of iron is the liver which accounts for about 5 per cent of iron leaving the plasma.

The aetiology of the anaemia of chronic disease

The aetiology of the anaemia of chronic disease is multifactorial and not fully understood. The pro-inflammatory cytokines interleukin 1 (**IL-1**), interleukin 6 (**IL-6**) and tumour necrosis factor-a (**TNF-a**) appear central in its pathogenesis. The following mechanisms are thought to operate in this anaemia:

direct inhibition of erythropoiesis

inhibition of erythropoietin production

enhanced erythrocyte phagocytosis

enhanced reticuloendothelial retention of iron

Direct inhibition of erythropoiesis

In animal studies the injection of TNF-a and IL-1 inhibits the production of mature erythrocytes by inhibition of the development of erythroid colony-forming units. It is of interest, that the colony-forming units are the most sensitive stage of erythroid development to erythropoietin, the administration of which corrects the anaemia induced by IL-1 (Schooley *et al*. 1987; Johnson *et al*. 1988; Johnson *et al*. 1989a).

Chronic exposure of nude mice to TNF-a provides a model more analogous to the situation in the anaemia of chronic disease. These animals develop an anaemia with low serum iron and normal iron stores. In addition, despite an increased concentration of erythropoietin, they have bone marrow depression of both burst-forming and colony-forming erythroid units (Johnson *et al*. 1989b). These findings may explain (i) the observation that monocytes/macrophages (which secrete pro-inflammatory cytokines) obtained from patients with anaemia of chronic disease inhibit the proliferation of erythroid colony-forming units (Roodman *et al*. 1983) and (ii) the clinical observation that suppression of the acute phase response (which is stimulated by the pro-inflammatory cytokines) produces an improvement in the

anaemia in active rheumatoid disease.

Finally, patients with rheumatoid arthritis treated with a monoclonal antibody against TNF-a increase their haemoglobin concentration (Elliot *et al*. 1994), while patients with cancer who received TNF-a (used as an experimental anticancer agent) had a fall in their haemoglobin concentration (Blick *et al*. 1987).

The inhibition of erythropoietin production

Erythropoietin is the hormone responsible for the regulation of erythropoiesis. It maintains a constant mass of red cells by stimulating the erythroid marrow to produce sufficient erythrocytes to replace the 1 per cent which reach their 120-day lifespan each day. There is a basal production of erythropoietin which can be increased one thousandfold in response to tissue hypoxia. Erythropoietin is produced predominantly by the cells of the renal mesangium, although during hypoxic stress the liver makes a significant contribution. It binds to specific receptors on erythroid progenitors in the bone marrow and increases the number of cells capable of differentiating into mature erythrocytes and augments the synthesis of haemoglobin.

The pro-inflammatory cytokines IL-1, TNF-a and IL-6 inhibit the production of erythropoietin in liver cell lines, providing a link between the acute phase response and the anaemia of chronic disease (Faquin *et al*. 1992).

For a given haemoglobin level the concentration of erythropoietin is less in patients with the anaemia of chronic disease than in patients with iron deficiency. In addition, whilst there is a significant negative correlation between the severity of iron deficiency and serum erythropoietin concentration, the same is not true for the anaemia of chronic disease (Takashina *et al*. 1990). Furthermore the ability of exogenous erythropoietin to overcome this anaemia can be taken as more evidence of an impaired erythropoietin response to anaemia. It seems likely that *in vivo* pro-inflammatory cytokines inhibit the production of erythropoietin and that this is responsible for the blunted erythropoietin response to anaemia seen in the chronic disease.

Abnormal iron utilization

The following abnormalities of iron metabolism in chronic disease have been reported:

1. an increase in the uptake of iron from the small intestine but a failure of the mucosal cells to release it into the plasma;
2. an increased uptake of iron into the reticuloendothelial cells of the liver and spleen;
3. enhanced macrophage phagocytosis of effete erythocytes with their consequent removal from the circulatory pool;
4. retention of iron within the cells of the reticuloendothelial system, making it unavailable for erythropoiesis.

It has been suggested that the following mechanisms contribute to abnormal iron utilization. The enzyme lactoferrin, released during phagocytosis, may compete with transferrin for iron binding. The lactoferrin–iron complex binds to specific receptors on liver and spleen macrophages, enters the cells and becomes incorporated into ferritin; thus preventing its use in erythropoiesis. Alternatively apoferritin (an acute phase protein) production is increased in active rheumatoid disease with consequent increase in iron binding reducing that available for erythropoiesis. However, neither of these abnormalities provides an explanation for effects seen at the intestinal mucosa (Lee 1993).

Shortened erythrocyte survival

The survival of erythrocytes in patients with active rheumatoid arthritis is reduced. Membrane-bound complement and/or immunoglobulins do not contribute to this except in special circumstances, neither is there any intrinsic defect in the erythrocyte. The shortened lifespan is probably secondary to an increase in phagocytosis of effete erythrocytes by macrophages due to a generalized activation of the immune system. If the bone marrow were functioning normally it should easily be able to overcome this slight decrease in erythrocyte survival. That it does not, implies that there is a relative failure of the marrow to respond to the degree of anaemia.

In summary

The anaemia of chronic disease has a multifactorial aetiology with the pro-inflammatory cytokines occupying a central role in the pathogenesis. Whilst there is evidence of abnormal iron metabolism (which forms the basis of the commonly used investigations), the lack of correlation between serum iron and marrow iron turnover combined with the finding that erythropoeitin can correct the anaemia all indicate that iron deficiency is not the limiting factor in the anaemia of chronic disease. The fundamental problem is a failure of the bone marrow to respond appropriately to anaemia. This is mainly due to cytokine inhibition of both erythropoiesis and erythropoietin production.

Diagnosis

Clinical findings

The diagnosis of anaemia of chronic disease should only be considered in the appropriate clinical setting. A complete history and physical examination must be performed. The anaemia of chronic disease normally takes 1 to 2 months to develop, the diagnosis is unlikely in a patient who has been unwell for only a matter of days (iron deficiency can develop in hours). A history of overt gastrointestinal bleeding should be sought and risk factors for this determined. Symptomatic anaemia indicates a rapid fall in haemoglobin; the most common cause for this is a gastrointestinal bleed. Physical examination may reveal melaena or signs of circulatory collapse, although in most instances it is unhelpful in determining the cause of anaemia.

Laboratory features

The acute phase response

The most commonly measured markers of the acute phase response are the erythrocyte sedimentation rate and the C-reactive protein. The differential diagnosis of the cause of anaemia in a patient with a known chronic disease would be simplified if a straightforward relationship between the magnitude of the acute phase response and the degree of anaemia could be formulated. Whilst it is common to observe change in anaemia fluctuating with disease course, a simple relationship has never been established. Clearly there are a large number of confounding factors which have prevented this, including the nature of the chronic disease, its duration and the drug therapy employed.

Figure 2 shows the haemoglobin concentration of over 400 patients with rheumatoid arthritis at presentation to an early arthritis clinic, plotted against increasing ranges of C-reactive protein concentration. Figure 3 shows the percentage who were anaemic. This was defined as lying 2 standard deviations below the normal population average concentration. The normal ranges for our laboratory were 13.4 to 17.4 g/dl and 11.4 to 15.4 g/dl for male and female subjects, respectively. None of these patients had received any disease-modifying therapy (including steroids). The following points are demonstrated:

1. The percentage of patients with anaemia and its severity increases with the magnitude of the acute phase response.
2. For a given level of C-reactive protein the haemoglobin is lower in females, but fewer lie outside the normal range.
3. On average the degree of anaemia is not severe until the C-reactive protein is markedly elevated.
4. A slight rise in the C-reactive protein is not associated with anaemia; in these circumstances the anaemia may warrant further investigation.

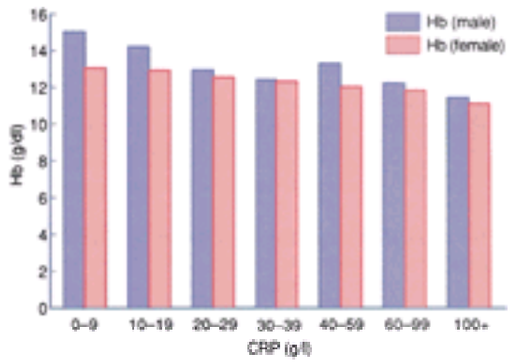

Fig. 2 The relationship between haemoglobin and C-reactive protein for patients presenting with rheumatoid arthritis.

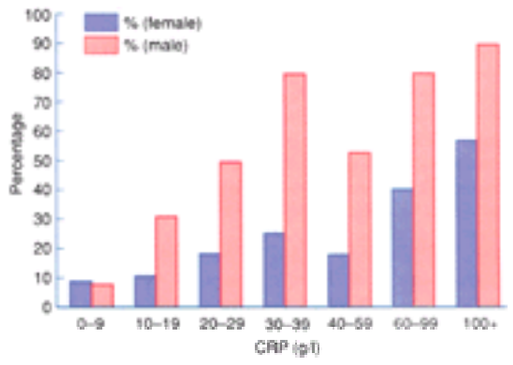

Fig. 3 The percentage of patients having anaemia at presentation with rheumatoid arthritis for increasing concentration of C-reactive protein.

Haematology investigations

In established chronic disease the haemoglobin level is rarely below 10 g/dl, a concentration less than this is more in keeping with a gastrointestinal bleed (Isenberg *et al*. 1986). Examination of blood films reveals a normochromic normocytic anaemia in 50 per cent of cases and a hypochromic microcytic picture in 30 per cent of cases. The latter is seen in the more severe chronic disease. Anisocytosis and poikilocytosis occur but not to the extent seen in iron deficiency anaemia. None of these features enable the anaemia of chronic disease to be distinguished reliably from iron deficiency. More sophisticated computer-assisted analysis of blood films can help to distinguish these conditions, although these techniques are not widely available. A high platelet count may be indicative of chronic gastrointestinal bleeding or active inflammation.

The definitive test to diagnose iron deficiency is the bone marrow aspiration. The presence of stainable iron stores in the marrow excludes iron deficiency as a cause for anaemia. The major drawback of marrow aspiration is its invasive nature.

Investigations of iron metabolism

Serum iron and total iron binding capacity

Under most clinical circumstances the serum iron is a measure of the amount of iron bound to transferrin. In an acute infection or inflammatory condition there is a rapid fall (within 24 h) in the serum iron, which persists as long as the illness does. Therefore the serum iron is low in both the anaemia of chronic disease and iron deficiency and does not distinguish between the two. Further problems with the interpretation of serum iron levels are (i) technical difficulties in measurement and (ii) the 10 to 40 per cent variation in levels seen in an individual during the course of the day.

Transferrin is measured indirectly by the total iron binding capacity of plasma. In the normal subject the serum iron is approximately 18 mmol and the total iron binding capacity 56 mmol, indicating that only about 30 per cent of the transferrin binding sites are occupied. Transferrin has a half-life of 10 days and is not subject to rapid change in its concentration, as such the total iron binding capacity remains relatively constant. It is one of the most useful tests to distinguish between chronic disease and iron deficiency. In iron deficiency the total iron binding capacity is elevated (due to increased hepatic synthesis of transferrin) whilst in chronic disease it is reduced (due to decreased hepatic synthesis of transferrin), although there is considerable overlap in the values of the two groups.

The transferrin saturation is calculated by dividing the serum iron by the total iron binding capacity and expressing the result as a percentage. The transferrin saturation is reduced in both chronic disease and iron deficiency, although to a greater extent in the latter. Again there is a wide overlap in the range of values obtained.

Ferritin

The iron storage protein, ferritin, is valuable in distinguishing between the anaemia of chronic disease and iron deficiency (Finch 1986; Porter *et al*. 1994). In patients without inflammatory disease the serum ferritin correlates with body iron stores (normal range is 20 to 500 mg /l in men and 10 to 200 mg/l in women) and therefore low ferritin indicates iron deficiency. In the rheumatoid patient the situation is more complicated because ferritin is an acute phase protein: a low serum ferritin indicates iron deficiency but a normal ferritin does not exclude deficiency in the presence of an acute phase response. Markedly high levels of ferritin are seen in particular myeloproliferative disorders and systemic juvenile chronic arthritis (see later).

Transferrin receptor

In the absence of chronic disease the concentration of the transferrin receptor in the plasma correlates with iron deficiency. The receptor concentration is increased in the anaemia of chronic disease, although not to the extent seen in iron deficiency. It is possible that this may prove to be a useful test to distinguish the two, although at present it does not confer any advantages over the conventional tests (Nielsen *et al*. 1994; Petterson *et al*. 1994).

In summary

There is no single diagnostic test for the anaemia of chronic disease. Table 2 summarizes the investigations that are possible. The diagnosis is made on the basis of an appropriate clinical picture, an elevated acute-phase response and the characteristic findings in the full blood count and biochemical indices of iron metabolism. The most useful indices are the total iron binding capacity, ferritin and serum iron. In most circumstances these will provide enough information to make the correct diagnosis.

		Anaemia of chronic disease	Iron deficiency
Clinical features	Systemic disease	present	absent
	Duration	> 2 months	variable
	Age	any	increased age
	NSAIDs	+/-	Yes
	Steroids	-	Yes
	Peptic ulcer history	-	Yes
Inflammatory markers	ESR	↑↑	N or ↑
	CRP	↑	-
Haematology indices	Haemoglobin	normally > 90 g/dl	May be < 10 g/dl
	MCV	Normal or ↓	↓
	Bone marrow	-	Absent iron stores
	Erythropoietin	↑	↑↑
	Response to iron	Poor*	Good*
Iron studies	Serum iron	↓	↓
	Ferritin	↑	↓
	TIBC	↓	↑
	Transferrin saturation	↓	↑
Biochemical indices	Serum urea	-	↑ (if recent bleed)
	Faecal occult bloods	+/-	positive

*Values marked are of greatest diagnostic significance
The following points are emphasized:
a A low serum ferritin indicates iron deficiency
b In the presence of an elevated acute-phase response a normal or slightly raised serum ferritin does not exclude iron deficiency
c In patients with acute systemic disease it is impossible not to administer some parenteral iron. Intravenous iron is normally given as iron dextran in a gastrointestinal bleed
ESR, erythrocyte sedimentation rate; MCV, mean corpuscular volume; NSAIDs, non-steroidal anti-inflammatory drugs; TIBC, total iron binding capacity

Table 2 Comparison of the typical features seen in the anaemia of chronic disease and iron deficiency

Treatment

The priorities in the treatment of the anaemia of chronic disease must be suppression of the disease activity and identification of any concomitant haematinic deficiencies. These measures are of obvious benefit to the patient and are relatively straightforward. Blood transfusion is used rarely, normally being reserved for the management of severe symptomatic anaemia or as a preoperative measure.

The availability of two recombinant forms of erythropoietin (erythropoietin-a and erythropoietin-b) provide a potential new therapy. The recombinant hormone is effective in the treatment of the anaemia of chronic renal failure, which is characterized by very low concentrations of erythropoietin. In contrast the concentration of erythropoietin is increased in the anaemia of chronic disease (with respect to the normal population), although there is a relative deficiency for the degree of anaemia. It is clear that the administration of recombinant erythropoietin can increase the haemoglobin to a normal level in the anaemia of chronic disease, the problem is the assessment of the cost–benefit of this.

Erythropoietin must be administered parenterally either intravenously or subcutaneously. The intravenous route has a higher bioavailability and peak serum concentration but a shorter half-life than that achieved by subcutaneous administration, although there are no distinct clinical advantages of one route over the other. Erythropoietin is normally commenced at a dosage of 50 to 150 U/g body weight thrice weekly, the dosage is then titrated against the response. A number of clinical studies have reported investigating the effectiveness of erythropoietin in the treatment of the anaemia of chronic disease in rheumatoid arthritis (Pincus *et al*. 1990; Salvarani *et al*. 1991; Petterson *et al*. 1993; Murphy *et al*. 1994). The following conclusions can be drawn:

1. Erythropoietin is able to correct the anaemia of chronic disease.
2. The effectiveness of erythropoietin is reduced in the presence of an elevated acute-phase response.
3. Erythropoietin increases the haemoglobin concentration by a direct effect on erythroid precursors in the marrow.
4. There is little evidence to suggest that erythropoietin has any disease suppressive activity, although in certain patients the ability to perform aspects of daily living is improved.
5. Treatment with erythropoietin can unmask latent deficiencies of haematinics (most commonly iron, but vitamin B_{12} and folate deficiency can occur). These should be monitored for, as a deficiency will limit the effectiveness of erythropoietin, and regular iron prophylaxis has been recommended.
6. Treatment with erythropoietin is associated with very few side-effects in the anaemia of chronic disease.

In summary, erythropoietin is effective in the treatment of anaemia of chronic disease and in some patients results in a symptomatic benefit. At present there is no place for its routine use in the treatment of anaemia of chronic disease in rheumatoid arthritis, except in special circumstances. It may prove useful for patients with severe symptomatic anaemia who are intolerant of conventional treatments (including blood transfusion), and in patients receiving autologous blood transfusion at the time of elective joint arthroplasties (Saikawa *et al*. 1994).

The major limiting factor preventing the use of erythropoietin is cost. Currently a 1000 U dose of erythropoietin costs £9. This translates to a cost of £8400 for a 60 kg patient receiving 300 U/kg per week for a year, and £1300 for a 1-month course at 600 U/kg per week prior to arthroplasty.

The acute phase response (see also Chapter 4.1)

The term acute phase response is used to describe the complex series of local and systemic events which accompany tissue inflammation (acute or chronic). It is normally self limiting and results in tissue repair. However if it becomes persistent, the process results in tissue damage and the systemic features of chronic inflammation.

Central to the pathogenesis of both the local inflammation and systemic effects are the pro-inflammatory cytokines interleukin 1 (IL-1), interleukin 6 (IL-6), and tumour necrosis factor-a (TNF-a). These products of macrophages, fibroblasts and endothelial cells are the mediators of the local and systemic effects of inflammation. Of particular note is their stimulation of the liver to generate the acute phase proteins whose measurement in the plasma can be used to quantify the magnitude of the acute phase response (Ganpathi *et al*. 1991; Mackiewicz *et al*. 1991; Thompson *et al*. 1992). The acute phase proteins most commonly measured are the C-reactive protein (measured directly) and fibrinogen (measured indirectly as the erythrocyte sedimentation rate and plasma viscocity). These measurements are non-specific markers of an inflammation but are often used clinically in the following situations:

1. discrimination between inflammatory and non-inflammatory conditions;
2. assessment of disease activity and response to therapy.

There are significant differences between basal concentration, incremental changes and response times in inflammatory situations of the acute phase proteins (see Chapter 4.1). The other determinant of the concentration of the acute phase reactants is the rate of catabolism. Compared with the other acute phase reactants the C-reactive protein has the distinct advantage of a constant rate of catabolism independent of other factors. In contrast, disseminated intravascular coagulation, intravascular haemolysis and complement consumption will all result in decreased levels of fibrinogen, haptoglobin, and complement and therefore give an underestimate of the magnitude of the acute phase response.

The erythrocyte sedimentation rate (ESR)

The ESR provides an indirect measure of the acute phase response. The ESR is a measure of the rate of sedimentation of erythrocytes in a vertical tube over a standard period of 1 h. The rate of sedimentation of erythrocytes is determined by the negative electrical charge on their surface which prevents aggregation. The presence of certain plasma proteins (particularly fibrinogen) reduces the negative charge on the erythrocyte surface causing an increase in aggregation and sedimentation. The relative contribution of the plasma proteins to the ESR are: fibrinogen 55 per cent, a $_2$-macroglobulin 27 per cent, immunoglobulin 11 per cent, and albumin 7 per cent (Stuart and Whicher 1988). Erythrocyte aggregation is also influenced by the number, shape, density and deformability of erythrocytes, so that the ESR increases with decreasing haematocrit. As the ESR predominantly reflects changes in the concentration of fibrinogen, there is generally a lag phase of 24 to 48 h between the onset or resolution of the inflammatory stimuli and changes in the ESR. However, as this reflects changes in the concentrations of several acute phase reactants (as well as immunoglobulins), it provides a wider screen for the detection of inflammatory disease than the measurement of a single acute phase protein. The major advantages of the ESR are its sensitivity, ease of performance, low cost and familiarity. The major disadvantages are its low specificity, the interobserver variation of its measurement and the wide range of other factors which will affect it. The relative merits of the ESR, plasma viscosity and C-reactive protein are shown in Table 3.

	ESR	Viscosity	CRP
Sample	Must be fresh	Can be stored	Can be stored
Method	Manual	Automated	Automated
Variables	Dependent on age, anaemia etc.	Independent of age and anaemia	Independent of age and anaemia
Half-life	Rises 24 to 48 h after tissue damage.	Rises 24 to 48 h after tissue damage	Rises 6 h after tissue damage
	Subsides with half-life of 4 to 6 days	Subsides with half-life of 4 to 6 days	Subsides with half-life of 48 h
Useful for monitoring	Chronic inflammatory change	Chronic inflammatory change	Acute inflammatory change

Table 3 The relative merits of the erythrocyte sedimentation rate, plasma viscosity and C-reactive protein in the monitoring of rheumatic disease

The plasma viscosity

The plasma viscosity, like the ESR, is determined predominantly by the concentration of fibrinogen. It has the same kinetics in response to inflammation as the ESR, but the advantage of being independent of age and erythrocyte concentration and morphology. In addition the test can be automated and performed on stored samples.

The C-reactive protein (CRP)

The CRP is generally accepted as the most accurate measure of the acute phase response and hence of tissue inflammation. In the normal individual the basal concentrations are extremely low or undetectable. As a consequence of this a patient's CRP concentration can increase many times from basal level and still lie within the normal population range whilst being markedly abnormal for that individual. In response to inflammation the concentration can rapidly increase up to one thousandfold. Even at these high concentrations the rate of catabolism is constant and therefore the plasma concentration is determined by the rate of synthesis. The CRP is not affected by any of the confounding factors which influence the ESR. In addition it can be quantified accurately even at very high levels of inflammation.

The rapid change in the concentration of CRP in response to changes in the degree of tissue inflammation make it the best measurement available for the monitoring of therapy in the rheumatic diseases. All three investigations are suitable for the screening of inflammatory disease when rapid changes in tissue inflammation are of less importance

Serum amyloid A protein is an acute phase reactant that shares many of the characteristics of the CRP and interest focuses upon it because it is the precursor of type AA amyloid fibrils. However, it is poorly immunogenic and there is no readily available assay for its measurement.

The clinical use of the measurement of the acute phase response

Rheumatoid arthritis

The CRP and ESR are commonly used as screening investigations for an inflammatory arthritis. In addition, the CRP can be used prognostically and to assess the contribution of disease activity to the anaemia of chronic disease (see previous section).

There is a good correlation between clinical measures of disease activity and the acute phase response measured by either ESR, plasma viscosity or CRP (Amos *et al*. 1977; Dawes *et al*. 1986; Scott *et al*. 1987). However, it should be emphasized that the kinetics of the CRP make it the only suitable test for monitoring rapid changes in the acute phase response, as occurs when systemic steroids are used. These may decrease the acute phase response by 50 per cent in 48 h, even after intra-articular injection. As a generalization the ESR is used for screening and the CRP for monitoring

In early rheumatoid arthritis, generalized osteoporosis is correlated significantly with an elevated CRP (Gough *et al*. 1994). When the disease process and secondarily the acute phase are suppressed by therapy there is a decrease in skeletal demineralization and stabilization of the functional state of the patient. If the patient's acute phase response appears elevated inappropriately for the clinical extent of disease the following should be considered:

1. Systemic amyloidosis—long-term chronic inflammation is associated with the development of secondary amyloidosis with deposition of amyloid fibrils in the heart, kidneys, liver, and gastrointestinal tract. The increased production of serum amyloid A is presumably responsible for the elevated ESR.
2. Infection—a concomitant bacterial infection will markedly increase the acute phase response. A particular concern is the development of septic arthritis that may be clinically unsuspected, with the physical signs of joint infection being attributed wrongly to a flare of rheumatoid disease. If this is considered seriously then joint aspiration and culture must be performed.
3. Malignancy—the development of occult malignancy must always be borne in mind.

The markedly elevated ESR

Modest elevations in the ESR (30 to 50 mm) are difficult to interpret and, especially in the absence of elevated CRP, a specific diagnosis may not be made. An ESR greater than 100 mm, conversely, is very specific for organic pathology and there are few conditions which present frequently to rheumatologists that are associated consistently with this level of ESR.

In polymyalgia rheumatica the ESR is markedly elevated but is not essential for the diagnosis. If raised the ESR (or CRP) can be used to monitor the disease and response to treatment. In giant cell arteritis, the raised ESR is a reliable indicator of disease activity, sufficient to be a major factor in dictating therapy.

In patients presenting with back pain and a markedly elevated ESR, myeloma, infective discitis, and osteomyelitis all need to be considered. Finally the possibility of the development of malignancy must be considered.

Elevated ESR/normal CRP

All the above conditions would also be accompanied by a markedly elevated CRP. However, there are occasions when these two are discrepant. These conditions are characterized by factors that will elevate the ESR but do not cause elevation of the acute phase proteins. Examples include anaemia, hyperlipidaemia, and hypergammaglobulinaemia. This is part of the explanation of the situation in systemic lupus erythematosus (see later) and Sjögren's syndrome.

The acute phase response in systemic lupus erythematosus (see Chapter 5.7.1)

In clinically active systemic lupus erythematosus, the ESR is elevated and may return to normal in remission. In contrast the CRP is rarely elevated in active disease, except in the presence of marked synovitis or concomitant bacterial infection (Pepys *et al*. 1982; Ter Borg *et al*. 1990). A clinical problem commonly encountered in the management of patients with systemic lupus erythematosus is to distinguish between an acute disease flare and the development of infection. The CRP can be helpful in this respect in that it is elevated in bacterial infection but not disease flares (a normal CRP makes infection an unlikely cause of an acute illness but an elevated CRP does not exclude a lupus flare). The reason why the CRP is not elevated in active lupus is not fully understood (Gordon and Emery 1993).

There is evidence to suggest that the circulating cytokines are not as active in systemic lupus erythematosus as in rheumatoid arthritis. The evidence for a hepatocyte response to TNF-a and IL-6 in active lupus disease is not consistent (Meijer *et al*. 1993). CRP, which is induced predominantly by IL-6, is elevated rarely except with serositis and then only modestly (Gabay *et al*. 1993). In contrast, a-acid glycoprotein, which is induced predominantly by TNF-a, can be elevated in flares of systemic lupus erythematosus alone. Similarly, the levels of increase of fibrinogen and depression of albumin are less in lupus than one would see in rheumatoid arthritis.

However, the failure to mount an acute phase response is not due to a deficiency in the capacity to produce CRP, because high levels are found during infection. This may be due to lower circulating levels of TNF-a and IL-6 in systemic lupus erythematosus without infection than in rheumatoid arthritis, or to the lack of another cytokine such as IL-11, which has recently been shown to promote the CRP response. In other inflammatory diseases such as rheumatoid arthritis, the acute phase response is associated not only with the hepatocyte effects but also with end-organ responses such as osteoporosis and thrombocythaemia. These features are seen to a lesser degree, if at all in systemic lupus erythematosus. This suggests that the cytokines or their soluble receptors are not elevated to the same degree or are not as active in lupus as rheumatoid arthritis. This may reflect differences in the cytokines, soluble receptors and other proteins produced in response to an increase in TNF-a or IL-6, which control the effects of these cytokines, as it is often difficult to isolate the effects of one or more cytokine when they are all part of a network of interacting proteins.

The acute phase response in adult Still's disease

Adult Still's disease is an acute systemic inflammatory condition with multiple non-specific clinical manifestations. These include fever, arthralgia and arthritis, lymphadenopathy, sore throat, and skin rashes. Elevated vitamin B_{12} levels are also found. The correct diagnosis is often difficult to make because their are no pathognomonic symptoms, physical signs or investigations. This means that a large number of investigations are performed to exclude other conditions, with consequent delay in the commencement of definitive therapy.

The characteristic haematological investigations are for normochromic normocytic anaemia (ACD), leucocytosis and thrombocytosis. There is an elevated acute-phase response with increased CRP and ESR. The abnormality of greatest interest is the serum ferritin, which is often dramatically elevated to more than 4000 mg/l (normal level is less than 300 mg/l) in active disease and may reach levels greater than 10 000 mg/l whilst the serum iron is low (Ohta *et al*. 1987a; Ohta *et al*. 1987b; Gonzales-Hernandez *et al*. 1989). Indeed in the appropriate clinical setting this may be taken as supportive evidence of the diagnosis and can be used to monitor the response to therapy (Schwaz-Eywill *et al*. 1992). There are a number of other conditions associated with a markedly raised ferritin including acute and chronic leukaemias, lymphomas, melanomas, germ cell tumours, and haemochromatosis, but in all of these it is unusual for the ferritin to be greater than 4000 mg/l. The elevation of the ferritin is due to its behaviour as an acute phase protein, but why it is elevated to such an extent in comparison with the other acute phase reactants in adult Still's disease is not known.

Haematological abnormalities in systemic lupus erythematosus (see Chapter 5.7.1)

Abnormalities of the erythrocyte

Perhaps the most common abnormality in patients with systemic lupus erythematosus is the anaemia of chronic disease. This is seen in between 30 and 50 per cent of patients. It has the features described in the previous section and will not be described further (Table 4).

Abnormalities of erythrocytes	Anaemia of chronic disease
	Autoimmune haemolytic anaemia
	Iron deficiency anaemia
	Chronic renal failure
	Microangiopathic haemolytic anaemia
	Evan's syndrome
Abnormalities of leucocytes	Lymphopenia
	Granulocytopenia
Abnormalities of platelets	Autoimmune thrombocytopenia
	Thrombotic thrombocytopenic purpura
	Acquired defects of platelet function
Clotting abnormalities	Antiphospholipid syndrome

Table 4 The haematological manifestations of systemic lupus erythematosus

A direct Coombs' test positive for autoimmune haemolytic anaemia is seen in 10 per cent of patients, and overt symptomatic haemolysis is uncommon. Haemolysis is secondary to immunoglobulin directed against antigens on the erythrocyte membrane. Complement bound to the erythrocyte membrane is attached normally to specific C3b receptors and not directed against erythrocyte antigens, and therefore does not induce haemolysis. Both warm and cold haemolysis occurs, although the former is more common. The degree of haemolysis is generally mild and does not require specific treatment. If the haemolysis is severe, immunosupression with steroids, azathioprine, and cyclophosphamide may be employed. Evan's syndrome is the combination of haemolytic anaemia and immune thrombocytopenia. Microangiopathic haemolysis is rare but can occur as a complication of the antiphospholipid syndrome (Jain *et al*. 1994; Nesher *et al*. 1994).

Iron deficiency anaemia is common and can develop secondary to drug therapy (e.g. non-steroidal anti-inflammatory drugs) or, extremely rarely, as a consequence of pulmonary haemorrhage due to pulmonary vasculitis. Anaemia will occur if chronic renal failure develops.

Abnormalities of leucocytes

Lymphopenia is a common feature of active disease. The condition is due to lymphocytotoxic antibodies (either of IgM or IgG class) directed against resting or active cells. Immunosupression of active disease produces an increase in the lymphocyte count.

Granulocytopenia is seen in active disease. It is due to a combination of central inhibition of granulocytopoiesis, splenic sequestration of granulocytes, and cytotoxic antibodies. The other major cause of granulocytopenia, which must never be forgotten, is as a consequence of drug therapy.

Abnormalities of platelets

A mild immune thrombocytopenia (100 to 150×10^9/l) occurs in up to 45 per cent of patients with active disease. Clinically significant thrombocytopenia (less than 50×10^9/l) occurs in 10 per cent of patients, who are at risk of bleeding. Up to 15 per cent of patients (especially in childhood) with lupus will present with thrombocytopenia similar to classical immune thrombocytopenia. This may precede the development of other signs of lupus by months or years. The thrombocytopenia is the result of increased peripheral destruction of platelets consequent upon autoantibodies directed against membrane antigens. Bone marrow examination shows normal or increased numbers of megakaryocytes to compensate for the increased peripheral consumption. In the antiphospholipid syndrome, anticardiolipin antibodies may have a direct role in platelet destruction.

In mild cases of immune thrombocytopenia no treatment is needed. In severe cases high doses of prednisolone (0.25 to 1 mg/kg) are required. The initial dose is maintained for 3 to 4 weeks and then titrated against the response. Steroid failures have been treated with intravenous immunoglobulin, splenectomy, vinca alkaloids, and cyclosporin.

In addition acquired defects of platelet function have been reported, including decreased aggregation and defective uptake of adenosine diphosphate and serotonin.

Clotting abnormalities

In patients with systemic lupus erythematosus there is an increased tendency to thrombosis due to a higher incidence of antiphospholipid antibodies, which predispose to the development of thrombosis. There are three serological tests commonly used to detect antiphospholipid antibodies:

1. Anticardiolipin antibodies—these can be measured quantitatively by immunoassay and correlate best with the presence of antiphospholipid antibodies. These are found in 15 to 40 per cent of patients.
2. Lupus anticoagulant—either an IgM or IgG antibody which reacts with the negatively charged phospholipid component of the prothrombin activator complex

resulting in a prolonged activated partial thromboplastin time. The name is a misnomer because it is encountered more frequently in patients without systemic lupus erythematosus and is associated with a clotting tendency. These are found in up to 2 per cent of patients with lupus.

3. False-positive VDRL test—antiphospholipid antibodies cross-react with phospholipid in the VDRL test to give a false-positive result when testing for syphilis serology.

A clinical syndrome termed the antiphospholipid syndrome (see Chapter 5.7.3) has been increasingly recognized in association with antiphospholipid antibodies (for review see Asherson and Cerevera 1992; Hughes 1993). The syndrome can be primary or secondary; it is primary if there is no evidence of a pre-existing connective tisssue disease (e.g. systemic lupus erythematosus), or secondary if the latter is present. The classical syndrome comprises widespread arterial and venous thrombosis, thrombocytopenia and recurrent abortions, although improved recognition of the condition has led to the realization that there are many more features (Table 5). These are thought to be attributable to the thrombogenic effects of the antiphospholipid antibodies. The range of possible mechanisms which results in thrombotic tendency associated with antiphospholipid antibodies include effects on platelet membranes, endothelial cells, and on clotting components such as prothrombin, protein C and protein S. The thrombotic tendency is dependent on the antibody titre, isotype (IgG), and the duration of time that the antibodies have been present

Site of thrombosis	Complications
Hepatic	Budd–Chiari syndrome
	Hepatic infarction
Adrenal	Addison's disease
Pulmonary	Thromboembolic pulmonary hypertension
Cerebral	Cognitive impairment
	Movement disorders
	Epilepsy
	Migraine
	Transverse myelitis
Cardiac	Cardiomyopathy
	Valvular disorders
Renal	Thrombotic microangiopathy
Dermatological	Livedo reticularis
	Chronic leg ulceration

Table 5 Complications of the antiphospholipid syndrome associated with thrombosis

The antiphospholipid syndrome occurs in 5 to 10 per cent of patients with systemic lupus erythematosus. It does not correlate clearly with disease activity and does not respond well to immunosuppression. The mainstay of treatment is long-term oral anticoagulation.

Leucocyte abnormalities in rheumatic disorders

Neutrophilia

The commonest causes of an increased neutrophil count (neutrophilia) in patients with rheumatic diseases are steroid therapy and infection. Other causes are shown in Table 6.

Common rheumatological causes	Steroid therapy	
	Infection	
	Active disease:	Rheumatoid arthritis
		Juvenile chronic arthritis
		Gout
Other rheumatological causes	Vasculitis:	Polyarteritis nodosa
		Giant cell arteritis
		Wegener's granulomatosis
Non-rheumatological causes	Tissue infarction	
	Metabolic:	Uraemia
		Diabetic acidosis
	Malignancy	
	Bleeding	
	Pregnancy	

Table 6 The causes of neutrophilia in patients with rheumatic diseases

Neutropenia

Neutropenia is defined as the circulatory neutrophil count being below 1.5×10^{9}/l. The most important causes are second-line agents and non-steroidal anti-inflammatory drugs used in the treatment of the rheumatic diseases. These drugs often cause marrow depression, in particular neutropenia. For some drugs, such as gold and penicillamine, this side-effect is not dose related but appears to be idiosyncratic and major histocompatibility complex (MHC) class II DR3 related. For other drugs, for example the cytotoxics, it is dose related and generally involves other cell lines as well. For other causes of neutropenia see Table 7.

Common rheumatological causes	Drugs:	Idiosyncratic
		Dose-dependent
	Active disease:	Systemic lupus erythematosus
Other rheumatological causes	Felty's syndrome	
Non-rheumatological causes	Viral infections:	Influenza
		Infectious mononucleosis
		Infectious hepatitis
	Bacterial infections:	Overwhelming sepsis*
		Typhoid
		Brucellosis
	Severe folate or vitamin B_{12} deficiency	
	Racial (common in Afro-Caribbeans)	
	Pancytopenia, any cause	

*Especially Gram-negative staphylococci.

Table 7 The causes of neutropenia in patients with rheumatic diseases

Presentation

Patients may complain of a sore throat or mouth ulceration, or may have signs and symptoms of infection. More commonly, they may be asymptomatic and the neutropenia only discovered on screening.

Management

If a drug is thought to be responsible for the neutropenia then it should be withdrawn immediately. Haemopoietic recovery normally occurs within one to two weeks. If

the patient is 'well' and afebrile, no specific treatment is necessary but they need to be monitored closely for a continuing deterioration in the neutropenia and for signs of infection. However, if the patient is unwell they require admission. The differential diagnosis includes infection and active disease. Neutropenia *per se* may produce a low-grade fever. An infection screen needs to be performed and bone marrow aspiration considered. The prognosis is particularly poor if the patient has a serious infection when a granulocytosis is first discovered. Broad spectrum antibiotics are required together with supportive therapy. The administration of recombinant human granulocyte-colony stimulating factor may help by reducing the duration of the neutropenia and thereby decreasing the incidence of sepsis. Its expense precludes its routine use at present.

Eosinophilia

Eosinophilia is defined as the number of eosinophils being greater than 0.4×10^{9}/l or greater than 5 per cent of the total white cell count, in the peripheral blood. History, examination and a few simple tests usually point to the cause of the eosinophilia. Often little is gained by further exhaustive testing to find a cause. For causes see Table 8.

- Drug reactions, e.g. gold induced rashes
- Severe rheumatoid arthritis: associated with episcleritis, subcutaneous nodules, vasculitis, pleuropericarditis, pulmonary fibrosis, high rheumatoid factor titres, raised gammaglobulin
- Vasculitis, e.g. polyarteritis nodosa, Churg-Strauss syndrome
- Sarcoidosis
- Eosinophilic fasciitis (localized infiltration of the connective tissue of the upper and lower limbs, usually sparing the digits. May lead to fibrosis and subsequent functional loss).
- Eosinophilic myalgic syndrome
- Non-rheumatological causes pulmonary disorders, e.g. bronchial asthma, tropical pulmonary eosinophilia, allergic bronchial aspergillosis, Loeffler's syndrome, hypereosinophilic syndrome; parasite infections; allergic reactions, e.g. hay fever; skin disorders, e.g. urticaria, pemphigus, eczema, dermatitis herpetiformis malignancy

Table 8 The causes of eosinophilia in patients with rheumatic diseases

Felty's syndrome

This syndrome was reported by Felty in 1924 (Felty 1924). He noted the association of rheumatoid arthritis, splenomegaly and neutropenia. One per cent of patients with rheumatoid arthritis are affected.

It is usually seen in patients with long-standing seropositive, nodular, deforming rheumatoid arthritis, with systemic involvement. It is more common in certain HLA genotypes; over 90 per cent of patients are DR4 positive with a striking proportion being homozygous for the HLA-Dw4 allele (a subtype of HLA-DR4) (Sanson *et al*. 1987; Lanchbury *et al*. 1991). Approximately one-third of patients have no active synovitis when Felty's syndrome develops. The splenomegaly is usually mild to moderate but it can be huge. Sometimes it may precede leucopenia by years. Other clinical manifestations include weight loss, lymphadenopathy, leg ulcers, skin hyperpigmentation, peripheral neuropathy, chronic indolent infections, and nodular regenerative hyperplasia of the liver (Moots *et al*. 1994). Bacterial infections are common due to the marked neutropenia and account for most deaths in this syndrome.

Laboratory investigations typically reveal high titres of rheumatoid factor and antinuclear antibodies, with hypocomplementaemia. Thrombocytopenia is seen in about 40 per cent of cases but is usually mild. The coexisting anaemia is usually consistent with the anaemia of chronic disease but with the addition of a reticulocytosis, in response to increased erythrocyte destruction in the spleen.

The neutrophil count is usually between 0.5×10^{9} and 2.5×10^{9}/l. Several mechanisms for the cause of this neutropenia have been postulated. It is generally too profound to be wholly accounted for by hypersplenism and may persist after splenectomy (Logue *et al*. 1981). Bone marrow examination has shown evidence of maturation arrest of the granulocyte cell line. Antigranulocyte antibodies and the presence of T lymphocytes in the marrow that inhibit granulopoiesis have also been demonstrated. Corticosteroid therapy often improves the neutrophil count in patients in whom these inhibitory T cells have been demonstrated.

There is no consistently effective therapy for this syndrome. Splenectomy, corticosteroids, methotrexate, gold, penicillamine, cyclophosphamide, cyclosporin, lithium salts, parenteral testosterone, and granulocyte-colony stimulating factor have all been used, with varying degrees of success in different patients (Dillon *et al*. 1986; Fiechtner *et al*. 1989; Markusse *et al*. 1990). Splenectomy does not correlate well with reduction in the risk of recurrent infections or with ulcer healing. When splenectomy is planned, it is important to protect the patient against infection by bacteria with polysaccharide coats, such as *Streptococcus pneumonaie* and *Salmonella* spp. This may be best achieved by vaccination with Pneumovax (protecting against *S. pneumoniae)* before splenectomy, or daily penicillin V if prevaccination is not possible. Corticosteroids, especially in higher doses, may make the infections worse. Sometimes treatment of the underlying disease process will lead to an improvement of the neutropenia. The use of second-line drugs is therefore not contraindicated in the presence of a leucopenia but judicious monitoring is necessary. Bone marrow aspiration is probably advisable before commencing such therapy in order to exclude marrow suppression. Methotrexate is probably the treatment of choice.

Large granular lymphocyte syndrome/granular lymphocyte expansion

This is a recently recognized syndrome of neutropenia, associated with a proliferation of large granular lymphocytes in blood and bone marrow. The lymphocytes have many azurophilic granules in the cytoplasm and tend to be a subset of T lymphocytes with CD3+ CD8+Leu7+ surface phenotype (Snowden *et al*. 1991). B-cell function is also abnormal with autoantibody production and marked hypergammaglobulinaemia. The actual white blood cell count may be normal or increased because of the lymphocytosis. Other features are thrombocytopenia, anaemia, splenomegaly, and arthritis. It occurs in 0.6 per cent of patients with rheumatic disease and tends to affect older patients early in the course of their arthritis. Generally it is a benign condition but treatment in more severe cases is with glucocorticoids and/or immunosuppressives. Intermittent chlorambucil has achieved a good clinical response in patients with weight loss, fevers, and night sweats. This treatment has also produced an increase in haemoglobin and/or neutrophils, a small fall in large granular lymphocytes, and reduction in splenomegaly (Snowden *et al*. 1991). Splenectomy is not recommended. The main reason for ill health in these patients is infection secondary to the neutropenia.

At times it can be difficult to distinguish between large granular lymphocyte expansion and Felty's syndrome. The definitive method requires consideration of lymphocyte morphology, bone marrow examination, and analysis of lymphocyte surface phenotype. The condition is contrasted with Felty's syndrome in Table 9.

	Felty's syndrome	Granular lymphocyte expansion
Neutrophil count	↓	↓
Lymphocyte count	↓	↑
Thrombocytopenia	Yes	Yes
Anaemia	Yes	Yes
Splenomegaly	Yes	Yes
Age of patient	Younger	Older
Duration of disease	Longer	Shorter
Prognosis	More severe	More benign

Table 9 Comparison of Felty's syndrome with granular lymphocyte expansion

Platelet abnormalities

Thrombocytosis

A raised platelet count is common in patients with active rheumatoid arthitis. There is a positive correlation between platelet count and disease activity. Extreme thrombocytosis is noticed with some extra-articular manifestations of the disease, particularly pulmonary involvement, peripheral neuropathy, and vasculitis. The mechanism is uncertain. Interestingly it does not predispose to an increase in thrombotic events. Other causes to be considered include acute bleeding and iron deficiency. In these cases, the platelet count will return to normal if the underlying disease process is treated.

Thrombocytopenia

Two important causes of thrombocytopenia to consider in patients with rheumatic diseases are autoimmunity and drugs.

1. Autoimmune thrombocytopenia: see lupus haematology section. It has also been reported in mixed connective tissue disease, dermatomyositis, and systemic sclerosis.
2. Drug-related thrombocytopenia: Many drugs used to treat rheumatic diseases can cause thrombocytopenia by marrow suppression. It is therefore paramount that patients are monitored closely with regular full blood counts whilst on these drugs. If the platelet count drops below 150×10^{9}/l the medication needs to be reviewed immediately and stopped. The platelet count usually recovers within the next couple of weeks, although it can take longer with some drugs, for example gold which has a long half-life. If the patient experiences severe thrombocytopenia with bleeding and marked purpura, then platelet transfusions may be necessary.
3. Other causes of thrombocytopenia are Felty's syndrome and large granular lymphocyte expansion. Infections may also be responsible and these include cytomegalovirus, hepatitis B, human immunodeficiency virus, subacute bacterial endocarditis, and Gram-negative sepsis.

Infections, in particular, need to be considered in patients with rheumatic diseases as these patients are frequently immunocompromised.

4.3 Biochemistry

Rosamonde E. Banks, Douglas Thompson, John T. Whicher, and Howard A. Bird

The rheumatologists' requirements of the clinical biochemistry laboratory vary according to the disease being managed. Automation of assays has led to a wider variety of biochemical estimations becoming more easily and inexpensively available. However, the contribution of the clinical biochemist to the diagnosis and management of the rheumatic illnesses is still relatively minor when compared with many other illnesses, possibly reflecting the relative chronicity and non-life-threatening nature of many of the rheumatic illnesses and the difficulty of devising new clinical laboratory tests when the aetiology of the disease is relatively uncertain. This chapter concentrates on those biochemical assays that are likely to be available in most hospitals for the routine management of rheumatic patients.

The clinical problem in rheumatology

Rarely is a single biochemical laboratory test truly diagnostic (except in the case of inborn errors of metabolism); rather they point to a pathological process or suggest damage or dysfunction of a particular organ, or they are used to monitor the course of a disease. As in most specialties, biochemical tests serve a number of well-defined purposes in rheumatology, which may be outlined as follows.

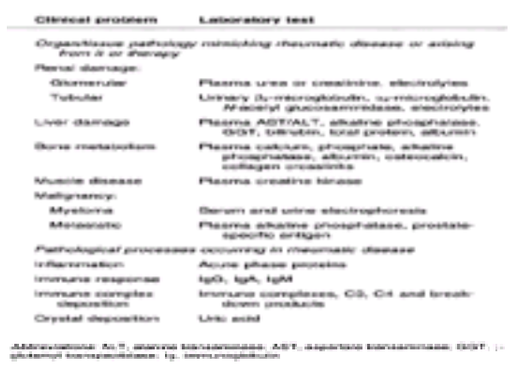
1. Indication of a pathological process and its intensity, e.g. inflammation, immune response, haemolysis, malignancy.
2. Indication of damage or dysfunction of organs, e.g. liver and kidney.

Tests may be used to:

1. Confirm or exclude a specific diagnosis. Several tests must be interpreted together with the clinical picture to create a probability of a diagnosis. Critical decisions are whether a particular organ or tissue is affected and what process (e.g. inflammation) is present.
2. Exclude other disorders which could (although deemed unlikely in the clinical context) give rise to the same symptoms. A panel of screening tests for other disorders is required, tailored to the clinical presentation. In a given situation these should always be used, thus preventing other quite different diagnoses from being overlooked. For example, malignant disease may cause myositis, myopathy or generalized symptoms suggestive of soft tissue rheumatism. However, normal test results never completely exclude a condition.
3. Assess and monitor disease activity. Prognosis and choice of therapy may depend on disease activity at presentation and control of therapy may depend on monitoring disease activity. Examples would include longitudinal measurements of acute phase proteins to assess disease activity in rheumatic diseases and the use of serum uric acid levels to monitor the effectiveness of long-term prophylactic allopurinol therapy for gout.
4. Detect a complication of the disease. This usually means detecting damage to an organ, such as the kidney, either at the time of diagnosis or during the course of the disease. Rheumatic diseases particularly associated with such complications include systemic lupus erythematosus, polyarteritis nodosa, Sjögren's disease, and gout.
5. Detect side-effects of therapy. Many of the drug therapies used in rheumatology can have unwanted side-effects, particularly in elderly people, often involving the liver or kidney. Sulphasalazine, azathioprine, and methotrexate are amongst this group of drugs.

The biochemical tests in rheumatology

Table 1 indicates the appropriate biochemical tests for assessing organ/tissue pathology and disease processes in rheumatic diseases, with an indication of the imprecision of these tests provided in Table 2. In the following section we will explain the use of these tests, suggest how they may be interpreted, and examine their clinical relevance in rheumatology. A guide to the use of these tests in the overall management of patients in rheumatology is provided in Table 3.



Clinical problem	Laboratory test
Organ/tissue pathology mimicking rheumatic disease or arising from it or therapy	
Renal damage:	
Glomerular	Plasma urea or creatinine, electrolytes
Tubular	Urinary β2-microglobulin, α1-microglobulin, *N*-acetyl glucosaminidase, electrolytes
Liver damage	Plasma AST/ALT, alkaline phosphatase, GGT, bilirubin, total protein, albumin
Bone metabolism	Plasma calcium, phosphate, alkaline phosphatase, albumin, osteocalcin, collagen crosslinks
Muscle disease	Plasma creatine kinase
Malignancy:	
Myeloma	Serum and urine electrophoresis
Metastatic	Plasma alkaline phosphatase, prostate-specific antigen
Pathological processes occurring in rheumatic disease	
Inflammation	Acute phase proteins
Immune response	IgG, IgA, IgM
Immune complex deposition	Immune complexes, C3, C4 and breakdown products
Crystal deposition	Uric acid

Abbreviations: ALT, alanine transaminase; AST, aspartate transaminase; GGT, γ-glutamyl transpeptidase; Ig, immunoglobulin

Table 1 Biochemical tests for assessing organ/tissue pathology and pathological processes in rheumatic disease

Analyte	Range	Units	Imprecision
Sodium	123–157	mmol/l	1.4
Potassium	3.7–6.9	mmol/l	0.08
Urea	3.3–17.1	mmol/l	0.32
Creatinine	149–627	µmol/l	9.8
Alkaline phosphatase	169–513	IU/l	12.6
Bilirubin	52–64	µmol/l	2.9
AST	51–189	IU/l	3.8
ALT	32–119	IU/l	3.7
GGT	40–148	IU/l	2.4
Calcium	1.80–3.55	mmol/l	0.06
Phosphate	1.09–3.09	mmol/l	0.06
Albumin	26–45	g/l	1.0
Creatine kinase	54–280	IU/l	20.3
Uric acid	0.212–0.409	mmol/l	0.012

The data are extracted, with permission, from the Wellcome Clinical Chemistry Quality Assessment Programme, End of Period Report, December 1996 (Wellcome Diagnostics, Dartford, England). Range refers to the analytical range over which the imprecision of each analyte was assessed. The imprecision shown is the mean within-laboratory imprecision of all British laboratories in the Programme for each analyte. These data are reproduced for illustrative purposes only and it is emphasized that individual laboratories should be consulted as to their reference ranges and precision data.
Abbreviations: ALT, alanine transaminase; AST, aspartate transaminase; GGT, γ-glutamyl transpeptidase.

Table 2 Imprecision of biochemical tests

Disease	At diagnosis		At follow-up
	A	B	
Soft-tissue rheumatism	N/A	Acute phase response, full profile, creatine kinase	N/A
Gout	Uric acid, acute phase response	N/A	[illegible]
Pyrophosphate deposition	N/A	Bone profile, uric acid	N/A
Polymyalgia rheumatica/temporal arteritis	Acute phase response	Creatine kinase, serum/urine electrophoresis	[illegible]
Osteoarthritis	N/A	Acute phase response, full profile	N/A
Rheumatoid arthritis	Acute phase response, rheumatoid factor	Full profile	[illegible]
Psoriatic arthritis	Acute phase response	Rheumatoid factor, full profile	Acute phase response annually
Ankylosing spondylitis	Acute phase response	Rheumatoid factor, full profile	Acute phase response annually
Systemic lupus erythematosus	Acute phase response, antinuclear antibodies	Rheumatoid factor, full profile	[illegible]
Polymyositis/dermatomyositis	Creatine kinase, acute phase response	N/A	Repeat tests and renal profile annually
Systemic sclerosis	Acute phase response	N/A	Repeat tests and renal profile annually

[illegible]

Table 3 Routine biochemical management of rheumatic patients

Organ or tissue pathology mimicking rheumatic disease or arising from it or from therapy

At presentation and during the course of the disease, the presence of various organ or tissue abnormalities which may either be the cause of the symptoms or occur as a result of complications of the disease or therapy, needs to be excluded.

Renal function

The tests available for the assessment of renal function are described below (reviewed by Turney and Cooper 1988; Waller *et al*. 1989; Flynn 1990; Duarte and Preuss 1993; Lindeman 1993; Moore, Jr. and Carome 1993) (see also Chapter 1.3.11).

Glomerular function

The two principal indicators of glomerular function are the permeability of the glomerular basement membrane and the glomerular filtration rate (**GFR**). The GFR can be assessed by measuring the clearance of substances that must fulfil the requirements of being freely filtered at the glomerulus, neither secreted nor reabsorbed by the renal tubule, be physiologically and metabolically inert, and that have a constant concentration in the plasma throughout the period of urine collection. Although the fructose polymer inulin is an ideal substance, the requirement of administration by intravenous infusion precludes its use routinely. An alternative is ^{51}Cr-labelled EDTA, the clearance of which can be assessed from the plasma radioactivity at one time-point after a single intravenous dose rather than collecting timed urine samples. However, disadvantages include cost and unsuitability of use during pregnancy. Although clearance of inulin or radioisotopes are the most accurate methods of measuring GFR, they are used less frequently than the more inaccurate methods described below, largely because of the relative complexity and cost (Duarte and Preuss 1993).

The GFR is most often assessed by measuring the creatinine clearance. This is not ideal as creatinine is secreted actively by the renal tubules, the assay of plasma creatinine is subject to interference from non-creatinine chromogens, the reference range is age dependent, and plasma concentrations may increase after exercise or after the consumption of cooked meat during the period of urine collection (24 h). Although creatinine clearance provides a reasonably accurate assessment of GFR when renal function is normal, as glomerular function becomes impaired the GFR is increasingly overestimated. This partly results from increased tubular secretion of creatinine, together with the decreasing inaccuracy of the plasma creatinine measurement as the relative contribution from the non-creatinine chromogen falls. The overall imprecision of creatinine clearance measurements can be high (up to 27 per cent coefficient of variation (CV), Flynn 1990) since it is calculated from three measurements, namely plasma, urinary creatinine, and 24 h urine volume, each having their own imprecision. The main sources of error include incomplete and inaccurately timed urine collection, and bacterial degradation of urinary creatinine. It is recommended that clearance measurements should only be undertaken when absolutely necessary (Turney and Cooper 1988).

In view of the inaccuracy and imprecision of measurements of creatinine clearance, the concentration of plasma creatinine is viewed by many to be a more useful indicator of glomerular function. Measurements of plasma creatinine are less imprecise than those of urinary creatinine, and the adult reference range for plasma creatinine is not affected by age, although it is sex dependent and affected by pregnancy and muscle mass. The plasma creatinine may be elevated falsely by drugs that block tubular secretion (e.g. cimetidine and salicylates), ketone bodies and bilirubin (which may interfere in some assays), exercise, and the consumption of meat. It is a relatively insensitive indicator of renal impairment, with no appreciable change in plasma creatinine until the GFR is reduced by about half, after which point the creatinine rises exponentially with the decline in GFR. The reciprocal of the creatinine concentration at several time-points may provide a better indicator of declining GFR (Turney and Cooper 1988). As the reciprocal of the plasma creatinine decreases linearly with progressive renal failure, the rate of progression of renal impairment can be determined from the slope of the line. Additional adverse occurrences or effects of therapy are thus apparent from a change in the slope of the line (Fig. 1).

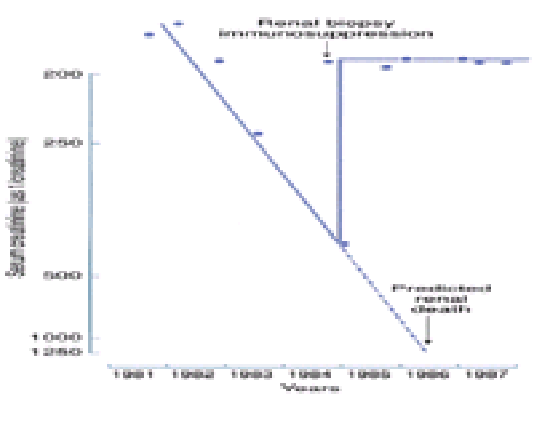


Fig. 1 The use of reciprocal plasma creatinine to monitor renal function. The reciprocal creatinine concentrations are shown for a female Caucasian (date of birth 18/8/41) who developed arthralgia, photosensitive skin rash and mildly positive serology for systemic lupus. Persistent proteinuria and a progressive rise in plasma creatinine were found. On nephrological referral 3 years later, a renal biopsy showed diffuse, proliferative glomerulonephritis with deposition of immunoglobulins and complement, and the patient was treated with prednisolone and cyclophosphamide. The graph illustrates the use of the reciprocal creatinine to monitor the progressive decline in renal function. With therapy, renal function improved and reached a new steady state, although it was permanently impaired. (Adapted from

Turney and Cooper 1988.)

The decline in GFR that occurs with increasing age is not reflected in the serum creatinine, which remains within the 'normal' range. This is due to the coincidental reduction in lean body mass and resultant decrease in endogenous creatinine production. When using the serum creatinine (S_{cr}) to predict the creatinine clearance (C_{cr}), there are several nomograms and formulae, such as the one below, which allow correction for effects of body weight and age (Cockroft and Gault 1976):

$$C_{cr} = \frac{(140 - \text{age}) \times \text{bodyweight (kg)}}{0.81 \times S_{cr}(\mu\text{mol/l})}$$

For an adult woman, the value obtained should be reduced by 15 per cent to allow for lower muscle mass. It must be emphasized that the analytical and preanalytical variability of creatinine measurements are inherent in such formulae.

Plasma urea is a less sensitive measurement than plasma creatinine and is influenced by the rate of protein catabolism, diet, fluid balance, infection, and concomitant medication such as corticosteroids (Turney and Cooper 1988; Moore, Jr. and Carome 1993). As the excretion of urea is very dependent on urine flow rate, dehydration leads to an elevated plasma urea, owing to increased reabsorption. In patients known to have chronic renal failure, intercurrent infection may drastically increase the rate of protein catabolism, with a deterioration of the biochemical abnormality and possible rapid clinical impairment. In this situation, plasma urea is a more rapid and sensitive indicator of the clinical state than is creatinine. If the patient with chronic renal failure is undergoing strict dietary control to reduce the rate of urea formation, measurement of creatinine is appropriate as the levels of urea may fall considerably as the result of the dietary measures alone. The urea:creatinine ratio can be used to indicate reductions in renal blood flow that occur as a result of either real or apparent hypovolaemia. A reduction of the normal ratio (approximately 1:20 SI units) indicates renal outflow obstruction, hypotension, increased protein intake, or dehydration.

Proteinuria can reflect either glomerular or tubular damage, and can be characterized as primarily glomerular, primarily tubular, or of mixed origin, based on the protein constituents of the urine (Waller *et al*. 1989). Haematuria together with proteinuria usually localizes the cause of the proteinuria to a glomerular pathology. Glomerular proteinuria is often associated with larger amounts of urinary protein (>2.5 g/24 h) and the urine contains proteins of moderate and high molecular weight to a much greater extent than in primary tubular proteinuria (4.4 g/24 h compared with 0.4 g/24 h). Proteinuria may also result from strenuous exercise and the possibility of Bence-Jones proteinuria should not be overlooked.

Tubular function

The proximal tubule is the most common site of renal tubular damage and substances normally reabsorbed at this site appear in the urine in increased concentrations (e.g. glucose, amino acids, proteins, phosphate, and potassium). The most sensitive test of proximal tubular reabsorption is the measurement of low-molecular-weight proteins such as b_2-microglobulin (11.8 kDa), a_1-microglobulin (27 kDa), and retinol-binding protein (21 kDa), which are filtered normally by the glomeruli and almost totally reabsorbed in the proximal tubule. Increased plasma concentrations of these proteins, such as may occur with b_2-microglobulin in lymphoproliferative disorders or when the GFR falls excessively in chronic renal failure, may also result in low-molecular-weight proteinuria as the tubular reabsorptive capacity may be exceeded. In acid urine b_2-microglobulin is unstable, thus favouring measurement of retinol-binding protein or a_1-microglobulin. However, the lack of rapid reliable assays currently limits their use.

Renal enzymes such as the lysosomal enzyme *N*-acetyl-d-glucosaminidase (NAG) and the brush-border enzyme alanine aminopeptidase, are released during damage to tubular cells and are sensitive markers, usually preceding changes in urinary protein. Such enzymes are of most use for monitoring the acute rather than the chronic state, where protein assays may be superior.

Clinical relevance in rheumatic disease

Soft tissue rheumatism and osteoarthritis are usually associated with normal renal function tests but it is important to exclude serious coincidental renal pathology. Similarly, renal function is virtually never impaired in the temporal arteritis-polymyalgia rheumatica syndrome (Sonnenblick *et al*. 1989). There is a high prevalence of fatal renal disorders in patients with rheumatoid arthritis (10 to 34 per cent; reviewed by Boers (1990)). Apart from drug toxicity, the kidney is not often clinically involved in systemic juvenile chronic arthritis or adult rheumatoid arthritis, with abnormalities mainly occurring as a result of amyloid deposition or, less frequently, vasculitis. Most patients with amyloidosis present with a marked proteinuria, and the disease runs a variable but slow course towards endstage renal failure (Turney and Cooper 1988) that can be monitored by the reciprocal of serum creatinine. It has been suggested that in view of the many renal-associated deaths in rheumatoid arthritis which are not amyloid-related, there may also be a 'rheumatoid arthritis nephropathy' (Boers 1990), which remains subclinical during the course of the disease because of insensitive screening methods.

Between 10 and 20 per cent of patients with ankylosing spondylitis have some renal abnormality (reviewed by Youssef and Russell 1990). These may be coincidental, related to therapy with non-steroidal anti-inflammatory drugs, the result of amyloid deposition that is associated with long-term ankylosing spondylitis, or alternatively due to IgA nephropathy.

Systemic lupus erythematosus, polyarteritis nodosa, and Sjögren's disease, which may complicate rheumatoid arthritis, all carry a much higher risk of renal involvement. Renal disorders, mainly mild interstitial nephritis with distal tubular acidosis, can occur in up to 30 per cent of patients with primary Sjögren's syndrome (reviewed by Boers 1990), although clinically overt renal disease is generally found in less than 5 per cent of patients. Vasculitis, which may be primary as in Wegener's granulomatosis and polyarteritis nodosa, or secondary to disorders such as rheumatoid arthritis and many of the autoimmune rheumatic disorders, may cause a glomerulonephritis with temporary or permanent glomerular dysfunction, a decrease in GFR, and ultimately renal failure.

Potentially serious renal disease may complicate systemic lupus (reviewed by Balow and Austin 1988) and regular renal assessment is essential. The onset may be insidious or abrupt, usually following a chronic course with remissions and exacerbations. The pathogenesis is complex and the renal disease may be glomerular, tubular, or vascular, with concomitant biochemical changes as described above, predominantly those of glomerulonephritis. Serial creatinine clearances have been reported to be of little use in patients with lupus nephropathy, as they do not accurately measure the direction or the magnitude of the change in GFR (Petri *et al*. 1988). Both plasma creatinine and qualitative urinary protein can predict mortality in systemic lupus (reviewed by Gladman 1990). However, there are patients with systemic lupus who have normal plasma creatinine concentrations and urinalysis but abnormal findings on renal biopsy.

Tests of renal function are essential in patients with gout, both at diagnosis and at regular intervals thereafter, in order to detect the important complication of renal damage, which may dictate the need for specific drug therapy with allopurinol. Approximately half of patients with chronic gout have proteinuria with normal plasma creatinine concentrations (Turney and Cooper 1988). The incidence of renal stones (predominantly uric acid) is in excess of 100-fold greater than in the general population. Hypertension and atherosclerosis may also result from renal damage, as well as being associated with gout.

Several drugs used in the treatment of the rheumatic diseases, particularly the disease-modifying antirheumatic drugs, may cause nephrotoxicity. If renal function is already compromised, the risks of nephrotoxicity may be greatly increased. In addition, with drugs which are excreted primarily by the kidney such as methotrexate, a decrease in renal function may lead to accumulation of the drug and increased toxicity. It is thus important that renal function is assessed prior to commencing therapy and monitored appropriately during therapy.

Liver function

The standard 'liver function tests (LFTs)', i.e. serum or plasma bilirubin, plasma aspartate aminotransferase (AST, previously known as glutamic oxaloacetic transaminase or GOT), alanine aminotransferase (ALT, previously known as glutamic pyruvic transaminase or GPT), alkaline phosphatase, g-glutamyl transferase (GGT), total protein, and albumin, are used routinely to identify the presence of and monitor the course of liver disease, although they are generally poor at identifying the precise pathology (reviewed by Johnson 1989, Rosalki and Dooley 1994). Several newer tests attempt to assess actual liver function by measuring the elimination

of substances such as caffeine or bile acids by the liver, but these are not routinely available and will not be considered here.

Serum bilirubin

Bilirubin is excreted in the bile after conjugation with glucuronide in the liver. Although less than 500 mg of bilirubin are produced each day from breakdown of haem, the liver is capable of conjugating up to three times this amount. Hyperbilirubinaemia is therefore an insensitive indicator of parenchymal liver disease. Clinical jaundice may not be apparent until the bilirubin concentration is more than twice the upper limit of normal. The major causes of hyperbilirubinaemia include haemolysis (usually accompanied by normal liver function tests), hepatitis, cirrhosis, gallstones, tumour infiltration, and drugs such as rifampicin that impair the handling of bilirubin.

Serum enzymes

The aminotransferases AST and ALT are released from damaged cells and are used as markers of hepatocellular integrity, although they are not liver specific, being released from other tissues such as skeletal muscle, heart muscle, and kidney. Very high activities (>10× the upper limit of normal) occur in acute hepatocellular disease, with even higher values (>20× the upper reference limit) strongly suggestive of acute hepatitis from drugs or viral infection. Very high values may also occur in shock, cardiac failure, or sepsis.

Total circulating alkaline phosphatase consists of several different forms (isoenzymes) with the main two in the healthy adult being derived from liver and bone. The liver isoenzyme is produced by hepatocytes adjacent to the biliary canaliculi and elevated plasma activities of alkaline phosphatase are found in extra- or intrahepatic bile-duct obstruction (cholestasis) as a result of increased synthesis. Normal or only mildly elevated levels are found in hepatitis. A high plasma alkaline phosphatase and low plasma aminotransferase indicate cholestatic jaundice, although cholestasis may be accompanied by hepatocellular damage and resultant increases in AST and ALT. Pregnancy also results in an elevated plasma alkaline phosphatase. If the elevation in alkaline phosphatase is unaccompanied by abnormalities of other liver function tests, a non-hepatic source should be considered. For example the most common cause of an isolated rise in plasma alkaline phosphatase is due to an increase in the circulating bone isoenzyme in Paget's disease. An hepatic origin of the alkaline phosphatase is indicated by the finding of a simultaneous elevation of a liver-derived enzyme such as g-glutamyl transferase, which does not occur in bone disease. This enzyme is sensitive but not tissue-specific and may be elevated either through hepatocellular damage or induction by drugs or alcohol. The finding of a normal g-glutamyl transferase result does not necessarily imply a bone origin for the alkaline phosphatase however, as an isolated increase in alkaline phosphatase is often the only abnormality in cases of liver metastases. A more specific approach is the actual determination of the alkaline phosphatase isoenzymes (reviewed by Moss 1987). Placental and intestinal alkaline phosphatases are 'true' isoenzymes, being encoded by individual structural genes. The kidney, liver, and bone isoenzymes are all encoded by the same gene but differ through tissue-specific glycosylation. Isoenzymes can be differentiated by their heat stability or more precisely through electophoretic separation, which is not always routinely available. An immunoassay measuring the bone isoenzyme has recently been developed, but it is still the subject of evaluative research.

Cirrhosis results in a modest increase of plasma aspartate aminotransferase and g-glutamyl transferase, sometimes accompanied by alkaline phosphatase. Drug-induced hepatitis may be primarily hepatocellular (often without jaundice) or the result of intrahepatic cholestasis with jaundice. The aspartate aminotransferase, g-glutamyl transferase, and alkaline phosphatase are usually raised, the last especially with cholestasis. Alkaline phosphatase is raised in many inflammatory conditions, primarily as part of the acute phase response. Sometimes inflammation elsewhere results in an inflammatory infiltration of the biliary tracts with modest jaundice and greater increases of alkaline phosphatase. The mechanism of this is not understood.

Clinical relevance in rheumatic disease

Systemic juvenile chronic arthritis may present with abnormal liver function, and abnormal transaminases are often found after salicylate therapy. In patients with rheumatoid arthritis, plasma transaminases are usually normal, although occasionally the aspartate aminotransferase may increase, suggesting low-level hepatitis. Between 7.5 per cent and 50 per cent of patients with rheumatoid arthritis have an abnormal alkaline phosphatase level, an abnormality which has been proposed to be primarily of hepatic origin, based on the finding (although variable) of simultaneous elevations of g-glutamyl transferase or 5'-nucleotidase, but it may reflect the acute phase response rather than hepatobiliary dysfunction. However, other studies attribute this increase to the bone isoenzyme and it is a question which still remains unresolved, both in patients with rheumatoid arthritis and in those with ankylosing spondylitis. Patients with rheumatoid arthritis have also been found to have elevated g-glutamyl transferase (less than 5 per cent to 77 per cent of patients depending on the study). It has been suggested that a latent or subclinical hepatobiliary pathology may exist in patients with rheumatoid arthritis, with an association between this involvement and disease activity (Aida 1993). The possibility of subclinical hepatobiliary damage is supported by the non-specific histopathological changes of liver biopsies from patients with rheumatoid arthritis (reviewed by Mills and Sturrock 1982; Aida 1993).

Serious hepatic pathology is not usually found in osteoarthritis, although a wider variation in results of liver function tests may be expected than would be encountered in a younger population.

Elevated plasma alkaline phosphatase may be found in patients with the temporal arteritis–polymyalgia rheumatica syndrome (Sonnenblick *et al*. 1989), with abnormal transaminases being infrequent and elevated serum bilirubin extremely rare. Resolution of the biochemical abnormalities occurs after successful corticosteroid therapy. Of patients undergoing liver biopsy, 73 per cent overall had positive findings, although the pathogenesis of the liver involvement in this illness is not clear.

In patients with polymyositis and dermatomyositis, lactate dehydrogenase (LDH) and aspartate aminotransferase may be elevated. An elevated serum alkaline phosphatase is a common finding in systemic sclerosis (approximately 25 per cent) and this condition is often seen in patients with chronic liver disease (reviewed by Weinblatt *et al*. 1982). Although most studies find little evidence of clinically significant hepatic disease in systemic lupus erythematosus (Weinblatt *et al*. 1982), liver disease as detected by altered liver function tests and confirmed in most cases histologically has been reported in more than 20 per cent of patients studied (Runyon *et al*. 1980). This was unrelated to aspirin-induced hepatitis, which is recognized as a potential complication in patients with systemic lupus.

Several of the drugs used in the treatment of the rheumatic diseases may be hepatotoxic, particularly sulphasalazine, azathioprine, cyclophosphamide, and methotrexate. It is essential that hepatic function is assessed before commencing therapy and at regular intervals thereafter.

Calcium and bone

An elevated plasma alkaline phosphatase, particularly in the absence of other abnormal liver function tests, may reflect an increase in the bone isoenzyme and hence indicate increased bone turnover. Appropriate measures can be used to identify the origin of the isoenzyme (as discussed previously).

Calcium is present in blood combined with plasma proteins (40 per cent, 1.0 mmol/l), complexed to anions such as citrate and phosphate (10 per cent, 0.25 mmol/l), or as the free ion (50 per cent, 1.2 mmol/l). The maintenance of the blood calcium is achieved by parathyroid hormone, which promotes calcium absorption from the gut and renal tubule and mobilization from bone, calcitonin, which has a less pronounced action tending to lower blood calcium, and vitamin D, which increases the blood calcium directly by acting on the gut and renal tubule and indirectly via a synergistic action with parathyroid hormone on bone (described in Chapter 2.4). As the secretion of parathyroid hormone is under direct feedback control by ionized calcium, it is this form of calcium that should ideally be measured. However, this is often not routinely available and total plasma calcium is usually assayed by one of a large number of available methods. Several preanalytical factors can affect the result (reviewed by Gosling 1986, Bourke and Delaney 1993), two of the most important of which are venous stasis and the posture of the patient at sample collection. Total plasma calcium should always be corrected for the plasma albumin concentration, as this corrected result shows a better correlation with ionized calcium. The simultaneous measurement of phosphate provides an indication of the pathology of any calcium abnormality, with calcium and phosphate concentrations usually changing in the same direction unless parathyroid hormone is inappropriately in excess or deficient, or unless renal failure is present.

Clinical relevance in rheumatic disease

Bone pains may be confused with pains of articular or soft-tissue origin. Bone pain in adults may be caused by osteomalacia, Paget's disease, bony metastases, myeloma, or very occasionally primary hyperparathyroidism. All these conditions, with the exception of myeloma, are associated with increased osteoblastic activity and a consequent raised plasma alkaline phosphatase due to an increase in the bone isoenzyme. A raised alkaline phosphatase of bone origin is most likely to be associated with Paget's disease. Myeloma is investigated easily by serum and urine protein electrophoresis, with the almost invariable finding of a paraprotein in the serum or Bence-Jones protein in the urine. Advanced osteomalacia may be associated with frank hypocalcaemia, while hypercalcaemia is invariably present in

primary hyperparathyroidism, and often in myeloma and bony metastases.

Serial biochemical assessments are not useful in soft-tissue rheumatism but plasma alkaline phosphatase and serum calcium should be measured to exclude osteomalacia. Similarly, clinical biochemistry plays no part in the management of calcium pyrophosphate deposition disease (CPPD), osteoarthritis, or osteoporosis with a normal calcium, phosphate and alkaline phosphatase. Occasionally, osteoporosis may be secondary to metabolic disorders such as Cushing's syndrome. As previously discussed, there is controversy as to whether elevations in the hepatic or the bone isoenzyme account for the elevated total alkaline phosphatase often seen in diseases such as rheumatoid arthritis, and to the relationship of this elevation with disease activity.

No routine biochemical markers for bone or cartilage turnover are yet available, although the use of substances such as osteocalcin, bone-derived alkaline phosphatase, hydroxyproline or the collagen-crosslinks deoxypyridinoline and pyridinoline as potential markers of matrix turnover is currently the subject of active research (reviewed by Peel *et al*. 1992, also see Chapter 2.4).

Muscle disease

Muscle pains may be due to myositis, with damage to muscle fibres resulting in the release of various enzymes. The most clinically useful is creatine kinase (CK). This is composed of two monomers designated M and B and exists in human tissues as three isoenzymes. The isoenzymes CK-1 (CK-BB), CK-2 (CK-MB), and CK-3 (CK-MM) differ in electrophoretic mobility. Skeletal muscle contains predominantly CK-MM (98 per cent) whereas CK-BB is confined mainly to the brain and thyroid. Myocardium contains both CK-MM and CK-MB, with a much greater proportion of CK-MB than skeletal muscle (30 and 2 per cent, respectively). Myocardial infarction, myopathies including those induced by alcohol and drugs, severe exercise, intramuscular injection, surgery, or hypothyroidism can all cause an elevated total creatine kinase. Abnormal levels can occur in asymptomatic female carriers of Duchenne muscular dystrophy. Most serum creatine kinase is normally CK-MM, rising with damage to skeletal muscle. Increases in CK-MB as a percentage of total creatine kinase are indicative of myocardial infarction, whereas an increase of CK-BB indicates brain damage.

Plasma electrolytes should also be measured to exclude electrolyte imbalance, particularly hypokalaemia, as a cause of muscle pain.

Clinical relevance in rheumatic disease

If soft-tissue rheumatism is suspected, measurement of creatine kinase may be required to exclude myositis, although this condition is usually obvious clinically. The myalgia accompanying polymyalgia rheumatica/giant-cell arteritis is not associated with abnormal serum activities of muscle enzymes. Other causes of myalgia, such as anxiety, depression, fibrositis, thyroid disease, and Parkinson's disease, must be excluded. Creatine kinase is the most reliable enzyme test in polymyositis and dermatomyositis, with plasma activity levels correlating with disease activity (Vignos and Goldwin 1972). Rarely, creatine kinase may be normal but an elevation usually distinguishes polymyositis from polymyalgia.

Several antirheumatic drugs including corticosteroids, d-penicillamine, aspirin, gold salts, and the non-steroidal anti-inflammatories, are known to cause myopathy (reviewed by Zuckner 1990).

Malignancy

Apart from metastatic malignancy of bone, malignant disease may cause myositis, myopathy, or generalized symptoms suggestive of soft-tissue rheumatism. Serum and urinary electrophoresis may be required to exclude myeloma, and plasma alkaline phosphatase and serum calcium analysis to exclude other neoplastic involvement. Prostate-specific antigen (PSA) in conjunction with digital rectal examination can be used to check for carcinoma of the prostate. Pain caused by such conditions affecting bone is interpreted frequently by the patient as arising in adjacent soft tissues. Further clinical tests will be required to investigate this.

Pathological processes occurring in rheumatic disease

The division between clinical chemistry and immunology laboratories is becoming blurred, particularly with the automation of many assays. The measurements used to detect and monitor the following pathological processes may be carried out in laboratories of either discipline. For completeness, they are mentioned briefly here, being covered in greater detail elsewhere.

Inflammation

The main biochemical indicator of the inflammatory episode is the acute phase response (see Chapter 4.1). Inflammatory cells release cytokines, which influence both local and systemic effects, that can be measured and may be of use as described elsewhere. In addition, enzymes and oxygen radicals are released at the inflammatory site, which may damage surrounding extracellular matrix elements. Enzymes, free radicals, and the products of free radical-mediated damage may be measured, although currently this is largely the province of the research laboratory (Holley and Cheeseman 1993).

The measurement of lysosomal and granular enzymes released from polymorphonuclear leucocytes has been used as an indicator of phagocytic activity, but has proved to be insensitive due to the short half-life of the free enzyme. The measurement of enzyme–inhibitor complexes such as elastase–a_1 proteinase inhibitor (E–a_1PI) has now been studied by several groups and may prove to be of future use, although further research is needed. A significant proportion of patients with active rheumatoid arthritis have raised concentrations of E–a_1PI complexes.

Immune response

Immune responses feature in many rheumatic diseases, being most notable early in the disease or during exacerbation. During a phase of immune stimulus, IgM is raised modestly, subsiding in 2 to 3 weeks to be replaced by IgG. Raised concentrations of IgG are found commonly, especially in the autoimmune rheumatic diseases. Infiltration of the synovium with plasma cells results in IgA production. Thus the immunoglobulin profile is complex and is related insufficiently to disease process or activity to be useful for differential diagnosis or monitoring.

Immune complex diseases

Although the presence of immune complexes is usually not in itself a very helpful marker of clinical disease or its treatment and is difficult to assay, significant deposition of complexes in the vascular system results in activation of mediator systems, notably complement, which may be measured. Complement activation implies the occurrence of immune complex mediated damage, indicating the need for therapeutic intervention. Total C3 and C4 concentrations may be measured as they are consumed by the process of activation, although their consumption may be masked by their increased synthesis as part of the acute phase response. Breakdown fragments of C3 or C4, for example C3a, are a much more sensitive indicator of complement activation. Changes in C4 are frequently more sensitive than those in C3, particularly in the case of systemic lupus erythematosus, when used in conjunction with anti-DNA antibody measurements.

Crystal deposition

Biochemical tests are mainly useful in the case of gout. The relationship between hyperuricaemia and gout has been reviewed by Becker (1988). Uric acid, the end product of the metabolism of purines, is present normally as the urate ion at physiological pH and has a low solubility. Saturation and consequently precipitation of urate crystals can occur after only minor elevations of circulating concentrations. The serum urate concentration is governed by the rate of excretion (approximately two-thirds via the kidneys and the remainder via the gut) and the rate of formation, which is dependent on the balance between dietary intake, *de novo* synthesis, and degradation of nucleotides. Serum levels tend to be higher in males, rise with age, and reference ranges vary between ethnic groups.

Gout may be secondary to conditions that cause increased formation or decreased excretion of uric acid, such as hyperparathyroidism or myeloproliferative disorders. Dietary factors and alcohol often exacerbate hyperuricaemia. Such conditions need to be excluded before appropriate treatment can be commenced. Gout is more often primary or idiopathic, being found in patients who have an elevated rate of urate synthesis (10 to 15 per cent) or inappropriately low excretion (85 to 90 per cent). The exact nature of the defects is not known. Measurement of the urinary uric acid excretion aids in the differentiation of the two mechanisms. Although the risk

of gout increases with a higher serum urate, hyperuricaemia does not necessarily imply the presence or the development of gout. Figure 2 shows clearly that while measurements of uric acid are useful, the relationship between the concentration of uric acid and clinical gout is not very clear. The definitive diagnosis of gout can only be made on the finding of crystals of monosodium urate in joint fluid. Gout may cause, or occur as a result of, renal failure, and assessment of renal function is essential in the interpretation of raised concentrations of uric acid. It is also prudent to screen at diagnosis for conditions sometimes associated, such as hypertension and hyperlipidaemia. Measurements of serum uric acid can be used to determine the efficacy of long-term prophylactic therapy with allopurinol or uricosuric agents. Hyperuricaemia has also been reported to occur in 10 to 20 per cent of patients with psoriatic arthritis (Lambert and Wright 1977), probably reflecting the increased breakdown of nucleoprotein with the rapid turnover of skin cells.

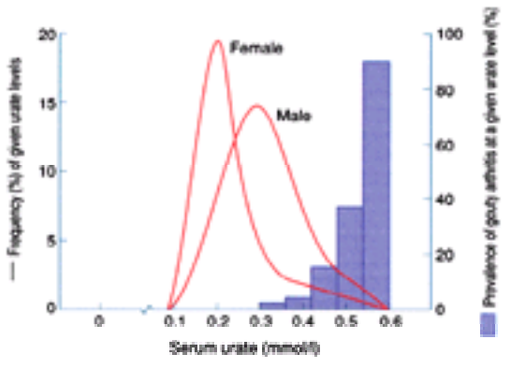

Fig. 2 Frequency distribution of serum uric acid values and the prevalence of gouty arthritis (adapted from Whicher *et al*. 1989). Serum urate concentrations are not normally distributed and the upper limit of the reference ranges (2 SD above the mean) are 0.42 mmol/l and 0.36 mmol/l for males and females respectively. Approximately 20 per cent of subjects with urate concentrations within the reference range suffer from gout and a significant percentage of individuals with hyperuricaemia are not affected by gout.

Although relatively uncommon as causes of the deposition of calcium pyrophosphate, metabolic disorders such as hyperparathyroidism, hypomagnesaemia, or hypophosphatasia should be excluded in pseudogout, using appropriate tests.

4.4 Microbiology and diagnostic serology

Geoffrey Scott

Optimal use of the microbiology laboratory

Many other chapters in this book are concerned with specific infections that directly or indirectly involve joints. This short chapter does not set out to iterate descriptions of these diseases but to give a brief idea of how microbiologists deal with specimens sent to their laboratories and the limitation of the tests that are applied. The aim of the microbiologist is to help the clinician make a more tangible diagnosis if infection or reactive arthritis are suspected. The clinician can help the microbiologist by ensuring that appropriate specimens are taken, that they get to the laboratory quickly, and by communication with the laboratory scientist or doctor so that all relevant tests can be done. The request form that accompanies a specimen is the principal method of communication, but some 50 per cent of request forms to this laboratory are completed inadequately. In most hospitals, microbiologists will see patients on request, examine notes, advise on prescribing of antimicrobials, and may even impose restrictions on their use. In an acute or difficult clinical setting, direct communication is worthwhile because it helps to ensure that someone in the laboratory will take a special interest in the processing of a specimen. In most laboratories, some simple tests, such as examination for acid-fast bacilli, will be made only if specially requested by the clinician or if there is some message cryptically encoded in the information given on the request form. Scientific purists would say that all tests should be done on very specimen and that they should be examined for 'all' possibilities. In practice, this would be impossibly expensive and time wasting. The interpretative microbiologist, perhaps more so than the haematologist or chemist, requires some sense of what the clinician is searching for. The more relevant (concise) history that can be given, the better.

In clinical pathology, it is important to consider the likelihood that a result is actually a true representation. Computer-printed results sometimes suggest a degree of scientific precision that, particularly in microbiology, may be unfounded. A patient must not be made to fit an unlikely diagnosis suggested by test results, especially when they are preliminary (Stokes *et al*. 1993). The sensitivity of a test is the percentage of the infected group detected as positive by the test. The specificity indicates the percentage of the negative group detected as negative by the test. These values are in themselves meaningless unless put into the context of the total number of tests done, and the expected rates of positives and negatives in a population. The figures that can be calculated to express these data are the predictive values of positive (**PVP**) and negative (**PVN**) test results, respectively (Easmon 1990). The problem in trying to calculate these values is that one needs to know how many in the population actually do or do not have the infection. PVP and PVN can be calculated for a new test when compared with a 'gold standard' test assumed to be 100 per cent sensitive and specific. An example would be the comparison of a new enzyme immunoassay for chlamydial antigen against culture of the organism (the 'gold standard'), or against amplification of chlamydial DNA. The last will inevitably detect more positives than culture, but it will be impossible to know whether they are truly positive for a variety of reasons, including difficulty in identifying specific DNA and the risk of contamination. When comparing two tests, it becomes obvious that one test can detect positives which the other cannot. Yet the more sensitive test will almost certainly have a higher rate of false positivity.

If a test gives a continuum of signals between positive and negative, a cut-off point has to be chosen to categorize its results. This is illustrated by the microbiology of urine specimens. The cut-off between positive and negative is chosen by examining large numbers of samples and selecting a point (10^5 c.f.u./ml) between the two peaks of the bimodal distribution of the concentration of bacteria present. Some of those with 'significant bacteriuria' will, by definition, have only 10^4 to 10^5 organisms per ml of urine. Rather than accepting this single result as meaningful, the microbiologist will hope to confirm or refute the suggestion of positivity by requesting a repeat test. In recently developed enzyme immunoassays, the cut-off between negative and positive is selected in exactly the same way. If the cut-off is selected at 20 units and the test has a result of 19 units, this should be reported as negative yet may well be positive. Only alternative, confirmatory tests can be of real help in these cases and the clinician must again avoid the temptation to make patients fit a dubious result. False-positive immunoassays are common in some conditions (for example, first-generation assays for antibody to human immunodeficiency virus), but repeated tests of different design and specificity will yield more reliable results.

Unless the sensitivity and specificity of a test are both 100 per cent, PVP and PVN will be markedly influenced by the prevalence of the disease in the population under study. Comparing likely isolation rates of chlamydia in patients attending a genitourinary medicine clinic (17 per cent) with those attending a rheumatology clinic (assumed 1 per cent), and using a test with sensitivity of 90 per cent (i.e., 1 in 10 positive patients give a negative result) and specificity of 95 per cent (1 in 20 tests are false positive), the PVPs in the two clinics would be 78 and 15 per cent, respectively. In the low-prevalence population this is of profound importance in trying to make a microbiological diagnosis in a patient with reactive arthritis.

Tests and their limitations

The influence of antibiotics on culture

Microbiological culture studies are relatively insensitive and will be almost certainly negative when the patient is already on antimicrobial agents. Prophylactic antibiotics are often prescribed as a matter of routine for orthopaedic operations, but when infection is suspected and the operation is partly for diagnostic purposes it is crucial that the administration of antimicrobials be delayed until after all the specimens have been taken. We advise that anaesthetists give the antimicrobials intraoperatively in infected cases.

Specimens

The rheumatologist will tend to send fluid or biopsies from joints or blood in order to diagnose bacterial infection, and special culture specimens from elsewhere (e.g. faeces, urethral fluid), or serum, to support the diagnosis of reactive arthritis. All specimens are treated in the laboratory as though a risk of infection to the staff. Contamination of the outside of a container is obviously a particular hazard, so all containers should be sent in a sealed, clear-plastic bag separate from the request form. Staples should not be used. Specimens that leak may be discarded in the laboratory because opening the bag poses a high risk to the staff. Unlabelled specimens and those accompanied by an inadequate request form should also be discarded. Laboratory staff should check with clinicians before a specimen is discarded to ensure that it can be replaced.

An outline of microbiological investigations is shown in Table 1.

Table 1 Outline of microbiology investigations for rheumatology patients

Synovial fluid (pus)

Specimens must be of the highest quality. It is crucial to take specimens using aseptic precautions. Interpretation of the relevance of a culture containing avirulent skin commensals such as coagulase-negative staphylococci, *Acinetobacter* spp., or a-haemolytic streptococci is almost impossible. Furthermore, the inoculation of any of these organisms into a damaged joint may well result in secondary infection.

In the laboratory, pus will be examined by Gram stain. Modified Giemsa is necessary to identify cell morphology. Methylene blue and acridine orange may reveal organisms that do not stain with Gram because they are damaged. Acridine orange will stain DNA and RNA, and will confirm the presence of micro-organisms, but will not reveal their classical morphology. When indicated, acid-fast bacilli are stained with auramine O and Ziehl-Nielsen.

The specimen is cultured under a range of conditions on non-selective media and, when a clue is given by the Gram stain, on selective media. It is quite common to see organisms in pus but for these not to grow, and this may reflect inhibition by host defences still present in the pus rather than insensitive culture conditions. Restoration of 'stressed' organisms is done very poorly in clinical laboratories. There is a move to apply special techniques used in food microbiology to clinical specimens. Essentially, the culture is enriched under optimal conditions for bacterial growth without any potentially suppressive selective pressure.

All fluids should be incubated alone and inoculated into enrichment broth or cooked-meat medium, then subcultured at 24 and 48 h. Dilution in broth may allow growth, even in the presence of antimicrobial agents.

It is better to send a good volume of fluid or pus rather than a swab of the pus. It is not worth looking for mycobacteria from a swab. If the specimen is aspirated with a syringe, send the capped syringe to the laboratory rather than decanting the pus into another container. Aeration of a specimen may reduce the yield of anaerobes. Anaerobes in joints are usually found only after penetrating trauma. The pus can be subjected to gas-liquid chromatography to demonstrate volatile fatty acids, which are products of anaerobic metabolism. This is a rather more technical way of identifying anaerobes than simply smelling the offensive odour of a specimen. Specific gas-liquid chromatographic patterns may, however, indicate a particular anaerobic genus, long before it has been cultured and identified.

Most fluids are cultured aerobically on enriched media (such as chocolatized blood agar), in an atmosphere of 5 to 10 per cent CO_2, and anaerobically because certain facultative anaerobes (e.g. *Streptococcus pyogenes*) show more characteristic colonial morphology under these conditions. Many true anaerobes require several days of incubation before they give visible growth.

If swabs of wounds are taken, they should be placed in transport medium supplied (e.g. Stuart or Amies). The best recovery that can be expected from a swab is less than 30 per cent of the organisms sampled. Swabs and pus from joints should in general not be refrigerated because of the risk of killing cold-sensitive organisms such as *Neisseria gonorrhoeae*.

Blood cultures

Blood cultures should be taken from any patient suspected of having pyogenic arthritis. Two sets taken by separate venepuncture at different times will increase the positive yield but it is not worth taking more. Disinfection of the skin twice with 70 per cent isopropyl alcohol allowed to dry is quite sufficient provided that the venepuncture is done deftly. Contamination of the culture with skin commensals nearly always follows poor technique or difficult venepuncture. Blood-culture bottles should be filled from a syringe before other sample containers because often these others are not sterile.

Handling the blood is dangerous. Needlestick injuries while changing needles and inoculating the bottles are very common, so extreme care must be taken. Some recommend not changing needles for this reason and because it has been shown not to reduce significantly the level of contamination. The bottles should not be overfilled with blood (easily done for bottles with a vacuum), because blood over a certain concentration is inhibitory to bacterial growth. Different style bottles require different sizes of inoculum. Most modern bottles have a cap over a sterile rubber membrane and the membrane should not be swabbed before inoculation.

Semiautomatic, vacuum ('Vacutainer', Becton Dickinson) blood-culture bottles are available but are not popular in the laboratory. Automatic systems have revolutionized the handling of blood-culture specimens but the special bottles required are, in general, not suitable for 'Vacutainer' phlebotomy.

Three main types of automatic culture detection systems are in use: detection of $^{14}CO_2$ released from labelled carbohydrate; detection of CO_2 by infrared spectrophotometry or some patented indicator system; and detection of increased pressure of gas within a bottle by a simple cap indicator. These systems do away with the routine subcultures, which are labour-intensive and lead to contamination of the cultures. They also accelerate the process of detection. It is not unusual for a blood culture taken during the night to cue positive in the morning with coliforms or *Strep. pneumoniae*, without visible signs of growth.

It is important to realize the limitation of the blood-culture system routinely used in the local laboratory. Do cultures regularly detect fastidious organisms such as neisseriae and brucellae? When in doubt, cultures should be specially subcultured on to rich medium after a week's incubation, but this will only be done by special request.

Antimicrobial sensitivity testing

In general, antibiotic tests will be done only when an organism has been isolated in pure culture. However, direct sensitivities can be done by plating the specimen and using antibiotic discs, but this depends on having seen an organism with characteristic morphology. The inoculum is inaccurate so the preliminary results are suspect until confirmed using the isolated organism in pure culture.

Antimicrobial testing is done in most laboratories by one of two methods. The principle of the first is that antimicrobials diffuse from a small filter-paper disc into agar in such a way that exponential concentration is proportional to the distance from the disc. A sensitive organism plated on to the agar is inhibited up to but not beyond the minimal inhibitory dilution of the antibiotic. The zone radius or diameter is then measured and recorded. In the United Kingdom, it is practice to compare the zone of inhibition of test organisms with a control of known sensitivity (Stokes method; Stokes and Ridgway 1987), but in the United States the size of the zone given by the unknown is compared with a database of known sensitive organisms (Kirby-Bauer method). A reduction in zone size indicates reduced sensitivity, which may be declared 'moderate' or 'resistant'. The advantages of the test are that the organism can be seen to have grown with characteristic morphology, that it is not contaminated, and that 'sensitivity' is a clear signal. The main limitations of the disc diffusion test are that it is standardized for fast-growing organisms and causes problems with difficult organisms (e.g. *Haemophilus* spp., *Neisseria* spp.). Some other specific problems are as follows:

1. Requirement for a special medium or culture conditions:
   a. enriched for *Neisseria*, *Haemophilus* etc.;
   b. thymidine-free—testing folate antagonists (sulphonamide etc.);

c. special supplements—pyridoxine for streptococci;
d. staphylococcal sensitivity to methicillin is temperature-dependent (best demonstrated at 30°C).

2. Poor diffusion of antibiotics (a small zone of inhibition is difficult to interpret) as with:
   a. glycopeptides—vancomycin and teicoplanin;
   b. polymyxin.
3. Inaccurate results:
   a. inappropriate sensitivity of inactivating enzyme producers, for example:
      i. *Enterobacter* spp. may appear sensitive to ampicillin yet always produce b-lactamase;
      ii. penicillin-resistant *Staph. aureus* often shows a good zone of inhibition to penicillin;
      iii. penicillin-resistant pneumococci may show a zone to penicillin but not to oxacillin.
   b. Organism shows heterogeneous resistance:
      i. *Staph. aureus* to methicillin.

The other method in common use involves the incorporation of antimicrobials into agar or broth at concentrations above and below the so-called breakpoint between sensitive and resistant. Unknown and control sensitive and resistant organisms are spot inoculated on to a series of plates incorporating different antimicrobials. Although this method gives more precise information about the minimal inhibitory dilution of an antibiotic against a certain organism, it also has flaws. If an organism does not grow, one cannot be certain that the organism was not dead when inoculated. The effect of penicillin against *N. gonorrhoeae* is a good example where there is a continuum of increasing resistance conferred by sequential changes in penicillin-binding proteins, permeability, and finally b-lactamase. It is impossible to know where to set the breakpoint in this situation.

Sensitivity to antibiotics of slow growers such as mycobacteria is best done by a modified agar incorporation method that has been standardized. Mycobacterial sensitivities should be ready 1 month after primary isolation but rapid sensitivity tests employing radiocarbon release as $^{14}CO_2$ from a suitable broth can be done in specialized laboratories. For the future, we may expect molecular methods for species identification and to detect important antibiotic resistance genes.

These examples illustrate the point that sensitivity testing of bacteria *in vitro* has problems whatever method is adopted. In addition, when large numbers of tests are done, there are likely to be transcriptional errors. When a patient does not appear to respond to recommended therapy, question first the appropriateness of the results of sensitivity tests, have them double-checked in the laboratory, and then consider the pharmacology of the antimicrobial selected.

The minimal inhibitory and the minimal bactericidal dilutions of an antimicrobial are tested in broth culture using highly accurate concentrations of antimicrobial. This is done for isolates causing infective endocarditis but may exceptionally be done also for a pyogenic arthritis that is failing to resolve. Antimicrobial activity can also be measured in synovial fluid as a check on pharmacokinetics. Experimentally, killing of organisms and the postantibiotic effect (inhibition of growth even after the antibiotic has been removed) may be measured; such tests are part of the development, and may influence the use, of new antimicrobials.

Antibiotic choice

Antibiotics chosen empirically for joint infections should be appropriate to the isolate or most likely organism, but also need to penetrate well. Some agents, such as chloramphenicol, co-trimoxazole, tetracycline, clindamycin, rifampicin, or metronidazole, are well absorbed from the intestine and will probably be effective when given orally. Most b-lactam antimicrobials are poorly absorbed and penetrate into bone and joint tissue poorly, so the first phase of treatment for acute pyogenic infections should be given parenterally in high doses.

Antimicrobials that penetrate well into joint fluid include tetracycline (useful for brucellae), co-trimoxazole (active against coliforms and some *Staph. aureus*), rifampicin and fucidic acid (very active against *Staph. aureus*, but should not be given alone), and chloramphenicol. Ciprofloxacin in recommended doses may not achieve sufficiently high concentration to inhibit *Pseudomonas aeruginosa*. Although absorbed from the gut and suitable for pseudomonal urinary infection, the antimicrobial should probably be given parenterally to achieve sufficiently high concentrations in the synovium. *Stenotrophomonas maltophilia*, an emerging nosocomial pathogen in immunosuppressed patients, is often resistant to ciprofloxacin and carbapenems so may be selected by the widespread use of these drugs. Nosocomial enterococcal infections are also selected by using cephalosporins.

Antigen detection

Tests for antigen detection have developed in two rather different directions. First, rapid tests, which usually depend on agglutination of latex particles, red cells, or staphylococci (binding Fc) coated with antibody, are sold in kit form to the routine laboratory for rapid detection or confirmation of common organisms found in certain specimens. An example would be *H. influenzae* type b in cerebrospinal fluid. Kits are designed so that a single test can be done economically, together with positive and negative controls. These tests have superseded countercurrent immunoelectrophoresis, which was cumbersome, slow, and insensitive.

The alternative tests for antigen are immunoassays (either radiometric or enzyme-linked), suitable for processing large numbers of specimens. These are often highly sensitive but may not be specific, so confirmatory tests of positives are required. Reference laboratories tend to develop and validate their own immunoassays. The classical application of successful immunodiagnosis of antigen is in the detection of hepatitis B virus surface antigen.

Despite antigenic diversity, it seems that, in practice, only a limited number of the antigenic shapes expressed on micro-organisms are useful for the detection of species. Monoclonal antibodies are preferred to polyclonal ones for their greater specificity, but polyclonals will usually include some antibody of great avidity, which can significantly improve a test. Sandwich immunoassays using high-avidity antibody capture and one highly specific antibody seem to be the most reliable. The antigen recognized by the antibody chosen should be common to and expressed on all of the species and subspecies that are to be searched for. Yet there should be no cross-reactivity with antigens on other species and this is unachievable. In an immunofluorescence test, where the antibody (directly or indirectly labelled) is applied to a clinical specimen and examined microscopically, it is possible for the experienced reader to detect alternative organisms or debris that appear to bind yet have a different shape from the organism under investigation. This indicates a serious problem with enzyme immunoassays in which positives are detected simply by a graded colour change. It must be assumed that certain of the results will be false-positive and that secondary confirmatory tests are required.

Specific DNA or RNA detection

Labelled, specific, single-stranded DNA probes will anneal with complementary DNA that has been cleaved into single strands at high temperature. The labelled complex is detected in the appropriate way (radioisotope detection or enzymatic colour change). This method appears to be specific (although it is often impossible to prove positives or negatives) but is not sensitive because it will detect only relatively large amounts of DNA present. Therefore, the label itself may be amplified by a chemical trick. Labelled DNA probes can also be made to anneal with ribosomal RNA, which will be present at a higher copy number than the DNA.

Alternatively, DNA segments in the test sample may be amplified using flanking sequences that define a specific segment and a heat-stable polymerase to replicate the DNA repeatedly. This is known as the polymerase chain reaction (**PCR**). Theoretically, one DNA molecule can be amplified to a detectable level but rather more than one molecule is needed for the test to work in practice. Nevertheless, the problem with DNA amplification is extreme sensitivity and false-positivity due to contamination: the test should be done away from laboratories where the organism being sought is routinely grown and handled. These tests are expensive, experimental, and not yet universally available.

Recent advances in PCR technology include 'nesting', using two pairs of primers, the second internal to the first, which increases the sensitivity of the test some hundred-fold and also the specificity. Secondly, viral and bacterial RNA can be amplified after it has been converted to complementary DNA by reverse transcription. Thirdly, the amplification product can be annealed to a specific labelled probe to confirm the specificity of the product.

Good examples of the useful application of PCR are to be found in the study of viruses that cannot (easily) be grown (e.g. hepatitis C virus, human immunodeficiency virus). A highly sensitive test such as PCR for hepatitis C virus is too difficult and expensive for screening of blood products even though seroconversion may take 3 to 6 months after infection.

These tests are, in general, experimental. When a new test is introduced, inevitably there is a exploratory period when the results are quite uninterpretable and unreliable.

Antibody detection

A single serum test for antibody almost never yields a definitive diagnosis. Even a confirmed positive antibody test for human immunodeficiency virus merely indicates exposure to, and latent infection with, the virus. It does not infer anything about the relation of the present symptoms and the stage of the disease.

Two specimens separated by at least 2 and preferably 4 weeks should be tested to make a diagnosis of a recent infection, especially when a positive test result is obtained. Only the evolution of titre can indicate how recent an infection was and then only within wide confidence limits. Some infections (e.g. legionellosis) are associated with a delayed rise in antibody, sometimes as long as 3 weeks after the onset of illness. Many infections fail to stimulate any detectable antibody response at all.

Antibody tests are the only way of making a non-invasive diagnosis in many infections that predispose to arthritis. Patients with polyclonal B-cell activation may show strong positivity in several tests and anamnestic responses are common.

The tests for antibody have developed enormous sophistication. Nevertheless, crude agglutination reactions are still made on dilutions of serum mixed with polyclonal antisera, usually as screening tests. This is the basis for screening tests for brucellae and enteric fever. Positive screening for *Brucella* agglutination in the routine laboratory is usually non-specific, cannot be confirmed in the reference laboratory by other immunoassays, and should not be taken automatically as indicating brucellosis.

With the high rate of false-positive tests in the first-generation enzyme immunoassays for human immunodeficiency virus, particularly in patients from Africa, it became conventional to confirm the specificity of antibodies by Western immunoblotting. The antigens of the organism under test are separated by chromatography and transferred to a membrane for reaction with the patient's serum. The patterns of reactivity are then compared with positive controls. Non-specific Western blot reactivity has been clearly shown not to indicate infection with human immunodeficiency virus. Western blotting may also be used to confirm the specificity of antibody in other conditions (e.g. Lyme disease) (Karlsson 1990). Enthusiasm for what was thought to be a very specific test has now waned because of difficulties in standardization and the definition of a positive test.

Specific tests have been developed over the years for certain organisms. They include the dye test for *Toxoplasma gondii*. This is still used as the 'gold standard' in reference laboratories, but routine agglutination tests have been replaced by highly sensitive latex-particle agglutination and specific IgM kits, which can be applied in routine laboratories. Some IgM kits have been found to be oversensitive.

The antistreptolysin-O titre for antibodies to *Strep. pyogenes* remains the mainstay of laboratory diagnosis of recent infection. It uses the neutralization of a standard inoculum of streptolysin by dilutions of the patient's serum. The indicator is haemolysis of sheep or human erythrocytes. However, the test is not specific and suffers false-positives and -negatives. Anti-DNAase B, streptokinase, and hyaluronidase can be measured in the specialist laboratory and may be useful additional tests.

It should be noted that the likelihood of accurate results from serological tests for antigen and antibody depend on how frequently the tests are done in the laboratory. Furthermore, commercial test kits are very expensive. Hence the reliance on reference laboratories for support and verification. Inevitably, such test results are delayed.

Acute joint infections (Fig. 1, Fig. 2, Fig. 3)

Fig. 1 Acute back pain with fever may be due to spinal osteomyelitis. Tuberculosis would be a common cause but in this case an aspirate of pus yielded *Brucella melitensis*. The patient came from Turkey.

Fig. 2 A chronic discharging sinus from the back of the finger of this man with psoriatic arthropathy surprisingly yielded *Mycobacterium tuberculosis*.

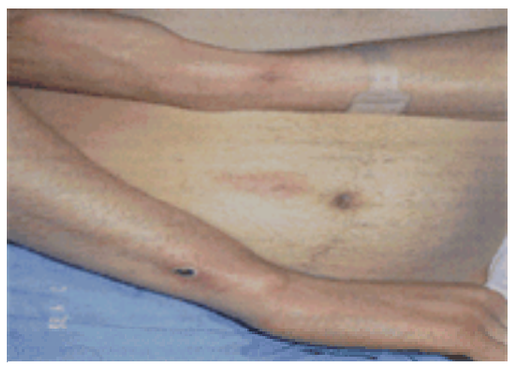

Fig. 3 This patient has acute arthritis of one knee and these skin lesions indicate bacteraemia particularly with *Neisseria gonorrhoeae*.

Acute joint infections engage a relatively small part of rheumatology practice in Europe and America. In certain parts of the world, however, brucellosis and

tuberculosis of joints are common. With increasing invasive health care, nosocomial bacteraemia, especially from intravenous-line infections, may contribute to some bone and joint infections.

Microbiological examination of fluid from an infected joint is only important because of the guidance the results ultimately give towards sensible chemotherapy. In the relatively few acutely inflamed joints that are infected, a very wide range of organisms is involved and, with very few exceptions, isolates have increasingly unpredictable sensitivity patterns to antimicrobials. Moreover, when positive, culture gives a firm diagnosis in a doubtful case.

Bacterial infections of healthy joints occur after bacteraemia with virulent organisms including *Strep. pneumoniae*, *Staph. aureus*, and *N. gonorrhoeae* but are much more likely to occur in joints damaged by other conditions such as osteoarthrosis or rheumatoid arthritis. Patients are often debilitated and on corticosteroids. In these patients, it is critical to make a positive diagnosis as soon as possible to prevent the inadvertent injection of steroids into an infected joint. Clinically, acute spontaneous pyogenic arthritis in a previously healthy individual is often restricted to one joint and is relatively easy to recognize, but may be much less evident when it supervenes on a chronic inflammatory polyarthropathy in a patient on steroids. To make a diagnosis none of the surrogate markers of infection (e.g. white blood-cell count, erythrocyte sedimentation rate, or C-reactive protein) compares favourably with direct examination of synovial fluid from inflamed joints or blood for relevant micro-organisms. It may be sufficient to take blood cultures and treat with antimicrobials on the basis of the most probable organism, in expectation of a positive culture in due course. However, it should always be the practice to consider sampling synovial fluid, which can also be examined for crystals and other important markers (see Chapter 4.6).

Routine cultures should readily yield *Br. melitensis* within a week but less certainly *Br. abortus*. Special cultures are needed for mycobacteria and negative results are not available for 8 or 12 weeks, depending on laboratory routine. Simple tests will distinguish *M. tuberculosis* from atypical species but the laboratory scientist will be reluctant to declare a species to the clinician until reference laboratory identification is completed.

The best way of monitoring the success of long-term therapy for deep *Staph. aureus* infections is to test serial sedimentation rates and C-reactive protein levels. Antibodies to staphylococcal a- and g-lysins should not be used to make a diagnosis of deep staphylococcal infection because false-positives may occur. However, if the diagnosis has been made by conventional culture, then serial assays of sera taken every 1 to 2 months or so can be done in parallel to monitor progress.

Investigation of reactive arthritis

Many infections predispose to reactive arthritis. There is considerable clinical overlap between full-blown Reiter's disease associated with HLA-B27 and so-called seronegative reactive arthritis. These conditions arise because of immune reactivity to organisms infecting particularly the genitourinary and gastrointestinal tracts. It may be possible to elicit a very specific, temporally relevant history of a symptom complex that points to a diagnosis. Common syndromes preceding arthritis are 'febrile rash' illness, diarrhoea, urethritis (sometimes with uveitis), and influenza-like illness with and without jaundice. Unless there is a preceding illness or accompanying signs, searching for the cause is likely to be fruitless.

Urethritis

It is important to search for the cause. When urethritis or prostatitis precedes arthritis, then it should be presumed to have been sexually acquired. Patients should ideally be examined in a department of genitourinary medicine, where there are facilities to take the optimal specimens and direct liaison with the laboratory. Furthermore, staff there will arrange contact tracing and may obtain circumstantial evidence for infection of the proband, by detecting chlamydiae or *N. gonorrhoeae* in an asymptomatic carrier partner.

The quality of the specimens is of great importance. For chlamydia, separate special swabs must be used for immunodiagnosis (enzyme immunoassay), immunofluorescence, DNA detection, and culture. Special transport media containing 2-sucrose phosphate and preservation at -70°C are required if the swabs are not to be inoculated directly into tissue culture. Special tissue culture is labour-intensive and does not detect 1/10 positives (by all tests) but has the advantage of being highly specific. The antigen-detection tests by immunofluorescence or by enzyme immunoassays tend to yield false-positives for a variety of technical reasons. Optimal diagnostic power in patients with low risk of chlamydial infection is obtained by doing several tests (Ridgway and Taylor-Robinson 1991). For the patient with posturethritis arthritis or Reiter's disease, diagnosis is important because eradicative antibiotic therapy is an important part of management, even though the immunological disease is usually not affected by such treatment.

Experimental methods, such as direct probes to detect chlamydial DNA or RNA, or DNA amplification, are under development. The direct probes are not particularly sensitive, but DNA amplification is oversensitive, very prone to contamination, and may yield false-positive results. Antigen-detection tests alone and DNA amplification are not yet specific enough to be absolutely sure about the meaning of a positive result.

The chlamydiae, therefore, are typical examples of organisms that commonly cause disease and are detected by rapid, simple means other than conventional staining and culture, that is, enzyme immunoassay and immunofluorescence of antigen, with DNA or RNA hybridization proving a useful experimental tool. In contrast, detection of gonorrhoea should be by culture.

The likelihood of detecting these organisms diminishes progressively with time from the acute infection. Therefore, the tests may be negative in patients with reactive arthritis. Although antibody may be detected, this does not help with the diagnosis of recent infection. A very high titre of antibody to *Chlamydia trachomatis* would be a pointer to the diagnosis.

However, the results of tests for antibody to *N. gonorrhoeae* are so totally unreliable that they should not be requested or performed.

Diarrhoea-associated reactive arthritis

When a patient gives a history of diarrhoea preceding the arthropathy then it is worth examining stools for continuing carriage of salmonellae, shigellae, and yersiniae, even though the acute illness may have occurred some time ago. All culture methods are selective, so lack sensitivity. Therefore, three separate stools should be examined to increase the value of a negative result. Intestinal biopsies may reveal organisms by immunofluorescence but this technique is very likely to be misleading because of cross-reactivity (de Koning *et al.* 1989). There is preliminary evidence that fluoroquinolones such as ciprofloxacin may be able to eradicate the carriage of certain organisms in the stool, but this action has not yet been shown to affect postdysenteric arthropathy

Yersinia enterocolitica causes a syndrome of prolonged diarrhoea with abdominal pain a particular feature (Cover and Aber 1989). Patients may have terminal ileitis and pseudoappendicitis. Five per cent of patients develop erythema nodosum or reactive arthritis or full-blown Reiter's disease. *Yersinia enterocolitica* serogroups 0:3 and 0:9 are particularly associated with postinfective arthritis in Scandinavia, in parallel with a high incidence of HLA-B27. Antibodies to *Yersinia*, particularly IgA, persist and can be measured in reference laboratories. Cross-reactivity between numerous O serogroups and other organisms (brucella, morganella, salmonella) and thyroid tissue antigens is likely to make agglutination tests for antibodies unreliable, although experimental enzyme immunoassays are under evaluation (Gronberg *et al.* 1989).

Non-specific illness

Short-lived, influenza-like illness predisposing to arthritis will probably not be diagnosed. From a survey of 10 microbiology laboratories, Waghorn (1995) discovered that the following serological tests might be performed on serum from a 30-year-old female with 'an influenza-like illness and arthralgia': (in order of frequency) rubella, parvovirus, *Mycoplasma*, influenza, *Chlamydia*, adenovirus, enterovirus, hepatitis B, Q-fever, Epstein–Barr virus, antistreptolysin titre, *Borrelia*, mumps, respiratory syncytial virus, *Yersinia*, *Legionella*, toxoplasmosis, syphilis, and cytomegalovirus.

More protracted illness would be a feature of glandular fever, toxoplasmosis, or hepatitis. It is worth checking particularly for evidence of recent anicteric hepatitis. Markers of recent infection with hepatitis B virus include antihepatitis B core antigen (IgM). Serial sera will also reveal the evolution of an acute infection or chronic carrier state. Hepatitis A virus IgM is specific to recent infection within the last 6 months because the carrier state does not occur.

Positive hepatitis C virus antibody tests occurred particularly in rheumatoid arthritis, implying a causal link until it was discovered that this reactivity was non-specific.

However, there have been a small number of case reports of reactive arthritis associated with this infection.

Rash illness

Common exanthematous infections such as rubella and parvovirus are associated with arthritis either during the latter stages of the acute infection, when the diagnosis is usually clear, or when the infection appears to have resolved. Serological tests are needed to make the diagnosis. Specific IgM tests are available for these organisms.

Lyme disease (see also Chapter 5.3.4)

The rheumatologist may be alerted to the possibility of Lyme disease as a cause of rheumatic symptoms during the secondary stage of the disease by concomitant rash, neurological signs, or myopericarditis. History of exposure, of known tick bite, and of the erythema chronicum migrans of the primary illness will also be useful. Large-joint arthritis is characteristic of the tertiary stage and there may or may not be skin and neurological manifestations.

Although the spirochaetes can sometimes be seen in biopsy material, realistically the diagnosis can only be made serologically and several methods of detecting antibody are available in kit form: indirect immunofluorescence (based on the fluorescent treponemal antibody test but using *Borrelia burgdorferi*), passive haemagglutination of red cells or latex beads coated with *B. burgdorferi*, various enzyme immunoassays, and a specific IgM capture test (Barbour 1988). Rheumatoid factor will give false-positives in the last. Many laboratories will do one of these as a screening test but will not do confirmatory tests except in an area of high prevalence (Schwartz *et al*. 1989). Most will rely on a reference laboratory to make confirmatory tests.

False-positives are common in all tests, probably because of exposure to commensal spirochaetes, and the most specific tests use a preliminary absorption step. Schwartz *et al*. (1989) found some discrepancies between test results from different laboratories. It is important that the screening test should be highly sensitive (and therefore gives some false-positives) so that positives are not missed. False-positives should be excluded by confirmatory tests but Western immunoblotting does not add much to the specificity of a good enzyme immunoassay (Karlsson 1990).

Rheumatic fever (see Chapter 5.3.12)

In the relatively rare condition of acute rheumatic fever, *Strep. pyogenes* may be obtained from the throat swab of the proband and family contacts several weeks after the acute infection. During an outbreak it is worth determining the serotype of any isolate. However, except in very unusual conditions, these are not consistently of one M-type (Kaplan *et al*. 1989). Certain M-types seem to be more commonly associated with rheumatic fever but this is probably an epiphenomenon and the diversity of types usually found suggests an epidemic cofactor, such as a coincident viral infection. No such cofactor has ever been identified. Isolation of *Strep. pyogenes* is a helpful indication but is not the mainstay of the diagnosis (Pope 1989). High titres, preferably with a demonstrated fourfold rise or fall in antistreptolysin-O and anti-DNAase B titres in serial samples, are the strongest supportive evidence for rheumatic fever. However, only 80 per cent of patients who fulfil the clinical criteria for acute rheumatic fever have a significantly raised antistreptolysin-O titre, and antibodies against other determinants may be more sensitive.

Conclusion

The rheumatologist can gain much information by using the diagnostic microbiology laboratory to the best advantage but can also expend much money and fruitless energy uncritically requesting irrelevant serology. Withholding antibiotics until all the relevant culture specimens have been taken and consultation over difficult cases may be helpful.

4.5 Autoantibody profile

P. J. Maddison

Autoantibodies are a prominent feature of autoimmune rheumatic diseases and are the subject of intensive study to understand the underlying pathogenesis of these disorders. At the same time methods to detect certain of these antibodies have provided the clinician with valuable tools to help diagnose and assess patients with connective tissue disease. It is becoming increasingly clear that autoantibodies in the context of autoimmune rheumatic diseases are directed against highly selected targets and are not just the result of non-specific polyclonal B-cell activation. Of the 2000 or more mammalian intracellular proteins only relatively few are targeted by autoantibodies (Christian and Elkon 1986). In many cases, when they occur they belong primarily to the IgG1 and IgG3 subclasses of IgG, are high affinity, and occur in large amounts, showing all the features of an antigen-driven, T-cell-dependent immune response. Antigen specific T cells have now been detected for some of these autoantigens (Fenning *et al*. 1995).

Table 1 lists antibodies which have a role in diagnosis, in predicting patterns of disease expression and prognosis and in assessing disease activity. Although at first glance there is a wide range of antibody specificities, in the individual patient the autoantibody profile is much more restricted and this can be used to our clinical advantage. It is now appreciated that certain antibody profiles are associated not only with a clinical diagnosis but also with particular clinical manifestations and, as a consequence, the prognosis. Therefore, once antinuclear antibodies (**ANA**) have been detected with a screening test, it is important to determine their specificity. To be of most use to the clinician, it is important that the serology laboratory should have the facility to detect a wide range of relevant antibody specificities.

Table 1 Serological tests in the assessment of patients with connective tissue diseases

Autoantibody tests should be planned, and the results interpreted, in the light of the clinical picture. Thus, in the situation where the clinician wishes to exclude the possibility of systemic lupus erythematosus, examination of the serum for ANA by indirect immunofluorescence is sufficient as a screening test and it is not cost-effective automatically to test for anti-DNA or other antibody specificities (Clough *et al*. 1989). If the ANA test is positive, then it is important to look for antibodies reacting with DNA or nucleic acid-binding proteins. In other clinical situations particular combinations of serological tests are indicated. For example, where systemic sclerosis is suspected clinically it is worthwhile from the beginning looking for antibodies to nucleolar antigens, kinetochore-related proteins, or topoisomerase 1 (Scl 70), since these antibodies have disease specificity and one or the others will be detected in over 85 per cent of patients with systemic sclerosis.

Antinuclear antibodies

The discovery of the lupus erythematosus cell phenomenon by Hargraves and colleagues (1948) led to the first serological test to be used in the diagnosis of systemic lupus erythematosus. The next landmark was the development of indirect immunofluorescence (Holborow *et al*. 1957), which has taken over from the lupus erythematosus cell test because it is more sensitive, simpler to perform, reproducible, and easier to interpret. Indirect immunofluorescence detects a wide range of autoantibodies and, therefore, is generally used as a primary screening test for ANA.

At one time thin sections of mammalian tissues, especially mouse or rat liver or kidney, were used as the substrate to incubate with the patient's serum. Now there is a trend towards using human cell lines grown as a monolayer on the glass slide. The advantages are that the cells lie on a flat plane allowing good recognition of both nuclear and cytoplasmic structures and that actively dividing cells present antigens only expressed during certain stages of the cell cycle, which are either absent or occur only in small quantities in the resting nuclei of tissue sections. At present, HEp2 epithelial cells, derived from a human larynx carcinoma (American Type Culture Collection CCL-23), are most widely used because both nuclei and nucleoli are large and enable a wide range of staining patterns to be recognized. They can be cultured in the laboratory or slides with monolayers of cells can be purchased.

The antinuclear antibodies fixed to the nuclear antigens are visualized by adding a fluorescein-conjugated antibody to human gammaglobulin and examining the slide under a fluorescence microscope (Fig. 1). Alternative enzyme-linked conjugates are now commercially available, after addition of which the slides can be examined under an ordinary microscope. The incidence of ANA depends upon the assay system, the titres chosen to separate positive and negative sera, the ability of the technician, and the type of microscope. Uniformity of the test between different laboratories has been aided by the availability of positive standards (Feltkamp 1990).

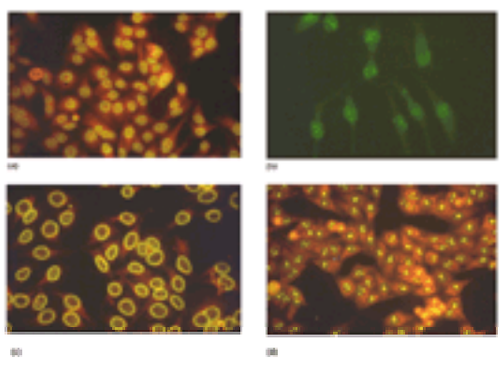

Fig. 1 Patterns of immunofluorescence using HEp2 cells: (a) speckled (pattern typical of anti-U1RNP); (b) centromere: characterized by discrete speckles in interphase nuclei which segregate on to the metaphase plate during cell division; (c) peripheral; (d) nucleolar.

The use of HEp2 cells enhances the sensitivity of this test in systemic lupus erythematosus so that antinuclear antibodies can be detected in 95 per cent of active, untreated patients. The main difference from using rodent substrates is the increased detection of patients with an immune response predominantly to Ro. However, a very small number of such patients are still ANA-negative even using HEp2 cells. As shown in Table 2, the specificity of the test for systemic lupus erythematosus is low (approximately 0.6) and antinuclear antibodies are frequently detected in other autoimmune rheumatic diseases and in a proportion of the normal population. Higher titres tend to occur in disease states than in normal subjects. Some reports have shown a fall in the frequency of antinuclear antibodies in the normal population after the age of 70 and have suggested that this is due to the earlier death of ANA-positive individuals (Hooper *et al*. 1972).

Systemic lupus erythematosus	Other autoimmune rheumatic diseases		Other diseases		Normal population
95%	Systemic sclerosis	80%	Chronic active hepatitis	100%	8%
	Sjögren's syndrome	80%	Drug-induced lupus	100%	
	Rheumatoid arthritis	50%	Myasthenia gravis	50%	
	Polymyositis	40%	Waldenström's macroglobulinaemia	25%	
	Polyarteritis nodosa	10%	Diabetes	25%	

Table 2 Antinuclear antibodies in various diseases using HEp2 cells as substrate

Different patterns of fluorescence can be observed, often reflecting the predominant antibody in the serum. It is difficult to attribute the pattern to a particular specificity and additional tests are required, but there are exceptions when the pattern of fluorescence can be clinically useful. Thus, a peripheral nuclear pattern is almost exclusively seen in systemic lupus erythematosus and often corresponds to the presence of anti-nDNA, although it only occurs in a small proportion of such patients. Similarly, antikinetochore antibodies (anticentromere, **ACA**) and high titres of antinucleolar antibodies are most commonly seen in the context of systemic sclerosis. For a comprehensive review of fluorescence patterns the reader is referred to Humbel (1993).

The titre of antinuclear antibodies frequently fluctuates but does not correspond well to clinical assessment of disease activity. The titre *per se* does not have prognostic significance.

Antibodies to DNA

Autoantibodies binding DNA have a central place in the immunology of lupus. Two broad groups of antibody specificity correspond to the major conformations of DNA: native, double-stranded DNA (**nDNA**) and denatured, single-stranded DNA (**ssDNA**). Antibodies to nDNA do not react with the free purine or pyrimidine bases but do react with some aspect of the secondary structure of the denatured molecule, generally with higher affinity. Recent evidence suggests that DNA circulating in the blood is always in the form of nucleosomes, i.e. closely associated with histones (Rumore *et al*. 1992).

In the past various techniques have been used to detect anti-DNA including immunodiffusion, haemagglutination, and complement fixation. With the availability of chemically-pure antigen it has been possible to develop sensitive and quantitative methods and now most laboratories use radioimmunoassays or enzyme-linked immunosorbent assays (**ELISA**). Either commercial kits are used or in-house assays. The Farr assay is a fluid phase radioimmunoassay in which antibodies combined to ^{125}I-labelled DNA are precipitated by 50 per cent saturated ammonium sulphate (Smeenk *et al*. 1990a). Modifications of this include the use of filters or an antihuman immunoglobulin serum. The Farr assay detects high avidity antibody. To detect antibodies to DNA by means of an ELISA, DNA has to be coated on to an ELISA plate. Being relatively negatively charged, nDNA in particular binds poorly to plastic and so the ELISA plate needs to be precoated with poly-l-lysine or, even better, protamine sulphate. Other methods have included the binding of biotinylated DNA to the plastic via streptavidin (Emlen *et al*. 1990) or to coat DNA to ultraviolet-irradiated plates (Zouali and Stollar 1986). During the assay, DNA-bound antibody is detected by adding (i) an antihuman immunoglobulin antibody conjugated to an enzyme such as horseradish peroxidase or alkaline phosphatase, and (ii) the appropriate substrate for the enzyme to produce a colour reaction, which is quantified by measuring the resulting optical density.

Different assay systems are not always comparable and are influenced by important factors such as characteristics of the DNA antigen, how the DNA is presented to antibody in the serum, and the reaction conditions. This is illustrated by a recent demonstration of the variability between commercial ELISA kits (Aviña-Zubieta *et al*. 1995).

The ELISA is more sensitive than the Farr assay because it detects low avidity antibody and can be used to distinguish its isotype. However, being polyanionic, DNA is a 'sticky' molecule with a tendency to bind serum proteins non-specifically. To minimize interlaboratory variation the chosen assay should be standardized using a freely available standard serum from the World Health Organization (Feltkamp 1990). When the Farr technique and an ELISA are compared, the former, according to some reports, is less sensitive but more specific for systemic lupus erythematosus (Smeenk *et al*. 1990b).

Antibodies reacting with nDNA have greatest relevance to the diagnosis of systemic lupus erythematosus (Aarden *et al*. 1976), but assays to detect these antibodies rely on a source of impeccably pure, double-stranded DNA. DNA extracted from *Escherichia col*, for example, needs to be treated with S1 nuclease, or purified on columns of diethylaminoethylcellulose. Radiolabelled, circular double-stranded DNA from the bacteriophage PM $_2$ also serves this purpose well or, alternatively, the synthetic polynucleotide, polydAT can be used. Indirect immunofluorescence using the haemoflagellate, *Crithidia luciliae* (Aarden and Smeenk 1981), is also an accepted technique for detecting anti-nDNA, combining strong sensitivity with high disease specificity (Smeenk *et al*. 1982). This micro-organism contains a giant mitochondrion which consists of pure nDNA and it is the fluorescence of this which constitutes a positive test. This technique is more sensitive than the Farr assay, since it detects antibodies with lower affinity; it can also be modified to identify complement-fixing antibodies.

Approximately 70 per cent of untreated patients with active systemic lupus erythematosus have anti-nDNA detected by the *C. luciliae* technique. These antibodies have a high degree of specificity (Table 3). The Farr technique, which selects out high avidity antibodies, is somewhat less sensitive and the ELISA more sensitive but less specific since low avidity antibodies are detected in other conditions. Antibodies reacting with purine and pyrimidine bases and other sites revealed by denaturing DNA are very commonly found in systemic lupus erythematosus but are also seen in a variety of other conditions (Table 3).

Disease	Anti-nDNA (%)	Anti-ssDNA (%)
Systemic lupus erythematosus	70	90
Drug-induced systemic lupus erythematosus	0	60
Chronic active hepatitis	5	60
Rheumatoid arthritis	5	25
Primary biliary cirrhosis	0	15
Normal subjects	0	5

Table 3 Incidence of antibodies to native and single-stranded DNA

There is evidence that antibodies to both nDNA and ssDNA have a role in pathogenesis. The presence of high avidity, complement-fixing antibodies to DNA are associated with an increased risk of lupus nephritis. In some patients, but not in all, a steady increase in anti-DNA levels followed by a sharp drop in titre precedes a clinical exacerbation (Smeenk *et al*. 1990b). Consequently there is value in monitoring serial serum anti-DNA levels. In studies where the relative proportion of high and low avidity anti-DNA antibodies was measured, clinical exacerbation was often heralded by an increase in high avidity antibodies (Smeenk *et al*. 1990b).

Antihistone antibodies

Antibodies to histones are detected in idiopathic and drug-induced lupus, rheumatoid arthritis, and other conditions including scleroderma-related disorders (Bernstein *et al*. 1985; Wallace *et al*. 1994). Histones are a set of basic proteins that organize chromosomal DNA in eukaryotes into nucleosomes which are the repeating units of chromatin. The nucleosome consists of the histone octamer $(H2A–H2B–H3–H4)_2$, approximately 200 base pairs of DNA and H1. Antibodies are directed to a range of epitopes expressed on individual histones, histone–histone complexes, and histone–DNA complexes (Burlingame and Rubin 1990). They can be detected by indirect immunofluorescence, typically producing an homogeneous nuclear pattern which can be abolished by acid treatment of the substrate (Fritzler and Tan 1978). These antibodies primarily react with the (H2A–H2B)–DNA complex which is exposed in chromatin. ELISA have also been reported (Burlingame and Rubin 1990) but can be affected by DNA contamination of the antigen preparation. Immunoblotting using commercial sources of extracted histones can be used to detect antibodies to all five histones, although only the reactivity to denatured individual histones is measured by this technique.

Antihistone antibodies are a striking feature of the immune response in drug-induced lupus, occuring in over 90 per cent cases. Although they lack disease specificity, the presence of autoantibodies primarily to histones in the appropriate clinical setting strongly suggests a drug-induced syndrome (Thompson *et al*. 1993). In syndromes induced by a variety of drugs including procainamide, quinidine, hydralazine, penicillamine, and sulphasalazine the antibodies are predominantly IgG against the (H2A–H2B)–DNA complex (Totoritis *et al*. 1988; Rubin *et al*. 1992; Bray *et al*. 1994).

Nucleic acid-binding proteins

The presence of antibodies reacting with certain highly conserved, nucleic acid-binding proteins present in eukaryotic cells is a very characteristic feature of autoimmune rheumatic diseases. The first observations were made over 30 years ago when antibodies to what are now called Ro and La were detected by immunodiffusion in the sera of patients with Sjögren's syndrome (Jones 1958; Anderson *et al*. 1961). Subsequent clinical interest in these systems results from observations that certain profiles of these antibodies are associated with particular patterns of disease expression within the spectrum of autoimmune rheumatic diseases.

Traditionally, these antibodies have been detected by immunodiffusion using buffered saline extracts of mammalian tissue, such as rabbit or calf thymus extract and human spleen extract. A range of prototype sera are used to detect a precipitin system. Counter-immunoelectrophoresis (Fig. 2(a)) is used frequently to screen sera but the Ouchterlony technique of passive immunodiffusion, which is slightly less sensitive, is sometimes needed to confirm comparisons with prototype sera, particularly if multiple precipitin systems are present (Fig. 2(b)). Increasingly, more sensitive methods of antibody detection are being used, such as immunoblotting (Fig. 3), protein or RNA immunoprecipitation (Fig. 4), and ELISA. With immunoblotting, specific antibodies are recognized by binding to a profile of proteins of particular molecular weight which have been separated by electrophoresis of a cell extract and transferred to nitrocellulose sheets. As a technique it is too labour intensive for the routine laboratory and suffers from the disadvantage of detecting antibodies only to epitopes on denatured proteins. However, it is a good way of demonstrating the profile of antibodies in a particular serum and determining the fine specificity of these antibodies and their isotypes. ELISAs using purified antigens have been developed and provide a sensitive, quantitative way of detecting these antibodies. Initially, immunoaffinity purified antigens were used but recombinant antigens are becoming available. Compared with immunodiffusion, these techniques increase the prevalence of these antibodies (Table 4). However, with the exception of anti-Ro which can be found in low titre in approximately 12 per cent of the normal population (Reichlin and Harley 1988), they are virtually confined to patients with autoimmune rheumatic diseases.

Key: (1) normal serum, (2) anti-U3RNP, (3) anti-ThRNP, (4) anti-PM-Scl, (5) anti-RNA polymerase-I/-III, (6) anti-RNA polymerase-I/-II/-III, (7) antitopoisomerase 1.

Specificity	Systemic lupus erythematosus		Normal sera	
	Immunodiffusion	ELISA	Immunodiffusion	ELISA
Anti-URNP	33	35	0.1	0.1
Anti-Sm	10	25	0.1	0.1
Anti-Ro	40	50	1	12
Anti-La	15	28	0.1	0.1

Numbers are percentages

Table 4 Frequency of antibodies to RNA-binding proteins: ELISA compared with immunodiffusion

Systemic lupus erythematosus

In systemic lupus erythematosus, antibodies react most frequently with four groups of RNA-binding proteins, namely Sm, U1RNP, Ro, and La (see Reichlin and Harley 1988 for a review). The Sm and U1RNP antigens are expressed on protein components of a series of small nuclear ribonucleoprotein (**snRNP**) particles, each with its distinctive uridine-rich RNA molecule (Van Venrooij and Sillekens 1989) (Fig. 5). Sm epitopes, for example, are expressed on proteins designated B_, B, D, E, F, and G, which are amongst core proteins found in all snRNP particles. The B and D proteins, however, are the major autoantibody targets. U1RNP epitopes are expressed on three proteins, designated 70-kDa, A, and C, uniquely found in association with U1RNA of which the 70-kDa and A proteins are the major targets. The U1RNP particle therefore expresses epitopes reacting with both anti-Sm and anti-U1RNP. Most anti-U1RNP sera react with epitopes on the 70-kDa protein of the U1RNP particle and virtually all anti-Sm sera bind simultaneously to the B', B, and D proteins, while the pattern of binding to other protein components varies from serum to serum. Sera containing anti-Ro react with a number of different Ro-bearing proteins complexed in ribonuclear protein particles with a distinctive series of small RNA species, which in humans are designated hY1–5 (Reichlin and Harley 1988; Pruijn *et al*. 1990). In contrast to Sm and U1RNP, Ro proteins have evolved through the species so that in some autoimmune rheumatic disease sera, antibodies react almost exclusively with human Ro. Autoimmune sera recognize two major proteins, a 60-kDa protein known as Ro60, which binds directly to hYRNA, and a 52-kDa protein known as Ro52 which does not bind to hYRNA (Boire *et al*. 1995) (Fig. 6). The relationship *in vivo* between Ro52 and the RoRNP complex is unknown. Another protein, calreticulin, initially reported to be the 60-kDa protein is an unrelated autoantigen (Rokeach *et al*. 1991). Antibodies to La react with a 50-kDa protein which transiently binds to transcripts of RNA polymerase III which include the Ro RNAs. The physical association of Sm and U1RNP on one hand and Ro and La on the other explains, at least in part, the linked antibody responses to these antigens.

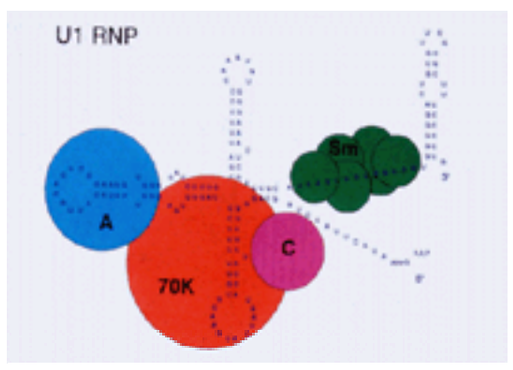

Fig. 5 The U1RNP molecule showing the relationship of U1RNP and Sm antigens to the U1RNA molecule (by courtesy of Dr G. Pruijn and Dr W. van Venrooij, University of Nijmegen, The Netherlands).

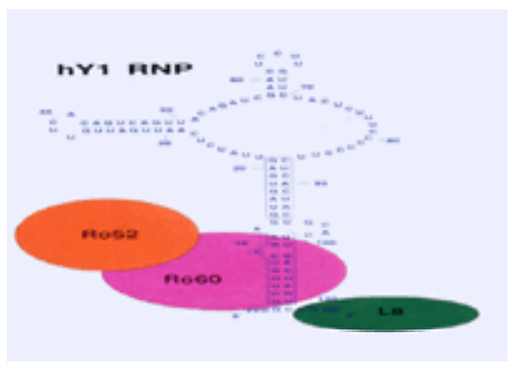

Fig. 6 The Ro/La particle showing the relationship of the Ro and La antigens to hYRNA (by courtesy of Dr G. Pruijn and Dr W. van Venrooij, University of Nijmegen, The Netherlands).

High titres of these antibodies, for example as detected by immunodiffusion, are found frequently and almost exclusively in the context of autoimmune rheumatic diseases (Table 5). Anti-Sm has the greatest specificity for systemic lupus erythematosus but there is a marked ethnic variation in the presence of these antibodies, being more commonly found in Afro-Caribbeans than in northern European Caucasoids (Arnett *et al*. 1988). These antibodies identify distinctive serological subsets within the spectrum of systemic lupus erythematosus. Antibodies to Sm frequently occur in association with anti-U1RNP and antibodies to La are virtually always accompanied by anti-Ro. It is apparent that these serological subsets are associated with certain patterns of disease expression (Table 5) in which they may have a

pathogenetic role.

Disease	Frequency of precipitins	Major specificities		Clinical association
Systemic lupus erythematosus	75	U1RNP	(30)	Raynaud's syndrome, deforming arthritis, mixed connective tissue disease.
		Sm	(10–25)	Vasculitis
		Ro	(40)	Photosensitive dermatitis, subacute cutaneous lupus erythematosus, Sjögren's syndrome, pulmonary fibrosis, neonatal lupus, congenital heart block
		La	(15)	
Sjögren's syndrome	60	Ro	(80)	Systemic disease, vasculitis, neurological disease
Systemic sclerosis	55	La	(30)	
Polymyositis	60	Scl-70	(20)	Diffuse scleroderma, cardiopulmonary disease
Non-connective tissue disease	<0.5	Jo-1	(20)	Interstitial lung disease
Normal subjects	<0.5			

Numbers are percentages.

Table 5 Antibodies to nucleic acid-binding proteins detected by immunodiffusion in connective tissue diseases

These antibodies are usually present from the beginning of the clinical presentation and are detectable throughout the course of the disease. The presence of high titres in an asymptomatic individual usually heralds the future development of an autoimmune rheumatic disease (McCune *et al*. 1987). Using an ELISA, fluctuations in antibody titre can be detected but there is an inconsistent relationship between titre measured in longitudinal studies and disease activity (de Rooij *et al*. 1990).

A variety of other antibody specificities, for example anti-PCNA (cyclin) (Asero *et al*. 1987), SL (Ki) (Sakamoto *et al*. 1989), and ribosomal P protein (Elkon *et al*. 1985), can be detected in systemic lupus erythematosus. They occur in a small proportion of sera and although clinical associations have been reported, such as anti-ribosomal P proteins and neuropsychiatric lupus, these associations require confirmation in larger, prospective studies and the role of these antibodies in 'routine' systemic lupus erythematosus serology is not yet defined.

Antibodies to ribosomal P proteins are directed predominantly to a conserved region of the C-terminus which is shared by the P proteins. They occur in approximately 10 per cent of patients with systemic lupus erythematosus but have been reported in a higher proportion with active disease with an association with diffuse neuropsychiatric manifestations (Elkon *et al*. 1994). However, this association is not apparent in all published studies (reviewed by Teh and Isenberg 1994). Reasons for discrepancies between reports include methodological differences for detecting anti-ribosomal P, a lack of uniform criteria for classifying patients with lupus involving the central nervous system, and demographic variation between the study populations. For example, anti-ribosomal P antibodies have been reported more frequently in certain ethnic groups, such as the Malaysian Chinese (Teh *et al*. 1993).

Sjögren's syndrome (see Chapter 5.10)

With sensitive techniques, antibodies to Ro and La can be detected in virtually all patients (Harley *et al*. 1986). They are a marker for Sjögren's syndrome developing in systemic lupus erythematosus, systemic sclerosis, and primary biliary cirrhosis. Several studies, including that of Pease *et al*. (1993), have shown that antibodies to Ro and La identify patients at greatest risk of developing extraglandular complications such as vasculitis. The fine specificity of anti-Ro antibodies may correspond to the clinical expression of Sjögren's syndrome as opposed to systemic lupus erythematosus (Ben-Chetrit *et al*. 1990; St Clair *et al*. 1994). In a recent study, Barakat *et al*. (1992), using synthetic peptides corresponding to regions of Ro60 in an ELISA, demonstrated that one peptide representing residues 21–41 of the protein was recognized by sera from the majority of patients with Sjögren's syndrome but only a minority of anti-Ro-positive sera from those with systemic lupus erythematosus.

Sjögren's syndrome in rheumatoid arthritis is usually not associated with anti-Ro. However, the small proportion of rheumatoid arthritis patients with anti-Ro have a distinctive clinical picture (Moutsopoulos *et al*. 1985; Tishler *et al*. 1994).

Mixed connective tissue disease

The concept of mixed connective tissue disease was predicated initially upon the identification of autoantibodies to U1RNP (Sharp *et al*. 1972). Whether or not mixed connective tissue disease is a distinctive autoimmune rheumatic disease is controversial. These antibodies produce a characteristic nuclear pattern on indirect immunofluorescence (Fig. 1(a)). Initially, the presence of these antibodies was confirmed by a haemagglutination reaction to an RNase-sensitive component of a buffered saline extract of mammalian tissue (extractable nuclear antigen, ENA). Subsequently, immunodiffusion became the standard assay in most serology laboratories. Using techniques such as immunoblotting or ELISA with recombinant protein components of U1RNP, it has been suggested that the reaction of antibodies to the 70-kDa polypeptide of U1RNP is an important serological marker for mixed connective tissue disease, whereas antibodies to U1RNP in the context of systemic lupus erythematosus are directed to epitopes on other polypeptides, particularly B'B (Habets *et al*. 1983; Reichlin and Van Venrooij 1991).

Systemic sclerosis (see Chapter 5.8)

Antibodies to kinetochore proteins (anticentromere antibodies), topoisomerase 1, and nucleolar constituents are very characteristic of systemic sclerosis and identify distinctive serological groups within the spectrum of the disease (Maddison 1988). Anticentromere antibodies can be detected in approximately 30 per cent of patients with systemic sclerosis, particularly in those with the limited cutaneous form of the disease. They include the majority falling into the so-called CREST subset, up to 90 per cent of whom have these antibodies. In contrast, antitopoisomerase 1, found in approximately 25 per cent of patients with systemic sclerosis, is seen mainly in those with diffuse scleroderma and systemic involvement, particularly of heart and lungs. Antinucleolar antibodies, detected in high titre by indirect immunofluorescence in approximately 40 per cent of patients with systemic sclerosis, react with multiple targets and can be defined further by immunodiffusion, immunoblotting, or immunoprecipitation (Reimer 1990) (Fig. 4). These include the PM-Scl system (antibodies occur in approximately 5 per cent of patients, many with associated myositis, and produce homogeneous nucleolar staining), U3RNP-associated fibrillarin (produce clumpy nucleolar staining on indirect immunofluorescence and are not associated with a particular clinical subgroup), and nucleolar 7–2 ribonucleoproteins (produce homogeneous nucleolar staining and are not associated with a particular clinical group). Autoantibodies to RNA polymerase I, II, and III (anti-RNAP) occur in approximately 15 per cent of patients in various combinations (Hirakata *et al*. 1993). Most patients have diffuse cutaneous disease and there is an association with the development of renal disease.

Dermato- and polymyositis (see Chapter 5.9.1 and Chapter 5.9.2)

Multiple antibody systems are found in polymyositis or dermatomyositis, and precipitin systems can be detected in 60 per cent of patients by immunodiffusion (Targoff 1989). Each specificity occurs in a small proportion of patients. Antibodies to Jo-1 (histidyl-tRNA synthetase) are the most common specificity, occurring in approximately 20 per cent of adult patients with polymyositis, especially those developing interstitial lung disease, but are not common in dermatomyositis or disease in children.

Antiphospholipid antibodies (seeChapter 5.7.3)

Antiphospholipid antibodies, which are responsible for the false-positive VDRL test in lupus, have been associated with a characteristic spectrum of features (Table 6) (Lockshin *et al*. 1990). A range of antibody specificities exists, including antibodies to cardiolipin which can conveniently be detected by ELISA. A less sensitive method is to detect lupus anticoagulant activity in specially esigned functional tests of clotting. Antibodies are found in a wide range of clinical settings including individuals in whom the 'antiphospholipid syndrome' occurs in the absence of other autoimmune rheumatic disease features. They are also found in a proportion of the normal population. Anticardiolipin antibodies occur in up to 40 per cent of systemic lupus erythematosus patients, but only a small proportion develop the associated clinical features. Those most at risk have high titres of IgG anticardiolipin antibody and/or a lupus anticoagulant.

Major features
- Recurrent arterial and venous thrombosis
- Recurrent pregnancy loss
- IgG anticardiolipin antibody and/or positive lupus anticoagulant

Additional features
- Thrombocytopenia
- Pre-eclampsis
- Livedo reticularis
- Multi-infarct dementia
- Chorea
- Lupoid sclerosis
- Immune thrombocytopenia
- Haemolytic anaemia
- Endocardial disease

Table 6 The 'antiphospholipid syndrome'

Antineutrophil cytoplasmic antibodies (ANCA)

A significant development in recent years has been the identification of antibodies to selected cytoplasmic targets in polymorphs and monocytes, primarily to myeloid-specific lysosomal enzymes (see Wiik 1995 for a review).

A standard method of detecting these antibodies is indirect immunofluorescence using normal neutrophils, carefully separated and fixed in ethanol. Using this technique, different patterns of fluorescence indicate different antibody specificities (Fig. 7). Many of the conflicting findings in the literature can be accounted for, at least in part, by the use of different methods of fixation.

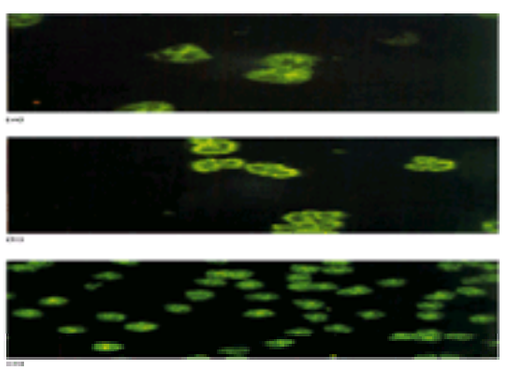

Fig. 7 Detection of ANCA using normal human polymorphonuclear leucocytes fixed in ethanol. (a) cANCA corresponding to antibodies to proteinase 3. (b) pANCA corresponding to antibodies directed to a variety of constituents, often myeloperoxidase but sometimes elastase and other lysosomal enzymes (by courtesy of Dr T. Wallington, Southmead Hospital, Bristol). (c) Atypical ANCA.

The typical pattern associated with Wegener's granulomatosis is coarse granular staining of the cytoplasm with central accentuation (**cANCA**) (Fig. 7(a)). cANCA corresponds to the presence of antibodies to a 29-kDa protein component of primary granules identified as serine proteinase 3.

The perinuclear pattern of ANCA (**pANCA**) (Fig. 7(b)) may be associated with antibodies to a variety of structures including myeloperoxidase, elastase, lactoferrin, cathepsin G, and other as yet unidentified cytoplasmic constituents. This pattern is artefactual and is due to the release of highly charged components of the primary granules on fixation of the cells, which are attracted to DNA.

The high specificity of cANCA for Wegener's granulomatosis has been demonstrated in several studies. Overall, sensitivity is 60 to 70 per cent for the disease depending on the patient population selected. cANCA are found in at least 90 per cent of patients with diffuse Wegener's granulomatosis and renal involvement but less commonly in patients with more localized disease. In some patients, measurement of the titre of cANCA provides an additional laboratory tool for assessing disease activity. However, since this is not true of all patients, changes in antibody titre have limited prognostic value (Kerr *et al*. 1993).

pANCA are found in a broader spectrum of vasculitis and in patients with idiopathic segmental necrotizing glomerulonephritis. Other patterns of ANCA are also seen. For example, a pattern distinctive from both cANCA and pANCA, and termed xANCA or atypical ANCA (Fig. 7(c)), is sometimes seen in patients with chronic inflammatory bowel disease, autoimmune hepatitis, and in a small proportion of patients with spondylarthropathies (Gross *et al*. 1993; Koh *et al*. 1995). Knowledge of the existence of these ANCAs is important in case physicians are misled towards a misdiagnosis of vasculitis.

Rheumatoid factor

Rheumatoid factors are antibodies directed against antigenic determinants on the Fc fragment of IgG. In rheumatoid arthritis, rheumatoid factor is polyclonal and reacts with a wide range of determinants on both the CH2 and CH3 domains of IgG including sites expressed by aggregated or denatured IgG, cross-reactive antigens shared by human and animal IgG, species-specific or even subclass-specific sites found only on human IgG, and genetically determined alloantigens such as Gm.

Rheumatoid factor is found in all classes of immunoglobulin. 'Classical' rheumatoid factor is a 19s IgM molecule which is still detected in many laboratories by techniques employing agglutination or flocculation of IgG-coated cells or particles. An example is the rheumatoid arthritis latex test that uses latex beads coated with human IgG which are cross-linked by rheumatoid factor to produce visible flocculation. This detects primarily IgM rheumatoid factor because of its high valency. The rheumatoid arthritis latex test also detects antiallotypic antibodies resulting from transfusion or pregnancy; thus, to increase specificity, techniques such as the Rose Waaler test have been used in which rheumatoid factor interacts with sheep cells coated with subagglutinating doses of rabbit IgG to cause haemagglutination. Since the presence of heterophile antibodies which react directly with sheep red cells can give rise to false-positive results, sera are usually tested in parallel with both coated and uncoated red cells and the difference in titres is expressed as the differential agglutination titre. Alternatively, the test serum is preincubated with uncoated sheep red cells (SCAT technique). Methods using rabbit IgG are less sensitive and give lower titres than the rheumatoid arthritis latex test because only a minor proportion of rheumatoid factors cross-react with rabbit IgG in rheumatoid arthritis. The presence of immune complexes or aggregated IgG can interfere with these techniques, sometimes to the extent that there is a false-negative result ('hidden rheumatoid factors'). Other methods for detecting rheumatoid factors are increasingly being used. These are laser nephelometry (Knight and Pritchard 1982), which is highly reproducible, and radioimmunoassays and ELISAs which are sensitive and quantitative and can be used to detect different isotypes of rheumatoid factor (Hay *et al*. 1975; Allen *et al*. 1981).

Tests for rheumatoid factor have some value as screening tests for rheumatoid arthritis, since rheumatoid factor is present in at least 75 per cent of patients with rheumatoid arthritis using a cut-off level for positivity which excludes 95 per cent of the normal population. In an early-synovitis clinic, for example, the combination of rheumatoid factor and low serum sulphydryl levels at the initial presentation with symptoms of less than 3 months' duration correctly predicted persistent disabling arthritis at 5 years in over 90 per cent of cases (Woolf *et al*. 1991). However, the clinical setting for interpreting this test is all important and the chance finding of rheumatoid factor on routine screening of a disease unlikely to be rheumatoid arthritis is of little clinical significance. Rheumatoid factor is not specific for rheumatoid arthritis (Table 7) and can be found, for example, during the course of certain infections and in approximately 15 per cent of the population over the age of 65.

1.	Rheumatoid arthritis	75%
2.	Other rheumatic diseases	Systemic lupus erythematosus, systemic sclerosis, Sjögren's syndrome, mixed connective tissue disease
3.	Acute viral infections	Mononucleosis, hepatitis, influenza etc., after vaccination
4.	Parasitic infections	Trypanosomiasis, malaria, schistosomiasis etc.
5.	Chronic inflammatory diseases	Tuberculosis, leprosy, syphilis, subacute bacterial endocarditis etc.
6.	Neoplasms	After irradiation or chemotherapy
7.	Other hyperglobulinaemic states	Hyperglobulinaemic purpura, sarcoidosis, chronic liver disease, cryoglobulinaemia

Table 7 Diseases commonly associated with rheumatoid factor

The presence of rheumatoid factor in rheumatoid arthritis indicates a poorer prognosis (Feigenbaum *et al*. 1979; Heliövaara *et al*. 1995) and a high frequency of systemic and extra-articular manifestations. The presence of high titres of IgG rheumatoid factor has been associated with necrotizing vasculitis (Allen *et al*. 1981).

Other serological tests in rheumatoid arthritis

Antiperinuclear factor can be demonstrated in up to 80 per cent of patients with rheumatoid arthritis (Berthelot *et al*. 1995). It is also found in a small proportion of psoriatic arthritis, juvenile chronic arthritis, autoimmune rheumatic diseases, and lung cancer but rarely in other clinical situations or in the normal population. There is no obvious relationship with disease activity or particular clinical manifestations. Recent studies suggest that the antigen target is related to human epidermal filaggrin and is the same as that recognized by so-called antikeratin antibodies (Sebbag *et al*. 1995).

Antibodies detected by immunoblotting to a 33-kDa protein in Hela cell extract were initially reported to be a highly specific finding in rheumatoid arthritis (Hassfeld *et al*. 1989). The RA33 protein has subsequently been shown to be homologous to the A2 protein of the heterogeneous nuclear ribonucleoprotein (hnRNP) complex (Steiner *et al*. 1992). Anti-RA33 antibodies have been found in approximately one-third of rheumatoid arthritis patients and have no relationship to rheumatoid factor, being occasionally detected in 'seronegative' rheumatoid arthritis. These antibodies are not specific for rheumatoid arthritis and are identified in other conditions such as systemic lupus erythematosus where their presence is associated with arthropathy, especially in erosive arthritis (Isenberg *et al*. 1994).

Variations in the carbohydrate content of IgG have been associated with rheumatoid arthritis and a restricted group of other diseases (Rahman and Isenberg 1995). In particular, the number of oligosaccharide chains attached to the C domains which lack the terminal galactose moiety (G0) is invariably raised in patients with active rheumatoid disease (Rademacher *et al*. 1988). In a recent study of undiagnosed patients with early-onset synovitis, a combination of a raised G0 and a positive rheumatoid factor gave a positive prediction factor of 94 per cent, significantly greater than either value alone (Young *et al*. 1991). In a similar study of 127 Dutch patients over a 6-year period, it was shown that the raised percentage of G0 correlated significantly with the number of swollen joints, number of prescribed second-line drugs, presence of rheumatoid nodules, and the radiological erosion score. Over the follow-up period, those patients whose first G0 level had been high had greater and more rapidly increasing erosion scores, a larger number of swollen joints, and were given more antirheumatic drugs (Van Zeben *et al*. 1994).

4.6 Joint fluid

J. Lawrence Houk

Formation, composition, and function of joint fluid

Joint fluid acts as a lubricant for the lining of the joint cavity. It is particularly effective for decreasing the coefficient of resistance during low-impact joint loading and motion, while its adhesiveness enhances joint stability and tracking. Joint fluid also is a vehicle providing nutrients to and removing metabolic products from the articular cartilage (Simkin 1991).

The fluid is composed of molecules filtered from plasma plus a glycoprotein, hyaluronate, produced by synovial cells. The composition and concentrations of synovial components are determined primarily by their molecular weights. Small molecules such as glucose, amino acids, uric acid, bilirubin, and several enzymes are filtered freely through the endothelium and synovial tissues. Consequently the concentrations of small molecules normally reflect those seen in plasma. The influx of larger molecules such as fibrinogen requires increased vascular permeability and is impeded normally by filtration through the synovial tissue meshwork of hyaluronate proteins. Accordingly large molecules found in serum are not normally present in joint fluid. Molecules leave the joint fluid via lymphatics. This process is usually unaffected by joint disease. Inflammation can change the normal distribution of joint fluid molecules. The inflammatory response can increase vascular permeability, allowing larger molecules such as fibrinogen to enter. These molecules account for the clotting of synovial fluid samples in abnormal fluid. At the same time, inflammation decreases vascular perfusion, thus reducing the number of small molecules that are available for diffusion into the joint fluid.

Indications for joint fluid examination

Why should joint fluid be examined? Even when performed by an experienced physician, the procedure is time-consuming. A busy outpatient practice does not allow for many delays, and consequently, joint fluid examination is often omitted from the evaluation of the patient with arthritis.

None the less, the results of a carefully conducted joint fluid examination usually have important diagnostic value. In fact, it may be the only source of a conclusive diagnosis. For example, a diagnosis of gout or calcium pyrophosphate crystal deposition disease cannot be certain unless the appropriate intracellular crystals are observed. Information gained from analysing joint fluid often provides more important data than any combination of blood tests or radiological procedures. In one report, treatment plans were changed in 53 per cent of 180 patients after synovial fluid analysis (Eisenberg *et al*. 1984).

The coexistence of two or more arthropathies is common, and at times only joint fluid testing can distinguish the diseases. Rheumatoid arthritis and osteoarthritis frequently occur simultaneously. Although conventional radiography can demonstrate the osteoarthritis, joint fluid evaluation may be necessary to reveal concomitant rheumatoid inflammation and suggest the correct decisions regarding therapy. Similarly, the risk of septic arthritis is increased in joints affected by rheumatoid arthritis and other arthropathies. A culture of joint fluid is the most sensitive and specific test for the recognition of a septic arthritis. Any articular site that is markedly more inflamed than other areas must undergo arthrocentesis to rule out infection. Gout, particularly the polyarticular form, can involve the hands, and tophi can occur in the region of the distal interphalangeal joints commonly involved in osteoarthritis (see Chapter 5.16). Microscopic examination of joint fluid for tophaceous material may be necessary to reveal this association. Likewise, gout and calcium pyrophosphate crystal deposition disease can coexist (Dieppe *et al*. 1988).

When should joint fluid be obtained? Generally joint fluid should be aspirated whenever a diagnosis has not been established or if there is a new articular event. Objective findings in a previously uninvolved area or increased swelling, pain, or erythema in an already affected site are indications for oint fluid aspiration. There is no absolute contraindication to an arthrocentesis unless the needle insertion site is in a potentially infected area. Joint fluid analysis should be considered a mandatory procedure in any individual with an unexplained articular effusion (Cohen *et al*. 1975).

When the examination of joint fluid is believed to be of diagnostic or therapeutic value it should be obtained without delay. In inflammatory disorders such as rheumatoid arthritis, simple rest can decrease inflammation; the joint effusion may resolve, and consequently, an opportunity for a diagnosis is lost. Monosodium urate and hydroxyapatite crystals can decrease over a period of time, occasionally in as little as 6 h (Kerolus *et al*. 1989). Thus, a delay in synovial fluid analysis may eliminate the only source of a diagnosis. Septic joints have to be diagnosed immediately. Postponement of fluid aspiration can result in delay of treatment, possibly resulting in joint destruction. On the other hand, antibiotics started before fluid aspiration can prohibit growth of the infecting organism in culture; the diagnosis may never be established with certainty, and the patient may be subjected to inappropriate treatment.

The arthrocentesis itself can be therapeutic. Joint capsule distension can produce pain, loss of motion, or both, particularly in the knee. Removal of fluid can rapidly reduce discomfort and allow restoration of movement. However, excess fluid should not be aspirated repeatedly just because it is present. The additional medical expense and even the small risk of arthrocentesis must be justified by the possibility of correcting the diagnosis or improving the patient's condition.

Sites accessible to obtaining joint fluid

Potentially, any diarthroidal joint or bursal space can be entered with a needle. However some areas are easier than others and some sites usually are not aspirated in a medical clinic setting. The knee is generally the simplest joint to enter but aspiration of the elbow, ankle, shoulder, and wrist as well as the olecranon or prepatellar bursas also should be a clinic procedure. A hip joint arthrocentesis is usually performed with fluoroscopic guidance. Aspiration of fluid from smaller joints is possible but frequently difficult. Pharmacological substances can be instilled into interphalangeal joint spaces with small (e.g. 30-gauge) needles but these joints are usually too small to enter with needles that are large enough for aspiration of viscous fluid. This is a particular problem when podagra is suspected. The bunion joint can be extremely tender to the slightest pressure, let alone the insertion of a hypodermic needle, even with topical anaesthesia.

Arthrocentesis should not be performed unless the precise site of inflammation is clear. Bursas or joints can be seeded with pathogenic microorganisms if the needle passes through an infected area such as an adjacent cellulitis. If there is any doubt as to the site and source of inflammation, the injection should be done through an adjacent uninflamed area. If this is not possible, then other methods such as magnetic resonance imaging should be employed to determine whether the joint or bursa

is involved.

Techniques of arthrocentesis

Aspiration

Equipment required for arthrocentesis is minimal. A 5 ml sterile disposable syringe will usually hold an adequate amount of the local anaesthetic. A 3 ml syringe is suitable for steroid injections. A 10 or 20 ml syringe may be necessary for the collection of large joint effusions. Small gauge needles, preferably a 30-gauge, are required for injecting the skin with the anaesthetic and entering small joints including the interphalangeal, metacarpal, and tarsal joints. Larger needles are used for aspirating fluid from larger joints. A 1&DFSF;1 2' 21-gauge needle will usually suffice for aspiration from the knee, ankle, shoulder, and wrist. An 18-gauge needle may be necessary if the fluid is thick. A 3&DFSF;1 2' 21-gauge spinal needle can be used to enter the knee joints of obese patients. A haemostat clamp is helpful for supporting the needle during syringe changes and also for removing the needle in the unlikely event that it breaks off during the procedure. Disposable gloves are not only advisable, but in the United States they are mandated by the Occupational Safety and Health Act.

An arthrocentesis should not be omitted because of the absence of absolute sterile conditions. Although some authors state that total sterile technique with sterile gloves and drapes is compulsory, other authorities believe that clean procedures, with sterile syringes and needles, are adequate (Cohen *et al*. 1975; Hasselbacher 1985; Gattar and Schumacher 1991a).

Descriptions of the entry sites for specific joints have been detailed elsewhere (Krey 1992b) (see Chapter 6.6). The entry site can be marked by pressure from the tip of the haemostat, the end of the needle cover, or the point of a retracted pen. The area is first cleaned with alcohol; an antiseptic solution such as povadine (Betadine) is then applied, and alcohol is wiped on the entry site. The skin can be anaesthetized with chloroethane (ethyl chloride) or fluroimethane spray. Alternatively, after the patient has been asked about a history of allergic reactions to the anaesthetic agent, the area can be anaesthetized by intradermal injection through a 30-gauge needle creating a weal with an agent such as 1 per cent lidocaine. If the injection is subdermal, it may be difficult to identify the site when inserting the larger centesis needle. To enter the joint, Gattar and Schumacher recommend that a 'quick decisive thrust through the skin' produces 'the least discomfort' (Gattar and Schumacher 1991a). I prefer an alternative, though time-consuming, approach that allows more cautious entry without causing pain (Fig. 1). When the skin has been successfully anaesthetized with the 30-gauge needle, the subcutaneous area is then infused with more of the anaesthetic agent. At this stage it is essential to suspend the procedure until the anaesthetic agent has taken effect. There is no point in using an anaesthetic drug unless time is allowed for it to work. The next target is the joint capsule. Careful probing can usually reveal this area without piercing the periosteum or articular cartilage. Furthermore, if anaesthesia is adequate and the needle is advanced slowly, accidental striking of the periosteum or articular cartilage will not cause significant pain. Painful needle injections can and should be avoided. Not only is the pain an unnecessary experience for the individual, but frequently the patient will never allow this procedure to be performed again.

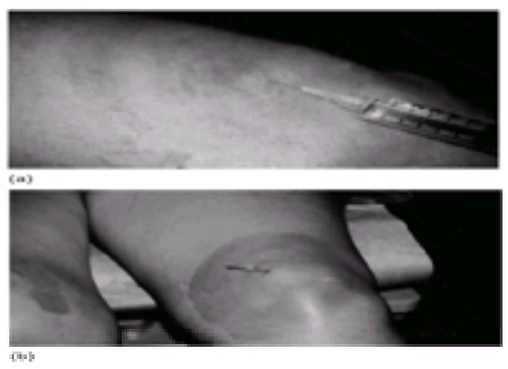

Fig. 1 (a) Anaesthetize skin with a 30-gauge needle. (b) Allow time for anaesthetic to take effect.

Aspiration of fluid from the joint cavity can be difficult if the fluid is loculated or very viscid. If fluid cannot be aspirated and infection is suspected, the joint can be irrigated with sterile saline and reaspirated. The needle may come out of the joint space when the distended joint capsule contracts during aspiration if it is not fully inserted. Leave a small amount of the anaesthetic in the joint (1 to 2 ml for large joints) as this may reduce the risk of infection because of the bacteriostatic properties of the solution.

Joint fluid collection and transportation

Synovial fluid for cell counts, differential, and Gram stain is put in a collection container with an anticoagulant, preferably with sodium heparin. Fluid for crystal examination is also stored this way. If a tube without anticoagulant is used, inflamed fluid may clot, making cell counts and crystal detection difficult. Lithium heparin or calcium oxalate anticoagulant tubes should not be used because they can form crystals which may cause confusion during microscopy. Aerobic and anaerobic cultures should be ordered routinely. Fungal and mycobacterium cultures should be requested only when there is clinical evidence of these diseases. Fluid for culture can be collected in the syringe, a Vacutainer tube, or blood culture bottles; however, if infection by *Neisseria gonorrhoeae* is a possibility, special care must be taken (Borenstein 1991). The joint fluid from suspected gonorrhoeal arthritis should be immediately plated onto chocolate agar and incubated in 5 to 10 per cent carbon dioxide. When an open laboratory is available, a technician should be summoned to put the fluid in culture as soon as it is aspirated. When the fluid must be transported to a laboratory, warm anaerobic transfer can be ensured by sending the fluid in the syringe.

Laboratories require that the syringe be covered with a sterile plastic cap to prevent accidental exposure to blood products. If there is only a small amount of fluid in a single collection container, make sure that the bacteriology laboratory does not centrifuge the specimen as, subsequently, an accurate cell count cannot be obtained.

Joint fluid tests

All specimens undergo a macroscopic examination for determination of fluid volume, clarity, colour, and viscosity. These evaluations are easy to do and provide essential diagnostic information. Clarity and colour should be observed in a clear glass container such as a Vacutainer tube. Plastic syringes are translucent and interfere with the accuracy of the determinations. Print can be read through transparent fluid; if the print appears as shades or blurs, the fluid is considered translucent. Sepsis can make the fluid opaque. Normal fluid is colourless or straw coloured. Viscosity is determined by the string test: joint fluid is made to drip from the syringe, and normal fluid will stretch out for 5 to 8 cm. Water-like drops indicate abnormally decreased viscosity.

All fluid should be examined for the presence of crystals and leucocytes. Gram stain and both aerobic and anaerobic cultures are indicated whenever infection is suspected. Infections can occasionally be associated with low white blood-cell counts. Thus, cultures should not be omitted because the fluid appears clear.

Although many other tests can be performed on joint fluid, few of them are of diagnostic value. Most authors agree regarding the relative value of joint fluid tests. Krey and Lazaro (1992) state that cultures, crystal examination, and leucocyte count with differential are the most useful tests. Shmerling *et al*. (1990) came to the same conclusion in a prospective study of joint fluid from 100 consecutive patients undergoing arthrocentesis. Lactate dehydrogenase levels were a sensitive marker of inflammation but had no greater diagnostic value than did leucocyte counts; protein measurements were likely to present 'misleading information'. The authors concluded that such tests should be omitted from routine diagnostic evaluation of synovial fluid. However, certain additional tests are helpful in specific situations. Glucose levels below 20 mg per 100 ml suggest infection but low levels can also occur in rheumatoid arthritis (Owen 1978). Accurate determination requires obtaining fluid after an 8-h fast and comparing it to serum glucose levels. The fluid should be placed in a fluoride tube to prevent further glucose metabolism. Rheumatoid factor can be present in the joint fluid and absent in the serum, but Baker (1991) states that this finding 'is not disease specific and does not require further evaluation'. Rodnan likewise noted that this finding is seen in other types of arthritis, including ankylosing spondylitis. However, Rodnan *et al*. (1963) further stated that 'demonstration of a positive agglutination reaction of synovial fluid may assist in the early diagnosis of rheumatoid arthritis when the serum has a negative reaction and the disease is confined to one or two joints'. Gas–liquid chromatography may detect volatile and non-volatile short-chain fatty acids from bacterial sources including gonococci. Thus, it may support the diagnosis of septic arthritis if antibiotics were started before cultures were obtained. Nucleic acid probes can detect DNA or RNA from microbes such as *Escherichia coli, Campylobacter jejuni*, or hepatitis B, but have not had extensive evaluation in joint fluid. Measurement of lipids,

urates, complement, circulating immune complexes, immunoglobulins, and antinuclear antibodies is of no value (Baker 1991).

One should decide the priorities of the tests to be done before aspirating the fluid. This forethought may prove to be crucial if only a small amount of joint fluid (less than 0.5 ml) is obtained. A delay in order to make these decisions or to find the correct tubes, culture transport vehicle, or syringe caps, can result in clotting or possible contamination of the fluid. If a microscope and trained personnel are available, small amounts of fluid should be analysed on site as follows: A drop of the fluid is placed on a clean slide, overlaid with a coverslip, and immediately examined for crystals and abnormal cells. The number of white blood cells is estimated. The coverslip and slide are than separated. A Gram stain can be performed on the slide smear and a Wright stain is done on the coverslip smear (Krey 1992a). The remaining fluid is then sent to the laboratory for culture.

If a microscope and other relevant supplies are not available, the fluid can be placed in a sterile vacuum container with anticoagulant and sent for white cell count with differential, culture, and crystal examination. Instructions accompanying the specimen should specify which test has the highest priority, should there be insufficient fluid for all three procedures. As mentioned previously, it must be ensured that the laboratory does not centrifuge any specimen destined for complete blood count and crystal analysis.

Reliability of test procedures

Unless joint fluid is examined promptly and reliably, the results can be worthless or even misleading. The macroscopic examination should be done immediately by the person performing the procedure. Ideally, the leucocyte count with a differential and examination for crystals should also be done on site. However, most outpatient medical facilities do not have the equipment or experienced staff needed for these tests. In this situation the synovial fluid must be sent to a hospital or commercial laboratory for further evaluation.

Unfortunately, studies indicate that many laboratories produce inaccurate results. Hasselbacher (1987) surveyed 39 hospitals in New Hampshire and Vermont regarding their experience and skill in joint fluid analysis. Their median frequency of joint fluid evaluation was only 1.5 times per month. The laboratories of 26 hospitals examined a reference synovial fluid, and there was a wide disparity in leucocyte counts and cell differentials. The results of crystal determinations were also frequently erroneous, because the crystals were not recognized or were identified inaccurately. Schumacher (1986) reported similar results from a study in which aliquots of 30 joint fluids were examined in four different laboratories. In 4 of the 30 specimens studied, the reported variations in the leucocyte count were large enough to change the fluid classification from an inflammatory to non-inflammatory type. The accuracy of the joint fluid analysis depends also on how soon testing is performed after the fluid has been aspirated. The leucocyte count starts to decline as soon as 1 h after aspiration; by 6 h, the drop is often large enough to result in misclassification. Refrigerating the fluid may slow the dissolution of monosodium urate crystals and reduce the formation of artefactual crystals (Kerolus *et al*. 1989).

Techniques for leucocyte and differential counting and for crystal identification

The risk that a hospital or commercial laboratory will produce inaccurate results, has led to a renewed interest in performing synovial fluid analysis on site. The following overview of fluid preparation methods includes references to more detailed descriptions.

Leucocytes are counted in the same way as peripheral white blood cells, except that normal saline, rather than acetic acid solution, is used for the diluent. Acetic acid at 2 mg per 100 ml will cause the fluid to clot. If red blood cells are present, they can be lysed by use of hypotonic saline (one part saline mixed with three parts distilled water) as the diluent. For the white cell count, aspirate the synovial fluid into a white blood-cell pipette to the 0.5 mark, dilute it with the saline to the 11 mark, and shake the pipette for 1 min by hand. Discard the first three drops from the pipette, then fill the clean haemocytometer. Count the leucocytes in all four large corner squares and multiply by 50 for the total cells per cubic millimetre (Krey 1992a). However, if the fluid appears clear on macroscopic examination, it can be placed directly without diluting onto the haemocytometer for counting.

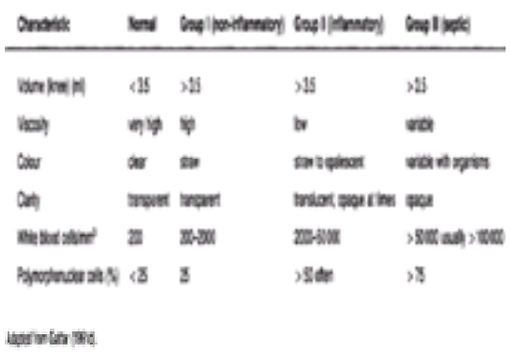
To prepare a specimen for a differential count, place a drop of sodium-heparinized joint fluid on a coverslip, overlay with a second coverslip and wait for a few seconds to allow the fluid to spread. Then separate the coverslips and allow them to dry. The smears are stained with Wright's stain for 3 min, and the stain is then drained off. Two drops of Giemsa stain are added, and the smear is flooded with distilled water which sits for 5 min. Following this, the stain is washed off with distilled water and passed for 1 s through a 95 per cent ethanol solution. The coverslip is washed again, dried, and mounted on a slide (Krey 1992).

A wet preparation can be made by placing one drop of fluid on a clean slide and applying a clean cover slip. If the amount of fluid in the syringe is not adequate, the needle can be flushed with either air or 95 per cent alcohol. The wet preparation is used to look for crystals and abnormal cells. A polarizing microscope with a red compensator is the best device for identifying crystals. Unfortunately, this apparatus is too expensive to be considered cost effective in most outpatient clinical settings. As an alternative, a standard microscope can usually be fitted with two polarizing filters, which will permit crystals on a wet smear to be visualized, and sometimes even identified.

Interpretation of examination results and differential diagnoses

Changes in joint fluid volume may indicate alterations in an inflammatory disorder. For example, a reduced amount of fluid on repeat aspiration of a septic joint may indicate an improvement. However, the aspirated fluid volumes can be misleading indicators, since complete evacuation of joint fluid is often difficult, particularly when it is very viscid or if loculation has occurred.

Decreased clarity of the synovia (i.e. turbidity) may indicate inflammation. Transparent fluid is characteristic of normal and group 1 non-inflammatory disease (Table 1). Translucent is characteristic of group II inflammatory (and occasionally, septic) fluids. Opaque fluid occurs in group III and is frequently septic.



Characteristic	Normal	Group I (non-inflammatory)	Group II (inflammatory)	Group III (septic)
Volume (knee) (ml)	<3.5	>3.5	>3.5	>3.5
Viscosity	very high	high	low	variable
Colour	clear	straw	straw to opalescent	variable with organisms
Clarity	transparent	transparent	translucent, opaque at times	opaque
White blood cells/mm³	200	200–2000	2000–50 000	>50 000, usually >100 000
Polymorphonuclear cells (%)	<25	25	>50 often	>75

Adapted from Gardner 1984 [5].

Table 1 Joint fluid characteristics

Although decreased clarity is usually due to increased leucocytes, other substances which can reduce clarity are crystals, lipids, fibrin, amyloid, and rice bodies (glistening white fragments produced by fibrin and collagen from degenerated synovial villi). Therefore, decreased clarity is suggestive of inflammation but is not absolutely diagnostic. Furthermore, normal clarity can occur during early inflammation that includes infection (Table 1). Normal joint fluid is colourless, or is straw coloured due to the presence of bilirubin. Inflammatory fluids are yellow. Septic fluids can be yellow, brown, or green. Cholesterol in joint fluid can cause a golden discoloration. A white or yellow pasty-looking fluid can result from urate or apatite crystals. Fluid speckled with dark particles indicates ochronosis (Hunter *et al*. 1974). Black or grey debris can be metal or plastic particles from total joint replacement. Lipids floating on top of the fluid may indicate an osteochondromal fracture (Lawrence and Seife 1971). The lipid layer should be investigated for the presence of bone marrow spicules, which is a further clue to existence of a fracture (Reginato *et al*. 1985). Increased viscosity occurs in hypothyroidism, acromegaly, and with mucinous cysts in osteoarthritis. Decreased viscosity is due usually to inflammation but oedema and bursal fluid also have low viscosities.

The mucin clot test is no longer considered to be a routine procedure, but it may be useful in distinguishing joint fluid from the anaesthetic or oedema fluid. The test is performed by putting a drop of joint fluid in acetic acid solution (2 mg/100 ml). Normal joint fluid clots, but when the hyaluronate molecules in the mucin have been

depolymerized by inflammation, the precipitate will be loose or will break up on agitation.

Joint fluid that clots when left in a syringe or non-anticoagulated tube indicates inflammation. Clotting occurs when fibrinogen and other clotting factors (prothrombin and factors V and VII) are present. These molecules are absent in normal fluid, occurring only in inflammation. The size of the clot is thought to be proportional to the extent of the inflammatory process (Cohen *et al*. 1975).

A microscopic examination may visualize abnormal cells. A finding of so-called Reiter's cells, i.e. macrophages that have phagocytosed a neutrophil, is not specific for Reiter's syndrome. Ragocytes are leucocytes, usually polymorphonuclear leucocytes, with large intracytoplasmic granules which can be visualized by light microscopy (Cherian and Schumacher 1983). These intracytoplasmic inclusions result from the phagocytosis of complement and immunoglobulins which, presumably, came from immune complexes. In 1965, Hollander and co-workers suggested that although cells with inclusion bodies are seen in several diseases, those containing complement and immunoglobulins are a feature of rheumatoid arthritis; accordingly, these authors referred to them as 'R.A. cells' (Hollander *et al*. 1965). Davis *et al*. (1988) noted that joints in patients with rheumatoid arthritis which contain a persistently elevated percentage of ragocytes are at greater risk for poor outcomes such as synovectomies and total joint replacement. Interestingly, ragocytosis might be seen in only a single joint, and, therefore, the results could not always be extrapolated to the entire disease process. Consequently the ragocyte status of a joint might influence treatment at least locally, or explain the lack of response of a single site when other joints seem well controlled with systemic therapy.

The joint-fluid leucocyte count allows a preliminary differential diagnosis. An increase of leucocytes, generally defined as a count exceeding 2000 cells/mm ^{3}, indicates inflammation. Normal joint fluid has fewer than 200 cells, and non-inflammatory fluids (group I) of arthritic joints have a leucocyte count between 200 and 2000/mm ^{3}. Conditions associated with inflammation (as defined by elevated white-cell counts) are listed in Table 2, but exceptions exist. The synovial white blood-cell count in systemic lupus erythematosus and other autoimmune rheumatic diseases can be in the non-inflammatory range. When rheumatoid arthritis is in remission or is controlled with anti-inflammatory medications, counts can be below 2000/mm ^{3} (Gattar and Schumacher 1991b). In one study, 27 per cent of 82 synovial fluid examinations in persons with gouty arthritis yielded results in a non-inflammatory range. Fluid from calcium pyrophosphate crystal deposition disease also can be non-inflammatory. The degree of leucocytosis seems to be proportional to the quantity of crystals (Cohen *et al*. 1975). Counts higher than 100 000 are usually seen in septic arthritis, but can also occur in rheumatoid arthritis, juvenile chronic arthritis, gout, calcium pyrophosphate disease, and Reiter's syndrome. A differential white-cell count can be very helpful in establishing a differential diagnosis. Krey and Bailen (1979) observed that when the leucocyte count was higher than 25 000 in a septic joint or in cases of gout, the average polymorphonuclear leucocyte count was at least 86 per cent. When the white cell count in these cases was higher than 50 000, the average polymorphonuclear leucocyte count exceeded 90 per cent. Although polymorphonuclear cells increased in individuals with rheumatoid arthritis who had more than 25 000 synovial white cells per cubic millimetre, the averages never exceeded 90 per cent, even when counts were greater than 50 000. Accordingly, polymorphonuclear counts higher than 90 per cent suggest gout or sepsis.

Group I — non-inflammatory	Group II — inflammatory
Osteoarthritis	Rheumatoid arthritis
Trauma	Crystal-induced synovitis
Internal derangement	Psoriatic arthritis
Osteochrondritis dissecans	Reactive arthritis
Osteochondromatosis	Whipple's disease
Charcot's arthropathy	Autoimmune rheumatic diseases
Subsiding inflammation	Polymyalgia rheumatica
Villonodular synovitis	Polychondritis
Hypertrophic osteoarthropathy	Sarcoidosis
Myxoedema	Behçet's syndrome
Acromegaly	Ankylosing spondylitis
Haemochromatosis	Juvenile rheumatoid arthritis
Gaucher's disease	Rheumatic fever
Ochronosis	Lyme disease
Paget's disease	Leukaemia
Sickle cell disease	
Milwaukee shoulder	

Adapted from Gardner (1981).

Table 2 Partial differential diagnosis of non-inflammatory and inflammatory arthropathies by joint fluid classification

Joint fluid eosinophilia was described in three individuals with Lyme disease by Kay *et al*. (1988). Other diseases associated with joint fluid eosinophilia are listed in Table 3.

- Rheumatic diseases:
  - Rheumatoid arthritis
  - Psoriatic arthritis
- Hypereosinophilic syndroma
- Infectious arthritides:
  - Tuberculosis arthritis
  - Lyme disease
- Allergic disease with arthritis:
  - Angio-oedema
  - Atopic history
  - Dermatographism
  - Urticaria
- Parasitic arthritides
- Haemorrhagic joint effusions:
  - Adenocarcinoma metastatic to synovium
  - Bilateral protrusio acetabuli following pelvic irradiation
- Posterthrography
- Postpneumarthrography
- Idiopathic

From Kay *et al*. (1988).

Table 3 Diseases associated with joint fluid eosinophilia

Blood in the joint fluid can be the result of a traumatic arthrocentesis or the conditions listed in Table 4. If the blood in the fluid is non-homogeneous or clumped it is more likely the result of trauma than of disease.

- Trauma with or without fracture
- Charcot's arthropathy
- Haemorrhagic diathesis:
  - Anticoagulant therapy
  - von Willebrand's disease
  - Haemophilia
  - Scurvy
  - Thrombocytopenia
- Haemangioma
- Tumour:
  - Pigmented villonodular synovitis
  - Synoviona
- Ruptured aneurysm
- Arteriovenous fistula
- Myeloproliferative disease with thrombocytosis
- Joint prosthesis

Table 4 Causes of haemorrhagic joint fluid

A variety of crystals may be identified by compensated polarized light microscopy. Monosodium urate crystals are usually needle shaped and visible under light microscopy, but sometimes they are small and difficult to visualize. Intracellular monosodium urate crystals confirm the diagnosis of gout. However, the presence of these crystals in an inflamed joint should not preclude obtaining cultures. Calcium pyrophosphate dihydrate crystals may be either rod-like or rhomboid. Their presence in phagocytic cells indicates calcium pyrophosphate deposition disease, of which there are several forms (McCarty 1975). When the laboratory reports the

presence of other crystals, the physician must determine whether or not these substances are of clinical significance. Although individual basic calcium phosphate (calcium hydroxyapatite) crystals can only be seen by electron microscopy, they form clumps that look like shiny coins under polarized light microscopy. They have been associated with periarticular problems including tendinitis and bursitis. Basic calcium phosphate crystals are also the pathological agent in 'Milwaukee shoulder' disease (Halverson *et al*. 1990). Other crystals associated with arthropathies include brushite (calcium hydrogen phosphate dihydrate), octacalcium phosphate, and calcium oxalate (Gattar and Schumacher 1991c).

The results of a Gram stain cannot be used to exclude the presence of a joint infection. Gram stains detect 75 per cent of staphylococcal infections, 50 per cent of most Gram-negative infections, and only 25 per cent of gonococcal infections (Goldenberg and Reed 1985).

Joint fluid findings in specific diseases

Osteoarthritis

Osteoarthritis is associated with a group I non-inflammatory fluid. It is usually clear and straw coloured with normal viscosity. The cell count is less than 2000 and the type is predominantly mononuclear. However, slight decreases in viscosity and a mild leucocytosis with cell counts up to 8000 can occur, with an even number of neutrophils to lymphocytes. The fluid volume varies from 1 to 50 ml.

Fragments of bone and cartilage may exist in the joint fluid specimen. Calcium pyrophosphate, basic calcium phosphate (calcium hydroxyapatite), and cholesterol crystals also may be present. Gibilisco *et al*. (1985) described knee fluid examined from 100 consecutive persons with osteoarthritis. In 60 per cent calcium pyrophosphate and/or calcium hydroxyapatite crystals were found. The individuals with crystals had more severe osteoarthritis on radiography and also tended to be older than persons without crystals. There was also an increased frequency of previous corticosteroid injections in the knees of the persons with crystals present. Patients with a higher percentage of crystals within cells tended to have more severe osteoarthritis. However, there was no difference in the leucocyte count between the fluids with and without crystals, but fluids with cell counts in excess of 2000 were excluded from the study. In some cases the radiological changes may precede the identification of synovial fluid crystals. In this situation, the crystals may be the result of the degenerative process rather than the cause. Possibly, in disease patterns not typical for primary osteoarthritis, calcium hydroxyapatite or calcium pyrophosphate crystals might be part of the pathological process (see below— calcium pyrophosphate crystal deposition disease).

Rheumatoid arthritis

The joint fluid in rheumatoid arthritis is usually inflammatory, and white cell counts can exceed 100 000/mm ^{3}. However, fluid occasionally may be in the non-inflammatory range, particularly if the disease has been suppressed with medications (Thomas and Carroll 1993). Neutrophils are usually predominant, but patients treated with non-steroidal anti-inflammatory drugs can demonstrate a preponderance of lymphocytes (Bahremand and Schumacher 1991). Fluid examined within the first 6 weeks of disease onset may also show more lymphocytes than polymorphonuclear cells, particularly when the synovial fluid white cell count is below 10 000 (Gattar and Richmond 1975). Extremely high white cell counts and a marked increase in polymorphonuclear cells, particularly when the knee is involved, suggest bacterial infection. Kortekangas *et al*. (1992) noted the median range of leucocytosis in infected knees from eight individuals with rheumatoid arthritis to be 118 600/mm^{3}, with a median polymorphonuclear leucocyte count of 93 per cent. As mentioned previously, a positive rheumatoid factor test of synovial fluid may help the early diagnosis of rheumatoid arthritis when the serum has a negative reaction and the disease affects only one or two joints (Rodnan *et al*. 1963). Glucose levels can be low, but this finding also occurs in septic arthritis.

Rheumatoid arthritis and crystal arthropathies rarely can coexist. Talbot *et al*. (1978) reported on 87 patients who were suspected of having both gout and rheumatoid arthritis.

Juvenile chronic arthritis

Synovial fluid is usually in the group II range with an average number of 11 400, but counts greater than 100 000 can occur. Also, there may not be a correlation between the fluid leucocyte count and the apparent extent of joint inflammation as group I results have been reported in inflamed joints. The main cell types are neutrophils but mononuclear cells can predominate. Glucose levels can be decreased (Cassidy and Petty 1995).

Punzi *et al*. (1992) suggested that higher polymorphonuclear counts in the synovial fluid may predict a polyarticular course (in contrast to a pauciarticular form) in persons with oligoarticular juvenile chronic arthritis.

Reiter's syndrome

Reiter's syndrome results in group II inflammatory fluid, but with white cell counts usually below 50 000 (Nordstrom *et al*. 1985). In 1967 Pekin and coworkers described an unusual macrophage in individuals with Reiter's syndrome, characterized by one or more intact, intracellular neutrophils (Pekin *et al*. 1967). This Pekin–Zvaifler, or Reiter's, cell was found subsequently in other arthropathies and is no longer considered diagnostic for this disorder.

Bacterial infection

Bacterial joint infections induce a marked inflammatory response in the joint fluid characterized by leucocyte counts higher than 50 000 cells/mm ^{3}, group III fluid; counts as high as 284 000 have been recorded. Lower counts can occur, however. Krey and Bailen (1979) examined 50 joint fluid specimens from individuals with culture-proven infections. Fifteen fluids had leucocyte counts below 50 000 cells/mm ^{3}. These individuals usually had mild, uncomplicated infections or serious associated disorders; some were on antibiotics. Regardless of the white cell count, the percentage of polymorphonuclear leucocytes is almost always over 90 per cent. As previously mentioned, negative Gram stains do not exclude a bacterial infection.

Viral arthropathies

The joint fluid white-cell counts in viral arthropathies can vary greatly from group I to group III ranges. The range in hepatitis B infection can vary from 145 to 90 000 cells/mm^{3} and in rubella from 1900 to 60 000/mm^{3} (Ytterberg 1993). Mononuclear cells sometimes predominate in the joint fluid, particularly in rubella and in parvovirus; this finding is rare in bacterial infections. Accordingly a viral infection should be considered whenever there is monocytosis in an inflammatory fluid.

Gout

The joint fluid in gout attacks is inflammatory. Leucocyte counts can exceed 50 000 with a predominance of polymorphonuclear cells. Viscosity is decreased. Crystals are needle or rod shaped in appearance but can be blunt. They are negatively birefringent, appearing yellow when aligned parallel to the axis of slow vibration of the red compensator on a polarizing microscope.

Crystals are present within polymorphonuclear leucocytes during acute attacks and visualization is required usually to confirm the diagnosis. However, the sensitivity of crystal analysis during an acute gout attack is 85 per cent (Wallace *et al*. 1977). Therefore, the failure to visualize crystals can not exclude the diagnosis of acute gout.

Monosodium urate crystals can be present extracellularly between episodes. Pascual (1991) analysed 74 joint fluid specimens from asymptomatic knees of 55 persons with gout. Monosodium urate crystals were still present in 36 of 37 persons who had previous attacks of gout in the sampled knee. However, only 8 fluid samples from 37 knees that had never been inflamed still showed crystals. Also, although the leucocytes counts were in a non-inflammatory range, they tended to be slightly higher in knees which had been the site of prior gout attacks.

In contrast, Rouault *et al*. (1982) did not detect a significant difference in the frequency of crystals between involved and non-involved joints in individuals with gout. They aspirated fluid from an asymptomatic first metatarsal phalangeal joint of 23 persons with gout. Crystals were present in 83 per cent of persons who had experienced previous podagra attacks in that joint compared with 67 per cent who had not.

Monosodium urate crystals can also be present in joint fluid in individuals with hyperuricaemia who have not experienced gout attacks, but this is uncommon (Rouault *et al*. 1982).

Gout attacks can occur in Heberden's and Bouchard's nodes (nodal osteoarthritis); a condition that is missed frequently (Simkin *et al*. 1983). Patients with coexisting disease are usually older than persons with gout. Many individuals are on diuretics. Lally *et al*. (1989) reported that 25 of 149 patients with gout developed episodes in distal interphalangeal or proximal interphalangeal joints affected with osteoarthritis. Thirteen of these individuals were women and the average age of onset was 71 years. In 11 persons involvement of these phalanageal joints was the intial or only manifestation of gouty arthritis. Seventy-two per cent were taking diuretics and 60 per cent had renal insufficiency. Most of the patients had radiographic changes indicative of gout in addition to the osteoarthritic changes, including soft tissue densities (tophi), large intra-articular erosions, non-marginal cortical erosions, and periarticular osteolysis. Crystal arthritis can coexist with septic arthritis. Baer *et al*. (1986) described 4 cases and studied 22 other patients from a literature review. Ten patients had coexisting gout, 13 had calcium pyrophosphate crystal inflammation, and in 3 persons both crystal diseases were present in the septic joint. The knee was the most commonly affected site. The authors stated that the combination of both diseases was often not recognized until late in the disease. They conclude that 'the detection of infection in a joint should not deter the physician from looking for a coexisting crystalline arthritis'.

Calcium pyrophosphate crystal deposition disease

McCarty *et al*. (1976) recognized six types of calcium pyrophosphate arthropathies. In a review on crystal deposition disease in the elderly, Doherty and Dieppe (1986) reduced this to two clinical forms—acute synovitis and chronic pyrophosphate arthropathy. The acute form resembles gout and was labelled the pseudogout syndrome by McCarty *et al*. (1962). The joint most often involved is the knee but attacks also involve the wrist, shoulder, and ankles. Episodes can include more than one joint but are usually not polyarticular. The synovial fluid is inflammatory (group II) with leucocyte counts in the range of 20 000 and the neutrophil count may exceed 90 per cent. The fluid may be bloodstained. Intracellular calcium pyrophosphate crystals confirm the diagnosis.

Chronic calcium pyrophosphate arthropathy occurs most often in elderly women and tends to involve primarily the knees but the wrists, shoulders, elbows, or ankles can also be involved. Individuals complain of pain and stiffness. Acute episodes superimposed on the chronic discomfort may be experienced. Physical examination may reveal bony joint enlargement with decreased range of motion. Patellofemoral crepitation may be present. Severe joint destruction can occur which may suggest a Charcot joint. Inflammatory findings with synovitis could resemble rheumatoid arthritis. The presence of inflammatory features, particularly synovitis in the knees, helps to distinguish this condition from osteoarthritis. Other features which differ between the two disorders include the sites of involvement. Osteoarthritis usually does not involve the wrists, elbows, shoulders, and ankles. Blood-stained fluid containing some neutrophils occurs more often in chronic calcium pyrophosphate arthritis. In addition, radiographic findings can be different in these two disorders (Doherty and Dieppe 1986). The presence of calcium pyrophosphate crystals supports the diagnosis. However, as mentioned above (osteoarthritis), these crystals as well as calcium hydroxyapatite can be seen in the fluid of joints afflicted by otherwise typical osteoarthitis. In this setting the crystals may be the result rather than the cause of the arthropathy.

Calcium pyrophosphate crystals may be linear or rhomboid. They have blunt ends in contrast to monosodium urate crystals that have sharp needle-like ends. Calcium pyrophosphate crystals are often more difficult to see than monosodium urate and can be confused with cholesterol, xanthine, or steroid crystals. Calcium oxalate arthropathy occurring in persons on haemodialysis can be clinically similar to calcium pyrophospate deposition diseases and the crystals may be confused on compensated polarized light microscopy (Reginato *et al*. 1986).

Although the presence of calcium pyrophosphate crystals can be suggested by ordinary light microscopy, a polarizing lens with a first order red compensator are usually necessary for conformation. Calcium pyrophosphate crystals are blue (weakly positively birefringent) when parallel to the axis of the compensator.

Whereas monosodium urate crystals can dissolve, particularly when left at room temperature, calcium pyrophosphate crystals remain stable in synovial fluid and can still be easily visualized up to 4 weeks after aspiration (McKnight and Agudelo 1991).

4.7 Genetic marker analysis

Rafal Ploski and Øystein Førre

Introduction

Many rheumatic diseases have a genetic component. In some of them the genetic component is very strong and is accountable directly for all the manifestations. In such cases there is usually a mutation that alters the function of one important gene, and these diseases are known as 'single gene diseases'. The pattern of inheritance of single gene diseases follows mendelian laws and the gene may be dominant or recessive. Osteogenesis imperfecta, Marfan syndrome, Ehlers–Danlos syndrome, and some forms of hereditary osteoarthritis are examples of single gene diseases that may be encountered by a rheumatologist.

The most prevalent rheumatic diseases, like rheumatoid arthritis, spondylarthropathies, systemic lupus erythematosus, and juvenile chronic arthritis, do not follow mendelian laws, although genetic factors play a role in all of them. The pattern of inheritance of these diseases is best explained by postulating that a number of different genes with relatively weak effects play a role in the pathogenesis in combination with environmental factors. These disorders will be referred to in this chapter as 'diseases with a complex inheritance'.

A polymorphic genetic marker is a trait which reflects variations in the DNA sequence between individuals. Phenotypic features and (glyco)protein, carbohydrate, or lipid molecules can all be used as genetic markers if they are determined by an allele of a single polymorphic gene. Many polymorphic genetic markers can be found by direct analysis of the DNA sequence. This is because all phenotypic variation is reflected at the level of coding or regulatory DNA sequences, and the analysis of DNA allows an exploitation of the polymorphism in the abundant non-coding regions of the genome.

The analysis of polymorphic genetic markers is essential for delineating the genetic component of any disease. For example, the recently developed approach of reverse genetics, which enables the responsible gene to be identified even when its function is not known, depends on an extensive analysis of a large number of polymorphic genetic markers. Once the genetic basis of a disease is known, genetic marker analysis can be useful clinically for the purposes of diagnosis and/or prediction of complications. Although genetic marker analysis is most rewarding in studies of single gene disorders, the example of HLA-B27 typing used in the diagnosis of ankylosing spondylitis illustrates that it may also be helpful in the investigation of diseases with a complex inheritance.

General approaches to identification of medically relevant genetic markers

A number of approaches exist aimed at finding genetic marker(s) located in the vicinity of the disease locus. Such marker(s) are needed usually for the eventual precise identification of the gene causing the disease. Further, in certain situations, they can be used in diagnosis even if the disease-gene is not known.

Genetic linkage, the classical approach

Genetic linkage is the associated inheritance of two or more alleles (of different loci) caused by their location close on the same chromosome. When any two loci are on different chromosomes their alleles segregate independently into the gametes and thus are transmitted independently to the progeny (Fig. 1(a)). However, if the loci are encoded on one chromosome their alleles are transmitted together unless crossing over occurs between them (Fig. 1(b)). The probability of crossing over between any two points on the chromosome generally increases in proportion to the distance between them. Thus, if loci are relatively close on a chromosome, crossing over between them will be rare. As a result, in related members of a family, the alleles of the considered loci will often occur together and linkage will be found.

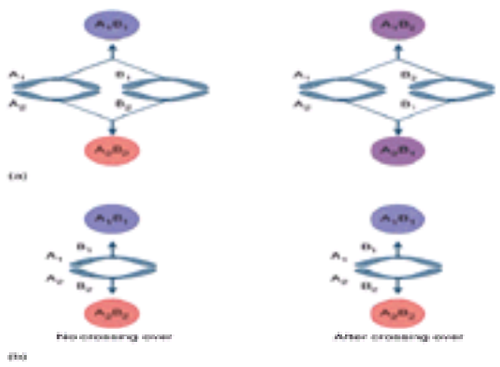

Fig. 1 Genetic linkage. The example used here is that of an individual who is doubly heterozygous for alleles of two loci A and B. (a) If A and B are on different chromosomes the A1, A2 and B1, B2 alleles segregate independently in the gametes and all their combination are equally frequent among the progeny. (b) If A and B are on the same chromosome the alleles are transmitted in parental combinations unless crossing over occurs. Linkage will be found between the A and B loci if they are so close that crossing over between them occurs at a frequency of less than 50 per cent.

The strength of the linkage is measured by the recombination fraction which corresponds to the percentage of gametes carrying combinations of alleles which were not present on the parental chromosomes. The recombination fraction is often expressed in centiMorgans. One centiMorgan, or 1 cM, corresponds to a recombination fraction of 1 per cent. In general, the stronger the linkage, the smaller the recombination fraction and the closer the locations of the two markers on the chromosome. Very roughly, a recombination fraction of 1 per cent can be expected if two loci are 1 Mb (1 million base pairs) apart.

A classical linkage study performed in medical genetics is based on an analysis of the cosegregation of a given marker with the disease phenotype in a family or families with many affected members. First, all the family members, both healthy and affected, are typed for a set of markers that are, as far as possible, evenly

distributed throughout the genome. Fewer markers can be typed for if the approximate location of the disease locus is known. The next step is to assess whether any of the markers cosegregate with the disease to a significant extent in the families concerned. A significant cosegregation indicates that the marker is located in the neighbourhood of the disease locus.

The statistical significance of any cosegregation observed is estimated by calculating the lod (logarithm of odds) score. The lod score is the logarithm of the ratio between the probability that the cosegregation is due to linkage and the probability that it has occurred by chance. A lod score of greater than 3 (corresponding to a ratio of probabilities of greater than 1000:1 in favour of linkage) is taken as evidence of linkage, while a lod score of less than –2 is usually sufficient to reject a hypothesis of linkage. A lod score of less than –2 means that chance alone is more than 100 times more likely to explain the data than a linkage model.

It is usual to calculate lod scores by assuming different recombination fractions between the marker and disease allele. The value which gives the highest score is accepted as being the most likely one, and can be used as a rough estimate of the distance between the marker and the disease locus.

Advanced methods of linkage analysis allow a large number of markers to be ordered in relation to the disease locus (multipoint analysis). It is also possible to study models that take into account incomplete penetrance of the predisposing gene and to test for genetic heterogeneity or for the presence of interactions between genes.

The power of the classical linkage approach lies in its sensitivity. Using a single informative marker, a relatively large region of chromosome (100 cM in theory, approximately 50 cM in practice) can be screened for the presence of a disease locus, provided a sufficient number of families are available.

The method's limitation lies in the fact that the results, including acceptance of the linkage together with the estimated recombination fraction, or rejection of the linkage hypothesis, are valid only if the exact pattern of inheritance of the disease is known. Thus, linkage analysis is a powerful tool in studies of classical mendelian traits, but is difficult to apply to diseases with a complex inheritance. Another disadvantage of this method as regards studies of diseases with a complex inheritance is that it requires relatively large pedigrees with many affected members.

Allele-sharing methods

Allele-sharing methods are a group of linkage-related methods which circumvent the limitations of the classical linkage approach because they do not require any presumptions about the way the disease is inherited and can be efficiently applied to very simple pedigrees. These methods are based on the idea that if a polymorphism predisposes for a disease, the chromosomal region where it is located will be shared by affected members of the family more often than expected.

The most commonly used method relies on the analysis of pairs of affected siblings. The first step is to identify an adequate number of families with at least two affected sibs (usually more than 50 such families are necessary). The sibs and the parents are then typed for a set of polymorphic markers and the number of alleles at each marker locus shared by each pair is determined. The sharing is defined as identity by descent (**IBD**), i.e. identity due to the inheritance of the same parental chromosome fragment and not just the presence of the same allele in two relatives (identity by state). Sharing in the form of IBD of no, one, or two alleles between two sibs should occur in 25, 50, and 25 per cent of cases, respectively. Whenever an increased frequency of pairs sharing one or two alleles is found, this indicates that the marker is linked to the gene predisposing for disease (Fig. 2).

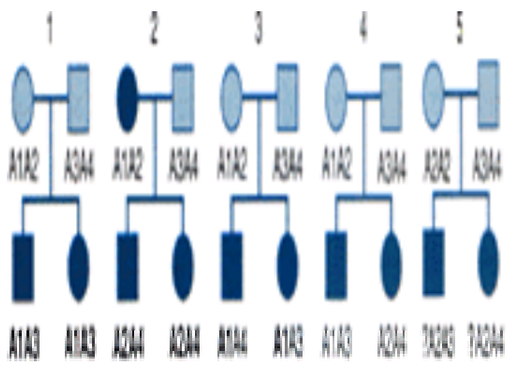

Fig. 2 Strategy of search for disease susceptibility genes based on affected sib pairs. In the example five pairs of affected sibs and their parents were typed for a marker A with four alleles (A1–A4). The alleles shared between the sibs due to identity by descent (IBD) are bold-faced. Two pairs (1 and 2) share two alleles, one pair (3) shares one, and one pair (4) shares no alleles as defined by IBD. One pair (5) is not informative because it cannot be resolved whether the sibs share one or no alleles as defined by IBD. The sharing in the form of IBD of no, one, or two alleles between two sibs should occur in 25, 50, and 25 per cent of cases, respectively. Whenever a significantly increased frequency of affected sib pairs sharing one or two alleles is found, this indicates that the marker is linked to the gene predisposing for disease. The squares and circles represent males and females, respectively. The black symbols denote affected individuals. Note that it is not important whether the parents are healthy or affected.

Allele-sharing methods have become increasingly popular in studies of diseases with a complex pattern of inheritance. Although in general these methods are less sensitive than classical linkage analysis performed in an optimal setting, this is more than compensated for by the fact that they are not dependent on information about the exact inheritance pattern of the disease or on a large and complex pedigree.

Association studies

This approach is known in epidemiology as a case–control study, and is based on determining the frequency of a polymorphic genetic marker in a group of unrelated patients and a group of healthy controls. When the marker occurs significantly more frequently among the patients than among the controls, it is said to be associated with the disease.

The statistical significance of an association is usually evaluated by the c^2 test or Fisher's exact test, while the strength of an association is often expressed in terms of an odds ratio (OR), sometimes also called Woolf's relative risk (Woolf 1956). Provided the disease is relatively rare, the odds ratio gives an approximate indication of how much more frequently the disease occurs among individuals carrying a given marker than in the population as a whole.

Frequent problems in association studies are unsuspected ethnic differences between patients and controls. Such differences can easily lead to false results and spurious associations because there is often considerable genetic variation between ethnic groups. As a solution to the problem, the patients' parents have been proposed as controls, since they are obviously well matched as regards ethnic background. A number of methods are available, all of which, in one way or another, take advantage of the pool of parental alleles that have not been transmitted to the patients (Falk and Rubinstein 1987; Julier *et al*. 1991).

An important factor to consider in designing and interpreting an association study is linkage disequilibrium (not to be confused with linkage). The statement that the alleles A1 and B1 (from different loci) are in linkage disequilibrium means that A1 and B1 are found together among a group of unrelated individuals more often than would be expected from their frequencies in the population. Linkage disequilibrium is especially strong in recently founded populations in which the haplotypes (i.e. sets of alleles encoded closely together on one chromosome) carried by the few founding individuals have not had time to 'mix' in the process of recombination. Similarly, linkage disequilibrium between A1 and B1 will also be found if the mutation which gave rise to the allele B1 has occurred relatively recently in an individual who carried the allele A1 on the same chromosome.

The occurrence of linkage disequilibrium has both advantages and disadvantages. The main disadvantage is that linkage disequilibrium complicates the interpretation of association studies. In general an association alone can never be accepted as a proof of significance of the given polymorphism for the disease pathogenesis because it may always be secondary to linkage disequilibrium with another gene in the region.

The advantage of linkage disequilibrium is that it provides an opportunity to detect an association even if the polymorphism being studied is not directly involved in the pathogenesis of the disease but is located somewhere in the vicinity of the disease locus. In favourable circumstances, and when a large number of markers are

studied, the presence of linkage disequilibrium can form the basis of an efficient strategy for precisely localizing the disease gene, known as linkage disequilibrium mapping (Hastbacka *et al*. 1992).

Linkage disequilibrium can be useful in genetic mapping provided it is not absolute, i.e. provided that certain alleles do not always occur together. The presence of a sufficient number of recombinant haplotypes is particularly important in the analysis of diseases with a complex pattern of inheritance in which the presence of single recombinants either among patients or controls is not very informative due to the low penetrance of the predisposing genes.

A very strong, practically absolute linkage disequilibrium occurs in the HLA complex between certain alleles encoding HLA-DR and -DQ molecules. As a result in many diseases which have long been known to be associated with certain alleles of these loci (for example juvenile chronic arthritis) it is still not clear which of the alleles is the one with primary association.

Linkage versus association

Linkage (found by the classical approach or by allele-sharing methods) and association both indicate that the gene predisposing for the disease is located in the neighbourhood of the studied marker. Linkage methods are more sensitive than those based on association and it often happens that a linkage but not an association is found (although the reverse is also possible) (Lander and Schork 1994). In general, a marker showing association with disease is likely to be located closer to the disease locus than a marker showing only linkage.

Markers showing association are potentially useful as a diagnostic test in sporadic individuals (for example B27 in diagnosis of ankylosing spondylitis). In contrast, markers showing linkage can be used to predict disease only if the proband comes from a family with many affected members (for example RFLP markers used in the prenatal diagnosis of osteogenesis imperfecta).

Detailed discussion of linkage and association methods can be found elsewhere (White and Lalouel 1987 ; Lander and Schork 1994).

Techniques used in genetic typing

Basic techniques of DNA analysis

Denaturation and hybridization

DNA is composed of four nucleotides which contain four different bases (guanine, **G**; cytosine, **C**; adenine, **A**; and thymine, **T**). In its native conformation a DNA molecule is a duplex consisting of two complementary strands kept together by specific non-covalent bonds formed between G and C as well as between A and T.

Denaturation or melting of DNA is the separation of the two strands of DNA molecule. Denaturation can be achieved by subjecting the DNA to high temperatures (95 to 100°C), alkaline pH, or certain chemicals such as urea or formamide. Generally, DNA rich in GC pairs melts at a higher temperature (or higher concentration of a denaturant) than DNA with a low GC content because the G:C bond is stronger than the A:T bond.

When the denaturing agent is removed, the complementary strands reform into duplexes and this process is called renaturation or hybridization. Under proper conditions, hybridization is very specific—a single strand of DNA will find its complementary molecule even in a highly complex mixture of other DNA fragments. Many molecular typing techniques rely in some way on hybridization of a specific single-stranded DNA fragment (called a probe) to its complementary sequence in the analysed sample.

Often hybridization assays are facilitated by blotting, i.e. immobilization of a sample of DNA on a solid foundation. Nylon or nitrocellulose membranes with high-affinity binding to DNA are most commonly used for this. The simplest method of blotting is the dot blot procedure, which consists of placing a droplet of DNA solution on to the surface of a membrane and leaving it to dry.

Gel electrophoresis

In its most commonly used form, gel electrophoresis enables nucleic acids to be separated according to their length. After going through the electrophoresis the molecules are grouped according to size in bands in the gel. A band can be visualized by staining with ethidium bromide (the easiest way) or by silver staining.

The gels are made from agarose or polyacrylamide. Agarose gels are simpler to prepare, but offer lower resolution than polyacrylamide gels, which can separate molecules that only differ in length by one nucleotide. Polyacrylamide gels, particularly those used for DNA sequencing, usually have a denaturing agent (urea) added, which prevents the formation of secondary structures and ensures that the DNA fragments migrate strictly according to their lengths.

Labelling

Labelling is the modification of macromolecules in a way that allows them to be easily detected. Many methods used in molecular genetics involve the labelling of nucleic acids. For example most hybridization assays are possible because the probe is labelled and can be detected with great sensitivity.

Labelling is achieved by attaching certain compounds to the end of the nucleic acid or by introducing modified nucleotides into the DNA molecule. These techniques are called end labelling and internal labelling respectively.

The classical labelling techniques rely on the use of radioactive isotopes of phosphorus or sulphur, followed by detection of the signal by autoradiography (i.e. exposure of a nylon membrane or the gel containing the labelled molecules on the photosensitive film).

Non-radioactive methods, particularly indirect immunoenzymatic methods, are also widely used (Guesdon 1992). These methods consist of labelling the nucleic acid with a small compound which does not affect the structure of the molecule and is relatively stable. Digoxigenin, biotin, acetylaminofluorene, and dinitrophenol are the most commonly used. The next step is to add an antibody specific for the label coupled with an enzyme like alkaline phosphatase or horseradish peroxidase. Finally, the labelled molecules are detected by adding a substrate from which the enzyme generates coloured or fluorescent products, or light (chemiluminescence).

Recently a group of direct fluorescent labels (usually referred to by their abbreviations: JOE, FAM, TAMRA, RO) have been developed. A useful property of these compounds is that they fluoresce at different wavelengths and can thus be differentiated when several of them are present.

Polymerase chain reaction (PCR)

PCR is an important method that enables millions of copies of a specific nucleotide sequence to be synthesized rapidly from a sample containing a minute amount of the relevant DNA (Mullis and Faloona 1987; Erlich *et al*. 1991). Before the invention of PCR, laborious methods of molecular cloning based on replication of DNA after it had been introduced into microorganisms had to be used. The principle of PCR is illustrated in Fig. 3.

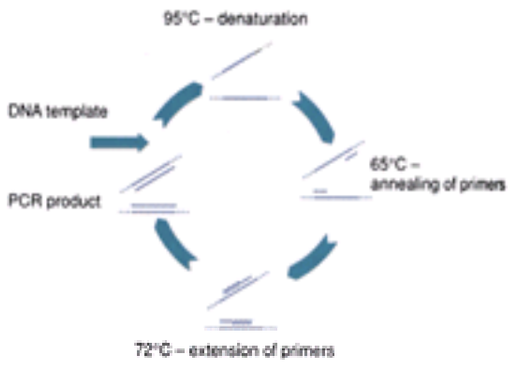

Fig. 3 The principle of the polymerase chain reaction (PCR). The PCR mixture contains sample DNA, two synthetic oligonucleotides or primers which anneal at the flanking regions of the sequence of interest, DNA polymerase (usually the thermostable Taq polymerase) and deoxyribonucleotides (i.e. substrates for the synthesis of DNA). The temperature of the reaction mixture is changed cyclically to permit denaturation of the target DNA, and annealing and extension of the primers. The PCR product synthesized in each cycle is used as a template in succeeding cycles and, therefore, the reaction is exponential. The temperatures shown are often modified to optimize the reaction.

PCR can also be used to modify the terminal regions of a DNA molecule. This is achieved by introducing the desired changes into the primers that are incorporated in the synthesized DNA. Although such primers are not fully matched with the target, they usually function well, especially if the mismatches are few and located far from the 3' end, where the polymerization begins. Examples of this type of modification are the introduction of a restriction site or the addition of a GC-rich sequence.

Despite its power, PCR has a number of limitations. (1) The synthesis is controlled by two oligonucleotide primers and, therefore, the sequences of the flanking regions of the amplified target need to be known. (2) PCR is very efficient when applied to sequences shorter than 2 kb, but longer sequences are usually difficult or impossible to amplify. (3) Owing to the relatively low fidelity of Taq DNA polymerase (the enzyme commonly used for PCR), artefactual mutations can be found in PCR products. A given mutation is present only in a small fraction of the synthesized molecules and, therefore, it generally does not pose a problem when the whole PCR product is analysed. However, when DNA produced by PCR is cloned (which allows single DNA molecules to be analysed) a large number of clones need to be analysed before any new sequence variant can be accepted as genuine. (4) The high sensitivity of PCR makes it prone to give false positive results when the sample is contaminated, especially when the contamination is caused by the products of previous reactions which are enriched enormously in the target sequence.

DNA for genetic analysis by PCR is isolated usually from peripheral blood. In our experience and that of Holodniy *et al*. (1991), it is important not to use heparin as an anticoagulant. Heparin interferes with the PCR, so that the samples have to be treated with heparinase before they can be used.

Principles of the main techniques of genetic marker analysis

Restriction fragment length polymorphism (RFLP)

This is used for the detection of variation in the distribution of recognition sites for restriction endonucleases in total genomic DNA with the aid of blotting and hybridization techniques.

Restriction endonucleases are enzymes which cleave DNA at certain sites when they recognize a specific sequence, usually four to eight nucleotides long. Owing to the large number of restriction enzymes, a single nucleotide substitution can often create or destroy the recognition site of one of them. The length of a DNA sequence between two restriction sites may also vary between individuals. In either case when genomic DNA from different individuals is digested by a given restriction enzyme, this gives rise to fragments of different lengths (Kan and Dozy 1978).

This restriction fragment length polymorphism, or RFLP, can then be analysed by the method described by Southern (1975). The method involves gel electrophoresis of digestion products followed by denaturation, blotting, and hybridization with a labelled probe complementary to the sequence in the neighbourhood of the polymorphic site (Fig. 4). Usually relatively long fragments of DNA such as cDNA (i.e. DNA obtained by reverse transcription of messenger RNA) or fragments of genomic DNA are used as probes, but synthetic oligonucleotides are also an alternative (Conner *et al*. 1983).

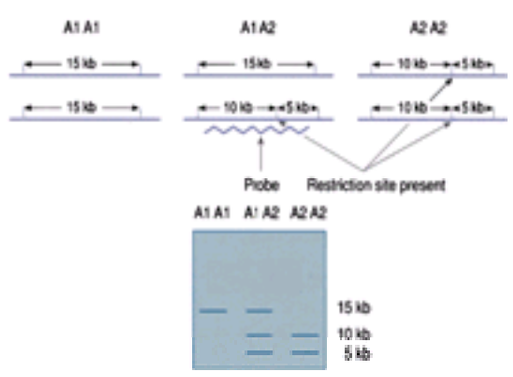

Fig. 4 The principle of analysis of restriction fragment length polymorphism (RFLP). The technique consists of digestion of genomic DNA with an appropriate restriction enzyme, gel electrophoresis of the resulting DNA fragments, denaturation, and blotting on to a membrane, followed by hybridization with a labelled probe annealing to the sequence around the polymorphic restriction site and autoradiography. The figure shows an example of band patterns corresponding to each of the three genotypes (designated A1A1, A1A2, and A2A2) generally found when there is one polymorphic restriction site and a probe derived from the surrounding region (as marked) is used. The A1 A1 and A2 A2 are homozygotes for the absence and the presence of the restriction site, respectively, whereas the A1 A2 is a heterozygote carrying the restriction site (the A2 allele) only on one chromosome.

The polymorphisms detected in the form of RFLP are often located in the non-coding DNA sequences such as introns or the flanking regions of a gene, and their exact positions are frequently unknown. This is because the majority of RFLP were discovered by random screening of different restriction enzymes until polymorphism detectable with a given probe was found. Such an approach is biased towards the detection of the polymorphism of the relatively poorly characterized non-coding regions of the genome because they are more prevalent and have a higher rate of mutation than the DNA sequences encoding proteins.

Before the discovery of PCR and the PCR-based techniques, the analysis of RFLP was the most important source of DNA-based polymorphic genetic markers.

PCR-based typing techniques

All the techniques from this group were made possible or were much simplified by the discovery of PCR. Unless otherwise stated, the first step in each method consists of PCR amplification of the appropriate region of DNA.

PCR-SSO (**SSO** stands for sequence-specific oligonucleotide) typing relies on the observation that under optimal conditions the stability of binding between a short DNA probe (typically 15 to 25 nucleotides) and the complementary target can be affected by a single nucleotide mismatch (Wallace *et al*. 1979; Saiki *et al*. 1986).

To perform the assay the PCR product is denatured, blotted on to a membrane, and hybridized with a labelled SSO probe. Usually the blotting is performed by the dot blot or related slot blot procedure. In the next step the membrane is washed in appropriately stringent conditions. If the blotted DNA does not contain sequences fully

complementary to the probe, the probe is removed, whereas the presence of a membrane-bound probe resistant to washing indicates that the DNA sample contains the relevant sequence (positive reaction) (Fig. 5(a)(i)).

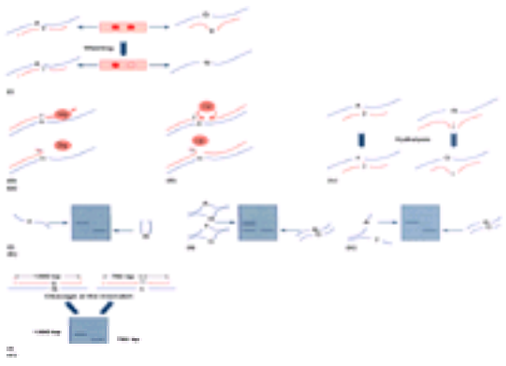

Fig. 5 Some of the commonest techniques used in the analysis of polymorphic genetic markers. The examples show analysis of DNA from two homozygous individuals carrying alleles differing by the substitution of G for A (or of G:C for A:T in double-stranded DNA) at the marker locus. The detection of the allele carrying A at the polymorphic position is shown as a positive reaction, while the G variant represents the negative control. The blue and red lines represent target DNA and probes respectively. The asterisk represents a label. (a) Typing techniques. (i) PCR-SSO typing. A labelled sequence-specific oligonucleotide (SSO) probe hybridizes with the blotted samples of denatured PCR product. During washing the probe bound to the mismatched sequences is removed. The red dots represent positive signals detected on the membrane. The detection method depends on the way the probe was labelled. (ii) Sequence-specific PCR. Under suitable conditions Taq polymerase will only extend a primer whose 3' end is fully complementary to the template DNA. (iii) Oligonucleotide ligation assay (OLA). The ligase (Lig) covalently joins two oligonucleotide probes only if their adjoining ends are correctly paired with the target DNA. (iv) Hybridization protection assay (HPA). An acridinium ester label is protected from hydrolysis only if the probe forms a fully matched hybrid with the target sequence. (b) Screening techniques based on detection of conformational changes in DNA molecules. (i) In single-strand conformation polymorphism analysis (SSCP), the single-stranded DNA is analysed by non-denaturing polyacrylamide gel electrophoresis. In the example the allele containing A migrates more slowly because of its different, 'more extended' conformation. (ii) In heteroduplex analysis, hybrids between the wild type and the mutated variant are created and their migration rate in non-denaturing polyacrylamide gel electrophoresis is compared with the migration rate of fully matched hybrids. The hybrids with mismatches (heteroduplexes) migrate more slowly because of their irregular conformation. (iii) In denaturing gradient gel electrophoresis (DGGE), the samples are analysed in a polyacrylamide gel containing an increasing concentration of denaturant. In the example shown the allele containing A starts to melt at a lower concentration of denaturant and thus migrates more slowly than the wild-type variant. (c) Techniques based on cleavage of mismatched nucleotides. A probe labelled at one end is added to the samples and allowed to hybridize. Next, the samples are treated so that cleavage occurs at the mismatched nucleotide and the products of the reaction are resolved by denaturing polyacrylamide gel electrophoresis. The presence of a band shorter than the length of the probe indicates the presence of a mismatch. The length of the band corresponds to the position of the mismatch relative to the beginning of the probe.

The PCR-SSO method allows quick analysis of a large number (up to a thousand) samples for the presence of particular polymorphism. If only a small number of samples are being analysed but many different polymorphisms need to be tested for, the reverse dot-blot PCR-SSO technique is useful (Saiki *et al*. 1989). In this assay a panel of SSO probes are immobilized on the membrane and hybridized with a suitably labelled PCR product. A modification of this approach is the microtitre plate oligotyping assay, which adapts the reverse dot-blot PCR-SSO protocol to the widely used techniques for protein analysis (enzyme-linked immunosorbent assay—ELISA), making the typing easy to automate (Cros *et al*. 1992).

Amplification refractory mutation system (**ARMS**) (Newton *et al*. 1989) and allele-specific PCR (**ASPCR**) (Wu *et al*. 1989) are similar although independently described assays based on the observation that under the appropriate conditions, Taq polymerase does not efficiently extend a primer with a mismatch at the 3' end (Fig. 5(a)(ii)). In this approach PCR is performed with the DNA sample using primers designed to be specific for sequences found only in a given allelic variant. The presence of a PCR product indicates that the analysed DNA contains the relevant sequence. A large number of polymorphisms can be analysed in a single PCR reaction if differently labelled primers are used (Gibbs *et al*. 1989). Although they are dependent on PCR, ARMS and ASPCR do not require prior PCR amplification.

Oligonucleotide ligation assay (**OLA**) (Landegren *et al*. 1988) is based on the particular features of a DNA-modifying enzyme called DNA ligase. In order to perform the assay, two oligonucleotide probes are designed: one probe is complementary to the target sequence downstream from the polymorphic position, while the other complements the polymorphic nucleotide and the immediately adjacent region upstream. The probes are mixed with the denatured sample of analysed DNA and allowed to hybridize with complementary sequences. In the next step the DNA ligase is added. The ligase will covalently link the two probes only if the nucleotides at their adjacent ends are correctly paired with the target DNA. Thus, the presence of the ligation product indicates the presence of a particular polymorphism in the analysed DNA (Fig. 5(a)(iii)).

By repeated cycles of denaturation, annealing, and ligation, the concentration of the ligated product can be increased linearly, which facilitates detection. An exponential accumulation of the product can be achieved by adding a second pair of primers that are complementary to the first (Wu and Wallace 1989). Owing to the analogies with PCR, this version of the technique has been called the ligase chain reaction (**LCR**). LCR is so sensitive that it can be applied directly to the sample of genomic DNA without the need for prior PCR amplification. The assay can be facilitated further by the introduction of thermostable DNA ligase (Barany 1991).

A simple typing assay can be designed if the polymorphism present in the PCR product creates a recognition site for a restriction enzyme (**PCR-RFLP** assay). Although the original protocol was relatively complex (Embury *et al*. 1987), the assay can usually be performed by digestion of the PCR product with the appropriate enzyme followed by agarose gel electrophoresis and visualization of the products by ethidium-bromide staining. The selection of the enzyme is facilitated by computer programs determining the distribution of all known restriction sites in a given sequence.

PCR-RFLP can sometimes be adapted to the analysis of polymorphisms which do not create a restriction site. This is done by introducing a mutation into the PCR product (via a partially mismatched primer) which creates the necessary restriction site together with a particular polymorphic sequence.

Hybridization protection assay (**HPA**) (Fig. 5(a)(iv)) (Arnold *et al*. 1989) is based on the use of oligonucleotide probes fluorescently labelled by acridinium ester. Under suitable conditions the acridinium-ester label is susceptible to hydrolysis when the probe is single-stranded or forms a hybrid with certain mismatches. However, when the probe hybridizes to the fully complementary sequence, this protects the label. To perform the assay, the labelled probe is mixed with the analysed DNA and allowed to hybridize with the complementary sequence. Next, a hydrolysing agent is added and the fluorescence is measured. A significant degree of fluorescence indicates that the sequence complementary to the probe was present in the analysed sample. This technique is very fast and easy to automate.

In general, the main feature of the methods discussed above is that the sequence of the genetic variants to be distinguished has to be known in advance. Thus they are useful in genetic typing but cannot be applied to screening for unknown polymorphisms.

All the above techniques can detect reliably even single nucleotide differences, and the choice of a particular method largely depends on the experience of the experimenter and the equipment available. PCR-SSO is the most widely used of the assays in this group, especially in the field of DNA-based HLA typing. Allele-specific PCR and PCR-RFLP are also popular because of their simplicity and speed.

Screening techniques

The methods discussed here are mainly used for the detection of novel sequence variations. All of them are facilitated by first amplifying the DNA by means of PCR.

The single-strand conformation polymorphism technique (**SSCP**) is based on the electrophoretic analysis of relatively short, single-stranded DNA molecules in a non-denaturing polyacrylamide gel (Fig. 5(b)(i)) (Orita *et al*. 1989). In such a gel, single-stranded DNA molecules adopt a three-dimensional conformation which depends on their nucleotide sequence. As the conformation can significantly affect the migration rate during electrophoresis, the polymorphic variants of the analysed sequence often appear as distinct bands. The method is quite sensitive and under optimal conditions almost 100 per cent of single nucleotide substitutions can be

differentiated (Sheffield *et al*. 1993).

The technique of heteroduplex analysis (Fig. 5(b)(ii)) exploits the conformational changes of double-stranded DNA molecules caused by the presence of mismatched nucleotides. The heteroduplexes (i.e. double-stranded DNA molecules containing mismatch(es)) can be detected because they often migrate more slowly than homoduplexes during electrophoresis in non-denaturing polyacrylamide gel.

Heteroduplexes can be created by adding the wild-type (i.e. 'normal') DNA to the sample expected to contain substitutions, followed by heating and cooling of the resulting mixture. The heating causes all the DNA molecules to be denatured, while the cooling causes renaturation. The heteroduplexes are formed because renaturation is possible not only between the fully matched strands but also between strands with some mismatches. The addition of exogenous DNA is not required if the analysed sample comes from a heterozygous individual and therefore contains both the normal and mutated variants.

Denaturing gradient gel electrophoresis (**DGGE**) (Fig. 5(b)(iii)) (Fischer and Lerman 1979) is based on the behaviour of double-stranded DNA molecules during their migration through a gel with an increasing gradient of chemical denaturant (urea and/or formamide). When a DNA molecule reaches sufficiently high concentrations of the denaturant, it starts to melt and slows down further migration through the gel. As a result of the complex interactions between nucleotides across the DNA helix, the exact concentration of denaturant required to initiate melting depends not only on the length and total base composition but also on the nucleotide sequence of the molecule. Even a single base-pair substitution may change the melting point of the whole DNA molecule sufficiently to allow separation from the original variant by DGGE.

The resolution of DGGE can be increased by attaching to the end of the analysed sequence a domain rich in guanine–cytosine pairs (a 'GC clamp') (Sheffield *et al*. 1989). This is usually done by incorporating the GC-rich domain into one of the PCR primers. The GC clamp acts by preventing complete denaturation of the analysed molecule during electrophoresis, which should be avoided because the retardation effect is lost after total separation of the strands.

DGGE is particularly powerful when combined with heteroduplex analysis. This is due to the fact that the presence of mismatch(es) destabilizes the DNA molecule and very often causes it to start melting in a lower concentration of denaturant than the fully matched duplex.

One general disadvantage of the above screening techniques is the decrease in sensitivity when long DNA fragments (more than 0.5 kb) are analysed. Further, even under optimal conditions none of the techniques are so sensitive that they are able to detect all cases of polymorphism. SSCP is the most widely used of these methods because of its technical simplicity and its relatively high sensitivity.

Screening techniques which help to localize polymorphisms

The techniques in this group enable the detection of unknown polymorphisms, and provide information about their location in the analysed DNA molecule.

In the approach based on selective cleavage of mismatched nucleotides (Fig. 5(c)), a labelled probe is added to the analysed sample and allowed to hybridize. The probes used can be relatively long (up to 1 kb). If the relevant sequence in the sample is not fully complementary to the probe, heteroduplexes are formed. In the next step the mismatched nucleotides are selectively cleaved by enzymatic or chemical methods, resulting in degradation of the probe into fragments that can be detected by gel electrophoresis. The occurrence of cleavage indicates the presence of polymorphism, and an analysis of the length of the cleavage products provides clues to the location of the polymorphism relative to the length of the probe.

Two cleaving agents can be used: ribonuclease A (Myers *et al*. 1985) or chemical cleavage with piperidine after treatment with hydroxylamine and osmium tetroxide (**HOT**) (Cotton *et al*. 1988). The ribonuclease A assay is simple, but has relatively low sensitivity and requires the use of an RNA probe. The chemical cleavage method has higher sensitivity, but is relatively laborious and necessitates the use of toxic substances. Both methods can be applied to the PCR-amplified DNA, although the use of total RNA isolated from suitable cells or total genomic DNA is also possible.

Another approach relies on the treatment of heteroduplexes generated as described in the previous section with a chemical (carbodiimide) which selectively modifies mismatched nucleotides (Ganguly and Prockop 1990). Heteroduplexes modified in this way are subsequently denatured and used as templates for the synthesis of complementary strands of DNA. The conditions are such that the synthesis terminates at the nucleotide modified by carbodiimide. Next, the extension products are analysed by gel electrophoresis. The presence of a fragment shorter than the analysed DNA molecule indicates that a mismatch was present whose position can be estimated from the length of the extension products.

The general advantage of the above group of techniques is that relatively long stretches of DNA (up to 1 kb) can be screened. However, because the assays are relatively laborious and do not have absolute sensitivity they are seldom used.

DNA sequencing

DNA sequencing is the only method which allows the definitive characterization of all the polymorphisms in a given DNA fragment. In general, sequencing methods are based on the generation of four groups of labelled DNA fragments whose lengths are related to the positions of each of the four nucleotides in the sequenced strand of DNA. The relative lengths of these four groups of fragments are subsequently determined by polyacrylamide gel electrophoresis (Maxam and Gilbert 1977; Sanger *et al*. 1977).

Recently DNA sequencing was considerably speeded up by the use of fluorescent labels and automated detection of the products of the sequencing reaction during the gel run. The application of four different fluorescent dyes allows the products of all four sequencing reactions to be run in a single lane. This increases the number of sequences that can be analysed by one gel and also improves the accuracy of the resolution by excluding artefactual lane-to-lane variation in electrophoresis. The detection and analysis process is automated and computer-based and, therefore, it is possible to get a printout of the sequence just after electrophoresis.

Before DNA can be sequenced it must be pure and present in relatively large amounts. This used to be achieved by laborious molecular cloning, but the discovery of PCR made it possible to omit this step, since the PCR product is generally pure enough to be sequenced directly, i.e. without prior cloning (direct PCR sequencing) (Rao 1994). In addition to its simplicity, this approach has the advantage of being insensitive to PCR artefacts.

Although DNA sequencing used to be a relatively laborious and difficult technique, the recent advances have made it a highly practical method, with many applications in genetic screening and typing.

Analysis of repetitive DNA sequences

Tandemly arranged, repetitive DNA sequences are an important class of genetic markers. Such sequences are very abundant, constituting about 10 per cent of the human genome. They frequently display length polymorphism caused by variations in the number of basic repeating units (Table 1).

	Satellites	Minisatellites (also called VNTR)	Microsatellites (also called STR)
Repeat unit	Depending on the family: a sequence of 5–6.25 bp, 68 bp, (Sau3A repeat) or 171 bp (alphoid repeat)	Usually a shared core consensus sequence similar to bacterial sequences known to promote recombination: GGTGGGCA-GAGACG	1–6 bp repeat Most often CA or CT or even a single A
Total length	Up to 5 Mb	Typically 0.5–30 Kb	Typically 100–250 bp
Distribution	Heterochromatin, mainly centromeres	Telomeric regions	Evenly throughout the genome
Polymorphism	+	+++	—
Significance	Basic biological research	Forensic medicine, linkage studies	Linkage studies, high-resolution genome mapping When expanded may cause disease

VNTR, variable number of tandem repeats.

Table 1 Characteristics of the main classes of the tandemly arranged, repetitive DNA sequences in the human genome (Cooper and Krawczak 1993)

The first repetitive sequences to be discovered were located mainly in the centromere regions of chromosomes and were very long. They were called 'satellite DNA' because they could be separated from the bulk of DNA by centrifugation.

Subsequently, another group of shorter, tandem, repetitive sequences characterized by very high polymorphism were found and christened 'minisatellites' (Table 1). Due to their high polymorphism, minisatellites are very useful in forensic medicine. In medical genetics, however, their application is limited because they occur mainly in the telomere regions of chromosomes (i.e. at the ends of the chromosomes).

Polymorphic minisatellites can be detected in the form of RFLP by Southern blotting. In this case the variation in the length of the DNA fragments generated by digestion with restriction enzyme is caused by differences in the distance between two restriction sites rather than by the presence or absence of one of the sites. Sometimes it is also possible to amplify the region containing the minisatellite by PCR and to assign alleles on the basis of the length of the PCR product (Jeffreys *et al*. 1988). However, this simple approach is limited by the low efficiency of PCR when applied to longer sequences. In particular, when a locus containing both short and relatively long alleles is analysed, it may happen that in a heterozygous individual only the shorter allele is amplified, falsely suggesting homozygosity.

The most recently discovered class of abundant repetitive DNA is represented by microsatellites or short tandem repeats (**STR**). The microsatellites consist of a number of copies of a very short sequence (1 to 5 bp long) and they are often polymorphic. In contrast to the previously discussed polymorphisms, the microsatellites are relatively evenly distributed throughout the genome. At a rough estimate, a microsatellite may be present every 20 kb in the genome, so that every gene may have one or more STR in its neighbourhood (Table 1).

The functional relevance of the microsatellite polymorphism found among healthy individuals is not clear. However, an excessive extension of the length of trinucleotide STR located within certain genes can seriously alter the function of these genes and cause disease. Fragile X syndrome, myotonic dystrophy, Huntington's disease, Kennedy's disease, and spinocerebellar ataxia are examples of diseases caused by such a mechanism.

A polymorphic STR can be analysed by PCR amplification of the block of repeat units in the presence of radioactively labelled nucleotides (internal labelling), followed by denaturing polyacrylamide gel electrophoresis and autoradiography (Weber and May 1989). However, several more efficient methods have recently been developed. A particularly powerful approach is based on PCR amplification of microsatellites using fluorescently labelled primers followed by electrophoresis with automated detection of the PCR products as they migrate through the gel (Ziegle *et al*. 1992). Both the principle and the equipment are the same as those used for automated DNA sequencing. The advantage of this method is that it is automated and enables three microsatellites with overlapping lengths to be run together in a single lane of the gel together with an internal molecular-weight standard.

Due to their abundance, even distribution throughout the genome, and polymorphism, the microsatellites are the single most important group of genetic markers known today. Their analysis has been crucial to the construction of the high-resolution map of the human genome (Weissenbach *et al*. 1992) and to the recent search for susceptibility genes to type I diabetes (Davies *et al*. 1994) and psoriasis (Tomfohrde *et al*. 1994). STR analysis is also likely to play a central role in any mapping of the genes that predispose to common rheumatic diseases.

Analysis of polymorphism in HLA genes and molecules

HLA molecules and the genes of the HLA complex

The HLA molecules are specialized receptors which bind fragments of antigen (peptides) and present them to the T lymphocytes. The interaction between the peptide–HLA complex and the T-cell receptor is the single most important step in specific immune responses. Depending on the circumstances, it can lead to the generation of cytotoxic T cells, the stimulation of antibody production by B cells, the recruitment of non-specific phagocytic cells in the immune response (delayed hypersensitivity response), or, in certain situations, the development of allergy. Apart from their role in the immune response, HLA molecules influence the selection of the T-cell repertoire in the thymus.

HLA molecules are subdivided into class I and class II molecules. The class I molecules interact with CD8 T lymphocytes and present, for the most part, peptides from the proteins located in the cytoplasm of the cell. The class II molecules interact with CD4 T lymphocytes and mainly present peptides derived from external antigens which have been internalized by the cell. Although there are certain differences between the HLA class I and class II molecules in the subunit composition (Fig. 6), crystallographic studies have shown that their three-dimensional structure is similar. Among their most notable similarities is that both types of molecules have characteristic peptide-binding grooves containing discrete sites (specificity pockets) that interact with side chains of the bound peptide (Brown *et al*. 1993; Guo *et al*. 1993).

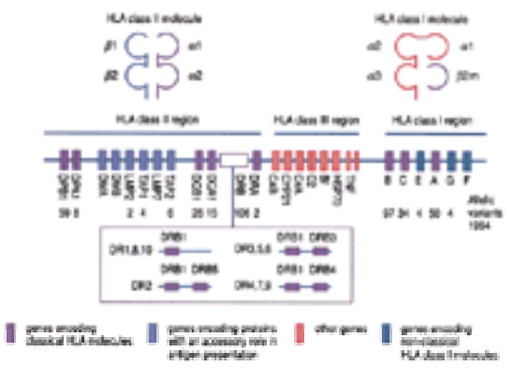

Fig. 6 HLA molecules (above) and schematic diagram of the HLA complex (below). HLA class I molecules consist of transmembrane glycoprotein (the heavy chain) non-covalently associated with a smaller non-polymorphic protein (b_2-microglobulin (b_2-m)). The extracellular portion of the heavy chain has three domains with an immunoglobulin-like structure (a_1–a_3 domains). There are three series of classical HLA class I molecules (HLA A, HLA B, and HLA C). The non-classical class I molecules, with a similar structure but with unclear functions, are called HLA E, HLA F, and HLA G. HLA class II molecules are heterodimers of two transmembrane units (a and b chain). The extracellular portions of each chain have two immunoglobulin-like domains (a_1, a_2 and b_1, b_2, respectively for the a and b chains). There are three different series of HLA class II molecules (HLA DR, HLA DQ, and HLA DP). In the class I molecules the peptide binding site (the groove) is formed by the a_1 and a_2 domains and in the class II molecules it is created by a_1 and b_1 domains. Only the loci known to be expressed have been included in the map of the HLA complex (i.e. not pseudogenes). The numbers of the allelic variants are according to Bodmer *et al*. (1994). The structure of the DR region differs according to the haplotype and in the majority of cases two functional DR molecules are encoded.

The genes encoding HLA molecules form a cluster called the HLA complex, which is located on chromosome 6 (Fig. 6). The only exception is the gene for b_2-microglobulin, which is found on chromosome 15. The HLA complex is subdivided into three regions, termed HLA classes I to III. The HLA class I region contains loci for both the classical (i.e. HLA A, B, and C) and the non-classical (i.e. HLA E, F, and G) class I antigens. The class II region harbours genes encoding the a and b chains of the DR, DQ, and DP molecules and the recently discovered genes for proteins involved in the processing of antigen. These include the *LMP2*, *LMP7*, *TAP1*, and *TAP2* genes as well as the *DMA* and *DMB* genes.

The products of both the *LMP* and *TAP* genes are important in the class I pathway of antigen presentation. The products of *LMP* genes form a part of a multisubunit proteinase complex (proteasome), which is involved in the degradation of cytoplasmic proteins into peptides. The *TAP* genes encode a transporter which delivers

peptides generated in this way into the lumen of the endoplasmic reticulum, where they bind to HLA class I molecules. The products of the *DMA* and *DMB* loci are necessary for the functioning of the class II presentation pathway, but their mechanism of action is not clear.

The HLA class III region encodes a number of proteins with immunological functions not directly involved in antigen presentation, such as complement components (C4, C2, Bf) and tumour necrosis factor (TNF). The genes for heat-shock protein 70 (HSP70) and an enzyme that participates in the synthesis of steroid hormones (CYP21) are also located in this region (Fig. 6).

In addition to the above-mentioned loci, the HLA complex harbours a large number of pseudogenes and expressed genes with unknown functions. All the available information on the genetic structure of the HLA complex has been compiled in a publicly accessible computerized database (Newell *et al*. 1994).

The HLA molecules and their genes are highly polymorphic. This polymorphism is reflected at the functional level by the differences in the repertoire of peptides that can be bound by various molecules. The polymorphism of HLA probably evolved because of the advantages it provides for the population. For example, the existence of a large number of different HLA molecules may decrease the chance that a single pathogen will cause a lethal disease in all members of a population. In keeping with the functional significance of HLA polymorphism, the majority of variable residues of both class I and class II molecules are clustered in domains which form the peptide-binding groove, especially at the sites determining structure and distribution of the specificity pockets (Guo *et al*. 1993).

Susceptibility to many diseases, including a number of common rheumatic disorders, is associated with certain HLA variants. It is not fully clear whether these associations reflect a direct role of the HLA molecules in the disease pathogenesis or whether they are secondary to linkage disequilibrium with a neighbouring gene. However, the central role of the HLA molecules in the immune response and the functional significance of their polymorphism suggests that the majority of disease associations are with the HLA molecules themselves.

HLA typing

The development of fast and accurate methods of HLA typing has always posed a challenge in the field of genetic marker analysis. The classical protocols for HLA typing rely on serological methods and are still in use, especially in typing for HLA class I, including the typing for HLA B27. The most widespread technique is the microcytotoxicity assay, which is based on assessing the viability of cells, usually leucocytes, which are incubated with a panel of antisera (and/or monoclonal antibodies) and complement. Cell death indicates the presence of the HLA type that the antiserum or monoclonal antibody was specific for. The microcytotoxicity assay was improved greatly by the application of antibody-coated immunomagnetic beads for purifying the cells used in the typing (Vartdal *et al*. 1986).

Unfortunately, serological typing, although simple to use, often fails to detect small differences between allelic variants and is particularly inefficient in the analysis of HLA class II polymorphism.

HLA class II typing with better resolution was made possible by a method based on the observation that T cells react strongly to all foreign (allogenic) but not self HLA class II molecules. In one version of this approach, lymphocytes from a typed individual are incubated with a panel of irradiated homozygous stimulator cells whose HLA class II types are known. Whenever lack of proliferation is observed it indicates that the individual carries the HLA type of certain given stimulator cells. The method is rather laborious and is seldom used today.

Isoelectrofocusing of isolated HLA molecules is another relatively sophisticated technique for HLA typing. Isoelectrofocusing is a form of electrophoresis that enables proteins to be separated on the basis of their net charge, and it is particularly powerful when combined with traditional electrophoresis in an approach known as two-dimensional gel electrophoresis. While this purely biochemical approach offers good resolution, it is laborious and technically difficult.

The major advance in HLA typing occurred when methods based on the analysis of DNA were introduced. The first widely used approach relied on the RFLP analysis of genomic DNA using locus-specific cDNA probes. The typing was made possible because correlations could be empirically established between certain RFLP and HLA types that have been determined by other methods.

DNA-based HLA typing benefited enormously from the discovery of PCR. Today PCR-based methods have come to dominate the analysis of HLA class II and are starting to be applied to the analysis of class I polymorphism. The most popular approach in class II typing relies on PCR amplification of the second exon of the analysed locus (where all polymorphic residues are located) followed by blotting and hybridization with a panel of 10 to 20 oligonucleotide probes (the PCR-SSO technique). PCR-SSO typing has been also applied to HLA class I typing, including assays for B27 (Hill *et al*. 1991) and its subtypes (Dominguez *et al*. 1992).

A number of other PCR based methods have been adapted to allow HLA typing. These include reversed dot-blot PCR-SSO, sequence-specific PCR, PCR-RFLP, techniques based on single-strand conformation polymorphism, heteroduplex analysis, hybridization protection assay, and direct sequencing of PCR products (Bidwell 1994). The latter technique, especially in an automated format, may well represent the ultimate solution to high-resolution HLA typing.

Nomenclature of the HLA system

One consequence of the tortuous history of HLA typing methods is the rather complex nomenclature, which differs according to whether serological specificities, T-cell-defined specificities, or the HLA genes are being discussed (Bodmer *et al*. 1994). The nomenclature of serologically defined HLA molecules is based on the name of the particular series (i.e. A, B, C, DR, DQ, or DP) followed by a number. The T-cell-defined specificities (only HLA class II) are designated as 'Dw', for the DR and DQ molecules, and 'DPw', for the DP molecules, followed in each case by a number.

The most precise nomenclature is based on the sequences of the HLA genes. Each gene is designated by the name of the locus followed by an asterisk ('*') and a four-digit number. The name of the locus is related to the associated series of serological specificities, while the number denotes the allelic variant. The first two digits of the number often correspond to the associated serological specificity, so that for example DRB1*0101 corresponds to a subset of DR1. There are, however, three exceptions to this rule: DR2, corresponding to DRB1*15 or *16; DR5, corresponding to DRB1*11 or *12; and DR6, corresponding to DRB1*13 or *14. The third and fourth digits denote the subtype. If the subtype is not known, only the first two digits are used: for example DRB1*01 denotes any subtype of DR1. In the case of alleles identical at the amino-acid level but differing at the nucleotide sequence, a fifth digit is added (for example DRB1*08031).

The three systems of nomenclature applied to the genes and/or molecules associated with serological specificity 'DR4' are shown in Table 2.

Serological specificity	T-cell defined specificity	DRB1 allele[a]
DR4	Dw4	DRB1*0401
DR4	Dw10	DRB1*0402
DR4	Dw13	DRB1*0403 DRB1*0407
DR4	Dw14	DRB1*0404 DRB1*0408
DR4	Dw15	DRB1*0405
DR4	Dw'KT2'	DRB1*0406
DR4	?	DRB1*0409 DRB1*04010 DRB1*04011 DRB1*0412 DRB1*0413 DRB1*0414 DRB1*0415 DRB1*0416 DRB1*0417 DRB1*0418 DRB1*0419

[a]Although each DR4 molecule is heterodimer of the α and β chains encoded by alleles of DRA and DRB1 loci, usually it is sufficient to specify only the DRB1 allele because of the very limited polymorphism of DRA.

Table 2 The three systems of nomenclature for the factors of the HLA system applied to the genes and molecules associated with serological specificity 'DR4' (Bodmer *et al*. 1994)

Genetic marker analysis in rheumatology

Prenatal diagnosis and genetic counselling in osteogenesis imperfecta

General features

Osteogenesis imperfecta is caused by defects in the structure or amount of collagen type I, which results in brittle bones. In the majority of cases the disease is inherited as an autosomal dominant trait. The molecular defect in osteogenesis imperfecta can be located at either of two unlinked loci which encode different chains of collagen type I (i.e. the COL1A1 and COL1A2 loci encoding the a_1 and a_2 chains of collagen type I, respectively).

Among the main features of osteogenesis imperfecta are the relatively high frequency of new (i.e. not inherited) mutations, the occurrence of mosaicism, and the fact that different mutations are usually found in different families. Mosaicism is a condition in which the mutated gene is only present in a fraction of the cells, and it results from new mutations occurring at an early embryonal stage of development. Mosaicism poses a problem in genetic counselling, since the probability that the child of a mosaic individual will inherit the disease may vary from 0 to 50 per cent, depending on the fraction of germ cells carrying the mutated allele.

Prenatal diagnosis and genetic counselling

In some cases the prenatal diagnosis of osteogenesis imperfecta can be performed by ultrasonography, which enables skeletal abnormalities to be demonstrated directly (Thompson 1993). A more sensitive method of diagnosis is the biochemical analysis of fetal cells obtained by chorionic villus biopsy or amniocentesis. The biochemical approach is based on the observation that the presence of defective chain(s) in the type I collagen leads to an excessive glycosylation of the mature molecules, which can be detected by gel electrophoresis (Cohn and Byers 1990). The method is rather time-consuming, however, since the fetal cells need to be expanded *in vitro* for approximately 1 month. It is also limited to chorionic villus biopsies because the cells obtained by amniocentesis produce a collagen that is different from the type I collagen necessary for the analysis.

An alternative approach is based on genetic analysis to determine whether the fetus carries the mutated gene. It is usually not known which mutation or even which locus (*COL1A1* or *COL1A2*) causes the disease in a particular family because of heterogeneity of mutations found in osteogenesis imperfecta. However, a number of markers defined by RFLP are known to be located in or very close to the COL1A1 and COL1A2 genes, making it possible to perform linkage analysis. In favourable circumstances, especially if a sufficient number of affected family members are available, linkage analysis may show a significant cosegregation (as measured by the lod score) between one of the RFLP and the disease. In such cases the RFLP provides a tag which enables the mutated gene in this family to be traced and a diagnosis to be made by typing the fetal DNA.

It may also be possible to find a marker linked with the disease gene on the basis of exclusion. The RFLP markers are so close to the *COL1A1* or *COL1A2* locus that the chance of recombination is negligible, and because osteogenesis imperfecta is known to be caused always by a mutation at one of these loci, it follows that one of the markers must be linked with the disease in every family. Thus, if other markers can be excluded, the one that remains has to be linked, even if it is not associated with a significant lod score. Such an approach may be successful even in relatively small pedigrees because a marker can be excluded on the basis of a single recombination event (Sykes 1993).

Although the linkage methods can be very powerful, their usage is limited to relatively extensive families with a history of disease whose members are available for collection of DNA samples. Furthermore, even when the family is large, the analysis may still be impossible if some of the key individuals are homozygous for the markers used. Another disadvantage of the method is that it cannot be used to estimate the chance of recurrence of disease among the children of a mosaic individual.

The best strategy in situations when linkage analysis fails is to focus on the direct identification of the mutation causing the disease in a given family. This has been achieved successfully with the use of methods based on cleavage of mismatched nucleotides in heteroduplexes as well as by PCR-based methods such as PCR-SSCP. Given the fast development of the DNA techniques, in the future, the direct identification of mutations is likely to play an increasing role in the genetic counselling in osteogenesis imperfecta.

Ankylosing spondylitis and other spondylarthropathies

Ankylosing spondylitis and other spondylarthropathies are associated with HLA B27 (Brewerton *et al*. 1973; Schlosstein *et al*. 1973; Benjamin and Parham 1990). In Caucasians, the B27 molecule is found typically in approximately 95 per cent of patients with ankylosing spondylitis compared with approximately 10 per cent of the whole population. The prevalence of B27 is similarly high among patients with juvenile ankylosing spondylitis, and is lower but still higher than normal among patients with reactive arthritis (60 to 80 per cent), arthritis associated with inflammatory bowel disease (50 per cent), and psoriatic arthritis (20 per cent). Typing for B27 has an established place in the clinical diagnosis of spondylarthropathies, and the recently proposed set of diagnostic criteria for spondylarthropathies includes B27 positivity (Amor *et al*. 1991).

Typing for B27 can be useful in a clinical situation provided the test results are interpreted correctly. It is important to realize that despite the strong association between B27 and ankylosing spondylitis, the majority (approximately 90 per cent) of B27-positive individuals do not have the disease. Thus, screening of the general population for the presence of B27 would not be helpful in identifying cases of ankylosing spondylitis.

However, as with any diagnostic test, the situation is different if there is some evidence that the patient has the disease before the test is performed (Khan and Khan 1982). For example, if on the basis of the clinical presentation the pre-test probability of ankylosing spondylitis is 50 per cent and the patient also turns out to be B27-positive, the post-test probability rises to 95 per cent, whereas in the case of a negative result it would be only 10 per cent. A reader familiar with the issue will realize that the above is generally true of any test with a sensitivity of 95 per cent and a specificity of 90 per cent (in the case of B27 typing, the sensitivity of the test equals the frequency of B27 among the patients, whereas the specificity is equal to the percentage of controls who are negative for B27).

The association between spondylarthropathies and B27 probably means that the B27 molecule is directly involved in the pathogenesis of the disease. This has been suspected for a long time because the increase in B27 has been found among patients with ankylosing spondylitis irrespective of their ethnic background, and also because all the subtypes of B27 that have been studied appear to be associated with the disease (Ivanyi 1992). Recently more direct evidence implicating the B27 molecule was obtained by showing that rats transgenic for human B27 develop a disease similar to ankylosing spondylitis (Hammer *et al*. 1990).

Whereas the presence of B27 is clearly important for the pathogenesis of spondylarthropathies, less is known about the role of other genetic factors. In two studies a relatively weak but distinct association with Bw60 was found among patients with ankylosing spondylitis in addition to the association with B27 (Robinson *et al*. 1989; Rubin *et al*. 1994). Recently it was suggested that homozygosity for a variant of the *LMP2* gene (*LMP2b*) could predispose to the development of acute anterior uveitis in the course of ankylosing spondylitis (Maksymowych *et al*. 1994). Our own studies have shown that both Bw60 and LMP2b homozygosity as well as HLA DRB1*08 and DPB1*0301 were all increased among patients with juvenile but not adult ankylosing spondylitis. Although the interpretation was complicated by linkage disequilibrium, there may indeed exist a non-B27, HLA-associated genetic component in certain forms of ankylosing spondylitis (Ploski *et al*. 1994c).

Rheumatoid arthritis

Susceptibility to rheumatoid arthritis is probably determined by the presence of a particular stretch of amino acids (the shared epitope) found in positions 67 to 74 of certain subtypes of DR4 (DRB1*0401, *0404, *0405, and *0408), DR1 (DRB1*0101), and DR6 (DRB1*1402) (Stastny 1978; Gregersen *et al*. 1987; Hansen and Nelson 1990). The shared epitope is found in up to 90 per cent of Caucasian patients with rheumatoid arthritis and in about 50 per cent of healthy controls.

All the DR molecules which carry the shared epitope show association with rheumatoid arthritis, although some associations are only apparent in certain ethnic groups. DRB1*0401, DRB1*0404, and DRB1*0408 are associated with the disease in Caucasians, DRB1*0101 is found to predispose to rheumatoid arthritis among Israeli Jews (and to some extent among Caucasians), and DRB1*0405 and DRB1*1402 are found in association with rheumatoid arthritis in Oriental populations and Yakima Indians, respectively. The different associations found among various ethnic groups are probably caused by differences in the prevalence of the various alleles in the general population. For example, DRB1*0405 and DRB1*1402 are relatively frequent among Orientals and Yakima Indians respectively, but occur only rarely among Caucasians.

Although the shared epitope determines susceptibility to rheumatoid arthritis, other regions of the HLA molecules may determine the severity of the disease. Patients who have severe disease that is positive for rheumatoid factor relatively often carry DR4, whereas those with mild, seronegative, rheumatoid arthritis tend to be DR1 positive (Dobloug *et al*. 1979; Winchester 1994; Ploski *et al*. 1994b). A particularly high risk of severe disease with extra-articular complications is associated with the carriage of two *DRB1* alleles encoding DR4, especially two copies of *DRB1*0401*, or *DRB1*0401* plus *DRB1*0404* (Weyand *et al*. 1992; Wordsworth *et al*. 1992).

The importance of the double dose of DR4 in determining the severity of rheumatoid arthritis is supported by studies of polyarticular juvenile chronic arthritis that is positive for rheumatoid factor. This subset of juvenile chronic arthritis probably represents relatively severe rheumatoid arthritis with an early onset and, interestingly, it shows an association with the carriage of two DR4-encoding alleles, like severe rheumatoid arthritis in adults (Nepom *et al*. 1984; Ploski *et al*. 1993b).

Typing for the shared epitope cannot help in the diagnosis of rheumatoid arthritis because of the relatively high prevalence of this sequence among healthy controls. However, typing aimed at identifying patients carrying a double dose of DR4 may have some potential in predicting the severity of the disease (Gough *et al*. 1994).

Early-onset, pauciarticular, juvenile chronic arthritis

Early-onset, pauciarticular, juvenile chronic arthritis, the most prevalent of the subsets of juvenile chronic arthritis, is a disease with relatively abundant HLA associations. DRB1*08 (Stastny and Fink 1979), DRB1*1301, DRB1*11, DRB1*12 (Stastny and Fink 1979; Glass *et al*. 1980; Reekers *et al*. 1983; Fernandez-Vina *et al*. 1994), and DPB1*0201 (Odum *et al*. 1986; Begovich *et al*. 1989) are all found in a larger proportion of patients than healthy controls. Among the patients, DPB1*0201 is frequently found together with DRB1*11, DRB1*12, DRB1*1301, or DRB1*03, suggesting that positive interaction predisposing to the disease occurs between these alleles (Van Kerckhove *et al*. 1990; Ploski *et al*. 1994a). The DRB1*04 and DRB1*07 alleles may have a protective effect against the development of this disease.

Early-onset, pauciarticular, juvenile chronic arthritis is often complicated by the occurrence of chronic iridocyclitis. The presence of DR5, in particular of the DRB*1104 subtype, may be a risk factor for the development of the eye disease, while DR1 shows a negative association with this complication (Giannini *et al*. 1991; Melin-Aldana *et al*. 1992; Ploski *et al*. 1993b). A polymorphism located in the promoter region of the interleukin 1a gene (chromosome 2, non-HLA-linked) may also predispose to the eye disease (McDowell *et al*. 1994). Interleukin 1a and the related interleukin 1b are proinflammatory cytokines, which play a role in the induction of fever, the acute-phase response, and the local inflammatory fibrosis and tissue destruction.

Another complication occurring in this disease is the development of relatively severe polyarticular joint involvement. Susceptibility to polyarticular disease in early-onset, pauciarticular, juvenile chronic arthritis may be increased by DQA1*0101 (or DRB1*0101, which is in strong linkage disequilibrium with it) (Van Kerckhove *et al*. 1991; Ploski *et al*. 1993b).

An interaction has been suggested between HLA and the genes encoding the antigen receptor of T cells in early-onset, pauciarticular, juvenile chronic arthritis. In two studies the frequency of the T-cell receptor *TCRVB6S1*2* allele (the Vb6.1b allele according to the previous nomenclature, encoded on chromosome 7) has been found to be increased among patients with pauciarticular, juvenile chronic arthritis who were positive for *DQA1*0101* (Maksymowych *et al*. 1992; Charmley *et al*. 1994). Interestingly, the polymorphism of *TCRVB6S1* has a distinct significance: the *TCRVB6S1*2* allele, in contrast to *TCRVB6S1*1*, is non-functional because it lacks one of the cysteine residues necessary for the correct folding of the protein. However, because in some cohorts of patients the association with *TCRVB6S1*2* could not be found, more studies are needed before definite conclusions can be drawn (Ploski *et al*. 1993a).

Unfortunately, although the immunogenetic associations in early-onset, pauciarticular, juvenile chronic arthritis are quite abundant, at present none of them can be regarded as sufficiently strong or well documented to be used as a test either in the diagnosis or in the prediction of the course of the disease.

4.8 Immune complex detection

Bryan D. Williams

Introduction

Immune complexes are formed when antibody interacts with the corresponding antigen(s); the antigen(s) may be tissue fixed or free in serum and other body fluids. This is a dynamic process and their clearance, which depends on many variables, normally plays a physiological role which is beneficial to the host and leads to the elimination of antigen. However, under certain circumstances immune complexes may persist in the circulation and subsequently localize in target tissue where they may elicit an inflammatory response. The basement membranes of blood vessels, glomeruli, the choroid plexus, and other organs are common locations for immune complex deposition.

The clinical setting in which circulating immune complexes deposit at multiple tissue sites and produce lesions is referred to as an immune complex disease. These diseases share certain common pathogenic mechanisms although the underlying causes may vary due to the different origins and nature of the antigens present in the immune complexes. The immune complex diseases have common pathological mechanisms and their clinical manifestations include glomerulonephritis, vasculitis, arthritis, skin eruptions, pleuritis, and pericarditis. Such multiple organ involvement is frequent in disorders that result from deposition of immune complexes from the circulation. Diseases resulting from local immune complex formation are associated usually with involvement of a single organ such as the kidney or thyroid gland. Considerable variations in the expression of disease features are seen between patients and in a given patient during the course of the disease.

Ideally to incriminate circulating immune complexes directly in the pathogenesis of human diseases certain criteria should be fulfilled. These would include the following.

1. Identification of the antigen and its binding to a specific antibody within the immune complex.
2. Components of the circulating immune complex should be identified within involved tissues which show histological features of vasculitis or glomerulonephritis.
3. If the antibody is of the appropriate isotype, evidence of hypercatabolism of complement should occur.
4. Circulating immune complex levels should correlate with disease features.

Few diseases in humans fulfil all of these criteria. However, it is widely believed that immune complexes are involved directly in the pathogenesis of several of the rheumatic diseases and contribute to the development and persistence of inflammation in blood vessels and other tissues.

Pathogenicity of immune complexes

Evidence of the pathogenicity of immune complexes has been well reviewed (Van Es *et al*. 1984; Salvido and Andres 1986; Virella 1990; Virella 1993). Characteristics of the immune complexes which predispose to their tissue deposition and pathogenicity are summarized in Table 1. Variation in the exposure time and the nature and persistence of the antigen significantly changes the biological properties of the immune complex formed. DNA of high molecular weight is removed very quickly from the circulation by the liver and as a consequence immune complexes containing such DNA are also eliminated rapidly from the circulation. Glycoprotein antigens containing exposed galactose residues may hasten the removal of small lattice immune complexes by interacting with galactose receptors on hepatocytes, and cationic (positively charged) antigens can interact directly with negatively charged tissue thereby contributing to local immune complex formation.

Table 1 Characteristics of immune complexes which are relevant to pathogenicity

Antibodies are the other essential constituent of immune complexes and they also influence the pathogenicity of antigen–antibody complexes. They achieve this by variations in isotype as well as antibody avidity. Isotype influences the glomerular deposition of DNA–anti-DNA complexes in NZB/NZW mice, a strain which develops

a lupus-like syndrome. The switch from IgM to IgG isotype occurs much earlier in the female than in male mice and coincides with the onset of clinical disease. IgG anti-DNA, rather than IgM anti-DNA, is associated with glomerular deposits and the isotype switch, therefore, favours the formation and glomerular deposition of pathogenic immune complexes. The production of antibodies of low avidity, another characteristic of NZB/NBW mice, also interferes with the effective elimination of antigen and predisposes to the formation of circulating immune complexes which subsequently deposit in tissues. Other factors which influence the formation and removal of immune complexes are summarized in Table 2. The complement system also plays an important physiological role in preventing the tissue deposition of immune complexes in normal individuals. The ability of the complement system to prevent immune complexes from precipitating from plasma and the role of the CR1 receptor on the erythrocyte membrane are two crucial components of this process (see Chapter 3.1). Only when defects occur in this system will immune complex deposition occur and an immune complex disease be produced (Inman and Day 1981).

Event	Variables
Exposure to antigen	Single event or sustained exposure Nature of the antigen Route of exposure Quantity
Antibody production	Previous exposure to antigen Genetically determined host immune response Affinity and isotype Quantity
Immune complex formation	Circulating or in situ
Fate of immune complexes	Modulation of lattice size by complement activation Inherited or acquired complement deficiencies Inhibition complement activation by drugs
Clearance	Capacity of the reticuloendothelial system Interaction with complement or Fc receptors
Deposition in tissue	Binding to erythrocyte CR1 receptors Blood flow and vessel structure Changes in permeability Affinity of the antigen for tissue components Prior tissue damage Pharmacological agents

Table 2 Dynamics of immune complex disease

Considerable research has been directed towards the development of specific, sensitive, and reliable techniques for the demonstration of immune complexes because of their pathogenic role in certain diseases. A large number of methods are applicable to the detection of complexes involving unknown antigens, but these are essentially based on either the physical or biological properties of the immune complexes. Historically the development of assays for soluble immune complexes started with physicochemical rather than immunological techniques, although currently nearly all the assays used in clinical practice are based on the latter methods. Techniques currently in use can be conveniently divided into two main groups, those that are antigen specific and a much larger, although more readily applicable group, the antigen non-specific tests. Not all of these assays, however, are suitable for routine clinical use. The ideal test should be both specific for the immune complex and sensitive for a range of immune complex characteristics, be simple to perform, use stable and easily stored reagents, require small quantities of serum, and allow the quantity of the immune complex to be estimated accurately and reproducibly.

Antigen-specific methods

The provocative antigen in a pathogenic immune complex is rarely known but when it is, either the antigen or its corresponding antibody can be detected in the circulation. Virus–antibody complexes have been visualized by electron microscopy in patients with hepatitis associated with the B antigen and in those patients who have developed polyarteritis nodosa; hepatitis B virus particles have been shown to be part of the circulating immune complex (Almeida and Waterson 1969). The presence of virus–antibody complexes in the blood of animals chronically infected with the lymphocytic choriomeningitis (**LCM**) virus had been inferred following a decrease in the infectivity of serum after the virus–antibody complex was precipitated by an antiglobulin antibody.

In the sera of patients with systemic lupus erythematosus, free DNA has been detected during phases of disease activity, often alternating in sequential longitudinal studies with the appearance of anti-DNA antibody (Koffler *et al*. 1974). Others have claimed that DNA–anti-DNA complexes are present in the serum of patients with active systemic lupus erythematosus since the concentration of anti-DNA antibody increases following digestion of the complex by DNAse (Harbeck *et al*. 1973). In other human diseases specific antibody has been identified by immunofluorescence in the granular immune complex deposits which accumulate in the renal glomerulus (Williams 1981). Methods of isolating and analysing the constituents present in immune complexes have been reviewed by Jones and Orlans (1981).

Antigen non-specific methods

Since the antigens in human sera in the majority of the immune complex diseases are unknown, the presence of immune complexes are identified most frequently on the basis of different physical, chemical, and biological properties of antigen-complexed IgG compared with free IgG. Most immune complex assays, therefore, employ molecular or cellular reagents that react preferentially with antibody when it forms part of an immune complex and less readily with free monomeric antibody. A problem associated with all of these methods is the possibility that non-specifically aggregated immunoglobulin may be detected and interpreted as reflecting the presence of immune complexes *in vivo*. Over 40 assays have been developed to detect immune complexes and these have varying degrees of specificity, sensitivity, and reproducibility; factors which, therefore, preclude the detection of all species of immune complexes with a single assay (Theofilopoulos and Dixon 1979).

Methods based on the physical characteristics of immune complexes

These techniques, which are now largely of historical interest only, are based on the increased molecular size or altered solubility of the immune complex compared with free antigen or antibodies. The methods used, summarized in Table 3, include ultracentrifugation, gel filtration, sucrose density gradient centrifugation, polyethylene glycol precipitation, and cryoprecipitation.

Table 3 Methods for detecting immune complexes

Ultracentrifugation

The use of analytical and preparative ultracentifugation has been discussed (Stanworth and Johns 1977). The important contribution of this technique to the demonstration of circulating immune complexes containing rheumatoid factor and to the understanding of the handling of radiolabelled antigen in animals in undeniable. However, its application is largely as a research tool and because of its low sensitivity it has little clinical use.

Gel filtration

Gel filtration allows macromolecular material of defined size and, therefore, distinguishable from free IgG and IgM to be separated and analysed for the characteristics

of an immune complex. A sensitive detection system for complement component C3, bound to serum fractions larger than IgG and free C3 has been used to identify immune complexes in the sera of patients with rheumatoid arthritis and other diseases. Although very sensitive this method is not readily adaptable for extensive clinical use (Williams and Slaney 1977).

Polyethylene glycol precipitation

Polyethylene glycol (**PEG**), an uncharged, water soluble, linear polymer, has unusual properties that are useful in detecting immune complexes. Twenty per cent PEG precipitates most monomeric IgG and many other proteins from serum but when its concentration is reduced to less than 3 per cent the precipitation of monomeric IgG decreases significantly without preventing the precipitation of immune complexes. Precipitation of the latter depends on the steric exclusion of the immune complex from the domain of the polymer. This technique has been used to evaluate the presence of immune complexes in the sera of patients with a variety of autoimmune rheumatic disorders on the assumption that IgG complexed with antigen precipitates more readily than monomeric IgG. Two main problems associated with this technique are its lack of specificity and the results obtained are influenced by the abnormally high concentrations of IgG present in the sera of patients with autoimmune rheumatic diseases. Furthermore the addition of PEG to serum also induces the aggregation of immune complexes (Creighton *et al*. 1973).

Cryoprecipitation

Cryoprecipitation refers to the reversible precipitation of proteins or protein complexes at reduced temperatures. These cryoprecipitates (cryoglobulins) frequently contain IgG and they have been classified into three types: type I composed of monoclonal IgG; type II composed of mixed cryoglobulins with a monoclonal component possessing antibody activity against polyclonal IgG; and type III containing mixed polyclonal cryoglobulins in which none of the components are monoclonal. Type III cryoglobulins occur in the sera of patients with a variety of autoimmune rheumatic disorders and their measurement is often useful in patient evaluation. Since cryoglobulins will precipitate from serum at different temperatures, samples should be either transferred to the laboratory within minutes or if this is not possible transferred in a thermos flask containing water at 37°C. After clotting at 37°C, serum is then stored at 4°C for up to 7 days before isolating the cryoprecipitate by centrifugation. After repeated washing the protein concentration is determined and expressed per millilitre of serum. The largest quantities of cryoglobulin are found with type 1 or type 11. Cryoglobulins containing IgM rheumatoid factor and IgG rheumatoid factor are present in sera from patients with rheumatoid arthritis, particularly in those with extra-articular disease (Schreiber and Maini 1984). In patients with severe rheumatoid arthritis, cryoglobulinaemia is common and frequently associated with nodules, digital vasculitis, leg ulcers, lung disease, and scleritis. There is a strong positive correlation between the presence of extra-articular disease and cryoglobulinaemia, and therefore the detection of cryoglobulin is useful in identifying a group of patients with a high morbidity and mortality. Recently type II cryoglobulinaemia has been strongly associated with concomitant hepatitis C virus infection and a high rate of false-negative serological tests. Hepatitis C virions and hepatitis C antibody are concentrated in the cryoprecipitate, most commonly in association with a rheumatoid factor of a specific idiotype (Agnello *et al*. 1992).

Identification of immune complexes by interaction with biological recognition units

Assays for the detection of immune complex can be divided into three major categories and the principles underlying each of these are shown in Table 4. In the solid phase assays the recognition unit is coated onto a plastic surface, this then interacts with the sample and the interaction is demonstrated finally by the binding of radiolabelled anti-immunoglobulins. In fluid phase assays the recognition unit is incubated with the sample and the bound and free units are separated by differential precipitation. In the cellular assays, cells bearing the appropriate receptors are incubated with the sample, the complexes attach to the cell surface receptors and are quantified by the addition of radiolabelled anti-immunoglobulins (reviewed by Kilpatrick and Weston 1985).

	Recognition	Interaction	Quantification
Solid phase binding assays	Coating plate with receptor molecule	Serum immune complex with coated receptor	Develop with labelled anti-immunoglobulin; express as amount of antibody bound to plate
Fluid phase binding assays	Serum immune complex with labelled receptor molecules	Separation of bound from free receptor using a precipitation step	Percentage of precipitated receptor
Cellular binding assays	Cells bearing the appropriate receptor	Serum immune complex interacts with cell receptor	Develop with labelled anti-immunoglobulin; express as amount of antibody bound to the cell

Table 4 Principles underlying immune complex assays

Most immune complex assays employ biological reagents and use molecular or cellular probes which react with antibody in the immune complex but not with free monomeric antibody. The reaction of immune complex with complement components afford several methods for immune complex detection. Complement-fixing immune complexes may be detected either by indirect measurement of complement consumption (e.g. anticomplementary activity) or by direct evaluation of the binding of immune complex to C1q, the first component of complement (adapted to produce to C1q-binding fluid phase or solid phase assays). Immune complexes that have reacted with the complement system have molecules of C3 deposited on their surface, such complexes can be identified in those assays which utilize conglutinin (e.g. conglutinin-binding assay) or antibodies to fixed complement components (anti-C3 assays). All these methods have in common a dependence on the reactivity of the immune complex with complement, although many circulating complexes fulfil this requirement those containing only IgG4, IgA, or IgE would not be detected.

A second group of assays that discriminate aggregated from monomeric immunoglobulins is based on the interaction of immune complexes with low avidity anti-immunoglobulins antibodies. Most of these methods are sensitive only for immune complexes containing IgG antibodies and all are influenced to varying degrees by the concentration of monomeric IgG. A third group utilizes the interaction of immune complexes with receptors present on cell membrane. The use of living cells makes standardization difficult, however, and the results may be influenced by antibodies present in the patient's serum which either bind directly to the cell membrane or interfere with cell metabolism. One lymphoblastoid cell line, known as the Raji cell line, is particularly suitable for detecting immune complexes because of the high density of complement receptors on its surface and the lack of surface immunoglobulin, coupled with small numbers of low affinity receptors for IgG Fc.

Methods commonly used for the detection of immune complexes in clinical samples

The five assays outlined in Fig. 1 have been found to be the most acceptable for clinical use since they are sensitive for a variety of immune complexes, relatively simple to perform, reproducible, and give a quantitative estimation of the concentration of immune complexes in serum (WHO/IUIS Working Group 1981).

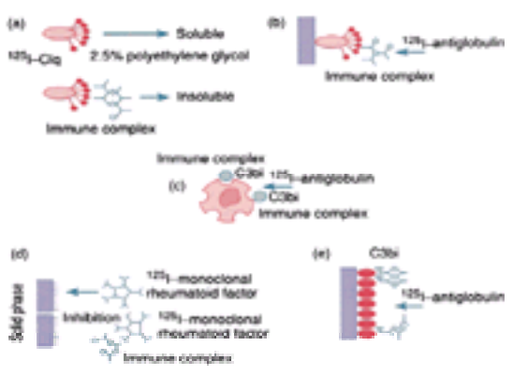

Fig. 1 Five methods found most acceptable by the WHO/IUIS Working Group (1981). (a) C1q binding assay. (b) C1q solid phase assay. (c) Immune-complex Raji cell

assay. (d) Monoclonal rheumatoid factor inhibition assay. (e) Solid phase conglutinin binding assay.

C1q molecules bind weakly to monomeric IgG1, IgG2, IgG3, and IgM, but this binding is much enhanced when these protein complex with antigen. However, C1q assays fail to detect immune complexes made with non-complement activating antibodies (IgG4) and also fail to detect complexes made with antibodies that activate complement preferentially by the alternative pathway. Whichever assays are used the results must be interpreted with a knowledge that various polyanions, DNA, endotoxin, heparin, and viruses may bind directly to C1q thereby reducing its specificity as a probe for immune complex detection.

C1q binding assay

This assay depends on the differential precipitation by PEG of free radiolabelled C1q from the C1q bound to the immune complex. In a modified assay, pathological sera are treated with **EDTA** (ethylene diamine tetra-acetic (ethanoic) acid) in order to prevent the incorporation of radiolabelled C1q into the endogenous C1qrs complex. The percentage of radioactivity precipitated corresponds to the C1q binding activity of the sample and provides a measure of the concentration of immune complexes present in the sample. PEG also favours the binding of C1q to immune complexes and once bound prevents their dissociation. This assay has advantages, therefore, in detecting low avidity immune complexes. The radiolabelled C1q is only present in small quantities but in the presence of EDTA there is competition between endogenous C1q and the labelled C1q for binding to the immune complex. This method has advantages over other C1q tests in that no positive results arise from the presence of DNA or endotoxin in the sample, presumably because complexes of these substances with C1q are not precipitable by the concentration of PEG employed. Free DNA, however, strongly inhibits binding of C1q to aggregated immunoglobulin. In addition there is no assurance that labelled C1q binds all complement-fixing immune complexes if, for example, the IgG sites are fully occupied with endogenous C1q. This assay is also liable to interference by binding of C1q to the anticoagulant heparin (Zubler *et al*. 1976a).

C1q solid phase assay

This test is based on the interaction of immune complexes or aggregates with C1q bound to polystyrene tubes. In these assays pathological sera are incubated in tubes internally coated with C1q; thereafter the amount of bound IgG is assessed with radiolabelled or enzyme-linked anti-IgG antisera. These tests are very sensitive and have the distinct advantage in that they are IgG specific. Since the developing antiserum is one directed against IgG, false-positive results from DNA, endotoxin, or other interfering substances are avoided (Hay *et al*. 1976).

Raji cell binding assay

This assay is based on the binding of complement-activating immune complexes to complement receptors on an lymphoblastoid cell line (Raji cells). These cells have large number of receptors for C3b but lack surface immunoglobin and have low numbers of low affinity receptors for the Fc portion of IgG. Immune complexes bound to the cells are quantified using a labelled anti-immunoglobulin antibody, the concentration of immune complexes being calculated by extrapolation from a standard curve prepared by adding increasing amounts of aggregated immunoglobin to normal human serum which provides a source of complement. This assay is sensitive but very high immune complex levels are recorded spuriously when antilymphocyte antibodies, found frequently in sera from patients with systemic lupus erythematosus, bind to the cell membrane.

Rheumatoid factor inhibition assay

This assay is based on the inhibition by immune complexes of the binding of radiolabelled rheumatoid factor to plastic wells which have been coated with immunoglobulin. The degree of inhibition achieved with the test sample is compared with that obtained by dilutions of a standard preparation of aggregated IgG. This assay is very sensitive, can detect IgG complexes as small as 8S, and is independent of the complement fixing properties of the immune complex. Disadvantages associated with this technique are the fact that it is influenced by high concentrations of monomeric IgG, it can only detect those immune complexes which contain IgG, and the presence of rheumatoid factor in the test sample may produce a false-positive result (Luthra *et al*. 1975).

Conglutinin binding assay

The binding of conglutinin to immune complexes is complement and calcium dependent and is specific for the inactivated form of C3, C3bi. Conversion of immune complex bound C3b to C3bi occurs very rapidly *in vivo* and a subsequent degradation of the C3bi molecule to C3c and C3d leads to loss of binding of the immune complex with conglutinin. The assay is performed by placing the test sera in plastic plates which have been coated with bovine conglutinin and determining the amount of bound IgG with a radiolabelled anti-IgG antibody. Aggregated human immunoglobulin incubated with normal human serum is used as a standard. The advantages of this assay are its specificity, the relatively simple technology involved, and the stability of the conglutinin at 4°C. Disadvantages are its preferential reactivity with large immune complexes and, given the specificity of the conglutinin, reactivity with immune complexes is lost following the degradation of the C3bi *in vivo* (Casali *et al*. 1977).

The sensitivity, the causes of false-positive and false-negative results, and the advantages, disadvantages, and main areas of clinical use of these assays are summarized in Table 5 and Table 6.

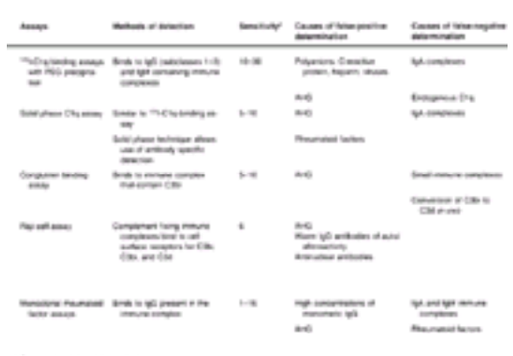

Table 5 Commonly used assays for detecting immune complexes

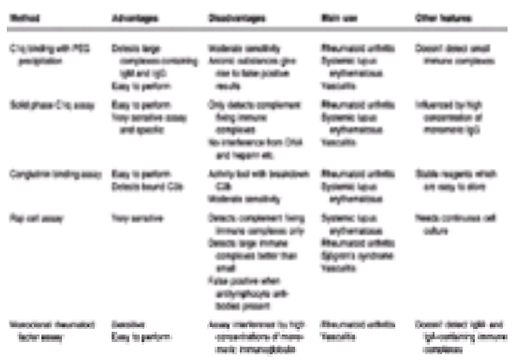

Table 6 Commonly used assays for detecting immune complexes

Problems associated with the use of antigen non-specific methods for detecting immune complexes

Specificity

There is no reagent which is capable of detecting all types of immune complexes. C1q reacts mainly with the complement-fixing IgG and IgM complexes whereas rheumatoid factor reacts only with IgG complexes, both complement fixing and non-complement fixing. Conglutinin and the Raji cells react only with complement-fixing immune complexes. In some instances the reactivity of the reagent may be transient, immune complex bound C3b is cleaved to produce C3bi thereby conferring reactivity with conglutinin, further degredation, however, results in the cleavage to C3c and C3d with subsequent loss of conglutinin binding activity. In general reagents that react with complement-fixing immune complexes will react more effectively with the large immune complexes that are more efficient activators of the complement system. Rheumatoid factor will react with immune complex as small as 8S.

Interfering substances

None of these methods differentiate antigen–antibody complexes from non-specifically aggregated immunoglobulin generated during sample collection or storage. A general problem with the use of biological reagents is that they have unknown or uncharacterized reactivities that give rise to false-positive results. C1q reacts with polyanions such as DNA, endotoxin, and heparin whilst some monoclonal rheumatoid factors used in the monoclonal rheumatoid factor binding assays cross-react with DNA. These assays are also subject to interference by endogenous rheumatoid factors that are present frequently in the sera of patients with autoimmune rheumatic disorders. The Raji cell assay reacts with both antilymphocyte antibodies and with certain antinuclear antibodies, the latter reaction being due to the presence of small quantities of DNA on the cell membrane. Assays which employ polyclonal rheumatoid factors are also prone to interference by the rheumatoid factors frequently present in the patients' sera.

A number of substances present in normal sera can also interfere with the immune complex assays. The greater reactivity of both C1q and rheumatoid factor reagents with aggregated IgG compared with monomeric IgG has been shown to be relative when quantitative assays are used. High concentrations of monomeric IgG will, therefore, interfere to varying degrees with several assays, and in EDTA-treated sera endogenous C1q interferes with the radiolabelled C1q in the C1q binding assay.

Standardization

Another general problem associated with these assays is that they are only semiquantitative; in addition to quantity, the size range of the immune complex will determine the extent of its reactivity. Therefore, expressing the results of a reference curve gives only relative results which differ with each assay and standard curve. The use of heat-aggregated IgG as a standard which is then used to quantify immune complex in pathological sera introduces additional variability into comparative studies of different assays. Since heat-aggregated immunoglobulin contains a heterogeneous population of aggregates, some of these will be detected preferentially by some assays. The variation in the shape of the standard curves obtained with a single heat-aggregated preparation renders assessment of the concentration of immune complexes in pathological sera somewhat imprecise. Additional practical problems involve the availability and stability of the biological reagents used, in particular the Raji cell assay requires the maintenance of living cell lines.

Manipulation of samples

In order to minimize the possibility of introducing artefacts, serum should be allowed to clot for 2 h without cooling in order to prevent the cryoprecipitation of some immune complexs. Samples ideally should be kept frozen, if possible at –70°C, and repeated freezing and thawing should be avoided. Use of heparinized plasma samples should be avoided.

Removing rheumatoid factor reactivity by immunoabsorbance by preincubation of the sample with IgG is to be avoided since it may partially deplete immune complexes or change the immune complex structure. For all tests performed on living cells toxic preservatives should be avoided.

Finally, because all antigen non-specific methods for detecting immune complexes are indirect, controlled experiments are necessary whenever immune complexes are demonstrated in new clinical disease. These should include the characterization of the size of the immune complex; fractionation in physical or chemical conditions known to dissociate immune complexes, thereby decreasing their size and biological activity; and confirmation that the assay becomes negative after removal of immunoglobulins from the test sample or after treatment known to alter the biological properties of immune complexes (e.g. reduction and alkylation).

Immune complexes in the rheumatic diseases

For the majority of the diseases listed in Table 7, many do not have the typical clinical manifestations which are associated with the tissue deposition of immune complexes. Most studies have simply demonstrated a positive result in one or more of the antigen non-specific immune complex assays. There have been, however, more detailed studies on systemic lupus erythematosus, rheumatoid arthritis, and the rheumatic syndromes associated with hepatitis B antigen. In addition some notable findings have emerged from more limited studies in patients with Lyme arthritis and vasculitis. Several comprehensive reviews of this subject are available (Williams 1981; Van Es *et al.* 1984; Virella 1990).

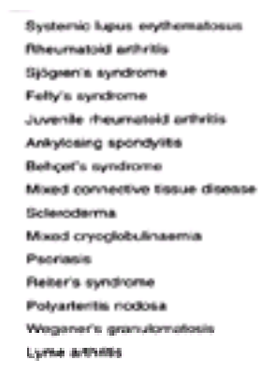

Table 7 Rheumatic diseases in which circulating immune complexes have been detected

Rheumatoid arthritis

Rheumatoid arthritis is a systemic disease characterized by a symmetrical erosive polyarthritis associated with the presence of IgM and IgG rheumatoid factor in the serum. The main antigenic site for activity of rheumatoid factor is the Fc portion of IgG, these molecules being able to form immune complexes in serum and synovial fluid either by self association or by interacting with monomeric IgG. These immune complexes are involved in the pathogenesis of the synovial lesions in rheumatoid arthritis. Synovial fluid from patients with rheumatoid arthritis frequently contains immune complexes composed of IgG–IgM rheumatoid factor and IgG–IgG rheumatoid factor which reacts strongly with C1q and IgM in the rheumatoid factor binding assay. The high molecular-weight complexes consist mainly of self-associating IgG rheumatoid factor, the intermediate-size immune complexes of monomeric IgG and IgG rheumatoid factor, while the 22S complexes demonstrated in serum consist of IgM rheumatoid factor bound to IgG.

Cryoglobulins containing either IgM or IgG rheumatoid factor are present in serum from patients with rheumatoid arthritis, particularly those with extra-articular disease. Levels are elevated in patients with severe rheumatoid arthritis and the frequency of cryoglobulinaemia exceeds 70 per cent in patients with extra-articular disease features which include nodules, digital vasculitis, rash, neuropathy, lung disease, and scleritis. Cryoglobulins are absent in patients with joint disease alone.

Cryoglobulinaemia is therefore a useful correlate of extra-articular disease and serves to define a group of patients in whom the morbidity and mortality are higher.

A variety of immune complex assays have been evaluated in a multicentre study, and of these six appear particularly effective in detecting the immune complexes present in sera from patients with rheumatic disease. These differences are highlighted in Table 8, which shows considerable variations in the degree of positivity recorded with the various assays in rheumatoid sera (Lambert *et al*. 1978). The fluid phase C1q binding assay and the Raji cell assay detect immune complexes much more frequently than the solid phase C1q, the monoclonal rheumatoid factor binding, and the conglutin binding assays. The lack of concordance between the three assays may be explained on the basis that the reactivity of rheumatoid sera is dependent on the function of both aggregate size and concentration. IgG aggregates of a defined size behave differently upon dilution in the three assays whereas IgG aggregates of similar size behave differently upon dilution in any one particular assay. The C1q binding, the monoclonal rheumatoid factor, and the Raji cell assays exhibit a high prevalence of positive results in both the synovial fluid and serum obtained from patients with rheumatoid arthritis. All studies which involve a comparison between serum and synovial fluid levels show higher concentrations of immune complexes in synovial fluid (Zubler *et al*. 1976b).

Data obtained from WHO collaborative study (WHO/IUIS Working Group 1981).

Table 8 Results of different immune complex tests in systemic lupus erythematosus and rheumatoid arthritis

The immune complex assay using monoclonal rheumatoid factor has shown a positive correlation between the presence of immune complexes and the anatomical stage and functional class of the disease (Luthra *et al*. 1975); C1q binding activity however correlates best with extra-articular disease features rather than the clinical stage of the disease (McDougal *et al*. 1982; McDougal and McDuffie 1991). Attempts to evaluate serum C1q binding activity with disease activity have produced variable results, positive correlations with disease activity being exhibited in only some studies.

Detecting immune complexes in the serum may however be helpful in the following situations.

1. In early arthritis, circulating immune complexes may be detected in serum several months before a definite diagnosis of rheumatoid arthritis can be made (Jones *et al*. 1981).
2. Circulating immune complexes are found in 70 per cent of sera from patients with seronegative rheumatoid arthritis and, therefore, their presence may help to distinguish seronegative rheumatoid arthritis from other seronegative arthropathies, e.g. Reiter's disease.

Carefully conducted prospective clinical studies show that indices which reflect the activity of the arthritis correlate with the fluid phase C1q binding assay (Nydegger *et al*. 1977). However, the correlation coefficient obtained was weaker than that from measuring the erythrocyte sedimentation rate. Some studies in which specimens were obtained serially from individual patients showed a correlation between C1q positivity and either the number of swollen joints or a composite joint index (Halla *et al*. 1979); many studies, however, emphasize the weak correlation existing between various immune complex assays and the systemic features of rheumatoid arthritis. Some therapies such as corticosteroids, slow acting antirheumatic agents (Forster and McConkey 1986), and cryofiltration (Krakauer *et al*. 1983) produce improvement in the clinical state and a parallel decline in the materials reacting in the various immune complex assays.

Systemic lupus erythematosus

The nature of the circulating immune complexes in the sera of patients with systemic lupus erythematosus has not been well defined, although occasionally immune complexes have been isolated and shown to contain both DNA and anti-DNA antibodies. Increased levels of circulating immune complexes generally correspond with active disease, high levels of antidouble-stranded DNA antibody, and reduced complement levels (Morrow *et al*. 1982). In a comparative study the highest frequency of immune complexes in the sera from patients with systemic lupus erythematosus was found using the Raji cell binding assay (91 per cent), the fluid phase C1q binding test (78 per cent), and platelet aggregation (74 per cent) (Lambert *et al*. 1978).

Clinical studies addressing the relationship between immune complexes and disease activity in systemic lupus erythematosus have produced conflicting results (Cano *et al*. 1977; Levinski *et al*. 1977; Inman *et al*. 1980; Lloyd and Schur 1981). In systemic lupus erythematosus no particular clinical disease manifestation has been found to correlate with the presence of antigen non-specific immune complexes detected using the solid phase C1q binding assay. Patients with lupus nephritis had a higher level of reactivity with the solid phase C1q binding assay if their renal disease was of the diffuse proliferative type rather than membraneous nephritis (Wener *et al*. 1987).

In systemic lupus erythematosus much uncertainty remains whether immune complex assays reflect changes in the activity of the disease. Even for a single assay, the fluid phase C1q binding assay, positive (Inman *et al*. 1980) and negative (Hamburger *et al*. 1982) correlations have been observed between disease activity and immune complex levels. The monoclonal rheumatoid factor binding assay shows a positive correlation with activity of extrarenal disease features of systemic lupus erythematosus, but no correlation could be shown between immune complex levels and renal function as defined by changes in the serum creatinine (Lloyd and Schur 1981). The role of immune complexes in inducing renal injury has been reviewed by Gauthier and Abrass (1992).

In a well-conducted prospective study (Abrass *et al*. 1980) using the solid phase C1q binding assay, immune complex levels were correlated with disease activity and the presence of nephritis and arthritis. In this study, changes in solid phase C1q binding predicted a change in disease activity leading to admittance to hospital or a change in medication. Changes in fluid phase C1q binding activity, anti-DNA antibody, and C3 levels were not predictive, however. Attempts at grouping features of the disease into cycles of activity and correlating either renal or extrarenal disease with the fluid phase C1q binding were unsuccessful. These authors concluded that the determination of C4 and CH50 levels were superior to the C1q binding activity in reflecting the evolving clinical course in patients with systemic lupus erythematosus. High levels of immune complexes, detected using the Raji cell assay, predicted the later development of lupus nephritis (Boyd *et al*. 1983).

Much disagreement remains, therefore, between immune complex levels and disease activity in systemic lupus erythematosus (see Inman 1982 for a review). Likely explanations include the use of different methods of immune complex detection, the retrospective nature of the studies, and the differing criteria adopted for patient selection. The introduction of bias into the study whereby patients with milder disease are excluded is an important factor. At present it seems premature to base therapeutic decisions on measurements of immune complex levels alone.

Other autoimmune rheumatic diseases

Sjögren's syndrome, mixed connective tissue disease, and vasculitis

Serum from patients with Sjögren's syndrome frequently contain immune complexes and these are best demonstrated using the C1q binding and the Raji cell assay (Lawley *et al*. 1979; Fishbach *et al*. 1980). The immune complex levels do not correlate with disease activity or the development of lymphoid infiltrates in organs (Lawley *et al*. 1979).

In patients with mixed connective tissue disease, circulating immune complexes have been found using the C1q binding, the Raji cell, and the monoclonal rheumatoid factor inhibition assays; approximately 81 to 90 per cent of the sera examined being positive with two assays and 65 per cent positive with one assay (Halla *et al*.

1979).

In patients with vasculitis the most useful test is the monoclonal rheumatoid factor binding assay. In patients with cutaneous vasculitis, the presence of fluid phase C1q binding activity was found to a far greater extent in the group with necrotizing vasculitis. In polyarteritis nodosa, the first report highlighted that up to 30 per cent of patients had circulating immune complexes containing hepatitis B antigen both in the circulation and tissue (Eye *et al*. 1977). Subsequent studies have shown a much lower incidence of hepatitis B antigen and many of the tests for immune complexes have been negative. Correlations between changing immune complex assay levels and the activity of the vasculitis are few in number, but in patients with necrotizing vasculitis the C1q binding and monoclonal rheumatoid factor assays appeared to predict changes in disease activity (Mackel *et al*. 1979). Changes in the above assays also parallel disease activity in patients with polyarteritis nodosa and Wegener's granulomatosis; effective therapy substantially diminished the frequency of positivity in the Raji cell assay but not the fluid phase C1q binding assay (Ronco *et al*. 1983). Other factors, however, may also contribute to the pathogenesis of vasculitis (reviewed by Smiley and Moore 1989).

Scleroderma

Approximately half of the patients with scleroderma have circulating immune complexes; patients with progressive systemic sclerosis have elevated serum immune complex levels when detected by the Raji cell assay. A positive assay result was more often associated with diffuse scleroderma, tendon friction rub, and positive antinuclear antibodies. Individual with immune complexes detected by the C1q binding test had a higher incidence of pulmonary involvement and were more likely to have rheumatoid factor present in their serum (Seiboid *et al*. 1982).

Juvenile rheumatoid arthritis

In this group, circulating immune complexes have been detected particularly in those patients whose disease was marked by systemic onset or polyarticular disease (Rossen *et al*. 1977).

Lyme arthritis

This disorder is characterized by a distinct skin legion, myalgia, and monoarticular or oligoarticular arthritis which can be transient, recurrent, or persistent. Almost all patients with Lyme arthritis have abnormally elevated C1q binding assays, but in those patients with skin lesions alone the positivity disappears as the rash resolves. A persistent positive result in the C1q binding assay is associated with neurological or cardiac complications, and persistent synovitis is associated with a high titre of C1q binding reactant in the synovial fluid. This association of persistent positivity in the C1q assay with neurological or cardiac complications is clinically useful information that is not provided by any other laboratory test (Hardin *et al*. 1979).

Clinical usefulness

The majority of the assays are antigen specific and, therefore, their diagnostic value is limited since the presence of immune complexes is not specific to any particular disease.

A single measurement in a given patient does not provide a good indicator of the clinical activity of the disease in patients with either systemic lupus erythematosus or rheumatoid arthritis. However, in suspected but not definite rheumatoid arthritis, the absence of immune complexes may be of diagnostic value in ruling out this disease, provided that the test used is of high sensitivity. Despite much published work on correlations between immune complex levels and disease activity, considerable uncertainty remains of the clinical usefulness of these assays. Although correlations are found in patients with rheumatoid arthritis between clinical activity and serum measurements of immune complex levels, these correlations are often weak and are dependent on the assay used. Patients with more severe extra-articular disease do however have higher levels, often with cryoglobulinaemia, in their sera. Resolution of the disease activity following the introduction of therapy is usually associated with a progressive decrease in immune complex levels. The finding of a raised level of immune complexes in a given patient, however, does not have any predictive value as to the type of disease that patient will subsequently develop. In patients with systemic lupus erythematosus there does continue to be a role for some of the immune complex assays, such as the solid phase C1q binding assay in conjunction with measurements of complement and anti-DNA antibody levels in assessing and predicting disease activity.

There is no ideal assay to measure immune complex levels in sera and in most clinical situations the correlations between the different techniques are poor. It would be advantageous therefore to use several assays, preferably those that depend on different principles for the identification of complexes in the circulation. The failure to demonstrate significant advantages of these techniques over simple measures of disease activity, such as the erythrocyte sedimentation rate, has lead to a limitation of their use in clinical laboratory practice. If used, the results obtained must be interpreted cautiously because of the number of interfering substances that are present in the sera or may be generated *in vitro*.

4.9.1 Imaging in adults

Peter Renton

Introduction

It is the aim of this chapter to provide a general overview of techniques currently available for the imaging of the musculoskeletal system. Changes in individual diseases will be described in the appropriate sections.

Radiology has undergone a major technological revolution in this generation and new methods of imaging are now available (Table 1). These are generally expensive and time-consuming. Investigations have to be tailored to the individual needs of the patient. Radiologists and clinicians have to work together to ensure that the needs of all are best matched.

Plain films
Linear tomography
Arthrography
Computed tomography (CT) scanning
Radionuclide scanning, including DEXA (bone densitometry)
Ultrasonography
Magnetic resonance (MR) imaging

Table 1 Radiological investigative techniques

Plain radiography

Conventional radiology is available generally and is usually the first imaging technique used. Changes in film and X-ray technology have occurred in recent years, often to the detriment of image quality. Faster films, rapid automatic processing, the use of rare earth screens, and ultimately the move away from analogue to digital imaging have not necessarily meant an improvement in image quality, but a lower radiation dose.

Plain film images of bones and joints are usually obtained in two planes. For many joints, e.g. the knee, this will mean at least an anteroposterior and lateral radiograph; for some joints, however, an oblique view is necessary, e.g. at the hip, as the lateral view of the pelvis superimposes the two hip joints.

Plain film imaging of soft tissues

Soft tissue swelling is an unfailing indicator of underlying musculoskeletal disease. It should always be searched for, especially in the target areas. It follows that images must be correctly exposed for both bone and soft tissue. Digital imaging allows operator control of these factors.

Soft tissue swelling is seen as an increase in width over involved bones or joints, i.e. over the ulnar styloid (Fig. 1) or over the 5th or 1st metatarsal head. The thickened soft tissues are also radiologically denser and, therefore, the involved area looks 'greyer' and the underlying bone detail is less well seen, as it is 'filtered' by the soft tissue thickening. Comparison can be made with an unaffected or normal joint.

Fig. 1 Rheumatoid arthritis. Soft tissue swelling over the right ulnar styloid.

If a swollen joint is not at a margin but more centrally situated, e.g. the 2nd to 4th metatarsophalangeal joint, then a general increase in density is seen together with alteration of local contours. Filling in of web spaces in between fingers, which become convex rather than concave, or similar soft tissue swelling over metatarsal heads projecting over basal phalanges may be seen.

Fat planes overlie joints and separate muscle bundles. They are seen on radiographs as fat is of lesser density and attenuates the beam less than muscle. Displacement of fat planes is an indicator of muscle thickening, oedema, or haemorrhage or, conversely, muscle atrophy. Joint effusions also displace overlying fat lines (Fig. 2).

Fig. 2 Rheumatoid arthritis. Pathological fracture through a large cyst is associated with elevation of the anterior fat pad (sail sign).

Plain film changes with soft tissue thickening and fat plane displacement

Skull

These changes occur following trauma, over fractures, and at sites of foreign bodies. They may be found in the paranasal air sinuses with trauma, infection, or tumour.

Cervical spine

On a lateral view of the cervical spine, the retropharyngeal soft tissues are applied closely to the anterior aspect of the upper four cervical vertebral bodies. Below C4 the tracheal translucency is situated around 1 cm anterior to the cervical spine. Air is seen occasionally in the oesophagus, and an anterior cervical fat stripe may also be present. Soft tissue thickening following infection, trauma, or malignancy is demonstrated by displacement of the air shadows (Fig. 3).

Fig. 3 Pathological collapse of the body of C2 with an associated large anterior soft tissue mass. The destructive lesion in this 27-year-old male was a chordoma.

Thoracic spine

In the thoracic region, soft tissues closely approximate to the vertebral bodies and are well demonstrated on a correctly exposed anteroposterior view. These are best seen on the left, are mainly pleural, and are separate from the descending aorta. These paraspinal lines are displaced by osteophytes and syndesmophytes but especially by bleeding in malignancy, trauma, infection, etc. Generally, the widest point of the soft tissue swelling lies at the site of maximal skeletal change (Fig. 4).

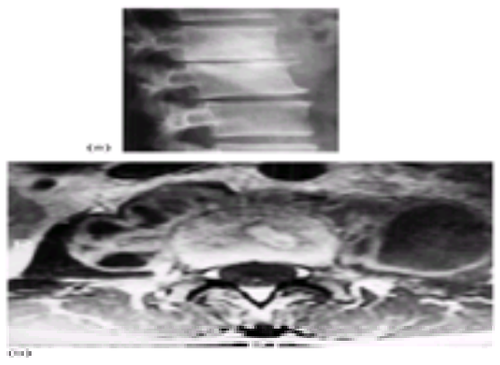

Fig. 4 Paraspinal soft tissue mass in spinal tuberculosis. (a) The radiograph demonstrates narrowing of an upper lumbar disc space with reversal of the curve. There is destruction of the adjacent end-plates with reactive new bone formation anteriorly, and a soft tissue mass is demonstrated anterior to the affected disc. (b) The axial MR images demonstrate not only the erosive destruction of the vertebral body but also psoas abscesses. The images are obtained after intravenous gadolinium and show both areas of enhancement and necrosis in the psoas muscles as well as anteriorly in the retroaortic tissues.

Lumbar spine

In the lumbar region the spine is not surrounded by air, but by soft tissues. Nonetheless, masses can still be assessed by inspection of the psoas and its overlying fat plane on an anteroposterior view, and by displacement of gut gas shadows on the lateral view. Similarly, sacral disease displaces the rectal gas shadow.

Shoulder

The axillary recess of the joint can be assessed on a plain radiograph and effusion diagnosed. Similarly, a large subdeltoid bursal effusion or, conversely, deltoid atrophy may also be assessed (Fig. 5).

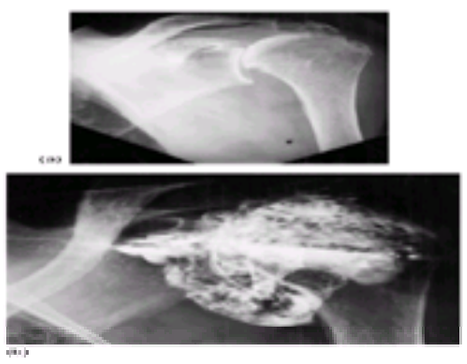

Fig. 5 Rheumatoid arthritis with a large effusion which can be seen on the plain film. (a) Upward subluxation of the humeral head is associated with marginal erosions, as well as erosion of the under surface of the acromion. The displaced fat plane beneath the glenoid and humeral head is seen on the subsequent arthrogram to represent the margin of the distended capsule. (b) A rotator cuff tear is demonstrated at arthrography with filling of the subacromial bursa. The distended joint capsule is demonstrated, especially inferiorly. Numerous loose bodies lie within the joint space. These may represent areas of synovial proliferation or osteochondral fragments but, in the main, represent fibrinous loose bodies.

Elbow

Anterior and posterior fat pads lie on the synovium and are usually just visible on the lateral radiograph. This is taken with the arm in the flexed position. Under these circumstances, the posterior fat pad is pressed inwards by the triceps tendon while the anterior capsule and fat pad are redundant. Effusions elevate the anterior fat pad more easily, therefore, than the posterior (Fig. 2). A 'sail' sign results, and is suggestive of a fracture given a history of trauma, especially if the posterior fat plane is elevated; this only happens with larger quantities of fluid.

Wrist

There are numerous bursae and tendons around the wrist. The tendons are surrounded by synovial sheaths. The wrist joint itself is a complex multicompartmental structure. Soft tissue swelling may occur at many sites (Fig. 1). These should be actively searched for in the arthritides, for instance, over radial and ulnar styloids. The lateral view should also be inspected. Pronator quadratus muscle lies on the palmar aspect of the distal radius and ulna, and a fat plane lies on it. Trauma to the distal radius or ulna elevates this fat pad, which assumes an abnormal convex palmar appearance (Fig. 6). Similarly, soft tissue swelling may be seen over interphalangeal joints, and especially at distal interphalangeal joints in cases of osteoarthritis, and over the dorsum of the carpus.

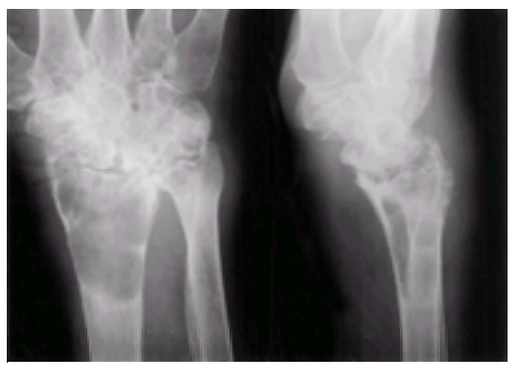

Fig. 6 Displacement of pronator quadratus. On the lateral view there is diffuse soft tissue swelling over the wrist in this patient with severe rheumatoid arthritis. The fat plane over pronator quadratus is displaced in a palmar direction over the large cyst in the distal radius.

Pelvis and hips

The acetabulum is difficult to visualize in a conventional anteroposterior film. For this reason, 45°-oblique views are needed to demonstrate the anterior and posterior pillars satisfactorily (Judet views). The obturator internus lies just inside the acetabulum and the fat line internal to it is seen as a thin stripe lying on, and parallel to, the iliopectineal line. Trauma to the acetabulum, malignant disease, or cortical bone destruction elevates the fat pad (Fig. 7).

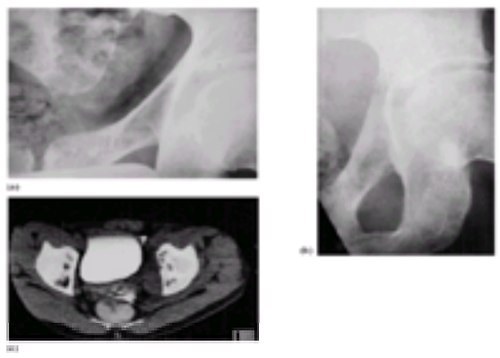

Fig. 7 (a) The initial radiograph shows early displacement of the fat pad over obturator internus. (b) Subsequent images of this region, including a CT scan (c), show progressive enlargement of this soft tissue mass with destruction of the overlying bone due to a reticulum cell sarcoma.

An effusion in the hip joint also displaces two commonly seen fat pads round the medial and lateral aspects of the femoral neck and, in the case of a monarthritis, comparison can be made with the normal side.

Knee

The suprapatellar pouch is seen in the undistended state arising almost vertically from the patellofemoral joint space. It is a thin (2 to 3 mm) parallel-walled or rectangular structure surrounded by fat. With progressive distension, it enlarges to a lentiform shape of soft tissue density surrounded by fat. On the anteroposterior view, fat planes lying on the synovium are projected on either side of the distal femur, concave outward and parallel to the distal femoral contour. With an effusion, these are displaced progressively laterally.

Ankle

Both malleoli lie directly subcutaneously. Bony trauma causes soft tissue swelling more proximally than damage to the collateral ligaments, which is associated with swelling distally.

Joint effusions are demonstrated on the lateral view. Anterior and posterior soft tissue masses project from the joint space and are seen as soft tissue densities, especially posteriorly where they project into the fatty triangle bounded by tendo-Achillis, calcaneus, and posterior tibia (Kager's triangle).

Behind this triangle lies the Achilles tendon, which inserts into the posterior aspect of the calcaneus, some 2 to 3 mm beneath its upper angle. Between tendon and bone lies a small, normally non-visualized bursa. The tendon is some 6 mm thick at the insertion, and sharply defined anteriorly and posteriorly by overlying fat. In the presence of Achilles tendinitis or posterior calcaneal erosive disease, the distal tendon thickens and its insertion, being oedematous, becomes poorly defined. The retrocalcaneal bursa enlarges, first fills the space known as the retrocalcaneal recess, then further encroaches into Kager's triangle (Fig. 8).

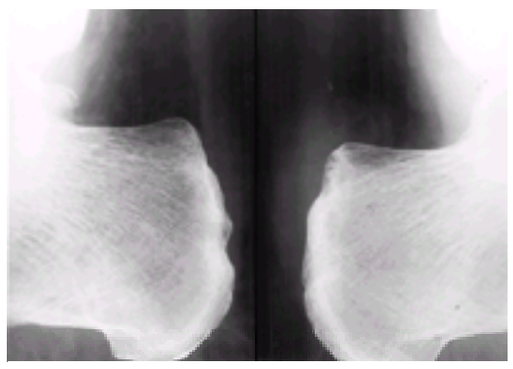

Fig. 8 Rheumatoid arthritis. Thickening of the retrocalcaneal bursa at the junction of tendo-Achillis and the calcaneus. A diffuse soft tissue mass protrudes into Kager's triangle.

Foot

Changes at the metatarsal heads mirror those seen in the hands. Early on in an erosive arthritis, therefore, particular attention should be paid to the soft tissues over the metatarsal heads.

Arthrography

The injection of contrast into joints has been in use for many years prior to the advent of image intensification. Knee arthrography was reported as early as 1904. Lindblom (1939) performed shoulder arthrography using Myodil by a technique of direct injection of the joint from above.

In the recent past the major use of arthrography has been in the knee, to demonstrate meniscal tears. In experienced hands, arthrography is as accurate as arthroscopy in the diagnosis of meniscal lesions (Table 2(a)) and probably more accurate in the diagnosis of lesions of the posterior horn of the medial meniscus. Arthroscopy is much more accurate, however, in assessing the status of the cruciate ligaments (Thijn 1982), even if intra-articular adrenaline (to diminish dilution of contrast by effusion) and linear tomography are used (Table 2(b)) (Ng *et al*. 1989).

	Arthrography (%)	Arthroscopy (%)
Medical meniscus	94	81
Lateral meniscus	90	94.5
Patellar chondropathy	55	99.5
Cruciate ligament lesions	69	97

After Thijn (1982).

Table 2a Comparison of accuracy rates

	Arthrography (%)	Arthroscopy (%)
Correct	69	97
Equivocal	1	3
False positive	12	0
False negative	18	0

After Thijn (1982)

Table 2b Accuracy of arthrography and arthroscopy for cruciate ligament rupture

In the shoulder, arthrography is mainly used to diagnose rotator cuff tears and restrictive capsulitis—tasks for which the examination is admirably suited, being cheap, quick, and requiring no particular expertise or expensive equipment (Fig. 5).

Both of these examinations, and possibly arthroscopy, are becoming extinct owing to the advent of magnetic resonance imaging (**MRI**). Indeed, our younger radiologists now never even see enough arthrograms to be trained adequately to perform them in the future.

Similarly, the use of arthrography of the temporomandibular joint to display the meniscus, and of the wrist to assess the triangular cartilage, is also in decline.

CT scanning

This technique uses X-rays to obtain axial images of the body in serial slices. The technique is therefore a tomographic one and because the attenuated beam, having passed through the patient, is detected and analysed by computer a much wider grey scale is available on the computer-based reconstructions than on X-ray film.

Axial tomography not only enables spatial relationships to be obtained in the sagittal and coronal planes simultaneously, but allows densities to be assessed visually and also directly from the computer, measured in Hounsfield units.

Enhancement with intravenous water-soluble iodine-based contrast media further opacifies vascular tissues, enhancing their intrinsic differences. This is especially the case with vascular tumours and infections while, conversely, avascular lesions do not enhance.

Using a radiographic technique, therefore, it is possible to differentiate between fat (which shows low attenuation), serous fluid, and blood, and between muscle and cortical and medullary bone.

Radionuclide scanning

Until the advent of MRI, isotope scanning was the most accurate method of demonstrating the presence of pathological change in bones and joints (Fig. 9). Even so, it seems to have been underused and plain films were, and still are, the basic diagnostic imaging tool. Technetium-99m phosphate images demonstrate increased blood flow to inflamed synovium in the early or vascular phase of the scan and, on delayed images obtained 3 h after injection, increased uptake is demonstrated at sites of increased bone turnover due to isotope deposition on hydroxyapatite crystals.

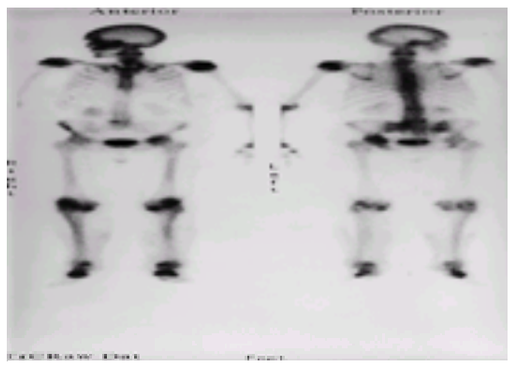

Fig. 9 Rheumatoid arthritis. Radioisotope bone scan showing increase in uptake in both shoulder joints, the left hip, both knees, and the hindfeet. (By courtesy of Dr A. Hilson, Royal Free Hospital.)

Radioisotope scanning is an invasive technique which, of course, depends on radioactivity—unlike MRI—and while there is good sensitivity, there is poor specificity for individual diseases. In one study, technetium-99m phosphate imaging was 11 per cent more sensitive than clinical examination and 72 per cent more sensitive than conventional radiographs. Similarly, early and persistently positive scans are a good prognosticator for subsequent erosive change, but chronic inactive erosions may often be negative at phosphate scanning (Rosenthall 1991). Spatial discrimination has been improved by use of **SPECT** (single photon emission computed tomography) imaging. The various arthropathies can only be distinguished by the distribution of the abnormal foci of increase in uptake.

Measurement of bone density

It is recognized that up to 50 per cent of bone mineral in a given area must be lost before being radiologically visible on plain films. In addition, subjectivity results in observer variation. Early methods for assessing bone density included photographic densitometry, an aluminium wedge being included on the film, or a cadaver metacarpal matched for age and sex. Images of the hand could also be used to measure cortical thickness in the metacarpal, and resorption of the cortex gives an indication of demineralization.

Unfortunately, there is poor correlation between bone mineralization in the axial and appendicular skeleton, as the hands and feet are subject to external influences—osteoarthritis at the wrist or body weight at the foot.

CT scanning can be used to assess bone density, especially in the spine, by comparing attenuation of single or dual energy CT beams with attenuation by phantoms which may be scanned simultaneously or separately. This technique does involve irradiation, especially superficially.

Photon absorptiometry

This uses a single source of photon energy through the radius or calcaneus, and absorption of the isotope by bone is compared with that in adjacent soft tissues.

Dual photon densitometry

This utilizes photons of two energies from a single isotope (gadolinium-153). The results are independent of thickness of local soft tissues (whereas single photon

absorptiometry requires a uniform thickness of soft tissue over the bony part being investigated). Radiation dose is relatively low and double photon absorptiometry is in particular accurate, with only 2 to 3 per cent error. Double photon absorptiometry enables both central and peripheral bone to be assessed.

Quantitative dual energy radiography (X-ray absorptiometry; DEXA)

This technique uses an X-ray tube rather than an isotope as the source, which results in greater resolution and speed of investigation (Sartoris and Resnick 1990). The X-ray source provides a beam alternating between two energies. The beam is finely collimated and also passes through a disc containing attenuating materials, used as a reference. A ratio of attenuation is given. This is now the technique of choice as it is precise, scanning time is short, and radiation dose low. Accurate measurements are taken most commonly from the lumbar spine and proximal femur and results are usually expressed in terms of the number of standard deviations above or below the mean of an age-related control population (Z-score) or of a young healthy adult population (T-score) (Fig. 10).

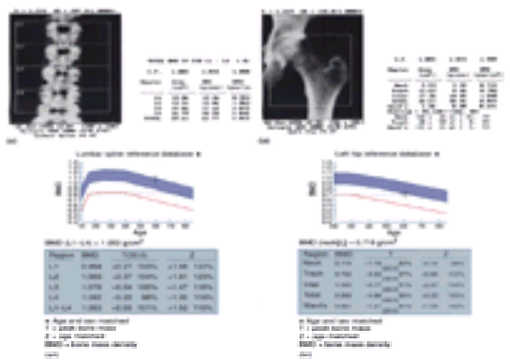

Fig. 10 (a) DEXA scan of lumbar spine. The scan shows an increase in density in the lumbar spine above the expected norm for the age, but this is probably because of the presence of osteophytes in degenerative disease; (b) further imaging of the neck of femur, however, shows the patient to lie exactly on the predicted value for bone density at her age.

Ultrasonography

Diagnostic ultrasound utilizes sound frequencies above those audible to the human ear, i.e. 20 000 cycles per second (Hertz). Frequencies in use clinically range from 2 to 10 MHz.

Ultrasound waves are generated by a piezoelectric crystal in the usually hand-held transducer, which both transmits the sound waves and receives back the resultant echoes. The returning signal impinges upon the crystal which converts the attenuated sound waves into electronic impulses, processed via a computer.

Images are displayed on a screen, film, or paper using a grey scale, or colour to show venous/arterial flow, or a combination of both. Real-time imaging allows dynamic continuous scanning of body parts. Linear images can be obtained in any plane of the body (Van Holsbeeck and Introcaso 1991).

Images obtained depend on the following:

1. The frequency of the ultrasound. The higher the frequency, the better is the resolution of the images, but the penetration of the body by sound waves is limited.
2. The nature of the tissues into which the sound waves must pass. Bone is totally refractory to sound waves (as is air) and so deep structures in joints are inaccessible. At the knee, therefore, the superficial ligaments and tendons are well imaged, as are the superficial parts of the menisci, but not the deep structures (Fig. 11).

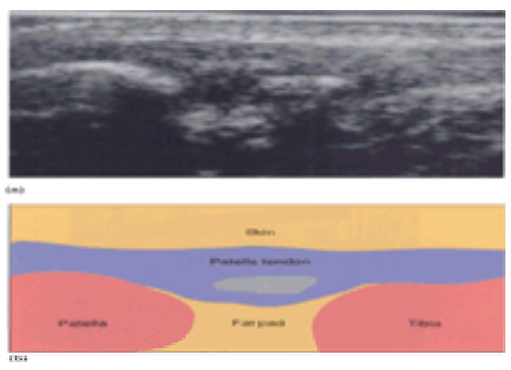

Fig. 11 Calcific tendinitis in a 27-year-old chauffeur with pain in his knee. Ultrasound of the patellar tendon shows a thickened proximal part with a hypoechoic area inferiorly. A large focus of calcium is seen. (By courtesy of Dr S. Burnett, St Mary's Hospital.)

3. The angle of incidence of the beam. Sound waves pass through matter and the speed of sound in a tissue varies with the nature of the tissue, materials of the greatest density transmitting sound at the highest velocity. Sound is also reflected at tissue interfaces, while the amount of reflected sound also depends on the angle of incidence of the beam, the least reflection occurs with a beam which is at right angles to the reflecting surface (Van Holsbeeck and Introcaso 1991). The returning pulses of sound characterize the tissues and tissue interfaces. A cyst is echo-free, calculi cast an acoustic shadow, and soft tissues show numerous interfaces, giving a complex but regular pattern if normal and a more irregular pattern in the presence of disease.

Ultrasound is thus used in:

1. joint disease to show effusions, intra-articular loose bodies or other structures, and the capsule and synovium;
2. surrounding ligaments and tendons;
3. muscles, tears, haematomas, and tumours;
4. vascular lesions—arterial and venous flow using Doppler.

It is not used in the diagnosis of bone disease.

The shoulder region is thus much more amenable to ultrasound investigation than the knee, as the rotator cuff is more accessible to the ultrasonic waves (Fig. 12).

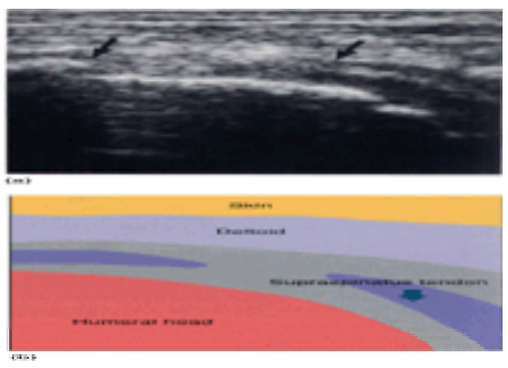

Fig. 12 Rotator cuff tear in a 56-year-old woman who fell off her horse. The free ends of the supraspinatus tendon (arrows) are seen deep to the deltoid. (By courtesy of Dr S. Burnett, St Mary's Hospital.)

Magnetic resonance imaging (MRI)

MRI does not involve ionizing radiation, but utilizes the different biophysical properties of the various constituents of the body tissues, especially the number of hydrogen nuclei or protons in a given tissue. MR images reflect the distribution of these nuclei. Grey scale changes on film reflect the number of protons in a given tissue, and reflect their behaviour in the externally applied magnetic fields.

These field strengths are generally between 0.5 and 1.5 T (Tesla). Such field strengths cause the hydrogen nuclei to precess or gyrate at frequencies in the range of radiowaves or radiofrequency (**RF**).

RF stimulation (i) excites protons and (ii) also brings them into phase with each other. Once the RF pulse is turned off, the system returns to normal. The protons return to a low energy state. A measure of the time taken for dephasing to occur is the T_2 (or transverse relaxation time) and the T_1 (or longitudinal relaxation time) is that taken for the protons to re-establish their equilibrium (Nixon 1987).

In most cases, the sequences used are simple T_1- and T_2-weightings. In T_1-weighted images fat is bright, fluid is grey, and bone is black. With T_2-weighted images, fat is less bright, fluid is very bright, and bone is black.

Fat suppression **STIR** (short tau inversion recovery) sequences cause the bright signal from fat to be suppressed completely. Muscle is therefore a more homogeneous grey (as the internal fat is black). Fat, and fatty marrow, is black. Fluid, however, remains very bright and so oedema, vascular tumours, fluid collections, and veins stand out clearly from the surrounding suppressed bone, muscle, and fat. Avascular and necrotic tissues are also black (i.e. of low signal) (Fig. 13).

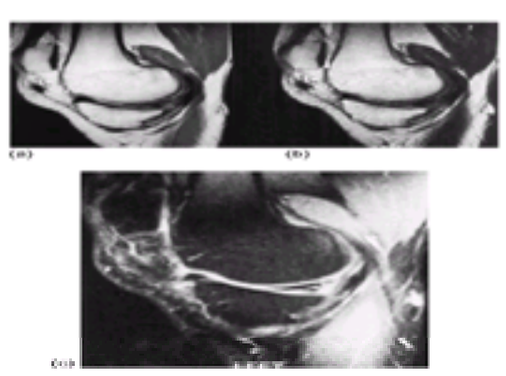

Fig. 13 Meniscal tears demonstrated with (a) T_1-, (b) T_2- and (c) STIR weightings. The STIR weighting has the added advantage of graphically demonstrating cystic change or oedema in the adjacent bone much more clearly than the other modes.

It should be noted that primary images can be obtained in any plane.

Fluid, fat, and medullary bone have the highest concentration of protons and, therefore, the signal from these structures is brightest, while those from cortical bone, tendon, ligaments, and menisci are lowest. Signal is also altered by disease, so that oedema, inflammation, or haemorrhage all cause local increase in signal. Cell death, however, decreases signal, as does calcification.

MRI is becoming the investigation of choice for the musculoskeletal system. It enables primary, not reformatted, images to be obtained in all planes, is non-invasive, and does not use ionizing radiation. Inherent differences in structure of the body tissues result in greater differences in grey-scale contrast than are obtainable by any other imaging technique.

Muscles, tendons, ligaments, fat, blood vessels, and marrow all have distinguishing features which can be manipulated further by using different weightings (Table 3). Cortical images are probably better obtained by using X-rays, however, either by conventional radiography or CT scanning.

Signal intensity	Tissue
Highest (white)	Fat Medullary bone
Grey	Articular cartilage
Intermediate intensity	Muscle
Low intensity (black)	Blood vessels* Ligaments, tendons Menisci Cortical bone

Reproduced from Benjuist, T. H. (1987). In *Magnetic resonance of the musculoskeletal system* (ed. T. H. Benjuist), by kind permission of the author and Raven Press.
*Normally flowing blood gives no signal. The appearance of vessels may vary with changes in flow and multiecho sequences.

Table 3 Signal intensity of musculoskeletal tissue

MR images the bone marrow well, especially fatty marrow. Fat generally gives a bright image both on T_1- and T_2-weighted sequences, but is suppressed, i.e. of low signal intensity, on STIR fat suppression sequences. Fluid, oedema, or inflammatory changes are bright on T_2-weighting and on fat suppression sequences, but approximate to muscle signal on T_1-weighted images. Changes in marrow due to oedema or inflammation are thus of reduced signal on T_1-weighting and increased signal on T_2-weighted and STIR sequences. Tumours, too, primary and secondary, alter the signal from marrow, and their extent can be assessed as well as other

features such as central necrosis or matrix mineralization, though this latter feature is also best assessed by X-ray (Table 4).

Disease process	T_1	T_2
Inflammation	Increased	Increased
Neoplasia	Increased	Increased
Fibrosis	–	Decreased
Fatty infiltration	Decreased	–
Interstitial haemorrhage	Increased	Increased

Table 4 General trend of relaxation time changes for some musculoskeletal disease processes

MR scanning is not inevitably successful and may be stressful to the patient. Older scanners were somewhat restricting, the patient being closely confined in a dark and noisy environment, leading to a patient rejection rate of around 2 per cent and also to degradation of images due to patient movement.

Sedation is rarely necessary in adolescents and adults. Intravenous sedation needs to be performed in an environment where the patient can be monitored. Non-ferromagnetic anaesthetic and resuscitation equipment is not inevitably available. Modern scanners are more open, or totally so, and are thus more likely to lead to a successful scan.

Before scanning, the presence of ferromagnetic and electric implants should be excluded. Metallic implants cause artefacts due to signal void or, on occasion, marked hyperintensity. Ferromagnetic implants cause a greater artefact than non-ferromagnetic, and are seen as an irregular area of low signal in and around the implant. Non-ferromagnetic implants may be associated with signal void, which does not significantly impair image quality. Larger field strength magnets also cause a larger artefact. A low signal artefact is thus seen to be due to both the presence of the metal itself and the surrounding effect on the magnetic field.

Pacemakers may be affected by the magnetic field and their presence creates image degradation. The pacemaker may move and pacemaker function may be interfered with. Current may be induced in leads sufficient to induce fibrillation or burns. Prosthetic heart valves are not generally a contraindication to MR scanning.

Ferromagnetic surgical clips can move in a magnetic field and their presence in a vulnerable situation, e.g. at an aneurysm, is a contraindication to MR scanning. Similarly, cochlear implants may be ferromagnetic. Some cochlear implants are held in place by magnets; others may be electronically activated. MRI should not be performed on these patients. Copper IUCDs are not ferromagnetic and are safely included in a scan.

Skin and body temperature are not increased by MRI but conductive materials may be heated and currents induced in leads resulting in burns.

Patients should also be screened for the presence of metallic foreign bodies, such as shrapnel, pellets, or bullets. It is often not possible to say whether pellets, bullets, or shrapnel are ferromagnetic. Movement may cause damage to adjacent vital structures. Blindness may result if intraocular metal fragments are displaced by the magnetic field. Metal workers should have radiographs of the orbit performed prior to MRI (Berquist 1991).

Imaging in rheumatoid arthritis

In patients with rheumatoid arthritis it is recognized that disease is often first seen in the feet rather than in the hands (Fletcher and Rowley 1952; Thould and Simon 1966; Brook and Corbett 1977). Erosions are first described at the metatarsophalangeal joints, and most commonly at the 5th metatarsophalangeal joint. The metatarsal head is eroded before the adjacent phalangeal base. The attention of the radiologist should therefore be drawn to this region first in a patient suspected of having rheumatoid arthritis.

Resnick *et al*. (1977) have drawn our attention to the concept of 'target areas'. Understanding of where change is likely to occur should draw our attention to those areas specifically in a proactive manner. The clinician has the benefit of having the patient before him, and so will know the sites of pain, swelling, and deformity. Erosions are a relatively late feature in the arthritides.

Radiological changes at joints include:

1. soft tissue swelling, local or general;
2. alteration in bony density;
3. joint narrowing and alignment changes;
4. periostitis;
5. surface irregularity, cortical loss, and erosions;
6. muscle wasting;
7. calcification or ossification in surrounding soft tissues.

The plain film diagnosis of erosive changes

Erosions have been studied extensively by Buckland-Wright (1983) and coworkers using macroradiography. This technique is probably impractical for use in conventional imaging departments. Images are obtained using a very small target (less than 15 m diameter). The object is placed close to the X-ray tube and the object-to-film distance is increased. According to Dacre and Buckland-Wright (1992), the advantages of using such a fine X-ray tube focus are (i) large magnification (up to × 10 or 20) and (ii) high spatial resolution, the smallest objects recordable being between 25 and 50 µm. According to these authors, changes are seen as early as 2 weeks after onset of symptoms (Fig. 14).

Fig. 14 Rheumatoid arthritis. Erosions demonstrated at macroradiography. (By courtesy of Dr J. C. Buckland-Wright, Guy's Hospital, London.)

Martel *et al*. (1980) described 'bare areas' of bone between articular cartilage and synovium, and pointed out that pannus logically would erode bone at this site which was free of cartilage. Erosions therefore commence as small areas of juxta-articular radiolucency adjacent to the margin of the articular cartilage. These lucencies are due to trabecular loss and cortical thinning. Small defects (0.1 to 0.3 mm diameter) begin to be seen in the cortex at sites of ingrowth of pannus. With progression of these changes, visible classical erosions form.

Migration of pannus below the articular cortex results in subchondral erosions and, with weakening of local bone, the articular cortex collapses (Fig. 15). Alternatively, direct invasion by pannus from above destroys articular cartilage and also causes subchondral invasion.

Fig. 15 Rheumatoid arthritis. Collapse of the femoral head associated with protrusio acetabuli.

Pressure erosions

Where two normally non-congruous bony surfaces approximate, and one moves on the other, well-corticated pressure erosions develop. With large rotator cuff tears, upward subluxation of the humeral head results in it eroding the undersurface of the acromion. Subsequently, the inferior glenoid lip erodes the adjacent humeral neck (Fig. 16).

Fig. 16 Rheumatoid arthritis. Upward subluxation of the resorbed humeral head has eroded the inferior aspect of the acromion and clavicle. The neck of the humerus is eroded by the glenoid, and the superior aspects of the 3rd and 4th ribs are also eroded superiorly.

In patients with wasting of the thoracic cage musculature, the scapula erodes the upper surface of the 2nd, 3rd, and 4th ribs (Fig. 16). This occurs with chronic rheumatoid arthritis, but also in old age and after polio. Proximal phalangeal subluxation in scleroderma and after Jaccoud's arthritis similarly allows the phalangeal base to erode the metacarpal neck (Fig. 17). In the foot, impinging malleoli cause defects on the adjacent talus.

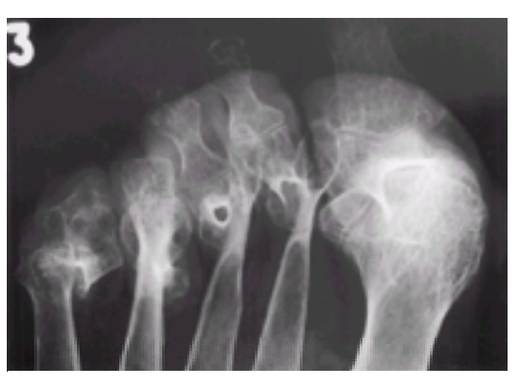

Fig. 17 Rheumatoid arthritis. Phalangeal subluxation causes pressure erosion of the metatarsal necks.

Sites of erosions in hands and wrists (Table 5)

	Wrist	Hand
Very early rheumatoid arthritis	Medial side hamate and base of 5th metacarpal joint Junction between hamate, capitate, base of 3rd and 4th metacarpal joints Medial side triquetral Lateral side head of ulna (inferior radioulnar joint) Styloid process of radius	2nd and 3rd metacarpophalangeal joints 3rd and 4th proximal interphalangeal joints
Early rheumatoid arthritis	Styloid process of ulna Medial surface of radius (inferior radioulnar joint) Scapholunate articular surfaces Lateral surface of scaphoid Lateral surface of base of 1st metacarpal joint Lateral surface of trapezium Lateral surface of capitate Subchondral erosion/cyst in epiphysis of radius	Remaining metacarpophalangeal and interphalangeal joints

From Blackburn-Wright (1984), reproduced by kind permission of the author and the British Medical Association

Table 5 Approximate order of the site of onset of erosions seen in the magnification radiographs of patients with 'very early' and 'early' rheumatoid arthritis

Buckland-Wright (1984) also demonstrated that erosions are symmetrical and bear no relation to hand dominance, though others do not agree. Erosions also vary in size, with the largest at the radiocarpal, medial carpometacarpal, and second and third metacarpophalangeal joints. It should be noted that in one study of patients with early rheumatoid arthritis, 23 per cent never developed erosions while, in those who did, in 48 per cent the erosions became static after 22 months, indicating how variable the process of erosive disease is (Brook and Corbett 1977). Moreover, radiographic progression of erosions can occur even when treatment successfully halts the acute clinical phase of the disease.

Much effort has been expended in assessing the status of rheumatoid disease at presentation and subsequently after treatment. Both conventional and special projections, e.g. of hands (Brewerton 1967), have been used. Films are often of different quality on different occasions, especially in multicentre trials. The author has participated in three such surveys; it is not an enjoyable experience. Films may be of such poor quality that an accurate staging is not possible. Observer variation even occurs when one radiologist is involved, let alone more than one, especially when viewing serial radiographs.

The importance of accurate imaging and reporting in assessing disease progress is self-evident, but using radiographic scoring methods is not only tedious but liable to intrinsic errors because of the factors discussed above. Different scoring methods can give contradictory results. The whole subject of scoring has been well researched (Kaye 1991). What is evident, however, is that MR is much more sensitive in demonstrating erosions and cysts than plain films.

Arthrography in rheumatoid arthritis

Arthrography in patients with rheumatoid disease demonstrates synovial proliferation and allows contrast to enter bone at sites of cortical defects and erosions. Larger subarticular cysts or geodes may fill with contrast. Debris is shown in the joint space as filling defects, often floating around freely. In the shoulder, a rotator cuff tear allows filling of the subacromial bursa (Fig. 5), while at the knee, adventitial cysts in communication with the joint may be shown at arthrography. The largest of these—the Baker's cyst—is an enlargement of the gastrocnemio-semimembranosus bursa which communicates with the posterior joint space. This cyst can be seen on a plain lateral radiograph as a fairly discrete, lobulated soft tissue shadow posterior to the knee. Loose bodies may lie in it, or if multiple densities are present inferoposterior to the knee, the presence of local synovial osteochondromatosis can be inferred (Fig. 18).

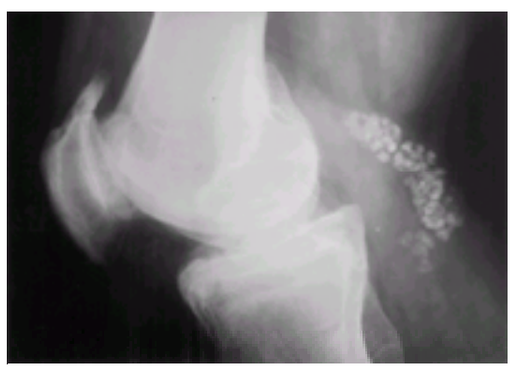

Fig. 18 Synovial osteochondromatosis. Numerous small ossicles are demonstrated posterior to the knee joint. There are so many that they cannot be held to be loose bodies; they must be in synovial osteochondromatosis. The distribution is that of a Baker's cyst.

Rupture of this cyst causes leak of synovial fluid into the calf, between skin and muscles or between soleus and gastrocnemius (Fig. 19). Rupture results in calf pain and swelling, mimicking a deep vein thrombosis. Should a venogram be performed as the first examination because of the need to exclude a deep vein thrombosis, the popliteal vein is seen to be displaced. Ultrasound is preferable as it confirms the presence of a cyst, the leak, and the absence of a deep vein thrombosis (Gompels and Darlington 1982). Arthrography followed by exercise fills the cyst, unless the defect in the cyst wall is filled with debris, but MRI of course demonstrates the cyst, the effusion, and the leak as well as the meniscal abnormality (Fig. 20).

Fig. 19 Ruptured Baker's cyst allows air or contrast to pass into the posterior musculature of the calf.

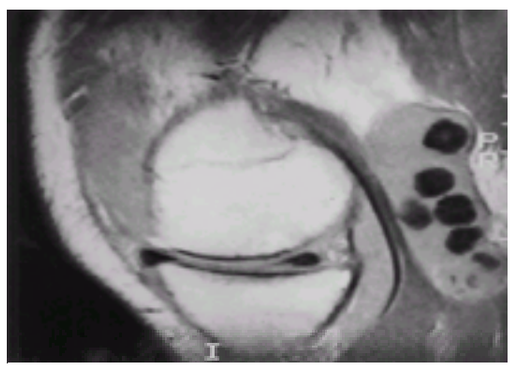

Fig. 20 Baker's cyst. MR scan of the knee demonstrating a large posterior cyst containing numerous loose bodies. This is associated with a tear of the posterior horn of the medial meniscus. Comparison can also be made with a plain film of a similar lesion (see Fig. 18).

Baker's cysts are associated with meniscal tears and other forms of internal derangement, presumably because of increased amounts of joint fluid and pressure in the joint. Rheumatoid and osteoarthritis are also associated with cysts and also with communicating cysts at the elbow and ankle. MRI shows a 5 per cent incidence of popliteal cysts in patients with internal derangement but a 13 per cent association with a ruptured anterior cruciate ligament (Fielding *et al*. 1991). Arthrography shows a much higher incidence of cysts, possibly because of the additive effect of distension by contrast and gas.

MRI in rheumatoid arthritis

As a result of the inherent contrast of MR images, the components of a joint, bone, and soft tissue are better defined than in any other modality. Synovial fluid,

synovium, cartilage, ligaments, tendon, and bone can all be identified, and pathology seen in them (Fig. 20).

Erosions are the pathognomonic change in rheumatoid disease and are seen at MRI as marginal low-signal defects in bone, while pannus shows on conventional images as an intermediate or soft tissue signal mass adjacent to the erosions. Effusions in joints or tendon sheaths are bright (brighter than pannus) on T_2-weighted views (Fig. 20).

It seems well accepted that erosions are seen earlier and more often on MR scans than on plain films. This is so for both large and small joints. The superiority of MR imaging in demonstrating erosions, subchondral cysts, effusions, tendinous and bone change, extra-articular collections of fluid, and pannus is so marked that MRI is, where available, the method of choice for detecting early change in rheumatoid arthritis (Beltran *et al*. 1987; Gilkeson *et al*. 1988; Poleksic *et al*. 1993).

The use of intravenous gadolinium with T_1-weighted sequences further distinguishes inflammatory from non-inflammatory fibrous pannus by demonstration of synovial enhancement where synovial proliferation is hypervascular. MRI is probably therefore the investigation of choice for the initial diagnosis of erosive disease and its progression (Fig. 21) but, because of its cost, complexity, and relative non-availability, is not likely to be in general use.

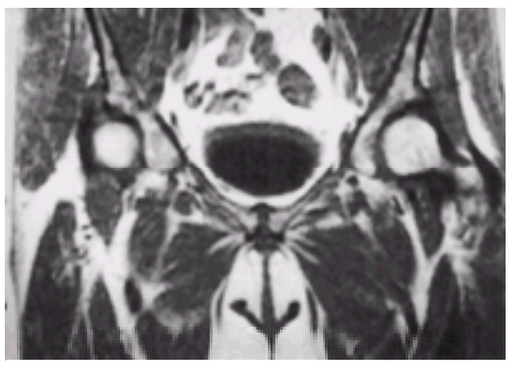

Fig. 21 Rheumatoid arthritis. Thickening of the capsule of the right hip joint is demonstrated with irregularity of the acetabular articular surface (T_1-weighting).

It has, however, been found that MR is better at demonstrating cartilage loss than any other imaging modality (Chan *et al*. 1991), so that a joint which appears normal on plain films is shown to have cartilage loss on MRI. This technique is also better than conventional radiography in demonstration of osteophytes, though CT does this equally well. MRI has the added benefit of demonstrating effusions and loose bodies without the necessity of joint injection, and demonstrates subarticular cysts and extra-articular cartilage change better than the other modalities (Fig. 20).

Changes at the C1–C2 interface: plain radiography, tomography, CT scanning, and MRI

Cervical spine involvement has been seen in up to 86 per cent of patients with rheumatoid arthritis and atlantoaxial subluxation occurs in up to 40 per cent. Ligamentous laxity and rupture may be associated with erosive change around the peg due to local pannus. Instability may involve anterior displacement of C1 or posterior displacement of the peg. A conventional lateral radiograph taken in flexion should not result in a space between arch and peg of more than 2.5 mm in an adult. Superior and lateral displacement of the peg also occur.

Erosion of the lateral masses at C1–C2 allows the odontoid peg to shift upward. The distance from the anteroinferior surface of C2 to McGregor's line should be more than 34 mm in men and 29 mm in women (McGregor's line is a line drawn from the back of the hard palate to the lowest part of the occiput).

Changes at C1–C2 can be clarified further by linear tomograms in the anteroposterior and lateral projections and, subsequently, by CT scanning, which also demonstrates local soft tissue change. A further development was the combination of CT with radiculography, i.e. after cerebrospinal fluid opacification. Such scans could be obtained in the flexed and extended states. This was, until the advent of MRI, the investigation of choice (Fig. 22).

Fig. 22 CT radiculography. (a) Normal relationship of peg, arch of atlas, theca, and cord in the axial mode, together with sagittal reconstruction. (b) In this patient with rheumatoid arthritis the odontoid peg is eroded (see lateral reconstruction) and no longer has an intimate relationship with the arch of atlas. There is a large soft-tissue mass interposed between the two. The cord is displaced posteriorly and the theca impressed upon. (By courtesy of Dr J. Steven, National Hospital, Queen Square.)

MRI of the craniocervical region

MRI is now the investigation of choice for imaging the craniocervical region. Pannus, cerebrospinal fluid, bone, and cord are all shown (Fig. 23). Scans can also be obtained in flexion and extension, but there is probably no advantage to this over a single MR study with plain lateral flexion and extension views and tomography to show erosions. In addition, the status of the cord can be assessed at MRI for oedema, gliosis, or atrophy (Aisen *et al*. 1987; Semble *et al*. 1988; Einig *et al*. 1990).

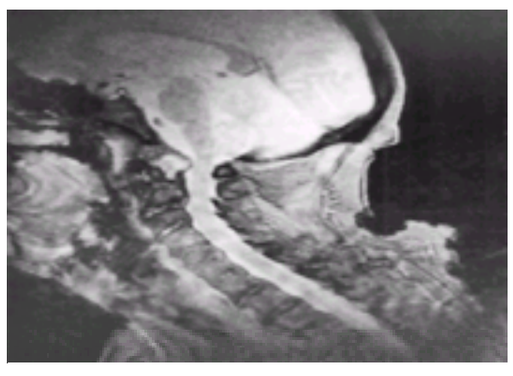

Fig. 23 Rheumatoid arthritis. MR sagittal T_2-weighted image shows erosion of the odontoid peg with pannus and compression of the cervical cord.

Imaging the spine

Anatomy of the lumbar spine

The lumbar spine is lordotic, convex anteriorly. In part this is because the lower lumbar vertebral bodies are greater in height anteriorly. At L5, the difference may be as much as 0.9 cm. At L1, however, the reverse is the case and the body of L1 may normally be wedged anteriorly. Similarly, the mid- and lower lumbar discs may be significantly thicker anteriorly (Farfan 1973).

Although it is often stated that the height of the L5/S1 disc is around 50 per cent of that at L4/5, in one small study 40 per cent of L5/S1 discs were thicker posteriorly that the L4/5 disc, and an even larger number showed the discs to be equal in height posteriorly.

With segmentation anomalies the intervening disc is rudimentary and diminished in height. Discs of smaller heights have diminished movement. The L5 disc may be high, i.e. at or just below the level of the iliac crest, or deep, i.e. much lower than the crest. Higher discs are said to be more vulnerable to degeneration. Disc degeneration in the lumbar spine has the highest incidence at the lumbosacral junction and the incidence decreases to be lowest at L1/2. If the lower lumbar disc is also sacralized, wholly or in part, i.e. associated with large L5 transverse processes, that disc will be small, 'protected', and less likely to be diseased.

The transverse processes at L5 may be the bulkiest and they may unilaterally or bilaterally articulate with, or be totally or partially fused to, the sacrum in some 15 to 30 per cent. Large transverse processes at L5 thus protect the disc below, but seem to be associated with increased levels of degeneration at the level above, which is thus high, 'free', and potentially unstable.

The sacrum also contributes to the lordosis as its upper surface is angled distoanteriorly. The L3/4 disc is aligned horizontally. Loss of the lordosis is shown by reduction of the angle that the lumbosacral disc makes with the plane of the L3/4 disc. Also, in a normal spine, the anterior surfaces of the vertebral bodies are always tangential to each other, while in a spastic painful or degenerate and immobile segment, adjacent anterior vertebral surfaces are in alignment.

The transverse processes are seen on a lateral view of the spine along a line drawn from the L1 transverse process to the anterior surface of the femoral head. On the anteroposterior film, the transverse processes differ in size and shape. The transverse process at L3 is often the most lateral and its inferior surface often the lowest to be inclined horizontally (Fig. 24). This is of benefit in trying to decide which lumbar vertebra is L3; of course the definitive way is to count down from C1.

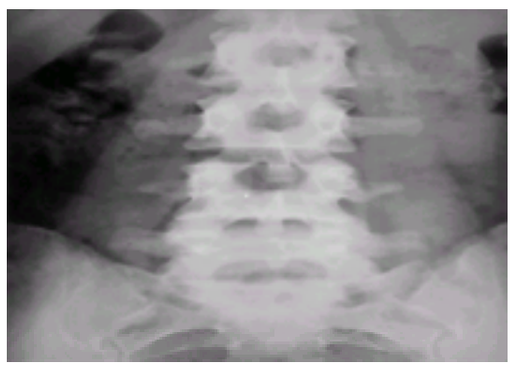

Fig. 24 Anteroposterior view of lumbar spine. The transverse processes of L3 are the lowest to be inclined horizontally.

The facet joints

The facet joints in the lumbar spine vary in their orientation. At L1, the facet joints have an almost vertical orientation but, passing inferiorly, change direction so that at L5/S1 the superior facet faces superiorly, medially, and posteriorly. Facets are generally symmetrically orientated. The angle of the facets to the midline is around 52° at the L5/S1 joint, and 10° less at L4/5. Facet asymmetry is also greatest at L5/S1. A high correlation has been reported between the side of increased facet rotation and disc protrusion with sciatica (Farfan 1973).

Facetal changes of osteoarthritis follow discal height loss. These changes are seen on plain films, especially with oblique views, and very well demonstrated at CT scanning, where bony hypertrophy and synovial thickening are seen to narrow the lateral recess and exit foramina (Fig. 25). Yellow ligament thickening is seen at axial imaging to indent the theca from behind, and posterolaterally.

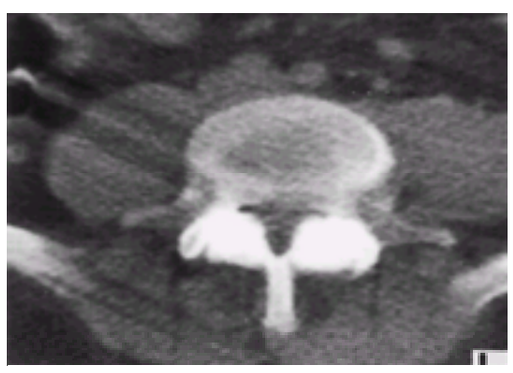

Fig. 25 A rather old scan, but a good example of facet hypertrophy causing lateral recess stenosis and a trefoil deformity.

Plain film demonstration of disc narrowing, facet slip and rotation, foraminal encroachment, and marginal new bone formation are all indicative of established discal degeneration.

Scoliosis associated with vertebral asymmetry is seen commonly on routine chest radiographs and occurs in up to 13 per cent of spines. It has been stated that these curves are due to primary vertebral asymmetry with a diminished body height on the concavity, as well as shorter pedicles and a flatter neural arch.

Pain sources in the spine

Pain may arise (i) in the motion segment and surrounding structures, comprising the discal nucleus and annulus, vertebral end-plates, and the two local facet joints, as well as surrounding ligaments and muscles; (ii) in the superficial structures around the spinous processes; and (iii) referred from spinal nerves and the sympathetic chain. Pain may arise in isolation but, because all three areas are interdependent, a complex pain pattern may result (O'Brien 1984).

The disc is the largest structure in the motion segment. The nucleus and inner annulus have no innervation but the outer annulus has a rich multilevel sensory nerve

supply. Similarly, the vertebral body has a rich sensory nerve supply.

The emerging nerve root occupies about 50 per cent of the exit foramen and so is compromised easily by changes in the local bone and soft tissue. The dura around the nerve is itself innervated anteriorly, but not posteriorly. The capsule of the facet joint (but not the synovium) has a three-level innervation. It is also likely that each anatomic level of the anterior and posterior longitudinal ligaments derive their innervation from the level above.

Patterns of spinal and referred pain are thus seen to be complicated because of the overlap of innervation (Fig. 26). Pain fibres are also present in the sympathetic chain which lies in close contact with the spine, and they too are affected by local disease, bony osteophytes, and lesions of the annulus (Fig. 27).

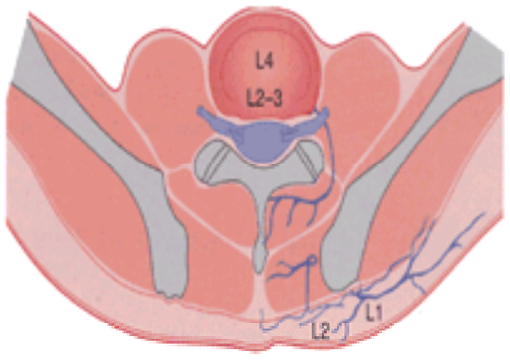

Fig. 26 Transverse section of the spine and associated structures at L4 to illustrate the different innervations of structures at the same anatomical level. (Reproduced from *Textbook of pain*, by courtesy of Mr J.P. O'Brien FRCS and Churchill Livingstone.)

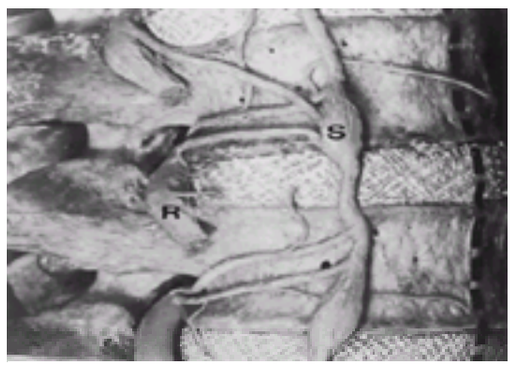

Fig. 27 Superficial view of lumbar spine demonstrating the nerve supply of the disc. Note the close proximity of the sympathetic chain to the disc and vertebral margin and also the communication between the nerve root and sympathetic chain just above the level of the disc. R, nerve root; S, sympathetic trunk. (Reproduced from *Textbook of pain*, by courtesy of Mr J.P. O'Brien FRCS and Churchill Livingstone.)

At least 50 per cent of the population suffers from back pain at some time. Abnormal anatomy predisposes to abnormal stresses on the disc. Discal degeneration is an inevitable fact of life; no spine remains unaffected. Discal arrowing causes alteration of facet alignment and subsequent degeneration. Exit foraminal encroachment by soft tissue and osteophytes compromise the emerging nerve roots.

Pathology in the disc

Many disc protrusions regress spontaneously with time and conservative therapy (Cowan *et al*. 1992). Diagnosis of degeneration based solely on MR or CT criteria often does not address the cause of pain and, indeed, inappropriate surgery may worsen the patient's condition.

Posterior annular circumferential fissures start to form in the lower lumbar spine as early as puberty (Fig. 28). Subsequently, the nucleus starts to dehydrate and radial tears occur, perhaps related to the orientation of facets.

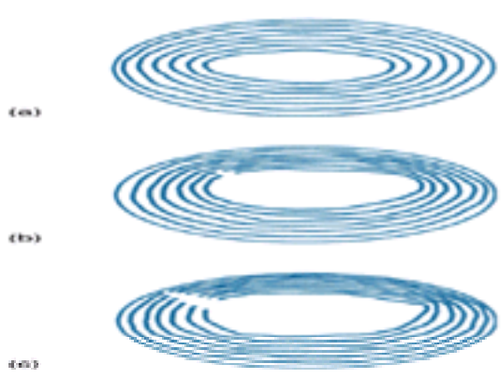

Fig. 28 Formation of radial fissure: (a) concentric laminae of equal number at all points around the circumference; (b) some of the inner lamellations become discontinuous and the clefts in the annulus become larger; (c) the annular clefts and the tears of the minor annular layers continue to form a radial fissure. (Reproduced from Farfan, H.F., *Mechanical disorders of the low back*, by courtesy of Lea and Febiger.)

Forces acting on the nucleus can cause both nuclear protrusion and annular fissuring, as well as end-plate fractures (Fig. 29 and Fig. 30); not to be confused with Schmorl's nodes, which are nuclear herniations through corticated defects in the end-plates which had transmitted blood vessels in infancy (Fig. 31).

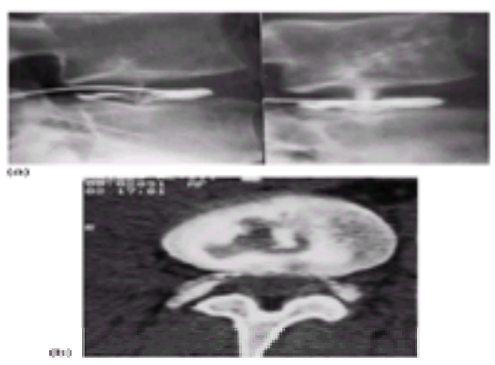

Fig. 29 End-plate fracture. (a) Discography. The initial radiograph shows a spurt of contrast going upwards from the nucleus into the end-plate of the overlying vertebral body. Subsequently, the defect is shown to be much larger, but patient movement occurred because of pain during injection. (b) CT scan showing contrast leaving the nucleus and entering the undersurface of the bone.

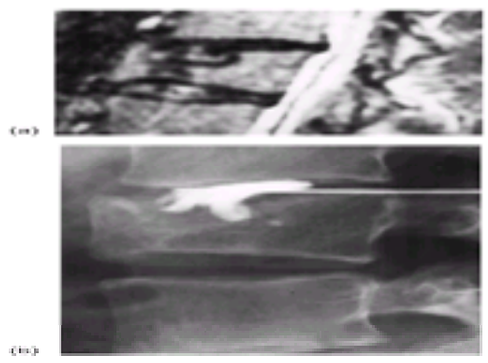

Fig. 30 End-plate fracture. (a) Defects are demonstrated on the upper surface of a lumbar vertebral body with depression of the cortex at MR scanning together with some loss of signal in the local disc. (b) At discography the defects are shown to fill with contrast injected into the nucleus.

Fig. 31 Schmorl's node. At discography defects around the injected disc are demonstrated at the upper and lower end-plates.

Osteophyte formation

Osteophytes are seen at vertebral marginal edges and so-called traction spurs some 2 to 3 mm away from the vertebral margin. Osteophytes are intimately related to, and are usually indicative of, local annular tears (Fig. 32). Traction spurs may be related to change in the more superficial layers of the annulus and adjacent anterior longitudinal ligament.

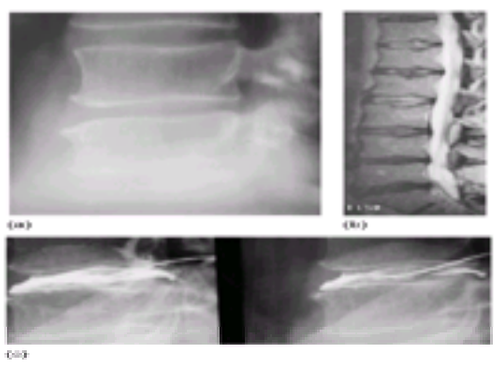

Fig. 32 Disc degeneration. (a) Plain tomography showing disc narrowing and anterior osteophytes. (b) MRI showing disc degeneration especially at L4/5. (c) Anterior and posterior annular tears at discography. Note vascular filling, presumably the result of superficial inflammation. Anteriorly, the contrast in the tear creeps over an osteophyte on the superior surface of the lower end-plate at that disc level.

Radiological investigation of low back pain

Griffiths (1991) has given us an algorithm for the radiological investigation of a patient with low back pain (Fig. 33). He recommends simple anteroposterior and lateral views as adequate for the first examination for the general practitioner or accident and emergency department, while the specialist may require further views. I habitually use lateral views in flexion to demonstrate loss of movement in both the cervical and lumbar regions.

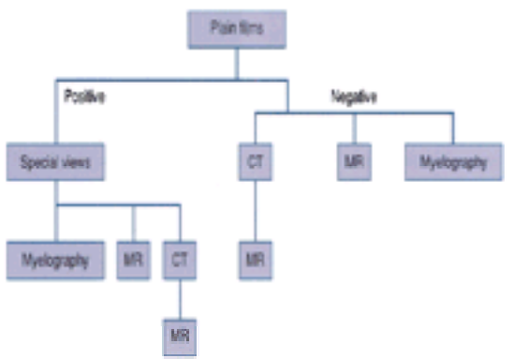

Fig. 33 Algorithm for radiological investigation. (Reproduced from *Imaging of the lumbar spine*, by courtesy of Dr H. Griffiths and Raven Press.)

Plain radiography

The plain film of the spine is rapidly obtained, cheap, and ubiquitously available. Much information can be obtained on the status of the motion segment. Is alignment normal and are disc heights preserved? Are there erosions, osteophytes, or traction spurs, indicating disc pathology? Rotational abnormalities can be assessed in both planes, together with an assessment of bony density.

End-plate density is lost with infection and increased with degeneration and instability. It is recognized, however, that up to 50 per cent of bone must be resorbed before foci of demineralization can be seen on the film. Marrow changes are thus better seen with isotope and MR scanning.

Myelography and radiculography

Intrathecal negative-contrast investigation of the spinal canal using air was first performed in 1921 and this was followed by the use of positive-contrast iodinated oil (Lipiodol/Myodil) in 1922. The bulging disc protrudes into the canal and causes a filling defect to be seen in the contrast. Oily media cause arachnoiditis and theoretically should have been removed after the study but, in practical terms, this was not always possible. Even though Myodil is very slowly absorbed naturally, remnants may be seen in the canal after many years. Early water-soluble media could only be used to examine lumbar nerve roots. If run higher up the body, fits and possible skeletal trauma resulted.

Using modern non-ionic media and fine non-bevelled needles, the incidence of meningism and other complications are lessened, but postlumbar-puncture headaches still occur, though these can be minimized if the patient is well hydrated by drip infusion, and given prophylactic cortisone in the drip. Only small volumes (10 ml of iohexol-240) need to be used to study lumbar roots. Unfortunately, only the areas reached by contrast can be investigated, i.e. the nerves are shown as far as the tip of the root sheaths, but even parts of these were not seen with oil-based media which were too viscid to enter the root sheath.

CT scanning

Axial scanning using CT added a new dimension to the conventional water-soluble contrast study. Delayed CT scanning allows total mixing of the contrast with cerebrospinal fluid. CT on its own demonstrates bone detail well and, in the axial mode, the discs, facets, lateral recesses, and pedicles are all clearly seen together with their relationships to theca and roots, even in the absence of intravenous contrast, so that CT alone has been used as a screening test, as a non-invasive study with no side-effects (other than those of a cumulative irradiation dose). If sufficient fine contiguous slices are obtained, reformatting allows visualization in any plane.

The examination is limited in extent by time, cost, and radiation exposure, so that a standard examination of the lumbar spine is usually only of the L3/S1 motion segments, and plain films are still needed to show higher levels, but most significant degenerative disease of the spine is below L3.

The combination of CT and radiculography gives better appreciation of the soft tissue interfaces, especially between disc, root, and theca, while at the same examination, the lateral recesses, facets, and yellow ligaments are better imaged than at radiculography. Some surgeons still request CT/radiculography, partly to show the recesses, as bone is better seen at CT, and also perhaps because of inherent conservatism (Fig. 34).

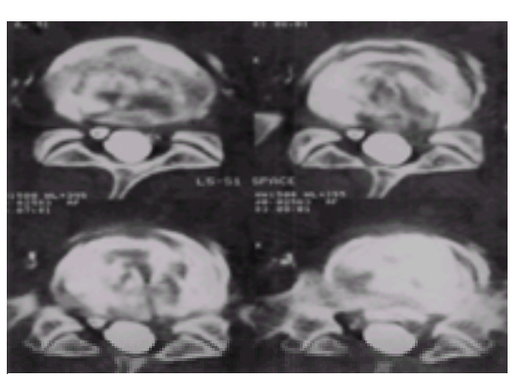

Fig. 34 CT discoradiculography. The degenerate disc is demonstrated with total loss of the normal nuclear/annular configuration. The bulging disc is demonstrated centrally and on the left side of the canal. It is associated with facet hypertrophy and lateral recess stenosis. The soft tissue of the disc is only partially opacified by contrast in the left lateral recess, but there is non-visualization of the S1 root on the left compared with its normal visualization on the right.

MRI of the spine

MR imaging of the spine has now largely replaced CT and radiculography. It is, as previously stated, non-invasive and allows multiplanar imaging. Metal implants in the spine sometimes contraindicate MRI but this technique can still be used to assess change in discs above, for instance, a fused level. In the postoperative spine, enhancement by gadolinium occurs with recurrent disc protrusions, but fibrotic masses do not enhance as they are relatively water-free.

Patients now undergo MR scanning as a primary investigation for back pain, and even plain films may be omitted. Apart from the fact that much can be learned from the plain film, the basic anatomy (see above) often cannot be inferred from a multisection scan—the wood cannot be seen for the trees. MRI shows changes as never before, and the number of positive diagnoses increases. There is apparently a resulting increase in the amount of spinal surgery performed the United States (Deyo 1994) but, as much recent work has shown, disc protrusion imaged at a particular level may not be the cause of the patient's pain as many such discs are asymptomatic (Jensen *et al.* 1994).

At MR scanning, bony changes are not as well demonstrated as at CT, though the low signal of cortical bone is shown. The disc height may be diminished, and nuclear signal decreased on T_2-weighted images. Disc protrusions, both posterior and anterior, are seen, especially against bright cerebrospinal fluid on T_2-weighted images (Fig. 35), and the displaced low-signal posterior longitudinal ligament on T_1-weighting.

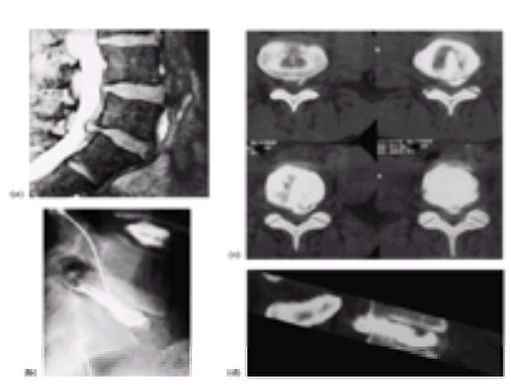

Fig. 35 Disc prolapse. (a) MR scan, T_2-weighted image. There is dorsal protrusion of a disc impinging upon the theca and narrowing the sagittal diameter of the canal. (b) The discogram demonstrates this lesion, showing a posterior annular tear with partial opacification of the bulge. A normal disc is demonstrated at the L4/5 level. (c) CT scanning following this study shows the degenerate disc with the central and left-sided protrusion. Sagittal reconstructions are also obtained (d).

Sagittal slices through the pedicles demonstrate the emerging nerve roots in exit foramina and show them against bright fat when normal, or impinged upon by soft

tissue or bony masses. Axial scans confirm these changes.

Discography

The role of discography in the diagnosis of spinal disc disease is controversial. Discography provides an image of disc anatomy and pathology. Discal injection also aims either to reproduce the patient's pain or to exclude that disc level as a pain source.

As far as disc anatomy is concerned, it might be stated with some justification that MRI demonstrates spinal anatomy and pathology more clearly, as (i) extradiscal structures are also displayed; (ii) the entire cervical, thoracic, or lumbar spine is imaged in one study; and (iii) the technique is non-invasive, not painful, and no risk is involved (these can include discitis or anaphylaxis at discography).

Prior to the advent of MRI, when plain films and myelography were standard techniques in the investigation of spinal pain, the limitations of myelography meant that discography had a perhaps greater diagnostic role. The relatively limited filling of root sheaths and opacification of roots meant that lateral disease could not be imaged. The theca is also not closely applied to the L5/S1 disc, but is separated from it by fat, so that the compressive effect of a protrusion at that level was not always seen.

MRI demonstrates disc degeneration and protrusion well, and multiple levels of often unsuspected abnormality may be seen. Discography can then indicate which particular disc or discs reproduce in part or whole the patient's pain. Thus, a pain-free level at discography, even in the presence of an MR abnormality, is an indication that this level need not necessarily be treated, while multiple levels of pain reproduction may indicate that more extensive surgery is indicated. In short, discography indicates which levels need or do not need intervention.

It has also become increasingly recognized that a painful disc can be associated with a normal MRI scan. Radial or circumferential tears of the disc or end-plate fractures may all be associated with pain in the presence of normal plain films, radiculograms, CT, and MR scans (it will be remembered that the outer fibres of the annulus are innervated) (Zucherman *et al*. 1988; Collins *et al*. 1990; Osti and Fraser 1992). MRI is said to be more sensitive than discography only in the diagnosis of disc herniation (Birney *et al*. 1992)—a finding that I am not wholly in agreement with.

A partial radial tear need not be associated with MR change and, as stated above, this tear antedates rather than follows degenerative change. It should also be recognized that interventional techniques, whether radiculography or discography, are not performed early on in the course of disease but in patients in whom delay, conservative treatment, and imaging have been of little benefit.

Normal and abnormal patterns at discography (Fig. 36)

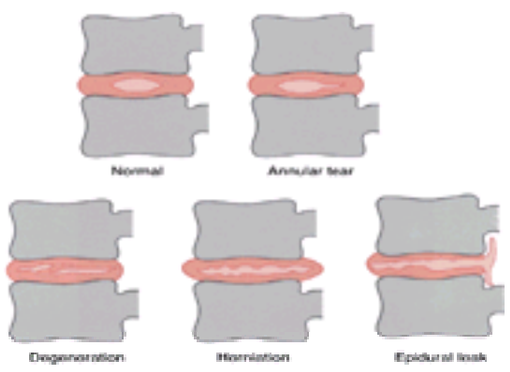

Fig. 36 Diagrammatic representation of the progression of discal degeneration, starting with an annular tear.

A plain film is an essential adjunct. Experience with discography leads to the realization that even so-called minor abnormalities on the plain film may be associated with discal pathology and pain. Osteophytes in particular, however small, can be associated with painful radial tears and do indicate underlying disc disease, as does loss of lordosis and minor malalignment on a lateral view, especially even minimal retrolisthesis of L5 on S1 (Fig. 37).

Fig. 37 An annular tear is associated with, and leads to, the osteophyte on the subjacent end-plate anteriorly. The osteophyte is the site of considerable reactive bone sclerosis. The disc is otherwise normal.

Obvious plain film changes are almost inevitably associated with discal pathology, which can be demonstrated at discography, but not inevitably with pain at injection.

MRI is said to be more sensitive than discography in the detection of herniation or prolapse of the disc because, of course, the posterior aspect of the disc is imaged directly. In practice, a torn annulus is associated with leak of contrast behind the disc, anterior to the displaced theca, displaying the bulge (Fig. 35), and very often vascular filling is demonstrated, presumably a result of chronic inflammatory changes around a degenerate disc (Fig. 29). Many studies are now in agreement that discography aids the diagnosis, plans treatment, and demonstrates pathology not shown by any other method. Discography may be combined with CT and even radiculography to give a total image of the diseased motion segment (Fig. 34) (Birney *et al*. 1990).

The spondylarthritides

New bone formation around the spine occurs in ankylosing spondylitis as well as in the other seronegative spondylarthritides. In ankylosing spondylitis, the changes may occur first at the thoracolumbar junction and spread in both directions. The new bone, or syndesmophyte, is usually vertically aligned in the annulus, gracile, and vertebromarginal (Fig. 38). This change follows the demonstration of vertebromarginal erosions which may be sclerotic and can give an impression of vertebral 'squaring' (Fig. 39). Non-marginal and floating syndesmophytes also occur in ankylosing spondylitis, but seem more common in the other seronegative spondylarthropathies (Fig. 40).

Fig. 38 Ankylosing spondylitis. Gracile, vertically orientated new bone runs between adjacent vertebral body margins.

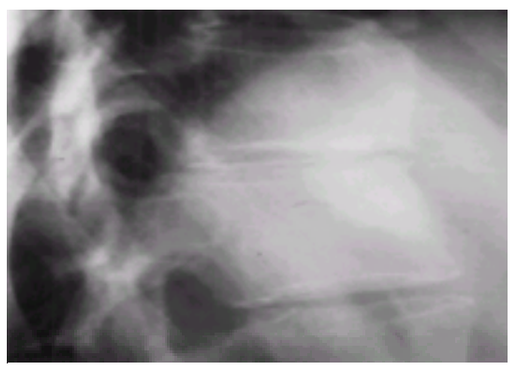

Fig. 39 Ankylosing spondylitis. Vertebral squaring results from margin erosion and also new bone laid down on the anterior concavity of the vertebral body.

Fig. 40 Psoriatic spondylitis. The presence of non-marginal and also 'floating' (non-attached) syndesmophytes is demonstrated in this seronegative spondylarthritis.

In the cervical spine, change occurs from C2 down, in continuity, and cervical spondylarthritis may be the presenting symptom in juvenile chronic arthritis and ankylosing spondylitis.

Ankylosing spondylitis

Paradiscal ossification in ankylosing spondylitis arises when the patient is relatively young, i.e. before discal degeneration. Disc heights are often then well-preserved, even in the elderly. On the lateral view of the spine in ankylosing spondylitis, the disc shows increased density, partly because of marginal new bone, but also because of discal nuclear calcification. This is seen as an added central density and occurs in other situations where there is bony fusion across discs (Fig. 41).

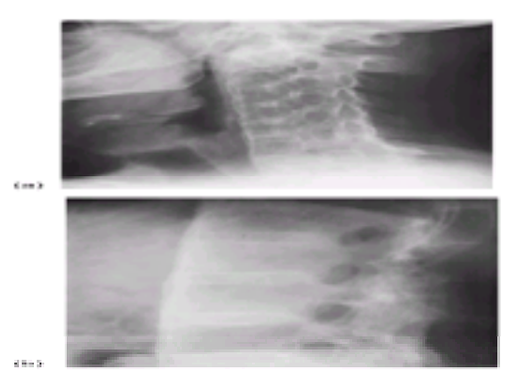

Fig. 41 Ankylosing spondylitis showing bony bridging with nuclear calcification.

Ankylosing hyperostosis (diffuse idiopathic skeletal hyperostosis, DISH; Forestier's disease)

In ankylosing hyperostosis, the new bone is accreted later on in life, is much more extensive, thicker, and florid, and is not necessarily seen in association with degeneration (Fig. 42).

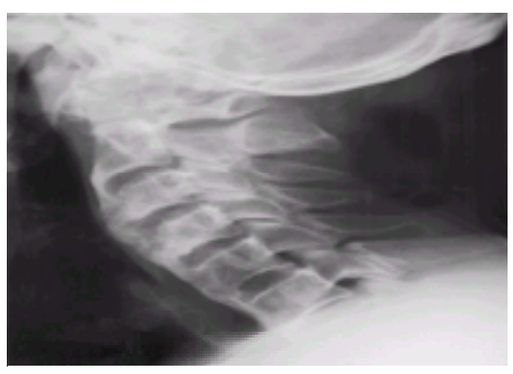

Fig. 42 Diffuse idiopathic skeletal hyperostosis. Preserved disc spaces are demonstrated in association with anterior ankylosis across many segments with a continuous bar of anterior new bone formation, which considerably increases the sagittal diameter of the vertebral body complex.

Paraspinal new bone can be seen on plain films and, as expected, on CT scanning. In ankylosing hyperostosis, it is especially well demonstrated in the thoracic spine on the right side on CT scanning, the left being spared presumably because pulsation in the descending aorta prevents its formation (Jones *et al*. 1988).

Ossification of the posterior longitudinal ligament (OPLL)

New bone formation is also seen in the distribution of the posterior longitudinal ligament of the spine as an isolated phenomenon (ossification of the posterior longitudinal ligament; OPLL), often in the Japanese race, but also in ankylosing hyperostosis. The bone here, as elsewhere, is well shown on CT scanning (Fig. 43) (Resnick *et al*. 1978; Tsuyama 1984).

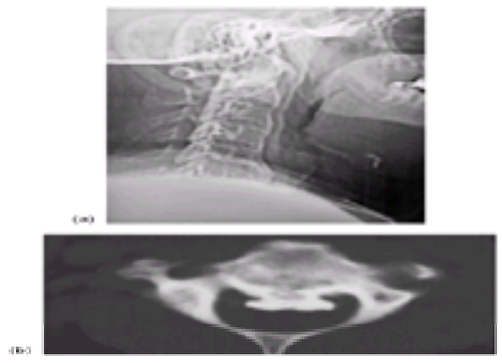

Fig. 43 Ossification of the posterior longitudinal ligament. To show the presence of new bone formation applied to the posterior aspect of the vertebral bodies of C2 and C3, considerably narrowing the sagittal diameter of the canal and indenting the theca.

Where bone formation is gross, increase in uptake of isotope is also seen in the spine in ankylosing hyperostosis and ankylosing spondylitis.

Imaging of the sacroiliac joints

Erosive change at the sacroiliac joints is the pathognomonic feature in ankylosing spondylitis. In children, the sacroiliac joints are poorly defined as the cortex is not readily visualized and, as a result, the joint seems wider than in the adult. Also, at isotope scanning, the images of the adolescent sacroiliac joints are more prominent—'hotter' and wider than in the adult. Fortunately, the sacroiliac joints are not normally affected early on in juvenile ankylosing spondylitis but, even so, the plain film diagnosis of erosive disease can be difficult to make in patients under 18 years of age.

In children and adults, infection of the sacroiliac joints is usually unilateral (Fig. 44). As with all infections, clinical onset of disease can antedate radiological change by up to 2 weeks. Gut gas, especially in sick children, also obscures the joint on plain radiographs.

Fig. 44 Unilateral sacroiliiitis in tuberculosis.

Plain radiography

Conventional imaging is a simple anteroposterior radiograph centred on the sacrum (Fig. 45). This is probably the least effective means of imaging the joint as the beam diverges from, and the joint converges to, the midline. It is therefore more logical to image the sacroiliac joint prone, as the beam then passes down the joint space parallel to the articular surfaces. Oblique views and a 30° shoot-up anteroposterior image demonstrate the sacroiliac joint cortices much better than a single anteroposterior vertical beam.

Fig. 45 Bilateral erosive sacroiliiitis in ankylosing spondylitis.

Linear tomography

Linear tomography is generally available and images are very satisfactory but it has been superseded by CT scanning (Fig. 46). CT scanning defines cortical bone

well; MRI is superior for assessment of soft tissues.

Fig. 46 Ankylosing spondylitis. Erosive sacroiliitis at CT scanning. There is narrowing of the sacroiliac joints bilaterally with erosive changes, initially confined to the lateral side of the joint. Reactive sclerosis is demonstrated in the underlying bone.

CT scanning

CT scans are useful in assessing the sacroiliac joints as the images are free of overlying gut shadows and the articular cortices can be assessed for erosions and fusion and subcortical cysts. Detail is generally better with CT scans than with plain films and, by altering windows, small erosions can be visualized (Fig. 46). Only a few images need be taken of what is quite a long structure as excess irradiation is to be avoided. Four to five 10 mm slices through the true joint at the mid- and lower thirds will generally enable the presence of erosions to be confirmed (Fig. 46).

Radionuclide bone scanning

Radioisotope scanning gives poor spatial resolution of sacroiliac joint disease but demonstrates pathology, albeit in a non-specific way by showing increase in uptake unilaterally or bilaterally. Unilateral sacroiliitis should be seen clearly because of asymmetric increase in uptake. Bilateral change can be more difficult to assess if uptake is symmetrically increased. On the delayed scan an increase in the ratio of counts between sacroiliac joints and sacral body of more than 1.4:1 was held to be significant (Fig. 47) (Ho *et al*. 1979), but it seems that there is too great a range of variation in the normal population for this test to be sufficiently accurate (Dequeker *et al*. 1978; Goldberg *et al*. 1978; Forrester 1990). Quantitative assesssment of increased blood flow to affected joints may be more sensitive. CT is probably better at defining bony change, even with unilateral disease.

Fig. 47 Ankylosing spondylitis. Radioisotope bone scan to show the sacroiliac joint/sacral uptake ratios. There is greater uptake in the right sacroiliac joint than on the left. The mean uptake on both sides is given, together with the mean uptake in the sacrum. (By courtesy of Dr A. Hilson, Royal Free Hospital.)

Fusion is a well-recognized sequel to endstage sacroiliitis—bilateral in ankylosing spondylitis but often unilateral in other seronegative spondylarthritides and following tuberculosis and other infections. Fusions at the sacroiliac joints are also seen in the elderly in whom no other evidence of ankylosing spondylitis exists, often in elderly females who might not be expected to have had sacroiliitis. It is also seen in patients with ankylosing hyperostosis, due to ligamentous and osteophytic ankylosis in the absence of erosions (Fig. 48) (Durback *et al*. 1988), and in patients with Paget's disease, thalassaemia, and X-linked hypophosphataemic osteomalacia.

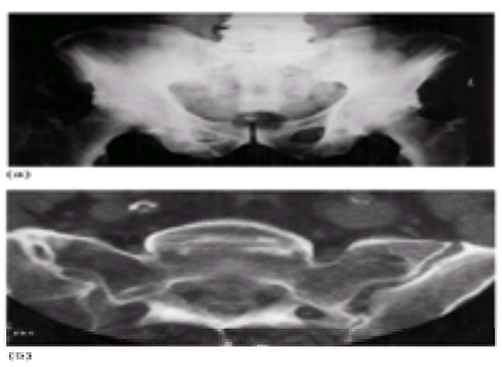

Fig. 48 Diffuse idiopathic skeletal hyperostosis. (a) There is new bone formation on the iliac crest and, in particular, superiorly at the sacroiliac joints, giving an impression of fusion across these. (b) CT scan to show new bone formation anteriorly across the sacroiliac joints in another patient with DISH. There are no erosions.

Imaging of joints

The shoulder

This topic has recently been reviewed (Gold *et al*. 1993). Ninety-five per cent of rotator cuff tears result from impingement.

Plain radiography

The presence of an impinging subacromial osteophyte and upward subluxation of the humeral head can be seen on the plain film. In the evaluation of impingement, an elevated humeral head on the plain film is compatible with tendinous narrowing or total rupture (Fig. 49).

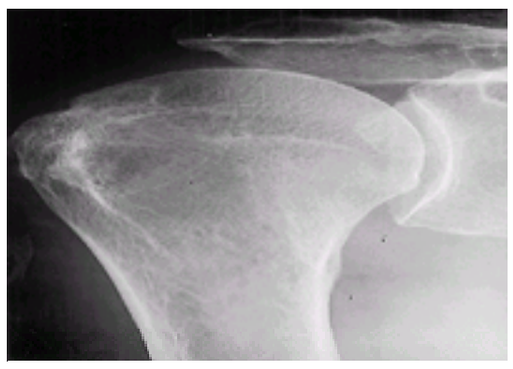

Fig. 49 Plain film prior to arthrography shows upward subluxation of the humeral head. Note the discontinuity of Mahoney's line (equivalent to Shenton's line at the hip). The undersurface of the acromion is irregular and there is a distal subacromial osteophyte.

Arthrography

The question of the presence or absence of a rotator cuff tear is answered easily at arthrography (Fig. 50 and Fig. 51), while restrictive capsulitis is shown at arthrography by demonstration of the contracted capsular outline and volumetric assessment of capacity (Fig. 52) (Resnik *et al*. 1984; Renton 1991a).

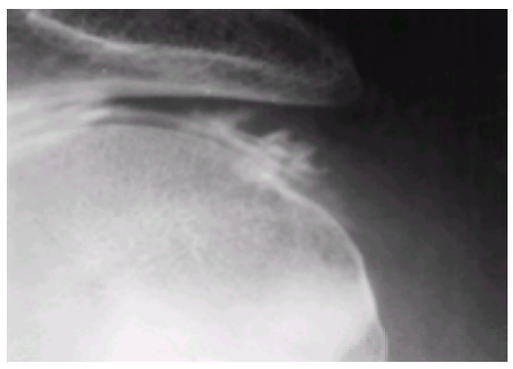

Fig. 50 Arthrogram of the shoulder showing partial tear of the rotator cuff. Irregularity of the inferior surface of the rotator cuff tendon is demonstrated. Contrast fills the tendon but does not reach the subacromial space.

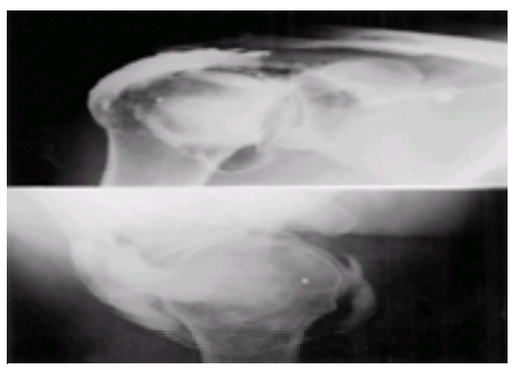

Fig. 51 Rotator cuff tear. Contrast medium now fills the subacromial bursa in continuity with the shoulder joint proper. On the axial view, the contrast medium in the subacromial bursa overlies that in the joint space proper.

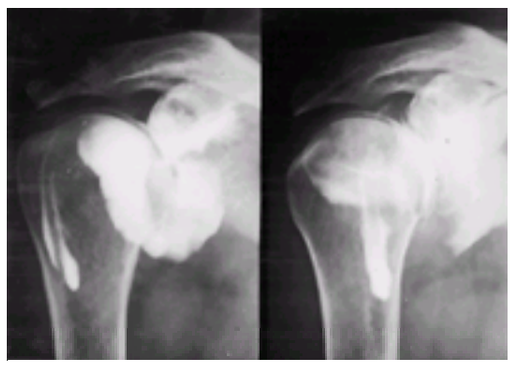

Fig. 52 Restrictive capsulitis. The capsule is reduced in size and is irregular. The long head of the biceps tendon sheath is filled as contrast medium seeks to escape from the tight shoulder joint capsule.

MR imaging

This is said to have 100 per cent sensitivity and 95 per cent specificity in the diagnosis of complete tears, while in the differentiation of a normal tendon from one affected by tendinitis with impingement, the sensitivity and specificity are 93 per cent and 87 per cent, respectively. For labral tears, these are also around 90 per cent (Iannotti *et al*. 1991). Changes of hypertrophy of bone and soft tissue at the acromioclavicular joint are seen to cause compression of the underlying supraspinatus, often associated with oedema (Fig. 53). The demonstration of a low-signal subacromial spur or osteophyte directs attention to the subjacent tendon, which may be thickened and oedematous, thinned, frayed, or frankly torn and distracted, allowing the humeral head to sublux upwards (Fig. 54).

Fig. 53 MR scan of the shoulder. Hypertrophy of the acromioclavicular joint causes changes of oedema in the subjacent supraspinatus tendon. More distally there is a tear of the rotator cuff tendon shown as an area of increased signal replacing the normal low signal of the tendon.

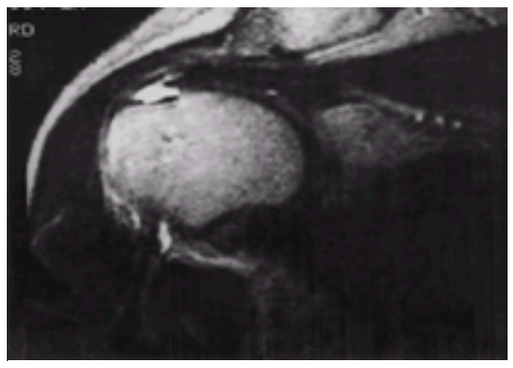

Fig. 54 MR scan of the shoulder. The tendon is seen to be retracted and fluid occupies the gap just proximal to the insertion into the greater tuberosity in a patient with a total rupture of the rotator cuff tendon.

Fluid is seen clearly on T_2-weighted or STIR sequences in the tendon, as well as in degenerative bone cysts at the greater tuberosity, and in the subacromial bursa. The deltoid may be atrophied.

Axial scans show the long head of the biceps and its relationship to the bicipital groove. Fluid may be present in the tendon sheath. The glenoid labrum is clearly seen in the axial plane (Fig. 55).

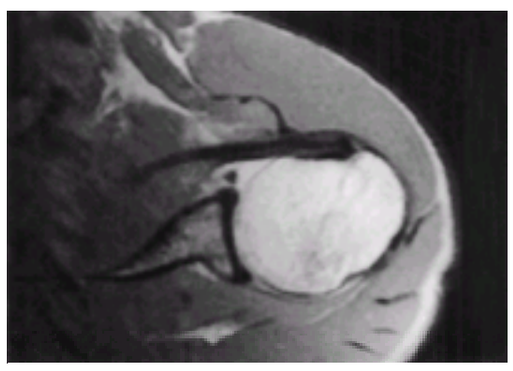

Fig. 55 Anterior labral tear. The detached portion is clearly demonstrated separately from the rest of the glenoid and the biceps tendon is showing entry into the bicipital groove.

CT arthrography/ultrasound

CT arthography does demonstrate these findings but is invasive and has been superseded by MRI, as has arthrography (see above), while ultrasound is operator dependent and the images may be difficult for others to interpret.

Necrotic changes or tendinitis in the supraspinatus and its tendon, on the other hand, are diagnosed at MRI but not at arthrography. The long head of the biceps tendon is seen at arthrography and, if CT is available concurrently, axial imaging by CT postarthrography will show the long head of the biceps, the glenoid labra (Fig. 56), and a possible Hill–Sachs or hatchet defect after recurrent dislocation (Fig. 57) (all, of course, are also seen at MRI) (Kieft *et al*. 1988).

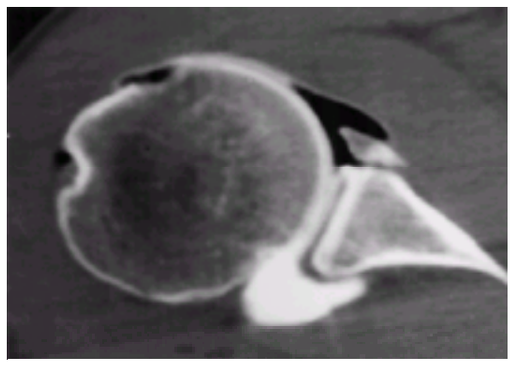

Fig. 56 CT arthrogram following trauma. The appearances are almost identical to those seen in Fig. 55. There is avulsion of the anterior lip of the labrum and the underlying corner of the glenoid.

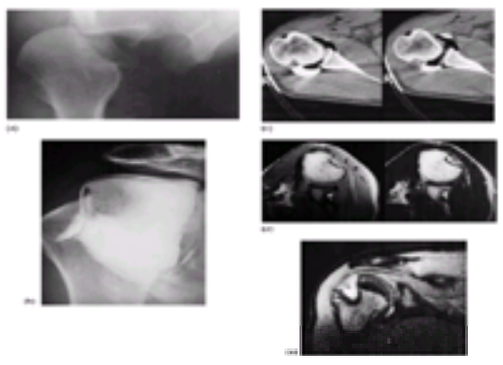

Fig. 57 Hill–Sachs or hatchet defect. Following anterior dislocation of the humeral head, especially if recurrent, a defect arises posteriorly following impingement upon the anterior lip of the glenoid. This may be demonstrated (a) on plain film, (b) at arthrography, (c) at CT, and (d,e) at MR scanning.

Arthrography is still in use at the shoulder as a quick, cheap screening test, though no doubt it too will be almost entirely superseded by MRI.

The elbow joint

Plain films have been discussed above.

Arthrography

Arthrography of the elbow has always been of limited use. It has been employed mainly for the diagnosis of loose bodies. Osteochondritis dissecans can also be shown. Unfortunately, the introduction of even the smallest of bubbles into a small joint makes the diagnosis of a loose body rather difficult.

Arthrography at the elbow can be single or double contrast. Using a single contrast technique, the contrast used must be diluted substantially as a dense contrast medium will hide a small lucent loose body, such as a fragment of cartilage avulsed into the joint. A double contrast technique, on the other hand, tends to cause bubbling, so that the diagnosis of a loose body is again made difficult. For this reason, a single contrast technique followed by conventional linear tomography has been utilized.

CT scanning

Opaque bodies in the joint are probably better demonstrated using CT. The cortex in particular of a detached loose body would be better shown by this technique. It may be that a single contrast technique using air alone might be more helpful or a double contrast technique using air and a little bit of contrast. In any case, with the advent of arthroscopy, it is likely that the use of arthrography, which never was very popular, will decline further.

MR imaging

There is no doubt that MR imaging of the elbow joint represents a substantial advance in the diagnosis, not merely of abnormalities of bone, articular cartilage, synovium, and joint space, but also in showing the related structures around the elbow joint. Fat suppression studies, especially of the elbow, are useful in showing changes of a local tendinitis at the medial and lateral condyles and adjacent flexor and extensor origins. As is generally the case, changes within the joint at the elbow are well shown at MR imaging.

The wrist

Plain films have been dicussed above.

Arthrography

Arthrography has been used at the wrist to demonstrate the integrity of the triangular cartilage. The radiocarpal joint is injected with contrast and a tear or defect in the triangular cartilage is then demonstrated by the passage of contrast medium into the distal radioulnar joint. Unfortunately, this tends to occur in around 15 per cent of normal individuals and tends to increase with age.

In addition, the integrity of the midcarpal joints is shown by failure of opacification of the mid- and distal carpal joints following radiocarpal injection. Opacification, therefore, of the distal joints of the carpus indicates that there is compartmental ligamentous damage.

CT scanning

CT scanning of the wrist has some use in the demonstration of rheumatoid change. In theory, it could also be used to demonstrate the integrity of the triangular cartilage, but only after the use of injected contrast.

MR imaging

MR imaging of the wrist is of course of great use in rheumatoid arthritis (see earlier section). In addition, however, MRI is used to demonstrate the integrity of the triangular cartilage and no doubt replaces arthrography where available.

On coronal images the cartilage should be seen extending from the ulnar styloid to the radius, on the radial aspect of the distal radioulnar joint. Failure to do so may indicate avulsion. Bright signal on T_2 images, and especially on fat suppression studies, demonstrates either internal degeneration of the meniscus or a complete tear.

The carpal tunnel syndrome is investigated using MR imaging. Bowing of the flexor retinaculum distally, oedema of the contents, and especially compression of the median nerve, which can be identified separately within the tunnel, are all indicators that the carpal tunnel syndrome is present. The flattened and compressed nerve becomes enlarged, both above and distal to the abnormal area.

The hip joint

Confirmation or exclusion of septic arthritis

The presence of fluid in the joint can be seen on a plain radiograph (Guerra *et al*. 1978). Ultrasound and MRI are more sensitive in diagnosing hip effusions and, using either fluoroscopy or ultrasound, the joint can be aspirated and contents analysed.

Arthrography

In both adults and children arthrography can be used after aspiration in the diagnosis of septic arthritis. Though contrast is said not to be bacteriostatic, joint fluid should be aspirated before contrast injection. Contrast demonstrates the state of the synovium, shows its contraction and irregularity, and also outlines areas of bone and cartilage destruction (Fig. 58).

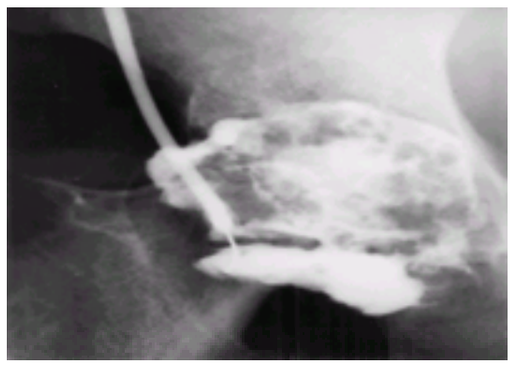

Fig. 58 Tuberculosis of hip. The presence of an irregular shrunken synovium is demonstrated together with erosion of the underlying bone at arthrography.

Arthrography is still very much in use in the assessment of prosthetic loosening and infection. Again, the joint is aspirated, the specimen sent for microbiological investigation, then contrast, usually around 20 ml, injected. Loosening is shown by contrast filling the lucent gap between bone and cement or prosthesis. The width of this gap, if present at all, should be less than 1 mm or less.

Tumours of synovium are infrequent. Benign lesions are pigmented villonodular synovitis (Goldman and Dicarlo 1988; Jelinek *et al*. 1989) and synovial osteochondromatosis. In pigmented villonodular synovitis, a distended capsule is associated with synovial proliferation and bone scalloping (Fig. 59). The joint space is preserved initially as cartilaginous destruction is a later phenomenon. Aspiration may give a serosanguinous fluid. Synovial chondromatosis is associated with multiple (four or more) pearl-like chondral tumours, either floating loose, or in the fronds of proliferating synovium (Fig. 18). When these pearls ossify, they may be seen on a plain film. Often the ossification is total, but a more irregular pattern may be found. Arthrography confirms the major radiological features—erosions, synovial proliferation, and loose bodies. Aspiration may give a clear fluid.

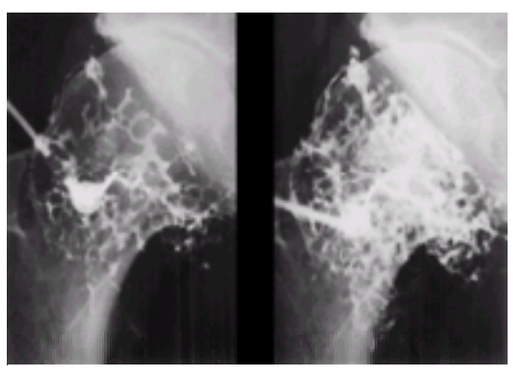

Fig. 59 Pigmented villonodular synovitis. At arthrography the frond-like proliferation of the synovium is demonstrated. This is associated with corticated erosion of the underlying bone.

With malignant synovioma, a patchily ossifying articular mass is associated with bone invasion.

The knee joint

It is easy to understand why MRI of the knee has superseded arthrography. This latter technique needs an experienced operator and preferably a fine-focus X-ray tube, which is not always available. MRI not only demonstrates superficial meniscal lesions, i.e. those to which contrast and air would have access, it also shows change within the meniscus not otherwise accessible to X-rays, as well as demonstrating the cruciate and collateral ligaments and the other extra-articular structures (see below).

Use of MRI

Accuracy rates are of the order of 95 per cent for the diagnosis of meniscal lesions (Mink *et al*. 1988), while the reported accuracy of arthroscopy is similar (Table 2) (Ireland *et al*. 1980; Thijn 1982). Fluid in the meniscus is shown as a band, or disc, of increased signal in the meniscus and may be graded accordingly (Fig. 60) (Mink and Deutsch 1990).

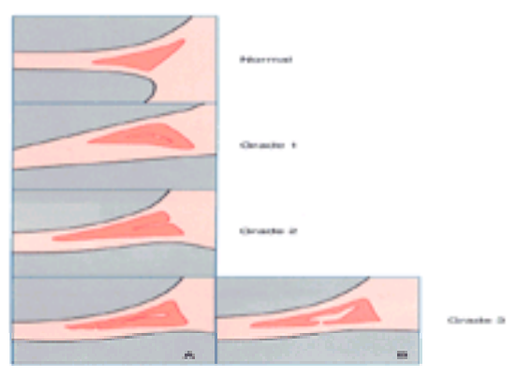

Fig. 60 Classification of meniscal change at MRI from normal to tear, according to Mink *et al*. (1993).

Areas of increased signal may be seen in adolescents and in older asymptomatic knees and are usually the result of myxoid degeneration (Stoller *et al*. 1987). Should the bright signal extend to the meniscal surface, a tear should be diagnosed and would be seen at arthroscopy. Equivocal or doubtful extension to the articular surface of the meniscus is responsible for false-positive diagnoses and, if in doubt, a tear should not be diagnosed (Kaplan *et al*. 1991).

Studies on American football players have shown progression from grade II to grade III lesions during the season, so that extension of intrameniscal degeneration to tear occurs (Reinig *et al*. 1991). Discoid lateral menisci and tears in them are also easily recognized (Fig. 61). Collateral ligament lesions in particular are well defined and disruption of the ligaments, local haemorrhage, and subsequent fibrosis may all be seen. The relationship between meniscal tears and degenerative changes in the underlying bone is clearly demonstrated (Fig. 62).

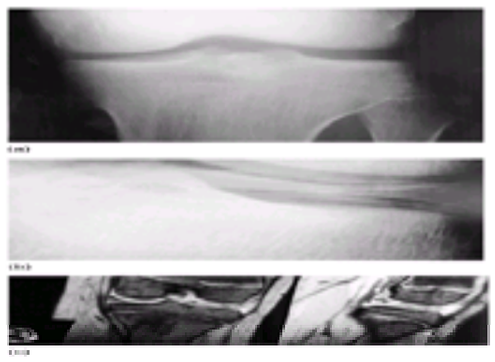

Fig. 61 Discoid meniscus. (a) The plain radiograph shows widening of the lateral compartment and often dishing of the lateral tibial plateau due to the mass effect of the enlarged mensicus. (b) On arthrography, instead of the normal triangular shape of the meniscus, its internal aspect is elongated and expanded. (c) The MR scan of a discoid meniscus shows the expansion of the meniscus, but also increased signal in it. This is extensive and presumably indicates widespread internal degeneration of the meniscus.

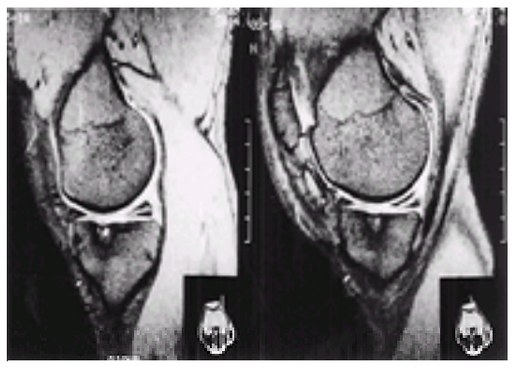

Fig. 62 MR scan of the knee showing a tear in the posterior horn of the medial meniscus and associated degenerative changes in the tibial plateau.

MRI is said not to be as accurate as arthroscopy in the diagnosis of stages I and II of chondromalacia patellae, but compares favourably for stages III and IV (Brown and Quinn 1993).

Arthroscopy was always more accurate than arthrography in the diagnosis of cruciate ligament tears (Table 2(b)). MRI demonstrates changes in the cruciate ligaments. The posterior ligament is better imaged as it is larger, while the anterior, besides being thinner, is also inclined at an angle to the midsagittal plane. It is thus necessary to image the anterior cruciate ligament with the limb in around 15° of external rotation.

Tears, in the acute phase, may be partial or rupture of a cruciate ligament may be total and are associated with fluid seen with T_2-weighted or STIR sequences. The tear may be seen, or total retraction may occur, so that the ligament is no longer visible along its normal course (Fig. 63).

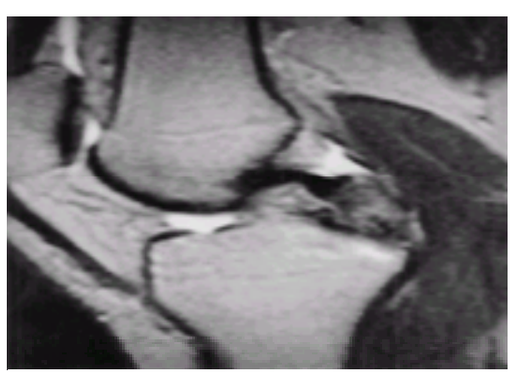

Fig. 63 MR scan of the knee. The posterior cruciate ligament is avulsed and has also taken the subadjacent cortical bone from the upper tibia with it. Note the oedema in the underlying tibial plateau.

When chronic, the torn ligaments fibrose and have an abnormal contour but need no longer be oedematous. The accuracy of MRI in the diagnosis of cruciate ligament lesions is up to 100 per cent in the literature (Lee *et al*. 1988; Mink *et al*. 1988).

The ankle

Arthrography at the ankle has been used to demonstrate tears of the collateral ligaments, even acutely after injury.

Tenosynovitis at the ankle tendons has been diagnosed by contrast injection of the tendon sheath, which is performed easily by direct puncture of the palpated tendon (Fig. 64). Tendon rupture, thickening, and synovial irregularity may all be seen and the images complemented by CT scanning but, again, this has been superseded by ultrasound and, especially, MRI (Fig. 65).

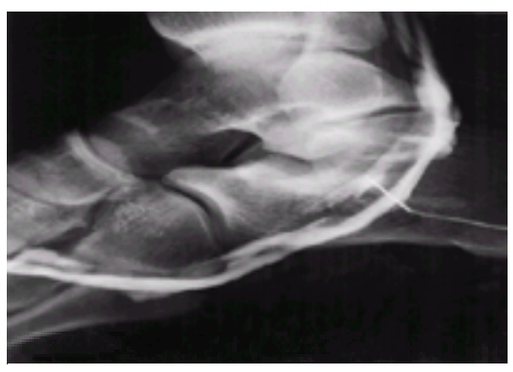

Fig. 64 Tenosynovitis shown at arthrography; peroneal tenosynogram. The irregularity of the synovial sheath is demonstrated in synovitis. The filling defect in the middle of the sheath is of course the tendon.

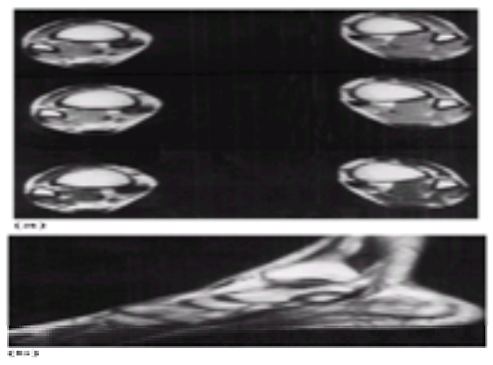

Fig. 65 Ruptured tibialis posterior tendon; sagittal and axial MR images. (a) The axial slices show both ankles. On the normal left side, the tendons behind the medial malleolus are well defined and compact. On the right, there is obvious thickening. This is due to retraction and the changes are easily identified then on the sagittal image (b).

MRI is good for evaluating structures at and around the ankle joint, including tendons and ligaments, as well as articular surfaces and the joint space.

Imaging of the hind foot

Pain in the heel is a recognized feature of seronegative and seropositive arthritis, described by Bywaters (1954). Erosions arise in varying sites around the heel, at target areas for the various arthritides, as described by Resnick *et al*. (1977). Erosions may be associated with a retrocalcaneal bursitis, seen on a soft-tissue lateral radiograph of the foot (Fig. 8).

Thickening of the distal Achilles tendon is also shown. Erosions occur above, at, and below its insertion on the posterior aspect of the calcaneus and will be associated with local increase in uptake on a radioisotope bone scan. Similarly, erosions form on the plantar surface of the calcaneus in the region of the origin of the plantar fascia in the seropositive and seronegative arthritides.

CT scanning demonstrates the bony erosions and can also show tendinous thickening, but the soft tissue changes are clearly demonstrated at MR imaging.

Resnick *et al*. (1977) demonstrated that 22 per cent of normal individuals have plantar spurs, which increase in incidence with age. Normal spurs are 4 mm or less in size and smooth in outline. Rheumatoid patients may have benign-looking spurs which may be painless, but fluffy irregular spurs occur in seronegative and seropositive patients, often associated with periostitis on the more distal inferior surface of the calcaneus, retrocalcaneal recess abnormalities, tendon thickening, and erosions. Benign spurs may become irregular with progression of disease and, similarly, irregular spurs may become smooth with remission of disease.

Spur formation is thus seen as a changing phenomenon in the long term. Larger, denser, and fluffier plantar spurs are strongly suggestive of Reiter's syndrome, in which posterior calcaneal spurs are rarely, if ever, found (Fig. 66) (Mason *et al*. 1959).

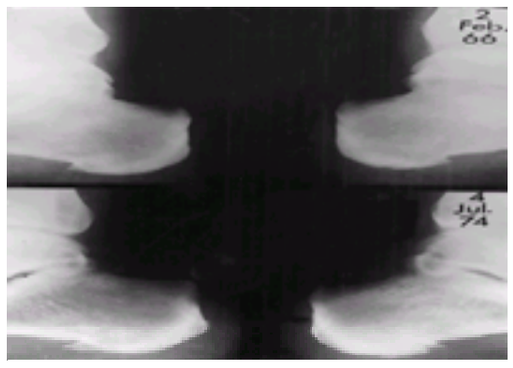

Fig. 66 Reiter's syndrome. A large, fluffy plantar periostitis is shown.

The tendo-Achillis and plantar fascia can be seen on a satisfactory conventional lateral radiograph, and the tendo-Achillis is also defined on CT (axial) images. The isotope scan is positive in the presence of erosions or enthesitis at musculotendinous insertions and may be positive in the early phase of the disease, before change is seen on CT or MR scans (when only the periosteum is affected).

MRI is of great value in defining soft tissue abnormality, showing thickening of tendons, local bursitis and oedema in tendon sheaths, plantar fascia, and calcaneus. These changes are seen on T_2-weighted images and especially fat suppression (STIR) sequences. Tears and tendinitis in the tendo-Achillis are especially well shown at MR scanning (Fig. 67).

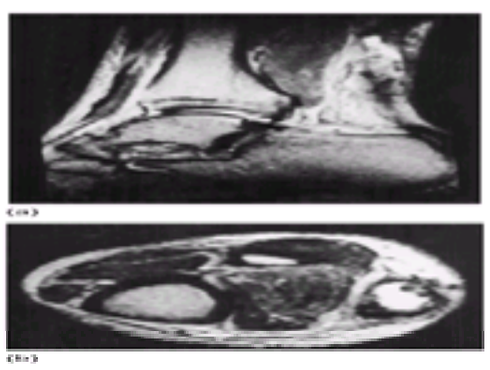

Fig. 67 MRI of the tendo-Achillis showing a degenerate and ruptured tendon. The capsule around the tendon seems intact but the space between the two frayed ends is filled with fluid.

Os trigonum

The os trigonum is seen in between 3 and 15 per cent of feet. It is almost certainly a tarsal accessory bone, rather than an old non-united fracture of the normal posterior process seen in 38 per cent of feet.

The ossicle is demonstrated clearly on a lateral view of the foot. It may be the cause of symptoms of pain and tenderness due to impingement in plantar flexion in

footballers or ballet dancers. The normal ossicle is smooth and well corticated, as indeed is the normal posterior tubercle, but with a normally lucent central medulla.

With chronic impingement, central sclerosis and cortical irregularity with pitting and local soft-tissue oedema result. These changes can all be seen on a plain lateral radiograph, as well as at tomography and CT scanning.

The radioisotope bone scan is of great value here as a screening test, an abnormal ossicle or tuberosity showing up as a strongly positive area (Fig. 68). Changes of osteonecrosis and soft tissue swelling are also seen at MR scanning (Renton 1991b).

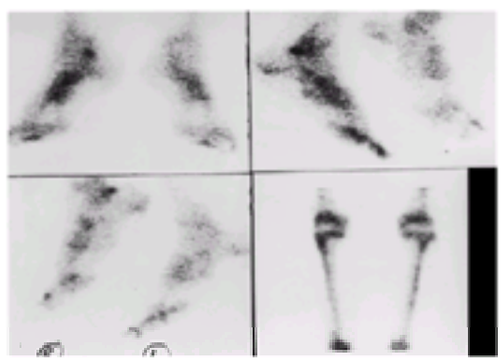

Fig. 68 Increase in uptake at the os trigonum.

The subtalar joint

There are three compartments of the subtalar joint—posterior, middle, and anterior. The posterior and middle lie parallel to each other, inclined at around 35 to 40° to the weight-bearing plane. Imaging on plain films of these compartments is performed with a lateral view in the weight-bearing plane. Weight-bearing films are more easily reproducible between examinations and between patients and, though static, demonstrate the foot in a position of function.

The axial view is taken with the X-ray beam projected along the line of the middle and posterior facets, i.e. at 35 to 40° to the weight-bearing plane. These views are easily performed. More complex views of the hindfoot are perhaps best avoided, especially as these joints are clearly demonstrated at CT scanning.

The peroneal spastic flat foot syndrome

Tarsal coalition exists in many forms. It has been shown to exist *in utero* and is the result of failure of segmentation of the cartilaginous primordia. The most common form is talocalcaneal synostosis, usually at the middle facet and well demonstrated on the axial view. Calcaneonavicular fusion is the next most commonly seen type, easily seen on an oblique view of the foot. These lesions become clinically manifest when the cartilaginous bridge between the ossific nuclei matures, usually into a continuous bar of bone (Fig. 69), though formes frustes are also found. The resulting fusion causes hindfoot rigidity and a flattening of the longitudinal arch, resulting in stretching pain and spasm in the peroneus longus tendon. The syndrome was seen in 2 per cent of Canadian army recruits (Harris and Beath 1948).

Fig. 69 Oblique radiograph of the foot demonstrates calcaneonavicular synostosis.

Plain radiographic changes are those of direct visualization of the fusion, and also indirect evidence of fusion—flattening of the longitudinal arch and talar beak formation.

CT scanning and, of course, MRI demonstrate the fusion directly. CT is superior in demonstrating cortical bone anatomy (Fig. 70). Isotope scanning demonstrates stress changes at the articular surfaces around the fusion.

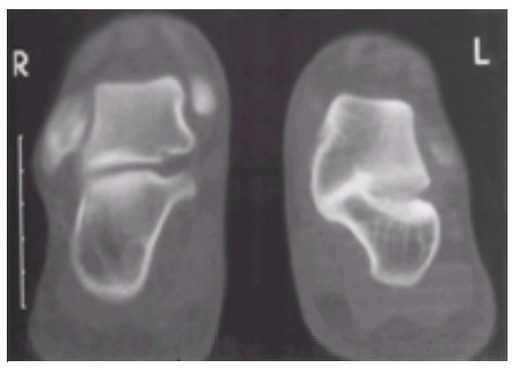

Fig. 70 Hindfoot fusion at the sustentaculotalar joint. Compare normal and abnormal sides. Best demonstrated at CT scanning.

Stress fracture in the foot

Stress fractures are caused by (i) regular, repeated submaximal stress on normal bone or (ii) normal stresses on abnormal, i.e. Pagetic, osteomalacic, or osteoporotic bone.

Stress fractures in the tarsus are usually calcaneal. As with stress fractures elsewhere, the history may be typical but no abnormality may be present on the initial radiograph. This is especially so in the elderly osteoporotic female or in those on long-term steroids in whom bone mass is much diminished and trabecular interruption cannot be seen. Under these circumstances, a radioisotope bone scan will be positive (Fig. 71), and a dense line representing bone compaction or

fracture healing will later show up on a lateral radiograph, tomograph or, especially, CT scan but, if the foot is rested, bony changes may never be seen on film.

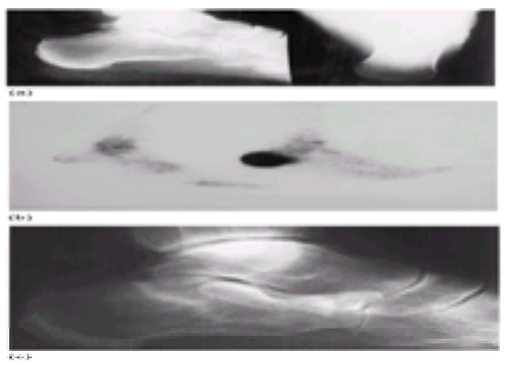

Fig. 71 Occult fracture of the calcaneum. (a) The initial radiograph shows no abnormality but a radioisotope bone scan (b) shows a gross increase in uptake in the calcaneum. (c) Another patient showing a stress or increment fracture in an osteoporotic calcaneum, seen as a serpiginous dense line extending to the upper cortex of the bone and reaching it at a right angle.

Stress lesions are well imaged at MR scanning, especially if the affected bone contains yellow marrow, i.e. fat. Stress lesions in bone show as ill-defined areas of decreased signal on T_1-weighted and increased signal on T_2-weighted and STIR fat suppression sequences (Fig. 72). These initial changes are the result of local oedema and are not as clearly shown in red marrow areas.

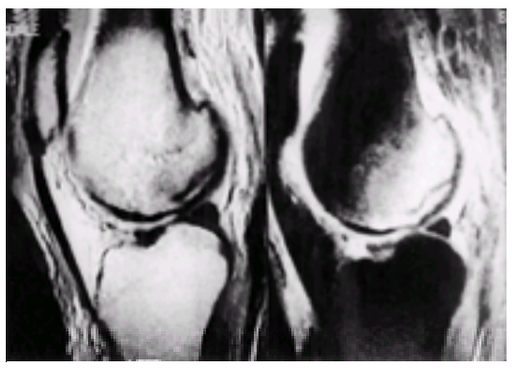

Fig. 72 Occult fracture of medial femoral condyle seen on a T_1-weighted image (a) as a serpiginous band of low signal extending to the posterior femoral cortex surrounded by some loss of the fatty bright signal. The bone oedema, however, is much better demonstrated on the STIR sequence (b).

Should a fracture line occur within the stress lesion (and this is not inevitable), it will be seen, as expected, as a serpiginous or straight, thin, low-signal band at right angles to the adjacent cortex, exactly as expected from a radiograph. It is likely that MRI is at least as sensitive as scintigraphy in the detection of early changes of trauma to bone (Yao and Lee 1988).

Osteoarthritis

It has been stated that MR is ideally the preferred imaging modality for the diagnosis and follow-up of rheumatoid arthritis and variants. Time, availability, and cost probably rule out its use in general clinical practice. The same can be said in the diagnosis of osteoarthritis which typically affects major joints. Again, plain films provide a cheap, quick, and simple method of imaging affected joints at onset and for follow-up. Changes in osteoarthritis include joint narrowing due to cartilage and meniscal destruction, marginal osteophytes, cyst formation and articular collapse, reactive sclerosis, and malalignment. Many of these changes relate to cortical bone and, therefore, they are well imaged on plain films and also at CT scanning (Fig. 73) or MRI (Fig. 74), which show the articular surfaces well. Axial imaging demonstrates the joint spaces, osteophytes, cysts, and changes in bony density especially well. Loose bodies are also well seen. The images may be enhanced by the use of single or double contrast arthrography.

Fig. 73 Osteoarthritis demonstrated at CT scanning. New bone proliferation is seen around the articular surfaces and internally within the joint on the femoral head.

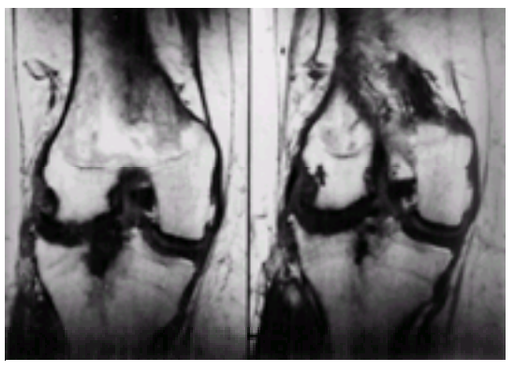

Fig. 74 Osteoarthritis demonstrated at MR scanning. Coronal images show irregular articular surfaces, marginal osteophytes, synovial proliferation and irregularity, or even loss of the adjacent meniscus.

Transient regional osteoporosis

Transient regional osteoporosis is an uncommon, painful condition first described in pregnant women, but more commonly seen in middle-aged men. It is associated with marked demineralization of bone around the hip seen on a plain film associated with preservation of the joint space, a feature which makes septic arthritis perhaps less likely in the presence of severe osteoporosis. The disease is self-limiting and clinical and radiographic changes revert to normal, usually within 6 months.

A radioisotope scan will show marked increase in uptake in the femoral head. The MR scan shows decreased marrow signal on T_1-weighted images, but generally increased signal on T_2-weighted studies—changes compatible with marked oedema (Bloem 1988)—and this may be seen, in the presence of a normal radiograph, early on in the disease.

Avascular necrosis

Deprivation of blood supply to cortex and medulla results in marrow cell death. No changes are seen on the plain film in the early phase, but this still has to be obtained to exclude other abnormalities and for a baseline study.

The early isotope scan demonstrates photopenia (Fig. 75) and subsequently, with repair, will show increased uptake around the abnormal devitalized area corresponding to healing at the zone of creeping substitution.

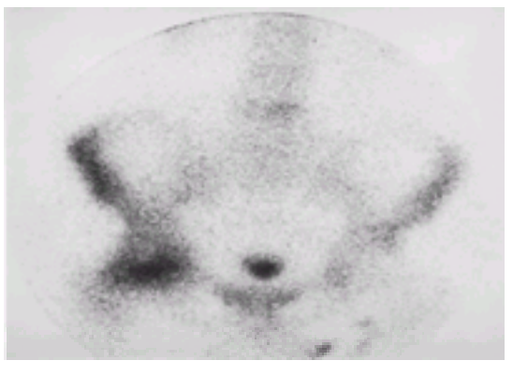

Fig. 75 Avascular necrosis. Radioisotope bone scan shows photopenia of the left femoral head.

Subsequent radiographs may demonstrate a subcortical crest of lucency which prognosticates structural failure and articular collapse (Fig. 76). The joint space remains intact until secondary osteoarthritis supervenes. The plain film may also subsequently show cyst formation and necrotic bone, which remains dense in the midst of demineralization and resorption.

Fig. 76 Avascular necrosis. A sclerotic rim of creeping substitution is seen beneath an area of structural failure of the femoral head.

At MRI, changes in ischaemia precede plain film change, and probably isotope scan changes too (Brower and Kransdorf 1990). Linear or confluent areas of low signal in epiphyses replace bright marrow signal on T_1-weighted images. The linear bands may be subcortical or deep in the bone. The position of the avascular areas can be assessed on axial, sagittal, and coronal slices (Fig. 77).

Fig. 77 Avascular necrosis of both femoral heads seen at MR scanning. The areas of low signal are avascular.

On T_2-weighted images, the low signal band often has a parallel adjacent area of increase in signal representing oedema, or even neovascularity.

It should be noted that even a negative MR scan does not rule out avascular necrosis, as there is a temporal lag between the initial insult and subsequent cell death. Serial studies may be necessary (Mitchell *et al*. 1986; Beltran *et al*. 1988).

4.9.2 Imaging in children

G. H. Sebag and J. F. Quignodon

Introduction

The use of imaging in paediatric rheumatology reflects the old adage that a child is not a small adult. This chapter will illustrate the specificity of joint imaging in children. Successful imaging of children requires a thorough knowledge of the anatomical variants resulting from growth and development, knowledge of paediatric diseases and their manifestations, and finally the need for radiation protection (Mandell *et al*. 1990). Furthermore, in this era of advancing imaging technology, knowledge of the relative values of available imaging techniques is necessary to optimize the management of children with arthritis. The theoretical basis of imaging techniques, including conventional radiography, radionuclide scanning, ultrasonography, computed tomography (**CT**), and magnetic resonance imaging (**MRI**) are described in Chapter 4.9.1. Each is being used in paediatric radiology. Changes in individual diseases will be presented in the appropriate section. As in adult radiology, investigations have to be tailored to the individual needs of the child, and radiologists and paediatricians must collaborate to ensure that the needs of all are best matched.

Practical considerations

High quality, diagnostic examinations of sick children can be obtained consistently with care, time, and patience. The child's co-operation usually requires an explanation of exactly what is going to happen in language that can be understood. It is also crucial to reassure the parents that the procedure will go smoothly and that they will be informed of the results.

Expertise in immobilizing and imaging children is essential to perform the examination quickly and efficiently (Poznanski 1976). It is important that technologists are trained in the handling of neonates, small infants, and small children. A number of immobilization devices are available; the simplest ones are very efficient (velcro straps, wooden immobilization boards, bags). Immobilization need not be traumatic to the child. It will allow better positioning for radiography, fluoroscopy, CT, MR, and radionuclide scanning and make motion much less likely. This will result in less radiation to the child as smaller fields can be used and the chance of repeat examinations is reduced. In some cases (especially children under the age of 6 years) it is necessary to use sedation for imaging procedures such as arthrography, CT, and MRI. The choice of drug and route of administration must be made on an individual basis according to the type of examination, the child, the facility, and the experience of the radiologist and the support team.

Musculoskeletal radiography

The plain film is almost always the initial imaging technique used in the evaluation of the musculoskeletal system. Its predominance in diagnosing, for example, fractures, bone tumours, congenital dysplasias, metabolic and inflammatory disorders, is confirmed by the fact that it is the only technique needed for most children. It is the most widely available modality and can be obtained more quickly and easily than any other type of imaging (Fig. 1). Plain films play an important part in localizing and defining the nature of a lesion, especially when the clinical history and physical examination are uncertain or not contributory. This property is especially true in infants and young children who do not localize pain accurately or effectively communicate symptoms to the physician. For example, plain films are invaluable in the diagnosis of the aetiology of limping of recent onset for which a traumatic cause is not obvious (Blumhagen 1994) (Table 1).

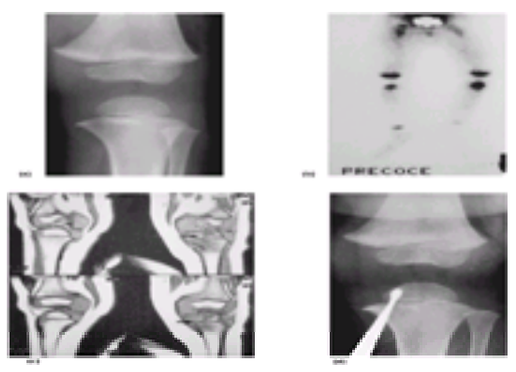

Fig. 1 Acute osteomyelitis in a 2-year-old boy. (a) Plain film: medial radiolucent area in the tibial metaphysis. (b) Bone scan: increased uptake in the upper left tibia. (c) T_1-weighted MR images confirm the previous findings and show the extension of the infection through the growth plate in the epiphysis (arrow). (d) Peroperative plain film confirms the MR findings.

Traumatic:
- fractures
- stress fractures
- non-accidental trauma
- foreign body

Inflammatory:
- transient synovitis
- osteomyelitis
- septic arthritis
- discitis
- soft tissue abscess

Congenital:
- congenital dislocation of the hip
- club foot
- spinal dysraphism

Avascular necrosis and related conditions:
- Legg–Calvé–Perthes' disease
- osteochondrosis
- osteochondritis dissecans

Slipped capital femoral epiphysis.

Neoplastic:

Table 1 Common causes of limping in children

As in adult radiology, conventional radiographs allow grouping of the various arthritides on the basis of the distribution and the pattern of joint space changes (Resnick 1988) (Fig. 2). However, radiological findings although very important are only one of the criteria by which arthritis is judged to be present and by which a specific diagnosis is established (Ansell 1990). Furthermore, assessment of disease progression (e.g. juvenile chronic arthritis) is made possible by repeating the plain films. In young children especially, radiographic changes (i.e. joint space narrowing indicative of cartilage loss) represent late and indirect signs of synovial disease.

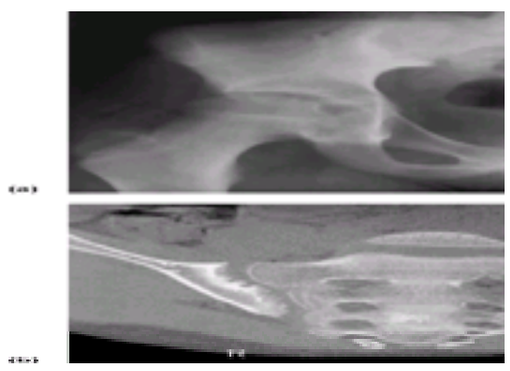

Fig. 2 Juvenile spondylarthropathy in an 11-year-old boy. (a) Plain film: lateral subluxation of the femoral head with lateral narrowing of the joint space. Sclerosis of the sacroiliac joint. (b) CT: sclerosis, irregularity, and erosion of the sacroiliac joint.

Technical considerations

Radiation protection must be a priority in children. Proper coning of the X-ray beam, use of high-speed intensifying screens, and the use of gonadal shielding all help reduce exposure. In the assessment of scoliosis, the frontal film is taken anteroposteriorly in order to reduce breast irradiation, and lateral view should be kept to the minimum in the follow-up. Other ways of reducing radiation to the patient include the use of digital radiography, if available. Electronic image manipulation permits viewing of segments of the image, adjustment of contrast, and measurement of curve or length. This reduces the need for repeat studies when the initial technique is unsatisfactory. Digital radiography has special applications for scoliosis and leg-length discrepancies, which require frequent follow-up examination (Kushner *et al*. 1986). Contrast manipulation allows the enhancement of soft tissue thickening and periarticular fat pad displacement. Evaluation of these structures are especially useful in infants and young children. At least two views at right angles, a true frontal and a lateral projection, should be obtained of the involved joint or extremity.

Correct positioning is important for accurate interpretation. A variety of radiographic guidelines (drawing lines, measurements of angle and distance) have been suggested to detect any distortion of the anatomical relationship. Use of guidelines is highly dependent upon proper positioning. For instance, tilting of the pelvis can result in false interpretation of hip position when evaluating an infant for congenital dislocation and/or dysplasia (Fig. 3).

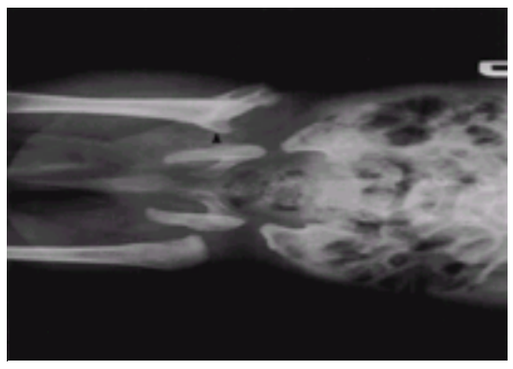

Fig. 3 Septic arthritis in a 4-month-old baby with dislocation of the left hip. Radiograph shows lateral displacement of the femoral head and new bone formation.

Recognition of even minimal pelvic and femoral rotation is necessary to avoid the false-positive interpretation of joint space widening, especially in a painful hip that is held typically in abduction and external rotation (Fig. 4). Unrotated pelvic views show symmetry of obturator foramina and of the medial acetabula as well as alignment of the pubic symphysis with the sacral midline. Joint space widening secondary to the accumulation of fluid in the hip joint has been found to be a more reliable sign in young children and infants. In older children, detecting fluid in the hip joint is best accomplished with ultrasound.

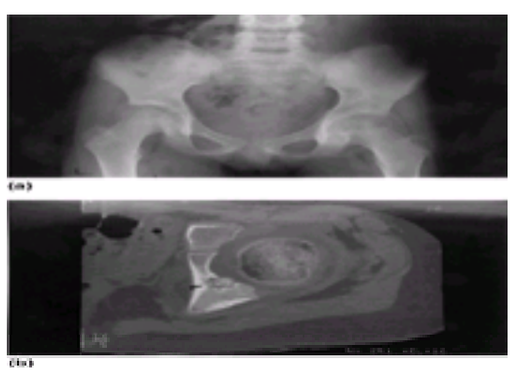

Fig. 4 Osteoid osteoma affecting the left hip in a 9-year-old boy. (a) Plain film: left hip effusion with severe osteoporosis. (b) CT scan: localizes the site of nidus in the acetabulum.

Frog-leg lateral views (in addition to anteroposterior neutral views) of the hip are mandatory when Legg–Calve–Perthes' disease or a slipped capital femoral epiphysis is suspected. The abnormal anterior subchondral surface of Legg–Calve–Perthes' disease and early posterior slippage are demonstrated better on these views.

In addition, it is useful to obtain comparative views of the normal side, especially in cases where abnormal findings are subtle. It is very useful in the assessment of the shape and size of the ossification centres (normal variants, advanced maturation). However, comparative views are not systematically required, although occasionally these, oblique, or other special views will facilitate a diagnosis. When choosing the right views, one must keep in mind that symptoms in children can be very confusing. For instance, children with discitis can experience symptoms suggesting lower extremity disease (limp, failure to bear weight, referred hip pain) and in

this case, a spinal view should be obtained.

Special views include :

- weight-bearing films, bending
- flexion views of the cervical spine (C1 to C2 dislocation)

These views are performed to determine whether a joint is stable or not. The C1 to dens distance is normally wider in children (as great as 4 to 5 mm) than in adults and flexion views are very useful to detect instability (Table 2).

Congenital hypoplasia of the dens and C1
Dislocation (anterior, rotatory)
Collagen vascular disease (juvenile chronic arthritis)
Trisomy 21
Storage diseases (Morquio disease)
Spondylo- and punctate epiphyseal dysplasia

Table 2 C1 to C2 instability

Growth abnormalities are an important issue in children with rheumatological disease. Epiphyseal overgrowth (caused by hyperaemia), epiphyseal deformities, accelerated ossification with premature fusion of growth plate, and compression fractures lead to malalignment and length discrepancy, especially in unilateral disease. Measurement is an important part in the evaluation of growth abnormalities. It includes estimation of valgus and varus angles, leg-length discrepancy, spinal curvature, femoral anteversion, and tibial torsion amongst others. Tables, charts, and graphs of standard measurements have been widely published and are referred to daily by practising orthopaedists and radiologists (Pettersson and Ringertz 1991; Ozonoff 1992). The use of these measurements correlated with the patient's skeletal age at each determination allows a prediction of future growth and effect and timing of surgery to be made (Pettersson and Ringertz 1991; Ozonoff 1992).

General growth abnormalities are influenced by the disease (type, onset, and duration), immobilization, and steroid therapy which lead to growth delay. Skeletal age assignment is the most common evaluation. After 1 year of age, the number, shape, and stage of development of the epiphyses in the left hand and wrist are compared with standards for various ages up to the time of epiphyseal fusion; the atlas of Greulich and Pyle (1959) is normally used. In addition, spinal growth in scoliosis can be estimated using Risser's method (Risser 1948) by assessing iliac crest development on the frontal view of the entire spine.

Osteoporosis, induced for example by immobilization and steroid therapy, can be assessed on plain films both in the appendicular and axial skeleton. Measurement of the cortical thickness of tubular bones is commonly performed (in metacarpals and tibia for instance).

Evaluation of musculoskeletal changes on plain films

Proper interpretation of plain films is pivotal in directing further diagnostic evaluation that can be both complex and expensive in children. Reading guidelines are therefore useful to enhance plain film interpretation skills. On a systematic basis, one should analyse:

- joint space (widening, narrowing, malalignment, ankyloses, calcification, gas) (Fig. 1 and Fig. 4)
- soft tissues (obliterated or displaced fat pads, calcification, ossification opacities, thickening and reticulation, tendon width changes) (Fig. 5 and Fig. 6)

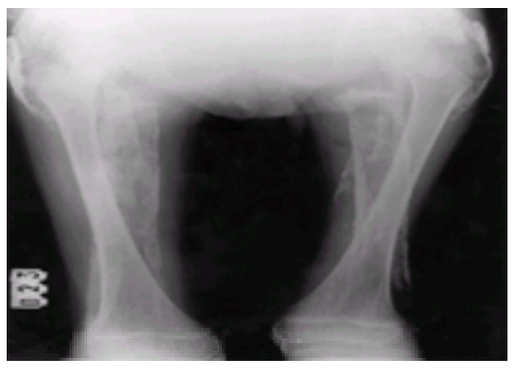

Fig. 5 Dermatomyositis in a 7-year-old girl. Plain film of extensive calcinosis in the subcutaneous tissue and in the muscles.

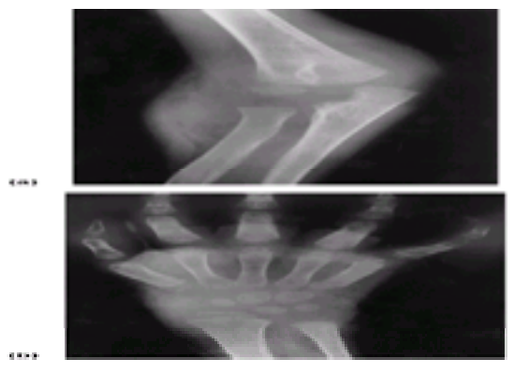

Fig. 6 Juvenile chronic arthritis in a 4-year-old boy at the early stage. Radiographs of the elbow (a) and wrist (b) show marked soft tissue swelling and joint effusion.

- bone density (increased or decreased, generalized or localized)
- epiphysis (shape, size, subchondral bone, defect, erosion)
- metaphysis (transverse bands, widening, cupping, destruction)
- growth plate
- diaphysis (cortical bone, periosteal reaction, tubulation)

The significance of these findings in children has been described widely (Thomas, P.S. *et al*. 1994).

By grouping the findings and using the complete range of the common causes of these findings, one can narrow the differential diagnosis (Swischuk *et al*. 1995)

(Table 2, Table 3, Table 4, Table 5, Table 6, Table 7, Table 8, Table 9, Table 10, Table 11, Table 12, Table 13, Table 14 and Table 15). This practical approach allows a proper interpretation of plain films, especially for clinicians or radiologists who practise paediatric rheumatology only occasionally.

Traumatic effusion and/or dislocation
Septic arthritis (hip, shoulder)
Transient synovitis (hip)

Juvenile chronic arthritis

Table 15 Periosteal bone reaction

Finally, knowledge of the normal is a prerequisite for recognition of the abnormal. Familiarity with appearances at the various ages of development is learned by experience but considerable help may be gained from atlases both of normal variants and of normal development at different ages (Keats 1991; Swischuk *et al*. 1993). The following points should be borne in mind:

1. the bone-within-bone appearance: most commonly seen in the spine in newborns and premature infants;
2. periosteal new bone seen in normal neonates up to about 3 months of age, especially in the femoral diaphysis;
3. transverse sclerotic lines in the metaphysis (growth recovery lines);
4. irregular ossification centre seen especially in the medial aspect of the lower femoral epiphysis;
5. fibrous cortical defect occurring particularly around the knee and located in the superficial bony cortex;
6. gas in the joint: the 'vacuum' joint effect commonly seen in the shoulders and the hips of infants.

Role of plain films in the management of children with musculoskeletal disease

Diagnostic study

Plain radiographs provide crucial information in the early stages of diagnosing disease in children (Jacobs 1982; Mandell *et al*. 1990; Swischuk 1994; Thomas, P.S. *et al*. 1994) (Fig. 1, Fig. 2, Fig. 4, and Fig. 7). For instance, in cases with non-specific clinical presentation (such as limp, failure to bear weight, joint pain, back pain) the findings of plain film can be straightforward:

Fig. 7 Talocalcaneal coalition in a 10-year-old boy with foot pain.

1. stress and pathological fractures (Fig. 8, Fig. 9, and Fig. 10);

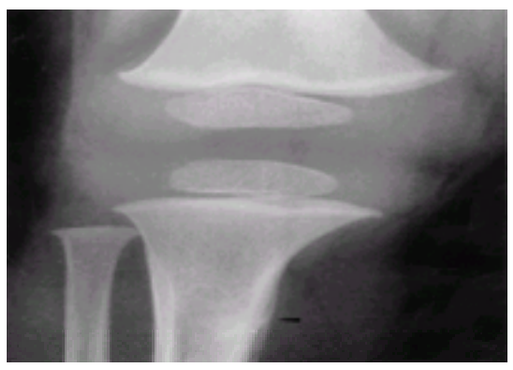

Fig. 8 Stress fracture in a 5-year-old boy. Area of increased sclerosis and periosteal bone deposition in the upper tibia.

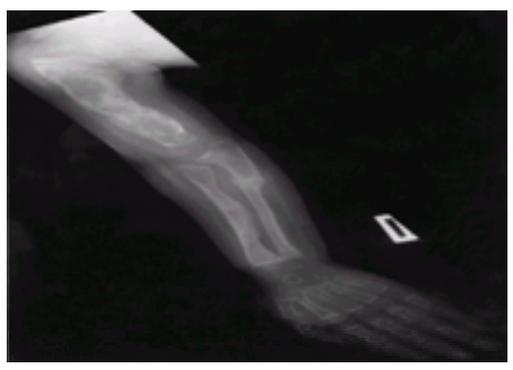

Fig. 9 Pathological fractures in a 2-year-old boy with osteogenesis imperfecta. Radiograph shows multiple fractures, diffuse decreased bone density, and transverse radiolucent metaphyseal bands.

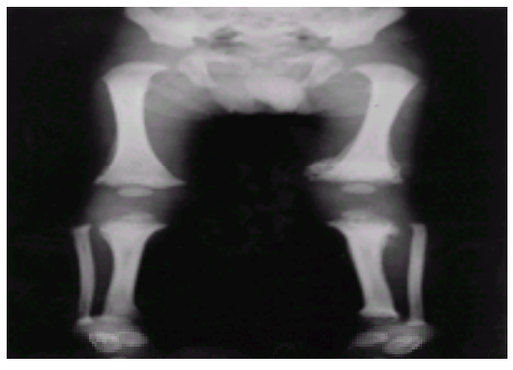

Fig. 10 Child abuse in a 4-month-old baby refusing to move his left limb. Radiograph shows bilateral metaphyseal corner fractures at different stages of healing.

2. transverse radiolucent metaphyseal band and osteolysis in metastatic neuroblastoma or leukemia (Fig. 11 and Fig. 12);

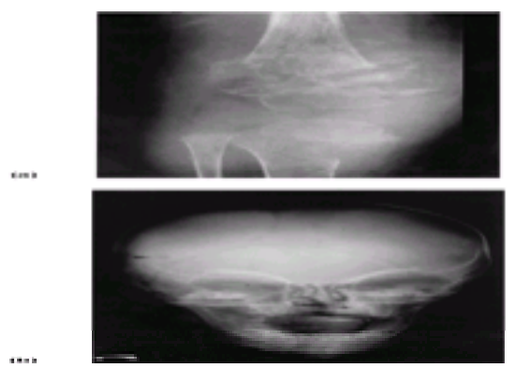

Fig. 11 Metastatic neuroblastoma in a 2-year-old boy with intense knee pain. (a) Radiograph of the knee. Extensive osteolysis and periosteal bone reaction. (b) Radiograph of the skull. Osteolytic area in the right parietal bone.

Fig. 12 Acute leukaemia in a 7-year-old-boy with wrist pain. Distal metaphyseal destruction of the cubitus on plain film.

3. joint effusion, subluxation of the femoral head with or without bone destruction in infant with septic arthritis of the hip;
4. posterior slippage of the femoral head indicative of slipped capital femoral epiphysis (Fig. 13);

Fig. 13 Slipped capital femoral epiphysis in an 11-year-old boy.

5. disc narrowing with indistinct vertebral endplate indicative of spondylodiscitis;
6. small subchondral fragment within a defect in the medial femoral condyle indicative of osteochondritis dissecans of the knee;
7. small crescentic subchondral lucency of the femoral head on the frog-leg view indicative of Legg–Calve–Perthes' disease.

Furthermore, in the imaging evaluation of bone tumours or tumour-like disorders, plain radiographs are pivotal in directing further investigations. Plain films are very

often sufficient to separate lesions into two categories:

1. those that should be left alone, such as:
   - non-ossifying fibroma
   - fibrous dysplasia
   - chondroid lesions (Fig. 14 and Fig. 15)

Fig. 14 Exostosis in a 13-year-old girl with a medial mass of the knee.

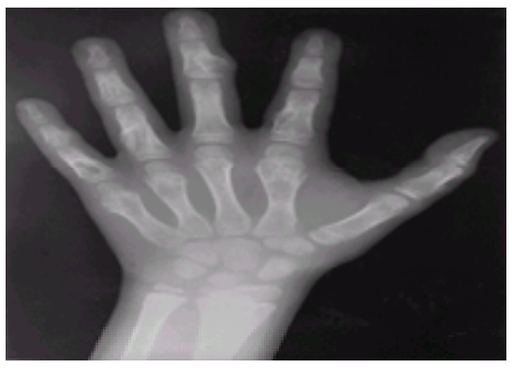

Fig. 15 Ollier disease in a 7-year-old boy with typical multiple enchondromas of the hand.

   - myositis ossificans
   - tumorous calcinosis
   - bone cysts
   - histiocytosis X (Fig. 16)

Fig. 16 Histiocytosis X in a 7-year-old boy with typical vertebra plana.

2. those that require intervention such as biopsy:
   - malignant lesions (sarcoma)
   - complicated lesions
   - undetermined lesions

It is important that developmental variations and benign lesions are not mistaken for malignancy. It is equally important that the diagnosis of malignancy is not delayed.

A skeletal survey is often required to establish if the lesion is solitary or polyostotic (histiocytosis X, fibrous dysplasia, malignancy) and to guide an eventual biopsy to the optimal site (Fig. 11, Fig. 12, and Fig. 16).

Chest films are often required in childhood rheumatic diseases. A frontal chest film is obtained most frequently. Lateral views are usually not much help but may be useful in the detection of pleural effusion and lymph node enlargement. Chest films are performed to rule out any pulmonary nodules, cavities or infiltrate, pleural effusion, mediastinal and/or hilar lymph node enlargement, and cardiomegaly (pericardial fluid, cardiac failure, myocarditis). Chest films are indicated especially in systemic juvenile chronic arthritis, systemic lupus erythematosus, scleroderma, dermatomyositis, Kawasaki disease, systemic vasculitis, sarcoidosis, rheumatic fever, the occurrence of a positive tuberculin test, or if otherwise clinically required.

Follow-up study

Conventional radiography is of major importance in evaluating disease progression and/or the effect of treatment in paediatric rheumatology in a reproducible and standardized manner (Jacobs 1982; Resnick 1988; Kaye 1990) (Fig. 2, Fig. 6, Fig. 17, and Fig. 18). In the literature, various methods of radiographic grading system have been proposed, especially in juvenile chronic arthritis and haemophilic arthritis (Pettersson *et al*. 1980; Pettersson and Rydholm 1984). Grading systems in adult rheumatology (such as the Steinbrocker method of evaluation of rheumatoid arthritis) have not be adapted for paediatric rheumatology (Steinbrocker *et al*. 1949).

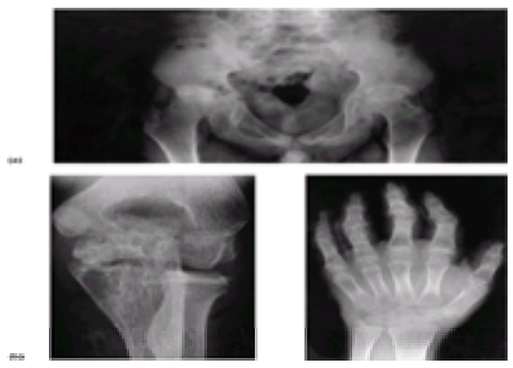

Fig. 17 Juvenile chronic arthritis in a 12-year-old girl with severe destructive abnormalities on the plain films of the hips (a), elbow (b), and the wrist and hand (c).

Fig. 18 Juvenile chronic arthritis in a 6-year-old girl with destructive abnormality on the plain films of the knee.

In children, less attention is paid to the loss of joint space. The reason is that estimating the joint space in children (especially young) is difficult because of :

- the thickness of the epiphyseal cartilage
- weight-bearing difficulties on the painful joint
- projectional error associated with flexion and/or valgus deformity
- joint space loss (often late and/or less prominent feature)

In children, scoring systems pay much attention to growth abnormality (Dale *et al*. 1994) (Table 16). In juvenile chronic arthritis, a radiographic classification system is often applied to the knee, which is the most commonly affected joint in childhood (Table 16 and Table 17).

Grade 0: normal condition

Grade I: slight abnormality
juxta-articular osteoporosis
± joint effusion

Grade II: growth abnormality
epiphyseal, patellar overgrowth

Grade III: destructive abnormality
overgrowth+marginal bony erosions
± malalignment

Grade IV: severe destructive abnormality
marginal bony erosions
epiphyseal deformations
malalignment

Grade V: mutilating abnormality
pronounced alignment changes and destruction
bony ankylosis

Table 16 Radiological grading system applied to the knee in juvenile chronic arthritis (Dale et al. 1994)

	Femur	Tibia	Patella
Osteoporosis	0–1	0–1	0–1
Enlargement of epiphysis or patella	0–1	0–1	0–1
Erosion	0–1	0–1	0–1
Subchondral cyst deformation	0–1	0–1	0–1
Deformed joint surfaces	0–1	0–1	0–1
Score	0–5	0–5	0–5
Total score		0–15	

Table 17 Radiological scoring of knee destruction in juvenile chronic arthritis (Petterson and Rydholm 1984)

Pettersson and Rydholm (1984) proposed radiological scoring of the knee joint destruction in juvenile chronic arthritis by dividing the joint into three separate compartments (i.e. femur, tibia, and patella). Each of the bones participating in the articulation is examined for signs of osteoporosis, enlargement, erosions, subchondral cysts, and deformity of the joint surface. The presence or the absence of these parameters in the joint is allotted 1 or 0 points, respectively (Table 17). This scoring method has a very significant correlation with the clinical status.

Finally, evaluation of complications of disease and treatment (especially therapy) is commonly performed by looking for: delayed bone age, decreased bone density, local growth abnormalities, compression fractures, avascular osteonecrosis, and instability of cervical spine.

Doppler ultrasonography

Doppler ultrasonography use has expanded greatly for the musculoskeletal system and has become a primary imaging tool for many aspects of paediatric rheumatology. In infants and young children, ultrasonography shows the cartilaginous forms of bones that cannot be visualized with plain radiography. Use of Doppler ultrasonography continues to increase as resolution of the equipment improves and anatomic structures become more easily identified with high frequency transducers (5 to 7 MHz). Ultrasonography is widely available, safe, non-ionizing and non-invasive, easily accepted by children, and can be performed at the bedside, in intensive care, or in a neonatal unit. Ultrasonography also allows dynamic stress examination of the hip joint.

Colour and pulsed Doppler facilitate identification of vascular anomalies. With the advent of power Doppler, visualization of femoral head vascularization is achievable consistently in newborns and shows promise in the detection of occlusion of feeding nutrient vessels (septic arthritis, congenital dislocation of the hip) (Fig. 19). Therefore, in some particular conditions, ultrasonography has become the primary imaging study performed, especially in the hip, replacing plain films. The early detection of hip dysplasia or dislocation allows prompt treatment and is the key to successful management. By treating this condition at a young age, most of the sequelae that occur when congenital dislocation of the hip goes unrecognized can be avoided.

Fig. 19 Femoral head vascularization in a newborn. Power Doppler visualizes the branches of the circumflex arteries.

Clinical screening programmes have been instituted for all neonates. The use of imaging has been allied closely with programmes for detection and treatment. In the newborn period, plain films are unreliable since the key structures of the hip are composed of cartilage.

On ultrasonographic images, the cartilaginous components of the acetabulum and femoral head can be distinguished from other soft tissue structures. Real-time ultrasonography permits multiplanar evaluation which clearly defines femoral head dislocation in relation to the acetabulum (Keller *et al*. 1988). The ability to observe changes in hip position with movement is a further advantage of ultrasonography. The benefits of using ultrasonography in the diagnosis and management of congenital dislocation of the hip have been widely reported (Kalifa *et al*. 1991).

Variations in technique exist and, regardless of the method used, sufficient experience with both normal and abnormal hips should be gained. Initial assessment should be performed by 1 month of age (Keller *et al*. 1988; Kalifa *et al*. 1991). In most cases, referral for initial assessment is a questionable or abnormal physical examination or presence of an increased risk factor (first borns, breech position, oligohydramnios, family history, congenital torticollis, foot deformities). From a posterior approach, ultrasonography can be used to assess hip position after application of an abduction splint.

Ultrasonography is very useful in the detection of joint effusion especially in the hip, which is commonly evaluated in children. The common indications are the child with a limp who refuses to bear weight on the limb, and suspicion of septic arthritis in newborns or infants. Thus the crucial question is whether or not the hip is involved and specifically whether there is fluid in the hip joint. The examination of the hip is quick and within minutes anterior accumulation of fluid with joint capsule distension can be detected (Fig. 20). It is more important to rely on the configuration and shape than on absolute measurements. Furthermore, comparison with the opposite hip is always helpful unless bilateral effusions are present.

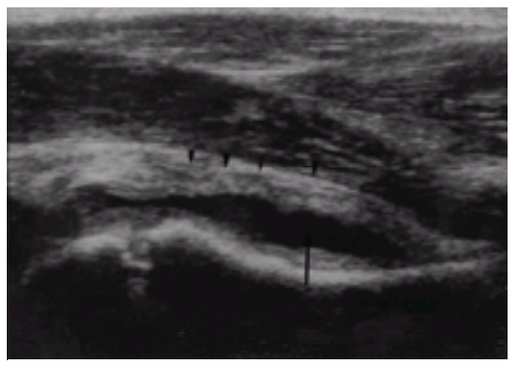

Fig. 20 Fluid in the hip joint. Ultrasonography shows anterior accumulation of fluid (arrow) with distension of the joint capsule and synovial thickening (arrowhead).

The use of ultrasonography is simple and more sensitive than plain films (reported sensitivity range: 88 to 100 per cent) (Marchal *et al*. 1987; Zieger *et al*. 1987). However, the nature of a joint effusion cannot be assessed accurately. We do not attempt to distinguish the different types of fluid and rely on the clinicians to determine which effusions should be tapped.

In the knee, ultrasonography can be used for evaluation of synovial hypertrophy, detection of synovial cysts, and exclusion of popliteal thrombosis (Fig. 21). In contrast, plain radiographs are not helpful in differentiating synovial effusions from synovial thickening. The distinction is easy with ultrasonography where synovial thickening appears as an irregular echogenic area surrounding the effusion (Fig. 20). Unfortunately, in chronic arthritis (such as juvenile chronic arthritis), ultrasonography does not permit reliable detection of joint loculation, which might make intra-articular injection of steroid difficult.

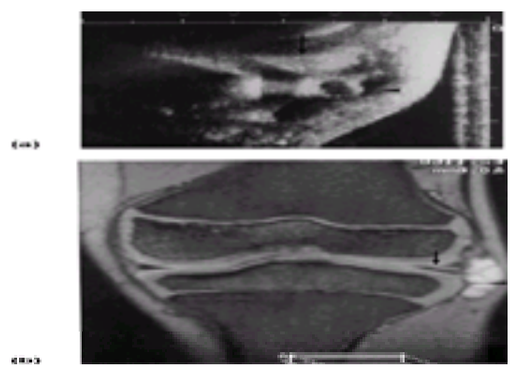

Fig. 21 Meniscal cyst in an 8-year-old boy with knee pain and medial mass. (a) Ultrasonography shows a cystic mass (arrowhead) adjacent to the medial meniscus (arrow). (b) Frontal T_2-weighted MR image shows a torn medial meniscus (arrow) and a meniscal cyst (arrowhead).

Cartilage erosions and thinning can be detected (Sureda *et al*. 1994). However, the whole surface of cartilage cannot be assessed. Ultrasonography does provide an objective method for observing disease course during therapy (Eich *et al*. 1994; Sureda *et al*. 1994).

Power Doppler also shows promise in evaluating the amount and the activity of pannus in juvenile chronic arthritis. Proliferative synovium, which is extremely

vascular, shows high power Doppler signal (Fig. 22).

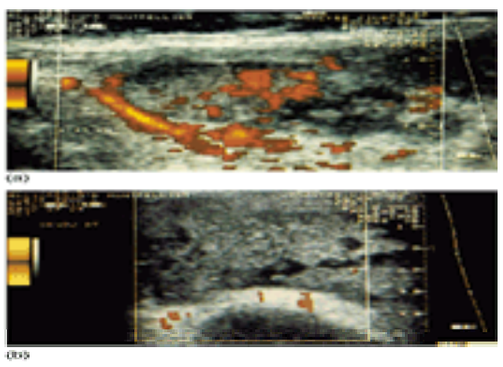

Fig. 22 Juvenile chronic arthritis affecting the knee in a 5-year-old girl (by courtesy of Dr A. Couture, Montpellier, France). (a) Power Doppler shows hypervascularization of the active pannus. (b) After intra-articular injection of steroid, there is a decrease of power Doppler signal within the pannus.

Finally, in a child presenting with a swollen red extremity, Doppler ultrasonography can be very useful by distinguishing:

- pyomyositis
- fluid collection (subperiosteal, abscess, bursitis)
- thrombophlebitis (Fig. 23)

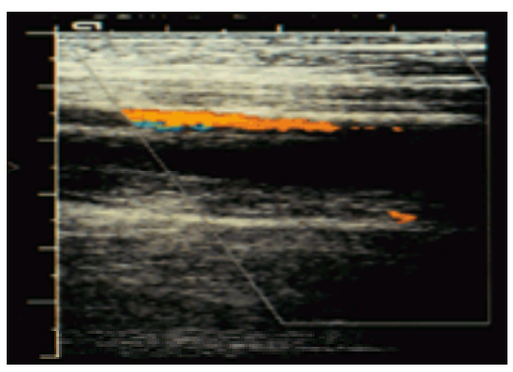

Fig. 23 Thrombophlebitis in a 15-year-old girl with Behçet's disease. Colour Doppler shows a thrombosis of the superficial femoral vein.

- non-opaque foreign body
- vascular malformation (Fig. 24)

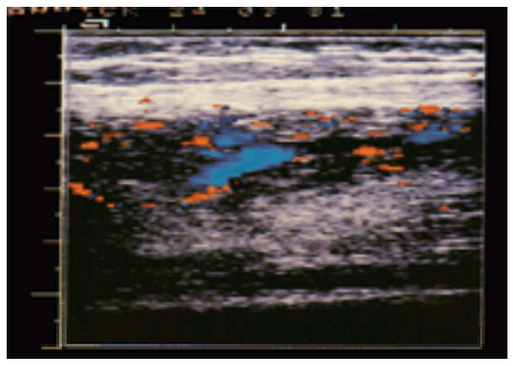

Fig. 24 Deep venous haemangioma of the calf in a 13-year-old girl with leg pain. Colour Doppler demonstrates a hypervascular lesion.

and guiding a needle for aspiration or catheter for drainage of fluid collection.

Ultrasonography can be employed easily in the initial evaluation and subsequent follow-up of soft tissue haemorrhage in trauma and bleeding disorders.

Abdominal ultrasonography can demonstrate peritoneal, pleural, and pericardial effusion, and hepatosplenomegaly in systemic juvenile chronic arthritis.

Echocardiography can demonstrate coronary aneurysms in Kawasaki disease or cardiac involvement in rheumatic fever.

Pulsed and colour Doppler can be useful in systemic vasculitis.

Arthrography and myelography

The use of arthrography and CT arthrotomography has decreased dramatically over the past few years in most paediatric practices because of the increasing availability of MRI and of arthroscopy. Arthrography requires general anaesthesia in young children and sedation in older children. The advantage of arthrography over CT and MRI is that it provides a dynamic study and depicts joints as they move. Hip arthrography is still an important test for assessing femoral head containment and assessing incongruity between the femoral head and the acetabulum (congenital hip dislocation, Legg–Calvé–Perthes' disease). It is an excellent tool in the operating room where it gives the surgeon an opportunity to visualize key relationships as the position of head is changed. It is a valuable aid for performing closed reduction in congenital dislocation of the hip and for guiding femoral or pelvic osteotomy in Legg–Calvé–Perthes' disease. Finally, arthrography is performed occasionally to aid detection of non-opaque loose bodies and the evaluation of articular surface irregularities.

Myelography has been widely replaced in children by CT and MRI, which are presently the first examinations to be performed. However, myelography is still very useful in the assessement of the cord in a few situations:

1. severe spinal deformities (spinal malformations, dysraphism, severe scoliosis) in which the interpretation of planar MR or CT images is very difficult;
2. surgical metallic spinal fixation in which the hardware creates CT and MR artefacts;
3. spinal instability (spondylolisthesis, spondylolysis) in which erected or dynamic films are crucial.

Angiography

In children, angiography is used only occasionally because of its invasive aspect and the low incidence of collagen vascular disease. In its place non-invasive,

vascular imaging modalities such as pulsed Doppler and colour Doppler ultrasonography, spiral CT angiography, and magnetic resonance angiography are now widely available. Multiple modalities can be performed including arteriography, phlebography, and direct percutaneous injection. Highly selective studies are now possible in infants using digital subtraction angiography, low osmolar contrast, and small catheters. Arteriography is indicated in the planning of resection of musculoskeletal tumours and can demonstrate neovascularity, displacement, encasement, or occlusion of major vessels.

Preoperative chemotherapy or embolization can be performed on children with sarcoma or an aneurysmal bone cyst. It also makes surgical procedure easier and less vascular. Therapeutic angiography can be particularly helpful in the management of synovial haemangioma. However, angiography cannot distinguish between malignant and benign disease. Cardiac angiography is indicated in Kawasaki disease to detect coronary aneurysms. Arteriography of the aorta and major arteries is useful in the evaluation of vasculitis, especially Takayasu's arteritis.

Balloon dilatation can be an effective treatment of arterial stenosis in Takayasu's arteritis. Phlebocavography is also very effective in the detection of thrombophlebitis and collateral flow in children at risk (Behçet's syndrome, coagulation disorders, lupus).

Radionuclide studies

Imaging the skeleton with bone-seeking radionuclide tracers offers the major advantage of high sensitivity in the detection of early pathological osseous changes in the entire skeleton (Van de Streck *et al*. 1994). In children, scintigraphy with bone-seeking and inflammatory agents, is the primary investigation to survey the skeleton for multifocal disease such as infection and malignancy (Fig. 1). Scintigraphy also provides critical information for the evaluation of musculoskeletal pain when plain radiographs are unrevealing. Disadvantages of bone scintigraphy are the lack of specificity and the poor spatial resolution. Correlating the results of a radionuclide study with information from other imaging techniques helps to overcome the lack of specificity inherent with this technique. The amount of radiation exposure during bone scintigraphy depends upon the radionuclide used and the dose administered. Children receive a portion of the adult dose calculated on the basis of body weight. The total body exposure from a technetium-99m bone study is comparable with that from a radiographic skeletal survey. Target organs such as the bladder and growth plates receive increased exposure. For bone scanning, the most commonly used and practical radiopharmaceutical in paediatrics is a phosphate compound labelled with technetium-99m.

The diagnostic accuracy of bone scintigraphy is closely related to the quality of the study. A technetium-99m bone scan is one of the most technically demanding nuclear imaging procedures. As with radiographs, meticulous attention should be given to positioning children for scintigraphic images. Positioning without rotation is essential. Homologous bones and joints must be shown with mirror-image positioning to allow careful comparison and detection of subtle asymmetry. Immobilization and/or sedation may be required. High-resolution techniques, using pinhole collimator views, are necessary to resolve small or subtle abnormalities that occur near the intense metabolic activity of the bone of the growing metaphyses of young children (Sullivan 1980). Long scanning times from 10 to 15 min per pinhole collimator view are required to obtain sufficient count density.

In general, images of the entire skeleton should be obtained even when symptoms are localized to a single site. This rule allows the recognition of unsuspected asymptomatic skeletal lesions. Pinhole views are used to resolve adequately the metaphyses, the epiphyses, and regions of the skeleton that are of specific clinical or radiological interest. Most false-negative diagnoses are secondary to metaphyseal lesions (osteomyelitis, corner fractures, and metastases) (Sullivan 1980). Familiarity with the scintigraphic appearance of the normal growth zone is necessary to detect subtle abnormalities in this region. The shape of the area of increased activity of the growth zone varies with age. In children of less than 18 months, the growth zone has an ovoid or elliptical form. After the age of 2 years, the growth zone is represented by a transverse linear band of increased activity that is always flat or slighty convex in the direction of the diaphysis. Moderate or marked convexity of this margin is abnormal. At all ages, the demarcation of the growth zone activity from the diaphysis is sharp.

Recent advances in nuclear radiology have improved the scintigraphic evaluation of musculoskeletal disease in children. A new generation of single-photon emission, computed tomography (**SPECT**) cameras can demonstrate subtle lesions that are undetectable by planar scintigraphy. State of the art SPECT systems feature multiple camera heads in a fixed ring design. More powerful post-processing has led to faster image reconstruction including sagittal, axial, and coronal planes and three-dimensional views. In paediatrics, SPECT has been particularly useful in the evaluation of the femoral heads for Legg–Calvé–Perthes' disease, in the evaluation of the lumbar spine for posterior element lesions (usually defects of the pars interarticularis), and finally in the evaluation of growth plate aberrations (varus and valgus deformity, cupped metaphysis, and post-traumatic arrest). In a study of 162 young patients presenting with back pain, SPECT demonstrated posterior element stress injury in 44 per cent, from which planar scintigraphy was abnormal in 20 per cent (Bellah *et al*. 1991).

Demonstration of occult fractures and sports injuries has increased in children with the use of bone scanning. Scintigraphic abnormalities, particularly of the tarsus and calcaneus, thought to reflect occult stress fracture, have been found in preschool children with unexplained lower extremity pain and normal radiographs (Englaro *et al*. 1992).

Bone scanning is useful in the evaluation of soft tissue and bone infection. Three phase bone scan is useful in the febrile infant or toddler when localization of infection can be difficult or in the older child with focal but non-specific complaints (Fig. 1). As in adults, scintigraphy help to distinguish a purely soft tissue infection from infection with bone involvement and to differentiate acute bone infarcts from acute osteomyelitis in children with sickle cell anaemia.

Leucocyte scans, using autologous cells labelled with indium-111 or technetium-99m detect osteomyelitis with high sensitivity (Lawson *et al*. 1994; Van de Streck *et al*. 1994). The use of leucocyte scans in paediatrics is more limited because of the moderately high radiation dose to the spleen. Leucocyte bone scans can be considered for children in whom the identification of a source of infection is critical and who can tolerate the removal of at least 20 ml of blood.

Other newer pharmaceuticals including polyclonal IgG, monoclonal antigranulocyte antibodies, and IgG fragments show promise as agents to detect inflammation (Oyen *et al*. 1992). A major advantage of these agents is the ease of preparation compared with that required for leucocyte labelling.

Finally, one disadvantage of scintigraphy is its low spatial resolution (Fig. 1). Therefore when a bone scans reveals a lesion that was not seen on plain films, the site of the lesion should be studied with a high resolution anatomical technique such as CT or MRI.

Computed tomography (CT)

The use of computed tomography has decreased dramatically over the past few years because of the superiority and increasing availability of MRI. However, CT is the better modality for imaging the mineralized portion of the bone, and is most effective when clinical evaluation, radiography, or bone scan have targeted a definite area.

The radiation dose received by a child during a CT examination is similar to that of multiple plain films and fluoroscopy. However, when multiple, overlapping thin slices are taken to obtain high resolution and/or three-dimensional studies, the volume of tissue irradiated is subject to more exposure than from a conventional radiograph.

Recent advances in CT software programs permit the data acquired from serial slices to be reformatted into any plane (even a curved plane) and to be reconstructed. The three-dimensional programs allow 'disarticulation' of joints and 'removal' or 'isolation' of any bone which may obscure the visualization of the underlying pathology or anatomy (Magid *et al*. 1988). Thus, three-dimensional CT provides a demonstration of complex anatomy, which can be of value in the management of complex malformations in children (Fig. 25).

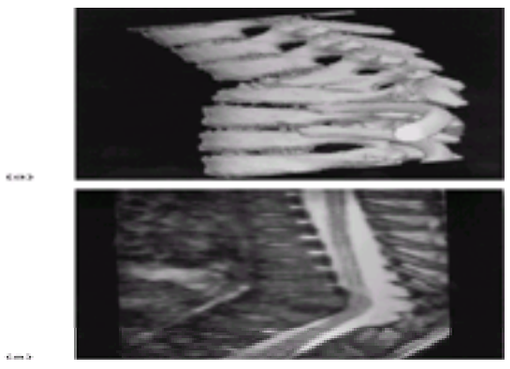

Fig. 25 Spondylodiscitis in a 12-year-old boy with dorsal kyphosis and vertebral block. (a) Three-dimensional CT shows the spinal deformity. (b) T_2-weighted MR image shows the cord compression.

The maximum preoperative information can be obtained by manipulating the data set in order to simulate the operative approach and the operation (osteotomy for instance). Three-dimensional CT can help in designing prostheses in children, notably in the hip (Swann 1993). This approach has proved to be valuable in a number of disorders such as neoplasms, malformation, or trauma affecting the pelvis, hip, feet, and spine.

Spiral CT, with the associated diminution of scanning times, facilitates high resolution and three-dimensional studies in children (Fig. 25).

CT techniques and software modifications have been developed so that quantitative measures of bone mineral can be performed. Evaluation of the lumbar spine for osteopenia is the usual procedure and normal values for children are available (Pettersson and Rydholm 1984; Gilsanz *et al.* 1988; Thomas, K.A. *et al*. 1991). CT offers an alternative to plain films for determining :

- femoral and tibial torsion (Hernandez *et al*. 1981)
- leg-length (using the scout view)

With careful positioning, almost any bone end can be imaged in a direct coronal or sagittal projection. In tarsal coalition, CT has proved to be the modality of choice. CT is the preferred method of evaluation in suspected cases of talocalcaneal coalition. The direct sagittal section is particularly valuable in demonstrating the anterior talocalcaneal articulation or coalition. For depiction of a calcaneonavicular coalition with CT, sections of the feet are obtained with the plantar surfaces perpendicular to the table.

The plane of the limb can be imaged directly with the gantry plane slightly off the true coronal or sagittal plane so as not to cut through the whole length of the bone (to avoid beam hardening artefacts). These views are particularly useful in the evaluation of partial closure of the growth plate. In these children, CT provides an excellent demonstration of the site and size of any bony bridges, but MR is the modality of choice for the evaluation of injured growth plate before the development of any bony bridge.

In sacroiliac arthritis, the orientation of sacroiliac joints and the ability to tilt the gantry to coincide with the plane of the joint make CT an excellent tool. The ability to demonstrate the joint completely with CT gives greater confidence in making a diagnosis of sacroiliac disease (Fig. 2).

CT remains the most satisfactory method for demonstrating sequestra in cases of chronic osteomyelitis (Hernandez 1985). CT is invaluable for definition of the osseous anatomy of lesions arising in bones that are difficult to image in two standard orthogonal planes, for example pelvis or vertebra, and for guiding a biopsy of such lesions when necessary.

CT has been an important adjunct to conventional radiography for the evaluation of the spine, however this role has now been challenged by MRI. CT offers the advantage of being more widely available especially in emergencies (trauma, spondylodiscitis). It is also the most sensitive modality for detecting calcification and ossification; this is invaluable for characterizing :

- calcifications in a chondroid matrix
- phlebolithis in soft tissue venous malformations or synovial haemangioma
- ossification in early myositis ossificans

CT is very effective in localizing precisely the site of the nidus of an osteoid osteoma (Fig. 4). Once the likely site of the osteoid osteoma has been determined with plain radiographs and/or bone scan, a high resolution CT study is performed in that limited area, and can be used to guide a biopsy. Attention should be directed to areas of high incidence of osteoid osteomas, such as the proximal femur where a reactive hip arthritis may be the presenting symptom (Fig. 4). Refinement of the technique has allowed percutaneous ablation of the nidus of osteoid osteoma.

Magnetic resonance imaging (MRI)

MR imaging has revolutionized the diagnostic evaluation of paediatric musculoskeletal disorders, becoming the modality of choice in many indications. The paediatric musculoskeletal system is ideally suited for investigation by MRI since it is the only technique which can clearly differentiate the individual components of the normal joints from one another (articular cartilage and fibrocartilage, growth plate, synovial membrane, joint effusion, ligaments). MRI also allows identification of bone marrow, muscles, tendons, fascia, nerves, and vessels with high contrast between these structures.

However one must not overlook the issue of clinical efficacy and cost-effectiveness. When deciding whether to use MRI, one should consider the financial cost, the time required, the need for sedation, and the operator dependency in comparison with good physical examination and conventional radiography. Therefore, physical examination must be performed and plain films obtained prior to any decision to use MRI. Thus cost-effectiveness is maximized and the diagnostic information of the MR study optimized by choosing the best protocol for a specific indication (Rubin and Kneeland 1994).

Technical considerations

Without the use of ionizing radiation, MR can safely produce high contrast, high resolution images of the paediatric musculoskeletal system in virtually any plane (Lawson *et al*. 1994). The success of MRI depends heavily upon multiple technical factors. The setting of the sequence needs to be adjusted for the individual examination. The magnetic field strengths and radiofrequencies currently employed with MRI produce no biological hazards. Immobilization is essential because of the intrinsic motion sensitivity of MRI. Unfortunately, the noise produced by the gradient coils of MR scanners disturbs young infants and children, albeit to a variable degree.

Some form of sedation may be required in young children but general anaesthesia is exceptional. MR examinations generally require more scan time (on the average 30 min) than do other imaging modalities such as CT and ultrasonography. Therefore, careful monitoring of children is essential (including heart rate, oxygen saturation). Newer magnet configuration designs such as small bore magnets for MRI of the extremities are being developed currently. They should be cheaper to build and run. 'Open' magnets are better tolerated by children and offer the potential for unrestricted motion studies and weight-bearing position (Lawson *et al*. 1994).

In children, the choice of the appropriate surface coil is crucial and is dependent on both the body part to be examined and the clinical question to be answered (Fig. 26). The smaller size of children may allow designated coils for adults to be used for a different body part of the child. In some instances, a coil designed to image an adult's head may be effective for imaging simultaneously both hips of an infant or a small child (or an 'orbit' coil for imaging a single joint). In plane spatial resolution of structures smaller than 1 mm with high signal and contrast-to-noise ratio is routinely achievable with this modality in children.

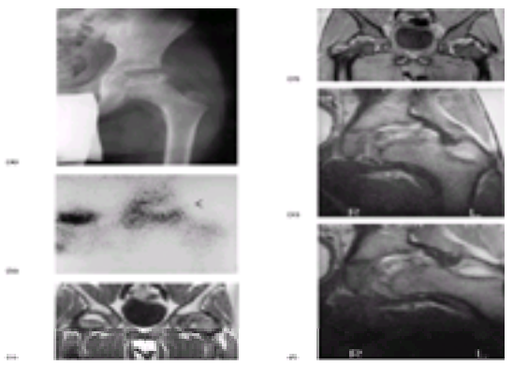

Fig. 26 Legg–Calvé–Perthes' disease involving the left hip in an 8-year-old boy. (a) Radiograph shows a typical fragmented appearance of the femoral head with lateral loss of containment. (b) Bone scan shows a decreased uptake in the necrotic bone. (c) T_1-weighted MR image shows the extent of necrosis (arrow). (d) Gradient-echo image shows the cartilaginous containment of the femoral head and the extent of the osteolytic area. (e–f) T_2-weighted MR images, without and with abduction, guide the femoral or pelvic osteotomy.

Pulse sequences

The appropriate choice of pulse sequences is critical to high-quality diagnostic MRI of the musculoskeletal system (Georgy and Hessenlink 1994; Rubin and Kneeland 1994). The ideal combination of parameters depends on the anatomy being examined and the suspected abnormality in addition to the available hardware, time constraints, and local preferences. Each sequence has relative advantages and disavantages. Spin-echo sequences are the mainstay of musculoskeletal MRI and are available on all MR systems producing either T_1, spin-density or T_2-weighted sequences (Fig. 27). Intravenous injection of paramagnetic contrast agent (gadolinium) is performed on T_1-weighted sequence (Fig. 27). The efficacy of spin-echo has been firmly established in various muskuloskeletal applications in the paediatric literature and any new sequence should be compared with spin-echo before its routine clinical use. The main disadvantage of spin-echo sequence is its relatively long acquisition time, especially for T_2-weighted sequences (7 to 14 min). More rapid imaging sequence is desirable in children in many cases.

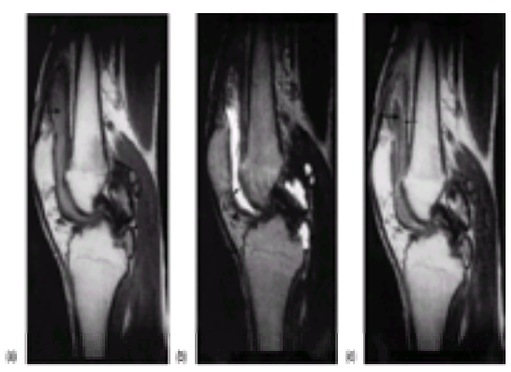

Fig. 27 Haemophilic arthropathy affecting the knee in a 14-year-old boy. (a) T_1-weighted MR image shows joint effusion (arrow) and synovial haemosiderin deposition (arrowhead). (b) T_2-weighted MR image shows articular surfaces with an arthrographic-like appearance (arrow). Haemosiderin deposition has a decreased signal (arrowhead). (c) Enhanced T_1-weighted MR image shows enhancement in the proliferative synovium (arrow) and allows a reliable distinction between active synovium and joint effusion (long arrow).

Gradient-echo and fast spin-echo allow faster imaging (Fig. 25). The use of gradient-echo with two-dimensional acquisition mode allows dynamic gadolinium-enhanced examinations studying musculoskeletal tissue vascularization and perfusion. This technique is maximized using post-processing software with pre- and post-contrast image subtraction (Fig. 28). The use of gradient-echo with a three-dimensional acquisition mode allows the highest spatial resolution (150 µm with a slice thickness of 0.7 mm) (Majundar *et al*. 1994). The acquisition of isotropic voxels allows reformatting in any plane and three-dimensional reconstruction.

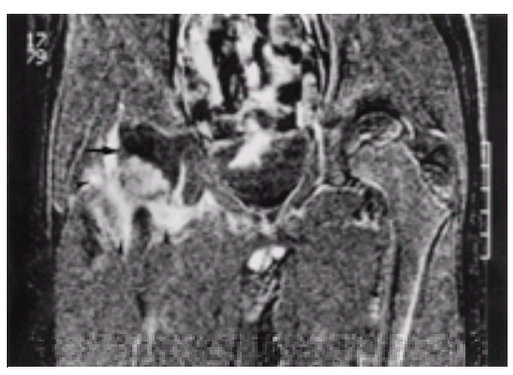

Fig. 28 Legg–Calvé–Perthes' disease mimicking a right hip arthritis in an 8-year-old boy. Enhanced substraction MR image shows an avascular right femoral head (arrow) with enhancing reactional synovitis (arrowhead).
