Of localized problems, the painful shoulder ranks highest in frequency and consequently has been better documented than most other soft-tissue lesions. Regional shoulder complaints rank fifth amongst the regional rheumatic diseases as a cause of incapacity or of visiting a physician. Data from general medical practices in the United Kingdom (Department of Health and Social Security 1986) suggest that approx. 1 in 170 of the adult population will present to their general practitioner with a new episode of shoulder pain each year. This contrasts with 1 in 30 for back pain.

Elderly people frequently have considerable functional impairment: 20 per cent of the elderly hospital population had shoulder disorders; less than one-fifth of these had sought medical attention (Chard and Hazleman 1987). The association between shoulder pain and occupation was highlighted in a study of the medical outpatient departments of six heavy industries by Bjelle *et al*. (1980). Approximately one-third of the outpatient visits were for non-traumatic musculoskeletal complaints, of which 30 to 50 per cent were neck–shoulder complaints. In the United States, the Health and Nutrition Examination Survey 1971–1975 studied the adult population aged 25 to 74 years. It found that 4.2 per cent had suffered from shoulder complaints and that shoulder abnormalities observed by a physician were present in 1.2 per cent; almost 40 per cent had associated neck complaints. In over 80 per cent the complaints had occurred during the year immediately before the study (Miller 1973). Health-care and insurance data support the influence of age and sex in relation to shoulder complaints amongst workers in production industries. The influence of age may partly be due to the frequent finding of degenerative changes of the rotator cuff that make this tissue highly vulnerable to trauma after the fifth decade. Also, women run a higher risk than men of developing shoulder complaints when working in production industries. Further studies are required to determine whether the age, sex, and occupation pattern seen with shoulder lesions is equally applicable to other soft-tissue injuries.

Tennis elbow or lateral epicondylitis affects 1 to 3 per cent of the population. It occurs mostly between 40 and 60 years of age, and usually affects the dominant arm. Most sufferers experience a recurrence of symptoms within 18 months. While some 40 to 50 per cent of tennis players suffer with tennis elbow, it is more frequent and severe in older players. Less than 5 per cent of cases in total are related to tennis and it is found more often in non-athletes. Labelle *et al*. (1992) report that an average of 62 days is lost from work per patient in industrial workers.

Defining the outcome

There is a very low rate of referral of soft-tissue problems to hospital and thus outcomes from hospital series do not reflect the outcomes from the syndrome as a whole. There is also considerable variation between different hospitals in the case severity of new attendees. This is partly a reflection of waiting-list time, and partly of the interests of general practitioners and hospital clinicians. Also, many conditions are self-limiting: half of patients presenting to general practitioners with soft-tissue back pain are better within a week and 90 per cent by a month.

Pathogenesis

Perhaps one of the biggest hindrances to progress in understanding soft-tissue rheumatism has been a negative attitude to the affected tissues, which are still thought to be inert, homogeneous structures. Their role in joint mechanics and pathology is often considered to be passive and secondary to that of other joint structures such as bone, cartilage, and synovium. These misconceptions are belied by recent studies demonstrating that these tissues are indeed metabolically active, interesting, and worthy of investigation.

As outlined above, many local causes of soft-tissue rheumatism are related to chronic, repetitive, low-grade trauma and excessive and unaccustomed use (both at work and at play), which both may partially interrupt the local blood supply. Incomplete attempts at healing and degeneration will render soft tissues more vulnerable in the older people in whom such lesions are more common. Since the vascular supply to adult tendon is poor, healing of these lesions is slow. Poor tendon repair and degeneration would appear to explain the chronicity of tendon lesions.

Tendon and ligaments: composition and function

Tendons are clusters of parallel collagen fibrils interspersed with a few fibrocytes; the collagen is almost all type I. Larger tendons consist of multiple fascicles separated by loose connective tissue containing nerve fibres and blood vessels. Ligaments may be of a similar structure, but usually exhibit less regular orientation of collagen and contain elastin. They function passively, being structurally superior to tendons for constant tension. Tendons, in contrast, must provide flexibility and resistance to tension, with concentration of force to an attachment area. Loading a tendon causes a brief alignment of fibres, then linear extension to the limit of elasticity. According to Hooke's law this is followed by failure of individual fibres and then rupture. The area of weakness should be the attachment to bone; but the loading is distributed evenly by a mechanism called 'fibre weave'. Therefore, tendons often fail at a distance from the attachment or enthesis.

The fan-shaped point of attachment of tendon to bone (the enthesis) is an area of great stress. It differs histologically from the rest of the tendon. The enthesis is traditionally made up of four zones: tendon, fibrocartilage, mineralized fibrocartilage, and bone. In the zone of mineralized fibrocartilage there is an increase in smooth endoplasmic reticulum, lysosomes, and intracellular lipid, and a more prominent Golgi apparatus.

Blood supply

Arterioles pass between the fascicles in the tendon. These freely communicate and are accompanied by venules and lymphatic vessels. Extensions of vessels from the muscles pass through the tendon and anastomose with those from the periosteum. Studies with radioactive isotopes have demonstrated that the enthesis has a particularly rich blood supply. It is believed that the blood supply to tendon is relatively abundant compared to the metabolic demands. However, there is reduced blood flow when tendons are under tension.

Nerve supply

This is sensory, there being no definite evidence of vasomotor control. Close to the attachment to muscles are found specialized afferent receptors. The nerve fibres from the tendon mainly follow the branch of the motor nerve to the muscle but some fibres form small branches that pass directly into nearby peripheral nerves.

Tensile strength

The tensile strength of normal tendon is greatly in excess of ordinary demands. This strength requires an intact blood supply, even partial interruption leads to a reduction. Normal tendon with a cross-sectional area of 1 cm^2 can support 600 to 1000 kg, which is similar to half that of steel.

Tendon lesions

Rupture

Severe trauma directly to a tendon will result in rupture. Marked strain on a tendon may also do this, although avulsion fracture at site of attachment is more likely. Analyses of spontaneously ruptured tendons have shown degenerative changes that include alterations in the size and orientation of collagen fibres, with increased deposition of proteoglycans between the fibres. The tenocytes have enlarged vacuoles, sometimes containing lipids, and cell necrosis is sometimes found. In some cases calcium is deposited (Kannus and Jozsa 1991).

Similar changes are found in human tendons removed at operation for degeneration of the rotator cuff and lateral epicondylitis (Chard *et al*. 1994).

Tenosynovitis

Inflammation of the synovial lining of the sheath through which a tendon moves may be the result of an inflammatory arthritic condition but is more commonly caused by trauma. It is often the result of unaccustomed exercise or repetitive work action. Tenderness, swelling, and crepitus on palpating the moving tendon are characteristic. When severe and chronic the tendon sheath becomes thickened, especially over bony prominences. Secondary thickening of the tendon distally may occur, producing snapping on movement of the thickened area through the inflamed sheath, for example trigger finger. Sites of tenosynovitis include the thumb (De

Quervain's tenosynovitis), finger flexors, flexor carpi radialis, common peroneal sheath, and tibialis posterior tendon. Treatment includes rest, splinting, local steroid injections, and sometimes surgical release.

Tendinitis

This is a poorly defined group of conditions where pain is attributed to strain or injury to tendons and their attachments to bone. In many cases the lesion is believed to be tenoperiosteal, for example lateral humeral epicondylitis (tennis elbow) and jumper's knee, and thus comes under the term enthesopathy. The most important tendon lesions in terms of frequency and severity are those affecting the shoulder, and these produce the majority of cases of shoulder pain.

Pathological studies (Fig. 1)

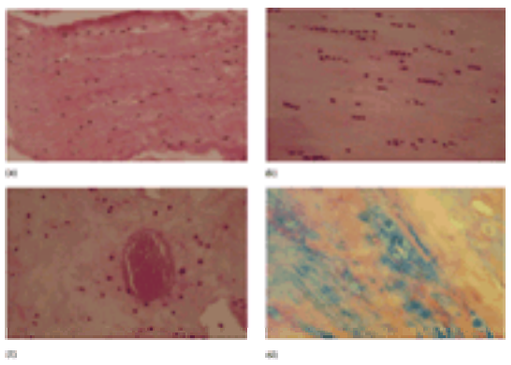

Fig. 1 Common histological findings in the human supraspinatus tendon: (a) tendon from a 19-year-old cadaver showing normal fibre structure with elongated fibroblasts between parallel fibre bundles (H and E); (b) ruptured tendon from a 65-year-old patient with tendinitis, showing region of fibrocartilage with rows of rounded, chondrocyte-like cells, which may be a pathological change or a normal adaptation to compressive forces acting on the tendon (H and E); (c) ruptured tendon from a 55-year-old patient with tendinitis, showing severe degenerative changes with no distinct fibrillar structure, scattered round cells, and a calcific deposit in the matrix (H and E); (d) specimen from a 76-year-old showing deposition of glycosaminoglycan between collagen fibrils and associated with rounded cells (Alcian blue/periodic acid–Schiff).

In vivo work has shown that tendon healing after damage probably involves the reaction of surrounding tissue and adhesion, without participation of the tendon tissue itself. Other studies have revealed that tendons are capable of responding to injury, although it does appear that most actively dividing cells are derived from the superficial part of the tendon.

The majority of cells obtained from tendon that are capable of replication *in vitro* are derived from the superficial layer (epithelium). The growth characteristics of the cell lines have been established by investigating DNA synthesis using thymidine incorporation in response to stimulation by fetal calf serum. No significant reduction in growth response with increasing age was found. Initial light-microscopic analyses of normal rotator-cuff tendons (Chard *et al*. 1989) suggest a general thickening of blood vessels, fewer tendon fibroblasts, increased mucopolysaccharide, and increased calcification with increasing age. An increase in cells resembling chondrocytes and hyperplasia of arteriolar intimal are seen (Yamanaka and Fukuda 1991).

Attention has been drawn to the unifying concept of the enthesopathies which suggests that local ischaemia is the common denominator. The enthesis is always at risk because the working muscle takes up most of the blood at the expense of the tendon and insertion. Other contributory factors include overstressing, muscular hypertonus, and excessive cooling. Endogenous factors such as impaired vascularization, metabolic disorders, endocrine disorders, trophic disorders, toxic damage, and even psychological factors may also influence damage to the enthesis. Tendons without sheaths are better supplied with blood than those with, and dynamic blood-flow studies *in vivo* in these regions may yield valuable information. This section has focused on the tendon and its pathology. Lesions of bursae, fascias, and muscle will be discussed later in the chapter.

Collagen is the basic framework of all soft tissues. Once a tear occurs within the collagen bundles, the defect is replaced by haphazard, loose connective tissue formed in the blood clot that initially fills the torn area. Thus the intrinsic structural strength may be reduced significantly, leading to impaired power, mobility, and skill, and further tears.

Tendon cells are metabolically responsive and capable of repair; they maintain the matrix composition by a balance between anabolic and catabolic processes (Abrahamsson 1991). Biochemical and cell biological studies have shown that diseased tendons have an increased concentration of dermatan and chondroitin sulphates, and a threefold increase in hyaluronan (Riley *et al*. 1994), indicating that a change in proteoglycan synthesis has occurred. There is also an increase in cell numbers, a reduced collagen content, possibly caused by an increase in collagen degradation, and in the majority an increased content of collagen type III. These changes are consistent with inflammation and a fibroproliferative response, presumably in an attempt to repair the tendon defect, although it is not known if this process is primary or secondary to the tendon rupture.

A highly specialized 'fibrocartilage' develops in regions of tendons exposed to compression (Evans *et al*. 1990), which differ biochemically and structurally from tension-bearing regions and have characteristics somewhere between those of classic tendon regions and articular cartilage (Vogel *et al*. 1993). Although type I collagen remains the principal matrix component, the cellular activity in these compressed regions includes the synthesis of both type II collagen and aggrecan.

Growth factors have anabolic effects on tissues, increasing matrix synthesis and reducing matrix breakdown. Cytokines such as interleukin 1 and tumour necrosis factor-a often have the opposite effect, decreasing matrix synthesis and up-regulating the proteinases that promote matrix breakdown. Recent studies have shown that tendons *in vitro* respond to interleukin 1 by altering the synthesis of matrix components and proteinases such as matrix metalloproteinases (Dalton *et al*. 1995). The production of excessive enzyme activity can exceed that of local inhibitors (such as tissue inhibitor of metalloproteinases) and so lead to collagen breakdown.

Recent interest has centred on the role of prostaglandin synthesis and release in response to soft-tissue injury due either to trauma or overuse. Prostaglandins may act synergistically with other inflammatory mediators such as histamine, serotonin, and bradykinin to potentiate both swelling and pain. Muscle injuries are associated with bleeding to a greater or lesser degree, and interstitial haematomas produce marked pain and loss of function. Muscle regeneration is a slow process. Strains affect muscles. With minor strains only fibres are damaged, with the muscle sheath left intact. With more severe strains there is partial or complete rupture of fibres and sheath. A sprain is an overstretch injury of a ligament. It may affect only a few fibres or lead to rupture.

Generalized soft-tissue conditions

Repetitive strain syndrome

Occupational repetition strain injuries have become, particularly in recent years, a significant source of disability at work. There is considerable confusion in diagnostic terminology and a wide variation in reported incidence between countries, perhaps reflecting the contrasting medical and more particularly, legal, attitudes to these conditions. Flexor tenosynovitis, rotator-cuff tendinitis, and lateral epicondylitis have all been described as 'occupationally' induced clinical syndromes; they have high rates of relapse—6 per cent for tenosynovitis of the wrist, for example. Repetitive strain injury has, however, more diffuse clinical features and no clearly defined pathological basis. Two conditions are currently recognized as work-related industrial injuries: PDA4—cramp of the hand or forearm, in people with an occupation entailing prolonged periods of handwriting, typing, or other repetitive movements of the finger, hand, or arm; and PDA8—traumatic inflammation of the tendons of the hand or forearm or the associated tendon sheaths in any occupation entailing manual labour or frequent or repeated movements of the hand or wrist. In general, as mentioned above, the increased incidence of these disorders appears to be due to new technology with advanced automation and mechanization. This has led to a need for rapid, repetitive movements, often of just the arms or even the hands and wrists alone. Although actual physical workloads may be lighter, it is this increased rate of work concentrated locally on an individual's musculoskeletal system that results in repetitive (repetition) strain injuries, and associated overuse syndromes. The influence of occupation on how we use or overuse parts of our body is striking. This suggests that were alternative ways of accomplishing various

activities to be developed, a part of the problem could be controlled. Ergonomic and behavioural studies would seem to have much to offer. Definitions of the association between work and rheumatic complaints have been suggested (World Health Organization 1988). They emphasize the multifactorial nature of work-related musculoskeletal complaints in industrial workers. The load from work may not only be physical; stress factors also are important in some workplaces. Predisposing factors such as age and anthropometric features must also be considered. Repetitive strain syndrome can be defined as follows:

1. a chronic pain syndrome;
2. affecting one or both neck–arm regions;
3. occurs in activities requiring controlled posture, often of a repetitive nature;
4. psychological factors contribute to the syndrome.

The clinical features consist of:

1. chronic pain in neck, chest wall, arm, and hand;
2. inability to achieve previous work performance or carry out full leisure activities;
3. variable hand–arm–forearm swelling with poor grip strength and taut proximal muscles;
4. often mild algodystrophy;
5. poor sleep pattern, often with mood changes.

Terminology

Arm pain associated with work, commonly known as repetitive strain injury, is currently sweeping the developed world. The most recent 'epidemic' began in Australia in the 1980s and has now 'spread' to the United States and United Kingdom. The term repetitive strain injury is perhaps misleading in that it implies that an actual 'injury' has been caused by repetitive movement. This has so far been difficult to establish, given the diffuse clinical features and absence of pathology in most cases. Also, there is no certain pathogenesis for repetitive strain injury that would justify the use of the term 'strain' and many sufferers develop their symptoms as a result of static rather than repetitive or dynamic muscle load (Littlejohn 1986).

Although an association between certain occupations and the incidence of repetitive strain injury has been described, there have been few studies designed to assess the connection properly. In Australia there was a sudden, dramatic increase in reporting symptoms that lasted around 18 months and was followed by an equally rapid reduction to baseline. The rise in cases was mirrored by increasing numbers of media reports on repetitive strain injury. This can be seen in Hocking's study carried out by Telecom Australia (Hocking 1987). Annual reports of repetitive strain injury increased from 109 in 1981 to over 1700 in 1985. Telephonists were most affected and telegraphists least. This order is the inverse of the keystroke rates, which are a few hundred an hour for a telephonist and over 12 000 an hour for a telegraphist. Cleland (1987) has described repetitive strain injury as a model of social iatrogenesis—the treatments, advice, and expectations provided by a wide range of people have provided an environment that has focused attention on discomfort about, and apprehension of, the potentially damaging effects of pain in the workplace. Through this process it is likely that a minor discomfort will be transformed into a protracted, painful, and disabling condition, precluding effective work and degrading quality of life.

The rapid decline in repetitive strain injury in Australia was due to several different factors. Work practices were changed, appropriate work breaks were instituted, and advice given about comfortable work stations. The term repetitive strain injury was also disposed of; if no specific diagnosis could be made, the condition was designated a regional pain syndrome.

Clinical features

Pain is the principal feature; this may be associated with inability to perform routine work or household activities. There may have been an underlying ache in the arm, shoulder or neck for some weeks before the onset of the pain syndrome, or it may follow a specific soft-tissue injury. Usually the symptoms begin around the wrist or forearm or elbow, and within days or weeks spread into the upper arm, shoulder, and neck. They may then involve the opposite side. Up to 20 per cent of patients develop more generalized pain involving the low back, buttock, and leg regions.

Generalized fatigue is common, and pain may fluctuate with activity, emotional stress or temperature change. In addition, patients report disturbance of their usual sleep pattern, with frequent waking and a feeling of tiredness in the morning. Examination shows an altered pain threshold.

Vasomotor changes in the forearm may be apparent and in the minority all the features of an algodystrophy syndrome may occur. The patient describes dysaesthesias in the hand and poor grip strength. There is a sensation of swelling but usually no objective evidence of this. Tender points in such as the first web space in the hand are also present. There is no evidence of synovitis, tenosynovitis, or neurological abnormality.

The syndrome is therefore one of regional pain, but the usual course is of prolonged pain for several months or years, irrespective of treatment or outcome of compensation. Once the regional pain syndrome has developed an exaggeration of tenderness when the patient is assessed for medicolegal purposes may be noted. No racial, social, or professional group has been spared, but the self-employed are not usually affected.

Several psychological factors come into play in occupations requiring rapid, repetitive movements. Indeed a significant body of opinion follows the concept of repetitive strain injury as a largely 'hysterical' or psychogenic illness (Awerbach 1985). A more accurate assessment would seem to be that physical, ergonomic, environmental, and psychological factors are involved in its onset and development.

Treatment

Management is similar to that of other chronic pain syndromes. Prevention and early diagnosis are important. If the full syndrome has developed the patient must be reassured that there is no tissue damage or injury, and that the symptoms are best thought of as a form of' overuse strain' that will recover with suitable modifications of activities.

It is necessary to treat any triggering ergonomic factor, either by modifying work activity or using a cervical collar. The patient should be encouraged to carry out regular exercise that involves stretching of tight, tender regions such as neck and shoulder. Sleep disturbance may require treatment with a hypnotic or low-dose tricyclic antidepressant.

If the syndrome has arisen in connection with paid employment, all the parties involved, including management, trades unions and third-party insurers, should be informed. An early return to work should be encouraged, but modification of work activity may be necessary when the pain is severe. Prolonged rest does not help, nor does the use of anti-inflammatory drugs or extensive physical treatments. Chronic pain is treated by gradually increasing activity under supervision.

Many patients with this problem are involved in disputes over compensation, litigation, or disability assessment. It has been suggested that the occurrence of chronic pain syndromes may be encouraged in those countries where compensation schemes include any symptoms that occur at work. This happened in Australia during the 1980s and is thought to have contributed to the pain syndrome 'epidemic' in that country. Prolonged medicolegal processes counteract any appropriate treatment programme (Littlejohn 1989).

The term repetitive strain injury implies a cause without defining the lesion. Ireland (1988) has emphasized that this condition predominantly affects women employed in low-paid, monotonous, unprestigious jobs. The employees placed the blame on the employment and thus on the employer. However, a small number of patients with this syndrome do present with genuine pain and disability and do not respond to current management. If no specific musculoskeletal diagnosis can be made, then one should look at social and psychological factors that might promote the pain. These should be addressed and the patient's pain put in its proper context. Occupational issues concerning a constrained and rigid posture, the work cycle, time spent in any one activity, work satisfaction, and social intervention at work are important.

The advice 'if it hurts, stop' runs contrary to all accepted principles of the behavioural management of chronic pain and may lead to chronicity. The involvement of a

clinical psychologist in the team, and an active occupational rehabilitation programme, helps most people to return to work.

Hand and arm problems of musicians

Musicians are prone to a variety of problems in the upper limb that produce significant disability; these include overuse syndromes, entrapment neuropathies, and focal motor dystonias. The diagnosis can be difficult as symptoms may be mild and only occur on playing. Episodes may be triggered by changes in repertoire, technique, and instrument, or by increases in daily playing time. The weight of a wind instrument such as the clarinet or oboe frequently leads to pain in the muscles of the first web space. Percussionists have a low prevalence of regional pain syndrome, presumably because their playing is more intermittent.

In reviewing several series of musculoskeletal injuries in musicians, Hoppmann and Patrone (1989) reported that of 179 injured musicians, 62 per cent had overuse syndrome, 18 per cent had nerve-entrapment thoracic-outlet syndrome, and 10 per cent had problems of motor control. Some of the musculoskeletal problems seen in musicians are listed in Table 4. Diagnosis and management are helped by a detailed knowledge of the instruments used and the specific dynamics of music making. Musculoskeletal problems are common in musicians of all ages and levels of skill. Recent research has included attempts to better define overuse, focal dystonia, and the role of hypermobility.

Overuse injury:
Specific tenosynovitis
Non-specific diffuse forearm pain
Entrapment neuropathies
Focal dystonia
Thoracic-outlet syndrome
Hypermobility syndrome
Osteoarthritis

Table 4 Musculoskeletal problems of musicians

Treatment must take into account the specific injury and the instrument played. Table 5 lists some of the treatments that are generally applicable. Greater consideration is being given to the ergonomics of music making and technique is being assessed as a risk factor.

Rest:
Complete or incomplete rest periods into practice
Technique:
Correct problem; noticing posture, muscle tone and movements that aggravate injury
Physical or occupational therapy:
Splints, exercise, adaptive devices
Relaxation techniques:
May include electromyographic feedback
Non-steroidal anti-inflammatory drugs or local steroid injections
Surgery:
Nerve-entrapment release

Table 5 Treatment of musculoskeletal injuries in musicians

Musculoskeletal problems in dancers

Overuse injuries are common, and many joints are stressed by ranges of motion exceeding those that anatomy readily permits. The most common problems are back pain, and damage to the ankle and foot. Some 70 to 80 per cent of professional dancers complain of back pain, and the repetitive movements of dance may lead to overuse injuries such as tendinitis, neuritis, and stress fractures (Ramel and Moritz 1994). Pre-existing hypermobility may predispose to injury, and in the case of stress fractures, osteoporosis secondary to eating disorders and amenorrhoea may play a part. In one ballet company 104 dancers sustained 309 injuries over a 3-year period (Garrick and Requa 1993).

Fibromyalgia

The two cardinal features of fibromyalgia are generalized chronic pain and diffuse tenderness at discrete anatomical sites. Fibromyalgia has been found in 2 to 5 per cent of the population, predominantly affecting women in their forties and fifties, and is recognized as the second most common disorder seen in North American rheumatological practice. In some patients the syndrome complicates the illness associated with established rheumatic diseases.

Fibromyalgia is a recognizable syndrome characterized by chronic, diffuse pain, an absence of inflammatory or structural musculoskeletal abnormalities, and a range of symptoms that include fatigue, and sleep and mood disturbances. Physical examination and laboratory testing are unrevealing, except for the presence of pain on palpation of characteristic soft-tissue sites, the tender points.

Despite the recognition of fibromyalgia by the World Health Organization in 1992, it remains a controversial condition and its existence as a distinct entity remains uncertain (Cohen and Quintner 1993). However, the concept of fibromyalgia is a useful one, allowing many investigations to be avoided and appropriate advice on treatment to be given.

Fibromyalgia may overlap with symptoms of, and the patient further impaired by, anxiety and depression; patients with fibromyalgia have high scores on anxiety and depression questionnaires. The term fibromyalgia syndrome does not imply causation and merely describes the most common symptoms. Many patients with 'chronic fatigue syndrome' fulfil the criteria for fibromyalgia and represent one end of a spectrum of presentation. Evidence for triggering viral infections is lacking in the majority of patients, and, unlike fibromyalgia, most 'postviral' syndromes are self-limiting and are not associated with tender sites. Common presenting symptoms are listed in Table 6.

Fatiguability: Often extreme, following minimal exertion Predominantly axial, often aggravated by stress and cold Diffuse and unresponsive to analgesics/NSAIDs (all severely limit daily activities)
Objective swelling of extremities
Paraesthesias, dysaesthesia of hands, feet
Waking unrefreshed
Poor concentration, depressed
Headache, diffuse abdominal pain
Altered bowel habit
Urinary frequency, urgency

NSAIDs, non-steroidal anti-inflammatory drugs.

Table 6 Common symptoms of fibromyalgia

The only tests required to exclude alternative diagnoses that may present with widespread pain, weakness or fatigue are listed in Table 7.

Differential diagnosis	Investigations
Hypothyroidism	Full blood count and ESR
Systemic lupus erythematosus	Calcium, creatine kinase
Inflammatory myopathy	Thyroid function
Hyperparathyroidism	Antinuclear factor
Osteomalacia	Plasma proteins
Parkinsonism	
Myeloma, carcinomatosis	
Polymyalgia rheumatica	

ESR, erythrocyte sedimentation rate.

Table 7 Differential diagnosis and investigation of fibromyalgia

The tender sites are central to the definition and understanding of this condition. The neck and back show many changes, but the other tender sites reveal no changes sufficient to account for the marked tenderness, and certainly no inflammation. The same sites become tender in regional pain syndromes. The points (Fig. 2) are unknown to the patient, and often quite far from the region of referred pain; so that the pattern cannot be exaggerated for psychological reasons. The tenderness can be quantified, whereas pressure over other sites shows a normal pain threshold.

Fig. 2 The 'tender' points.

However, it should be emphasized that the very existence of this condition is a matter of considerable debate. Doubts have been expressed about the validity of both the symptoms reported by patients and the signs observed; some deny the existence of the condition because no objective pathological findings are demonstrable. However, in 1990 the American College of Rheumatology published criteria for the classification (Table 8). According to this set of criteria (American College of Rheumatology 1990), fibromyalgia is a syndrome of widespread pain, by definition affecting both sides of the body and the upper and lower segments. Its symptoms may also include sleep disturbance, fatigue, and stiffness. The most important feature is, however, the 'tender point' count, first described by Smythe (1989). Smythe has suggested that the pain experienced by patients with fibromyalgia is referred pain from mechanical stresses in the lower neck and low back. Studies by Lewis and Kellgren in the 1930s (Kellgren 1939) demonstrated that irritation of superficial and deep structures in the spine can produced both referred pain and also referred tenderness. Maigne (1972) demonstrated that irritation of posterior branches of spinal nerves could produce referred pain, referred tenderness, skin-rolling tenderness, and reactive hyperaemia in the anatomical distribution of the involved nerves. However, these observations have not been confirmed in patients with fibromyalgia, and the diffuse nature of pain in fibromyalgia suggests that spinal factors alone are not responsible for the clinical syndrome.

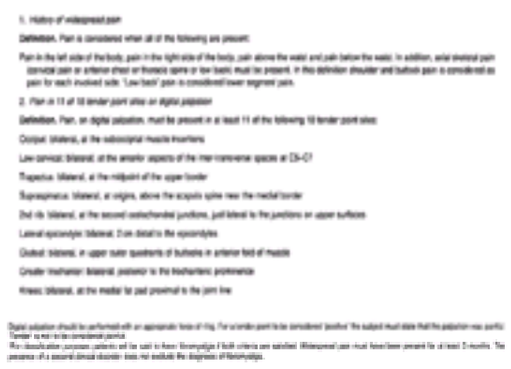

Table 8 American College of Rheumatology criteria for fibromyalgia

In drawing up the criteria for the diagnosis of fibromyalgia syndrome there has been much emphasis on the presence of tender points. It might therefore be asked whether it is possible to distinguish between fibromyalgia and a myofascial trigger-point pain syndrome simply by finding tender points in the former and trigger points in the latter. Myofascial trigger-point pain syndromes usually develop after trauma to the affected muscle or muscles, and the pain is alleviated by deactivating the hyperactive nerve endings at trigger points by one or other of a variety of methods, including the insertion of dry needles. Janet Trowell has written extensively on the subject and shown that each muscle in the body has its own specific pattern of trigger-point pain referral (Travell and Simons 1983).

Rheumatologists in general are not in the habit of looking for trigger points and those that have made a special study of fibromyalgia have never adequately addressed themselves to the question of whether some or perhaps all of the tender points in this condition could be trigger points. It would seem that most rheumatologists simply examine muscles for tender points and do so by applying pressure to them with outstretched fingers rather than by rolling the fingers firmly across them, and because of this tend to overlook the presence of any trigger point containing palpable bands.

It could be argued that tender points and trigger points must be one and the same, as the nociceptive hyperactivity that must be responsible for making the points so tender must also make the nerve endings at these sites at least potentially capable of triggering pain. Recently, it has been suggested that in patients with fibromyalgia, trigger points and tender points many represent the same abnormality. There are no longitudinal studies of myofascial pain to determine if a subset of patients evolves into a more characteristic fibromyalgia syndrome.

Aggravating factors for fibromyalgia include exhaustion, lack of fitness, disturbed sleep (which may affect the way pain signals are modulated or transmitted), and anxiety. The following are commonly associated: tension headaches, paraesthesiae, subjective swelling of joints, and primary dysmenorrhoea.

In 1975, Smythe and Moldofsky recorded electromyograms and electroencephalograms in 10 patients suffering from so-called 'fibrositis' (Moldofsky *et al*. 1975). The electroencephalographic changes showed that each patient had a disturbance of stage IV, non-rapid eye movement (**REM**) sleep. This disturbance is brought about by the rapid, 8 to 10 cycles/s a-rhythm, normally found in REM sleep, intruding into the usual slow, 1 to 2 cycles/s d-rhythm of stage IV deep sleep. Sleep disturbances have subsequently been reported in 60 to 90 per cent of patients with fibromyalgia, but are also recognized as not specific, seen in many other conditions, and in as many as 15 per cent of healthy individuals (Scheuler *et al*. 1988).

A further study in healthy normal volunteers showed that the same a-intrusion into the d-wave pattern of deep sleep could be produced experimentally by disturbing the volunteers' sleep by hand contact or a buzzer (Scheuler *et al*. 1988). When this intrusion occurred the sleepers developed general musculoskeletal pain and tenderness similar to that seen in 'fibrositis'. After a few nights of normal sleep the pain disappeared. These studies led to increasing recognition of fibrositis and the concept of fibrositis as we understand it today.

Some patients have no difficulty in getting off to sleep, consider that they sleep soundly, and yet awake with a general feeling of tiredness, fatigue, and general stiffness. Others experience this feeling after a light, restless sleep. It is not known whether changes in sleep physiology in fibromyalgia are the primary disturbance, with the muscle pains occurring secondary to these, or whether similar electroencephalographic changes develop as a secondary event in those whose sleep is disturbed as a result of pain. There is still insufficient evidence to link fatigue with specific sleep disturbances.

Psychological disturbances are seen only in the minority of people with fibromyalgia. However, emotional upsets and stress seem capable of bringing on the symptoms. Case–control studies on patients with fibromyalgia and matched controls with rheumatic diseases have shown a higher prevalence in fibromyalgia of depression, sexual and physical abuse, and eating disorders preceding the onset of the disease. Psychological stresses are frequent before its onset in adolescents.

There have been studies suggesting a deficiency of the neurotransmitter serotonin in fibromyalgia, with lower concentrations of its metabolites in cerebrospinal fluid. However, if serotonin deficiency was central to the pathophysiology of fibromyalgia, we would expect improvement on treatment with serotonergic drugs such as fluoxetine, which does not appear to be the case. Endorphins and substance P are other neurotransmitters that have been extensively studied in fibromyalgia. Endorphins were found to be normal, whilst substance P was increased in cerebrospinal fluid; however, healthy controls were used, which prevents firm conclusions (Russell *et al*. 1994).

Treatment

Whether we label sufferers as having fibromyalgia or not, there is no doubt that many have diffuse pain, sleep disturbances, fatigue, and tender points. There is no specific treatment and the prognosis is poor, but individual patients may be helped, by an adequate explanation of the condition, to learn to live better with it and so avoid further unnecessary investigations and drug treatments.

At present, tricyclic antidepressants and aerobic exercises are the treatments that have been most extensively studied. Both have a moderate degree of benefit. Cognitive behavioural approaches and multidisciplinary treatment programmes have also been used in an attempt to help patients gain control over their symptoms, but both are time-consuming and expensive and require fuller study. Aspects of management are summarized in Table 9 and of treatment in Table 10.

Educate patient

Educate patient's family

Keep investigations to minimum and stop ineffective drug therapy

Use interventions to improve sleep disturbance and improve aerobic fitness

Table 9 Principal strategies for management of fibromyalgia

Low-dose amitriptyline:
- Initially give 25 mg at night

Graded aerobic exercise regimen:
- Individualized for patient
- Encourage frequent but small amounts
- Encourage continuation despite pain
- Set increasing weekly targets

Coping strategies:
- Behavioural therapy
- Yoga

Table 10 Treatment of fibromyalgia

As many patients have suffered disappointment, blows to self-confidence and esteem, together with pain and exhaustion, they often find it hard to believe they can recover; they therefore require much encouragement from doctor and therapist. The absence of inflammation in soft tissue is now accepted. This explains the lack of efficacy of non-steroidal anti-inflammatory drugs and corticosteroids. Patients with fibromyalgia are aerobically unfit. There is no evidence to suggest that they have any primary muscle abnormality nor do they suffer from defects in energy metabolism. Aerobic fitness training unfortunately only produces slight benefit.

Tricyclic antidepressants in small doses of 10 to 30 mg are often helpful in improving the quality of sleep, in reducing morning stiffness, and in alleviating pain. However, overall the prognosis is poor and the condition tends to take a protracted course (Felson and Goldenberg 1986).

Conclusions

The opponents of the concept of fibromyalgia consider it a 'non-disease' and suggest that the label is likely to create a population of 'worried well', with adverse social and psychological consequences. The Australian experience with the diagnosis of repetitive strain injury warns us of the possibility of negative disease labelling. The converse argument is that the term fibromyalgia provides the patient with a structure for understanding the condition. Many patients have had numerous diagnoses and investigations, and the average duration of symptoms before the diagnosis of fibromyalgia is made is 5 years. Once it is made and explained, anxiety and frustration often disappear.

Opponents of the fibromyalgia label argue that by labelling a non-disease doctors are legitimizing patients' sickness behaviour. However, the converse is that the term fibromyalgia, put in its proper perspective, provides a health-care professional with the basis to recommend activity rather than inactivity, work modification rather than

work termination, and coping strategies.

The clinical syndrome that we now call fibromyalgia has been present for a long time. The facts that it is poorly understood and there are no objective physical and laboratory abnormalities do not mean that the patient is not ill or in distress. Physical and emotional pain may be disabling. We must guide patients away from sickness behaviour; we must also focus on the complicated psychosocial and biological factors that distinguish individuals who cope well with their symptoms from those who remain disabled in chronic pain (Goldenberg 1995). Physicians have taken an entity that existed for centuries, given it a new name, and created a major health issue by elevating it in importance and suggesting it deserves disability coverage (Carette 1995).

Hypermobility

The term 'hypermobility syndrome' is used to describe a common disorder in which seemingly otherwise healthy individuals present with articular and/or spinal symptoms for which no explanation is forthcoming, other than their joint hypermobility. The degree of hypermobility relates to the degree of ligamentous laxity. These patients are susceptible to torn muscles and ligaments, and are also predisposed to traumatic and degenerative changes of joints, and prolapsed discs. Dislocation of joints is more likely to occur. Persistent low back pain in the absence of an identifiable anatomical lesion in hypermobile patients is called 'the loose back syndrome'.

Normal individuals have a wide range of joint mobility, apart from the influence of age, sex, and race. Hypermobility diminishes steadily throughout childhood and more slowly during adulthood. Females show a greater range of joint movement than males. Generalized ligamentous laxity, the prerequisite of joint hypermobility, is seen in about 10 per cent of healthy individuals; the majority suffer no ill effects. The diagnosis of joint hypermobility depends on the ability to perform a series of passive joint manoeuvres. The Beighton scale (Beighton *et al*. 1989) is the measurement of choice (Table 11); the maximum score is 9.

Scoring 1 point on each side
Passive dorsiflexion of the fifth metacarpophalangeal joint to 90°
Apposition of the thumb to the flexor aspect of the forearm
Hyperextension of the elbow beyond 10°
Hyperextension of the knee beyond 10°
Scoring 1 point
Forward trunk flexion placing hands flat on floor with knees extended

Table 11 The 9-point Beighton scoring system for joint hypermobility

The diagnosis is commonly missed, for clinicians are trained to look for loss of range of joint and spinal motion and so fail to recognize an increase in range. Hypermobility syndrome has to be distinguished from the less benign heritable disorders of connective tissues such as the Marfan and Ehlers–Danlos syndromes and osteogenesis imperfecta, with which it shares a number of common features. This distinction is not always easy. Echocardiography, ophthalmic examination, and genetic studies may be required to define the phenotype in individual families.

Tissues that rely for their structural integrity on the tensile strength of collagen may be affected. The skin may be soft and develop striations. An association between mitral-valve prolapse, aortic incompetence, and hypermobility has been reported. There is an increased incidence of abdominal hernia, and rectal and uterine prolapse. Bone fragility may also be present and stress fractures can occur.

Articular features

The clinical effects of hypermobility depend on its degree and are irrespective of its cause. Patients present with a wide variety of traumatic and overuse lesions including joint or tendon-sheath synovitis, friction lesions at insertions of tendons or ligaments, rotator-cuff lesions, or back pain. Others suffer the effects of joint instability, such as flat feet and recurrent dislocation or subluxation. Arthralgia can occur and tends to improve over the years as the joints lose some of their hypermobility. There is also presumptive evidence to suggest that premature osteoarthritis may be a direct consequence of joint hypermobility.

There is a female preponderance of 85 per cent in this syndrome, which reflects the greater laxity of their joints. All patients have a varied pattern of locomotor disorders and it has been suggested that people with hypermobility do not present with different rheumatological problems from other patients; but that they have them in greater variety.

Hypermobility in healthy individuals should not be considered as just a liability. It seems to be an important selection factor enabling them to compete successfully in athletics, music, and ballet. Since inherent joint laxity enables the dancer to achieve impressive ranges of joint movement without effort, hypermobile individuals tend to be selected for ballet schools, upon which their connective tissue abnormality ceases to be an asset and becomes a liability.

Patients with hypermobility syndrome present with an unusual collection of seemingly unconnected locomotor symptoms. Unless the clinical examination is thorough and looks for increased range of joint and spinal movement, the syndrome will be overlooked. It is a common condition and patients are often pleased that someone can explain their symptoms.

Aetiology

Studies of families have provided evidence for a dominant mode of inheritance. Within individual families, females are more frequently and more severely affected than males. Females tend to present with arthralgia and mitral-valve prolapse, while males tend to develop dislocations and back pain (Child 1986). The mitral-valve prolapse is usually mild and has no haemodynamic significance.

Skin biopsies show abnormalities in the architecture of the collagen bundles. The normal gradation between the coarser deep and the fine superficial bundles is lost, and a more uniform deposition of the fine bundles prevails throughout the dermis. At the biochemical level there are raised ratios of collagen type III:types II + I, indicating a significant imbalance in the two major collagen types present.

Treatment

Management (Table 12) must first include an explanation of the symptoms. Patients need to know they have a condition that doctors recognize and that they do not have Marfan syndrome with its less favourable prognosis.

1. Discuss condition and reassure that pain is not imaginary
2. Inform that although children may inherit joint hypermobility they will not necessarily have symptoms
3. Patients with mitral-valve prolapse require antibiotic prophylaxis
4. Anti-inflammatory drugs no more effective than analgesics
5. Stretching exercises aim to restore movement into hypermobile range
   Conventional physiotherapy disappointing
6. Patients should try to avoid activities that provoke or aggravate symptoms

Table 12 Management of hypermobility

Symptoms arising in unstable, weight-bearing joints may be relieved by an appropriate exercise routine, in an attempt to allow muscle to compensate for ligamentous laxity. Many of the complications of hypermobility (osteoarthrosis, ligamentous or muscle tears) are treated along conventional lines. However, the arthralgia and the 'loose back syndrome' can be difficult to treat, apart from noting aggravating factors and trying to avoid them. These pains respond poorly to non-steroidal anti-inflammatory drugs and conventional physiotherapy.

Localized soft-tissue lesions

The painful shoulder

More than 90 per cent of lesions causing the painful shoulder result from extracapsular soft-tissue conditions (Table 13). The glenohumeral joint is a multiaxial joint that permits the greatest freedom of movement of any joint in the body, allowing placement of the hand for optimal function, although this is at the expense of stability. Ligamentous support is important in maintaining the stability of the shoulder joints, and muscles act as prime movers at the shoulders as well as providing some dynamic stability at the glenohumeral joint.

Rotator-cuff lesions

Tendinitis:
- Supraspinatus
- Acute calcific supraspinatus
- Infraspinatus and subscapularis

Rupture:
- Partial
- Complete

Bicipital syndromes

Tenosynovitis of long head

Rupture of long head

Subacromial bursitis

Usually secondary to adjacent pathology

Frozen shoulder (adhesive capsulitis)

Shoulder–hand syndrome and referred pain

Table 13 The painful shoulder

Shoulder pain may be seen in association with several medical conditions and may be referred from cervical, thoracic, or abdominal sources. The mechanism of injury may also help in making a diagnosis. A fall on to an outstretched arm can give rise to glenohumeral instability in the younger person or a rotator-cuff tear in the elderly person. A fall on to the point of the shoulder may result in injury to the rotator cuff or acromioclavicular joint. Throwing injuries tend to stress the capsule and ligaments of the glenohumeral joint, and can also give rise to rotator-cuff or bicipital tendinitis.

Complaints of shoulder pain are frequently related to occupation. Bjelle *et al*. (1979) have documented this association: they monitored the medical departments of six heavy industries and found that approximately one-third of visits were for non-traumatic musculoskeletal complaints, of which 30 to 50 per cent were neck–shoulder complaints.

Hagberg (1981a) and Hagberg (1981b) studied the relation between task demand and shoulder pain, and assessed endurance and fatigue. It was found that if the arm is held abducted and in forward flexion at a right angle, the supraspinatus and upper trapezius demonstrate fatigue within 5 min. With a variable workload and repetitive forceful shoulder flexion, the lower trapezius fatigues and there is associated discomfort in the lower neck for as long as 24 h after exertion. Workers were also filmed to gain objective estimates of workload. These physiological insights suggest task modifications that might lead to more comfortable working patterns. Job rotation, shorter exposure times, and job sharing may all lessen shoulder discomfort. These studies suggest that shoulder or neck disorders in industrial workers are multifactorial in origin and that pre-existing disease is important among the causative factors. Workers with chronic shoulder pain were significantly older and women were at higher risk than men of developing shoulder complaints.

A pain history is essential as the location and type of pain varies between conditions. Pain referred from the cervical spine is often maximal over the suprascapular region, with associated paraesthesias or pain in the upper limb. Acromioclavicular and sternoclavicular pain is usually well localized in the involved joint. Pain from the rotator cuff is usually felt at the outer aspect of the upper arm. Capsulitis tends to give rise to an intense aching deep in the shoulder. Night pain tends to be of two main types, either a sharp pain associated with movement indicative of a rotator-cuff tendinitis or acromioclavicular pathology, or pain of a deep, constant aching more suggestive of capsulitis or a rotator-cuff tear.

Examination should include close inspection for deformity, muscle wasting, and abnormalities of scapulohumeral movement. Palpation should assess the presence of tenderness, swelling, and instability as well as trigger points. Active and passive ranges of motion of both shoulders should be assessed in the planes of abduction, forward flexion, and external rotation, both with the arm by the side and at 90° abduction (Table 14).

Lesion	Painful arc	Pain increased by:
Supraspinatus tendinitis, calcific deposit or incomplete tear	Yes	Resisted abduction
Infraspinatus tendinitis	Yes	Resisted external rotation
Acromioclavicular joint disease	Yes; pain begins later in abduction (not below 90°) and increases as full elevation is reached	Local palpation; resisted adduction
Subscapularis	No	Resisted internal rotation
Bicipital tendinitis	No	Resisted flexion and supination of the elbow Tender bicipital groove

Table 14 Clinical features of some extracapsular shoulder lesions

Periarticular conditions affecting the shoulder can be loosely grouped into those with and without capsulitis. If there is no capsular involvement, then passive joint movement is largely unaffected whereas active movement may be limited by pain or weakness. In capsulitis there is a generalized restriction of movement (Dalton 1989).

Rotator-cuff disorders

As outlined above, these range from mild tendinitis following an episode of glenohumeral instability in the young patient to a complete tear in an older patient. The cuff is subjected to stresses when the arm is in the raised position, and impingement can occur as the supraspinatus tendon is compressed between the humeral head and the overlying acromion, coracoacromial ligament, and the inferior border of the acromioclavicular joint. As the rotator cuff becomes inflamed and thin its function as a depressor of the humeral head is compromised, and migration of the humeral head due to the unopposed action of the deltoid gives rise to further impingement. In the degenerative cuff this can result in a cuff arthropathy with degenerative changes in the subacromial and glenohumeral joints (Neer 1983).

Rotator-cuff tendinitis

While any of the tendons of the rotator cuff may be affected by tendinitis, it most commonly affects the supraspinatus portion of the cuff close to its insertion to the humeral head. Overuse, with resultant wear and tear and relative avascularity, may be important in inducing degeneration of the tendon.

In the young adult, rotator-cuff tendinitis usually presents acutely after an activity such as throwing. In middle-aged individuals the onset is more gradual, reflecting the underlying chronic change in the tendon, with pain aggravated by movement into abduction on elevation. Pain at night occurs when lying on the affected side. Active movements may be restricted by pain, but passive range is usually maintained and in the more chronic cases a secondary capsulitis may further restrict the shoulder movement.

Examination shows a painful arc of abduction, usually occurring between 70 and 120°, and then when lowering the shoulder there is often a 'catch' of pain as impingement occurs. Passive movement is usually full and pain-free if there is adequate muscle relaxation. In the older patient there is often involvement of the acromioclavicular joint.

Pain felt in the upper arm may suggest involvement of the cervical root, although this is more likely to present with upper trapezius or suprascapular pain referred down into the arm. Pain on active arm movement and impingement testing helps in confirming a rotator-cuff tendinitis, and the preservation of passive range of movement helps differentiate a tendinitis from a capsulitis. In patients under the age of 25 years, tendinitis is usually due to an underlying instability, which can be confirmed on examination.

Some cases of supraspinatus tendinitis are associated with calcific deposits visible on radiographs (Fig. 3). The exact mechanism responsible for the deposition of the calcium hydroxyapatite crystals in the tendon is unclear (Uthoff and Sarkar 1989). The deposits may remain asymptomatic or produce chronic symptoms with nagging discomfort in the region of the affected tendon. The crystals may also be extravasated into the subacromial bursa, causing acute bursitis with intense shoulder pain, loss of movement, severe tenderness, swelling, and muscle spasm. Fever, sweating, and other systemic symptoms may be present, mimicking gout or septic arthritis.

Fig. 3 Radiograph showing calcification of the supraspinatus tendon in the shoulder.

Infraspinatus and subscapularis lesions

These are less common and do not tend to calcify. While the symptoms are usually similar to those of supraspinatus tendinitis, pain induced by resisted external or internal rotation (Table 14) usually allows the correct diagnosis to be made.

Management

This is often difficult because of the patient's continuing participation in aggravating activities. Rest is necessary to prevent the condition becoming chronic. Initial treatment should aim to reduce inflammation with non-steroidal anti-inflammatory drugs and physical methods such as ultrasound. When there is no response, a subacromial injection of corticosteroid can be used.

In addition to improving pain, treatment should also aim to restore the range of movement and the normal biomechanics of shoulder movement, particularly a normal scapulohumeral rhythm. Then a strengthening programme of exercises should be given, with particular attention to restoring the rotator-cuff muscles to their function of stabilizing and depressing the humeral head.

The younger patient with instability requires a rehabilitation exercise programme and rarely requires injection. The older patient with a degenerative rotator cuff and associated pathology of the acromioclavicular joint may not be helped without surgery. The major indication for surgery is pain and, in the presence of an intact rotator cuff, failure to respond to conservative treatment within 1 year. Surgery consists of subacromial decompression by resecting the coracoacromial ligament, and an anterior acromioplasty. If there is pathology of the acromioclavicular joint, this also requires attention. Full-thickness tears can be demonstrated by arthrography, ultrasonography, or magnetic resonance imaging. Arthroscopy is also useful.

Tears of the rotator cuff

Tears of the rotator cuff may be acute or chronic, partial or full thickness, and are most common in patients over the age of 50 years. They usually occur at the enthesis; degenerative changes and alterations in collagen composition may explain the susceptibility to tearing at this site (Kumagai *et al*. 1994). The mechanism of injury is a fall on to the outstretched arm. Partial tears may occur after trauma at any age and may present as a painful arc syndrome; full active range of movement may be preserved. Complete tears are associated with marked weakness of abduction and external rotation, or of flexion, depending on the tendon involved; passive movement is full. Pain can be severe and there may be no history of injury. Partial tears may be difficult to differentiate from tendinitis, but there is often an inability to maintain the arm in abduction when lowering it from a raised position. Atrophy of supra- and infraspinatus muscles often follows, and weakness of external rotation reflects the size of the tear. Rupture of the tendon of the long head of the biceps is frequently associated with chronic disease of the rotator cuff.

Chronic, full-thickness tears are found in up to 25 per cent of cadavers at autopsy. Cuff arthropathy occurs when there is superior migration of the humeral head against the under surface of the acromion, which happens when the incompetent rotator cuff fails to stabilize and depress the humeral head and therefore counteract the pull of the deltoid.

Radiographs show degeneration and sclerosis of the rotator cuff, and cystic changes at the greater tuberosity. Osteophytes may be present at the inferior margin of

the acromioclavicular joint. The subacromial space is narrowed if there is a complete tear.

Treatment

Partial tears of the rotator cuff should initially be managed conservatively in a similar way to tendinitis of the cuff, although corticosteroid injections should be avoided within 6 weeks of injury. Acute ruptures in the young or active patient should have early surgery. In the older or less active patient it is usual to give a trial of conservative treatment. The treatment of large tears is controversial. It now seems that adequate decompression combined with anterior acromioplasty and debridement is preferred over extensive surgical procedures (Burkhart *et al*. 1994). Surgery should also be considered where there is associated rupture of the biceps tendon, as these patients are more likely to develop a cuff arthropathy.

Bicipital syndromes

The biceps tendon is seldom involved in isolation and involvement usually occurs with tendinitis or impingement of the rotator cuff, or with glenohumeral instability. As with rotator-cuff tendinitis, the young patient should be assessed for joint instability. Acute rupture is usually a result of overuse such as in weight-lifting.

Pain is felt over the anterior aspect of the shoulder, with localized tenderness over the tendon in the bicipital groove. Pain may be reproduced on resisted elbow flexion, although various provocation tests are inconsistently positive. Rupture of the tendon leads to a characteristic increase in the muscle belly of the biceps on resisted elbow flexion.

The tendon of the long head of the biceps tendon may be involved at its attachment to the superior glenoid labrum or as it runs in the bicipital groove.

Treatment

This consists of rest, physical procedures including laser therapy, and non-steroidal anti-inflammatory drugs. Care should be taken not to inject the tendon with corticosteroid. It is essential to assess whether the tendinitis is primary or secondary to pathology or instability of the rotator cuff, as failure to treat these causes will lead to a recurrence.

In chronic resistant cases, surgery may be required; either subacromial decompression or tenodesis, depending on the cause. Rupture of the tendon is usually treated conservatively, except in the occasional young patient where upper-arm strength is essential for their sport.

Subacromial bursitis

In most cases the bursa becomes inflamed as part of the impingement process and coexists with an underlying rotator-cuff tendinitis. In chronic cases the bursa becomes fibrotic and surgical excision or debridement may be necessary.

Acute traumatic bursitis may be differentiated from rotator-cuff tendinitis by the presence of increased tenderness and fluid at the subacromial space. Rest and physical treatment usually result in resolution.

Acromioclavicular syndrome

This is seen as an acute condition following trauma, usually after falls or contact sports. Septic arthritis can also rarely occur. Disruption of the joint may be seen in association with fractures of the clavicle. More common are injuries to the joint itself, which are graded I to III depending on the degree of disruption of the joint capsule and supporting ligaments.

Pain is well localized to the top of the shoulder, and the joint is often tender and swollen. Abduction is often limited. In complete disruption of the joint a visible step deformity is seen.

Treatment

For most injuries treatment is largely symptomatic with analgesics and a sling for a few days. Controversy exists over the management of complete dislocation of the joint. Surgical stabilization is usually unnecessary and has a high failure rate.

Patients with persistent pain at the acromioclavicular joint should be treated with an intra-articular corticosteroid and non-steroidal anti-inflammatory drugs. Long-term treatment is as for osteoarthritis of the joint.

Frozen shoulder (adhesive capsulitis)

This condition may occur spontaneously but can follow other lesions of the rotator cuff or trauma. In addition, conditions that produce pain (e.g. the referred pain of myocardial infarction) or immobility (e.g. from stroke or polymyalgia rheumatica) of the shoulder or arm can predispose to the development of a frozen shoulder. Early arthrography may reveal a small, shrunken, thickened capsule and some insist that these changes need to be present to make a diagnosis of adhesive capsulitis (Neviaser and Neviaser 1987).

Primary capsulitis can be defined as a condition of unknown aetiology in which there is a painful, global restriction of active and passive glenohumeral movement in all planes, in the absence of joint degeneration. Underlying conditions associated with this condition include diabetes mellitus, thyroid disease, and pulmonary disorders such as tuberculosis (Risk and Pinals 1982). Until recently, few pathological studies had been performed; Bunker and Anthony (1995) found features compatible with fibromatosis.

Onset under the age of 40 is uncommon; frozen shoulder is slightly more common in women than men and involvement of the contralateral shoulder occurs in up to 17 per cent of patients over the subsequent 5 years. There is severe night pain and pain on movement; improvement is gradual and spontaneous but may take 1 to 3 years. The extent of the recovery is variable and a clinically detectable limitation of shoulder movement can be seen in up to 15 per cent of patients (Bulgen *et al*. 1984).

Diagnosis is largely on clinical grounds as few abnormalities are found on investigation. Differentiation from rotator-cuff tendinitis is possible as there is global restriction of passive movement rather than simply loss of abduction and flexion.

Patients with even minor degrees of frozen shoulder may develop a secondary, reflex-sympathetic dystrophy syndrome—the shoulder–hand syndrome. This consists of a symptom complex characterized by an immobile painful shoulder associated with a swollen, painful, cold, and dystrophic-looking hand. The lesion may progress until the patient is left with a painful, tender, useless hand.

Treatment

The emphasis in the early stages should be on pain relief and the prevention of joint restriction. Analgesics are more effective than non-steroidal anti-inflammatory drugs; physiotherapy with interferential can reduce pain and reduce muscle spasm, and exercises within the limits of pain to maintain joint mobility are encouraged.

Intra-articular corticosteroid injections have improved pain and range of movement, although no long-term benefit has been shown. Oral corticosteroids have improved pain but not range of movement. No treatment has been consistently shown to affect rate of recovery or limit restriction of movement.

Distension of the subscapular bursa by arthrography and forced mobilization can result in immediate pain relief (Nobuhara *et al*. 1994). Manipulation under anaesthetic is sometimes advocated to restore joint movement by rupturing the inferior capsule. Care is required and very active early rehabilitation is necessary in

the postmanipulation period to maintain joint mobility. If this treatment is contemplated, it is recommended that it be reserved for the adhesive stage and not the early, painful phase.

This condition is very painful and disability prolonged. It is essential that the patient understands this and for their expectations to be appropriate.

Glenoid labrum tears

There has been considerable recent interest in tears of the glenoid labrum. The labrum is a fibrocartilaginous and fibrous structure attached to the glenoid that supports the stability of the joint by serving as an attachment site for the glenohumeral ligaments. Clinical features of tears include shoulder pain, especially with overhead activities, and snapping and catching on movement. Because the biceps tendon originates at the superioglenoid with its labral attachment, pain may be present in the anterior shoulder on resisted forward flexion with the elbow extended and forearm supinated (Speed's test) (Payne 1994).

The painful elbow

Pain round the elbow is commonly caused by soft-tissue lesions (Table 15), but care must be taken to exclude pain referred from the cervical spine, brachial plexus, and shoulder, and examination of the neck and shoulder is important in the assessment of elbow pain.

Humeral epicondylitis
Lateral:
Tennis elbow
Medial:
Golfer's elbow
Biceps and triceps tendinitis
Tear of brachialis muscle
Olecranon bursitis
Traumatic:
Student's elbow
Secondary to inflammatory joint disease
Friction neuritis of ulnar nerve

Table 15 The painful elbow

Humeral epicondylitis

Lateral involvement (tennis elbow) is much more common than medial involvement (golfer's elbow). In spite of their sporting connotations, both occur more frequently in those performing repetitive movements with their arms, for example operating machinery, using a screwdriver or doing housework, although some 40 per cent of tennis players do suffer from tennis elbow.

In tennis elbow there is pain over the lateral aspect of the elbow with localized tenderness near the lateral epicondyle. In general, tenoperiosteal lesions can be separated from intra-articular conditions because movement of the related joint is full, there is tenderness at the tenoperiosteal junction, and contraction of the muscle attached to the affected tendon reproduces the pain. About 1 to 3 per cent of adults are affected by it; usually they are aged between 40 and 60 years, the dominant arm being most frequently affected (Hamilton 1986). Resisted dorsiflexion of the wrist exacerbates the pain with the elbow in extension, and there is a reduction in grip strength. Tenderness is usually maximal over the lateral epicondyle. Thermography usually shows a discrete 'hot spot' on the side of the elbow. The range of movement of the elbow is usually normal. In golfer's elbow there is a tender spot at the medial epicondyle owing to a lesion of the common flexor tendon, and pain is induced by flexing the wrist against resistance with the elbow fully extended.

Pain on resisted flexion alone indicates the rarer brachialis muscle lesion, with pain and tenderness that is less well localized and found behind the biceps tendon. Although uncommon, such a tear is particularly prone to develop myositis ossificans, which in the early stages produces a warm, firm mass that can be mistaken for a tumour. It is unusual to have a lesion at the site of the triceps insertion into the olecranon. Lesions usually occur in this tendon at the musculotendinous junction. Ligamentous lesions do not usually occur in isolation; they are usually associated with traumatic synovitis of the joint.

Radial tunnel syndrome or compression of the posterior interosseous nerve can produce lateral elbow and forearm pain. These nerve entrapments are due to compressive lesions caused by fibrous bands in front of the radial head, or an abnormal origin of extensor carpi radialis brevis.

It is thought that the majority of patients have a musculotendinous lesion of the common extensor tendon at the attachment to the lateral epicondyle, especially that portion derived from extensor carpi radialis brevis. Macroscopic tears in the extensor tendon are occasionally found at operation, but these may have been caused by repeated steroid injections. Some cases show mesenchymal transformation suggestive of a chronic traction effect. Age is an important factor since lateral epicondylitis is uncommon before 30 years. Sometimes there may be bilateral involvement, either due to increased stress placed on the unaffected arm or as a general tendency to soft-tissue lesions in that individual.

Management (Table 16)

Early/mild	Rest, splinting
	Anti-inflammatory drugs/gels
Persistent	Local corticosteroid injections
	Ultrasound
Resistant	Manipulation?
	Surgery—lateral release

Table 16 Management of lateral epicondylitis

Reduced activity may result in improvement, particularly in early cases. Corticosteroid injections have been widely used; hydrocortisone is preferable to longer-acting preparations, which may lead to skin atrophy. Approximately 90 per cent of patients respond, but there may be increased pain for up to 48 h following injection and a significant number of cases recur. The injection may be repeated once after 4 weeks.

Non-steroidal anti-inflammatory drugs are often used but there is little evidence of their efficacy. A cock-up wrist splint reduces tension on forearm extensors and may help resolution. Numerous physical forms of treatment have been used but the efficacy of most is unproven (Chard and Hazleman 1989). Ultrasound, by its ability to cross myofascial planes and concentrate near bone, has theoretical advantages; in one study the rate of relapse was less with ultrasound than after corticosteroid injection (Binder *et al*. 1985).

Up to 40 per cent of patients have recurrent symptoms and some minor discomfort can persist for years. Early treatment may improve prognosis; firm strapping of the forearm muscles just distal to the elbow joint or the use of commercial elbow splints may be helpful. Patients should be advised to avoid straining the arm for some 2 months. Graded exercises to strengthen the forearm muscles may be advised, especially in sporting lesions.

Up to 10 per cent of patients fail to respond to physiotherapy. Surgical treatment, which attempts to correct the presumed pathological changes, can be helpful. Excision of tissues around the epicondyle or removal of a synovial fringe of the radiohumeral joint are the most common procedures.

Olecranon bursitis

The superficial bursa over the olecranon process is commonly involved in rheumatoid arthritis (with nodule formation) or gout, but can also be affected by trauma or infection. In the acute stage it distends with fluid, with prominent signs of acute inflammation. If it becomes chronic the wall can be greatly thickened. As the posterior wall of the bursa is so close to the periosteum of the olecranon, pain can be felt down the border of the ulna.

Treatment

Aspiration of the bursa reduces symptoms and allows examination of the fluid to exclude infection and the presence of crystals. If no infection is suspected, local steroid injections are effective; a compressive elastic bandage may help prevent the recurrence of swelling. If recurrent, non-infective bursitis occurs then surgical excision may be necessary. The presence of infection requires appropriate antibiotic treatment and surgical drainage may be necessary.

The painful wrist and hand (Table 17)

Dupuytren's contracture
Tenosynovitis—including De Quervain's
Stenosing tenovaginitis
Rupture of tendons
Ganglion
Median nerve compression—carpal tunnel syndrome
Ulnar nerve compression—in Guyon's canal

Table 17 The painful wrist and hand

Both seropositive and seronegative arthritides have a predilection for inflammatory involvement of the synovial structures of the tendons and joints in the wrist and hand. Tenosynovitis denotes an inflammation of the synovial lining of the tendon sheath, usually accompanied by inflammation of the contained tendon. The clinical manifestations are pain, tenderness, and swelling, with 'crepitus' that is palpable when the tendon moves within the inflamed sheath.

The flexor tendon sheaths enclose the tendons of flexor digitorum superficialis and profundus to their insertions on the middle and distal phalanges, respectively. The tendon sheath of the thumb flexor pollicis longus extends proximally to the carpal tunnel. The flexor sheath of the little finger is often continuous with the common flexor tendon sheath in the wrist. Segmental condensations in the digital flexor sheaths prevent bowstringing of the tendons.

Stenosing tenovaginitis

Stenosing tenovaginitis is primarily a fibrosis of the tendon sheaths with intrathecal narrowing of the lumen, especially involving sites near bony prominences where tendons pass through fibrous rings. This more commonly affects the flexor than extensor tendons in the hand. If a fibrous nodule develops in the flexor tendons, a 'trigger finger' can result, which further limits function. The finger often locks in flexion. Extension can be forced with difficulty and is often painful. Palpation during muscle action may reveal a mobile nodule within a tendon sheath of a finger or palm. Its incidence as an isolated lesion following overuse is low. The most common cause of a trigger finger or thumb is overuse from repetitive grasping activities.

Management

The management of stenosing tenovaginitis consists of modification of hand activity, gentle exercises, and non-steroidal anti-inflammatory drugs. Extension splinting of the affected digit at night prevents painful flexion during sleep. One or two corticosteroid injections into the affected tendon sheaths are effective in the majority. Surgical transection of the fibrous annular pulley of the finger or thumb flexor sheath is rarely required.

De Quervain's tenosynovitis

This common lesion, caused by repeated minor trauma, results from involvement of the tendon sheaths of abductor pollicis longus and extensor pollicis brevis. The patient complains of pain on using the thumb or wrist. Tenderness is maximal in the 'snuffbox' area between the two tendons, and there is often a visible tender swelling about the radial styloid. Pain can be elicited by forced ulnar deviation after placing the patient's thumb in the palm (Finkelstein's sign).

The tendon sheath, which is normally about 0.75 mm thick, increases in thickness three- or fourfold, and there is cellular infiltration with increased vascularity of the sheath, inflammatory proliferation of the epitendon, and expansion of part of the tendon to form a nodule.

It has been reported for years that De Quervain's is more common in assembly-line workers involved in repeated grasping movements between finger and thumb, and with rapid pronation–supination movements of the forearm, although most studies cannot demonstrate an association with occupation. It is 10 times more prevalent in women.

Treatment

The symptoms often resolve spontaneously with rest, but can be recurrent or persistent. Immobilization of the wrist and thumb by thermoplastic splinting is often helpful. Attention to hand activities with avoidance of tasks that require repetitive thumb movements or pinch grasping is important. In patients with more severe or persistent pain, one or more local corticosteroid injections are often helpful, giving relief in some 70 per cent. Surgical decompression of the first extensor compartment, with or without tenosynovectomy, is indicated in those with persistent or recurrent symptoms for more than 6 months.

Tenosynovitis and peritendinitis crepitans

By definition tenosynovitis is a disorder of the tenosynovium. It has been described after trauma in an industrial context for many years, affecting the long extensors of the fingers at the wrist and less commonly the long flexors. Tenosynovitis occurs after unusually active use of the wrist over a period of days or weeks. Tenosynovitis and peritendinitis crepitans are two distinct syndromes. Both present with pain, particularly on resisted movement, and there is usually localized swelling, tenderness, and crepitus. The distinguishing feature is the site of the lesion. In tenosynovitis the swelling and tenderness are confined to the synovial sheaths and the wrists, and respond to rest and local steroid injections. Peritendinitis crepitans presents with pain, tenderness, and swelling at the musculotendinous junction above the upper limit of the tendon sheaths in the forearm. It usually responds to rest, and to ultrasound.

Since 1947 tenosynovitis has been a United Kingdom Department of Health (and Social Security) prescribed industrial disease. It was intended to compensate manual workers suffering from tenosynovitis induced by excessively rough or arduous work. More recently, tenosynovitis has come to be used incorrectly as a generic term covering not only traumatic tenosynovitis and paratendinitis crepitans but a wide variety of non-specific aches and pains in the forearm, which trades union health-care advisers and members may often simply call 'teno'. The epidemiological evidence for the accepted overuse syndromes is substantial, although often clouded in recent years by differences in the terms used to describe these disorders and also by the emotional arguments pertaining to repetitive strain disorders (see above).

There is little doubt that the common occupational disorder known as peritendinitis crepitus is related to overuse. Biopsies were first carried out by Von Frisch in 1909; he found oedema with congestion of the peritendinous tissues, mainly at the musculotendinous junction and often around the muscle (Thompson *et al*. 1951). In more recent descriptions it is clear that local anatomical considerations are important (Williams 1977).

Dupuytren's contracture

This condition, of unknown aetiology, produces progressive thickening of the palmar fascia and causes flexion contracture predominantly affecting the ring and little fingers. It is commonly bilateral and can also involve the plantar fascia. The palm of the hand becomes indurated and lines of fibrosis with nodules and skin puckering run along the tendons, causing progressive fixed flexion of the metacarpophalangeal and proximal interphalangeal joints.

The rate of progression is variable and surgical fasciectomy should be performed only when disability is severe, but should be considered before amputation becomes the only alternative.

Management

Treatment depends entirely on the rate of progression and severity of the lesions. In patients with mild disease, local heat, stretching exercises, and the use of protective padded gloves during heavy manual tasks are often helpful. In more severe lesions with pain and inability to straighten the fingers, intralesional steroids may be beneficial. In those with progressive digital contracture of more than 30°, and functional impairment, a palmar fasciectomy with or without a skin graft is indicated. The risk of recurrence is greater in those with a family history or active bilateral disease.

Ganglia

Ganglia are tense, uni- or multilocular, cystic swellings that develop in relation to a joint capsule or tendon sheath and contain a clear, jelly-like substance. They vary in size and can be so tense that they may be mistaken for a bony swelling. They are sometimes provoked by injury or arthritis, but often occur spontaneously.

Entrapment neuropathy (carpal tunnel syndrome)

Nerve compression can occur at any site where a peripheral nerve passes through an opening in fibrous tissue or an osseofibrous canal. The clinical diagnosis, if in doubt, may be confirmed by electromyography, although the electromyogram can be normal in up to 8 per cent (Wilcox and Bilbao 1993), the results becoming abnormal only if significant demyelinization or axonal loss occurs.

Entrapment of the median nerve in the carpal tunnel at the wrist is the most common entrapment lesion. It is more frequent in women. Most cases are idiopathic or caused by unaccustomed repetitive use, but compression in the carpal tunnel may be associated with rheumatoid arthritis, myxoedema, acromegaly, pregnancy, and the contraceptive pill. Fracture, deformity, or dislocation of the carpal bones can cause similar problems. Early symptoms include painful tingling in the wrist and hands, mainly affecting the thumb, index, and middle fingers, but often symptoms are poorly localized. The pain may occasionally extend up the arm well above the wrist and often interferes with sleep. Patients try to obtain relief by hanging the affected limb out of the bed. Later, weakness (first in the abductor pollicis brevis) develops. Diminution of sensation to touch and pin-prick, usually over the palmar aspects of the distal phalanges of the index and middle fingers, may be found. Untreated, wasting of the muscles of the thenar eminence develops. Electromyography is helpful where the clinical diagnosis is in doubt. A delay in motor or sensory conduction velocity across the wrist confirms the diagnosis, although no electrical abnormality may be detected in early cases.

Treatment (Table 18)

1. Splinting–may be curative; especially if of recent onset
2. Local corticosteroid injection; second injection can be given if improvement not complete
3. Non-steroidal anti-inflammatory drugs; can be helpful if underlying inflammatory lesions such as tenosynovitis
4. Surgical release of transverse carpal ligament is definitive treatment; indicated when response to conservative measures inadequate, when there are progressive or persistent neurological changes, or when there is muscle atrophy

Table 18 Management of carpal tunnel syndrome

Conservative measures may suffice when symptoms are of short duration. Patients with progressive increases in distal motor latency times on repeated electromyograms should be considered for surgery. Most patients, however, do not need surgical decompression, and certainly not as initial treatment (Harter *et al*. 1993).

Splinting

This is simple, and if successful in relieving symptoms it often helps to confirm the diagnosis. A volar wrist splint that keeps the wrist in a vertical position is helpful at night, and splinting alone may be sufficient to relieve symptoms.

Local corticosteroid injection

This is also effective when the disease is of short duration and where there is slight muscle wasting. A second injection can be used but more frequent injections may lead to tendon rupture. Gelberman *et al*. (1980) found that the best response to injection was in patients who had had symptoms for less than a year and in whom there was no significant muscle atrophy or weakness.

Surgery

Surgical release of the transverse carpal ligament is the definitive treatment. It is indicated when response to conservative treatment is inadequate, if there are progressive or persistent neurological changes, or there is muscle atrophy. If there is also marked tenosynovitis, then a tenosynovectomy may also be necessary. Surgery relieves symptoms in about 90 per cent. Pain for more than 5 years preceding surgery indicated a poor prognosis, and diabetics do less well (Haupt *et al*. 1993).

Ulnar tunnel syndrome

Entrapment of the ulnar nerve can occur in Guyon's canal at the wrist. The most common causes are a ganglion and inflammatory joint disease. When compression occurs in the proximal portion of the ulnar tunnel the patient will have combined sensory and motor deficits, paraesthesias in the hypothenar region and the fourth and fifth fingers, as well as weakness of the intrinsic muscles of the hand. More distal lesions may present with either motor or sensory impairment. Electrodiagnostic studies are helpful in determining the site of entrapment and in defining which branches are involved.

Treatment

If conservative measures such as avoidance of trauma to the palm do not result in improvement, then surgical decompression may be necessary.

The painful hip

Soft-tissue lesions around the hip are common, particularly in sportsmen and -women. Some of the lesions are listed in Table 19.

Muscle strains:
Adductor
Iliopsoas
Rectus femoris
Rectus abdominis
Osteitis pubis
Inflamed bursae:
e.g. iliopsoas; trochanteric
Nerve entrapment:
e.g. ilioinguinal (T12–L1); lateral femoral cutaneous (meralgia paraesthetica)

Table 19 The painful hip

Meralgia paraesthetica

This is caused by entrapment of the lateral femoral cutaneous nerve, which is entirely sensory and arises from the second and third lumbar roots. It passes under the lateral aspect of the inguinal ligament just medial to the anterior superior iliac spine, the most common site of entrapment.

This condition may arise from direct pressure from belts or tight-fitting garments and may be associated with pregnancy, diabetes, and trauma. Patients complain of a burning pain and dysaesthesias in the sensory distribution of the nerve. The diagnosis can be confirmed by electrodiagnosis or a nerve block.

Treatment

It is often self-limiting, and removal of the aggravating factor is usually enough. Local injection of corticosteroid may be helpful. Surgical decompression can be carried out if the symptoms are chronic, although the results can be disappointing.

Groin pain

This occurs particularly in runners, and 5 per cent of football injuries are of the groin (Harris 1974). It may lead to prolonged disability. Pain arising from the symphysis pubis may account for about 5 per cent of hip pain. The onset of pain is usually insidious and in most cases there is no history of acute trauma. The pain is suprapubic, medial inguinal or proximal medial thigh. The pain settles with rest and returns with activity. The sensation of a 'click' on getting up from a sitting position indicates some instability at the symphysis.

On examination there is tenderness over the symphysis; adductor spasm and any discrepancy in leg length should be looked for. Any pain lasting for more than 4 weeks requires radiological assessment; radiographic changes include widening, irregularity, and sclerosis of the margins of the symphysis.

Treatment

Treatment is conservative, with strengthening of the abdominal musculature and increasing mobility at the hip joints the most important measures. Osteitis pubis is a disabling condition and its treatment may take 12 months or longer. Any predisposing factors should be identified and treated. In the acute phase, rest is essential, non-steroidal anti-inflammatory drugs are commonly prescribed, and steroid injections into the symphysis pubis may be of benefit. Results of fusing the symphysis have been disappointing—the procedure tends to place additional stresses on the hips and sacroiliac joints.

Bursitis and tendinitis

Trochanteric bursitis is the most common cause of pain about the hip joint. The soft tissues that cross the bony posterior portion of the greater trochanter are protected from it by the trochanteric bursa. Patients suffer a deep aching pain on the lateral aspect of the hip, which increases with activity. Active abduction of the hip when lying on the opposite side typically accentuates the discomfort.

The iliopectineal bursa is deep to the iliopsoas tendon over the front of the hip joint and communicates with it in 15 per cent of cases. The symptom is pain in the groin that irradiates along the anterior aspect of the thigh.

Adductor tendinitis is frequently seen in sportsmen and -women. Pain is localized to the medial aspect of the groin, and there is tenderness and pain exacerbated by movement. The differential diagnoses include tumour, stress fractures, and soft-tissue infections.

Treatment

This consists of non-steroidal anti-inflammatory drugs, local steroid injections, and physical forms of therapy including ultrasound. Only a few chronic cases require surgery.

Snapping hip

Some patients complain of hip pain associated with an audible and palpable snapping sensation of the lateral aspect of their hip. It is an uncommon syndrome noted most frequently in adolescents and young women, and it occurs in activities such as climbing or walking upstairs. The treatment is similar to that of trochanteric bursitis.

Piriformis syndrome

The piriformis is a deep external rotator of the hip. Symptoms include a deep posterior hip pain with shooting, burning symptoms, often confused with sciatica owing to

the anatomical proximity of the muscle to the sciatic nerve.

Ischiogluteal syndrome

A strain of the muscles originating from the ischial tuberosity presents as a posterior pain around the hip. Physiotherapy is the mainstay of treatment.

The painful knee and shin (Table 20)

Patellar tendinitis
Rupture of quadriceps apparatus
Apophysitis of tibial tubercle—Osgood–Schlatter disease
Bursitis:
Prepatellar
Infrapatellar
Popliteal cysts:
semimembranosus
Baker's cyst
Anserine
Infrapatellar fat-pad lesions
Medial and lateral ligament injuries
Tendon lesions
Anterior tibial syndrome

Table 20 The painful knee

Tendons, ligaments, and bursae are the soft-tissue structures around the knee from which pain may originate. When assessing the knee, the clinical history is more valuable than the findings of clinical examination. The patient's account of the symptoms and their onset will usually make it possible to decide which structures in the knee have been damaged and how seriously.

Tendinitis

The insertions of the tendons around the knee may become inflamed due to overuse or in association with an inflammatory arthropathy. It may be difficult to differentiate tendinitis from the medial ligament syndrome and bursal inflammation.

Patellar tendinitis

The ligamentum patellae may become painful and tender at its attachment to the upper or lower pole of the patella or at its distal attachment to the tibia. The condition is due to increased degeneration of the patellar tendon. Prolonged and heavy exercise, such as jogging or jumping, predisposes to this condition, which usually occurs in young adults. The majority of cases respond to rest and non-steroidal anti-inflammatory drugs. Steroid injections may be effective but should be used cautiously to avoid tendon damage; surgical exploration is occasionally necessary.

Pes anserinus tendinitis

The pes anserinus insertion may become inflamed, but this may be indistinguishable from anserine bursitis and the medial ligament syndrome. In cases of anserine tendinitis, rest is usually curative but in persistence a local injection of steroid may be required.

Popliteus tendinitis

There is pain over the lateral aspect of the joint produced by overuse and leading to inflammation of the popliteus tendon and paratendon. Symptoms usually settle with rest and non-steroidal anti-inflammatory drugs.

The biceps tendon is attached to the head of the fibula, and inflammation will cause pain around the tendon insertion, felt particularly when the knee is flexed against resistance and the area pressed firmly.

Pain in the back of the knee may arise from a hamstring injury. The pain usually comes on acutely after sudden activity without adequate warming-up.

Osgood–Schlatter disease

Apophysitis of the tibial tubercle at the insertion of the patellar tendon occurs predominantly in adolescent children and is another common cause of pain in front of the knee. The condition is more common in boys than girls; symptoms include localized tenderness and swelling at this site. Pain can be reproduced by resisted knee extension; radiographs may be abnormal and show an isolated spicule of bone at the site of the swelling. In most patients the condition improves spontaneously with rest but sometimes the pain may persist for several years, and injection, plaster immobilization, or even excision of the bony spicule may then be required. A similar, but rare, condition can occur at the lower pole of the patella (Sinding–Larsen syndrome).

Bursitis

Some bursae are in direct contact with the knee joint while others are separate. As with bursae elsewhere, acute or chronic inflammation, infection, and involvement in systemic diseases such as gout and arthritis can occur.

Acute bursitis is characterized by classical signs of acute inflammation, with intense, localized tenderness and marked restriction of movement. Chronic bursitis may follow acute episodes but is much more commonly associated with repeated trauma. The bursal lining becomes thickened and cells degenerate; adhesions, villi, and calcareous deposits eventually develop. The degree of inflammation, muscle weakness and wasting, and limitation of movement can vary widely, making diagnosis difficult.

Prepatellar bursitis (housemaid's knee)

The bursa is subcutaneous and inflammation usually results from repeated kneeling, but can follow a fall on to the patella. Infection of the prepatellar bursa gives a characteristic red, shiny appearance over the knee and is often mistaken for an infected knee joint. When chronic, 'melon seed' bodies and fibrous bands form in the thickened, enlarged bursa.

The majority of cases settle with rest and the avoidance of kneeling. Occasionally, aspiration is necessary and the fluid should be sent for microscopy and culture. Recurrent episodes of inflammation may require surgical excision of the bursa.

Infrapatellar bursitis

This small, deep bursa occupies the space between the upper part of the tibial tuberosity and ligamentum patellae, separated from the synovium by a fat pad. When inflamed, the fluid obliterates the depression on each side of the ligament, the fluctuant swelling being most marked when the knee is actively extended. The treatment is the same as for prepatellar bursitis.

Popliteal cysts (Baker's cysts)

Synovial cysts in the popliteal fossa are usually referred to as Baker's cysts. They may arise from the semimembranosus bursa when they communicate with the knee joint or from a posterior rupture of the knee joint capsule. Cysts are common in children and are of no serious significance, although in young adults there may be quite severe pain after exercise. The most common course is gradual resolution. If the cyst does not resolve, it may extend into the calf, or burst, with fluid tracking down the fascial planes of the calf, mimicking an acute deep venous thrombosis. The signs are similar but differentiation can usually be made from the history of swelling in the popliteal fossa and the sudden onset of pain. Arthrography of the knee joint establishes the diagnosis but must be performed early after the onset of symptoms as the leak may seal off after a few days. CT scanning and ultrasonography can also aid diagnosis.

Treatment in children should be conservative as they usually settle spontaneously and there is a high recurrence rate after surgery. Treatment in adults should be aimed at the underlying pathology. Aspiration and injection of steroid can be helpful but reaccumulation is frequent. A large cyst that is causing pain or interfering with knee movement should be excised.

Anserine bursitis

The tendons of sartorius, gracilis, and semitendinosus all cross the lower medial side of the femur and attach by a common tendon beneath which lies the bursa. Pain is felt diffusely on the medial aspect of the knee, but tenderness can usually be localized to the area of the bursa. Knee range is normal but contracting the hamstrings induces pain. The bursa is often inflamed in elderly, obese women with a valgus deformity and is also a common source of pain in inexperienced joggers, often being mistaken for joint injury.

The conditions of anserine bursitis, medial ligament syndrome, and pes anserinus tendinitis may be difficult to separate. Treatment is initially rest and non-steroidal anti-inflammatory drugs. In persistent cases, local steroid injections are usually curative.

Ligament injuries

If a patient has injured the knee in such a way that the structures on the medial side have been stressed, damage to the medial ligament must be suspected. Clinical examination may reveal tenderness localized to the upper and lower attachment of the ligament to the femur or tibia, respectively. The diagnosis can be confirmed by stressing the medial ligament; this will reproduce the pain or demonstrate ligament laxity. It is more common in females. Treatment is initially conservative with rest and heat. Persistent symptoms respond to a local steroid injection.

Pellegrini–Stieda disease

Pain over the femoral insertion follows injury to the medial collateral ligament. The area is tender and pain occurs on stressing the ligament. There is calcification at the ligament insertion, which probably forms in a haematoma following injury. The condition is usually self-limiting with rest but local steroid injections relieve persistent cases.

Anterior knee pain

This is common in adolescence, and the term should be applied to patients in which no specific cause can be found. Conditions such as patellar malalignment, Osgood–Schlatter disease, and trauma should be excluded. It is usually bilateral and occurs in adolescent girls. The pain is often present at night and worse after sport.

Many patients have poor quadriceps strength but no demonstrable patella instability or malalignment. Some patients have tight hamstrings and wearing high-heeled shoes may also cause the symptoms. The condition is usually self-limiting.

Treatment is conservative and involves isometric quadriceps-strengthening exercises and hamstring stretching exercises. Wearing high-heeled shoes should be avoided.

External-compartment syndromes

Exercise-induced pain of the lower extremity may prove difficult to diagnose and treat, and can be due to several conditions including stress fracture, periostitis, claudication from entrapment of the popliteal artery, peripheral nerve entrapment, and the compartment syndromes.

Exercise increases compartment width and volume by 20 per cent and patients with this syndrome have higher pressures before, during, and after exercise (Clinton and Solcher 1994). Patients complain of pain over the affected compartment that increases during exercise, is relieved by rest, and is occasionally associated with neurological symptoms. The diagnosis is confirmed by measuring intracompartmental pressure during exercise. Surgical release by fasciotomy usually relieves symptoms; it is most successful in the anterior compartment.

Anterior tibial syndrome

This condition consists of severe pain in the anterior aspect of the leg, associated with foot drop. occurring after exercise, and relieved by rest. It is thought to be the result of a tight fascia compressing the muscles in the anterior tibial compartment of the leg. There are many predisposing factors, of which exercise is the most common. Surgery gives relief.

The painful heel (Table 21)

Pain behind the heel
Achilles tendon lesions:
Rupture—partial/total
Central core degeneration
Ossification
Peritendinitis (Achilles tendinitis)
Bursitis:
Subachilles (retrocalcaneal)
Subcutaneous (postcalcaneal)
Retrocalcaneal apophysitis (Sever's disease)
Pain under the heel
Plantar fasciitis
Calcaneal apophysitis and spurs
Tender heel pad

Table 21 The painful heel

Painful disorders of the ankle and foot are common. Many are due to inappropriate footwear, foot deformities, and weak muscles. The diagnosis can usually be made after taking a detailed history and careful examination of the joints, soft tissues, nerve and blood supply, and of the lumbar spine.

Pain can arise from either the posterior or plantar aspects of the heel. Most lesions occur in people who walk or stand a great deal and are particularly common in athletes. Whatever the cause, the pain tends to be aggravated by walking and relieved by rest. Accurate localization of tenderness is important in diagnosis.

(a) Pain behind the heel

Tendon rupture

Complete or partial rupture of tendon may occur after vigorous activity. In the young, the musculotendinous junction tends to be the site of rupture, while in the old the tendon itself is at risk. It occurs in patients with pre-existing tendinitis, or in those receiving corticosteroids or following local corticosteroid injections. Complete rupture is easily recognized by loss of anatomical continuity and function. Partial rupture is more difficult to diagnose. Active plantar flexion of the ankle may be preserved but is painful. Initially, swelling and marked tenderness are noted just above the tendon insertion, with exquisite pain on movement. Later, a more irregular swelling due to fibrous tissue develops, with continuing pain on movement.

Orthopaedic treatment with immobilization and/or surgery is required (Plattner 1989).

Central core degeneration of the Achilles tendon

This must be differentiated from the more common peritendinous lesion, as tendon rupture is much more likely and local steroid injections are contraindicated. Onset is less dramatic than with partial rupture, but other clinical findings can be similar.

Pain gradually increases as the day progresses. Careful examination also reveals a localized tender nodule or thickening, 3 to 6 cm above the insertion to the calcaneum.

Peritendinitis (Achilles tendinitis)

This is the common cause of chronic, persistent, and often annoying pain at the back of the heel. It occurs most commonly but by no means exclusively in athletes, especially long-distance runners. In the acute stage there is diffuse swelling and tenderness on both sides of the tendon, sometimes accompanied by crepitus. Later, signs become less obvious but pain and tenderness recur with exercise. The symptoms usually develop gradually, distinguishing this from rupture of the tendon, and occasionally the tendon may calcify. Inflammation of the peroneal tendons behind the lateral malleolus causes pain when the muscle is contracted, as when walking over rough ground. Tendinitis here may be the presenting feature of rheumatoid arthritis.

Treatment

This consists of rest, avoiding the provocative occupational or athletic activity, shoe modification, and a heel raise to reduce tendon stretching during walking. Physiotherapy, including local heat and gentle stretching exercises, and occasionally a splint in slight plantar flexion, all help. Corticosteroid injections should not be given as they may predispose to rupture (Da Cruz *et al*. 1988). Surgical excision of the inflamed peritendinous tissue is rarely required.

Bursitis

Subachilles (retrocalcaneal) bursitis may also cause pain at the lower end of the Achilles tendon. Physical examination reveals the bulging, tender bursa on either side of the Achilles tendon with normal movement of the ankle joint. Dorsiflexion of the foot aggravates the pain by compressing the bursa. Frequently, the patient can recall trauma involving the foot. The diagnosis can be confirmed by radiography (showing obliteration of the retrocalcaneal recess).

Treatment

Rest, modification of activities, and a heel pad to elevate the heel are usually sufficient. A walking cast and/or a corticosteroid injection can be helpful. Surgery is rarely required.

Subcutaneous (postcalcaneal) bursitis

A more superficial bursitis can develop over the tendon attachment as a result of poorly fitting shoes; here the swelling is lower down, larger and fluctuant. Inflammatory changes in the overlying skin are common.

Treatment

This consists of rest, padding, and wearing a soft, non-restrictive shoe. Local corticosteroid injections should be avoided.

Retrocalcaneal apophysitis (Sever's disease)

The insertion of the Achilles tendon into the calcaneum can become inflamed, resulting in symptoms of pain and tenderness behind the heel; this usually occurs in boys aged between 9 and 15 years. A heel pad and restriction of activities usually result in improvement.

(b) Pain under the heel

Plantar fasciitis

In weight bearing, stress is placed on the long plantar ligament and fascia that supports the longitudinal arch of the foot. An enthesopathy can develop at the point of attachment of the ligament to the heel. Pain and tenderness may be confined to the point of attachment but can be much more widespread; it is always aggravated on walking. The presence of a calcaneal spur on the radiograph is not necessarily significant as it is also commonly seen on films of asymptomatic heels. Plantar fasciitis may be associated with the seronegative arthritides, such as Reiter's syndrome and ankylosing spondylitis, but is usually seen in the middle aged or obese as a result of repetitive trauma from athletic activities, occupations that involve excessive walking or standing, or from changes in footwear.

Tender heel pad

This causes pain in the hind part of the heel on standing or walking. The tough fibrofatty pad beneath the prominent weight-bearing part of the calcaneus is tender to finger palpation. The area of tenderness is well localized and may be a result of simple contusion; in most cases there is no history of trauma and in these patients the tenderness may result from obesity combined with excessive walking in unsatisfactory footwear, or from mild inflammation of uncertain origin.

Treatment

Treatment is similar to that for plantar fasciitis and also for a painful foot pad. Rest, reducing the weight-bearing pressure by using a soft heel pad, or weight reduction in obese patients are usually sufficient. Local injections of corticosteroids are often helpful. Occasionally a moulded orthosis or heel cup is required. Surgery is rarely indicted (Lester and Buchanan 1984).

The painful foot (Table 22)

Anterior flat foot—dropped transverse arch
Injuries to the spring ligament
Plantar digital neuritis—Morton's metatarsalgia
Tarsal tunnel syndrome
Plantar warts and callosities
Hallux valgus (bunion)
Dorsal exostoses with bursae

Table 22 The painful foot

'Flat feet' (pes planus)

'Flat feet' rarely cause symptoms in the young. In adolescents they may be part of a general postural defect. At this age, especially in boys, spasmodic flat foot is caused by peroneo–extensor spasm. The foot is rigid and painful, and symptoms are worse on walking.

Pain usually results from unaccustomed physical activity, weight gain or from ill-fitting shoes, causing ligamentous strain. Physical findings include a loss of the medial longitudinal arch on weight bearing, with medial and plantar displacement of the navicular and talar head. In severe cases the calcaneus is everted (valgus). A callosity can develop over the prominent talar head. In chronic pes planus deformity, secondary changes in the tarsal bones, spring and plantar ligaments, and in Achilles tendon, are common.

Treatment

No treatment is required for the asymptomatic flat foot. Pain and impaired function are indications for treatment. A soft arch support often gives relief. Exercises to strengthen the intrinsic muscles and good-fitting shoes are often helpful. In patients with hyperpronated foot a moulded orthotic device is often necessary.

Pes cavus

This is characterized by a high medial arch and is usually a hereditary condition. Shoe modifications to accommodate the high instep and claw toes with cushioned arch supports are often helpful. Stretching exercises of the toe extensors may also be taught.

'Spring' ligament

The 'spring' or plantar calcaneonavicular ligament supports the talonavicular joint from below and may be strained, leading to deep-seated pain on weight bearing.

Metatarsalgia

Patients with anatomical abnormalities of the feet, such as claw toes or equinus deformity, are liable to develop pain under the metatarsal heads on walking. Metatarsalgia, or pain around the metatarsal heads, is not itself a diagnosis. Between the metatarsal heads and the skin lie the flexor tendons and their sheaths, and, in the case of the great toe, the sesamoids in the flexor brevis hallucis. Inflammatory joint disease can produce inflammation of the tendon sheaths and causes generalized pain.

Soft or firm metatarsal pads placed proximal to the metatarsal heads, weight reduction in obese patients, or strengthening of the intrinsic muscles by toe flexion exercises are all helpful in treatment. If symptoms persist a metatarsal osteotomy and/or resection of the metatarsal head are indicated.

Hallux valgus

Hallux valgus (bunion) is an example of an adventitious bursa resulting from prolonged pressure over a bony prominence as a result of valgus deformity of the hallux. It is frequently inflamed. Initially, treatment consists of padding to reduce pressure and advice on suitable footwear. If these measures prove unhelpful, surgical treatment may be necessary.

Tibialis anterior pain

Pain in the mid-foot may arise around the insertion of the tibialis anterior after strenuous walking. Pain on the medial side of the foot as the point of insertion of the tibialis posterior tendon on the navicular is more common, and is particularly severe if the patient has an accessory navicular bone.

Dorsal exostoses

Some patients develop a bony prominence on the dorsum of the foot at the joint between the navicular and the cuneiform bone. Excessive friction may lead to the formation of a bursa.

Entrapment syndromes in the foot

Tarsal tunnel syndrome

This syndrome occurs more frequently than is suggested by isolated reports in the literature (Goodchild *et al*. 1965). Compression of the posterior tibial nerve under the flexor retinaculum below the medial malleolus can lead to burning pain and paraesthesiae under the medial side of the longitudinal arch of the foot. Symptoms are often mistaken for other foot disorders. Pain may awaken the patient at night and relief may be obtained by walking about. There is often tenderness over the nerve, and there may be vasomotor changes and weakness of toe flexion. Electrodiagnostic studies confirm the diagnosis.

Treatment includes corticosteroid injections and orthotics. Neither is consistently effective. Surgical decompression gives excellent results in the majority.

Lateral popliteal nerve lesions

The lateral popliteal branch of the sciatic nerve lies superficially against the head and neck of the fibula, where it is susceptible to compression especially when sitting with legs crossed, kneeling or wearing knee pads. Anaesthesia and periods of unconsciousness present particular risks. The symptoms are pain and tingling in the lateral aspect of the leg and dorsum of the foot, associated with weakness of dorsiflexion and eversion of the foot. Wasting of tibialis anterior, peroneal, and extensor digitorum brevis can occur. The high-stepping gait is typical. Electromyography can confirm the diagnosis.

Morton's metatarsalgia (plantar digital neuritis)

Patients complain of a sharp pain in the forefoot shooting through to the toes, usually the third and fourth. There may be tingling or even numbness in the adjacent sides of the third and fourth toes. The pain is localized between the metatarsal heads and the transverse metatarsal compression may produce a palpable click. The condition is caused by interstitial fibrosis compressing the digital nerve just before it divides into its two terminal branches and leading to the development of a

neuroma. In the early stages, well-fitting shoes with or without a metatarsal bar, give relief. Excision of the thickened tissue effects a cure, but may lead to numbness. One can decompress the nerve by release of the transverse metatarsal ligament.

Management of patients with soft-tissue rheumatism (general comments)

It is worth repeating that one feature common to all of the soft-tissue rheumatism syndromes is a tendency to spontaneous remission. Many of the syndromes improve in weeks and few persist significantly beyond 6 months. Therefore a clear diagnosis allows the physician to reassure the patient that arthritis is not present and that the prognosis is good. However, failure to resolve is often due to further injury. Few of the conditions require complete rather than selective rest. Detailed treatment has been discussed throughout the chapter.

Tenosynovitis around the wrist may respond to immobilization in a light forearm splint, maintaining the wrist in a position of optimum function (10–15° extension), and compression of the median nerve may respond to night splinting alone. The acutely painful shoulder also benefits from rest, mobility being maintained by pendular exercises. Physiotherapy in the acute stages only exacerbates the condition. Rest is essential for the painful heel and foot. Raising the heel of the shoe reduces tension on the Achilles tendon, and Elastoplast strapping will help immobilize the ankle. If there is flattening of the medial arch of the foot, then physiotherapy and an arch support may be helpful.

The short-term use of non-steroidal anti-inflammatory drugs may be necessary. Their immediate use is beneficial in limiting the pain and swelling of soft-tissue trauma. Many soft-tissue lesions respond to a local injection with steroid and anaesthetic. Some experience in the various techniques is necessary before reasonable success can be obtained. The correct choice of needle size makes a great deal of difference to the amount of pain experienced, and the amount that is injected varies according to the type of lesion.

The choice of steroid and local anaesthetic varies from user to user but, in practice, preparations differ significantly in their duration of action, and for most purposes the shorter-acting hydrocortisone acetate is suitable. The longer-acting steroids, methyl prednisolone acetate and triamcinolone hexacetonide, may cause skin atrophy when used for superficial lesions such as tennis elbow. After the injection there may be an increase in symptoms for up to 48 h and patients should be warned of this possibility. About 80 per cent of patients gain symptomatic benefit from these injections. It is important not to inject the tendoachilles itself, as this may predispose to rupture. In spite of decades of use of ultrasound in treating a wide spectrum of musculoskeletal disorders, its effectiveness remains unproven. Persistent lesions may require further injections but if conservative measures fail, surgery may be required.

Conclusion

About seven people in every hundred who visit their general medical practitioner seek help with symptoms arising from the soft tissues. The loss of work resulting from these symptoms is of the order of 11 million days annually. However, most soft-tissue lesions are eminently manageable, as discussed above.

5.15 Osteoarthritis

Michael Doherty and Adrian Jones and T. E. Cawston

Introduction

Osteoarthritis is the commonest condition to affect the joints of man. As such it is a major cause of locomotor pain, the single most important rheumatological cause of disability and handicap, and an important health care challenge with major resource implications (Steven 1992; Yelin 1992; Badley *et al*. 1994). Indeed it has been estimated that 15 per cent of the United Kingdom population greater than 55 years of age have symptomatic osteoarthritis of the knee (Fig. 1). Osteoarthritis has, however, only recently become a significant focus of clinical interest and research. Previously considered a boring 'wear and tear', 'degenerative' disease that must be accepted as the inevitable consequence of trauma and ageing, osteoarthritis is increasingly viewed as a dynamic, essentially reparative process with potential for health intervention and prevention.

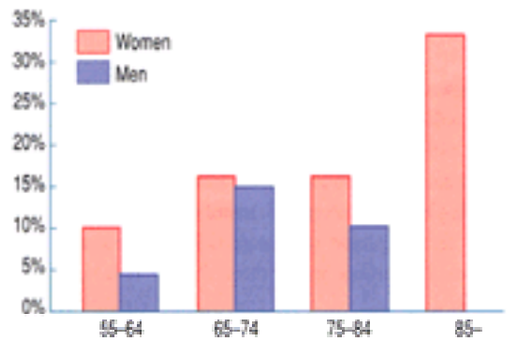

Fig. 1 Prevalence of symptomatic knee osteoarthritis by age group and gender in a United Kingdom community population. Derived from McAlindon *et al*. (McAlindon *et al*. 1992).

Historical perspective

At the turn of the century, pathologists and radiologists differentiated two main categories of chronic arthritis—atrophic and hypertrophic. The former was characterized by synovial inflammation with erosion or atrophy of cartilage and bone; it encompassed several disease entities including rheumatoid arthritis. Hypertrophic arthritis, by contrast, was characterized by more focal cartilage loss, minimal evidence of inflammation, and by hypertrophy of adjacent bone and soft tissues; this group became synonymous with osteoarthritis (Goldthwaite 1904) (Fig. 2). Since there were recognized associations with ageing and previous joint trauma, this led to ready acceptance of the alternative term 'degenerative joint disease'. With the major rheumatological interest focusing on inflammatory arthropathies, osteoarthritis was often used as a 'non-inflammatory' control disease, and even as a surrogate for normal joint tissue, in clinical and laboratory research. The term 'osteoarthrosis' was often used, therefore, to emphasize absence of overt inflammation.

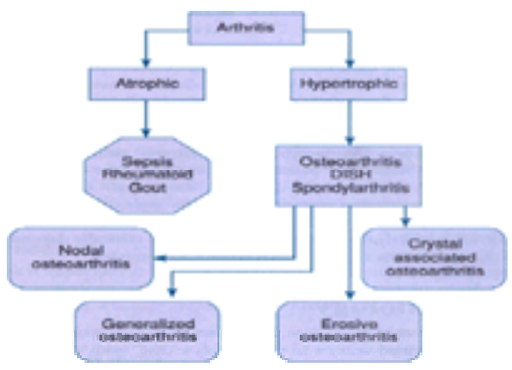

Fig. 2 The increasing differentiation of arthritis subtypes.

Advances in cartilage biochemistry and the recognition of calcium crystal-associated disease subsets proved important factors in renewing interest in this condition. Although clinical and histological inflammation is not as florid as in rheumatoid arthritis or seronegative spondylarthropathies, it is an undoubted component in many cases. Thus the term osteoarthritis is now generally preferred.

Definition of osteoarthritis

Concepts of osteoarthritis are still changing and there is no universal agreement on its definition. A current working definition of osteoarthritis is:

a condition of synovial joints characterized by cartilage loss (chondropathy) and evidence of accompanying periarticular bone response.

It is noteworthy that chondropathy may occur without hypertrophic bone response (e.g. polychondritis, rheumatoid arthritis), and periarticular new bone may develop without chondropathy (e.g. 'traction' spurs); it is only when the two occur together in synovial joints that the term osteoarthritis is appropriate.

The drawbacks of this working definition include:

1. exclusion of joints with early (initial) change—the very joints we need to study in order to elucidate aetiopathogenic processes;
2. emphasis on cartilage and bone—even though all other joint components (synovium, capsule, entheses, muscle) demonstrate change (Fig. 3);

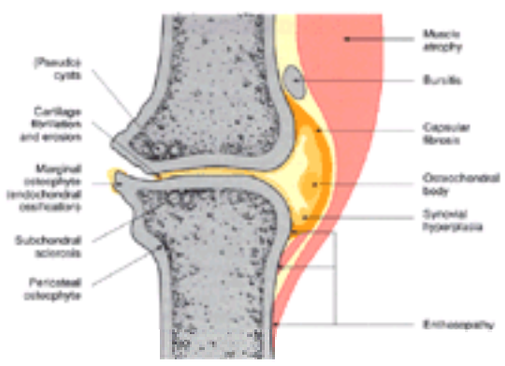

Fig. 3 Joint tissues affected in osteoarthritis. Redrawing from Doherty (ed.) *Color Atlas and Text of Osteoarthritis*. Wolfe, London. (Doherty).

3. structural rather than physiological emphasis—with no consideration of biological, symptomatic, and functional consequences.

Nevertheless, given these caveats, such a definition is a practicable starting point for examination of existing clinical, epidemiological, and experimental data. The American College of Rheumatology has devised criteria for classification of symptomatic osteoarthritis of knee (Altman *et al*. 1986) (Fig. 4), hand (Altman *et al*. 1990), and hip (Altman *et al*. 1991) that incorporate clinical, laboratory, and/or radiological features. Although these criteria will distinguish osteoarthritis from other painful joint conditions (the basis of their development) there remain questions about their use in other settings. In population studies they may be insensitive and do not detect asymptomatic disease. Many questions thus remain to be resolved. It is likely that future definitions will be critically dependent on the populations and use for which they are intended.

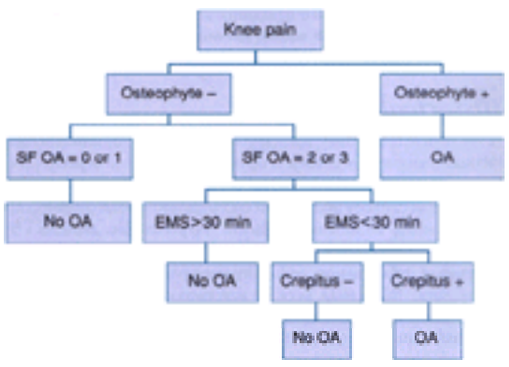

Fig. 4 Decision tree based classification of knee osteoarthritis according to the American College of Rheumatology classification criteria. Derived from Altman *et al*. (Altman *et al*. 1986).

Epidemiology

Current epidemiological data in osteoarthritis is beset by a lack of generally accepted criteria to distinguish a 'case' from a 'non-case'. Histopathological changes are obviously not appropriate for living subjects, and most surveys rely on radiographic features for definition and assessment of severity. Of the various radiographic criteria, the most widely employed are those of Kellgren and Lawrence (Kellgren and Lawrence 1957). Although differing in detail by joint site and by publication, these grade osteoarthritis into four categories depending on the presence and degree of various features (Fig. 5). Although these features purport to measure various pathological changes occurring in cartilage and subchondral bone (Table 1), there are problems with both validity and reproducibility. Particular problems include:

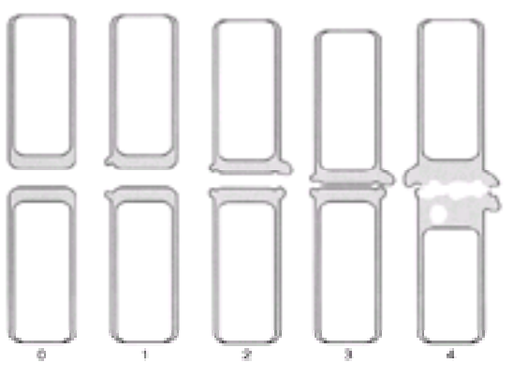

Fig. 5 Basis of Kellgren and Lawrence grading scheme. Grade 0, normal; Grade 1, minimal osteophyte, normal joint space; Grade 2, definite osteophyte, possible joint space narrowing; Grade 3, definite osteophyte and joint space narrowing; Grade 4, definite osteophyte and joint space narrowing with sclerosis and abnormal joint contour.

Pathological change	Radiographic abnormality
Cartilage fibrillation, erosion	Decrease in interosseous distance (localized)
Subchondral new bone formation	Sclerosis
New cartilage formation and endochondral ossification	Osteophyte
Fibrous-walled pseudocysts resulting from fluid intrusion or myxoid degeneration	Subchondral cysts
Trabecular compression	Bone collapse/attrition
Fragmentation of osteochondral surface; cartilage and bone metaphasis in synovium	Osseous ('loose') bodies

Table 1 Radiographical–pathological correlates in osteoarthritis

1. lack of distinction between isolated and chondropathy-associated osteophyte, the aetiological factors for which may vary;
2. the ignoring of clinical status, symptoms, and function;
3. inappropriate assumptions about disease progression in grading systems which combine several features, such as that of Kellgren and Lawrence.

Although attempts to define osteoarthritis clinically have been made (Claessens *et al*. 1990; Hart *et al*. 1991; Altman 1991) the lack of a suitable gold standard, poor correlation with currently accepted surrogate 'gold standards' (e.g. radiology), and poor reproducibility have hampered their widespread adoption.

Such problems in the definition of osteoarthritis, radiograph interpretation, and clinical measurement make the epidemiology of osteoarthritis difficult to analyse (Peyron 1979; Spector and Cooper 1993) but several broad conclusions may now be drawn.

Descriptive studies

Autopsy studies suggest that the majority of subjects over age 65 have evidence of osteoarthritis in at least one joint site at the time of death. Prevalence estimates from such studies tend to be higher than those from radiographic surveys, perhaps because the whole joint surface is available for study (Rogers *et al*. 1990).

Radiographic studies also report high prevalence in the middle-aged and elderly. This prevalence varies according to joint site and age, giving different patterns of distribution at different ages. For example hand interphalangeal joints and first metatarsophalangeal joints are affected commonly and at a relatively young age, whereas glenohumeral and shoulder joints are affected less commonly and principally in the elderly. From available large radiographic studies (Mikkelsen *et al*. 1970; Lawrence 1977; Felson 1988; Van Saase *et al*. 1989) the following generalizations can be made.

Age

This is a major determinant of prevalence at all important sites including hands, knees, and hips. Prevalence is low under age 45 years. Polyarticular osteoarthritis (³5 sites involved) is also rare in those aged less than 45 years. Prevalence increases up to age 65, when there is involvement of at least one joint group in at least 50 per cent of the population. Continuing increase in prevalence in those over age 65 is less clear cut, and indeed a plateauing out of prevalence in the very old has been suggested (Bagge *et al*. 1992) (Fig. 6).

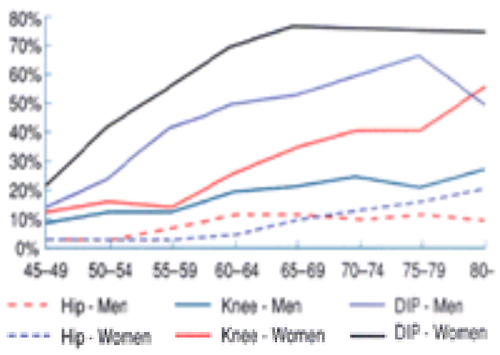

Fig. 6 Prevalence of radiological osteoarthritis by age group and gender in a Netherlands community population. Derived from van Saase *et al*. (van Saase *et al*. 1989).

Gender

This is important at some, but by no means all, joint sites. Although there is little or no gender difference in the prevalence of mild osteoarthritis, a female preponderance becomes more apparent:

1. for severe grades of osteoarthritis;
2. in older age groups;
3. for osteoarthritis of the hands and knees.

There is also a polyarticular form of hand osteoarthritis that has a predilection for perimenopausal women—so-called nodal generalized osteoarthritis. This is discussed further below.

Ethnic group

Given the difficulties of representative sampling and reproducible assessments, comparison between populations shows surprising similarity in age-specific prevalence by joint site (Van Saase *et al*. 1989). Possible exceptions are:

1. hip osteoarthritis, which shows substantially lower prevalence among black and Oriental populations than among whites;
2. polyarticular hand osteoarthritis, which appears to be less common in African and Malaysian populations.

Geographic variation—'endemic osteoarthritis'

Several forms of disabling polyarticular osteoarthritis occur with high frequency in certain geographical locations (Sokoloff 1985). The best described are Kashin-Beck disease (south-eastern Siberia, northern China, North Korea) and Mselini disease (limited to the Zulu and Tonga tribes of south-east Africa). Other forms of endemic osteoarthritis occur in Malnad and elsewhere in India. These conditions share in common:

1. onset during the first or second decade;
2. variable growth restriction;
3. characteristics of acquired rather than inherited disease;
4. involvement of impoverished rural communities.

The conditions radiographically most closely resemble those of spondyloepiphyseal dysplasia, and histologically show chondronecrosis as a likely initial event (Fig. 7). The cause(s) of endemic osteoarthritis remain unknown, though mycotoxins elaborated by moulds on local grains and abnormalities of trace elements (e.g. selenium) in soil or water have been investigated.

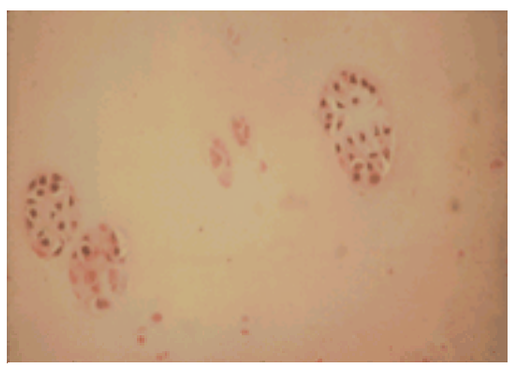

Fig. 7 Radiograph of coronal slab section of femoral head in Mselini hip disease. From Sokoloff in *Color Atlas and Text of Osteoarthritis* (ed. M Doherty). Wolfe, London (Sokoloff).

Analytical studies

Individual risk factors for osteoarthritis may conveniently be viewed as:

1. those influencing or marking a generalized predisposition to the condition;
2. those resulting in abnormal biomechanical loading at specific sites (Fig. 8).

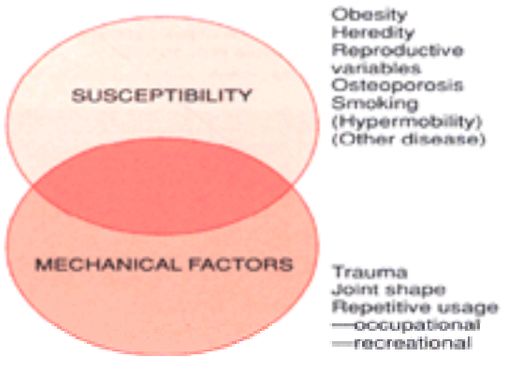

Fig. 8 Susceptibility to osteoarthritis: interaction between generalized and local factors.

Generalized susceptibility

Obesity

This is closely associated with knee osteoarthritis (odds ratio 4.5 for men, 9.0 for women, for those 50 per cent above ideal body weight compared to those at ideal body weight) but interestingly not at the hip (Lawrence *et al*. 1990; Felson *et al*. 1992). At the knee, obesity precedes rather than follows knee osteoarthritis and indeed weight loss may prevent the development of knee osteoarthritis (Felson *et al*. 1992) (Fig. 9). It is associated with radiographic change irrespective of whether symptoms are present or not, arguing against obesity resulting from more sedentary lifestyle of those with painful knees. It is also true, however, that obesity increases the risk of knee pain for a given degree of structural change. The mechanism relating obesity and osteoarthritis remains speculative although the apparent lack of association with hip osteoarthritis suggests metabolic or systemic factors rather than a purely mechanical explanation.

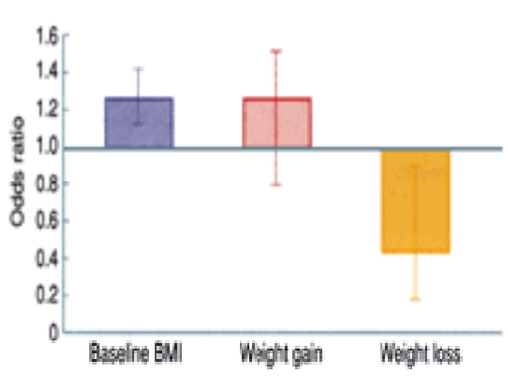

Fig. 9 Risk of symptomatic knee osteoarthritis per 2 units of body mass index (BMI) expressed as odds ratio and 95 per cent confidence interval. Derived from Felson *et al*. (Felson *et al*. 1992).

Genetic factors

A strong familial tendency is recognized for nodal generalized osteoarthritis, a polyarticular form of osteoarthritis occurring mainly in women of perimenopausal age. This is confirmed by family and twin studies (Lawrence 1977). Heberden's nodes appear to be inherited independently as an autosomal dominant trait with greater penetrance in women (Stecher 1953). The genetics and pathogenic mechanism remains unknown but associations have been reported with HLA A1, B8 haplotypes and with the a-1-antitrypsin MZ phenotype (Pattrick *et al*. 1989a). In addition, an increased incidence of IgG rheumatoid factors (Hopkinson *et al*. 1992) and a high frequency of immune complexes in cartilage and synovium of hips removed from nodal generalized osteoarthritis compared to pauciarticular osteoarthritis patients (Cooke 1985) has led to speculation of an autoimmune aetiology (Doherty *et al*. 1990). It is hypothesized that an unidentified 'single-shot' insult occurs in a genetically predisposed individual. This triggers an immunological response, leading to polyarticular damage and initiation of the osteoarthritis process (Fig. 10). However, because it is a single temporal insult the repair process wins through, 'compensates', and results in a good outcome, other than for leaving the structurally abnormal

joints that we recognize as 'nodal generalized osteoarthritis' (Doherty *et al*. 1990). These findings have not yet been confirmed.

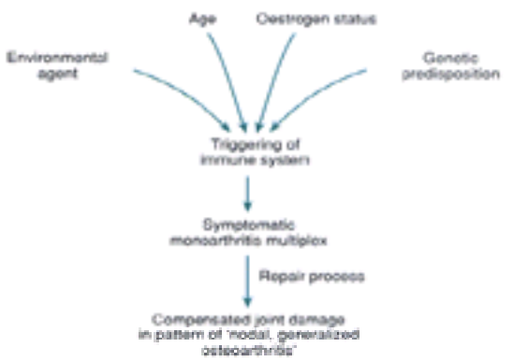

Fig. 10 Hypothesis explaining nodal generalized osteoarthritis as an 'autoimmune' condition.

An association with the COL2A1 gene has been demonstrated for hereditary forms of premature polyarticular osteoarthritis with mild dysplasia (Knowlton *et al*. 1990). It has also been found in some, but not all, forms of hereditary osteo-opthalmoarthropathy (Stickler's syndrome), an hereditary disease with variable ocular and midfacial abnormalities and a premature osteoarthritis-like syndrome (Williams and Jimenez 1993). Similar associations of type II collagen defects with nodal generalized and sporadic osteoarthritis have not been found.

Reproductive variables

Polyarticular osteoarthritis has a strong female predominance, a frequent onset around the menopause, and reported associations with previous hysterectomy, gynaecological surgery, and possible alterations of sex hormone binding globulin. This has led to the suggestion that hormonal factors are important in this subgroup (Spector and Campion 1989). Manipulation of sex hormones in animal models of 'osteoarthritis' and identification of oestrogen receptors on chondrocytes lend some support to a role for hormonal modulation. Similar treatment in humans has been unsuccessful in established osteoarthritis (Kellgren and Moore 1952).

Bone density

A negative association is reported between osteoporosis and osteoarthritis at certain sites (Lane and Nevitt 1994). The strongest evidence relates to the hip, where several studies support a negative correlation between hip osteoarthritis and risk of femoral neck fracture. In patients with polyarticular osteoarthritis, studies of bone density have produced conflicting results, with obesity a frequent confounding factor. One explanation for this negative relationship, if true, is that weak bone may absorb excessive impact loading and thus protect joint cartilage from damage and subsequent osteoarthritis. Certainly, in the converse rare situation of osteopetrosis, where the skeleton is diffusely sclerotic, a high incidence of premature polyarticular osteoarthritis is reported.

Cigarette smoking

A protective influence of smoking on knee osteoarthritis, after correction for possible confounding factors, is reported from the Framingham study (Felson 1988). Other studies have produced both confirmatory and contradictory results and the issue is not yet resolved. The observation is intriguing, however, but the mechanism is unclear. Smoking is a risk factor for osteoporosis, has antioestrogenic properties, and has many effects on cell function. It is unclear which, if any, of these is important.

Other suggested factors

Less definite associations are reported with diabetes, hypertension, and hyperuricaemia, which are independent of obesity. Clearer associations with acromegaly and haemochromatosis are evident (Jones *et al*. 1992). An increased frequency of osteoarthritis in subjects with generalized hypermobility has also been suggested, due either to associated connective tissue abnormality or joint trauma, but rigorous epidemiological support for this is still required.

Local mechanical factors

Trauma

Major direct injury is accepted as a predisposing cause of osteoarthritis (Wright 1990). Intra-articular fracture affecting the articular surface is probably associated with osteoarthritis although much of the evidence is retrospective nd uncontrolled. Major injury, particularly fracture, may also alter mechanical loading and predispose to osteoarthritis at distant sites, as with fractures of the femoral shaft (hip osteoarthritis) (Fig. 11), scaphoid (wrist osteoarthritis), tibia (ankle osteoarthritis), or humerus (shoulder osteoarthritis). Although trauma may be a predisposing factor that determines the site of osteoarthritis, mechanical insult alone is usually an insufficient cause for its development. For example following total meniscectomy not everyone develops knee osteoarthritis. Furthermore, the increased frequency of postmeniscectomy osteoarthritis in subjects with a generalized predisposition to osteoarthritis (i.e. those with distal interphalangeal joint osteoarthritis) compared to those with no such predisposition supports interaction between generalized (constitutional) and local (mechanical) factors (Doherty *et al*. 1983).

Fig. 11 Asymmetric hip osteoarthritis following previous trauma on the right side in a patient (Ledingham *et al*. 1992).

Joint shape

Abnormalities of articular contour, that may lead to abnormal load transmission across the joint, have particularly been linked with predisposition to osteoarthritis at the hip and knee. It is well established that childhood hip disorders such as Perthes' disease, slipped capital epiphysis, and congenital dislocation lead to premature hip osteoarthritis. It has been suggested that lesser degrees of acetabular dysplasia account for a proportion of hip osteoarthritis amongst younger subjects, though the impact of such mild developmental abnormality in causing later hip osteoarthritis is questionable, with a recent study suggesting it is of little importance (Croft *et al*. 1991). Cooke has suggested that mild, often unrecognized, dysplasia of the femoral condyles may similarly predispose to knee osteoarthritis via mechanical effects (Cooke 1985). Abnormal contour following intra-articular fractures may also contribute to premature osteoarthritis.

Occupational and recreational activities

Data in this area were conflicting but a consensus is now emerging (Cooper 1995). For example repetitive impact loading and trauma have been implicated in reported increased frequencies of osteoarthritis in miners (knees, spine), cotton workers (distal interphalangeal joints), and pneumatic drillers (elbows), though conversely parachutists, ballet dancers, and runners show no obvious increased risk of osteoarthritis. It may be that at some sites trauma is more important in selecting the site and severity of the condition than in determining whether osteoarthritis will develop or not. For example examination of patterns of osteoarthritis in the hand suggests that usage may influence distribution of osteoarthritis in the hand (Hadler *et al*. 1977), though evidence for an increase in frequency from repetitive usage is lacking.

At the hip, several studies have now shown a convincing increased incidence of osteoarthritis in farmers. The mechanisms underlying this association are unclear but repetitive trauma is suggested. At the knee there is increasing evidence that repetitive knee bending may be harmful (Felson *et al*. 1991). This association has only been clearly demonstrated in men.

Clinical features

Symptoms and impact of osteoarthritis

The principal clinical features of osteoarthritis are symptoms (pain, stiffness), functional impairment, and signs (primarily anatomical change). Though interrelated, there is often marked discordance between these three.

Symptoms

Although pain is the chief complaint its origin is not at all clear. Hyaline cartilage is aneural and this means that metabolic or structural alteration in this tissue is unlikely to be directly perceived as painful. Several other mechanisms of symptom production have been suggested (Fig. 12). These include:

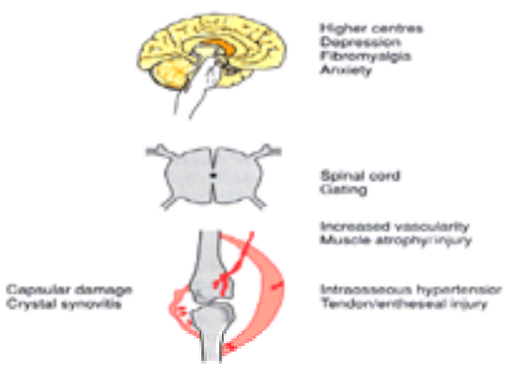

Fig. 12 Potential sites of pain perception and/or modification in osteoarthritis. Redrawn from Jones and Doherty (1992).

1. stimulation of capsular pain fibres and mechanoreceptors by intra-articular hypertension consequent upon synovial hypertrophy, increased fluid production, and decreased joint compliance;
2. inflammatory mediators stimulating pain fibres in the synovium and capsule;
3. stimulation of periosteal nerve fibres by intraosseous hypertension accompanying osteoarthritis;
4. perception of subchondral microfractures, painful enthesopathy, and bursitis that accompany structural alteration, muscle weakness, and altered usage;
5. maladaptive changes in the spinal cord and brain leading to persistent pain perception.

It has been suggested that these different mechanisms may produce different pain characteristics with, for example, pain predominantly:

1. on usage—being due to mechanical or enthesopathic problems;
2. at rest—being inflammatory in origin;
3. at night—being due to intraosseous hypertension.

The last of these may be a particularly poor prognostic factor and indicates severe damage. Pain in osteoarthritis may, however, be a transient feature and can be absent in spite of severe joint damage (Fig. 13). Correlation between pain and radiographic change varies according to site. It is best at the hip and then knee, with the poorest correlation occurring in the hands and spinal apophyseal joints. Joints with more severe radiographic change are more likely to be symptomatic than those with mild change (Fig. 14) but irrespective of structural change, pain is more common in women (Lawrence *et al*. 1990). As with any locomotor or other pain, the subjective magnitude and perception of pain may be greatly influenced by factors such as personality, anxiety, and/or depression. Indeed, several recent studies have demonstrated that these psychological factors may be much more important in determining symptomatic outcome. One study has even gone further and suggested that factors associated with radiographic outcome may be independent of and distinct from those associated with knee pain and disability (Davis *et al*. 1992). This has led at least one author to question whether we should in fact ignore the entity we try to describe as osteoarthritis and instead concentrate on knee pain (Hadler 1992).

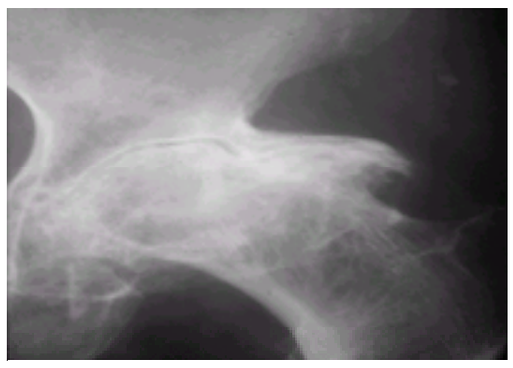

Fig. 13 Radiograph of an asymptomatic individual with severe radiographic osteoarthritis change.

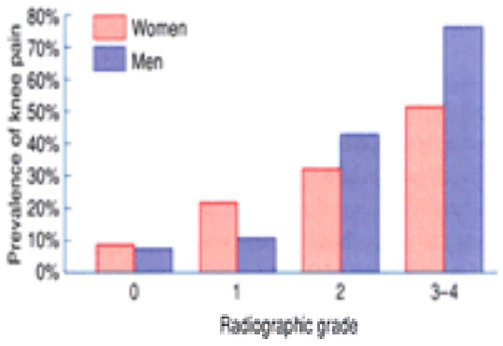

Fig. 14 Prevalence of knee pain by radiographic grade and gender in a United States community population. Derived from Davis *et al*. (Davis *et al*. 1992).

Stiffness is the other chief complaint. This is often described as 'gelling' of the joint after inactivity with difficulty in initiating movement. Prolonged morning or inactivity stiffness, often taken as a reflection of inflammation, is uncommon but may occur, particularly in patients with chronic pyrophosphate arthropathy.

Some patients may complain of joint swelling and deformity (particularly of hands), and coarse crepitus, even in the absence of other symptoms.

Functional impairment

Disability results from reduced range and control of movement and from pain. Handicap, of course, will vary according to individual patient requirements and aspirations. The pain and functional consequences of osteoarthritis are responsible for the huge burden of morbidity in the community. Severe knee and (less commonly) hip disease result in a massive health care problem to a generally older and otherwise fitter population. In addition to morbidity, cumulative mortality rates among subjects aged 55 to 74 in the National Health and Nutrition Examination Survey (NHANES-I) were significantly greater (relative risk 1.1) for women but not men with knee osteoarthritis (Lawrence *et al*. 1990). An increased mortality has also been associated with knee osteoarthritis in Sweden (Danielsson and Hernborg 1970).

Signs

Several features may occur in any combination and primarily reflect altered joint structure. These include:

1. crepitus, presumed due to an irregular articular surface;
2. bony enlargement, due to osteophyte and remodelling;
3. deformity;
4. instability;
5. restricted movement;
6. stress pain.

Varying degrees of synovitis (warmth, effusion, synovial thickening) may accompany joint line tenderness. Muscle weakness and wasting may also be apparent. Periarticular sources of pain, demonstrated by point tenderness away from the joint line and by stress testing, are commonly identified at the knee and hip.

Osteoarthritis 'subsets'

Since osteoarthritis is a process that may be triggered by diverse constitutional and environmental factors, a wide spectrum of clinical expression and outcome is to be expected. Attempts to define and classify osteoarthritis as a single disease entity have not been entirely successful and attempts have been made to separate osteoarthritis into more homogeneous groupings or 'subsets' so as better to define aetiological factors and prognosis.

Osteoarthritis was initially classified as primary (no cause identified) or secondary (an obvious cause identified, such as trauma or dysplasia). Indeed such a distinction is still retained in the American College of Rheumatology criteria (Altman *et al*. 1991). Such artificial separation has often proved unsatisfactory due to:

1. frequent lack of an identifiable cause, resulting in a large heterogeneous primary group;
2. overlap between subsets, as shown for example by the influence of predisposition to 'primary' generalized osteoarthritis in determining development of postmeniscectomy 'secondary' osteoarthritis (Doherty *et al*. 1983).

In addition to identifiable predisposing factors, the following more objective features have therefore often been used as a further basis of subset differentiation:

1. joint site involved (hip, knee, hand);
2. site within a joint (medial tibiofemoral, lateral tibiofemoral, patellofemoral);
3. number of joints involved (one, few, many);
4. presence of associated crystal deposition;
5. presence of marked clinical inflammation;
6. radiographic bone response (atrophic, hypertrophic).

A number of 'subsets' have emerged which differ in a number of such characteristics. It is important to note, however, that sharp distinction between subsets does not exist. Many of the above characteristics represent different aspects of the osteoarthritis process (the balance between damage and repair), and may dominate the clinical picture at just one phase in the evolution of the condition. One 'subset' may thus evolve into another, and different 'subsets' may exist at different sites within the same individual. Possibly the most important distinction is simply by site and number of joints involved; predisposing factors are increasingly being associated with specific joint sites, or to polyarticular as opposed to pauciarticular involvement. It follows that knowledge concerning pathogenesis, risk factors, or treatment success of osteoarthritis cannot necessarily be extrapolated from one site to another.

Nodal generalized osteoarthritis

This is perhaps the best recognized subset, characterized by:

1. polyarticular finger interphalangeal involvement;
2. Heberden's and Bouchard's nodes;
3. female preponderance;
4. peak onset around the menopause;
5. good functional outcome for hands;
6. predisposition to osteoarthritis of the knee, hip, and spine;
7. marked familial predisposition.

The typical patient is a woman in her forties or fifties who develops discomfort followed by swelling of a single finger interphalangeal joint. A few months later another interphalangeal joint becomes painful, then another producing a 'stuttering' onset polyarthritis of distal and proximal interphalangeal joints ('monoarthritis multiplex'). Affected interphalangeal joints may feel very stiff, be tender, and show tight posterolateral swelling with overlying erythema. Aspiration of such swellings may reveal viscous, clear, hyaluronate-rich 'jelly': these cysts represent mucoid transformation of periarticular fibroadipose tissue and may communicate with the joint. Each interphalangeal joint tends to go through a symptomatic phase while swelling and deformity become established, resulting in perhaps 1 to 3 years of episodic discomfort and stiffness. In almost all cases symptoms then subside, leaving the patient with typical posterolateral firm Heberden's (distal interphalangeal joint) and

Bouchard's (proximal interphalangeal joint) nodes, characteristic lateral deviations of interphalangeal joints (Fig. 15), and radiographic evidence of osteoarthritis (Fig. 16). In addition to finger interphalangeal joints, the first carpometacarpal, metacarpophalangeal, and interphalangeal joints of the thumb are commonly affected: other joint involvement in the hand and wrist, however, is usually restricted to the index and middle metacarpophalangeal, scaphotrapezoid, and pisiform-triquetral articulations. The prognosis seems to be good.

Fig. 15 Typical appearance of multiple Heberden's and Bouchard's nodes in nodal generalized osteoarthritis.

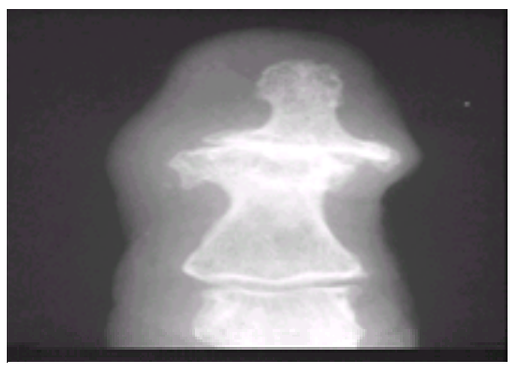

Fig. 16 Radiograph of distal interphalangeal joint showing many of the typical radiographic features of osteoarthritis (joint space narrowing, sclerosis, osteophyte).

Nodal generalized hand osteoarthritis is associated with an increased frequency of osteoarthritis at other sites, particularly knees, hips, first metatarsophalangeal joints, and cervical and lumbar apophyseal joints (Kellgren and Moore 1957). This concept of 'generalized osteoarthritis', with hand involvement as the marker for predisposition, was first described by Haygarth in 1805 and is supported by several studies (Roh *et al*. 1973; Acheson and Collart 1975; Solomon 1983). One such survey (Acheson and Collart 1975) suggests division into two groups (although such distinction is not supported by others):

1. nodal generalized osteoarthritis;
    a. nodes
    b. distal interphalangeal joint involved more than proximal interphalangeal joint
    c. marked female preponderance
    d. familial aggregation
2. non-nodal generalized osteoarthritis;
    a. proximal interphalangeal joint involved more than distal interphalangeal joint
    b. more equal sex distribution.

The inevitable problem that arises is that one or just a few Heberden's nodes and limited interphalangeal joint osteoarthritis are common, often asymptomatic findings in the elderly, and when should the title 'nodal generalized osteoarthritis' be applied? Although criteria for this have not been defined, some studies suggest that involvement of even a single interphalangeal joint may be important (Croft *et al*. 1992). Polyarticular hand osteoarthritis has been reported to be associated with certain intra-articular patterns of large joint osteoarthritis, for example concentric as opposed to superior pole osteoarthritis of the hip (Marks *et al*. 1979). This evidence supports the notion of nodal generalized osteoarthritis as a distinct condition.

Erosive ('inflammatory') osteoarthritis

This relatively uncommon condition is characterized by the following:

1. hand interphalangeal joint involvement;
2. often florid inflammatory component;
3. radiographic subchondral erosive change;
4. tendency to interphalangeal joint ankylosis.

The condition clinically resembles nodal generalized osteoarthritis in beginning as an additive polyarthritis of finger joints (Ehlich 1972). Inflammatory symptoms and signs, however, are often marked though episodic. Unlike nodal generalized osteoarthritis, proximal and distal interphalangeal joints are equally involved and, less frequently, index and middle metacarpophalangeal joints. Interphalangeal joint instability, which is rare in nodal generalized osteoarthritis, is common and, since there is also occasional spontaneous ankylosis of one or a few interphalangeal joints, the prognosis for hand function is less favourable than nodal generalized osteoarthritis (Pattrick *et al*. 1989b). The principal hallmark of this condition is the presence of subchondral erosive change (Fig. 17) which may lead to a 'gull's wing' appearance as remodelling occurs (Fig. 18). Early, florid subchondral erosive change is easily recognized, but lesser degrees of erosion, particularly in established cases, may prove difficult to distinguish from cysts and subchondral bony change of nodal generalized osteoarthritis. Indeed, although described as a separate clinical subset, recent data has questioned whether this is really the case or whether erosive osteoarthritis is merely an extreme end of the spectrum of nodal osteoarthritis (Cobby *et al*. 1990) although there is no evidence for predisposition to generalized osteoarthritis in this subset.

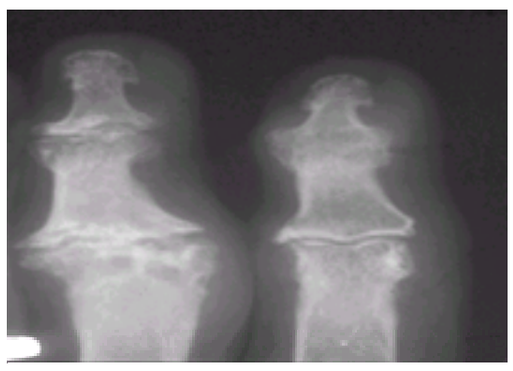

Fig. 17 Subchondral erosive change in erosive osteoarthritis.

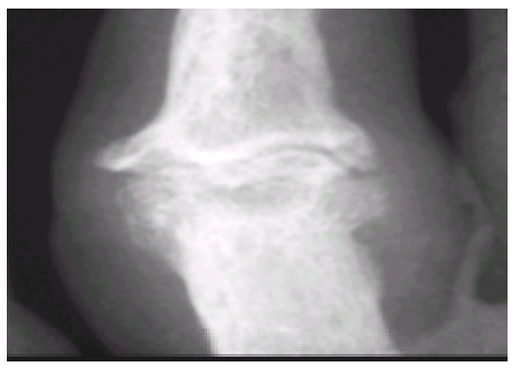

Fig. 18 'Gull's wing' deformity in erosive osteoarthritis.

Microscopically the synovium is infiltrated with lymphocytes and monocytes, and pannus may be seen. The nature of this inflammatory, destructive condition is unknown although it is of interest that similar hand changes may occur in some patients with Sjögren's syndrome. Of note, perhaps, is that 15 per cent of 170 patients presenting with Sjögren's syndrome and erosive osteoarthritis subsequently developed seropositive rheumatoid arthritis (Ehlich 1975).

Large joint osteoarthritis

Knee osteoarthritis

The knee is a commonly affected site. Involvement is usually bilateral, particularly in women and in the elderly. Although osteoarthritis may affect the knee as a mono- or pauciarticular problem, this site shows strong association with hand osteoarthritis (Kellgren and Moore 1952; Acheson and Collart 1975; Cushnaghan and Dieppe 1991). Population data demonstrates most frequent involvement of the medial tibiofemoral compartment (Fig. 19), severe bone and cartilage attrition at this site giving rise to the characteristic varus deformity (Fig. 20). The patellofemoral compartment, however, is often omitted from large studies, but when included it appears to be equally if not more commonly involved than the medial compartment, both symptomatically and radiographically (McAlindon *et al*. 1992) (Fig. 21).

Fig. 19 Predominant medial compartment osteoarthritis at the knee (standing anterioposterior radiograph).

Fig. 20 Typical varus deformity of knee osteoarthritis.

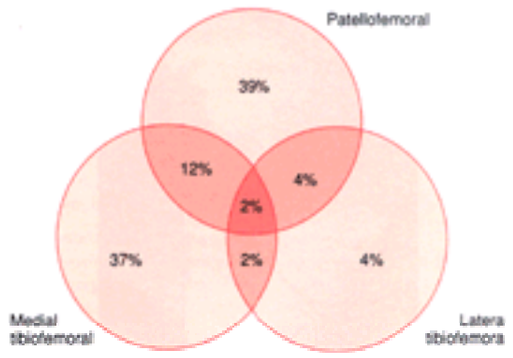

Fig. 21 Sites of radiographic involvement of knee osteoarthritis in patients with radiographic change in a community survey in the United Kingdom. Derived from McAlindon *et al*. (McAlindon *et al*. 1992).

Risk factors for development of knee osteoarthritis include previous trauma (e.g. meniscectomy), obesity (Felson 1988), generalized osteoarthritis, distal femoral dysplasia (Cooke 1985), and female gender and repetitive occupational knee bending (Felson *et al*. 1991). Smoking may be protective at this site (Felson 1988). Prognosis is discussed further below.

Recently, differing patterns of risk factors have been described in different compartments within the same joint. For example in some studies tibiofemoral disease has been more strongly linked to previous trauma and male gender whereas patellofemoral disease is more commonly symmetrical and occurs in women.

Hip osteoarthritis

Study of this joint has been particularly bedevilled by diverse classification systems which have reflected the differing interests of both orthopaedics and rheumatology at this site. Although hip involvement may occur in the context of nodal generalized osteoarthritis or involvement at other large joint sites, subdivision is usually made primarily on the basis of local radiographic patterns. Two groups have particularly been emphasized:

Superior pole osteoarthritis

The commonest pattern, this is characterized by focal cartilage loss in the superior part of the joint (Fig. 22). Osteophyte formation is most prominent at the lateral acetabular and medial femoral margins, often in combination with thickening (buttressing) of the cortex of the medial femoral neck (Fig. 23). Subchondral sclerosis and cyst formation on both sides of the narrowed joint may be marked. Originally it was suggested that this pattern is:

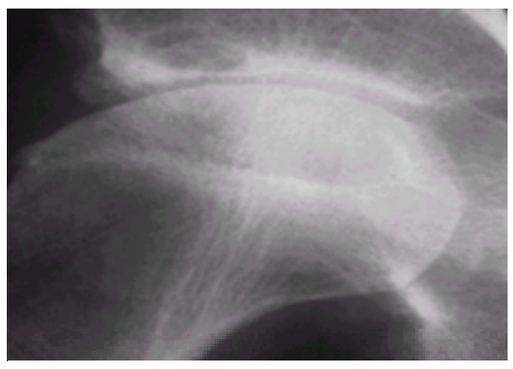

Fig. 22 Superior pole pattern of hip osteoarthritis (early) showing localized reduction in interosseous distance with focal sclerosis at the superior part of the joint, minor femoral osteophyte, and acetabular roof cyst.

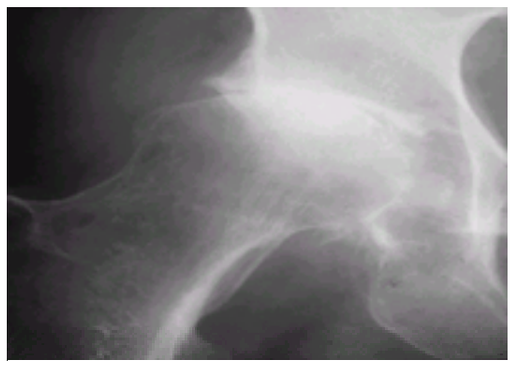

Fig. 23 Superior pole osteoarthritis (late) showing superolateral femoral head migration, bone attrition, and 'buttressing' medial periosteal osteophyte of the femoral neck.

1. more common in men;
2. mainly unilateral at presentation;
3. likely to progress, with superolateral (Fig. 13) or superomedial femoral migration;
4. commonly secondary to local structural abnormality.

Recent studies have questioned whether there is often an underlying structural abnormality (Croft *et al*. 1991). In a hospital based population, progression has been confirmed to be more likely than in other patterns (Ledingham *et al*. 1993).

Central (medial) osteoarthritis

This less common pattern shows more central joint space loss, with less prominent femoral neck buttressing. It is suggested that this pattern is:

1. more common in women;
2. commonly bilateral at presentation;
3. the pattern that particularly associates with nodal generalized osteoarthritis;
4. less likely to progress (with axial or medial migration) (Fig. 24).

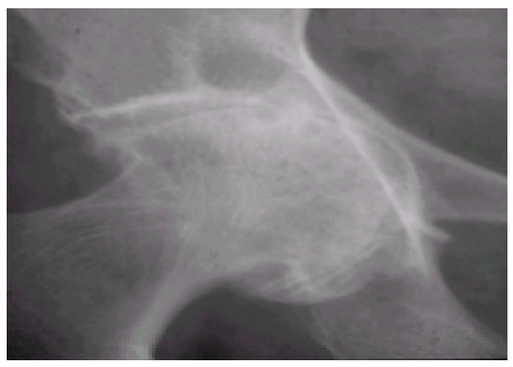

Fig. 24 Medial pole osteoarthritis, showing progression to a protrusio acetabuli deformity.

Other patterns are described (e.g. concentric) and many patients have 'indeterminate' radiographic patterns. Most disease is symmetrical unless there is a structural alteration in joint loading (Ledingham *et al*. 1992). Differentiation of these patterns does appear warranted since there may be differences in the association with hand osteoarthritis (Solomon 1976; Marks *et al*. 1979), and in prognosis (Danielsson 1964; Ledingham *et al*. 1992).

Suggested risk factors for development of hip osteoarthritis include previous hip disease (e.g. Perthes', slipped femoral epiphysis), acetabular dysplasia, avascular necrosis of the femoral head, severe trauma, generalized osteoarthritis, and occupation, particularly farming. The natural history of symptomatic hip osteoarthritis, as with osteoarthritis in general, is poorly documented, and it is impossible to predict outcome for the individual.

Crystal-associated subsets (see also Chapter 5.16)

A number of particles are commonly identified in synovial fluid and other tissues from osteoarthritis joints, most notably calcium pyrophosphate dihydrate and apatite (i.e. carbonated hydroxyapatite and other basic calcium phosphates) (Fig. 25). The origin and role of such particles in the osteoarthritis process remain unknown (Doherty and Dieppe 1988; Dieppe *et al*. 1988). By analogy with urate crystals in gout, it was initially assumed that such crystals were injurious and the cause of specific 'crystal deposition disease' (McCarty 1976). Certainly calcium pyrophosphate dihydrate and apatite are demonstrably inflammatory agents; being particulate they might also exert deleterious mechanical effects by deposition within cartilage and by acting as wear particles at the surface. However, the not uncommon occurrence of these crystals in asymptomatic, otherwise normal joints, the lack of association with specific locomotor disease, and the critical dependence of crystal identification on the technique used to detect them (Swan *et al*. 1994) has questioned such a direct pathogenic role. Multiple factors may influence deposition of these crystals, and it currently seems that calcium pyrophosphate dihydrate and apatite, in the context of osteoarthritis, most likely reflect underlying metabolic or physical facets of the process, thus potentially acting as markers for differing forms of joint response. In some situations (e.g. pseudogout) the crystals may provoke inflammation; in most others the crystals exert little phlogistic or mechanical effect, and are protected by protein coating from direct interaction with cell membranes and mediators of inflammation.

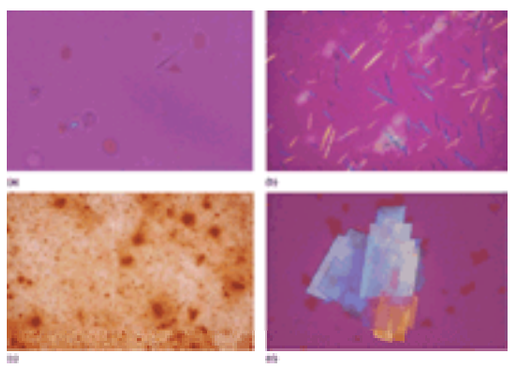

Fig. 25 (a) calcium pyrophosphate dihydrate, (b) monosodium urate monohydrate, (c) apatite, and (d) cholesterol crystals.

Pyrophosphate arthropathy

Calcium pyrophosphate dihydrate crystal deposition is the commonest cause of chondrocalcinosis (calcification of fibro- and hyaline cartilage). Although McCarty has proposed a complex clinical classification of 'pseudo-' syndromes (McCarty 1976) (Table 2), the simpler term 'pyrophosphate arthropathy' is often used to encompass those cases with accompanying arthritis. The three common clinical presentations are as:

Type	Pseudosyndrome	Presentation
A	Pseudogout	Acute or subacute synovitis
B	Pseudorheumatoid	Subacute attacks often with chronic systemic upset
C	Pseudo-osteoarthritis	Osteoarthritic change with superimposed acute synovitis
D	Pseudo-osteoarthritis	Osteoarthritic change without superimposed acute synovitis
E	Asymptomatic chondrocalcinosis	Asymptomatic radiographic finding
F	Pseudoneuropathic	Rapidly destructive often atrophic joint disease

Table 2 Classification of calcium pyrophosphate dihydrate related 'pseudosyndromes'

1. acute synovitis;
2. chronic arthropathy;
3. an incidental finding.

Other presentations are rare.

Acute synovitis ('pseudogout')

This is a common cause of acute monoarthritis in the elderly. Acute attacks may be the only manifestation of otherwise asymptomatic calcium pyrophosphate dihydrate deposition but in older patients, particularly women, they may often be superimposed upon a background of chronic symptomatic arthropathy. Any joint may be involved including the first metatarsophalangeal joint, 'pseudopodagra,' but the knee is by far the commonest site, followed by the wrist, shoulder, ankle, and elbow. Concurrent attacks in more than one joint are uncommon, and polyarticular attacks are unusual.

The typical attack develops rapidly with severe pain and swelling which is maximal within 6 to 24 h of onset. Overlying erythema is common and examination reveals a very tender joint with signs of marked synovitis (increased warmth, tense effusion, joint line tenderness, and restricted movement with stress pain). Fever is common, and elderly patients particularly may appear unwell and mildly confused, especially with knee or multiple joint involvement. Aspirated synovial fluid is inflammatory (low viscosity, turbid) and often blood stained. The cell count is usually very high, with predominance of neutrophils (>90 per cent). The diagnosis is confirmed by demonstration of synovial fluid crystals particularly if these are intracellular. Calcium pyrophosphate dihydrate crystals are poorly visualized by plain light microscopy, but can be seen under compensated polarized light microscopy (× 400). Calcium pyrophosphate dihydrate crystals (Fig. 25) are recognized by:

1. morphology—predominantly rhomboid or rod-shaped, occasionally needle-shaped;
2. size—approximately 2 to 10 μm long;
3. weak positive birefringence;
4. inclined extinction—15 to 20°.

'Twinning' of crystals, leaving a chip at one corner, is occasionally seen. Calcium pyrophosphate dihydrate crystals are less easily identified and often less numerous than urate crystals. They may often be missed unless carefully sought. Examination of a spun deposit may increase the detection rate. As with other synovial fluid particles, the use of polarized light microscopy is associated with a false positive and negative rate but identification by more definitive analytical means, such as infra-red spectrophotometry, electron microscopy, and X-ray diffraction, although ideal, is impractical for routine diagnostic purposes. The main differential diagnosis of pseudogout is sepsis and indeed these may coexist. Synovial fluid gram stain and culture should always be undertaken.

Acute attacks are self limiting and usually resolve within 1 to 3 weeks. Most episodes develop spontaneously but several provoking factors are recognized which may precede the attack by 1 to 3 days—the commonest being stress response to intercurrent illness (Table 3). Calcium pyrophosphate dihydrate crystals principally form in fibro- and hyaline cartilage, and it is 'shedding' of preformed, naked (i.e. not protein coated) crystals into the joint space, rather than acute crystallization, that is thought to be the mechanism of the attack. This is the one clear instance where calcium pyrophosphate dihydrate crystals are the likely cause of inflammation and

arthritis.

Intercurrent illness (e.g. chest infection)
Direct trauma to joint
Surgery (especially parathyroidectomy)
Blood transfusion, parenteral fluid administration
Institution of thyroxine replacement therapy
Joint lavage

NB Most cases develop spontaneously.

Table 3 Factors that may trigger acute pseudogout

Chronic pyrophosphate arthropathy

This common subset has several characteristics including:

1. predominance in elderly females;
2. an often florid inflammatory component possibly with superimposed acute attacks;
3. particular involvement of the knee;
4. frequent involvement of joints and joint compartments uncommonly affected by 'sporadic osteoarthritis';
5. frequent 'hypertrophic' radiographic appearance;
6. calcification of articular structures;
7. synovial fluid calcium pyrophosphate dihydrate crystals.

Large- and medium-sized joints are principally involved, with the knees being the most usual and severely affected site, followed by wrists, shoulders, elbows, hips, and midtarsal joints. In the hand, metacarpophalangeal joints (particularly index and middle) are the commonest, most severely affected. Symptoms are usually restricted to just a few joints, though single or multiple joint involvement also occurs; acute attacks may be superimposed upon chronic symptoms. Affected joints show signs of osteoarthritis (bony swelling, crepitus, restricted movement) and varying degrees of inflammation. Synovitis may be marked and is usually most evident at the knee, radiocarpal, or glenohumeral joints. Knees typically demonstrate bi- or tricompartmental involvement, with marked, usually predominant patellofemoral disease. In severe cases fixed flexion with either valgus or varus deformity may occur. Examination often reveals more widespread but asymptomatic joint abnormality; nodal generalized osteoarthritis, for example, is a common accompaniment.

The radiographic changes of this arthropathy are basically those of osteoarthritis with cartilage loss, sclerosis, cysts, osteophyte, and osteochondral bodies. Characteristics which may, however, permit distinction include:

1. atypical joint and intra-articular distribution compared to uncomplicated osteoarthritis;
2. often prominent, exuberant osteophyte and cyst formation (particularly at the knee).

These combined features may present a distinctive 'hypertrophic' appearance and distribution that suggest calcium pyrophosphate dihydrate even in the absence of radiographic chondrocalcinosis (Fig. 26). Many cases of pyrophosphate arthropathy, however, appear not dissimilar to 'uncomplicated' osteoarthritis. Furthermore, since nodal generalized osteoarthritis often coexists it is common to find otherwise typical osteoarthritis changes in some joints, with more distinctive changes of pyrophosphate arthropathy at others. It is probable, therefore, that pyrophosphate arthropathy is part of the spectrum of osteoarthritis rather than a truly distinct entity. As discussed further below the presence of crystals may tell us something about the underlying pathophysiological processes at work in the joint.

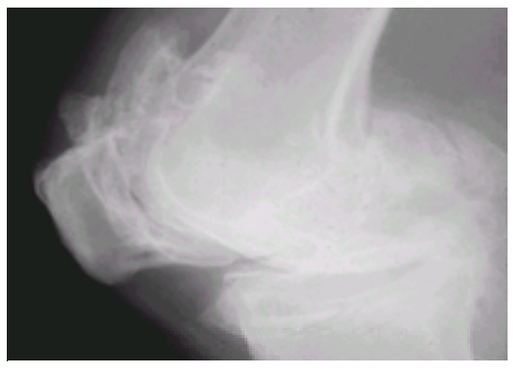

Fig. 26 Exuberant osteophytosis in patellofemoral compartment in pyrophosphate arthropathy.

P>Radiographic calcification may affect several joint tissues, but need not be present for the diagnosis of pyrophosphate arthropathy. Chondrocalcinosis most commonly affects fibrocartilage, particularly knee menisci, wrist triangular cartilage, and symphysis pubis, but it also occurs in hyaline cartilage, particularly in the knee, glenohumeral joint, and hip. It appears as thick linear deposits parallel to and separate from subchondral bone (Fig. 27). Chondrocalcinosis may be localized, for example to one knee, but usually affects several joints. If absent from knees, wrists, and symphysis pubis it is unlikely to be present elsewhere and thus views of these regions are often recommended for screening for its presence. Capsular and synovial calcification is less common, and usually most obvious at metacarpophalangeal joints (Fig. 28) and the knee. Calcium pyrophosphate dihydrate deposition can occur in tendons, particularly the Achilles, triceps, and obturators, and is typically linear and extensive. This is in comparison to apatite deposition which is typically discrete and nummular. Diffuse calcification of bursae such as the subacromial, olecranon, and retrocalcaneal is an occasional finding. Chondrocalcinosis and calcification are both dynamic features that may increase or decrease with time. Chondrocalcinosis may become less evident particularly if cartilage thickness is lost, or if crystals are 'shed' from cartilage during acute or recurrent inflammatory episodes.

Fig. 27 Isolated chondrocalcinosis of both hyaline (linear, parallel to bone) and fibrocartilage (triangular calcification).

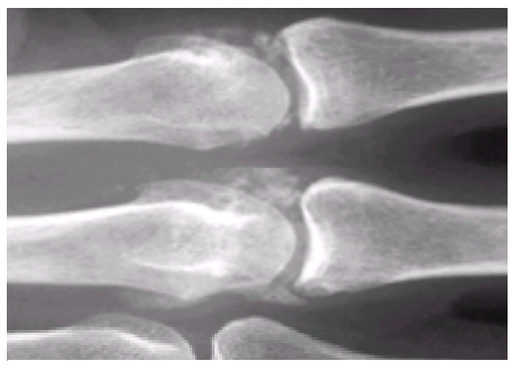

Fig. 28 Metacarpophalangeal joint radiograph in patient with pyrophosphate arthropathy showing calcification of synovium/capsule.

Incidental finding

Isolated chondrocalcinosis is a common age-associated phenomenon and as such is often observed as an incidental radiographic finding in the elderly. The only large population-based radiographic survey to study this is the Framingham study (Felson *et al*. 1989) which in the age range 63 to 93 showed an increasing overall prevalence with age ranging from 3 per cent in those aged <70 years, to 27 per cent in those >85 years (Fig. 29). A female preponderance was confirmed (relative risk 1.33), but was less pronounced than that derived from patient series. Although less well documented, it is likely that asymptomatic pyrophosphate arthropathy, like uncomplicated osteoarthritis, is common.

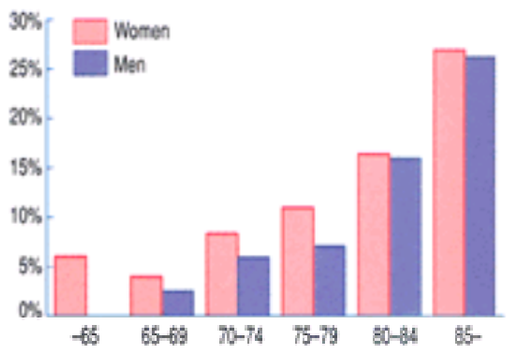

Fig. 29 Prevalence of radiographic chondrocalcinosis by age group and gender in a United States community population. Derived from Felson *et al*. (Felson *et al*. 1989).

Uncommon presentations

Polymyalgia rheumatica

This may be suggested if marked proximal stiffness accompanying glenohumeral and polyarticular involvement occurs.

Ankylosing spondylitis

Severe spinal stiffness, particularly in certain familial forms, may cause 'pseudo-ankylosing spondylitis'. True spinal ankylosis occurs in certain Chilean families.

Meningitis

Acute attacks in axial sites may cause self-limiting meningitic episodes. It is difficult to confirm these episodes although improvements in imaging has led to better recognition of such calcium pyrophosphate dihydrate deposits.

Tendinitis and tendon rupture

Acute inflammatory episodes relating to calcium pyrophosphate dihydrate deposition in tendons are described for triceps, flexor digitorum, and Achilles tendons, and tenosynovitis is reported for hand flexors and extensors. Tendon rupture is a rare complication.

Carpal tunnel syndrome

This may result from flexor tendon involvement or from wrist synovitis. Less frequently, combined median and ulnar nerve entrapment at the wrist may occur.

Bursitis

This may occur in the olecranon, infra-patellar, and retrocalcaneal bursae but is uncommon and is usually associated with widespread pyrophosphate arthropathy.

Tophi

Tophaceous (tumoral) calcium pyrophosphate dihydrate deposition is rare, but has been reported in both intra- and periarticular locations. Such deposits are usually solitary and develop in areas of chondroid metaplasia without predisposing metabolic abnormality or evidence of calcium pyrophosphate dihydrate deposition elsewhere. They produce spotty radiographic calcification and are commonly biopsied as malignant lesions, the diagnosis following histological examination (Fig. 30).

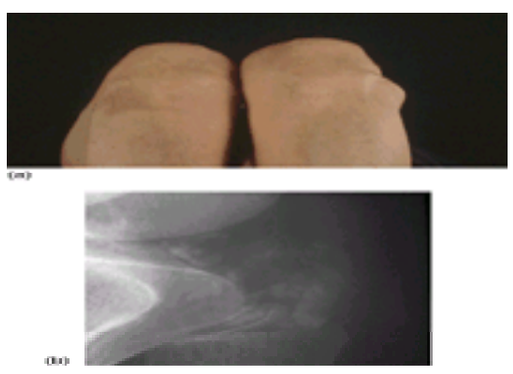

Fig. 30 Tophaceous pyrophosphate deposition superolateral to the tibiofibular joint; (a) clinical picture and (b) radiograph of the same site.

Associations of calcium pyrophosphate dihydrate deposition

A number of associations of calcium pyrophosphate dihydrate crystal deposition are recognized (Table 4). The mechanisms that underpin them are ill understood. Several possible mechanisms may be important for crystal formation including:

Positive	Negative
Ageing	Rheumatoid arthritis
Familial predisposition	
Joint insult, osteoarthritis	
Metabolic disease	

Table 4 Associations of calcium pyrophosphate dihydrate crystal deposition

1. changes, usually an increase, in relevant solute concentration;
2. presence of nucleating factors;
3. presence or absence of promotors or inhibitors of crystal growth;
4. the kinetics of crystal removal and dissolution.

In relation to calcium pyrophosphate dihydrate there is evidence to support mechanisms involving an increase in ionic product (calcium × pyrophosphate) and/or influence by promoters or inhibitors of crystal formation/growth in the cartilage matrix, the site of the majority of crystal formation. The precise nature of such matrix factors, however, is not known.

Age

Ageing is perhaps the single major predisposing factor. Indirect association could come from the positive correlation with osteoarthritis, but chondrocalcinosis commonly occurs in otherwise normal cartilage and this association remains unexplained. Inorganic pyrophosphate levels in synovial fluid from normal knees show no increase with age, suggesting that age-related alteration in matrix factors are most likely to be responsible.

Genetic

Chondrocalcinosis is reported from most countries and racial groups but only one study has defined a specific racial predisposition. Genetic predisposition, however, is well described from several countries and different ethnic groups including Czechoslovakia, Chile, Holland, France, Canada, Germany, Sweden, United States, Spain, Japan, Israel, and United Kingdom (Doherty *et al*. 1991a). Two main clinical phenotypes have been emphasized:

1. early onset in the third and fourth decades, florid polyarticular chondrocalcinosis, and varying severity of arthropathy, ranging from mild to severe, destructive;
2. late-onset oligoarticular chondrocalcinosis and arthritis, mainly affecting the knee, that is indistinguishable from sporadic pyrophosphate arthropathy.

The latter form may be more common than generally recognized since the late onset of clinical expression presents difficulties in confirming familial disease. An association with benign childhood fits is reported in one United Kingdom family with early onset polyarticular chondrocalcinosis. Autosomal dominant inheritance occurs in most families but the genetic basis has not been identified. A primary cartilage abnormality is supported by histological study of Swedish and Japanese cases, the former demonstrating proteoglycan depletion that precedes crystal formation, the latter showing hypertrophic lipid-laden chondrocytes in areas of calcium pyrophosphate dihydrate deposition. Conversely a generalized abnormality of pyrophosphate metabolism is suggested by two reports of increased intracellular pyrophosphate concentration (skin fibroblasts or transformed lymphocytes) in French and American kindreds. This finding is not present in five United Kingdom kindreds (Doherty *et al*. 1991a), thus suggesting differing genetic mechanisms in different kindreds.

Metabolic and endocrine

Although numerous metabolic associations are described, many reflect no more than chance concurrence of common age-related conditions (Table 5). The strongest evidence relates to hyperparathyroidism and haemochromatosis. Less certain evidence implicates hypothyroidism. With rare conditions convincing evidence is provided by occurrence of premature chondrocalcinosis in just a few cases, as with hypophosphatasia and hypomagnesaemia. The status of other previously implicated diseases such as Wilson's disease, ochronosis, and acromegaly remains unclear (Jones *et al*. 1992). These associations are rationalized through putative effects on pyrophosphate metabolism, extrapolated largely from *in vitro* data. Suggested mechanisms include:

	Chondrocalcinosis	Chronic arthritis
Hypophosphatasia	√	×
Hypomagnesaemia	√	×
Hyperparathyroidism	√	×
Haemachromatosis	√	√
Hypothyroidism	√	×
Gout	?	×
Acromegaly	?	×
Familial hypocalciuric hypercalcaemia	?	×
X-linked hypophosphataemic rickets	?	?
Wilson's disease	×	×
Ochronosis	×	×
Diabetes mellitus	×	×

Table 5 Metabolic diseases associated with calcium pyrophosphate dihydrate deposition

1. reduced breakdown of pyrophosphate by alkaline phosphatase due to;
   a. reduced enzyme levels, in particular hypophosphatasia
   b. presence of enzyme inhibitors such as calcium, iron, copper
   c. lack of enzyme cofactors such as magnesium
2. enhanced crystal nucleation e.g. by iron and copper;

3. increased calcium concentration e.g. hyperparathyroidism;
4. increased pyrophosphate production through parathyroid hormone stimulation of adenylate cyclase e.g. hyperparathyroidism;
5. decreased crystal solubility e.g. hypomagnesaemia;
6. altered cartilage matrix promoting crystal formation e.g. hypothyroidism.

Effects on pyrophosphate metabolism are certainly supported by elevated synovial fluid pyrophosphate levels in structurally normal knees of patients with hyperparathyroidism, haemochromatosis, or hypomagnesaemia, and elevated urinary pyrophosphate levels in hypophosphatasia (Doherty *et al*. 1991b). Mechanisms other than effects on pyrophosphate may also operate: bone and cartilage changes may be marked in these disorders, and in those with arthropathy, calcium pyrophosphate dihydrate deposition may be secondary to joint damage, mediated via alterations in matrix factors.

Joint insult

Several observations support a relationship between preceding joint insult and subsequent development of chondrocalcinosis. These include the high frequency of premature chondrocalcinosis localized to knees that have undergone menisectomy or surgery for osteochondritis dissecans as well as reports of localized pyrophosphate arthropathy as a late complication of juvenile chronic arthropathy, joint instability, and trauma. However, the apparent negative association between calcium pyrophosphate dihydrate deposition and rheumatoid arthritis, suggests that the primary association of calcium pyrophosphate dihydrate is with hypertrophic tissue response/osteoarthritis rather than with joint damage *per se*. Indeed those few patients with coexistent rheumatoid arthritis and calcium pyrophosphate dihydrate deposition often demonstrate an atypical, hypertrophic response with exuberant osteophytosis and remodelling suggestive of an essentially reparative response (Fig. 31).

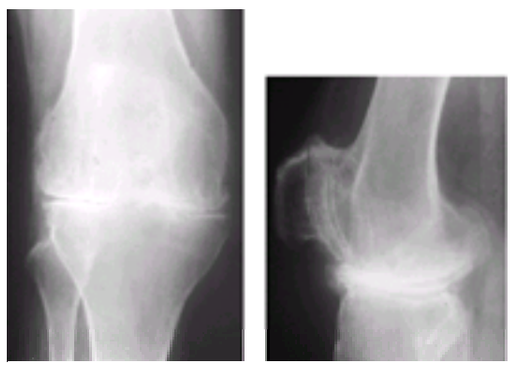

Fig. 31 Rheumatoid arthritis at the knee modified by calcium pyrophosphate dihydrate deposition. There is marked pan-compartmental joint space loss but, in addition, there is marked osteophytosis and little osteopenia.

Apatite associated arthropathy

This uncommon condition has the following characteristics:

1. confinement to elderly, predominantly female subjects;
2. localization to large joints;
3. rapid progression of arthropathy with instability;
4. marked attrition of cartilage and bone;
5. abundant apatite in synovial fluid and synovium.

This condition has a number of synonyms, including 'Milwaukee shoulder', 'basic calcium phosphate deposition disease', and 'analgesic hip'. Typical patients are elderly women with rapidly progressive arthropathy of the hip, shoulder, or knee. Usually only one or a few joints are affected. Onset is often quite sudden and within a few weeks or months the patient has severe rest and night pain, and shows large, cool effusions, with gross instability. Aspirated synovial fluid is often blood-stained and shows retained, high viscosity and only a modest increased cellularity. Alazarin red S staining at acidic pH shows multiple calcium containing aggregates (Fig. 25), confirmed as apatite, most commonly carbonate substituted hydroxyapatite, by more definitive means. The principal radiographic features are marked attrition of cartilage and bone, with a paucity of osteophyte and sclerosis, that is a markedly 'atrophic' appearance (Fig. 32). The differential diagnosis includes sepsis, an atrophic neuropathic joint, and late avascular necrosis.

Fig. 32 Radiograph of apatite associated destructive arthritis of the hip, showing apparent increase in joint space (non-loaded film), marked loss of bone (femoral and acetabular components), and minimal bone response.

The pathogenesis of this condition, particularly as regards the role of the apatite aggregates, is controversial (Halverson and McCarty 1988). McCarty and colleagues have emphasized the presence of activated collagenase in synovial fluid, a proliferative response to crystals in the synovium, and the frequency of accompanying periarticular calcification. They therefore suggest that apatite that has been deposited in capsule and periarticular structures is enzymatically 'strip-mined', the free apatite then interacting with synoviocytes, resulting in further collagenase release, further strip-mining, and progression of arthropathy and instability via an 'amplification loop'. Others, however, have not confirmed increase in collagenase activities, and suggest that the apatite primarily originates from subchondral and marginal bone. The non-specific finding of apatite in varying quantities in other arthropathies, and even in small amounts in normal joints, is consistent with this interpretation. The speed of onset and progression, lack of overt inflammation, marked bone loss, specificity to certain anatomic sites, radiographic similarity to late avascular necrosis, and neuropathic joints support the contention that this arthropathy reflects a widespread nutritional catastrophe for the joint, possibly initiated by age-related compromise of subchondral bone blood flow. The large amount of observed apatite may thus simply reflect the rapidity of bone damage.

Other hypotheses seem less plausible; for example the suggestion that this condition results from non-steroidal anti-inflammatory drug usage and is a specific 'iatrogenic Charcot arthropathy', seems unlikely on current evidence (Doherty 1989).

Mixed crystal deposition

Comparison of clinical and radiographic features of typical calcium pyrophosphate dihydrate and apatite associated arthropathies shows marked contrasts, though each clearly falls within the spectrum of 'osteoarthritis'. The finding of both calcium pyrophosphate dihydrate and apatite in the joints of some patients is common

although there is little evidence that their combined presence is associated with particular clinical or radiographic characteristics, apart from a possible tendency to a more destructive, widespread osteoarthritis at the knee (Dieppe *et al*. 1988). Rather than classifying joints containing calcium pyrophosphate dihydrate, apatite, or calcium pyrophosphate dihydrate plus apatite as separate conditions it seems more reasonable to view these calcium crystals as markers of varying processes within the osteoarthritis joint, with calcium pyrophosphate dihydrate crystals marking a tendency to hypertrophic response, and plentiful apatite a tendency to atrophic response to insult (Fig. 33). If this is the case and osteoarthritis is regarded as a spectrum with varying balance between chronic injury and repair, frequent concurrence of both calcium crystals (in the same joint, in different joints of the same individual, at the same time or during differing phases) would be expected. In joints showing preponderance of either hypertrophic or atrophic processes (i.e. the two ends of the spectrum) the likelihood of a single crystal species would be higher. Although this may be true for typical cases, several reservations are necessary:

Fig. 33 Diagrammatic representation of calcium pyrophosphate dihydrate and apatite occurring as particulate 'markers' of a tendency to hypertrophic and atrophic osteoarthritis respectively.

1. Crystal identification is not an all-or-nothing phenomenon and is critically dependent on the experience and diligence of the observer as well as the methods employed (Swan *et al*. 1994).
2. There may not be distinct associations with different crystal types. In a study examining unselected osteoarthritis patients no real distinct characteristics, either clinical or radiographic, could be associated with the presence or absence of different crystal types (Pattrick *et al*. 1993).

Osteoarthritis at other joint sites

Selection of osteoarthritis for certain joint sites is striking. For example compared to osteoarthritis of interphalangeal joints, hips, or knees, involvement of the elbow, glenohumeral joint, or ankle is unusual and principally confined to the elderly.

Osteoarthritis of spinal apophyseal joints (particularly lower cervical and lower lumbar segments), first carpometacarpal, and/or first metatarsophalangeal joints is common and may occur as part of a pattern of generalized osteoarthritis (nodal or non-nodal) or as an isolated feature. In addition to nodal generalized osteoarthritis and trauma, suggested associations include:

1. metatarsus primus varus and the first metatarsophalangeal joint;
2. congenital structural anomalies, adjacent spondylosis deformans, and osteoarthritis at the apophyseal joints;
3. nodal generalized osteoarthritis, pyrophosphate arthropathy, and repetitive (principally occupational) trauma at the elbow, index, and middle metacarpophalangeal joints.

As with other arthropathies, the predilection of osteoarthritis for certain sites, with sparing of others, remains unexplained. However, one intriguing, unifying hypothesis is that human joints most commonly affected by osteoarthritis are in general those that have undergone the most rapid evolutionary change, particularly in regard to bipedal locomotion and oppositional grip (Hutton 1987). Such joints may not have had sufficient evolutionary time to fully adapt to the tasks demanded of them. They therefore have insufficient mechanical reserve, and thus fatigue and 'fail' more commonly than joints that have had longer to adapt to their new function.

Osteoarthritis as part of other disease

If, as we have discussed, osteoarthritis represents the inherent repair process of synovial joints, then osteoarthritic features would be expected to occur during certain phases of other defined arthropathies. For example in rheumatoid arthritis, osteophytosis, sclerosis, and remodelling may become prominent during later, less inflammatory periods of the disease. In such instances 'osteoarthritis' can be seen as an accompanying process of tissue response/repair rather than an acquired second condition.

The same considerations pertain to other inflammatory, metabolic, or structural arthropathies. Ochronosis and spondyloepiphyseal dysplasia, for example, are sometimes included within the umbrella of osteoarthritis since many of their radiographic features are typical of osteoarthritis. Similarly, endemic forms of osteoarthritis need consideration in their own right. For clinical purposes, however, it may still be useful to consider together conditions that may result in non-inflammatory arthropathy with radiographic changes predominantly of osteoarthritis (Table 6). An atypical presentation, however, should lead one to search for a defined, possibly treatable underlying cause. Many are rare, and have distinct clinical and radiographic features. In patients with 'osteoarthritis' one should consider specific predisposing factors when there is:

Generalized 'osteoarthritis'	(Spondylo-) epiphyseal dysplasia Ochronosis Haemochromatosis Wilson's disease Endemic osteoarthritis (e.g. Kashin–Beck disease)
Pauciarticular, large joint 'osteoarthritis'	Neuropathic joints syringomyelia—shoulders, wrists, elbows diabetes—hindfoot, midfoot tabes—knees, spine
	Acromegaly
	Avascular necrosis (mainly proximal and distal femur, proximal humerus)

Table 6 Principal conditions with presentations and radiographic changes that may simulate osteoarthritis

1. premature onset osteoarthritis, i.e. less than 45 years;
2. an atypical joint distribution, e.g. prominent metacarpophalangeal and radiocarpal involvement in haemochromatosis;
3. premature onset of chondrocalcinosis, i.e. less than 55 years;
4. florid polyarticular chondrocalcinosis at any age.

Investigations

Osteoarthritis is a diagnosis made on clinical and radiological grounds. To date there are no satisfactory criteria or specific laboratory tests. Furthermore, radiographic changes of osteoarthritis are commonly present but often asymptomatic. The problem is not usually to decide whether osteoarthritis is present but whether it is the

cause of the problem. Investigation plays little part in this decision, which should be made by a thorough clinical examination. Some investigations may be necessary to exclude alternative diagnoses or predisposing disease.

Osteoarthritis is not associated with extra-articular disease, synovitis is usually only mild or moderate, and overt immunological abnormality is not a feature. Changes reflecting an acute phase response (anaemia, thrombocytosis, elevated erythrocyte sedimentation rate and/or C-reactive protein) or overt immunological abnormality (autoantibodies, complement breakdown products) are therefore usually absent. However, evidence of a marked acute phase response occurs with pseudogout, and modest elevation of erythrocyte sedimentation rate and C reactive protein may occur in the 'inflammatory' subsets of osteoarthritis, particularly chronic pyrophosphate arthropathy. IgG rheumatoid factor (but not Rose Waaler or Latex) positivity may be more common in nodal generalized osteoarthritis than age-matched controls (Hopkinson *et al*. 1992). Presence of such modest or isolated abnormalities are therefore not against the diagnosis of osteoarthritis, particularly in elderly patients in whom coexistent disease is common. A search for predisposing metabolic or endocrine disease may be undertaken in selected patients with atypical distribution or premature-onset of osteoarthritis, atypical radiographic features, or early-onset or polyarticular chondrocalcinosis; such patients usually have other clinical or radiographic clues, and routine 'screening' for all known predisposing diseases is inappropriate.

The only investigations that are of importance in terms of determining the presence of osteoarthritis, the degree of structural and physiological change, and the presence of associated crystal deposition are plain radiographs and other forms of imaging. Synovial fluid analysis may also be useful. Here we shall only discuss selected aspects of imaging, and the potential for future biochemical 'markers' of the osteoarthritic process.

Imaging

Imaging aims to establish the diagnosis, to assess severity, delineate the likely pathology involved, and help exclude alternative diagnoses. Methods include plain radiographs, magnetic resonance imaging, ultrasound and radioisotope scanning. The objective of the user determines the most appropriate modality. Generally techniques that demonstrate structural change do so at the expense of demonstrating current biochemical/physiological activity and vice versa. As discussed below, a possible exception to this may be magnetic resonance imaging.

Plain films

Radiographs give an anatomical picture, that is they demonstrate past structural change rather than current 'disease activity'. Bony structures are readily defined but soft tissue imaging is more difficult. In particular, cartilage is not directly visualized and its thickness has to be inferred by assuming that it comprises the vast majority of the distance between two articulating bones, that is the interosseous distance. Focal cartilage loss is very difficult to detect and the bony changes reflect relatively late pathological abnormalities. Nevertheless, the availability of radiographs and their widespread current and historical use in studying osteoarthritis make them still the principal imaging modality for diagnosis, assessment, and follow-up.

Joint space narrowing, osteophyte, subchondral radiolucencies, and sclerosis are the classic radiological signs of osteoarthritis (Fig. 34). A spectrum of changes exist for each of these signs, there is no fixed correlation between one sign and another, and no one feature has really been shown to have particular discriminatory value, although osteophyte at the knee may be a relatively good predictor of knee pain in epidemiological studies (Spector *et al*. 1993). Additional features and complications may also be visualized including:

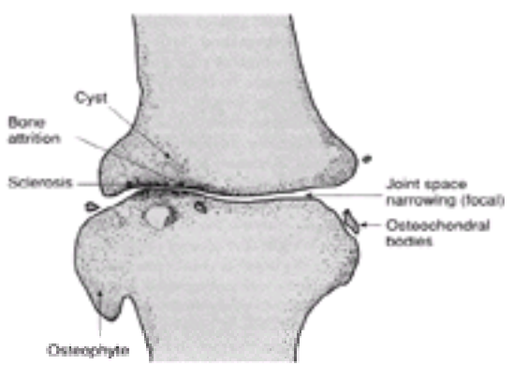

Fig. 34 Major radiographic features of osteoarthritis.

1. effusions;
2. the osseous component of osteochondral ('loose') bodies;
3. joint alignment;
4. subluxation.

Absence of features of other arthritides is expected although the radiographic diagnosis of osteoarthritis does not exclude other coexisting disease. Osteoarthritis may also be secondary to previous bone and joint disease.

Plain films facilitate subsetting of osteoarthritis by:

1. the distribution of osteoarthritis change within a joint, e.g. superior pole, medial, and concentric patterns of hip; patellofemoral and tibiofemoral knee osteoarthritis;
2. the emphasis on individual osteoarthritis features, e.g. hypertrophic versus atrophic appearance;
3. demonstration of additional features, e.g. calcification of cartilage and other joint structures in calcium pyrophosphate dihydrate deposition.

Some of these features may, however, be distorted by overlying structures and magnification effects resulting from the divergence of the X-ray beam. Attempts to improve the reproducibility and interpretability of plain radiographs have been made. Some involve standardization of positioning, the use of multiple observers, the use of different views and specialized radiographic techniques. Aspects of these are discussed further below.

Plain radiography of specific joints

Hand

The pattern of involvement of the interphalangeal joints helps to distinguish osteoarthritis and erosive osteoarthritis from rheumatoid and psoriatic arthropathy. For this purpose a single posteroanterior view of the hand may be satisfactory although it is possible such a view does not detect posterior osteophytes. The distinctive changes are (Fig. 35):

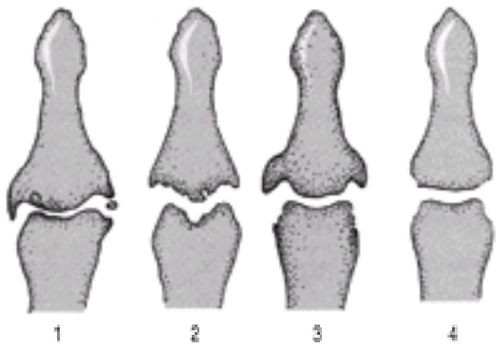

Fig. 35 The radiographic differences between (a) osteoarthritis, (b) erosive osteoarthritis, (c) psoriatic arthritis, and (d) rheumatoid arthritis.

1. osteoarthritis: bone sclerosis, focal narrowing, and lateral subluxation unaccompanied by erosion;
2. erosive osteoarthritis: changes of osteoarthritis plus erosions which are through the subchondral bone plate;
3. psoriatic arthritis: marginal erosions associated with a bone response, 'proliferative erosions'.
4. rheumatoid arthritis: marginal 'bare area' erosions unassociated with bone proliferation;

Knee

Weight-bearing films of the knee show the functional position of the limb and may allow more precise information on the extent of joint space narrowing (Messiah *et al*. 1990). To assess the less involved compartment, or to detect soft tissue laxity, stress views may be required. However, the changes of fibrillation, cartilage narrowing, and cratering are focal. Attempts to detect early change by using a semiflexed weight-bearing view have been suggested although difficulties with precise patient positioning are still evident. Recent evidence has confirmed that the patellofemoral joint is an important site of involvement of osteoarthritis (McAlindon *et al*. 1992). To date there is no consensus on the best plain radiographic method to be used to assess this joint and the choice lies between a lateral view or a 'skyline' view of the patella (Jones *et al*. 1993). Further work is necessary to establish the optimum view.

Hip

Traditionally this is taken as a non-weight-bearing anteroposterior view of the pelvis. This has the advantage of incorporating both hips on the same radiograph although gonadal dosage may be a problem. Evidence suggests that at the level of population studies such a view may be satisfactory with minimum joint space the best criteria to define a case. It is possible that this view does not provide full information of involvement of the hip since early change may be focal and posterior. The role of additional or stressed views is, however, not yet established.

Sacroiliac joints

In the sacroiliac joints, osteophyte and joint space loss may need to be distinguished from inflammatory sacroiliitis. The latter gives erosion and intra-articular ankylosis, whereas osteoarthritis gives more focal joint space narrowing and focal sclerosis with overlying osteophytes. These are usually anterosuperior or inferior, and may be identified by discontinuity of trabecular lines across the joint in contrast to continuous lines of ankylosis (Fig. 36). Usually a single anteroposterior view of the pelvis is obtained as for the assessment of the hip but such a view may be difficult to interpret since the joint margins may overlap. In this situation a coned posteroanterior view of the sacroiliac joints may help.

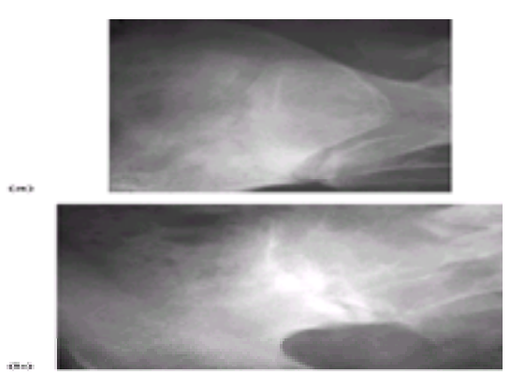

Fig. 36 (a) Sacroiliitis compared to (b) sacroiliac osteoarthritis.

Foot

A common site of osteoarthritis, this is not usually incorporated in radiographic surveys. A single posteroanterior radiograph of the foot is probably the simplest method required to demonstrate involvement of the first metatarsophalangeal joint. Specialized views would be required to demonstrate involvement of the tarsus and ankle joints but these are not usually employed in studies.

Spine

This can be a difficult area to assess for osteoarthritis. Changes suggestive of osteoarthritis, sclerosis, joint space narrowing, and osteophyte are virtually universal in middle-aged and elderly adults. These are particularly evident in the lower cervical and lower lumbar spine and may involve the facet joints and in the cervical region the uncovertebral joints (the joints of Luschka). In addition, similar changes are seen in the intervertebral discal joints. The precise views necessary to detect spinal osteoarthritis are not clear but lateral lumbosacral and cervical views are probably the most appropriate.

Disease of the spine, particularly if it involves the facet joints with subsequent osteophytosis, may result in either foraminal compression of the nerve roots or canal stenosis. Although plain views, particularly if oblique foraminal views are taken, may demonstrate narrowing (Fig. 37), more specialized techniques such as magnetic resonance imaging or computed axial tomography are usually required.

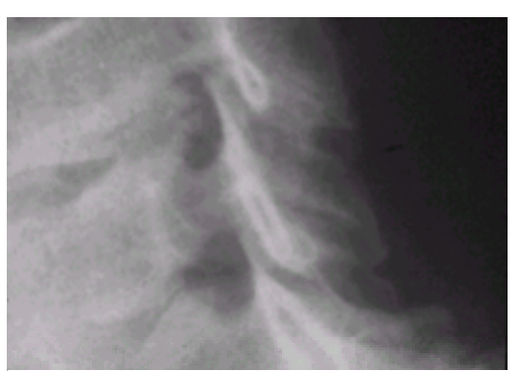

Fig. 37 Foraminal osteophytic encroachment in the neck of a patient who presented complaining of intermittent numbness and paraesthesia of the right arm.

Standardization of the assessment of plain radiographs

Attempts have been made to standardize and quantitate image analysis. Two approaches have been used. The first has used atlases of standard films against which to compare the study films (Kellgren and Lawrence 1957; Kallman *et al*. 1989; Burnett *et al*. 1994), the second has tried to assess radiographic features using automated approaches. Using an atlas, two further approaches have been employed.

The first has attempted to produce a single a grade of osteoarthritis from a combination of different radiographic features. The use of such a 'global osteoarthritis' grade is attractive since it simplifies statistical analysis and means a joint is assigned to only one of a few radiographic grades. There are dangers with such an approach. Firstly it assumes a hierarchy of change that may not exist. For example in the Kellgren and Lawrence grading system the presence of osteophyte is a *sine qua non* for the diagnosis of osteoarthritis. Yet, histologically and arthroscopically, osteoarthritis, in terms of typical focal cartilage loss, may occur in the absence of detectable osteophyte. Similarly, in moving between grades it is by no means clear that the 'developing' features are indicative of deteriorating osteoarthritis. For example the development of osteophyte has been suggested to be a potentially beneficial process acting to improve joint stability.

The alternative approach which has gained increasing favour is to grade for individual features of osteoarthritis such as osteophyte, joint space narrowing, cysts, and sclerosis. This has the advantage of not assuming a particular hierarchy of change or inter-relationship of features. However a large amount of descriptive data is generated for each joint which is difficult to combine. Simply summating scores for each feature is probably not valid. No consensus has been reached as to which approach is preferable.

In an attempt to reduce interobserver error, various manual and semiautomated methods have been evaluated particularly in the measurement of joint space. For an individual radiograph such an approach may be very reproducible particularly if an automated computerized method is used. Problems still remain regarding the obtaining of reproducible radiographs upon which to make the measurements (Spector 1995).

Modified radiographic techniques

Microfocal radiography is a magnification technique that allows higher resolution imaging, with the possibility of stereoscopic reconstruction. This technique appears particularly useful in showing early subchondral bone abnormalities and demonstrating small changes in joint space width over short periods of time (Buckland-Wright *et al*. 1990). Requirements of relatively long exposures and special equipment confine this method to a research tool but one which has particular potential in longitudinal studies (Spector 1995).

Some of the limitations of plain films can be overcome by tomography. This produces cross-sectional images that thus avoid problems of interpreting overlying structures. Images of spinal apophyseal joints are possible, and the pattern of sacroiliac disease is made clearer. In general this technique has been superseded by the newer technique of computed axial tomography.

Arthrography allows cartilage to be coated with contrast and thus be demonstrated, but this is invasive and unsuitable for routine or sequential use. It has a place, however, in demonstrating associated meniscal disease although this role is rapidly becoming superseded by magnetic resonance imaging.

Magnetic resonance imaging (see also Chapter 4.9.1)

This method uses the properties of hydrogen ions, principally those in water. Since cartilage contains a high proportion of water, it can allow cartilage to be imaged. The potential and limitations of this modality in respect to osteoarthritis are still being explored. There are several problems including:

1. limited resolution, since each image is reconstructed from information from a volume of tissue;
2. the magnetic effects of bone, particularly when juxtaposed to cartilage;
3. resolution of synovial fluid from cartilage, since both have a high water content.

However, by using different scan sequences it may be possible to resolve these problems as well as to obtain information on the process involved in osteoarthritis.

Radionuclide studies

Isotope bone scans give information on perfusion and bone activity. The mechanism of bone uptake is non-specific, but is more sensitive than radiographs at identifying involvement. Perhaps its most significant role in assessment of osteoarthritis is its ability to detect abnormalities before radiographic signs are identified, and to identify patients with 'active' disease who may go on to show progression (Hutton *et al*. 1986; Dieppe *et al*. 1993). This may prove useful in evaluation of drugs and other interventions before severe joint damage has occurred.

Ultrasound

This modality requires no radiation exposure and permits imaging of cartilage and tendons. Problems of access and sound distortion mean that its value is restricted and currently it remains a research tool. Nevertheless, it has been shown to give distinction between normal, fibrillated, and thin cartilage at the knee (Aisen *et al*. 1984). It may prove of value in the early detection of cartilage abnormalities.

Potential markers of tissue destruction, inflammation, and repair in osteoarthritis

There is considerable interest in measuring biochemical markers in synovial fluid or serum to allow the diagnosis of diseases, to follow progression of disease and response to treatment, and to determine disease prognosis and mechanism. Osteoarthritis involves active cellular processes of biosynthetic activity and matrix turnover and measurement of these parameters could allow these processes to be monitored. Such studies are based on two assumptions.

1. When cartilage is damaged there is a loss of matrix components, cytokines, or proteinases into synovial fluid, the lymphatic system, serum, and urine.
2. This loss is quantitative, with changes in concentration reflecting changes in rates of turnover.

The first of these assumptions is proven but data to support the second are confounded by unknown physiological variables. For example the concentration of fragments in synovial fluid depends not only on the rate of release from cartilage, but also on the volume and turnover of joint fluid and the speed of lymphatic drainage (all difficult to quantify). Similar problems apply to measurements in serum or urine: although they are more readily accessible compartments, the concentrations in them reflect release from all joints (normal and abnormal) and from other cartilage sites; selective, rapid elimination by the lymph nodes or liver, and the possible influence of renal and liver disease complicate interpretation. Finally, it is essential to know what a 'marker' signifies in terms of joint physiology: a reduction in the concentration of a cartilage marker after an intervention may be interpreted as reduced cartilage breakdown, it may signify inhibition of matrix synthesis or reflect the absence of any remaining cartilage within the joint (Fig. 38).

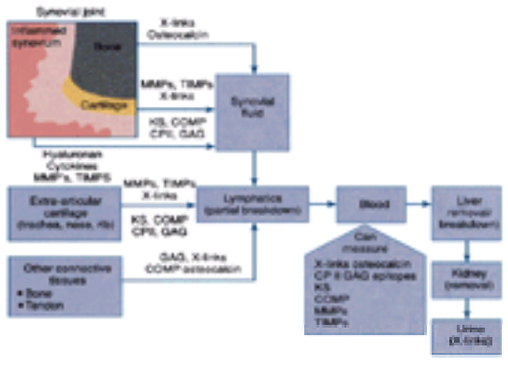

Fig. 38 Physiology of potential 'markers' of the osteoarthritic process.

Some of the biochemical products that have been investigated are listed, in Table 7, Table 8, and Table 9 along with the advantages and disadvantages of any particular parameter or method of measurement. The usefulness of these markers is not confined to osteoarthritis, as the principle of joint damage/repair is common to other conditions. At present there is no marker in biological fluids that can be used for diagnosis or for monitoring of the progression of osteoarthritis (Lohmander 1994).

Tissue	Markers	Indicates	Osteoarthritis		Rheumatoid arthritis	
			Serum	SF	Serum	SF
Synovium	Hyaluronan (hyaluronic acid, hyaluronate, HA)	Synovitis, HA synthesis stimulated by IL-1 and TNF-α	↑	ND	↑	↑
Cartilage	C-propeptide of type II collagen	Synthesis of cartilage type II collagen	↑	↕	↑	↑
	Type II collagen α chain fragments	Degradation of cartilage type II collagen	Studies in progress			
	Cartilage oligomeric protein	Synthesis and/or degradation?	ND	↕	↑	ND
	Cartilage matrix protein	Synthesis and/or degradation? only present in non-articular cartilages	ND	ND	↑	ND
Proteoglycan aggrecans	Keratan sulphate	Synthesis/degradation of aggrecan	↑	↕	↓	↑
	Core protein	Degradation	+	↕	+	↑
	Intact chondroitin sulphate epitopes e.g. 846, 3B3	Probably synthesis	↑	+	↑/0[a]	↑
Bone	Bone sialoprotein	Synthesis/degradation	Studies in progress			
	Osteocalcin	Synthesis	↑	↕	+	↑
	3-hydroxypyridinium (pyridinoline and deoxypyridinoline) cross-links	Degradation	Urine only			

ND=not determined, SF=synovial fluid, [a]acute disease only.

Table 8 Changes in matrix markers of tissue destruction, inflammation, and repair in osteoarthritis and rheumatoid arthritis

Assay	Advantages	Disadvantages
Where?		
Serum	Easy collection All patients	Dilution of marker Contribution from other tissues
Synovial fluid	Local to inflamed joint	Infrequent aspiration Small proportion of patients Low levels may result when large volumes of synovial fluid are produced
Urine		Difficult to collect 24-h urine Final level depends on rate of clearance in other compartments
How?		
Immunoassay	Rapid measurement of total level	Also measure non-functional protein
Activity assay	Measures biological activity	Often inhibitors also present, therefore sample may require fractionation

Table 9 Measurement of matrix markers of tissue destruction, inflammation, and repair (NB low levels may result when most of the cartilage tissue has been destroyed)

Cytokines

As little inflammation is present in osteoarthritic joints the measurement of cytokine levels is not helpful in osteoarthritis (Westacott *et al*. 1990).

Matrix components

Proteoglycan and glycosaminoglycan fragments

Because of their relatively rapid turnover many studies have estimated protein and carbohydrate moieties of the large, aggregating proteoglycans (aggrecan) of cartilage. Using immunoassays it has been shown that:

1. Radiographic loss of cartilage in rheumatoid arthritis correlates with a decline in the proteoglycan concentration of synovial fluid (Saxne *et al*. 1985; Poole 1993).
2. High concentrations of proteoglycan in synovial fluid occur in acute reactive arthritis and decline during remission after steroid injection (Saxne *et al*. 1986).
3. Large amounts of proteoglycan fragments occur in synovial fluid with transient synovitis and septic arthritis of the hip in children, and in adults after acute mechanical derangements of the knee (Lohmander *et al*. 1989).
4. Keratan sulphate is raised in synovial fluid in pseudogout and acute Reiter's disease, with significantly lower levels in osteoarthritis and chronic pyrophosphate arthropathy (Ratcliffe *et al*. 1988).

Thus, an increase in proteoglycan fragments in synovial fluid appears to occur only in acute inflammatory conditions, presumably reflecting accelerated breakdown.

Serum keratan sulphate is higher in osteoarthritis, particularly 'hypertrophic' osteoarthritis, than in normal controls (Thonar *et al*. 1987; Sweet *et al*. 1988), but overlap between normal and osteoarthritic individuals is marked. Studies with animal models of osteoarthritis have almost without exception failed to show significant changes in the serum keratan sulphate in early lesions. Nevertheless, the variability of the serum keratan sulphate is less within than between patients. Rather than reflecting the status of cartilage in osteoarthritic joints, elevated levels may thus signify a systemic increase in cartilage matrix turnover and ultimately prove useful in identifying individuals at risk of developing osteoarthritis.

Rather than attempting to detect the increased rate of a normal process (e.g. the release of keratan sulphate from cartilage), it would be preferable to identify a released antigen more distinctive of abnormal tissue. Epitopes that detect changed sequences in sulphation in chondroitin sulphate chains that are found infrequently in normal mature cartilage appear to be increased in experimental models. In experimental canine osteoarthritis, for example, the expression of a chain-terminal chondroitin sulphate epitope (3B3) is greatly increased in proteoglycan from operated joints as part of the pattern of increased synthesis and turnover that also results in longer chondroitin sulphate chains: the distribution of such epitopes varies greatly in chondroitin sulphates of different origin, and their expression is closely controlled during biosynthesis (Caterson *et al*. 1990). The biological significance of the chondroitin sulphate epitopes have yet to be determined. However, they may provide useful markers of processes occurring in cartilage before major joint damage.

Collagen fragments

The C-terminal propeptide of type II collagen is cleaved off at fibrillogenesis and not retained by interaction with other matrix constituents, and is therefore a molecule with the potential for identifying repair. In urine, the determination of collagen cross-links derived from cartilage (pyridinoline) and bone (pyridinoline and deoxypyridinoline) has provided a sensitive measure of tissue breakdown (Seibel *et al*. 1989). These cross-links are only present on mature collagen; thus relative amounts may indicate different forms of stages of arthropathy involving the degradation of bone and cartilage. Recent studies using immunoassays have shown that collagen crosslinks can also be shown to be raised in osteoarthritis in serum samples (Risteli *et al*. 1993; Robins *et al*. 1994).

Little progress has been made in following the release of type II, IX, or XI fragments into synovial fluid as a measure of the dismantling of the collagen fibrillar network. Caution has to be used in synovial fluid studies as often the centrifugation of the fluid to remove any neutrophils or other cells is sufficient to sediment some of the collagen fragments. Further work is needed to establish the usefulness of the measurement of collagen fragments in osteoarthritis.

Proteinases and inhibitors

Measurement of proteinases and inhibitors in serum is often difficult as levels can be low and sometimes below the level of detection (Lohmander *et al*. 1994). Collagenase, gelatinase, stromelysin, and TIMP are present in synovial fluid but are difficult to measure as the fluid has to be fractionated before measurement to allow enzyme activity to be measured whilst inhibitors are also present (Cawston *et al*. 1984). The development of immunoassays has shown that stromelysin (Lohmander *et al*. 1993), collagenase, and tissue inhibitor of metalloproteinase (TIMP) (Clark *et al*. 1994; Shinmei *et al*. 1992) are elevated in osteoarthritis synovial fluids although there is a large variation between patients and considerable overlap between disease groups. It is not yet known if high levels of proteinase or low levels of inhibitor correlate with excess joint damage. The results are also difficult to interpret as much of the metalloproteinases present are still in proenzyme form and consequently pose no threat to the joint structures until activated. Some studies have suggested that the measurement of proteinase-inhibitor complexes are more indicative of cartilage breakdown although these results are still to be confirmed in prospective studies. Raised levels of collagenase-TIMP levels in osteoarthritis are infrequent or at least below the level of detection for the immunoassays (Clark *et al*. 1994). Many studies have investigated single samples of synovial fluid from patients. Recently Lohmander *et al*. were able to show that levels of stromelysin and TIMP remained raised for long periods after traumatic injuries in knee joints (Lohmander *et al*. 1994) and this kind of study where individual patients are followed up sequentially with clinical, radiographic, and biochemical markers measured for individual joints represents the best way forward to evaluate these markers.

Diagnosis

The diagnosis of osteoarthritis is essentially clinical and many comments regarding this have already been made in the section on investigations. There are several different clinical problems.

The patient with pain

This is the commonest clinical situation. The priorities in this situation are to determine whether:

1. 'osteoarthritis' is the cause of the symptoms;
2. there is an articular or periarticular cause for the pain;
3. there are predisposing or adverse factors for the development or progression of osteoarthritis;
4. there is another underlying arthropathy;
5. how pain is being caused and modified.

Resolving these difficulties depends on a careful clinical history and examination; radiography and laboratory investigations play a relatively minor role. The examination aims to:

1. localize the site of the pain—joint line or periarticular;
2. detect the presence of clinical signs of osteoarthritis—crepitus, bony swelling, restricted range of motion;
3. define any adverse features—obesity, malalignment, abnormal usage (occupational or habitual);
4. rule out features of other arthropathy—e.g. rheumatoid arthritis, gout, seronegative spondylarthropathy;
5. determine factors aggravating the pain response—e.g. coexistent fibromyalgia, depression, sleep disturbance.

The radiograph merely serves to confirm the presence of the structural changes of osteoarthritis that may or may not be attributable to the symptoms. Since the radiograph is relatively insensitive, particularly in early disease, a normal radiograph does not rule out a diagnosis of osteoarthritis. Conversely, as has already been discussed, an abnormal radiograph is not necessarily the cause of symptoms.

The radiographic finding

It is not uncommon for patients to have radiographs taken following an acute episode of pain or trauma, particularly of the spine, and for osteoarthritic changes to be discovered. The difficulty then lies in knowing what, if anything to do regarding these findings. Undue emphasis on the structural changes can result in patients being unduly alarmed and adopting inappropriate illness behaviour. Again a careful clinical history and examination is necessary to determine the association between the current clinical problem and any structural change.

Neurological findings

Neurological finding are important, particularly in the lumbar and cervical spine where osteophytosis of the facet or apophyseal joint may lead to foraminal encroachment and subsequent nerve root compression. Peripheral nerve entrapment may also occur as a result of osteophytosis or synovitis. Possible sites for this are the ulnar nerve at the ulnar groove and the median nerve in the carpal tunnel. In such a situation, particularly in the spine, magnetic resonance imaging, computed axial tomography, and, now less commonly, contrast radiculography is necessary to fully elucidate the nature and presence of nerve compression.

As well as direct pressure on a nerve, vascular claudication may also occur, particularly in the lumbar spine, giving rise to the syndrome of spinal claudication. In this situation, exercise results in neurological signs and symptoms in the legs. The diagnosis is essentially based on the history but evidence of canal stenosis is sought, usually with computed axial tomography or magnetic resonance imaging.

In all situations, particularly in the spine, it is essential, in view of the high prevalence of abnormal structural findings in asymptomatic individuals, to ensure that there is a good match between clinical findings and demonstrated structural abnormalities.

Pathogenesis

The nature of osteoarthritis

It has been widely suggested that osteoarthritis is a process, rather than a disease, that shows variability in outcome. Support for this comes from several considerations:

1. osteoarthritis has accompanied man throughout his evolutionary history;
2. a similar process occurs in other animals that have fused epiphyses in the adult;
3. radiographic osteoarthritis is very common in adults, showing increased frequency with age;
4. in most instances osteoarthritis occurs without symptoms or disability, and its radiographic presence is not necessarily the explanation of locomotor pain;
5. symptoms relating to osteoarthritis are often phasic and may not necessarily be associated with a poor prognosis.

Such phylogenetic preservation, discordance between symptoms and structural change, and generally good outcome suggest that osteoarthritis reflects the inherent repair process of synovial joints (Fig. 39). In most cases this metabolically active process keeps pace with a variety of triggering insults and is non-progressive. In some, however, it fails to compensate, resulting in 'joint failure' (decompensated osteoarthritis) with perceived symptoms and disability. This interpretation partly explains the marked heterogeneity of osteoarthritis—a wide variety of 'insults' triggering a repair reaction but each resulting in a different pattern of involvement. As with any biological process, multiple constitutional and environmental factors may further modify the response, leading to variable outcome.

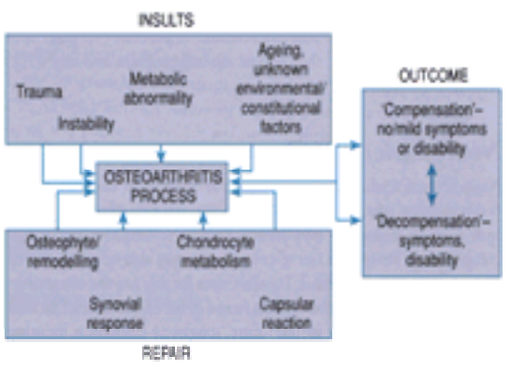

Fig. 39 Diagrammatic representation of osteoarthritis as the inherent repair process of synovial joints.

The mechanical, genetic and metabolic factors that may 'insult' the joint and thus trigger the osteoarthritis process have been discussed above. Indeed most evidence regarding the initiation of osteoarthritis in man derives from such studies since diagnosis of the early stages of sporadic osteoarthritis *in vivo* is currently not possible. The response of the joint to these insults has been studied by a variety of methods including *in vivo* animal models, *ex vivo* studies on tissue explants, and from pathological human tissue. The results from such studies and the insights which they give into the nature of osteoarthritis are discussed below.

Structure and metabolism of osteoarthritic tissues

Investigation of human osteoarthritis tissue is problematic: pathological studies often focus on late 'end-stage' osteoarthritis of surgically-derived large joints, whilst cadaveric studies examining 'early' osteoarthritis lack clinical correlates. All such studies are confounded by the heterogeneity of osteoarthritis and by restriction to single time point examination. Much work on pathophysiology therefore derives from animal models and *in vitro* experiments. Animal models often employ small quadrupeds, utilize invasive mechanical or chemical insult to stimulate joint response, or investigate hereditary forms of premature joint failure; the time scale is often short; and immature rather than mature animals may be used. Although some models (e.g. cruciate section in the adult dog) appear closer to human osteoarthritis than others, such contrasts with the clinical situation in man have raised questions as to their relevance. Rather than considering them as models of osteoarthritis, they are probably best viewed as a means of studying, in a well defined and controlled situation, dynamic biochemical and structural events at the earliest stages of joint insult. Thus, while animal models and human studies *in vitro* provide useful insights, caution is required in drawing together the available disparate data to develop a more complete understanding of pathophysiology relevant to human osteoarthritis.

Structural changes

The histological changes characteristic of osteoarthritis cartilage from humans and animal models are well described (Mankin 1974; Brandt 1988) and include:

1. reduction in stainable proteoglycan;
2. fibrillation;
3. collagen crimping;
4. chondrocyte multiplication or migration (cloning);
5. loss of cartilage (Fig. 40).

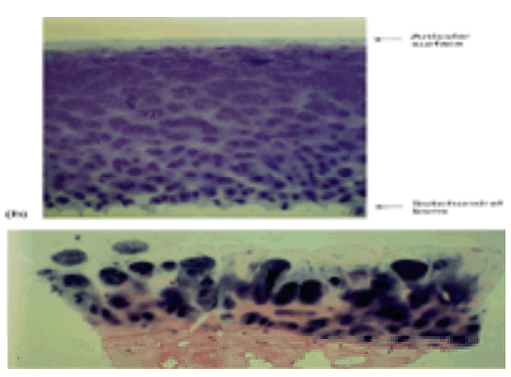

Fig. 40 (a) normal and (b) osteoarthritic human articular cartilage (toluidine blue). Note the extensive cell clustering, loss of metachromatic staining, fissuring of the tissue, and duplication of the 'tide-mark' in the osteoarthritis specimen.

Initially, localized areas of softening present a pebbled texture at the surface, followed by disruption along collagen fibre planes (tangential 'flaking', vertical 'fibrillation'). At the earliest stage of surface erosion and irregularity cartilage appears moderately hypercellular with alteration in staining quality of the matrix; the tidemark may also show irregularities and violation by blood vessels. As increasingly deep clefts form in cartilage, nearby matrix is depleted of metachromatic material indicating loss of proteoglycans. Microscopic changes are also apparent in cells, and necrosis ('ghosting') is often present. More common, however, is focal proliferation producing clumps ('clones') of chondrocytes, often surrounded by intense metachromatic material indicating increased proteoglycan. Such cell proliferation and metabolic activity represents attempted 'intrinsic' repair. With continuing movement fibrillated cartilage in habitually loaded areas may abrade to expose underlying bone, with progression to variable degrees of structural damage. It is noteworthy, however, that fibrillation itself is not necessarily progressive.

Indeed, it is a normal finding in adult human joints (e.g. hip, knee, humeroradial joint) in areas of cartilage that are habitually unloaded. In addition to intrinsic repair, 'extrinsic' repair commonly occurs by formation of new cartilage at the joint margin or in subchondral bone; such cartilage is generally more cellular than pre-existing hyaline cartilage and the chondrocytes are evenly distributed throughout the matrix. Extrinsic repair is with fibrocartilage, containing predominently type I collagen. Proliferating nodules of fibrocartilage arising from underlying marrow spaces may protrude through defects in the bone surface, occasionally coalescing to form a near continuous layer of replacement tissue.

In parallel with the cartilage changes, new bone formation occurs in subchondral bone and at the joint margins (central and marginal osteophyte), and occasionally beneath adjacent periosteum (e.g. femoral neck 'buttressing'—periosteal osteophyte). Osteophyte forms through the process of endochondral ossification, either by vascular penetration of existing cartilage or from marginal foci of cartilaginous metaplasia, particularly at capsular and ligamentous insertion sites. The location of osteophyte is characteristic for individual joints. Proliferation of subchondral bone is most apparent beneath areas of cartilage erosion and fibrillation. In such areas the tidemark is generally more irregular, thickened, and reduplicated (showing often three or more parallel tidemarks); new bone and thickening of existing trabeculas gives rise to sclerosis seen radiographically. With gross cartilage loss repeated motion may polish the bone ('eburnation') and, as a result of increased local stress, surface bone additionally may undergo focal pressure necrosis. Subarticular cysts (more correctly 'pseudocysts') predominate where overlying cartilage is thinned or absent. Pathologically, cysts show features of bone necrosis (loss of trabeculas, fibromyxomatous degeneration of marrow), frequently contain dead bone, cartilage, and amorphous material, and are surrounded by a rim of reactive new bone and fibrous tissue. They are thought to result from high intra-articular pressure transmitted through defects (microfractures) in the overlying cortex, or from intraosseous hypertension generated through abnormal loading and force transmission in the mechanically altered joint. As with fibrillation, both marginal osteophyte and cysts may occur in the absence of other features of osteoarthritis, reflecting bone response to mechanical stimulation.

Separated fragments of cartilage and bone may form 'loose bodies', undergo dissolution, or become incorporated into the synovium and proliferate locally. As they grow, their centres necrose and calcify, and periodic extensions give rise to a concentric ringed appearance: endochondral ossification of these bodies may follow vascular invasion. Osteochondral bodies may also arise in synovium by chondroid metaplasia of fibroblastic cells.

The synovium becomes both hypertrophic and hyperplastic, and the capsule thickens and contracts. In the synovium lymphoid follicles, as well as more diffuse infiltration by T and B lymphocytes and macrophages (DR positive), may be identified (Revell *et al*. 1988), often with accompanying diffuse and perivascular fibrosis. Synovial extension onto the articular surface (i.e. pannus) is common, particularly at the hip, but both synovitis and pannus are less extensive and aggressive than in rheumatoid arthritis, synovitis usually being confined to synovium rimming the cartilage. Haemosiderin staining of synovium, reflecting previous intra-articular bleeding, is common in large joints, and occasionally is marked. The role of particulate debris (osteochondral fragments, calcium crystals) in producing chronic inflammation is uncertain but, in general, synovitis is regarded more as a secondary, usually late phenomenon than a primary, early event in osteoarthritis.

Calcification is an integral part of new bone formation, and many osteoarthritis joints show evidence of calcium crystal deposition in cartilage, with presumed secondary uptake in synovium. Carbonate-substituted hydroxyapatite is the commonest particulate identified, particularly adjacent to hypertrophic and degenerating chondrocytes (Ohira and Ishikawa 1987). Calcium pyrophosphate dihydrate crystal deposition also associates with osteoarthritis at certain sites, particularly in the elderly (Felson *et al*. 1989). The relationship between calcium crystal formation and osteoarthritis is unclear.

Despite loss of bone and cartilage in some parts of the joint, the net effect of new cartilage and bone formation is an increase in joint size and remodelling of shape. The balance between degradative and reparative features is variable and leads to varying consequences with respect to joint congruity, stability, and load transmission. Associated periarticular abnormalities (muscle atrophy, bursitis, enthesitis) are a common accompaniment to established osteoarthritis. The radiographical–pathological correlations seen in osteoarthritis are outlined in Table 1.

Metabolic changes

Though changes occur in all joint tissues in osteoarthritis, most experimental work has investigated cartilage (Maroudas and Urban 1980; Hardingham and Bayliss 1990). The extracellular matrix of cartilage is complex, and its composition and turnover vary:

1. in different joints;
2. at different locations within the same joint;
3. through the depth of the tissue.

The initiating insult (e.g. mechanical, metabolic) also varies and age-related changes occur. It is sometimes, therefore, difficult to identify common events in osteoarthritis (Table 10).

Table 10 Metabolic changes in osteoarthritic cartilage

Analytical studies

The changes in composition of osteoarthritis cartilage, which are markedly different from those due to ageing, include:

1. an increase in water content;
2. a loosening of the 'collagen network' with a reduction in collagen fibre size, though the collagen concentration and phenotypes appear normal;
3. a reduction in proteoglycan concentration with a smaller proportion of total proteoglycan in aggregates, and alteration in proteoglycan structure.

Whereas ageing human cartilage undergoes some degree of dehydration, osteoarthritis cartilage has an increased water content. This increase is one of the earliest changes detected in animal models—initially within loaded regions but eventually involving all of the cartilage. This change probably reflects a defect in the arrangement of collagen fibres that allows proteoglycans to swell. The marked swelling of osteoarthritic cartilage when placed in hypotonic solutions *in vitro* is consistent with a loosening of the collagen network, and ultrastructural studies using animal models confirm early loss of orientation among superficial collagen fibrils, with individual fibrils being more widely spaced than normal. This basic structural change may arise in type II collagen fibres themselves (Maroudas *et al*. 1986), or more likely in cross-link molecules such as type IX collagen, a decrease of which (with little change in production) is reported in the rabbit postmeniscectomy model and in human osteoarthritis. A recent study (Bonassar *et al*. 1995) has shown that this increase in swelling can be mimicked by treatment of cartilage with stromelysin.

A decrease in proteoglycan content is the most consistent feature found in all studies of osteoarthritis. The main finding for glycosaminoglycans in human osteoarthritic cartilage is a decrease in keratan sulphate content. This is a real event, not merely reflecting a decrease in cartilage thickness (the deeper layers of normal cartilage are richer in keratan sulphate than the surface zones). The concomitant decrease in chondroitin-6-sulphate relative to chondroitin-4-sulphate gives an overall composition akin to that of immature cartilage, suggesting that, in osteoarthritis, chondrocytes revert to a chondroblastic state and synthesize fetal-like, immature proteoglycan. Because of the uncertainty over the production of the proteoglycan, however, it remains unclear in established human osteoarthritis if such

changes are biosynthetic or arise primarily from catabolic events.

Changes in keratan sulphate:chondroitin-6/-4-sulphate ratios are an inconsistent finding in animal models, and such changes may principally occur late in the pathogenesis. Specific modifications in the sulphation of chondroitin sulphate chains, however, appear early in animal models (at 3 months in Pond–Nuki model) and may relate to larger chain size; in addition, proteoglycans from cartilage with activated chondrocytes react with monoclonal antibodies to novel sequences of sulphation on chondroitin sulphate chains (similar epitopes being detected in proteoglycan from human osteoarthritis and normal immature cartilage). The significance of these structural changes in chondroitin sulphate is unknown, though one function may be to increase matrix binding of growth factors, thereby increasing the local pool of these agents.

There is little evidence from animal or human studies to suggest that proteoglycan is lost from the matrix through any abnormalities in its ability to aggregate. Aggregation of proteoglycan appears to be normal, and although the hyaluronan content of osteoarthritic cartilage is reportedly low, there appears sufficient to accommodate the reduced concentration of proteoglycan (Brocklehurst *et al*. 1984). The hyaluronan-binding regions of most proteoglycan monomers in osteoarthritic cartilage appear fully functional. In most animal models this also applies to newly synthesized proteoglycans, even though they are often larger than normal. In cartilage from late-stage human osteoarthritis, the assembly of newly synthesized proteoglycans into aggregates in the extracellular matrix appears faster than in normal adult joints, and more similar to that in immature cartilage. This aspect of proteoglycan structure could profoundly affect turnover rates and complicate further our understanding of mechanisms of cartilage repair.

Growth factors and cytokines

Matrix synthesis

The compositional changes occur as chondrocytes respond to a variety of growth factors and cytokines and so alter the rate of proliferation or either synthesis and/or degradation of these matrix components (Goldring 1993). A number of cytokines and growth factors are listed together with the possible effect shown on matrix metabolism (Table 11).

Growth factor	Major function in cartilage
TGFβ	Chondrocyte proliferation, promotes matrix synthesis, modulates IL-1 effects, increases proteinase inhibitors
PDGF	Proliferation of chondrocytes
bFGF	Proliferation and differentiation of chondrocytes, MMP production
IGF-1	Proliferation of chondrocytes, increases GAG synthesis
IL-1	Increases production of MMPs, PGE_2, and other cytokines; inhibits GAG synthesis
TNF-α	Similar catabolic effects as IL-1
IL-6	Increases proteinase inhibitor production, proliferation of chondrocytes

TGFβ, Transforming growth factor β; IL-1, interleukin-1; PDGF, platelet derived growth factor; IGF-1, insulin growth factor; TNF-α, tumour necrosis factor α; MMPs, Matrix metalloproteinases; PGE_2, prostaglandin E_2; GAG, glycosaminoglycans; IL-6, interleukin-6.

Table 11 Effect of cytokines and growth factors on chondrocyte metabolism

Chondrocytes can increase their biosynthesis to counteract increased loss, particularly early rather than late in the process. For example in the Pond–Nuki model (section of the anterior cruciate ligament in the mature canine stifle joint), chondrocytes from macroscopically normal cartilage show increased incorporation of ^{35}S-sulphate as an early feature that predates fibrillation, and other areas of cartilage that do not proceed to fibrillation may also show this change. In other models early hypermetabolic activity cannot be demonstrated, and whether increased synthesis occurs in early human osteoarthritis remains speculative.

In established human osteoarthritis, the variability in proteoglycan synthesis reported from different centres (i.e. increased or normal) may reflect sampling differences as much as variability of osteoarthritis itself. For example in reports of increased ^{35}S-sulphate incorporation by human osteoarthritic cartilage, with correlation between synthetic activity and histological grading (Ryu *et al*. 1984), the high-scoring samples could be mainly mid- and deep-zone cartilage, which in normal tissue contains cells with higher synthetic rates. After 'correcting' for topographical and zonal sampling, no difference in proteoglycan synthesis is apparent between osteoarthritic and normal, age-matched cartilage at the hip or knee (Brocklehurst *et al*. 1984). There is some evidence that proteoglycan synthesis is decreased in human osteoarthritis and it is also possible that these synthetic rates are affected by the drugs taken by patients. In late human osteoarthritis it is therefore unclear whether chondrocytes are metabolically hyperactive or whether their potential reparative response has been inhibited or lost.

Chondrocytes show an increased rate of synthesis of type II collagen, as with proteoglycans, early in animal models. The long turnover time of type II collagen in adult cartilage might suggest that mature chondrocytes have little chance of even minimal repair of defective collagen network. Nevertheless, an increase in collagen synthesis in human osteoarthritic cartilage has been demonstrated (Lipiello *et al*. 1977). When type II collagen fibrils form in the extracellular matrix, the N- and C-propeptides are removed by specific proteases and are lost from the matrix. Increased C-propeptide (CP-II) is found in human osteoarthritic compared to normal cartilage, mainly in the lower mid- and deep zones rather than the surface and upper mid zones where collagen degradation is more prevalent (Dodge and Poole 1989). There may thus be the potential for limited repair in deep zones, but an effective response in late osteoarthritis, when major disruption in collagen architecture has occurred, seems less likely.

Type X collagen, with its presumed role in mineralization, is regarded as a unique marker for hypertrophic chondrocytes, which are also rich in alkaline phosphatase activity. In osteoarthritic cartilage the alkaline phosphatase activity is very high, not just in the deep but also in the mid-zones (Fig. 41), and deposition of type X collagen once again becomes evident. Such characteristics are reminiscent of immature cartilage, and suggest that chondrocytes throughout the cartilage are resuming their potential to mineralize.

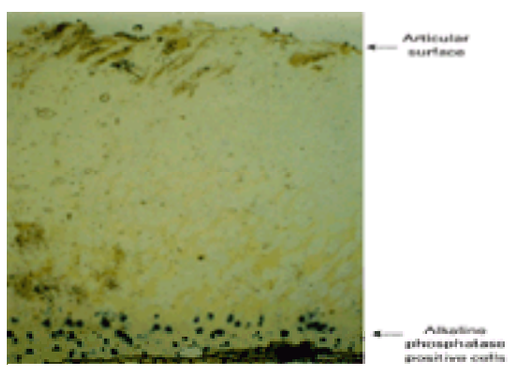

Fig. 41 Localization of alkaline phosphatase in human osteoarthritic cartilage (55-year-old patient).

Matrix degradation

Just as anabolic growth factors can influence matrix synthesis, the proinflammatory cytokines can increase matrix degradation. Both interleukin 1 and tumour necrosis factor are present in cartilage which is degrading extracellular matrix (Table 11) (Hammerman 1989; Goldring 1993). These cytokines when added to cartilage rapidly cause the release of proteoglycan with the later release of collagen fragments (Ellis *et al*. 1994). At the same time the synthesis of matrix components is also down regulated. It is not known exactly how proteoglycan and collagen turnover is increased in response to these cytokines but the levels of the matrix metalloproteinases

are increased (Murphy *et al*. 1991). This family of zinc and calcium dependant proteinases can degrade the proteins of the extracellular matrix at neutral pH and are divided into three main groups—the collagenases, the stromelysins, and the gelatinases (Fig. 42) (Woessner 1992; Brinkerhoff 1991). These enzymes contain common sequences of amino acids; the N-terminal domain contains a characteristic sequence of zinc-binding histidines and contains the catalytic zinc whilst the C-terminal domain determines the differences in substrate specificity. The matrix metalloproteinases can be controlled at different points (Fig. 43) which include stimulation of synthesis and secretion by cytokines, activation of proenzyme forms, and the inhibition by specific inhibitors called TIMPs. These enzymes are found in osteoarthritic cartilage and osteoarthritic cartilage appears deficient in endogenous protease inhibitors (Woessner 1992). This imbalance between matrix metalloproteinases and their inhibitors is likely to play a part in the accelerated breakdown of the matrix (Hammerman 1989; Dean *et al*. 1989). Specific inhibitors of matrix metalloproteinases are able to prevent both proteoglycan and collagen release from resorbing cartilage *in vitro* and in animal models (Andrews *et al*. 1992; Cawston *et al*. 1994). Other proteinases are also implicated in the destruction of cartilage in osteoarthritis (Buttle *et al*. 1993).

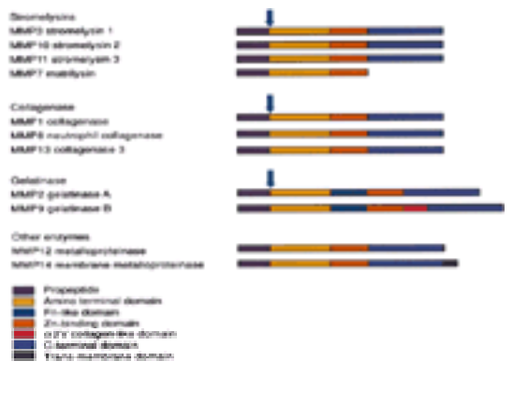

Fig. 42 Metalloproteinase domain structure.

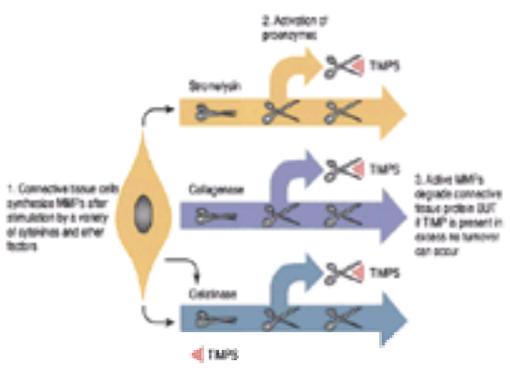

Fig. 43 Control of metalloproteinase activity.

Recently, the analysis of the fragments released from resorbing cartilage have been studied in order to determine degradative mechanisms. Proteoglycans released from osteoarthritic cartilage during culture *in vitro* cannot interact with hyaluronan and presumably have lost their hyaluronan-binding region. Analysis of the proteoglycan fragments suggest that an unidentified metalloproteinase called aggrecanase is responsible, as the cleavage site in the aggrecan molecule is not cleaved by any known enzyme (Sandy *et al*. 1992). Other studies have used a unique epitope hidden in native collagen but exposed by proteolytic cleavage to follow collagen turnover. In osteoarthritis, cartilage collagen cleavage can be shown by immunohistochemistry in both the superficial and intermediate zones (Hollander *et al*. 1994; Poole 1993).

Debate still continues over the relative importance of cartilage and bone changes in the initiation and progression of osteoarthritis. It is recognized that physiology and structure are initimately linked and that all joint tissues (including synovium, capsule, and periarticular tissues) interact together. Thus 'weakening' of cartilage and surrounding tissues and 'stiffening' of subchondral bone will each be deleterious in all tissues. All locomotor tissues require continuing physical stimulation to sustain normal development, nutrition, and adaptation. Interestingly, many of the metabolic and structural responses of cartilage and bone seen in animal models only develop if joint loading continues, suggesting that the potential repair process of joints is similarly driven by this physiological need. A more pressing question, of course, is what stops all joints progressing once cartilage loss and altered biomechanics have occurred. Articular cartilage has only a limited ability to 'repair' whereas bone is able to remodel and readily adapt to changing biochemical requirements. With respect to progression or non-progression in osteoarthritis, it may be that bone response and less investigated aspects (e.g. neuromuscular control, capsular fibrosis) will also prove to be important.

Management

There is no proven, effective treatment for the osteoarthritis process. Nevertheless, considerable benefit to the patient can be achieved by often very simple interventions, and surgery for severe 'end stage,' particularly large joint, osteoarthritis is excellent. The principal goals of management are:

1. education of the patient about osteoarthritis;
2. pain relief;
3. achieving and maintaining optimal joint and limb function.

A wide variety of modalities are available to realize these goals (Table 12), and an approach to management is outlined in the Management Summary (Box 1). As with any branch of medicine, an 'holistic' approach is appropriate and more likely to succeed. The frequent discordance between structural change, symptoms, and function is pertinent; since pain and physical handicap are the main clinical problems arising from osteoarthritis, their causes and treatment usually need consideration as independent issues.

Goals of management

Table 12 Current management of osteoarthritis

Box 1 Management summary

- Education concerning osteoarthritis
- Protect compromised joints from excessive loading, e.g.:
  - Reduce obesity
  - Modify inappropriate daily/occupational activities
  - Use a walking stick
  - Shock-absorbing insoles
  - Correct leg length discrepancy
- Maintain aerobic fitness, e.g., with swimming and/or walking
- Maintain joint motion and stability
  - Regular movement - 'little and often'
  - Muscle strengthening exercises
- Reduce pain and stiffness, e.g.:
  - Physiotherapy
- Intermittent analgesics
  - Consider topical NSAIDs
  - Consider occasional courses of NSAIDs
  - Consider peri- and intra-articular injection
  - Consider TENS and nerve blocks for severe pain
- Reduce impact of pain and disability
  - Treat depression, anxiety, fibromyalgia
  - Consider coping strategies
  - Modify patient environment to reduce handicap
- Consider surgery for:
  - Persistent severe pain
  - Disability

General approach

Successful management centres on careful questioning and examination of the patient. The history should yield clear information particularly about:

1. symptoms and their impact on the patients life;
2. functional disability;
3. functional requirements and thus the level of handicap;
4. patient expectations both from osteoarthritis and its treatment;
5. psychological factors including specific concerns and depression.

Careful examination should determine the:

1. extent of locomotor abnormality;
2. origin of current pain, either articular and/or periarticular;
3. degree of accompanying synovitis;
4. presence of instability;
5. local and general muscle condition;
6. evidence of accompanying fibromyalgia, neurological, or other relevant medical disease.

An accurate diagnosis can thus be made, the extent of the problems assessed, and any associated factors identified. An individual management programme can then be constructed. The results of such interventions need to be reviewed and the programme modified as the patient's characteristics and requirements change. As symptomatic osteoarthritis is a potentially complex problem, it often requires a co-ordinated approach.

Helping the patient understand osteoarthritis

The myth that osteoarthritis is an inevitable, progressive wear and tear disease of old age persists. This leads to negative attitudes in both patients and doctors and may encourage inappropriate action, for example reduced activity for fear of 'wearing the joints out'. It is important that all those involved in patient management have similar concepts so that conflicting information is avoided. It is also important to address the questions that the patient wants answered, and to respond in a manner understandable to the patient. For example most patients want to know about diet, exercise, and factors in their life that may have brought on their arthritis; explanation of cartilage and bone changes may have little relevance for them. Although the natural history of osteoarthritis is poorly documented, available data suggests that it is often considerably better than patients expect. This is not only true for hand involvement in nodal generalized osteoarthritis but also at the hip and knee. A reasonably optimistic, though not unrealistic, approach is therefore justified.

Addressing mechanical factors

Protecting compromised osteoarthritis joints from excessive or unusual loading often reduces pain. Obesity increases loading on many, not just 'weight-bearing', joints during daily activities, and obese patients are best advised to lose weight. Some prospective data suggest that such weight loss may prevent the development of osteoarthritis (Felson *et al*. 1991). Its role in established osteoarthritis, though logical, is unproven. An initially reducing, though well balanced and 'healthy' diet should therefore be encouraged. Appropriate use of a walking stick for hip or knee osteoarthritis will help reduce loading through the affected joint, and shock-absorbing footwear (e.g. 'trainers') may reduce impact; both manoeuvres may benefit symptoms. Altered mechanics due to leg length discrepancy may produce pain which is commonly periarticular and correction with a heel raise should be undertaken.

Occupational therapy advice concerning 'joint protection' and appropriate manoeuvres for activities of daily living may markedly reduce unnecessary overloading of upper and lower limb joints. Modification of both workplace and home activities should be considered if appropriate. Appropriate advice regarding sexual activity may also be helpful, particularly for women with hip osteoarthritis and their partners.

The integrity of articular tissues is maintained, and repair of damaged cartilage facilitated, by normal movement and loading of the joint. Patients should therefore be advised to keep active, within the bounds of common sense. 'Little and often' is prudent advice and particular emphasis should be on aerobic exercise since this has been demonstrated to be of symptomatic benefit in osteoarthritis (Minor *et al*. 1989; Kovar *et al*. 1992). Bland and Cooper recommend a comprehensive 'rest–exercise programme' based on the rationale that activity aids repair, whereas rest allows rehydration and recovery of cartilage after loading (Bland and Cooper 1984). It is difficult to obtain direct evidence for this in man, but there are considerable experimental data to support this concept. Data on the efficacy of muscle strengthening regimes in improving osteoarthritis are surprisingly sparse and often poorly controlled. The finding, however that quadriceps weakness is closely associated with disability in knee osteoarthritis (McAlindon *et al*. 1993) has led to renewed impetus to explore this area. In contrast, more evidence exists that aerobic exercise that improves fitness as well as improving self-efficacy may be beneficial in osteoarthritis (Minor *et al*. 1989; Kovar *et al*. 1992). All patients with osteoarthritis should be encouraged to maintain activity.

Direct attempts to relieve symptoms

A variety of physical measures, such as local heat, cold, massage, or hydrotherapy, may give temporary pain relief. Such modalities are usually administered initially by physiotherapists, and there is considerable interpatient variability as to which may help.

Simple analgesics and non-steroidal anti-inflammatory drugs are commonly used with good benefit. They should be regarded as an adjunct, rather than substitute, for other treatments. Comparative studies suggest that non-steroidal anti-inflammatory drugs are just marginally, or even no more effective than analgesics (Bradley *et al*. 1992; Williams *et al*. 1993; March *et al*. 1994). Non-steroidal anti-inflammatory drugs are, however, associated with a significant number of side-effects, particularly in the elderly. Simple analgesics should therefore be tried first, including a trial at maximal regular dosage. If unsuccessful, sequential trials of several non-steroidal anti-inflammatory drugs may be considered. There is currently no convincing evidence that one non-steroidal anti-inflammatory drug is superior to another in the symptomatic relief of osteoarthritis. There are, however, emerging differences in the side-effect profiles of different non-steroidal anti-inflammatory drugs (see Chapter 3.5.1). It would therefore seem prudent to begin with a drug with a lower incidence of gastrointestinal side-effects such as ibuprofen or nabumatone before using alternative agents. Due to marked interpatient variability several non-steroidal anti-inflammatory drugs may have to be tried to find which best suits the individual. The patient should be made aware that the aim of these drugs is to reduce, rather than abolish, pain and that they need only be taken when symptoms are bad. Symptoms in osteoarthritis are often phasic: repeat prescribing is to be avoided, and if a patient is taking an non-steroidal anti-inflammatory drug with apparent benefit they

should still regularly experiment by stopping the drug to see whether it is still needed. The possibility that non-steroidal anti-inflammatory drugs may affect the osteoarthritis process remains controversial.

Topically applied non-steroidal anti-inflammatory drugs offer considerable theoretical advantage over oral preparations in terms of reduced side-effects. Although there may be benefit for small superficial joints (e.g. hands) and ossibly the knee, deep-seated large joints (particularly hip and glenohumeral joints) are less amenable to this approach. It remains unclear whether such agents are any more effective than simple rubefacients.

If pain is thought to be predominantly periarticular in origin, due to enthesopathy or bursitis, then local injection of corticosteroid, possibly with local anaesthetic to the tender site, may prove helpful. Indeed one study has even suggested that peripatellar injection is as effective as intra-articular injection in knee osteoarthritis (Sambrook *et al*. 1987). Even temporary symptom improvement may permit involvement in other aspects of the management programme (e.g. exercise), and engender a more positive approach by the patient.

In patients with symptoms unresponsive to other measures, local injection with corticosteroid may produce temporary benefit, permitting involvement in physiotherapy and exercise, or allowing the patient to undertake a 'special event', for example a holiday or a family occasion. Anecdotally single injection at some sites, notably the thumb base, may provide surprisingly prolonged relief. Intra-articular injection of steroid, however, is controversial. Although studies in knee osteoarthritis show benefit over saline injection this effect is short-lived, probably lasting less than 6 weeks (Gaffney *et al*. 1995). Furthermore, the possibility of steroid-induced cartilage attrition (derived from animal work) is often cited when the issue of injection frequency is raised. The data from animal models is, however, conflicting. Individual patients, often those too infirm or otherwise unsuitable for alternative approaches, undoubtedly derive considerable benefit from occasional injection.

Patients with chronic pyrophosphate arthropathy and persistent synovitis who respond only temporarily to steroid injection may gain more prolonged control of synovitis and symptoms from intra-articular radiocolloid (Doherty and Dieppe 1981). Whether successful control of synovitis alters long term outcome is unclear.

Intra-articular hyaluronate preparations are now available for use in some countries. Their symptomatic benefit has been demonstrated in some but not all clinical trials. Their role is currently unclear. Not all patients derive benefit and most regimens require weekly injections over a period of 3 to 5 weeks. Although putative 'chondroprotective' effects have been demonstrated *in vitro* this has yet to be demonstrated in man. Whether such agents will become more widely available and used is to our minds unclear. Other intra-articular agents, such as the superoxide dismutase inhibitor orgotein, have also undergone promising clinical trials but as yet they remain experimental therapies.

Joint, principally hip, distension with saline is claimed to offer quite prolonged symptomatic benefit. It is a technique used principally in Europe. The proposed rationale is that capsular stretching, with or without rupture, results in reduced intra-articular hypertension.

For patients with troublesome knee synovitis joint lavage with saline either arthroscopically or via percutaneous irrigation may offer benefit, sometimes for several months. The mechanism of this non-specific treatment is unclear.

Local nerve blocks, particularly suprascapular and obturator blocks for glenohumeral and hip osteoarthritis, are also worthy of consideration. These have less side-effects, and are generally more effective than major, centrally acting analgesics. A word of caution has been raised by retrospective studies that have suggested more rapid deterioration in patients treated in this manner. Since these procedures are usually used in patients unfit for or awaiting replacement arthroplasty this fear may be unwarranted.

Coping with osteoarthritis

The ability to cope with chronic pain and disability varies greatly between individuals, and depends on multiple factors. Depression, often unrecognized, is certainly common in patients with osteoarthritis and is perhaps too often overlooked, preventing appropriate treatment. Fibromyalgia (chronic fatigue syndrome) may also be common, and again needs recognition and incorporation into the management programme. Even in the absence of depression, anxiety, or fibromyalgia, 'coping strategies' may improve the individual's response to pain and disability without altering the nature of the condition itself. Certain aspects of complementary medicine (e.g. herbal and dietary additives, magnets, charms) may fall into this category, as can meditation, yoga, psychotherapy (group or individual), and religion. Many patients turn to such supportive activities themselves, though it is apparent that many doctors, whilst perfectly happy with the concept of 'placebo effect', still underestimate and therefore underuse such strategies.

Surgery (see also Chapter 6.1)

The biggest revolution in osteoarthritis therapy undoubtedly has been the treatment of severe disease by surgery. The three principal surgical interventions for hips and knees are osteotomy, arthroplasty, and arthroscopy.

Osteotomy provides immediate pain relief, possibly by reduction in raised intraosseous pressure, and long-term benefit, presumably by alteration of mechanical forces and correction of joint deformity. These observations demonstrate that pain relief can occur without altering joint damage, and that the osteoarthritis joint surface can repair with fibrocartilage, which can function adequately for everyday use. Osteotomy needs careful planning and precision for success, and is still used at the knee, and by enthusiasts at the hip.

The overt success of hip arthroplasty has encouraged widespread use of this procedure. Surgeons, however, now face the growing challenge of revision and salvage operations for failed arthroplasties, and this is one aspect where osteotomy carries major advantage. Given the unpredictable natural history of large joint osteoarthritis, the frequency of the condition, and cost-benefit ratio in relation to non-operative therapy, the indications and timing of replacement surgery present difficulties. As new medical interventions become available the role of surgery will require continual reappraisal.

Arthroscopy is increasingly used for osteoarthritis. It allows direct inspection of the articular surface enabling the detection and assessment of minor degrees of articular cartilage damage. It also allows visualization and surgical correction of ligamentous and meniscal injury. These are increasingly being recognized as important accompaniments and possibly even initiating factors in osteoarthritis. Finally it is also a means whereby joint lavage and removal of 'loose bodies' can be performed. The precise role of arthroscopy in the management of osteoarthritis still remains to be defined (Casscells 1990).

Can we modify osteoarthritis ?—the concept of 'chondroprotection'

The possibility of therapeutic manipulation of the osteoarthritic process (in favour of repair) has gained momentum in the last decade. Much interest focuses on the already available non-steroidal anti-inflammatory drugs, though hyaluronate, sulphated glycosaminoglycans, and cartilage extracts have also been examined in this respect. At present, convincing human data on such compounds are lacking; nevertheless, this is a growing and potentially exciting field that has relevance beyond the sphere of osteoarthritis.

There is considerable *in vitro* and *in vivo* evidence that different non-steroidals may:

1. variably influence several aspects of cartilage metabolism;
2. show either detrimental or protective effects in spontaneous or induced animal models of 'osteoarthritis' (Ghosh 1988).

The mechanisms of such actions remain unexplained but appear largely independent of prostaglandin inhibition. They could well affect either the amount of cytokine produced or the response of chondrocytes to cytokines. Interestingly, susceptibility to influence by non-steroidals appears greater for osteoarthritic than for normal cartilage. This could relate to:

1. increased drug delivery from the hypervascular synovium and breaching of the calcified zone by subchondral vessels;
2. enhanced drug penetration due to the increased surface area of fissured cartilage and its altered charge characteristics;
3. increased susceptibility of stimulated chondrocytes.

Notwithstanding certain problems with such experimental data (Doherty 1989), it is apparent that many non-steroidals have suppressive effects on proteoglycan

synthesis and other aspects of cartilage metabolism that may be considered potentially detrimental; conversely, others have little or no suppressive effects at concentrations usually attained in man, and may be beneficial to compromised cartilage. Such observations cannot be directly extrapolated to the clinical situation of human osteoarthritis, and unfortunately there are few studies to date that have directly addressed whether non-steroidals influence (beneficially or detrimentally) the process of osteoarthritis in man.

The possibility that non-steroidal anti-inflammatory drugs are detrimental to osteoarthritis of the hip is supported by two studies reporting greater radiographic destructive change in patients taking indomethacin (Ronningen and Langeland 1979) or regular non-steroidals (Newman and Ling 1985) than in those receiving no indomethacin or infrequent non-steroidals. Both studies, however, can be criticized in terms of retrospective design, small numbers, radiographic assessment, and lack of control for factors that may influence progression. Different conclusions were reached in a prospective study of both osteoarthritic and rheumatoid hips, which implicated obesity, but not non-steroidals in the rate of loss of femoral head height (Watson 1976). A more recent prospective study of patients with osteoarthritis of the hip (Rashad *et al*. 1989) found more rapid radiographic progression and a shorter interval before surgery in patients taking indomethacin compared to those taking azapropazone. However, this study is again readily criticized, for example, in terms of radiographic assessment, lack of control for risk factors for progression, questionable criteria for surgical intervention, and lack of blinding in respect to treatments. It is known that several different non-steroidal anti-inflammatory drugs exert profound inhibition of heterotopic new bone formation after hip arthroplasty—an effect that would not be expected to be beneficial to the remodelling of osteoarthritic joints (Doherty 1990).

Some recent progress has been made with the design of low molecular weight inhibitors of the matrix metalloproteinases that have been shown to be effective *in vitro* and in animal models *in vivo* at preventing cartilage breakdown (Cawston 1995). Such compounds are under development and need to be tested in man to determine if cartilage and bone can be protected from degradative enzymes (Vincenti 1994). These trials are likely to be lengthy and costly as the destruction of tissue is relatively slow but such compounds could protect osteoarthritic cartilage.

The problem remains that, because of the heterogeneity of osteoarthritis, the chronicity of the condition, the discordance between anatomical, functional, and symptomatic manifestations, and unresolved difficulties of assessment, studies seeking to demonstrate even marked differences between drugs prove impracticable to organize. An alternative strategy may be to follow two treatment cohorts of patients with unilateral osteoarthritis of the knee (at high risk of developing this condition on the other side) and observe whether one cohort demonstrates less recruitment of osteoarthritis at new sites than the other.

Though cartilage may be the best understood component and the usual focus of interest, it should be remembered that other joint tissues (bone, capsule, synovium, muscle) may also influence the outcome of osteoarthritis. The term 'chondroprotection' is thus misleading; therapeutic modifications (good or bad) of all joint tissues requires consideration.

Prognosis

For such a common disease, the prognosis of osteoarthritis is largely unknown. From the data that is available one can be relatively optimistic about outcome for most patients. Attempts have been made to define the outcome for different subsets of osteoarthritis. By and large this has been difficult to do. The data will now be discussed by joint site and by osteoarthritis subset.

Knee

There is some data available regarding prognosis for knee osteoarthritis. The natural history of knee osteoarthritis may be less favourable than that for hips. Hernborg and Nilsson observed clinical and radiographic deterioration in the majority of cases followed for 10 to 18 years, with varus deformity, earlier age of onset, and being female relating to worse prognosis (Hernborg and Nilsson 1977). Isolated osteophytosis alone was shown not to associate with subsequent development of osteoarthritis change. In a long-term (12-year) study investigating cartilage loss in the general population (Schouten *et al*. 1992) obesity, presence of generalized osteoarthritis, age and varus/valgus knee deformity were all associated with progressive loss of cartilage. In a study of hospital-referred patients, only the presence of inflammation and calcium pyrophosphate deposition was associated with progression (Ledingham *et al*. 1995). In addition to increased morbidity, knee osteoarthritis is associated with increased mortality (Danielsson and Hernborg 1970; Lawrence *et al*. 1990).

Hip

The general view of inevitable progression in the majority of hip osteoarthritis patients may be unwarranted. In a 10-year, follow-up study, Danielsson found deterioration in symptoms in only 17 per cent of hip osteoarthritis subjects, symptoms improving over this period in 59 per cent, and completely resolving in 12 per cent; radiographic changes similarly showed progression in only a minority of cases, principally those with initial superolateral migration (Danielsson 1964). Furthermore patients with apparently progressive osteoarthritis who then improve with spontaneous 'healing' on radiographs (remodelling and partial restoration of joint space) are well described (Perry *et al*. 1972). Possible risk factors for progression (rather than development) include: superior pole pattern (Danielsson 1964); obesity (Watson 1976); presence of chondrocalcinosis at other sites (Menkes *et al*. 1985); and possibly non-steroidal anti-inflammatory drug usage (Ronningen and Langeland 1979; Newman and Ling 1985; Rashad *et al*. 1989). Evidence for the latter, however, is far from convincing (Doherty 1989).

Hand

The prognosis for hand osteoarthritis is generally good. Symptoms and hand function of nodal generalized osteoarthritis patients examined two or more decades after onset is no worse than that of similarly aged subjects with no hand osteoarthritis (Pattrick *et al*. 1989b). In contrast, in erosive osteoarthritis, in which bony ankylosis and instability is more common, long-term functional outcome may be worse (Pattrick *et al*. 1989b).

Functional outcome for thumb base involvement, carpometacarpophalangeal joint, and scaphotrapezoid disease is less clear-cut but again may be relatively poor.

Spine

Prognosis for osteoarthritis of the spine is unclear. This is largely because of the difficulty of correlating symptoms with structural change. In cases of either cord or nerve root compression prognosis is unclear, with deterioration often being slow.

Chronic pyrophosphate arthropathy

The natural history of chronic pyrophosphate arthropathy is poorly documented. Despite often severe symptoms and structural change at presentation, one 5-year, hospital-based, prospective study (Doherty and Dieppe 1988) suggests that most patients run a benign course, particularly with respect to small and medium-sized joint involvement. As expected symptomatic deterioration occurred mainly in large lower limb joints, but even in severely affected knees (the usual presenting site), two-thirds of patients showed stabilization or improvement of symptoms. The commonest radiographic change is an increase in osteophyte with bone remodelling, rather than progressive cartilage and bone attrition. Nevertheless, severe, progressive 'destructive pyrophosphate arthropathy' may occasionally occur, particularly at the knee, shoulder, and hip. This is virtually confined to elderly women or in association with haemochromatosis and may cause problematic recurrent haemarthrosis and a radiographic appearance of marked destruction resembling a Charcot or neuropathic joint.

Apatite associated destructive arthropathy

The prognosis of this form is seemingly poor with the majority having marked joint destruction requiring joint replacement.

5.16 Crystal arthropathies

Ann K. Rosenthal

The crystal arthropathies include gout, calcium pyrophosphate dihydrate (**CPPD**) deposition disease, the basic calcium phosphate (**BCP**)-associated syndromes, and calcium oxalate arthritis. The most common forms of crystal-associated arthritis are readily diagnosed at the bedside, and yet continue to present many challenges to the clinician.

Gout

History

Gout is one of the oldest known forms of arthritis, and holds a unique place in the history of medicine. Famous physicians such as Hippocrates (1886) and Sydenham (Copeman 1964) made observations about gout which remain true centuries later. Gout has served as a paradigm for the study of other types of crystal-associated arthritis and as a prime example of the way in which understanding the pathophysiology of a disease leads to the development of effective therapy.

Uric acid was first identified in a renal calculus in the late 1700s by Scheele (1776), but it was not until 1899 that Freudweiler (1899) showed that intra-articular injection of uric acid crystals mimicked attacks of gouty arthritis. Decades later, uric acid crystals were identified in synovial fluids (McCarty and Hollander 1961). Based on the prescient work of Garrod (1876) in the 19th century, the link between gout and hyperuricaemia was established. Progress was aided by the discovery that an enzyme involved in purine metabolism was responsible for the Lesch–Nyhan syndrome (Seegmiller *et al*. 1967). Subsequently, from knowledge of purine and uric acid metabolism, effective drugs for hyperuricaemia were developed.

Definition

The term gout is derived from the latin word 'guta' meaning a drop, and originally may have referred to a drop of poison or evil humor. However, gout remains poorly defined as a clinical descriptor (Simkin 1993). In its most general sense, it is a group of diseases characterized by hyperuricaemia and uric acid crystal formation. These clinical syndromes include gouty arthritis, tophaceous gout, uric acid nephrolithiasis, and gouty nephropathy. In its more narrow and perhaps more commonly used definition, gout refers to arthritis caused by uric acid crystals.

Epidemiology

Gout is not an uncommon disease. Recent statistics from the United States show a self-reported prevalence of 13.6/1000 persons in adult males and 6.4/1000 persons for females (Collins 1988). In older studies utilizing physician diagnoses, gender specific rates were 5 to 6.6/1000 in men and 1 to 3/1000 in women (Lawrence *et al*. 1989). Similarly, in a study of patients in the Scottish Highlands, the overall prevalence of physician-documented gout was 3.4/1000 (Steven 1992). With an estimated prevalence of 1 per cent among adults in the United States, gout is the most common cause of inflammatory arthritis in men (Lawrence *et al*. 1989). Despite effective therapy, it is estimated that 37 million working days per year in the United States have been lost to gout (Hochberg 1991).

Incidence rates for gout are more difficult to ascertain. A longitudinal study of American medical students showed an incidence of 1.7 cases per 1000 person-years of follow-up (Roubenoff *et al*. 1991). Similar results were obtained from the Framingham data (Abbott *et al*. 1988). Gout may be more common in certain areas of the world such as Java (Darmawan *et al*. 1992), and among certain races (Lennane *et al*. 1960).

There is good evidence to suggest that average uric acid levels have been slowly rising over the last two decades (Gresser *et al*. 1990). Self-reported prevalence studies also show a parallel increase in the prevalence of gout (Lawrence *et al*. 1989)

The known risk factors for gout are well characterized and mirror risk factors for hyperuricaemia (Table 1). Gout is clearly more common in men and is rare in women prior to menopause. Overall, less than 5 per cent of patients with gout are female (Lally *et al*. 1986). Mean urate levels rise at puberty in boys and remain 1 to 2 mg/dl higher in men than women until menopause, when gender differences in uric acid levels diminish. Serum urate levels increase with age in both men and women (Becker 1988). The peak incidence of gout in men is between the fourth and sixth decade (Hall *et al*. 1967). In women, it is between the sixth and seventh decade (Puig *et al*. 1991).

Male gender
Age >40 years
Obesity
Family history
Alcohol use
Renal insufficiency
Hypertension

Table 1 Risk factors for primary gout

Primary gout is associated with a variety of medical conditions. Some such as obesity, renal insufficiency, and diuretic use clearly cause hyperuricaemia. Serum urate levels are directly correlated with body weight (Seidell *et al*. 1986). Obesity is a particularly important risk factor for gout in men (Roubenoff *et al*. 1991). Similarly, alcohol use increases uric acid levels by providing a dietary source of purines (Gibson *et al*. 1984). Ethanol increases lactic acidaemia thus interfering with the excretion of uric acid (Lieber *et al*. 1962), and increases adenine nucleotide catabolism via acetate intermediaries (Puig and Fox 1984) At one time, alcohol (particularly port wine and moonshine or unbonded whisky) was also an excellent source of lead (Ball and Sorenson 1969).

Other risk factors for gout such as hypertension, family history, and coronary artery disease may not be causally associated with high uric acid levels. Hypertension occurs in 25 to 50 per cent of gout patients (Grahame and Scott 1970), and a similar percentage of untreated hypertensives will have hyperuricaemia (Wyngaarden and Kelley 1976). Gout is also associated with hypertriglyceridaemia (Scott 1977). The association between gout and coronary artery disease is somewhat controversial (Myers *et al*. 1968; Emmerson 1974; Abbott *et al*. 1988). Gout may be associated with atherosclerosis only because of the high prevalence of obesity and hypertension in gout patients (Abbott *et al*. 1988). Alternatively, gout may be an independent risk factor for coronary artery disease (Gertler *et al*. 1931). Lastly, between 6 and 18 per cent of patients with gout will have a family history of gout (Neel 1947).

Risk factors for gout in women are not as clearly defined as those for men. As in men, age, renal insufficiency, and diuretic use are certainly linked with gout in women. However, other male risk factors such as body weight and alcohol intake may not play as important a role in gout in women (Puig *et al*. 1991).

Pathophysiology

Delineating the pathophysiology of gout requires an understanding of purine metabolism, as uric acid is an end product of purine biosynthesis. Hyperuricaemia is a necessary but not a sufficient condition for the development of gout; and although the mechanisms of excess uric acid accumulation are well defined, the subsequent phases of crystal formation and release into tissues remain less well characterized.

Purine metabolism

Purines are derived from two sources. They are ingested in food or are generated via a complex *de novo* synthetic pathway (Wyngaarden and Kelley 1976). The synthetic pathway is outlined in Fig. 1. Components of the purine ring are complexed to the donor substrate phosphoribosylpyrophosphate (**PRPP**). These are then taken through a 10-step process culminating in purine nucleotide formation. PRPP is also used as a substrate for pyrimidine and pyridine synthesis. Thus, the first committed step in purine synthesis is catalysed by the enzyme amidophosphoribosyl transferase (**amidoPRT**). The *de novo* synthetic pathway requires heavy energy consumption in the form of ATP (Holmes 1978). Consequently, numerous enzymes for salvaging and interconverting premade purines exist to recycle these energy-rich compounds. Two salvage enzymes are particularly important in gout. These are hypoxanthine guanine phosphoribosyl transferase (**HPRT**) and adenine phosphoribosyl transferase (**APRT**).

Fig. 1 Simplified scheme of normal purine metabolism in man. PRPP synthestase, phosphoribosylpyrophosphate synthetase; amidoPRT, amidophosphoribosyl transferase; HGPT, hypoxanthine guanine phosphoribosyl transferase; 5'-NT, 5'-nucleotidase.

Control of normal purine metabolism in man is well understood. The first commited step in purine biosynthesis is rate limiting. AmidoPRT is allosterically activated by its substrate PRPP and inhibited by purine nucleotides, its end products (Holmes *et al*. 1973). The enzyme PRPP synthetase is similarly regulated, but is less sensitive to small changes in end-product concentrations (Yen *et al*. 1981; Becker and Kim 1987). Thus, control of purine metabolism is negatively affected by purines themselves and positively influenced by PRPP (Becker and Kim 1987; Itakura *et al*. 1981).

Uric acid metabolism

Uric acid is ultimately formed from purine nucleotides through the intermediate compounds xanthine, hypoxanthine, and guanine by the enzyme xanthine oxidase. It is a terminal product as no mammalian uricase exists. Uric acid is made primarily in the liver. The average pool size is 1200 mg in men and 600 mg in women. In both men and women, about two-thirds of the total uric acid pool is turned over each day (Scott *et al*. 1969). Uric acid pools in patients with gout are always larger than normal, usually in the range of 2000 to 4000 mg. In patients with tophi, uric acid burdens can be as high as 30 000 mg. (Benedict *et al*. 1949; Bishop *et al*. 1951; Sorenson 1959).

Two-thirds of uric acid is renally excreted (Buzzard *et al*. 1955; Sorenson 1960). The remainder is degraded by gut bacteria via the process of 'intestinal uricolysis' (Wyngaarden and Stetten 1953). The renal handling of uric acid is complex and not fully understood. It entails a four-step process beginning with glomerular filtration, followed by active reabsorption in the proximal tubule, tubular secretion at some distal site, and ending with postsecretory tubular reabsorption (Levinson and Sorenson 1980) (Fig. 2).

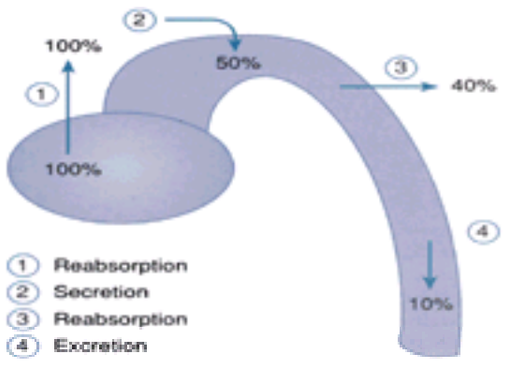

Fig. 2 Simplified scheme of renal excretion of urate. (1) reabsorption after filtration, (2) secretion in the proximal tubule, (3) reabsorption at some distal site, and (4) excretion in the urine.

For the sake of discussion, we will divide the known metabolic causes of hyperuricaemia associated with gout into three catagories: causes of primary gout, defined inborn errors of metabolism, and aetiologies of secondary gout.

Mechanisms of hyperuricaemia in primary gout

Primary gout is simply defined by the absence of any identifiable underlying disease causing hyperuricaemia. This criterion defines the largest group of patients with gout. Most of these patients are older men and 80 to 85 per cent are hyperuricaemic on the basis of underexcretion of uric acid (Wyngaarden and Kelley 1985). There is no difference in rates of intestinal uricolysis in patients with primary gout compared with controls (Sorenson 1962). Thus, the site of the abnormality in patients with primary gout who underexcrete is most likely to be at the kidney. Simkin (1977b) has shown that most patients with primary gout have low fractional uric acid excretion rates. The mechanism of underexcretion remains to be elucidated but is most likely a defect in secretion or reabsorption rather than in filtration (Reiselbach *et al*. 1970).

A minority of patients with primary gout have high urinary uric acid levels and excessive *de novo* purine synthesis. The best evidence to date supports a role for increased PRPP availability or decreased purine nucleotide concentrations (thus diminishing feedback inhibition of the synthetic enzymes) in patients with primary gout who overproduce (Levinson and Becker 1993).

A recent study of purine metabolism in women with primary gout showed similar abnormalities to men with primary gout (Puig *et al*. 1994).

Inborn errors of metabolism causing hyperuricaemia

The enzyme defects associated with gout often present as precocious gout in childhood or early adulthood in the setting of a strong family history of gout. There are three well-characterized enzyme defects causing hyperuricaemia. Together these account for less than 5 per cent of cases of gout. These are summarized in Table 2 and include HPRT deficiency, PRPP synthetase superactivity, and glucose 6-phosphatase (**G6P**) deficiency.

Syndrome	Pattern of inheritance	Mechanism of hyperuricaemia
HPRT deficiency (Lesch–Nyhan)	X-linked	HPRT deficiency increases PRPP
Increased PRPP synthetase	X-linked	Overactivity of PRPP synthetase
von Gierke's disease (G6P deficiency)	Autosomal recessive	Increased activity of amidoPRT, decreased renal excretion due to acidaemia

Table 2 Inherited metabolic disorders causing gout

HPRT deficiency produces hyperuricaemia by increasing *de novo* synthesis of purine nucleotides through increased availability of the substrate PRPP, which stimulates synthesis. In its most complete form, HPRT deficiency results in the Lesch–Nyhan syndrome (Lesch and Nyhan 1964). This syndrome presents in early childhood with severe mental retardation, self-mutilation, choreoathetosis, spasticity, hyperuricaemia, and premature gout. Although it is linked to the X chromosome, there are two reported cases in girls (Yukawa *et al*. 1992). Partial defects of HPRT result in hyperuricaemia alone without the severe neurological consequences of complete HRPT deficiency (Kelley *et al*. 1967). Some patients with partial HPRT deficiencies may have subtle neurological impairments (Kelley *et al*. 1969). The diagnosis of HPRT deficiency can be made by measuring HPRT activity in erythrocytes (Kelley *et al*. 1969). In partial deficiencies, activity levels vary from less than 1 to 70 per cent of normal values. Over 26 different genetic mutations have been described in HPRT deficiency (Wilson *et al*. 1983).

Increased PRPP synthetase activity was described by Sperling *et al*. (1972) in two brothers. Overactivity of this enzyme results in increased PRPP levels and causes profound premature hyperuricaemia. The trait is inherited as an X-linked dominant condition (Yen *et al*. 1978). Three kindreds each with a different genetic mutation have been well characterized. Gout and renal stones develop in the second and third decades in affected males.

The third well-characterized enzyme defect associated with gout is glucose 6-phosphatase deficiency (Alepa *et al*. 1967). This is also known as glycogen storage disease type I, or von Gierke's disease. It presents in childhood with characteristic short stature, hepatomegaly, and recurrent hypoglycaemia. Less frequently, a bleeding diathesis may accompany the syndrome. Affected patients cannot release glucose from premade glycogen stores. Subsequent hypoglycaemia results in ATP catabolism, lactic acidaemia, and elevated levels of free fatty acids, pyruvate, and triglycerides. Hyperuricaemia in this syndrome is due to two effects. Renal excretion of uric acid is diminished because other organic anions compete for transport in the kidney. Overproduction via the *de novo* synthetic pathway due to decreased feedback inhibition of amidoPRT also occurs (Itakura *et al*. 1981). Hyperuricaemia is often present from infancy, with gout occurring as early as 10 years of age. In its classic form, the inheritance is as an autosomal recessive disorder. Some forms of partial enzyme deficiency have been described (Nuki and Parker 1979).

Causes of secondary gout

The causes of secondary gout are well defined. Some may result in hyperuricaemia on the basis of overproduction of uric acid, such as tumour lysis syndrome, myeloproliferative disease, haemolytic amaemia, and psoriasis. All of these conditions are characterized by increased cell turnover with a subsequent increase in purine synthesis and catabolism.

Alternatively, conditions such as renal failure and many drugs produce hyperuricaemia and gout by promoting undersecretion of uric acid. Although mild renal insufficiency from any cause is a risk factor for gout (Berger and Yu 1960), certain forms of kidney disease such as autosomal dominant polycystic kidney disease may be preferentially associated with gout (Mejias *et al*. 1989). Interestingly, endstage renal disease often produces hyperuricaemia, but these patients rarely develop gout (Richet *et al*. 1965; Sarre and Mertz 1965).

Lead exposure is a cause of secondary gout. Saternine gout, which is associated with heavy lead exposures (often from the ingestion of lead-laden whisky), is rare today. Lead interferes with renal excretion of uric acid by altering the tubular transport of urate. It affects purine metabolism by altering purine nucleotide turnover

(Ludwig 1957; Forkas *et al*. 1978). Lead levels are increased in gout patients. Whether this phenomenon is primary or secondary to the renal insufficiency that often accompanies gout remains to be determined. Industrial lead exposure occurs in plumbers, pipe fitters, painters, steel workers, battery plant employees, and vehicle mechanics (Hochberg 1991). Recent changes in environmental safety standards may reduce lead exposure in these settings.

Drugs commonly associated with hyperuricaemia are listed in Table 3.

Drugs causing overproduction	Drugs causing underexcretion
Ethanol	Ethanol
Fructose	Salicylates (< 2 g/day)
Cytotoxic drugs	Cyclosporin
Vitamin B_{12}	Diuretics
Warfarin	Ethambutol
	Pyrazinamide
	Levodopa
	Angiotensin
	Vasopressin
	Laxatives
	Nicotinic acid
	Nitroglycerin
	Methoxyflurane

Table 3 Drugs associated with hyperuricaemia and gout

Urate crystal formation (Fig. 3)

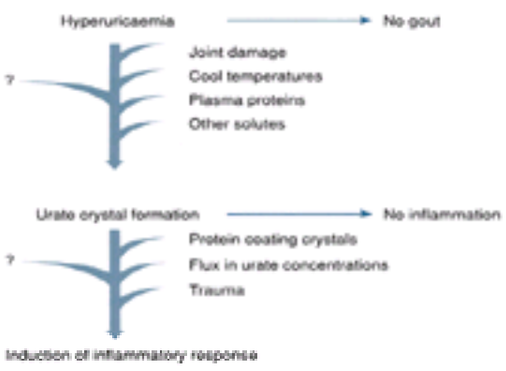

Fig. 3 Overview of factors influencing the development of gouty arthritis.

We know little about why uric acid crystals form *in vivo*. Yet, because the vast majority of patients with hyperuricaemia never develop gout (Hall *et al*. 1967), it is these processes of crystal formation and release that define clinical gout.

Our current understanding of urate crystal formation is based on knowledge of the biochemistry of urate, *in vitro* studies of crystallogenesis, and the histopathology of gout. Urate is present in two forms in the body. At neutral and alkaline pH, the monosodium salt (**MSU**) predominates. At acidic pH, such as in urine, the primary form is uric acid. Both forms are relatively insoluble, although uric acid is less soluble than its salt (Peters and Van Slyke 1946). A solution is supersaturated with monosodium urate at 37°C at concentrations greater than 6.4 mg/dl (Peters and Van Slyke 1946). Cooler temperatures decrease urate solubility (Loeb 1972), thus predicting the association of gout with distal joints.

In vitro studies of crystallogenesis have yielded conflicting results in regard to the influences of serum, synovial fluid, and many individual plasma proteins, including albumin and proteoglycans, on crystal formation (Katz and Erlich 1986; McGill and Dieppe 1991b). Crystal formation is probably enhanced by IgG and type I collagen (McGill and Dieppe 1991b). In addition, urate crystals themselves initiate further crystal formation. McGill and Dieppe (1991a) and others (Tak I>et al. 1980; Burt and Dutt 1986) demonstrated increased crystallogenesis in the presence of 'particulate-free' synovial fluid from patients with gout compared with those with rheumatoid arthritis or CPPD deposition disease, suggesting the presence of as yet uncharacterized promoters of crystal formation in gouty fluid.

Urate crystals have a unique distribution in the body. They prefer sites rich in connective tissue, such as synovium, cartilage, tendon, skin, and the renal interstitium (Sokoloff 1957). Gouty arthritis often develops in previously damaged joints. Disturbances of proteoglycan metabolism or collagen structure may promote crystal formation and release (Katz and Erlich 1974; Wilcox and Khalaf 1975; Perricone and Brandt 1978). Joint effusions may also affect urate crystal formation. Because the diffusion of urate through the synovial membrane is less than that of water (Simkin 1977a), resorption of water in a joint with an effusion during recumbency would increase the effective urate concentration and promote crystal formation.

Pathogenesis of the acute attack (Fig. 4)

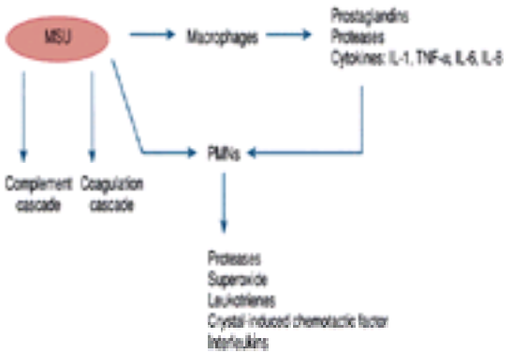

Fig. 4 The mechanisms through which monosodium urate (MSU) crystals cause inflammation in the joint.

Once monosodium urate crystals form in the joint, they may induce an acute attack of gouty arthritis. Urate crystals clearly cause inflammation (Seegmiller *et al*. 1962); yet we are unable to explain why they are present in synovial fluids from asymptomatic uninflamed joints (Pascual 1991). The type and quantity of protein coating the crystals may affect their ability to induce inflammation. IgG is found in association with MSU crystals and increases cell activation (Russell *et al*. 1983). Terkeltaub *et al*. (1991) demonstrated a role for the lipoprotein apoE in inhibiting crystal-induced inflammation.

The effects of uncoated MSU crystals on cells are well characterized. The cells that urate crystals first encounter in the joint are most probably macrophage-like synovial cells. Here they induce the release of vasoactive prostaglandins, proteases, and proinflammatory cytokines including interleukin 1 (**IL-1**), IL-6, and IL-8 which initiate a vigorous inflammatory response (DiGiovine *et al*. 1987). Recruited polymorphonuclear leucocytes release proteases, superoxides, leukotrienes, and interleukins when exposed to MSU crystals. (Abramson *et al*. 1982; Cheung *et al*. 1983b; Bhatt and Spillberg 1988). MSU crystals activate complement via the

classical pathway (Giclas *et al*. 1979). They also promote the release of Hageman factor and the subsequent activation of bradykinin, kallikrein, and other coagulation factors (Ginsberg *et al*. 1980).

The mechanisms through which they stimulate these cells remain to be elucidated. Certainly, some crystals are phagocytosed and cause lysis of the phagolysosome, release of its toxic contents, and death of the cell (Schumacher and Phelps 1971). Other effects may be mediated through cell membrane perturbations (Mandel 1976). The highly charged surfaces of MSU crystals may bind to and cross-link membrane receptors, thus mediating some of the crystals' immediate effects (Burt and Jackson 1990).

The factors that terminate an acute attack remain unclear. One hypothesis suggests changes in crystal size and protein coating render the crystals less inflammatory. These changes may be mediated through generation of oxygen free radicals by polymorphonuclear leucocytes (Marcalongo *et al*. 1988).

Tophus formation

Tophi are soft tissue deposits of urate. We know little about how and why they form. Palmer *et al*. (1989) proposed that tophi are urate-lowering organs. Based on histological studies, they proposed that acini of macrophages develop in areas of high local urate concentrations. These organized cells actively transport urate from the interstitial fluid to the centre of the acinus. They grow to a certain size and then fuse with other acini, eventually forming tophi. Further work is necessary to confirm this theory.

Clinical features

We will discuss the clinical features of acute and chronic gout, and renal syndromes associated with uric acid.

Articular gout is often divided into four clinical stages. The first stage is defined by asymptomatic hyperuricaemia. This is followed by acute gouty arthritis and then by another asymptomatic phase termed intercritical gout. When allowed to proceed untreated, some patients will go on to develop chronic tophaceous gout.

Acute gout

The first clinical symptom of gout is usually an acute, self-limited, monoarticular inflammatory arthritis affecting the joints of the lower extremities. Gout has a predilection for the first metatarsophalangeal joint. As many as 50 to 70 per cent of first gout attacks occur in the big toe (Delbarre *et al*. 1967; Grahame and Scott 1970). Other frequently involved joints include those of the foot, ankle, knee, wrist, elbow, and the small joints of the hands. The large axial joints and those of the spine are uncommon sites for early acute gout attacks.

The onset of an attack occurs suddenly and often late at night or early in the morning. Patients will describe very severe pain, associated with swelling, extreme tenderness, and redness overlying the joint. Without intervention, the attack will usually subside within 5 to 7 days (Bellamy *et al*. 1987). Low-grade fever, malaise, and anorexia may occur. The attack may be preceded by brief twinges of pain (petit attacks) in the affected joint.

Common precipitants of acute attacks include excess alcohol intake, intercurrent illness, surgery (Bartles 1957), starvation, trauma, and the initiation of drugs that alter urate metabolism. All of these precipitants alter serum urate levels.

Physical examination shows signs of inflammation with erythema, warmth, and swelling over the joint, often extending to the overlying skin. There is exquisite tenderness over the affected joint. Not infrequently, an overlying cellulitis or accompanying tenosynovitis occurs. The skin may desquamate in the later days of an attack. Acute gout can also occur in bursas, and gout is a common cause of acute inflammatory olecranon bursitis (Canosa and Yood 1979).

After the attack resolves, the patient will be completely asymptomatic. This phase is referred to as intercritical gout. Most patients will go on to have an additional attack within 2 years of the first attack (Gutman 1973). In one study, 78 per cent had recurrent attacks within 2 years, and after 10 years, 93 per cent had had more than one attack. Untreated, the intercritical phases become shorter. Interestingly, they still present an opportunity for diagnosis, as many joints will still have urate crystals in the synovial fluid during the intercritical phase if they were involved in a previous attack, and urate-lowering therapy has not been initiated (Pascual 1991).

Chronic tophaceous gout

In the later stages of untreated disease, clinical manifestations characteristically change. Acute attacks are more often polyarticular. The intercritical stage shortens, and repeated joint damage results in permanent deformities, loss of motion, chronic pain, and tophi (Nakayama *et al*. 1984).

Polyarticular gout occurs in late stage disease, although some patients present earlier with polyarticular attacks (Raddatz *et al*. 1983; Lawry *et al*. 1988). Intercritical stages are short or non-existent and involvement of atypical sites including the upper extremities, the spine, and axial joints may ensue (Lagier and MacGee 1983; Varga *et al*. 1985). After repeated attacks in a single joint, deformity and loss of motion may occur.

Tophi are deposits of urate embedded in a matrix composed of amorphous urates, lipids, proteins, and calcific debris (Fig. 5). Tophi are usually subcutaneous, but they can occur in bone and other organs including the heart valves and the eye (Ferry *et al*. 1985; Gawoski *et al*. 1985). Classic sites include the pinna of the ear, bursas around elbows and knees, the dorsal surfaces of the metacarpophalangeal joints, and the Achilles tendon. Tophi are not distinguishable on physical examination from rheumatoid nodules or other subcutaneous nodules. There is no accompanying inflammation and they are usually painless. The overlying skin may be taut and shiny. A thick white or whitish-yellow exudate is seen if the skin integrity is compromised.

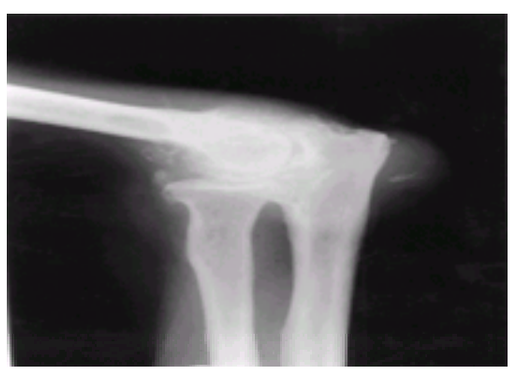

Fig. 5 A tophus in the olecranon bursa appears as a typical soft tissue density with a small amount of calcification.

Tophi or chronic polyarthritis may occur as early as 3 years or as late as 42 years after the first acute attack. In the pretreatment era, 50 per cent of patients with gout had tophi after 10 years of disease (Gutman 1973). Currently, about 5 per cent of patients with gout will have tophi (O'Duffy *et al*. 1975). Their occurrence is directly correlated with serum urate levels, and they identify a group of patients with severe and prolonged hyperuricaemia (Nakayama *et al*. 1984). Another group at risk of developing tophi and olyarticular gout are elderly women with primary nodal osteoarthritis on diuretic therapy (Macfarlane and Dieppe 1985).

Other articular manifestations of gout

Gout has been variably associated with avascular necrosis of the femoral head (Hunder *et al*. 1968; Stockman *et al*. 1980). Patients with gout may also have a higher prevalence of chondrocalcinosis (Dodds and Steinbach 1966).

Renal disease and gout

The relationship between kidney dysfunction and gout remains complex and confusing. Three renal syndromes are associated with gout. Urate crystals can form in the renal interstitium causing urate nephropathy. Uric acid can acutely precipitate in the collecting tubules resulting in uric acid nephropathy. Lastly, uric acid nephrolithiasis may occur.

Urate nephropathy

The pathological changes that define urate nephropathy are common. MSU crystals in the renal medulla are associated with a giant-cell inflammatory reaction (Sokoloff 1957). The clinical significance of these pathological findings, however, remains unclear. Renal insufficiency is unequivocally common in patients with gout, but controversy exists as to the aetiology of this renal dysfunction. Current dogma states that urate crystals themselves produce only a minor amount of renal damage. Most of the renal disease associated with gout is secondary to inadequately controlled hypertension and other comorbidities (Fessel 1967; Berger and Yu 1960).

Uric acid nephropathy

Excluding nephrolithiasis, the renal syndrome most often associated with uric acid today is acute uric acid nephropathy (Reiselbach *et al*. 1962; Frei *et al*. 1963). This often occurs in an acutely ill, dehydrated patient treated with cytotoxic drugs for a lymphoproliferative disorder. An acute obstructive uropathy ensues with oliguric renal failure. Uric acid crystals form in the collecting tubules and are found in the urine. Uric acid/creatinine ratios are often greater than 1.0. This complication can be avoided with adequate hydration and the prophylactic administration of allopurinol prior to initiating chemotherapy.

Uric acid nephrolithiasis

The association between gout and nephrolithiasis is well established (Yu and Gutman 1967). Prevalence figures for renal stones vary between 10 and 42 per cent of patients with gout. Of these stones, 84 per cent are uric acid stones. Risk factors for developing uric acid stones include elevated urinary uric acid levels, and low urine pH (Plante *et al*. 1968; Yu 1981). Half the patients excreting greater than 1100 mg uric acid per day will have stones (Yu and Gutman 1967). Interestingly, however, only 20 per cent of patients with uric acid stones are hyperuricaemic (Talbott 1957). Patients with gout also are at a higher risk for non-urate stones. Of the 16 per cent of stones in patients with gout that do not contain uric acid, 8 per cent are calcium oxalate, 4 per cent are calcium phosphates, and 4 per cent are mixed stones. It is postulated that uric acid serves as a nidus for calcium oxalate crystal growth. Alternatively, or in addition, levels of inhibitors of calcium oxalate stone formation may be decreased in the urine of patients with gout.

Laboratory investigation

Investigation of the patient with an acute attack

Synovial fluid analysis remains the single most important diagnostic study in the patient with suspected gout. Synovial fluid is usually easily obtained from a large joint, while often only a drop of fluid or blood from the joint or adjacent tissues is necessary to provide a sample for definitive diagnosis of gout in a small joint. Synovial fluid is typically inflammatory with a mean white cell count of 20 000 cells/mm ^{3}. Most cells are polymorphonuclear leucocytes. Viscosity is often poor. A definite diagnosis can be made if typical, negatively birefringent, needle-shaped crystals are seen in the fluid with a polarizing light microscope (Fig. 6). They may be extra- or intracellular. Rarely one may see spherules of uric acid in acute gout (Fiechtner and Simkin 1981).

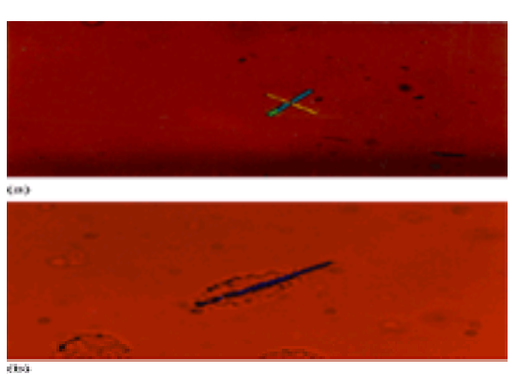

Fig. 6 Typical, needle-shaped, negatively birefringent crystals are seen under polazing light microscopy in the synovial fluid of patients with gouty arthritis. These crystals may be extracellular (a) or intracellular (b).

Few other laboratory studies are of significant clinical utility in diagnosing acute gout. Serum uric acid levels during the acute attack may not reflect pre-attack levels and can not be used to make a diagnosis of gout in the absence of urate crystals in the synovial fluid. One may see a peripheral leucocytosis, an elevated erythrocyte sedimentation rate, and increased levels of other acute-phase reactants during an acute attack. Synovial fluid cultures and Gram stains may help rule out concurrent infection. Radiographs are often normal during early episodes of gout. They may be useful to differentiate other problems such as fracture or infection from acute gout. Often soft tissue swelling is the sole radiographic finding in early gout.

Evaluation of the patient with recurrent attacks

Serum uric acid levels and 24-h urine collections for creatinine and uric acid may be helpful in evaluating the patient once the acute attack has subsided. Serum urate levels over 7 mg/dl define hyperuricaemia in most laboratories. Values of urinary uric acid over 1000 mg/day on an unrestricted diet define patients that overproduce, and may influence the choice of therapy. Patients suspected of a primary metabolic disorder should have a 24-h urine sample tested for creatinine, protein, and uric acid and a careful family history taken. If urinary uric acid levels are high, levels of enzyme activity for HPRT, PRPP synthetase, and glucose 6-phosphatase can be measured in specialist laboratories.

In later disease, gout has a typical radiographic appearance (Block *et al*. 1980; Barthelemy *et al*. 1984). The hallmarks of radiographic gout are due to the presence of tophi in or near the joint. In the soft tissues, tophi appear eccentric and nodular (Fig. 5). A small percentage of them calcify. Tophi may occur in or near a joint or distant from periarticular tissues. As a soft tissue tophus enlarges, it may encroach on the adjacent bone and produce a cortical erosion with focal periosteal new bone formation. This occurrence results in an erosion with a typical overhanging margin, present in 40 per cent of gouty erosions (Martel 1968) (Fig. 7). When in the joint, tophi produce marginal erosions with a characteristic 'punched out' or sclerotic border (Fig. 8). Erosions are particularly common on the medial and dorsal portions of the first metatarsal head. Similar changes can affect the digits of the hand. Bony abnormalities of the periosteum may occur in association with tophus formation. Specifically, a 'lace pattern' of finely striated periosteal reaction may develop adjacent to a tophus (Fig. 9). Rarely, bony proliferation may occur at the ends or shafts of long bones (mushrooming). Diaphyseal thickening may also occur. The joint space is characteristically well preserved until late in the disease. When joint space narrowing does occur it affects all joint compartments symmetrically, similar to other inflammatory joint disorders (Fig. 10). Bones may be osteopenic from disuse, but are usually well mineralized.

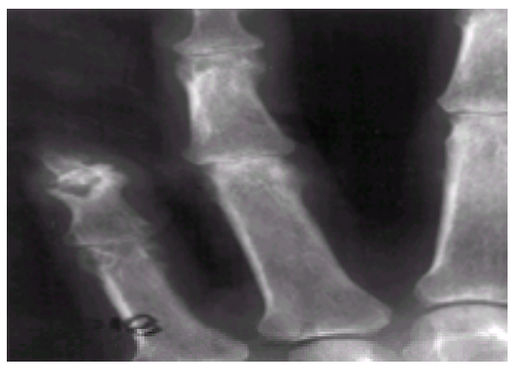

Fig. 7 A typical gouty erosion with overhanging margins is seen on the medial aspect of the proximal interphalangeal joint in this radiograph.

Fig. 8 An interosseus tophus appears as a 'punched out' or sclerotic erosion at the base of the proximal phalanx of the thumb.

Fig. 9 On the lateral aspect of the distal metatarsal joint, a lace-like periosteal reaction adjacent to a tophus can be seen.

Fig. 10 Extensive bony destruction and deformities are seen with far-advanced gouty arthritis of the foot.

Diagnosis

A definitive diagnosis of gout can only be made by the identification of urate crystals in the synovial fluid of an affected joint. Identification of urate crystals in tophi also allows a definitive diagnosis to be made. In the absence of these findings, other clinical criteria may be used to make a putative diagnosis of gout (Wallace *et al*. 1977). As crystals may be present in the intercritical phase, one may aspirate an asymptomatic but previously affected joint to establish a definite diagnosis.

Many clinical conditions can mimic acute gout (Table 4). These include infectious arthritis, other crystal-associated arthropathies such as pseudogout or BCP-associated periarthritis, or trauma. Patients with palindromic rheumatism may give a similar history of self-limited monoarticular attacks associated with exquisite pain, tenderness, and erythema near the affected joint. Rarely, other causes of polyarticular inflammatory arthritis, particularly psoriatic arthritis or Reiter's syndrome, may present with monoarticular self-limited attacks of the lower extremities which may be confused with gout. Once tophi and deformities occur, gout can be misdiagnosed as rheumatoid arthritis. As many as 30 per cent of patients with gout will have positive serum rheumatoid factors (Kozin and McCarty 1977).

CPPD disease (pseudogout)
BCP arthritis
Cellulitis
Erythema nodosum arthritis
Trauma
Palindromic rheumatism
Reiter's syndrome
Psoriatic arthritis
Rheumatoid arthritis

Table 4 Clinical conditions that mimic gouty arthritis

Management of gouty arthritis

Management of gouty arthritis can be divided into three phases: treatment of acute gout, treatment of chronic or tophaceous gout, and preventive measures.

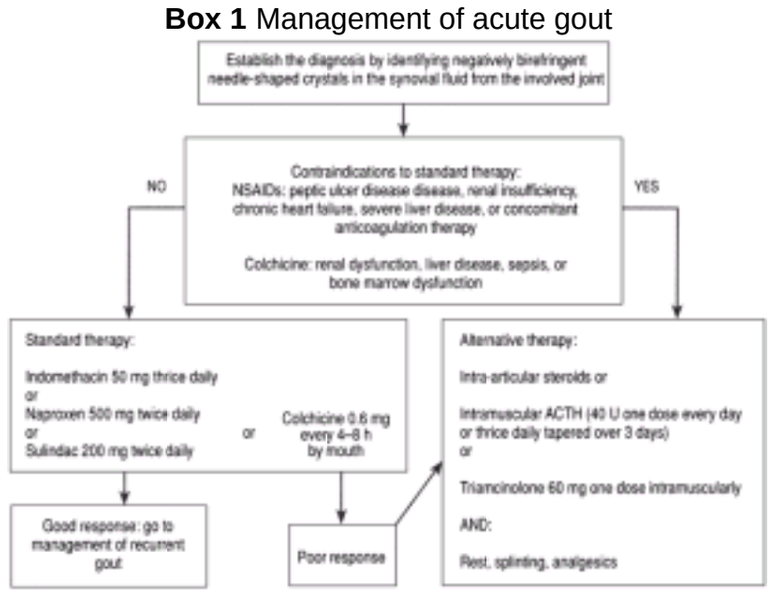
Preventive measures

Gout is a significant public health problem despite our excellent therapy. Hochberg (1991) suggests that we may be able to decrease the incidence of gout with preventive measures such as avoiding excess weight gain, reducing risks for hypertension, avoiding diuretic therapy, controlling alcohol intake, and minimizing occupational lead exposures. The efficacy of such interventions remains to be proven.

Management of acute gout

Traditional therapies for acute gout include non-steroidal anti-inflammatory drugs (**NSAIDs**), colchicine, and steroids. Rest and splinting of the affected joint may be helpful adjuncts to any pharmacological therapy. The management of acute gout is summarized in Box 1.

Box 1 Management of acute gout



NSAIDs

NSAIDs have replaced colchicine as the most commonly used drugs in the treatment of acute gout (Wallace 1977; Stuart *et al*. 1991). They interfere with the inflammation induced by MSU crystals (Abramson and Weissmann 1989). Traditionally, indomethacin has been the NSAID of choice in acute gout, but probably has no advantage over other NSAIDs (Sterling 1991). Sulindac may be better tolerated in those patients at high risk of renal side-effects from NSAIDs (Ciabottoni *et al*. 1984). In general, drugs with a shorter half-life achieve quicker therapeutic plasma levels and faster relief of pain.. With treatment, symptoms should subside within 3 to 5 days. NSAIDs are contraindicated in patients with significant renal insufficiency, peptic ulcer disease, concurrent warfarin therapy, or liver disease.

Colchicine

Colchicine is the oldest drug for gout, but its safety remains controversial. When used correctly, it can be very effective with a rapid onset of action. Colchicine tends to be much more effective in the early hours of an attack and loses efficacy with time. The mechanism of action of colchicine is unknown. It inhibits polymorphonuclear leucocyte function through its action on microtubules, but may also have very specific effects on crystal-induced inflammation (Roberge *et al*. 1993). Colchicine can be given in intravenous and oral forms.

Current recommendations for intravenous use are cautious (Moreland and Ball 1991) (Table 5). A dose of 1 to 3 mg diluted in 20 ml of normal saline can be slowly instilled into a large vein. Another 1-mg dose can be given 6 h later if the clinical response is incomplete. The maximum dose is 4 mg in 24 h. No additional doses should be given for 7 days after the initial dose. Intravenous colchicine is particularly useful for patients unable to take oral medications. Now that parenteral forms of NSAIDs are available, its use may decline further. Absolute contraindications to the use of intravenous colchicine include significant renal or hepatic compromise, bone marrow suppression, or sepsis. It should be used with great caution in patients with mild renal or hepatic disease, and, for example, those on daily oral colchicine prophylaxis. Side-effects range from venous sclerosis or tissue damage from extravasation of colchicine, to fatal bone marrow failure. Other side-effects include renal or hepatic failure, disseminated intravascular coagulation, and neuromuscular toxicity. Deaths from misuse of intravenous colchicine have been reported (Roberts *et al*. 1987).

(1) Intravenous colchicine should not be given in patients with:
- Creatinine clearance <10 ml/min
- Significant active liver disease or extrahepatic biliary obstruction
- Sepsis
- Bone marrow depression

(2) Intravenous colchicine should be used cautiously in patients on oral colchicine prophylaxis, with poor venous access, or with any degree of hepatic or renal compromise

(3) Recommended doses should not exceed 3 mg intravenous per 24 h or 5 mg orally per 24 h

Table 5 Recommendations for the use of colchicine

Oral colchicine is currently used more frequently than the intravenous form. It is given as an initial 0.5 to 0.6 mg dose which is repeated every 1 to 2 h until gastrointestinal symptoms ensue or pain resolves. Doses should not exceed 5 mg in 24 h. Similar side-effects are reported for oral and intravenous forms. Oral colchicine, however, has a higher incidence of gastrointestinal side-effects and a lower incidence of major toxicities, probably because the tolerated dose is lower.

Corticosteroids

Corticosteroid use in gout has endured much ebb and flow in popularity during recent years. Although ACTH has been used for many years to treat gout, textbooks of the last two decades cautioned against systemic steroids because of concerns about rebound symptoms and inconsistent results (Gutman and Yu 1952). More recently, there has been a resurgence of interest in their use in gout. Regimens for acute gout include intramuscular ACTH (Axelrod and Preston 1989; Ritter *et al*. 1993), intramuscular triamcinolone (Siegel *et al*. 1994), and oral steroids (Groff *et al*. 1990) (Table 6). These regimens are safe and well tolerated. Their efficacy remains to be proven. They may be particularly useful for patients in whom NSAIDs and colchicine are contraindicated (Ritter *et al*. 1993). The use of intra-articular steroids is less controversial. Although no studies of the efficacy of intra-articular steroids have been published, they remain a mainstay of therapy in patients unable to tolerate more traditional therapies (Hollander 1953).

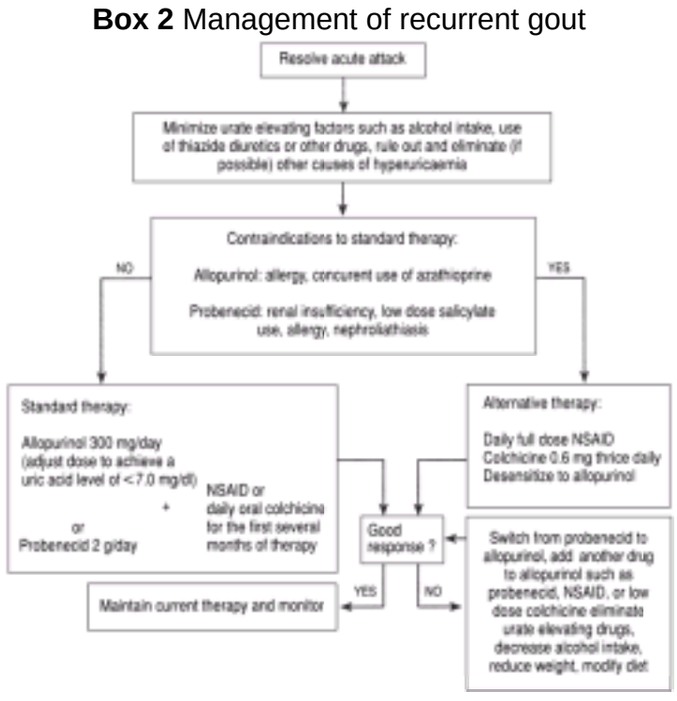
Drug	Dose	Route of administration	Length of use
Triamcinolone acetonide	60 mg	Intramuscular	Give once, repeat in 48 h if needed
Prednisone	20–50 mg with daily taper	Oral	3–20 days (mean 10 days)
ACTH	40 IU	Intramuscular	Give once
ACTH	40–80 IU	Intramuscular, intravenous or subcutaneous	Every 6 h then every 12 h then each day for 3 successive days

Table 6 Regimens for use of corticosteroids in acute gouty arthritis

Prophylactic therapy

Drugs which reduce serum uric acid levels such as allopurinol and probenecid are the standard therapies available for prophylaxis of gout attacks. Colchicine and NSAIDs are less commonly used as prophylactic drugs, but may also decrease attack frequency and severity when used alone or in combination with other therapies. Indications for the use of prophylactic drugs include recurrent attacks, tophi, severe or polyarticular disease, renal disease, or an inborn error of metabolism causing gout. Urate-lowering therapies are traditionally not started during an acute attack and are initiated concurrently with a 2-week course of low-dose colchicine or a NSAID. This regimen may avoid the risk of precipitating an acute attack by rapidly lowering uric acid levels. Goals of therapy are to decrease attack frequency, dissolve tophi, and maintain serum uric acid levels in the normal range. The management of recurrent gout is summarized in Box 2.

Box 2 Management of recurrent gout



Allopurinol

Allopurinol is the drug most commonly used for the prevention of acute gout and the treatment of chronic tophaceous gout (Stuart *et al*. 1991). It is a xanthine oxidase inhibitor and thus decreases uric acid production. It may also have other actions (Adriani and Naraghi 1985). It is very effective in lowering serum uric acid levels and is the drug of choice for patients with renal insufficiency, a history of nephrolithiasis, or tophi. It is also indicated in patients who clearly overproduce uric acid such as those with tumour lysis syndrome or primary metabolic defects. Allopurinol is usually given as a once daily dose of 300 mg. The dose should be adjusted downward in the presence of significant renal compromise. It may be increased to a maximum of 900 mg/day to achieve normal uric acid levels. The onset of action is rapid and effects can be seen as early as 4 days to 2 weeks (Wyngaarden *et al*. 1965; Rundle *et al*. 1966). Allopurinol interferes with the metabolism of azathioprine, potentiating its marrow-suppressive effects (Boston Collaborative Drug Surveillance Program 1974), and may augment anticoagulant effects of warfarin (Self *et al*. 1957). In general, the incidence of side-effects with allopurinol is low (less than 2 per cent). The most common side-effects include a hypersensitivity syndrome of rash and fever (McInnes *et al*. 1981; Singer and Wallace 1986). Life-threatening reactions, including fulminant hepatitis, interstitial nephritis, and toxic epidermal necrolysis, are even more unusual (Lupton and Odom 1979). Patients with renal disease may have a greater incidence of drug allergy (Singer and Wallace 1986). Allopurinol can be given cautiously to an allergic patient using available desensitization regimens (Northridge and Almack 1986; Fam *et al*. 1992).

Uricosurics

Probenecid and sulphinpyrazone are the most commonly used uricosuric drugs. They interfere with the renal handling of urate by altering organic anion transport, thus increasing urate excretion (Gutman and Yu 1957). Usual doses of probenecid are 0.5 to 2 g given in twice daily doses (Boger and Strickland 1955). Sulphinpyrazone is given in doses of 300 to 400 mg/day (Emmerson 1963). Both drugs are well tolerated and effective. Maximum doses of 3 g/day of probenecid and 800 mg/day of sulphinpyrazone are occasionally necessary to return the levels of serum uric acid to normal. Uricosurics are contraindicated in patients with nephrolithiasis and ineffective in patients with significant renal compromise, or those using acetylsalicylates. Side-effects include rare hypersensitivity reactions, rashes, gastrointestinal complaints, and nephrotic syndrome (Reynolds *et al*. 1957; Hertz *et al*. 1972).

Benzbromarone is a uricosuric drug available in Europe, that is effective in the presence of renal insufficiency. At doses of 25 to 125 mg/day, it may lower values of serum uric acid in patients with serum creatinine levels as high as 2.0 mg/dl (Zollner *et al*. 1970).

Colchicine

In patients who are unable to take allopurinol or a uricosuric drug, daily low-dose oral colchicine may be useful in preventing further attacks of gout (Yu and Gutman 1961). It is given in doses of 0.5 to 1.2 mg/day. Unfortunately, serious side-effects have occurred even on this low-dose regimen in patients with renal insufficiency or liver disease (Neuss *et al*. 1986).

Drug combinations and other therapies

Patients who continue to have gout attacks on a single prophylactic drug can be treated with a combination of medications. The combination of probenecid and colchicine is more effective than probenecid alone (Paulus *et al*. 1974). Small numbers of patients have been reported to respond to a combination of allopurinol and a uricosuric (Kuzell *et al*. 1966) when either one alone was ineffective. Other measures such as eliminating the concurrent use of urate-elevating drugs, decreasing alcohol intake, weight reduction, and improving medication compliance may also help achieve control of uric acid levels in refractory patients. Rarely, patients with long-standing uncontrolled disease have permanent joint dysfunction which is best treated surgically. Tophi may occasionally require surgical removal with a low incidence of recurrence (Smyth 1953).

Uricase has been used as a novel approach to gout therapy. This enzyme dissolves uric acid crystals and has been used successfully in a small number of patients (Chua *et al*. 1988; Rozenberg *et al*. 1993). In some cases, polyethylene glycol treatment of the uricase was used to reduce its immunogenicity (Chua *et al*. 1988).

Management of nephrolithiasis

Patients with uric acid stones are best managed with adequate hydration, urinary alkalinization (with bicarbonate or acetozolamide), and allopurinol. Potassium citrate may be used in place of allopurinol if necessary (Pak *et al*. 1986). This regimen is also effective in preventing calcium oxalate stones in patients with hyperuricaemia (Pak *et al*. 1981).

Gout in the transplant recipient

In the late 1980s, it was noted that an unusually large number of cases of gout were occurring in renal transplant patients. This coincided with the popular use of cyclosporin as an immunosuppressant. Hyperuricaemia occurs in 30 to 84 per cent and gout in 7 to 9 per cent of patients with renal transplants who are treated with cyclosporin (Lin *et al*. 1989). The incidence of gout in patients with heart and lung transplants on cyclosporin is also significantly increased (Burak *et al*. 1992). Gout in these patients is often more severe than primary gout. Polyarticular and tophaceous gout occurs earlier in cyclosporin-induced gout than in primary gout (Baethge *et al*. 1993). Post-transplant patients can be particularly difficult to treat because of contraindications to the use of NSAIDs and colchicine, resistance to systemic steroids which they take chronically, and concerns about interactions between allopurinol and azathioprine. These patients are frequently on diuretics, and their risk of infection is high because of their compromised immune status. In the acute management of gout in the transplant patient, an arthrocentesis is usually warranted to eliminate the possibility of infection. Once a diagnosis is established, intra-articular steroids and systemic pain medications may be helpful. Chronically, some of these patients may be treated with uricosurics. If allopurinol is indicated, azathioprine can be reduced to one-third of its usual dose and 50 to 100 mg of allopurinol can be added. Blood counts should be carefully monitored during the initiation of allopurinol therapy.

Prognosis

In the era of antihyperuricaemic therapy, the prognosis for patients with gouty arthritis is excellent. Moreover, despite the association of hyperuricaemia with heart disease, hypertension, and renal insufficiency, there is no evidence that patients with gout have decreased longevity compared with controls who do not have gout.

Calcium pyrophospate dihydrate (CPPD) disease

CPPD disease is the second most common form of the crystal-associated arthritides. Unlike gout, the pathophysiology of CPPD disease remains poorly understood, and consequently no specific therapies for this arthropathy exist.

History

CPPD disease was initially described by McCarty *et al*. (1962) in the early 1960s. While studying crystals from synovial fluid of patients with presumed gout, it was noted that some crystals were resistant to dissolution by uricase (McCarty *et al*. 1962). On further characterization, these crystals were composed of calcium pyrophosphate dihydrate (Kohn *et al*. 1962). Similar crystals were subsequently identified in the synovial fluid from patients with both acute and chronic arthritis (McCarty 1966). They were noted to be associated with advanced age, radiographic chondrocalcinosis, and a characteristic pattern of severe joint degeneration. Our understanding of the pathophysiology of CPPD crystal formation remains rudimentary.

Definition

No concensus as to the proper nomenclature of CPPD disease exists. CPPD disease or CPPD deposition disease are the terms most commonly used to refer to the arthritis caused by CPPD crystals. Other terms used similarly include CPDD disease and pyrophosphate arthropathy (McCarty 1982). The acute form of CPPD disease is commonly referred to as pseudogout. Chondrocalcinosis, a frequent associated finding, is defined by the radiographic presence of finely stippled calcification in articular hyaline and fibrocartilage. Although these deposits are usually composed of CPPD crystals, other mineral forms have been identified in pathological specimens with chondrocalcinosis (McCarty 1966).

Epidemiology

Because the clinical syndromes associated with CPPD crystals are heterogeneous and may mimic other rheumatic diseases, the prevalence and incidence of CPPD deposition disease is difficult to define. Small studies have suggested a prevalence rate as high as 0.9/1000 (O'Duffy 1976), a figure about half that of gouty arthritis. Gender predominance varies from study to study, but symptomatic CPPD disease may be more common in women (Bergstrom *et al*. 1986a; Bergstrom *et al*. 1986b; Felson *et al*. 1989). The average age in the largest collection of symptomatic patients with definite or probable CPPD disease is 72 years (Ryan and McCarty 1993).

Most studies on prevalence have relied on data from autopsies or are based on radiographic chondrocalcinosis. These studies clearly demonstrate that CPPD crystal deposition increases with age. Autopsy studies show prevalence rates of 20 per cent in knee joints from patients over the age of 60 years (Mitrovic *et al*. 1988). CPPD crystals are unusual in joints of patients under the age of 60, and may be present in about 50 per cent of nonagenarians (Mitrovic *et al*. 1988). Radiographic studies confirm this pattern. An overall prevalence of chondrocalcinosis of 8.1 per cent in the population between the ages of 63 and 93 was noted in Framingham, Massachusetts. Age-specific rates rose from 3.2 per cent in the 65 to 69 year age group to 27.1 per cent in patients over the age of 85 years (Felson *et al*. 1989). Similar results were described in Nottingham. Prevalence rates were 6 per cent in the 55 to 64 age group and 32 per cent in people over 75 years of age (Jones *et al*. 1992a).

CPPD disease usually occurs sporadically. However, familial cases in the Chiloean Islands of South America (Reginato *et al*. 1975), France (Gaucher *et al*. 1977), Spain (Balsa *et al*. 1990), Mexico, (Richardson *et al*. 1983), and Canada (Gaudreau *et al*. 1981) have been well characterized. Familial CPPD occurs prematurely and is often associated with very severe arthritis presenting in the second and third decades. Although the genetics of these kindreds are variable, most show an autosomal dominant pattern of inheritance (Ryan and McCarty 1993). The incidence of familial CPPD disease may be underestimated (Rodriguez-Valverde *et al*. 1988).

Like gout, CPPD disease is associated with a variety of other medical conditions. Unlike gout, the pathophysiological connections between CPPD disease and these disorders is not always apparent. Associated conditions can be divided into definite and possible associations. Definite associations include hypomagnesaemia (Milazzo *et al*. 1981; Salvarini *et al*. 1989), hypophosphatasia (O'Duffy 1970; Whyte *et al*. 1982; Chuck *et al*. 1989), haemochromatosis (Hamilton *et al*. 1981), Wilson's disease (Feller and Schumacher 1972; Golding and Walshe 1977), and hyperparathyroidism (Bywaters *et al*. 1963; McGill *et al*. 1984). Possible associations include gout (Stockman *et al*. 1980), ochronosis (Reginato *et al*. 1973; Rynes *et al*. 1975), familial hypocalciuric hypercalcaemia (Marx *et al*. 1981) and perhaps other causes of sustained hypercalcaemia, diabetes mellitus (Solnica *et al*. 1966; Boussina *et al*. 1971), and X-linked hypophosphataemic rickets (Taylor and Hothersall 1991). An association with hypothyroidism is controversial (Jones *et al*. 1992a). An excellent review of these associated diseases was recently published (Jones *et al*. 1992a)

Clinical features

CPPD disease is a clinically heterogeneous disorder causing both acute and chronic arthritis. Its presentations have been separated into seven syndromes based on clinical features (Ryan and McCarty 1993) (Table 7).

Type	Clinical description	Frequency (%)
A	Pseudogout/acute inflammatory monoarthritis	25
B	Pseudorheumatoid/polyarthritis with synovitis	5
C and D	Pseudo-osteoarthritis/joint degeneration with (type C) or without (type D) acute attacks	50
E	Lanthanic/asymptomatic	?
F	Pseudoneurotrophic/severe joint destruction with or without neuropathy	Rare
Others	Tophaceous CPPD deposits Spinal CPPD deposition Crowned dens syndrome Spinal stenosis	Rare

Table 7 Clinical presentations of CPPD disease

The most commonly recognized form of CPPD disease is the acute arthritis known as pseudogout (or CPPD disease type A). Pseudogout is often clinically indistinguishable from gout, hence its name. It is characterized by the acute onset of pain, warmth, erythema, and swelling usually affecting a single joint. The knee is most commonly involved. Other large joints such as shoulders, wrists, elbows, and ankles may be affected. Pseudogout occurs only rarely in small joints. Attacks are variable in duration, lasting from 2 to 108 days (O'Duffy 1976). Few other signs or symptoms are present. Precipitants of acute attacks include intercurrent illnesses, stroke, trauma, surgery (particularly parathyroidectomy; Glass and Grahame 1976), and rapid diuresis (O'Duffy 1973; O'Duffy 1976).

In the extremely elderly or ill patient, acute pseudogout may have a dramatic presentation. High fever, hypotension, and delerium may mimic sepsis or other systemic diseases (Bong and Bennett 1981).

CPPD disease may have a rheumatoid-like (type B) presentation. This form of CPPD disease accounts for less than 5 per cent of patients with CPPD disease. Symptoms include generalized joint pain and stiffness. The large joints such as knees, wrists, and elbows are commonly involved. Morning stiffness may be prolonged. Synovitis is noted on physical examination. Features which distinguish CPPD disease from rheumatoid arthritis include the absence of small joint involvement, negative serum rheumatoid factor, and the presence of CPPD crystals in the synovial fluid of involved joints. In addition, patients with rheumatoid arthritis have polyarthritis which flares in phase, while the patients with pseudorheumatoid disease will have joint flares out of phase with one another (Ryan and McCarty 1993).

More than 50 per cent of patients with CPPD disease present with an osteoarthritis-like syndrome. These patients are classified as having the type C and type D forms of the disease. They have pain, stiffness, and limited range of motion of the affected joints. Joints not commonly involved in osteoarthritis may be affected, such as shoulders, elbows, and wrists. Examination shows little or no synovitis. Radiographs may show severe degenerative joint disease. Patients with the type C disease differ from those with type D in that they have acute attacks superimposed on chronic symptoms. Patients with the type D disease do not have acute attacks.

CPPD disease type E is clinically silent. It is also referred to as lanthanic CPPD disease. It is picked up incidently as radiographic chondrocalcinosis. This may be the most common type of CPPD disease.

Type F (or neuropathic) CPPD disease remains controversial and is rare; although described in patients with tertiary syphilis and severe neurotrophic arthritis (McCarty 1966). A similar clinical picture can be seen even in the absence of significant neuropathy (Menkes *et al*. 1976).

Although this classification scheme is helpful in describing patients with CPPD disease, not all cases are easily catagorized. The scheme does serve to emphasize the clinical heterogeneity of this disorder and the fact that CPPD disease must be considered as a cause of acute and chronic, inflammatory and non-inflammatory arthritis.

Tophaceous deposits of CPPD crystals have been described, but are not commonly seen (Jones *et al*. 1992b). In the wrist they can cause median nerve compression (Rate *et al*. 1992). In the spine, they may involve the ligamentum flavum and have been reported to produce symptoms of central canal stenosis (Delamarter *et al*. 1993) as well as cervical myelopathy (Berghausen *et al*. 1987). The crowned dens syndrome involves the deposition of CPPD (or BCP) crystals around the atlantoaxial joint and is a cause of acute neck pain (Bouvet *et al*. 1985). CPPD deposits rarely occur in tendons, bursas, and bone (Jones *et al*. 1992b; Kanterewicz *et al*. 1993).

Laboratory investigation

CPPD disease is defined by the presence of CPPD crystals in the synovial fluid of affected joints. Synovial fluids should be collected in heparin-containing tubes and carefully examined under polarized-light microscopy for the positively birefringent rhomboidal crystals of calcium pyrophosphate dihydrate (Fig. 11). These crystals may be sparse or abundant and can be either intra- or extracellular. Their number is not correlated with the degree of inflammation in the joint (Ryan and McCarty 1993). Synovial fluid from patients with acute pseudogout may have cell counts as low as 500 cells/mm^3 or as high as 50 000 cells/mm^3. The mean cell counts are similar to those of acute gout (20 000 cells/mm^3) with greater than 90 per cent polymorphonuclear leucocytes (Ryan and McCarty 1993). Fluid may be haemorrhagic, particularly early in an attack (Ryan and McCarty 1993). Many synovial fluids will also contain BCP crystals (Rachow *et al*. 1988). During the acute attack, serum levels of acute-phase reactants may be elevated.

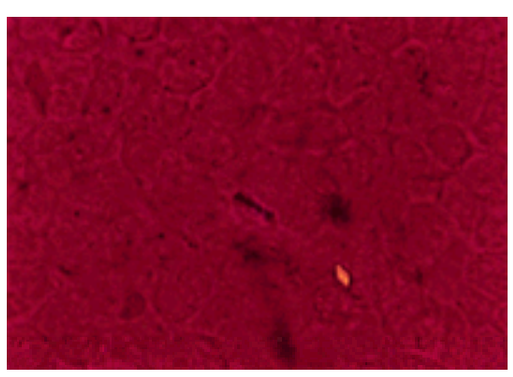


Fig. 11 Typical, positively birefringent crystals of calcium pyrophosphate dihydrate are seen here. Note the rhomboid shape and the weak birefringence.

Radiographs of the affected joint may not be helpful in establishing a diagnosis acutely. However, the presence of chondrocalcinosis increases the likelihood of CPPD disease. Chondrocalcinosis is found in both fibrocartilage and hyaline articular cartilage. Common sites for chondrocalcinosis are the menisci of the knee (Fig. 12), the triangular cartilage of the wrist (Fig. 13), and the symphysis pubis (Fig. 14) (Ryan and McCarty 1993). Other radiographic changes may provide helpful supportive data. Typical findings include eburnation, joint space narrowing, and subchondral cyst formation (Resnick *et al*. 1977). Osteophyte formation is variable, but may be less common than in osteoarthritis. Progressive destruction of the joint with bony collapse and loose body formation occurs frequently in CPPD disease.

Fig. 12 Chrondrocalcinosis is seen as finely stippled calcification of the cartilage in the knee.

Fig. 13 Chrondrocalcinosis is seen in the triangular cartilage of the wrist.

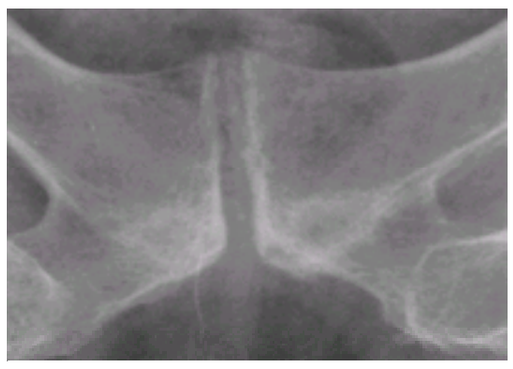

Fig. 14 Chrondrocalcinosis is seen in the pubic symphysis.

The distribution and pattern of radiographic involvement may be helpful in differentiating CPPD disease from osteoarthritis. CPPD disease affects joints not commonly involved in osteoarthritis. Axial involvement with intervertebral disc calcification, sacroiliac erosions, and subchondral cysts of the facet joints occur with CPPD disease. In the knee, tricompartmental involvement or isolated patellofemoral abnormalities are seen with CPPD disease more commonly than with osteoarthritis. Cortical erosions on the femur superior to the patella and osteonecrosis of the medial femoral condyle may also be diagnostic clues to CPPD disease (Lagier 1974; Watt and Dieppe 1983).

Patients with CPPD disease should be screened for one of the unusual metabolic disorders that promotes premature CPPD deposition. Laboratory evaluation should include serum levels of calcium, magnesium, phosphate, iron, and measurement of iron-binding capacity, and alkaline phosphatase.

Diagnosis

A definite diagnosis of CPPD disease can only be made when typical crystals are seen in synovial fluid with polarized-light miscroscopy. Phase-contrast microscopy may be a useful adjunct in detecting crystals. Radiographic changes can be used to establish a probable diagnosis. Diagnostic criteria based on crystal identification and radiological findings have been proposed (Ryan and McCarty 1993).

The differential diagnosis of pseudogout is much the same as that of gout. Infectious arthritis, trauma, and other crystal-associated arthropathies are the conditions that are most often mistaken for pseudogout. The chronic arthritis of CPPD disease can be mistaken for osteoarthritis, any one of the seronegative spondylarthropathies, rheumatoid arthritis, or neurotrophic arthritis.

Pathogenesis (Fig. 15)

Fig. 15 Scheme of the pathogenesis of CPPD crystal deposition.

The pathogenesis of CPPD disease remains obscure. Conceptually, CPPD crystal deposition, like gout, can be divided into phases of crystal formation, crystal release, and the induction and cessation of an inflammatory response. Using gout as a paradigm, much of the work on the pathophysiology of CPPD deposition rests on the theory that various metabolic abnormalities lead via a final common pathway to CPPD crystal formation. Unlike gout, the nature of this final common pathway remains unclear. Both radiological and histological studies of affected joints implicate cartilage as the primary site of CPPD crystal deposition. Crystals form in both fibrocartilage and the mid-zone of hyaline articular cartilage. The smallest and presumably the earliest crystals are found adjacent to chondrocytes or may replace the

chondron (Pritzker *et al*. 1988). Crystals occur less commonly in synovium and tendon and may form in areas of chondroid metaplasia in these tissues (Beutler *et al*. 1993).

In cartilage, crystals are associated with large or 'hypertrophic' chondrocytes which contain unusual inclusions (Masuda *et al*. 1989). These are not seen in osteoarthritic cartilage. Fragmented collagen fibres and histochemical markers associated with degenerated cartilage such as type I collagen, S-100 protein, and the proteoglycan, dermatan sulphate, have been identified near crystal deposits (Masuda *et al*. 1989).

Theoretically, three components influence CPPD crystal formation. Changes in local concentrations of calcium and pyrophosphate as well as alterations of cartilage matrix might favour crystallogenesis. Despite the association between sustained hypercalcaemia and CPPD disease, no consistent changes in local calcium concentrations in affected joints have been documented (Ryan and McCarty 1993). Moreover, treatment of hyperparathyroidism, for example, does not usually ameliorate the arthritis (Pritchard and Jessop 1977). Studies of crystal formation in gels implicate a role for matrix in influencing crystal formation (Mandel and Mandel 1985), but in general the influence of matrix changes has been difficult to approach in the laboratory. For these and other reasons, much of the work on CPPD crystal formation has concentrated on pyrophosphate metabolism.

Pyrophosphate levels are elevated in the synovial fluids of patients with CPPD disease when compared with patients with other types of arthritis (Silcox and McCarty 1974). Moreover, skin fibroblasts from patients with familial CPPD disease have higher levels of pyrophosphate than those from normal controls (Lust *et al*. 1981). *In vitro*, normal hyaline and fibrocartilage elaborate extracellular pyrophosphate while other joint tissues do not (Ryan *et al*. 1981).

Thus, disordered pyrophosphate metabolism appears to have a crucial role in CPPD crystal formation. Whether this pyrophosphate is generated extracellularly through the activity of the family of ectoenzymes known as nucleoside triphosphate pyrophosphohydrolases (Huang *et al*. 1994), or is made inside the chondrocyte (Rosenthal *et al*. 1991), remains unclear. A role for transforming growth factor-b, a cartilage growth factor involved in repair, is supported by its unique ability to stimulate pyrophosphate elaboration by cartilage (Rosenthal *et al*. 1991), and to increase articular cartilage vesiculation (Derfus *et al*. 1994).

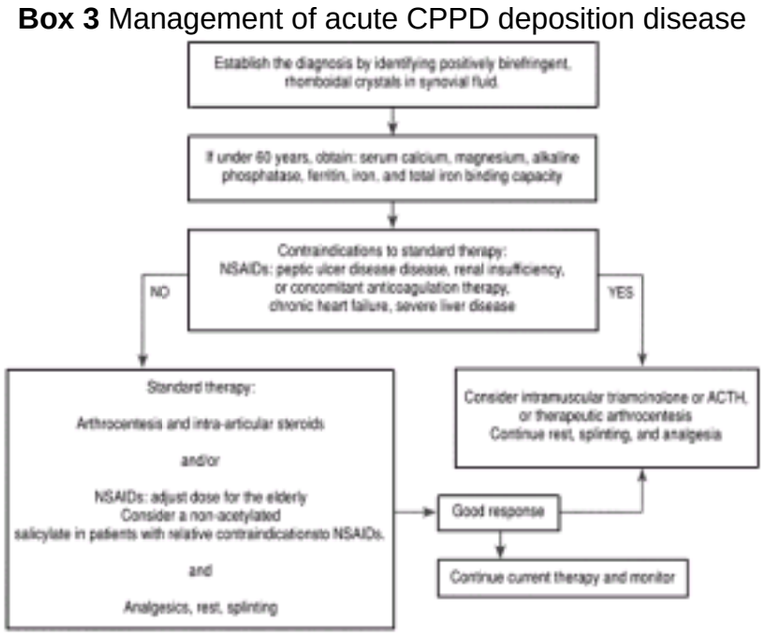
Understanding pyrophosphate metabolism may aid in determining the link between CPPD disease and its associated metabolic disorders. For example, magnesium is a cofactor of pyrophosphatase, which hydrolyses pyrophosphate to phospate. Thus, low magnesium would prevent action of this enzyme and favour elevated pyrophosphate concentrations in the joint. Similarly, hypophosphatasia which is characterized by low alkaline phosphatase activity could cause elevation of pyrophosphate levels by decreasing pyrophosphate hydrolysis.

When concentrations of pyrophosphate and calcium as well as matrix conditions are favourable, CPPD crystals form. Clinical symptoms arise when crystals are released into the synovial space. The mechanisms through which crystals are released into the joint space remain unknown. It has been postulated that trauma or sudden changes in crystal solubility may induce crystal release. Like MSU crystals, CPPD crystals are phlogistic and initiate an inflammatory response similar to that initiated by gout crystals (Malawista *et al*. 1985). The smallest crystals may be the most inflammatory (Ishikawa *et al*. 1987). Like gout, the factors terminating an acute attack remain speculative.

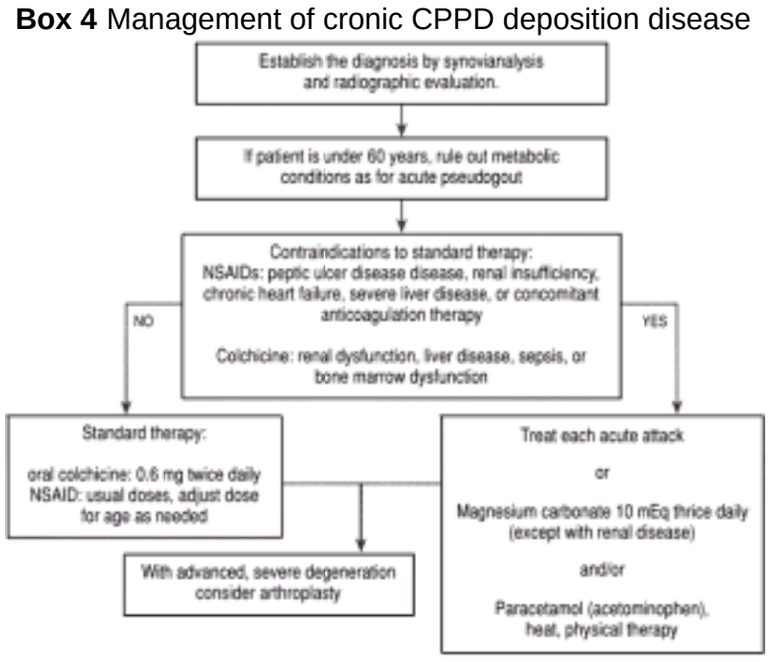
Management

Because our understanding of the pathophysiology of CPPD disease is inadequate, we have no specific treatments for this disorder. Standard therapies include NSAIDs, intra-articular corticosteroids, and colchicine. The management of acute and chronic CPPD deposition disease is summarized in Box 3 and Box 4.

Box 3 Management of acute CPPD deposition disease



Box 4 Management of cronic CPPD deposition disease



NSAIDs are the most commonly used therapy for CPPD disease. There are no controlled trials of their efficacy and no single NSAID is preferable over others. Sulindac may be renal sparing (Ciabottoni *et al*. 1984), and may be safer than other NSAIDs in this elderly population.

Joint aspiration with intra-articular instillation of corticosteroids remains a mainstay of therapy for patients with pseudogout. Although no prospective trials of intra-articular corticosteroids in CPPD exist, two retrospective studies support the their effectiveness in shortening the duration of an acute attack (O'Duffy 1976; Masuda and Ishikawa 1987). As in gout, there has been a resurgence of interest in using parenteral corticosteroids, particularly ACTH, for acute pseudogout. Doses vary between 40 IU and 80 IU given every 8 h with a 3-day taper (Ritter *et al*. 1993).

Intravenous colchicine is of proven efficacy in acute pseudogout (Spilberg *et al*. 1980). However, the age and comorbidities of patients with CPPD disease often preclude its use. Low-dose oral colchicine may be useful prophylactically. At doses of 1 mg/day, it reduced the frequency of acute attacks of pseudogout in one small study (Avarellos and Spilberg 1986).

Other less traditional treatments for CPPD disease have been proposed. Magnesium carbonate increases the solubility of CPPD crystals and acts as a cofactor for pyrophosphatases. At a dosage of 10 mEq thrice daily, magnesium carbonate decreased the severity of symptoms in patients with chronic CPPD deposition disease (Doherty and Dieppe 1983). Intra-articular Arteparon®, a glycosaminoglycan polysulphate, was demonstrated to decrease pain, stiffness, and immobility in one

uncontrolled trial (Sarkozi *et al*. 1988). Intra-articular yttrium-90 combined with steroids was also effective in patients with chronic knee pain from CPPD diseases (Doherty and Dieppe 1981). Intramuscular gold has been used in patients with a pseudorheumatoid presentation with reportedly good results (Ryan and McCarty 1993). Rest, splinting, and eventual joint replacement may be helpful adjunctive measures.

Prognosis

The prognosis for CPPD disease patients is not known. Most cases of acute pseudogout are alleviated with standard therapy. However, as no good prophylactic treatment exists, and the disease often coexists with severe joint degeneration, many patients have unrelenting symptoms from CPPD disease.

The basic calcium phosphate (BCP)-associated syndromes

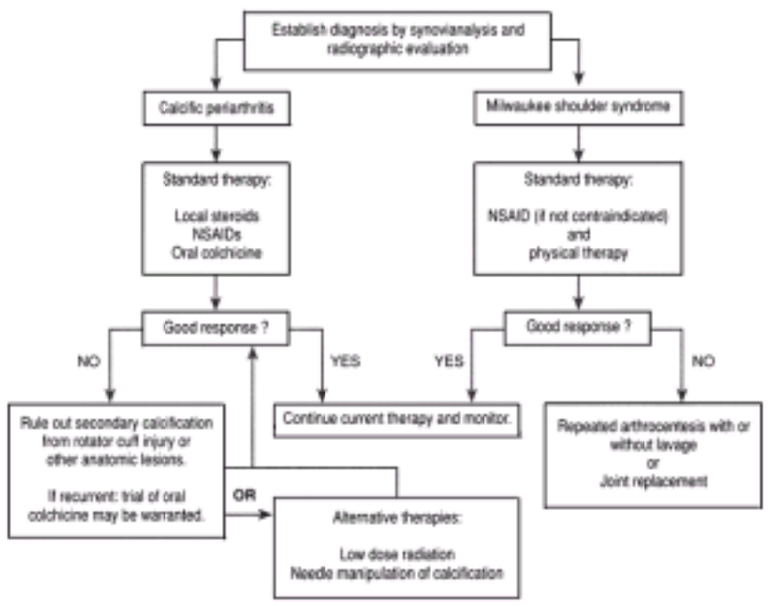
BCP crystals include hydroxyapatite, octacalcium phosphate, and tricalcium phosphate. These crystals are often (less accurately) referred to as apatite or hydroxyapatite crystals. They are associated with a wide variety of clinical syndromes as illustrated in Table 8. The management of BCP crystal diseases is summarized in Box 5.

In joints
- Milwaukee shoulder syndrome
- Osteoarthritis
- Erosive arthritis
- Acute inflammatory arthritis
- Mixed crystal deposition

Near joints
- Periarthritis:
  - Shoulder
  - Upper extremity in women
  - Pseudopodagra
- Calcific tendinitis and bursitis

Table 8 Rheumatic syndromes associated with BCP crystals

Box 5 Management of BCP crystal disease



History

Calcific periarthritis and tendinitis have been recognized for many years, and a clinical syndrome similar to Milwaukee shoulder syndrome was described by Robert Adams in 1857 (McCarty 1989). With the identification of BCP crystals in the synovial fluid of patients with arthritis (Dieppe *et al*. 1976), interest in these crystals and their biological effects grew. Although several BCP-associated syndromes have recently been characterized, there is still much to learn about the significance and distribution of BCP crystals.

Arthritis associated with BCP crystals

Milwaukee shoulder syndrome

This unusual form of arthritis is one of the better defined of the BCP crystal-associated syndromes (McCarty *et al*. 1981; Halverson *et al*. 1984; Halverson *et al*. 1990). Milwaukee shoulder syndrome was initially described in 1981 as a severe shoulder arthropathy of elderly women.

Thirty patients with Milwaukee shoulder syndrome have been carefully described. (Halverson *et al*. 1990). The syndrome is more common in women then men. Patients describe a gradual onset of mild to moderate shoulder pain that is often bilateral and worse at night. Symptoms are more severe on the dominant side. Knee pain, stiffness, and swelling may also occur. Instability, large effusions, and loose bodies are noted on examination of the shoulder. A history of trauma or overuse may antedate the development of this syndrome. Renal disease may also be a predisposing factor (Halverson *et al*. 1987).

Radiographs show exaggerated joint degeneration (Fig. 16). Glenohumeral joint space narrowing, deformities of the humeral head with focal osteoporosis, small osteophytes, loose bodies, and calcifications are particularly characteristic. Large and extensive rotator cuff tears are commonly seen on arthrograms. Knee involvement is common and differs from primary osteoarthritis in that the lateral compartment is often predominantly involved. Synovial fluids have low white blood-cell counts (less than 500 cells/mm^3). Particulate collagens and variable levels of active proteases have been identified in effusions from patients with Milwaukee shoulder syndrome. CPPD crystals are present in one-third of patients. There is currently no widely available method for detecting or quantifying BCP crystals. They can not be reliably identified with conventional or polarized-light microscopy. Stains such as Alizarin red are sensitive but not specific for BCP crystals (Halverson and McCarty 1979). Characteristic crystals can be seen under electron microscopy. At certain centres, a semiquantitative radiometric assay based on diphosphonate binding is in use (Halverson and McCarty 1979).

Fig. 16 This radiograph illustrates typical findings in Milwaukee shoulder syndrome. Note the abnormally high position of the humeral head.

The pathogenesis of Milwaukee shoulder syndrome remains an area of active research. BCP crystals are mitogenic and induce the elaboration of collagenase and other proteases from synovial fibroblasts (Cheung *et al*. 1981) and chondrocytes (Cheung *et al*. 1983a). These proteases may be responsible for the extensive destruction of joint structures seen in this syndrome.

No specific therapy is available for Milwaukee shoulder syndrome. Some patients may respond to conservative treatment with analgesics such as NSAIDs and repeated joint aspirations. The utility of intra-articular corticosteroid injections remains unclear. With far-advanced disease or collapse of the humeral head, shoulder arthroplasties may be indicated.

The prognosis for recovery of motion and decreased pain in patients with far-advanced joint degeneration is poor.

BCP crystals in osteoarthritis

BCP crystals are found in 30 to 60 per cent of synovial fluids from patients with osteoarthritis using widely available detection techniques (Dieppe *et al*. 1979; Gibilisco *et al*. 1985). Small or sparse submicroscopic crystals may be found in even higher percentages of osteoarthritic synovial fluids when carefully examined (Swan *et al*. 1994). The quantity of BCP crystal present correlates with the degree of radiographic degeneration. There is no association between synovial fluid cell count (Dieppe *et al*. 1979) or the pattern of radiographic appearance (Halverson and McCarty 1986) and BCP crystals. Thus, the significance of these crystals is unclear.

Erosive arthritis associated with BCP crystals

Several patients with erosive arthritis associated with BCP crystals have been described (Schumacher *et al*. 1981; Zwillich *et al*. 1988). These patients have peripheral or axial arthritis with acute attacks. Pre-existing renal disease, chronic arthritis, and tophus-like subcutaneous nodules have also been described. Radiographs show bony erosions and calcifications. ACTH and colchicine improve symptoms in some patients.

Acute arthritis associated with BCP crystals

A small number of patients with an acute gout-like syndrome associated with BCP crystals in the synovial fluid have been reported (Schumacher *et al*. 1977). These patients have elevated synovial fluid cell counts and normal radiographs. They may represent an early stage of the erosive arthritis described above.

Mixed crystal deposition

BCP and CPPD crystals frequently coexist in a single joint (Dieppe *et al*. 1977; Rachow *et al*. 1988). It is more common to see these crystals together than to identify either one alone. No clear radiographic or clinical syndromes have been characterized on the basis of the coexistence of these two crystals.

Syndromes associated with non-articular BCP crystals

Periarthritis associated with BCP crystals

BCP crystals often cause periarthritis. BCP periarthritis occurs most often around the shoulder joint of people between the ages of 30 and 60 years. Familial forms, involving multiple sites, have been described (Marcos *et al*. 1981). Renal failure may predispose to BCP deposition. Patients usually present with acute pain, warmth, erythema, and swelling in the affected area lasting for several weeks. The diagnosis is suggested by the presence of extrarticular calcium deposits on radiographs.

Two variants of BCP periarthritis have been characterized recently. The first is periarthritis involving the hand and elbow in young women (McCarthy *et al*. 1993; Yosipovitch and Yosipovitch 1993). This occurs in otherwise healthy young women without an antecedent history of trauma. Several patients had recently given birth and were breast feeding. The symptoms are acute and severe and are often misdiagnosed as gout or cellulitis. Sites of involvement include the lateral epicondyle of the elbow, the wrist, and the finger joints. Symptoms respond dramatically to intralesional corticosteroids. Follow-up radiographs demonstrate resolution of the calcific deposits within 7 to 36 days.

The term hydroxyapatite pseudopodagra has been used to refer to BCP periarthritis of the first metatarsophalangeal joint. These patients present with acute pain, swelling, warmth, and erythema of this joint (Fam and Rubenstein 1989). It often occurs in young women and is clinically indistinguishable from gout. Radiographs show amorphous periarticular calcifications. No patients had metabolic abnormalities, although pseudopodagra has been reported in pregnancy (McCarty 1991). Attacks are self-limited, lasting 1 to 3 weeks, and respond to conservative treatment with NSAIDs. Intralesional corticosteroids have also been used with good success (McCarty 1991).

Calcific tendinitis and bursitis

This syndrome frequently involves the shoulder. It is often clinically indistinguishable from traumatic tendinitis or bursitis. Patients present with acute onset of severe pain in the affected area lasting several weeks. The radiographic presence of amorphous calcific deposits and the absence of antecedent trauma suggest this diagnosis. Calcific deposits in the shoulder may also occur with chronic rotator cuff injuries. These deposits occur at the insertion site of the rotator cuff on the humerus and are not reabsorbed with time. In contrast, the calcifications of calcific tendinitis occur in metaplastic fibrocartilage within the rotator cuff and disappear with time (Sakar and Uthoff 1984). The pathophysiology of calcific tendinitis is unknown. Treatment with NSAIDs and intralesional corticosteroids usually results in rapid improvement. Colchicine may also be of some benefit (Swannell *et al*. 1970).

Calcium oxalate arthritis

Calcium oxalate crystals produce an unusual form of arthritis. Although seen most commonly in patients with renal failure on dialysis, calcium oxalate arthritis has also been described in patients with bowel disease and primary oxalosis, a rare inborn error of metabolism.

Epidemiology

There are no good studies of the incidence or prevalence of calcium oxalate arthritis in susceptible populations. Primary oxalosis is quite rare. In contrast, 90 per cent of patients on long-term haemodialysis have pathological evidence of calcium oxalate deposition in kidney and bone tissue (Fayemi *et al*. 1977).

Ascorbic acid supplementation is an added risk factor in patients on dialysis (Balcke *et al*. 1984), although oxalate arthritis has been reported in patients on dialysis who did not receive ascorbic acid supplements (Rosenthal *et al*. 1988). Other risk factors include short bowel syndrome from bowel bypass surgery or inflammatory bowel disease, dietary excesses of unusual foods such as rhubarb, and thiamine and pyridoxine deficiencies (Williams and Smith 1968) (Table 9).

Endstage renal disease on dialysis
Short bowel syndrome
Unusual diets rich in rhubarb, spinach, or ascorbic acid
Thiamine deficiency
Pyridoxine deficiency
Primary oxalosis

Table 9 Conditions associated with calcium oxalate arthritis

Clinical features

Oxalate arthritis most often occurs in the setting of renal failure. No large-scale studies of affected patients exist. Patients usually present with acute mono- or oligoarticular arthritis involving the small joints of the hands particularly the proximal interphalangeals and the metacarpophalangeals. Oxalate arthritis may be symmetric, and is often accompanied by tenosynovitis. Bursal involvement has also been described. Unlike gout, initial episodes may be prolonged and chronic arthritis may rapidly develop.

Primary oxalosis results from one of two defined enzyme deficiencies (Williams and Smith 1968). It is inherited as a recessive trait. Patients with primary oxalosis succumb to endstage renal disease in their early twenties. They have diffuse oxalate deposits at autopsy which may also involve articular tissues. Acute and chronic arthritis (Hockaday *et al*. 1964) as well as tenosynovitis (Cohen and Reid 1935) have been described in these patients, but identification of crystals in affected joints has been difficult (Hockaday *et al*. 1964).

Diagnosis

The diagnosis of calcium oxalate arthritis is made by identifying characteristic crystals in synovial fluid from affected joints. Calcium oxalate crystals may be of two morphologies (Hoffman *et al*. 1982; Reginato *et al*. 1986). The more commonly identified type is weddelite or calcium oxalate dihydrate. This is a positively birefringent bipyramidal crystal (Fig. 17). Less commonly, calcium oxalate monohydrate (whewellite) occurs. Whewellite is polymorphic and may be seen as chunks, rods, ovals, or microspherules. Scanning electron microscopy and X-ray diffraction are often necessary to confirm the identities of these crystals.

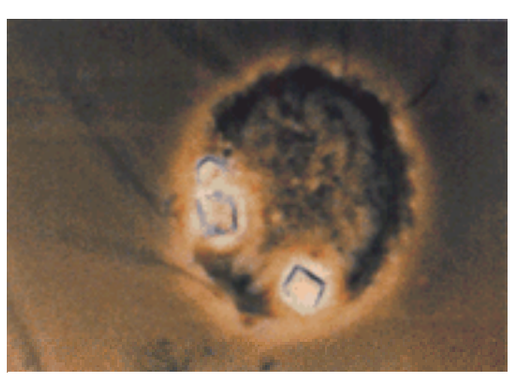


Fig. 17 The typical bipyramidal crystals of calcium oxalate dihydrate are seen here inside a cell.

Synovianalysis usually shows clear or bloody fluid with normal viscosity. Cell counts are typically low and often neutrophils predominate, although large mononuclear cells have also been described (Hoffman *et al*. 1982).

Radiographs are not diagnostic but may be helpful. Miliary calcific deposits in the soft tissue can be seen. Similarly, vascular calcification is a common finding. Less commonly, bony abnormalities such as localized or metaphyseal sclerosis, pseudoarthroses, and pathological fractures can be seen (Milgram 1974; Gherardi *et al*. 1980; Nartijn and Thijn 1982).

Pathophysiology

Oxalic acid is a metabolic end product of amino acid synthesis and ascorbic acid metabolism. It is well absorbed from the gut and is renally excreted. Hence oxalate may accumulate in tissues from excess absorption, overproduction, or underexcretion. Renal failure causes underexcretion of oxalate and levels are high in patients on dialysis. Neither haemo- nor peritoneal dialysis adequately clears oxalate from tissues (Op de Hock *et al*. 1980). Causes of overproduction include the enzyme defects of primary oxalosis, and thiamine and pyridoxine deficiencies. Dietary excesses of spinach, rhubarb, and ascorbic acid supplements may also raise oxalate levels. Excess intestinal absorption may be due to short bowel syndrome from any causes. The most common associated bowel disorders are bowel bypass syndrome from obesity surgery and inflammatory bowel disease.

Once oxalate crystals form in articular tissues, they are released by unknown mechanisms and initiate an inflammatory response (Faires and McCarty 1962).

Management

There is no specific treatment for calcium oxalate arthritis. In general, response to conventional therapies including NSAIDs, intra-articular corticosteroids, colchicine, and increased dialysis are poor. The grim outlook for patients with primary oxalosis may be brightened by early liver transplantation before renal failure has developed (Watts *et al*. 1991).

Other crystals

Other types of crystals can be identified in synovial fluid. These crystals are listed in Table 10. Commonly seen crystals are illustrated in Fig. 18, Fig. 19, and Fig. 20.

Crystal	Morphology	Setting	Significance
Lipid	Round	Trauma	Uncertain
Cholesterol	Plate-like	Unclear	Uncertain
Steroids	Any shape, very bright	After injection	Recent steroid injection
Cryoglobulin	Polygonal, positively birefringent	Cryoglobulinaemia	
Charcot-Leyden	Bipyramidal or hexagonal	Hypereosinophilia	
Cystine	Hexahedral, weak or bright	Cystinosis	
Xanthine	Rhomboidal or plate-like	Xanthinuria	

Table 10 Other crystals found in synovial fluid

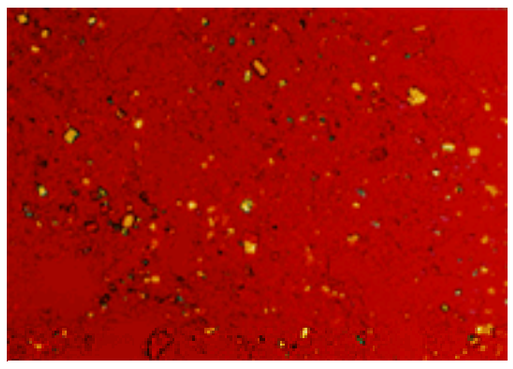

Fig. 18 Steroids crystals can be seen in synovial fluids after intra-articular corticosteroid injections.

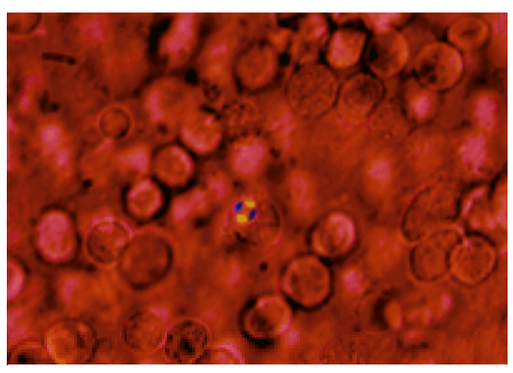

Fig. 19 The typical appearance of lipid crystals in synovial fluid.

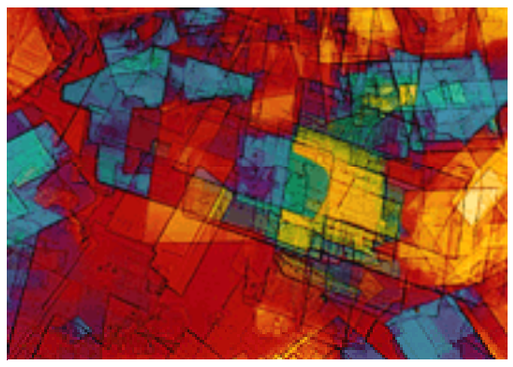

Fig. 20 The typical appearance of cholesterol crystals in synovial fluid.

5.17.1 Osteoporosis and osteomalacia

A. K. Bhalla

Introduction

Disorders of bone that lead to a reduction in bone mass and strength cause much suffering in the population and often present to the rheumatologist with pain, fractures, and deformity. The most common bone disorder in Western nations is osteoporosis, although globally osteomalacia or rickets secondary to vitamin D deficiencies are more common. Unlike osteomalacia, in osteoporosis the mineralized bone, while reduced, is normal; the disorder can be defined as a reduction in bone mass and strength resulting in an increased risk of fracture with minimal or no trauma. The term 'osteopenia' is sometimes used to delineate a state of reduced bone mass, for example identified during radiological investigation or bone mass measurement, without fracture.

Osteoporosis

Definition

Until recently there was no internationally agreed definition of osteoporosis. A 1991 Consensus Development Conference defined osteoporosis as 'a disease characterised by low bone mass and micro architectorial deterioration of bone tissue, leading to enhanced bone fragility and a consequent increased risk in fracture' (Consensus Development Conference 1991).

This definition of osteoporosis has been accepted by the World Health Organization (**WHO**), which has now also defined osteoporosis on the basis of bone density. The categories of disease as defined by the WHO 1994 criteria based on bone mineral density are shown in Table 1.

Disease category	BMD or BMC value
Normal	Not less than 1 SD below young adult mean value
Low bone mass (osteopenia)	More than 1 SD below young adult mean value but not less than 2.5 SD below young adult mean value
Osteoporosis	More than 2.5 SD below young adult mean value
Severe osteoporosis (established osteoporosis)	More than 2.5 SD below young adult mean value in the presence of one or more low-trauma or fragility fractures

BMD, bone mineral density; BMC, bone mineral content.

Table 1 Categories of osteoporosis as defined by WHO based on bone mineral density (after Kanis *et al*. 1994*a*)

These diagnostic criteria for osteoporosis do have some limitations and are likely to be changed in time. It is important to remember that they apply to postmenopausal women and it is not yet agreed what criteria should be applied to men or to young individuals who have yet to attain skeletal maturity, or to special situations such as corticosteroid osteoporosis. Kanis *et al*. (1994*b*) suggest that, since in some populations the risk of fracture in men is substantially lower for bone mineral measurements within their own reference range, diagnostic criteria of 3–4 SD below a young reference mean may be more appropriate. In addition, different cut-off values may be appropriate for different communities since differences in the risk of hip fractures between communities cannot solely be explained on the basis of bone mineral density.

Epidemiology

In the Western world osteoporosis causes considerable suffering in individuals over the age of 50, and, because it predisposes to skeletal failure and fractures, is responsible for consuming an enormous amount of the budget devoted to health care. The main sites of fracture traditionally thought to be related to osteoporosis are the vertebral body, proximal femur, distal forearm, the proximal humerus, and pelvis, of which the first three are more common (Fig. 1) (Riggs and Melton 1986). The risk of an osteoporotic fracture is greater in women than men, and in both sexes the risk varies appreciably between countries. In women from the United States and Europe, the lifetime risk of a hip fracture at the age of 50 is 17.5 per cent whilst the lifetime risk of a hip fracture in a male is 6 per cent. The lifetime risk of a vertebral fracture is estimated at 15.6. per cent for women and 5 per cent for men, and the risk of having either a fracture of the femur or the distal forearm is approx. 40 per cent in women aged over 50 years and 13.1 per cent in men (Table 2) (Melton *et al*. 1992).

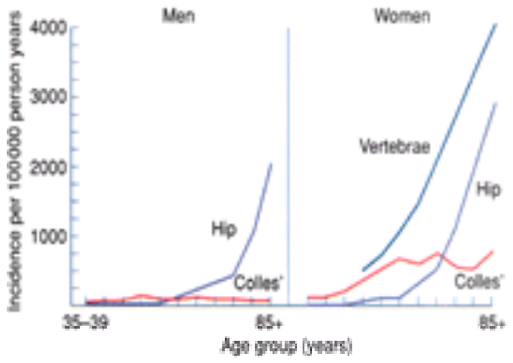

Fig. 1 Incidence rates for the three common osteoporotic fractures (Colles', hip, and vertebral) in men and women, plotted as a function of age at the time of the fracture (reproduced from Riggs and Melton 1986 with permission).

Fracture site	Lifetime risk (%)	
	Men	Women
Hip	6.0	17.5
Vertebral	5.0	15.6
Distal forearm	2.5	16.0
Any of the above	13.1	39.7

Table 2 Lifetime fracture risk in 50-year-old white men and women (Melton *et al*. 1992)

As discussed below, the three most common fractures have different sex ratios and incidence rates at different decades. The incidence of fractures of the distal forearm in women increases soon after the menopause, with a peak incidence between the ages of 50 and 65 (there is a peak in the risk of falls in women aged 45 to 60 years), while in adult males the incidence rates remain constant. Presumably the attempt to break the fall by stretching out the arm accounts for this fracture. In contrast, fractures of the proximal femur show an exponential increase in incidence much later in life, with a 20-fold increase between the ages of 65 to 85 years (where the incidence of falls increases by only twofold) and a male:female ratio of 1:2. This indicates that the probability of a fall resulting in a fracture of the femoral neck is modulated by other age-related factors. Such factors would include the progressive loss of bone with ageing (Winner *et al*. 1989), and a tendency, with increasing age, for a greater likelihood of a fall on the hip than on the hand, presumably due to neuromuscular impairment making it less likely that he or she has enough time to break the fall by throwing out an arm (Grimley Evans 1990).

Proximal femoral fracture

Hip fracture, the most serious complication of osteoporosis, usually follows a fall from a standing position, although it may occur spontaneously. The occurrence of hip fracture has a seasonal variation in both hemispheres. Hip fractures occur more frequently during the winter months; the majority follow falls indoors and therefore are not related to slipping on ice. In most Western countries the incidence of hip fractures has been rising steadily and not all the increase can be explained by an ageing population (Boyce and Vessey 1985; Obront *et al*. 1989). In Sweden the total number of hip fractures between 1950 and 1985 has increased sevenfold while the number of inhabitants over the age of 50 has doubled during this period (Fig. 2). A large part of the increase in hip fracture is due to an increase in the age-adjusted incidence of hip fractures (Obront *et al*. 1989).

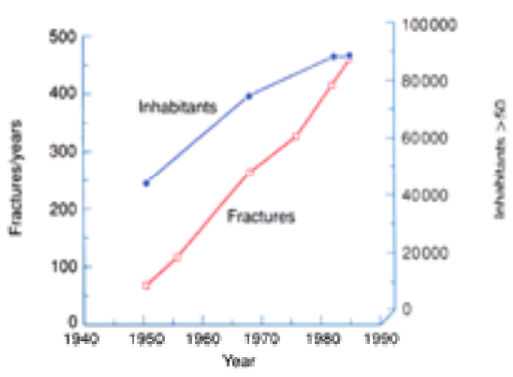

Fig. 2 The relation between the total number of fractures of the hip and the population over 50 years of age in Malmo, Sweden (reproduced from Obront *et al*. 1989 with permission).

In the United Kingdom the incidence of hip fractures rises exponentially with age in both sexes (Fig. 3) and with an approximate 2:1 female to male incidence. This fact, and because there is a large number of elderly women in the population, results in over 80 per cent of all hip fractures occurring in women over the age of 65.

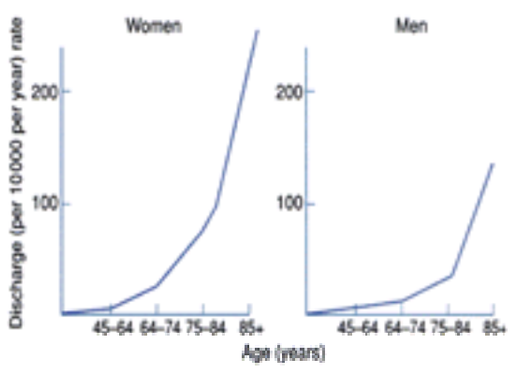

Fig. 3 Hospital discharge rates for fractured neck of femur by age and sex in England, 1985 (derived from Royal College of Physicians 1989).

There were 46 000 hip fractures in England and Wales in 1985 and current estimates suggest that 60 000 occur annually (Advisory Group on Osteoporosis 1994). In 1989 the Royal College of Physicians estimated that if the 1985 age- and sex-specific incidence rates continue to double every 30 years, then by the year 2016 there

will be 117 000 hip fractures annually. Using 1985 incidence rates the probability of a woman sustaining a hip fracture before the age of 85 in the United Kingdom is 12 per cent; for a man it is 5 per cent. In the United Kingdom the direct hospital cost for hip fractures in 1985 were about £160 million. The most recent estimate, using 1992/93 prices, suggests that in England alone the acute inpatient costs will be £237 million, and additional costs of long-term and community care could be a further £444 million (Advisory Group on Osteoporosis 1994).

In the United States there were 238 000 hip fractures in 1986 in adults over the age of 50 years, and, assuming that current age-specific incidence rates remain unaltered, then by the year 2020 there will be 347 000 hip fractures. The annual acute-care costs will rise from the current sum of $8 billion by four- to eightfold.

Hip fractures are recognized as major health problems in Western countries, but there is a belief that since most fractures occur in Caucasian populations the problem may not affect the nations of Asia, South America, and Africa. However, using current incidence rates of hip fractures in various parts of the world to projected populations in the year 2050, it has been estimated that the number of hip fractures occurring world-wide each year will rise from 1.6 million in 1990 to 6.26 million by 2050. Whilst in 1990 nearly half the hip fractures occurred in North America and Europe, with 31 per cent in Asia, by the year 2050 50 per cent of hip fractures will occur in Asia, with 13 per cent in Europe and 12 per cent in North America. Thus osteoporosis, particularly hip fractures, will become a world-wide problem requiring preventative strategies to be developed in regions where currently it is thought not to be a major problem (Cooper *et al*. 1992).

Hip fractures result in considerable mortality. Surveys suggests that between 10 and 40 per cent of all patients who fracture a hip die within 12 months of the fracture (Fig. 4) (Aitken 1987). The excess mortality may, in part, be due to the presence of more coexisting morbidity in patients with fractures than in the age-matched, non-fractured population. In a prospective study, patients admitted with a hip fracture alone has 0 per cent mortality at 1 year compared to 14 per cent and 24 per cent if two or three or more additional medical conditions were present (Svensson *et al*. 1996).

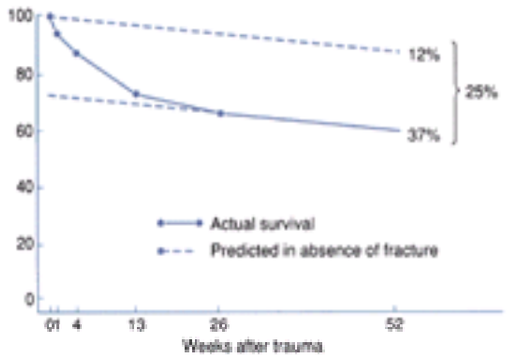

Fig. 4 Relation between survival and passage of time since femoral-neck fracture in women (reproduced from Aitken 1987 with permission).

Risk factors for hip fracture

Recently, two large, well-conducted studies have examined the role of risk factors in hip fracture (Table 3) (Cummings *et al*. 1995; Johnell *et al*. 1995). Cummings *et al*. (1995) followed 9516 women aged 65 or over for 4 years and identified 192 incidences of hip fractures. These investigators reported that a maternal history of hip fracture doubled the risk of hip fracture, with a relative risk of 2 falling to 1.8 after adjusting for bone density. Women with a history of any previous fracture since the age of 50 showed an increased risk of hip fracture (relative risk 1.5), confirming previous observations (Cooper *et al*. 1988). Other identifiable risk factors included height at the age of 25 (odds ratio 1.3 per 6 cm), a finding also noted by Meyer *et al*. (1993). The reason for this association may be that tall women have further to fall and that they also have a longer hip axis (the distance from the greater trocanter to the inner pelvic ring), which has been associated with a greater risk of hip fracture (Faulkner *et al*. 1993).

Maternal history of hip fracture
Low body-mass index
Height age 25
Short fertile period
Previous hyperthyroidism
Previous treatment with benzodiazepines or anticonvulsants
Poor mental score
Poor depth perception
Low physical activity

Table 3 Important risk factors for hip fractures in women

Johnell *et al*. (1995) found no significant adverse effect of smoking, unlike Cummings *et al*. (1995), who could show a significant effect of smoking in an age-adjusted model only, but not after multivariate adjustment for factors such as weight, poor health, and inadequate exercise, all of which were more pronounced in smokers. The relation between calcium intake and hip fractures remains controversial in view of the inconsistent findings in these two epidemiological studies. Cummings *et al*. 1995 found no relation between dietary calcium intake and hip fracture, while in the European study (Johnell *et al*. 1995) a low intake of milk was associated with a significantly increased risk. The increased risk was, however, confined to that 10 per cent of the population with a calcium intake of less than 240 mg daily.

The incidence of hip fracture rises depending on the number of risk factors present. For example, those with two or less risk factors had an incidence of 1.1 hip fractures per 1000 women years compared to an incidence of 19 in those with five or more risk factors. The risk of fracture is greatly increased if bone density is reduced (see Fig. 5) in association with other risk factors (Cummings *et al*. 1995). In the European study (Johnell *et al*. 1995), risk factors such as late menarche, poor mental score, low body mass index, reduced physical activity, low sunshine exposure, and low intake of calcium explained about 70 per cent of the total risk of fracture. Further studies are required to confirm these observations.

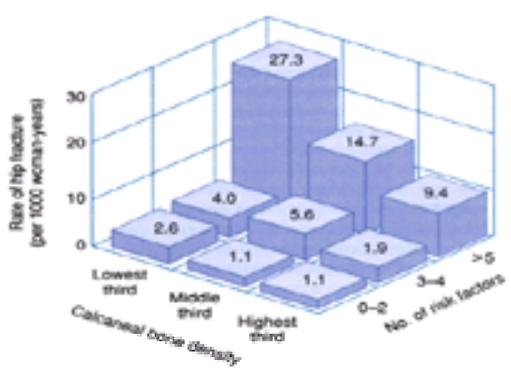

Fig. 5 Annual risk of hip fracture in relation to number of risk factors and calcaneal bone density (after Cummings *et al*. 1995).

Vertebral fractures

The prevalence of vertebral fractures is not accurately known since there is no universally agreed definition of vertebral fracture and they are often asymptomatic so that clinical diagnosis may be delayed until multiple fractures have occurred, leading to spinal deformity and loss of height. The socioeconomic costs of vertebral fracture are therefore unknown.

Epidemiological studies on the prevalence of vertebral fractures have often used differing criteria for defining a fracture and currently there is no accepted definition of vertebral fracture based on the degree of deformation. The criterion for defining a wedge fracture varies from a 20 to 30 per cent reduction in anterior or posterior height of the vertebra compared with adjacent vertebrae, and the lack of agreement may account for the discordant results from studies of drugs, such as fluoride, in established osteoporosis. A clinically significant vertebral fracture requires a deformation of at least 20 to 25 per cent and more minor deformities may reverse spontaneously (Kleerekoper 1992).

The incidence of vertebral fractures increases with age and about 20 to 30 per cent of women aged over 60 may have an asymptomatic vertebral fracture on routine radiography. In cross-sectional studies in the United States, it has been estimated that each year 538 000 postmenopausal women will sustain their first vertebral fracture (Riggs and Melton 1986). The prevalence of vertebral fractures in the United Kingdom has been estimated at 7.8 per cent and the prevalence rises with advancing age from 4.3 per cent at 55 to 59 years to 27.8 per cent at 80 years or over (Cooper *et al*. 1991). It has recently been estimated that 40 000 clinically diagnosed vertebral fractures occur annually in postmenopausal women in the United Kingdom. Studies of the Scandinavian population show not only an age-related increase in incidence of vertebral fractures, but also a fourfold increase in incidence and prevalence between 1950 and 1980 (Benger *et al*. 1988). The prevalence of vertebral fracture increases with decreasing bone density and approaches 50 per cent in those with vertebral bone density below 0.6 g/cm ^{2} as measured by dual-photon absorptiometry (Riggs and Melton 1986). A recent European epidemiological study suggests that the prevalence of vertebral deformities is 12 per cent in women (range 6–21 per cent) and 12 per cent in men (range 8–20 per cent). The prevalence increased with age in both sexes with a steeper rise in women. In women aged 76 to 79 the prevalence was 24.7 per cent compared to 18.1 per cent in men (O'Neill *et al*. 1996). Using the prevalence figures for the United Kingdom from the study, it is estimated that 900 000 men and 1 million women between the age of 50 and 79 years have vertebral deformity, and, even if only 1 out of 3 is symptomatic, 350 000 more will seek medical advice and help (O'Neill *et al*. 1996).

Distal radius fractures

The incidence of fracture of the distal radius (Colles' fracture) after a fall increases in women after the age of 40 and continues to rise until age 65, when it reaches a plateau. No such increase is observed in men (Fig. 1). The reason for the plateau in incidence rates in females after the age of 65 is unknown, but may relate to the incidence patterns of fall with advancing age. In older women, impaired neuromuscular co-ordination is more likely to lead to a fall on the hip than on the wrist whereas a younger woman may be able to break the fall by outstretching her arms. It is assumed that the fracture after trauma is the result of rapid loss of trabecular bone following the menopause. There is a peak in the incidence of falls between the ages of 45 and 60 years in women, which may contribute to the incidence of this fracture (Winner *et al*. 1989). The occurrence of a Colles' fracture may provide an early warning of osteoporosis in the affected individual.

Classification

There are several causes of osteoporosis and it may be either primary or secondary (Table 4).

Physiological or primary
Postmenopausal (type I)
Age-related (type II)
Idiopathic
Juvenile
Secondary
Endocrine
Cushing syndrome
Hyperparathyroidism
Hypogonadism
Thyroid toxicosis
Hypopituitarism
Insulin-dependent diabetes mellitus
Drugs
Corticosteroids
Excess thyroxine replacement
Heparin
Anticonvulsants
Methotrexate
Haematopoietic
Multiple myeloma
Lymphoma, leukaemia
Mastocytosis
Immobilization
Idiopathic hypercalciuria
Gastrectomy and other bowel disease
Osteoporosis of pregnancy
Inflammatory disorders
Rheumatoid arthritis
Ankylosing spondylitis
Congenital
Osteogenesis imperfecta

Table 4 Classification of osteoporosis

Physiological or primary osteoporosis has been divided into two main types by some as type I (postmenopausal) and type II (age-related) osteoporosis. Type I osteoporosis affects predominantly trabecular bone and is associated with an increased risk of wrist and vertebral fractures, while type II affects both trabecular and cortical bone leading to hip fractures. In practice there is considerable overlap between these groups, since patients with vertebral fractures have a greater risk of having a fractured hip and vice versa. In most patients with osteoporosis, distinguishing primary from secondary osteoporosis may be difficult since many factors may be present in one individual, for example a postmenopausal, elderly woman on corticosteroids.

Physiological osteopenia or age-related osteopenia affects all individuals and occurs in cortical and trabecular bone. It leads mainly to hip and vertebral fractures, but other fractures, such as in pelvis or humerus, are also common. Individuals with age-related osteoporosis have reduced bone mass at all sites, with values in the lower half of the distribution range (for further discussion see below under peak bone mass).

Postmenopausal osteoporosis (type I)

Bone loss in women aged between 40 and 65 years is primarily due to loss of ovarian function, as predicted by Albright (Albright *et al*. 1976). Most studies suggest that, in postmenopausal women, bone loss began perimenopausally and will decrease exponentially after 5 to 8 years to match the slower, age-related loss (Krolner and Nielsen 1982). Even though 80 per cent of the skeleton consists of cortical bone, loss occurs predominantly in bones of primarily trabecular structure since the surface area of trabecular bone is four times that of cortical bone. The rapid bone loss is due to increased resorption superimposed on the age-related loss.

The mechanism by which oestrogens protect the skeleton is unknown. An early hypothesis suggested that malabsorption of calcium was the primary event that leads to removal of calcium from the skeleton. This is unlikely since calcium alone cannot reduce postmenopausal bone loss. In addition, reduced absorption of calcium would be expected to activate the release of parathyroid hormone (**PTH**) and increase the production of 1,25(OH)$_2$D (calcitriol), whereas the opposite is usually found in postmenopausal women. An alternative theory suggested that the menopause is accompanied by a relative deficiency in calcitonin reserve or secretion (Reginster *et al*. 1987), leading to a partial removal of the inhibitory effects of this hormone on osteoclastic bone resorption. However, other studies have not observed impaired calcitonin secretion after the menopause, and patients who have been rendered calcitonin-deficient by thyroidectomy do not have an increased risk of osteoporosis, which would strongly argue against a major role for calcitonin in postmenopausal bone loss (Stevenson 1988). Recently, oestrogen receptors have been identified in human osteoblast-like cells (Eriksen *et al*. 1988) and osteocytes (Braidman *et al*. 1995), which suggests that oestrogen can act directly on bone. One effect of oestrogen on bone cells is to increase the release of anabolic cytokines such as transforming growth factor-b (TGF-b), a potent regulator of osteoblast proliferation and a potential coupling agent between bone resorption and formation in the remodelling cycle (Gowen 1991). Peripheral blood monocytes from women with 'high turnover' osteoporosis, histologically defined as having increased bone resorption and bone formation, synthesize higher amounts of the catabolic cytokine interleukin (**IL**) 1 than those from women with 'low turnover' osteoporosis, in whom bone formation is impaired (Pacifici *et al*. 1987). Furthermore, in the early years after ovarian failure, when bone resorption is rapid, the increased synthesis of IL-1 by monocytes can be blocked by oestrogen replacement therapy (Pacifici *et al*. 1989). Similarly, oestrogen decreases the release of tumour necrosis factor (**TNF**)-a from circulating monocytes of postmenopausal but not premenopausal women (Ralston *et al*. 1990). The increased production of IL-1 and TNF-a by *ex vivo* cultures of monocytes after a surgical oophorectomy was reversed by oestrogen replacement (Pacifici *et al*. 1991). It is likely that IL-1 and TNF play an important part in bone loss associated with oestrogen deficiency.

Two other cytokines, IL-6 and IL-11, may also be targets for the antiresorptive effect of oestrogens (Manolagas and Jilka 1995). To explore the hypothesis that osteoclasts and granulocyte/macrophages arise from common haemopoietic progenitor, the genesis of osteoclasts in animal models of osteoporosis was assessed by using bone marrow culture and counting granulocyte/macrophage colony-forming units. Ovariectomized mice had a high number of granulocyte/macrophage colony-forming units from bone marrow as well as from spleen than normal controls, which correlated with a greater number of osteoclasts present in their bone. This effect was prevented when animals were treated with either oestrogens or antibodies to IL-6 (Jilka *et al*. 1992). The hypothesis generated by this study was that IL-6 directs the genesis of osteoclasts in oestrogen-depleted animals. More recently the same group have also shown that IL-11 may also play a critical part in osteoclast differentiation and development in an oestrogen-depleted state (Girasole *et al*. 1994). Thus, oestrogens may maintain bone mass by inhibiting the release of cytokines that stimulate bone resorption, probably by an effect on osteoclast differentiation, while upgrading the synthesis of other cytokines involved in bone formation. This interrelation between oestrogens, cytokines, and bone resorption may turn out to be much more complicated, but also offers a potential for targeting therapy of osteoporosis.

Age-related ('senile') osteoporosis (type II)

Type II osteoporosis, as defined by Riggs and Melton (1986), affects men and women of 70 years or older, resulting in hip and vertebral fractures, although fractures at other sites are also common. The vertebral fractures are of the wedge variety leading to dorsal kyphosis, and often the deformity is painless, the result of gradual, age-related loss of trabecular bone. Unlike type I osteoporosis, the incidence of hip fractures in type II osteoporosis is only twice as great in women as in men, suggesting that the age-related bone loss is important in the pathogenesis of this disorder (Fig. 1). It has been suggested that the two important factors responsible for the slow phase of bone loss are defective osteoblast function and renal endocrine failure. The impaired production of 1,25(OH) $_2$D by the kidney leads to decreased calcium absorption and secondary hyperparathyroidism. Low concentrations of 1,25(OH) $_2$D have been found in some elderly patients with hip fractures but concentrations of PTH have not been found to be elevated in all studies. However, in a recent trial on the prevention of hip fractures by vitamin D and calcium supplementation, the effect of these two drugs was to reduce the high normal concentrations of PTH in the elderly population and at the same time reduce substantially the risk of hip fractures (Chapuy *et al*. 1992). In some studies, serum 1,25-dihydroxyvitamin D_3 is found to be lower in women with postmenopausal osteoporosis than in age-matched controls, and the density and function of vitamin D receptors in the intestine were also lower in such individuals. Since synthesis of 1,25 dihydroxy vitamin D_3 in response to PTH may be impaired in women with postmenopausal osteoporosis, one can generate a hypothesis that reduced calcium intake and vitamin D synthesis lead to increased activity of PTH, then producing an attempt to correct the deficiency by stimulating the renal la-hydroxylase to synthesize more 1,25 dihydroxy vitamin D_3. As this pathway is less efficient, calcium deficiency persists and the increased PTH leads to increased bone resorption.

Idiopathic osteoporosis

This defines the occurrence of osteoporosis in premenopausal women or men under the age of 60 who do not have an obvious secondary cause for the disease. The male:female ratio is usually 10:1 and presentation is usually with vertebral compression fractures. Some individuals may be found to have mild forms of osteogenesis imperfecta. A subgroup of males with idiopathic osteoporosis has 'high bone turnover' osteoporosis with hypercalcuria and may be treated with antiresorption drugs such as calcitonin and bisphosphonates (Perry *et al*. 1982); most of the others have defective osteoblast function with low rates of bone formation (Jackson *et al*. 1987).

Juvenile osteoporosis

This is an uncommon disorder that occurs before, or at the onset of, puberty and affects both sexes equally. The pathophysiology is unknown. The child usually presents with pain in the lower back, hip, and feet, and fractures of weight-bearing joints and collapsed vertebrae. There is no consistent biochemical abnormality, and radiographs may show osteopenia, fracture and vertebral abnormalities, and scoliosis. The differential diagnosis includes osteogenesis imperfecta and osteomalacia, and other secondary causes should be excluded. There is no specific treatment for this disorder and recovery occurs as puberty progresses, with a return of bone mass towards normal. In some patients, however, fractures lead to deformity of the spine or extremity, and it is important that once the condition is diagnosed, non-weight-bearing and supportive physical therapy be made available.

Endocrine causes

Corticosteroids

Endogenous Cushing syndrome or chronic treatment with glucocorticosteroids is a well-recognized cause for severe osteopenia and fractures (especially of the vertebrae and ribs, sites that contain predominantly trabecular bone) and sometimes occurs without other evidence of glucocorticoid excess. In endogenous Cushing syndrome the prevalence of osteoporosis may be as high as 50 per cent and the incidence of spontaneous fractures 19 per cent (Ross and Linch 1982). In iatrogenic disease the prevalence of fractures may vary from 2 to 17 per cent, but the incidence may depend on the dose of drug used and its duration (Reid 1990). Asthmatics on a mean dose of 12 mg prednisolone over 7 years had a 34 per cent prevalence of vertebral fractures (Luengo *et al*. 1991). In a retrospective study of patients with severe asthma on corticosteroids, vertebral fractures were found in 11 per cent of patients admitted to hospital (Adinoff and Hollister 1983). An even higher prevalence was found in a small prospective study of patients with asthma, with 42 per cent having vertebral and hip fractures (Adinoff and Hollister 1983). An increased incidence of fractures has also been noted in patients with rheumatoid arthritis treated with glucocorticoids. Michel *et al*. (1991) reported a 34 per cent prevalence of vertebral fractures in patients with rheumatoid arthritis on corticosteroids. A more recent study using morphometric techniques found a 12 per cent prevalence in postmenopausal women under 65 years of age with rheumatoid arthritis compared to 6 per cent in matched controls, with no increase in prevalence in those treated with doses of prednisolone below 7.5 mg (Spector *et al*. 1993). Postmenopausal females with rheumatoid arthritis on a mean daily dose of prednisolone 7 mg experienced twice as many vertebral fractures as patients not receiving prednisolone (Laan *et al*. 1992). A case-controlled study suggested a doubling of the risk of hip fractures in patients with rheumatoid arthritis receiving glucocorticoids (Cooper *et al*. 1995).

Individuals at greatest risk of glucocorticoid-induced osteoporosis are postmenopausal women and men over the age of 50 years, as well as prepubertal children, in whom corticosteroids also delay skeletal growth.

Reduced bone mass in patients treated with corticosteroids has been demonstrated at multiple skeletal sites, including primary cortical bone in, for example, the femoral head, using a variety of techniques including quantitative computed tomography and dual-energy X-ray absorptiometry. Trabecular bone with its larger surface area seems particularly prone to loss. Vertebral bone density may be reduced by as much as 40 per cent in patients treated with a moderate dose of corticosteroids (Laan *et al*. 1993*a*). Bone loss from trabecular regions may occur very rapidly, especially in the first year of treatment (Laan *et al*. 1993*b*).

The diagnosis of corticosteroid-induced osteoporosis is relatively easy in a young patient who sustains fractures whilst on corticosteroids. However, it is a more difficult diagnosis to make in an older patient where there may be other risk factors such as postmenopausal osteoporosis. Although osteoporosis has been defined on the basis of bone density using the WHO criteria, the definition of postmenopausal osteoporosis may not be relevant to corticosteroid-induced osteoporosis since there is evidence that fractures in patients treated with corticosteroids occur at higher bone density (Luengo *et al*. 1991). This difference makes it difficult to identify the individual at risk, particularly on the basis of pretreatment measurements of bone density.

The pathogenesis of glucocorticoid-induced osteoporosis is controversial since these drugs may affect calcium and phosphate metabolism, either directly or indirectly through actions on bone, kidney, and intestine (Fig. 6). Corticosteroids may indirectly enhance bone resorption and directly suppress bone formation by decreasing osteoblast function and maturation. The increased osteoclastic bone resorption by corticosteroids is secondary to reduced intestinal absorption of calcium leading to a rise in PTH, and in animals parathyroidectomy abolishes the osteoclastic response to steroids. The hypothesis that secondary hypoparathyroidism plays a part in the osteoporosis which results from glucocorticoid excess leading to a decrease in intestinal calcium absorption and increased urinary excretion of calcium has been put in some doubt by recent studies showing that, when intact PTH is measured, its concentrations do not change with the use of glucocorticoids.

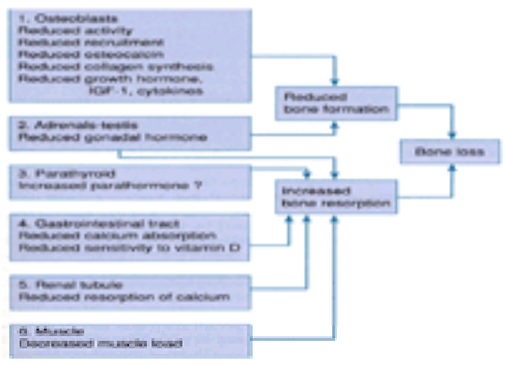

Fig. 6 Pathogenesis of glucocorticoid-induced osteoporosis.

Another mechanism for steroid osteoporosis may be through inhibition of secretion of calcitonin, a hormone whose major effect is to inhibit bone resorption. Decreased intestinal absorption of calcium by glucocorticoids was thought to be due to decreased production of 1,25-dihydroxyvitamin D_3 from its precursor, 25-hydroxyvitamin D_3. This is unlikely, since recent studies indicate that the circulating concentrations of these vitamin D metabolites are unaltered and that the defect in calcium absorption cannot be overcome entirely by dietary supplementation with them. The mechanism of action is probably indirect, and, since glucocorticoid receptors are present in the small intestine, glucocorticoids may interfere with the binding of 1,25-dihydroxyvitamin D_3 to its receptor in the intestine or affect the function of important enzymes in the mucosal cell needed for calcium absorption and transport.

Excessive exogenous use of corticosteroids may lead to a reduction in testosterone and contribute to bone loss seen in males. In females the adrenal synthesis of androgens may also be reduced due to suppression of endogenous corticosteroid synthesis.

Hyperparathyroidism

Primary hyperparathyroidism is a relatively common disorder with a prevalence in adults estimated at 0.1 to 0.2 per cent. The disease is most common between the fifth and seventh decades of life, and is three times more common in women than men, the female predominance arising entirely from an increased incidence after the menopause (Bhalla 1986). Most patients with mild hyperparathyroidism are asymptomatic, the diagnosis being made during a biochemical screening when a high serum calcium is detected. PTH stimulates osteoclastic bone resorption by an effect primarily on osteoblasts, which in turn release a factor or factors that cause bone resorption or enhance osteoclastic activity. In young individuals, increased bone resorption may be compensated for by increased bone formation, but in older individuals, and in particular postmenopausal females, the compensatory mechanism is less efficient, leading to reduced bone mass in the axial and the appendicular skeleton (Devogelar *et al*. 1984; Martin *et al*. 1986), which, however, does not affect all patients. There is conflicting evidence for recovery of bone mass after parathyroidectomy and further studies are necessary (Martin *et al*. 1986). Since reduced bone mass is a predictor of fractures, parathyroid-mediated bone loss should result in an increased risk of fracture but this possibility remains controversial. Some studies have reported a higher prevalence of spinal fracture (Dauphine *et al*. 1975) that others have not been able to confirm (Wilson *et al*. 1988).

Hypogonadism

All causes of hypogonadism lead to bone loss and may be associated with an increased risk in osteoporotic fractures. Amenorrhoea, whether primary or secondary, is associated with decreased bone mass and increased risk of fracture. Women with endometriosis who are treated with antagonists to luteinizing hormone-releasing hormone develop reversible hypo-oestrogen states in which trabecular bone loss occurs but recovers once treatment is discontinued (Matta *et al*. 1981). Similarly, women with hyperprolactinaemia and anorexia nervosa accompanied by amenorrhoea develop spinal osteopenia that in some cases leads to vertebral fractures. Amenorrhoea is observed in elite female athletes, who develop a reduced spinal bone destiny compared to that of eumenorrhoeic runners (Drinkwater *et al*. 1984), indicating that exercise alone cannot protect the skeleton in the face of oestrogen deficiency. The duration of amenorrhoea, from whatever cause, that will lead to irreversible bone loss is unknown, but is thought to be more than 6 months. Testosterone deficiency is present in approx. 30 per cent of men with spinal osteoporosis; they usually present in the sixth decade but most have symptoms of hypogonadism in the preceding 20 to 30 years (Jackson and Kleerekoper 1990). In males, hypogonadism from any cause may be associated with osteoporosis, including those with Klinefelter syndrome, hypogonadotrophic hypogonadism, hyperprolactinaemia, anorexia nervosa, and mumps orchitis.

Hyperthyroidism

In thyrotoxicosis, bone turnover may be significantly increased due to enhanced recruitment and increased resorption. Patient with a past history of thyrotoxicosis when compared with those who have not had thyrotoxicosis have an increased relative risk of hip fractures of 2.4 (Cummings *et al*. 1992). Thyrotoxicosis causing high-turnover osteoporosis should be thought of in elderly individuals in whom the diagnosis may not be clinically obvious and will be dependent on laboratory testing. Excessive thyroxine replacement in the hyperthyrotoxic individual may also increase bone loss, although the evidence for this is conflicting.

Nutrition

Calcium

While bone mass can may be transiently increased by calcium supplementation in adolescents, there is no evidence to suggest that above-normal intakes of calcium influence the peak bone mass (see 'Management of osteoporosis' below).

Drugs

The effects of glucocorticoids and thyroxine have been discussed above. Chronic heparin therapy can lead to decreased bone mass by enhancing PTH-mediated bone resorption, but warfarin is not associated with this complication despite a low circulating osteocalcin and impaired carboxylation of osteocalcin in warfarin-treated patients. Chronic administration of anticonvulsants lead to disturbance in calcium and vitamin D metabolism. These drugs increase the activity of hepatic microsomal mixed oxidases, leading to increased catabolism of steroid hormones (including vitamin D) and resulting in reduced concentrations of 25-hydroxyvitamin D [**25(OH)D**]. In addition, anticonvulsants directly suppress calcium absorption and antagonize the effects of PTH and vitamin D metabolites on bone. The end result is osteopenia and osteomalacia, particularly if there are other risk factors such as immobility, although not all individuals on chronic therapy are so affected. Methotrexate and other chemotherapeutic agents may affect skeletal metabolism and mass by a direct toxic effect on bone cells or by inducing hypogonadism. The use of antagonists or agonists to luteinizing hormone-releasing hormone to induce ovarian failure in premenstrual tension syndrome and endometriosis results in bone loss that is reversible if treatment is discontinued within 6 months.

Malignancy

Malignant infiltration and replacement of marrow tissue occur in multiple myeloma, lymphoma, leukaemia, systemic mastocytosis, and diffuse bony metastases. Myeloma is usually characterized by focal lytic lesions associated with the accumulation of myeloma cells, but in a small number of patients a diffuse loss of bone that mimics primary osteoporosis occurs. The increased bone resorption is due to the production of osteoclast-activating cytokines such as IL-1 and TNF-a and -b by plasma cells (Garrett *et al*. 1987). In lymphoma a generalized osteoporosis and hypercalcaemia may be the result of local synthesis of 1,25(OH) $_2D_3$ by malignant tissue. Mast cells secrete various products (heparin, histamine, prostaglandin) that could lead to increased osteoclastic bone resorption, and increased numbers of mast cells have been reported in the bone marrow in primary osteoporosis (Fallon *et al*. 1983).

Immobilization

Prolonged immobilization leads to disuse osteoporosis affecting trabecular and cortical bone. The rate of bone loss may be as high as 5 per cent per month for the

first 6 months, after which it slows down to a new steady-state and some recovery is possible on resuming weight-bearing activities. Immobilization leads to increased bone resorption and decreased bone formation associated with hypercalciuria, and to an increase in plasma calcium, increased risk of renal stone formation, and potential suppression of PTH, 1,25(OH)$_2$D and calcium absorption.

Inflammatory disorders

Rheumatoid arthritis

In rheumatoid arthritis, bone loss can be periarticular, a hallmark of the disease, or a more generalized form, as demonstrated in histological, computed tomographic, and dual-photon absorptiometric studies (Dequeker and Geusens 1990). Increased rates of bone loss have been demonstrated by neutron-activated analysis of total body calcium. The pathogenesis of localized osteoporosis involves the production of numerous cytokines such as IL-1, IL-6, transforming growth factor-b, TNF, other growth factors, prostaglandins, and mast cell products (Dequeker and Geusens 1990). At present it is unclear whether all or only some patients with rheumatoid arthritis are affected by generalized osteoporosis, and when present its clinical significance is debatable. While it is not surprising that patients with long-standing destructive and disabling disease have low bone mass (Verstraeten and Dequeker 1990), population-based epidemiological studies show an increased risk of fracture in patients with rheumatoid arthritis, related to age, impaired ambulation, body mass, and corticosteroid use (Hooyman *et al*. 1984; Cooper and Wickham 1990). Factors likely to lead to osteoporosis in rheumatoid arthritis are shown in Table 5. Usually, local factors such as cytokines exert their effect within the local microenvironment. Some cytokines, such as IL-1 and IL-6, may have systemic actions such as the induction of fever and the acute-phase response during inflammation. In rheumatoid arthritis, large amounts of local factors are produced within the joint and have the potential for systemic absorption affecting bone turnover at distant sites. Elevated serum IL-1 that correlates with disease activity has been demonstrated in patients with rheumatoid arthritis (Eastgate *et al*. 1988). However, various inhibitors that may antagonize cytokines have also been found in both serum and synovial fluid (Arend and Dayer 1990) and the net systemic effect on bone turnover of cytokine produced during joint inflammation is unclear. Some studies have demonstrated an association between disease activity and decreased bone mineral content (Sambrook *et al*. 1986) whilst others have not (Rosenspire *et al*. 1980). The difficulty in identifying a correlation between disease activity and bone mineral content is not surprising as almost all the studies involve cross-sectional measurements of the latter, a reflection of long-term accumulation of acute changes in bone turnover, with measurements of disease activity that varies relatively rapidly and may be associated with short-term changes in bone turnover best made by serological and urinary markers of bone metabolism.

Systemic actions of inflammatory products associated with disease activity
Alterations in circulating sex and calcitropic hormones
Altered calcium metabolism
Changes in load bearing of the skeleton
Effect of drugs used in treatment of arthritis

Table 5 Potential factors causing generalized osteoporosis in rheumatoid arthritis

During inflammation an alteration in the circulating levels of hormones has the potential for directly affecting bone turnover or modulating the effects of local factors. Various hormonal disturbances have been described in rheumatoid arthritis, such as changes in circulating sex hormone levels, but their significance in terms of disease activity and bone turnover is unclear. Sambrook *et al*. (1988) found a decreased oestrone, dehydroepiandrosterone sulphate (**DHEAS**), and testosterone; they suggested that the reduction in oestrone and testosterone, but not DHEAS, was secondary to the use of prednisolone. They also noted that reduced DHEAS in postmenopausal women with rheumatoid arthritis correlated with reduced bone mineral density of the femoral neck, suggesting that the disease itself may somehow reduce production of adrenal androgens. A decreased free and total testosterone have been found in some males with rheumatoid arthritis but the significance is as yet unclear. There are conflicting results on the effects of rheumatoid arthritis on calcitropic hormones. In most studies, the circulating levels of 25(OH)D, calcitonin, and PTH are reportedly normal but some have shown a low 25(OH)D (Dequeker and Geusens 1990).

Although calcium malabsorption has been described in patients with rheumatoid arthritis, the majority of workers have reported normal serum calcium and phosphate as well as urinary calcium excretion.

Decreased physical activity leads to decreased functional loading of the skeleton resulting in increased bone resorption. Decreased bone mineral content at the femoral neck and lumbar spine of patients with rheumatoid arthritis is significantly correlated with functional activity and is probably one of the major factors responsible for the bone loss associated with rheumatoid arthritis.

Drugs used in the treatment of rheumatoid arthritis may affect bone loss adversely by affecting bone cell activity or favourably by reducing inflammation and indirectly its effect on bone loss. Corticosteroids in high doses result in generalized bone loss and an increased rate of fracture (Hooyman *et al*. 1984; Cooper *et al*. 1995). This adverse effect is not as obvious at lower doses and there is conflicting evidence as to whether bone loss occurs with doses of less than 7.5 mg of prednisolone per day (Sambrook *et al*. 1986; Butler *et al*. 1991). The effect of intermittent intravenous corticosteroids is unclear, although they are likely to result in an acute suppression of bone metabolism that may be cumulative with frequent treatment. Non-steroidal anti-inflammatory drugs *in vitro* affect osteoblast and osteoclast function and prostaglandin and cytokine production (Gowen 1991), but an adverse independent effect on bone loss has not been demonstrated. The effect of disease-modifying antirheumatic drugs on generalized bone mineral content has not been studied extensively. The rate of generalized bone loss in patients with rheumatoid arthritis on disease-modifying antirheumatic drugs was not different from those not taking them in one study (Reid *et al*. 1981), but others have shown that the drugs prevent bone loss or increase bone mineral content (Kalla *et al*. 1991), probably by suppressing disease activity and thereby improving mobility.

Ankylosing spondylitis

Patients with severe ankylosing spondylitis often develop a dorsal kyphosis, and radiological findings of anterior vertebral wedging in the dorsal spine and of biconcave vertebrae suggest moderate osteoporosis (Ralston *et al*. 1990). Early reports on the prevalence of fractures in ankylosing spondylitis found a low prevalence of vertebral fractures (Wilkinson and Bywater 1958; Hanson *et al*. 1971; Hunter and Dubo 1978; Hunter and Dubo 1983). These studies also indicated that fractures were related to spinal trauma and correlated directly with the duration of the disease. In contrast, other studies such as by Ralston *et al*. (1990) found a much higher prevalence of fractures. Ralston *et al*. (1990) also observed that the development of fractures in their patients correlated directly with disease duration, and noted that vertebral fractures occurred spontaneously and were not related to trauma Cooper *et al*. (1994) found a significantly increased risk of clinically diagnosed vertebral compression fractures in patients with ankylosing spondylitis, but no increase in the risk of limb fractures.

Reid *et al*. (1986), using absorptiometry, reported high bone mineral density of the lumbar spine in patients with ankylosing spondylitis, but Will *et al*. (1989), also using dual X-ray absorptiometry, reported reduced bone mineral density in the lumbar spine and femoral neck of patients with early ankylosing spondylitis when spinal mobility and radiographs were still normal. In patients with more advanced disease there was a further reduction of bone density at the femoral neck and the carpus, suggesting that in ankylosing spondylitis bone loss is progressive and initially involves trabecular bone but later also cortical bone. The same group studied patients with early disease and matched them with same-sex siblings of similar physical activity. The bone density of the femoral neck was reduced in the group with ankylosing spondylitis, indicating that the reduced bone mass is a result of bone loss related to disease rather than failure to achieve adequate bone mass within families with ankylosing spondylitis (Will *et al*. 1990). The reduction of bone density in early ankylosing spondylitis was confirmed by Devogelar *et al*. (1992) and Lanyi *et al*. (1993); in patients with well-established ankylosing spondylitis, both groups of investigators noted increased bone density that was the direct result of syndesmophyte formation. Decreased density of hip bone has also been noted in ankylosing spondylitis (Will *et al*. 1989; Mullaji *et al*. 1994). The pathogenesis of reduced bone density in ankylosing spondylitis is unclear. Since reduced bone density has been found in patients with early disease who have normal spinal mobility, it is unlikely that immobilization of the spine is the primary event. Will *et al*. (1989) suggest that osteoporosis in ankylosing spondylitis is a primary pathological event due to the inflammatory nature of the disease. However, the precise mechanism by which inflammatory mediators are responsible for bone loss remains to be

elucidated.

Clinical features

Typically a patient with osteoporosis is a thin Caucasian female aged between 50 and 70 years who presents with back pain resulting from vertebral fractures. Pain is usually of spontaneous onset, well localized, aggravated by movement, and radiates anteriorly to the lower rib cage and around the flank into the abdomen and thigh. Compression of nerve roots is uncommon and the painful episode usually subsides after 4 to 6 weeks. Some patients, particularly after multiple vertebral fractures, develop a constant dull pain in the lower thoracic or lumbar area that shows many of the features associated with mechanical disorders of the spine. Compression of vertebrae, particularly in the lumbar area, is associated with loss of height, which may be the sole complaint in some patients in whom vertebral compression has been painless. Anterior wedging of the vertebrae leads to a dorsal kyphosis (also known as 'dowager's hump'), with downward angulation of the ribs and a reduction in the gap between the ribs and the iliac crest of the pelvis. Contact between the lower ribs and the iliac crest may cause severe pain in the abdomen and inguinal area. Abdominal protuberance results from downward pressure on the abdominal cavity and may be associated with reflux oesophagitis and a feeling of fullness at meal times (Fig. 7).

Fig. 7 Severe dorsal kyphosis and protuberant abdomen in a 75-year-old woman with osteoporosis.

Patients with appendicular fractures, usually of the wrist and femur, are often seen in emergency departments, although in the elderly individual a diagnosis of a hip fracture may be easily missed as pain may be minimal.

Pathogenesis

Bone growth and peak bone mass

During childhood and adolescence, growth and modelling leads to an increase in the size, shape, strength, and composition of bone. With the closure of the growth plate (also called the epiphyseal cartilage), growth ceases, but the need for mineral homeostasis and skeletal self-repair by removing and replacing effete bone is served by remodelling, a process that continues throughout life. In remodelling, unlike modelling, the sequence of bone formation and resorption is anatomically and quantitatively coupled. The resorption of a given amount of bone is followed by the deposition of an equivalent amount of new bone, but after the age of 35 to 40 years, presumably due to decreased osteoblastic activity, the amount of bone laid down is less than the amount resorbed during each remodelling sequence and leads to the bone loss seen with ageing.

A rapid gain in bone mass occurs in infancy and adolescence in both sexes. In early childhood males and females have similar bone mass, but after puberty males have a greater amount of cortical bone than females. In girls there is a dramatic increase in bone density during puberty and those with low oestrogen concentrations and a history of irregular menses attain a lower bone mass. Bone density in both white and black girls is similar during the early stages of puberty and an increase is observed only in the later stages of puberty, but at a greater rate in black than white girls. Using computed tomography to measure axial bone density, Gilsanz *et al*. (1991) observed that black and white girls have similar bone density in the early stages of puberty; at Tanner stage 4 and 5 of puberty, bone density increased substantially in both races, with black girls achieving a greater increase (39 per cent) than white girls (11 per cent) (Fig. 8).

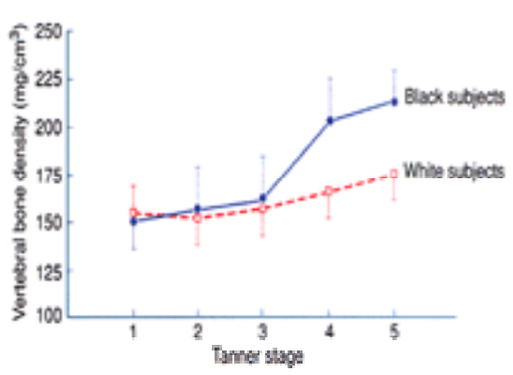

Fig. 8 Vertebral bone density in normal black (●) and white females (□) during different stages of sexual development (adapted from Gilsanz *et al*. 1991).

Peak bone mass, or maximal bone density, is usually achieved in the third decade. Between 85 and 90 per cent of peak bone mass is accumulated during longitudinal growth (i.e. before age 20), but following the closure of the growth plate a further increase in bone mass in the axial and appendicular skeleton occurs between the ages of 20 and 35. Studies by Davies *et al*. (1990) suggest that a gain in bone mass of 3 to 6 per cent per decade may occur from the third decade. Further increases may be possible by changing lifestyle and behavioural patterns (e.g. increased exercise and calcium intake) in adolescence, and it has been suggested, but not yet proven, that increasing the peak bone mass may be an effective means of preventing the consequences of age-related and postmenopausal bone loss. The amount of peak bone mass present at the age of 30 to 35 years is determined by genetic and environmental factors, with the former accounting for 80 per cent. Females achieve a lower peak bone mass, which may explain their increased risk of skeletal fractures in later life. The variance in bone mass between monozygotic twins is less than with dizygotic pairs (Pocock *et al*. 1987) (Fig. 9), and daughters of women with spinal crush fractures achieve a lower peak bone mass than age-matched daughters of non-osteoporotic females, indicating the genetic factors behind peak bone mass. Bone density at several sites (spine, hip, and forearm) is more similar between monozygotic twins than dizygotic twins (Pocock *et al*. 1987) (Fig. 10). The intraclass correlation, a measure of the proportion of the total variance in bone density due to variability among twin pairs, is approx. 0.8 in monozygotic twins and 0.3 in dizygotic twins. If bone mass was entirely genetically determined, the intraclass correlation would be 1.0 and 0.5 in monozygotic and dizygotic twins, respectively (Pocock *et al*. 1987; Slemenda *et al*. 1990*a*). An alternative way of examining the contribution of the environment to bone mass is to look at the maximum within-pair differences in bone density. At all sites, the mean differences between dizygotic twins are almost twice as great as the mean differences between monozygotic twins (Fig. 10). In monozygotic twins the within-pair difference is due to environmental and behaviour factors, and defines the amount of bone mass that may be changed by altering environmental factors. Further evidence for genetic factors is provided by the finding of greater bone mass in black than white individuals, yet the former may have a less suitable environment for skeletal development. The reason for the greater bone mass in black individuals is unclear, but, at least in girls, the difference is apparent at puberty. The mechanism of this effect remains to be elucidated, with increased resistance to the bone-resorptive effects of the calcitropic hormones, namely PTH and 1,25-dihydroxyvitamin D_3, postulated by some (Bell *et al*. 1985) but not confirmed by others.

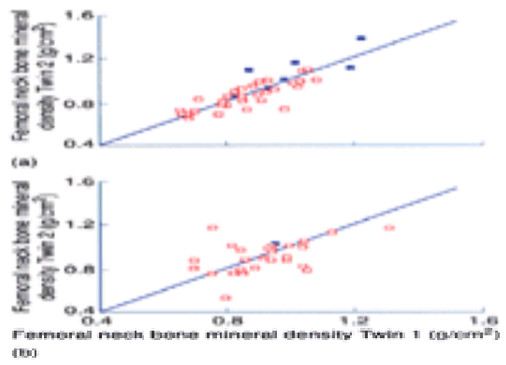

Fig. 9 Correlation of femoral-neck bone mineral density between (a) monozygotic (MZ) twins and (b) dizygotic (DZ) twins showing male (■) and female (☐) twin pairs (reproduced from Pocock *et al*. 1987, with permission).

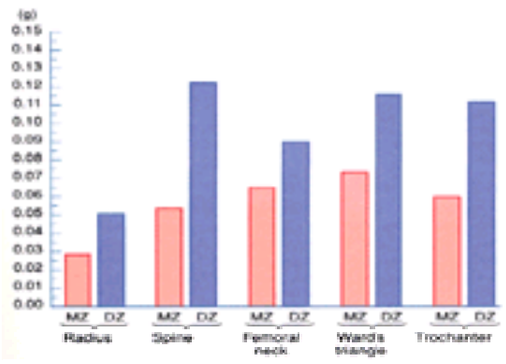

Fig. 10 The mean absolute value of within-pair bone mineral density difference between monozygotic (MZ) and dizygotic (DZ) twins for all skeletal sites (reproduced from Slemenda *et al*. 1991, with permission).

Environmental factors have an important influence on peak bone mass, not only during adolescence but also during the consolidation phase when statural growth has ceased. The influence of nutritional factors, particularly calcium, has attracted considerable attention but remains a matter of debate. Matkovic *et al*. (1979) found that metacarpal cortical bone mass was greater and the incidence of hip fractures lower in regions of the former Yugoslavia where calcium intake was higher. However, increased calcium intake may be associated with an improved socioeconomic status and nutrition, so that it is difficult to be certain that calcium intake was the sole factor for improved metacarpal bone mass. Results from a 3-year double-blind, placebo-controlled trial involving 6- to 14-year-old monozygotic twin pairs, in which one twin received 1 g of calcium supplements daily while the other received placebo, suggest that increased calcium intake leads to a more rapid increase in bone mineral density in growing children (Johnston *et al*. 1992). It is too soon to know whether this early increase leads to a higher peak bone mass or to an earlier establishment of peak bone mass that later does not differ from that of the control twins. Nevertheless, these studies indicate that a population-based strategy for management of osteoporosis may be through improving dietary calcium intake in childhood.

Physical inactivity leads to bone loss and increased physical fitness leads to a greater bone mass in the axial and appendicular skeleton (Pocock *et al*. 1986). In children, weight-bearing physical activity is associated with a moderate increase in bone mass at several sites, which may translate into a greater peak bone mass and a reduced incidence of osteoporotic fractures (Slemenda *et al*. 1991). Excess physical activity, however, is to be avoided, since it may lead to hypothalamic amenorrhoea and bone loss (Drinkwater *et al*. 1984). Although initially the lower bone mass in oligoamenorrhoeic and amenorrhoeic athletes, compared to eumenorrhoeic athletes, was only seen in the lumbar spine, recent studies using improved measurement techniques suggest that bone loss occurs at several sites (Rencken *et al*. 1996). Furthermore, following the return of normal menses, bone mass in these females remains below normal (Drinkwater *et al*. 1990).

Vitamin D receptor gene polymorphism and osteoporosis

Twin studies suggest a strong genetic effect on bone mass, with heritability estimates of 0.5 to 0.9. Higher concentrations of osteocalcin, a marker of increased bone turnover, were reported in twins with a particular vitamin D receptor (*VDR*) gene polymorphism (Morrison *et al*. 1992). Subsequently the same group, using monozygotic and dizygotic twins, noted that 75 per cent of the genetic component of bone density ould be attributed to polymorphism of the *VDR* gene (Morrison *et al*. 1994). Similar findings, but with a weaker correlation, were noted in a British population of postmenopausal females (Spector *et al*. 1995). Ferrari *et al*. (1995) suggested that *VDR* gene polymorphism may predict the rate of changes in spinal bone density in elderly people. However, the association between allelic variations in the *VDR* gene and bone mineral density has not been confirmed by others; both sides of the controversy have been discussed recently (Eisman 1995; Peacock 1995). Thus, Hustmyer *et al*. (1994) found no evidence of linkage between *VDR* alleles and bone density at the spine, hip or wrist in white female twins in the United States. Similarly, in French premenopausal women no association was found between *VDR* alleles and bone density or bone turnover (Garnero *et al*. 1995). At present the difference between these studies is difficult to explain. It is possible that *VDR* gene alleles make a much smaller difference than expected to peak bone mass, which might have been missed in some studies. Alternatively, Parfitt (1994) suggests that *VDR* polymorphism may be linked to another gene polymorphism that regulates bone turnover and that this linkage is influenced by environmental factor(s), which in turn may be confined to one geographical area.

Age-related bone loss

Until the age of 35 to 40 years the amount of bone formed equals the amount removed at each remodelling unit. Thereafter there is a slight mismatch, with less bone being formed, and this results in an age-related loss of bone that is universal in humans and affects all skeletal sites. In both sexes, trabecular and cortical bone mass decline by 6 to 8 and 2 to 4 per cent per decade, respectively. In postmenopausal females, further bone loss occurs associated with declining ovarian function, and in the vertebrae the trabecular loss may be as high as 5 to 10 per cent per year (Stevenson 1988), while cortical bone loss may be 2 per cent per year. The rapid rate of bone loss after ovarian failure, a consequence of the decline in circulating oestrogen level, decreases exponentially over 5 to 8 years eventually to match the age-related bone loss (Krolner and Nielsen 1982).

The mechanism of age-related bone loss is unknown but several possibilities exist. Calcium absorption declines with age in both sexes, as does the ability of the intestine to adapt to a reduced calcium intake by improving absorption. Furthermore, the reduced ability to synthesize 1,25-dihydroxyvitamin D, due to reduced activity of the renal 1a-hydroxylase, will affect intestinal calcium absorption. Reduced calcium absorption will lead to chronic stimulation of parathyroid glands and the increased PTH will accelerate bone loss by stimulating osteoclasts and increasing the number of remodelling units at which uncoupling has occurred. Other factors of importance in age-related bone loss include defective osteoblast function, the conversion of haemopoietic marrow into fatty marrow with loss of precursor cells and locally generated growth factors, and impaired reserves and secretion of calcitonin (Stevenson 1988).

Diagnosis

Risk factors

Since it is easier to prevent than to treat established osteoporosis, it has been suggested that assessment for risk factors may be used to select individuals at sufficient risk and offer them further investigation (Riggs and Melton 1986). These risk factors are detailed in Table 6.

Race (white or Asian)
Premature loss of ovarian function
Postmenopausal
Short stature and low body-mass index
Positive family history
Nulliparity
Low calcium intake
Inactivity
Excessive alcohol intake
Smoking
Long-term use of corticosteroids

Table 6 Risk factors for osteoporosis

The major risk factors are race, loss of ovarian function, and peak bone mass. As mentioned previously, peak bone mass is predominantly genetically determined and racial origin is important in that it is likely that black individuals achieve a greater peak bone mass than white. Loss of ovarian function is associated with bone loss, and premature ovarian failure and amenorrhoea lead to reduced bone mass and are associated with increased risk of osteoporosis. Cigarette smoking may indirectly be harmful to the skeleton because it increases the metabolism of oestrogen, and smokers tend to have a slim build and lower body weight. Obesity may be protective to the skeleton of postmenopausal females by increasing the forces transmitted through it and by increasing conversion of androstenedione to oestrone in fatty tissue (Schindler *et al*. 1972). Females of small build tend to have reduced bone mass. Daughters of women with vertebral osteoporosis tend to have reduced bone mass and a positive family history may be regarded as a risk factor. While risk-factor assessment has been useful for epidemiological studies, its ability to predict bone mass and risk of fracture is poor and it cannot be relied upon to estimate the presence or absence of osteoporosis in individual patients (Slemenda *et al*. 1990*b*; Cooper *et al*. 1991).

Bone mass measurement

A high correlation exists between bone mineral density and bone strength and therefore the risk of fragility fracture. Several prospective studies suggest that the best means of assessing risk of fracture is through measurement of bone mineral density (Johnston *et al*. 1991).

Conventional radiology is a relatively insensitive method of assessing bone mass. Morphological changes, readily assessed semiquantitatively by such methods as the metacarpal index, vertebral body index, and the Singh index for the proximal femur, have been and are still used as a basis for bone mass assay where other techniques are unavailable, but these methods cannot detect early bone loss and also lack sensitivity. Reliable measurements of bone mass can be accurately and precisely obtained by a number of techniques (Table 7). In general these techniques calculate bone mass by measuring tissue absorption of photons obtained from a radioactive or X-ray tube source (Cohn 1991).

Technique	Sites	Radiation dose (μSv)	Units of measurement
Radiogrammetry	Carpus	(Skin dose)	Metacarpal index
	Femoral neck	Carpus 50–500	Singh index
	Vertebrae	Lumbar vertebrae 10 000–240 000	Vertebral body index
Single photon absorptiometry	Forearm	50–100	g/cm g/cm^2
Dual-photon absorptiometry	Lumbar spine Femoral neck Forearm Whole body	10–40	g/cm^2
Dual X-ray absorptiometry	Lumbar spine Femoral neck Forearm Whole body	10–40	g/cm^2
Quantitative computed tomography	Lumbar spine Femur Tibia Forearm	100–10 000	g/cm^2 g/cm^3
Ultrasound	Calcaneus Patella	No ionizing radiation	AVU (apparent velocity of ultrasound) (m/s) BUA (broadband ultrasonic attenuation) (dB/MHz)

Table 7 Techniques available for the measurement of bone mass *in vivo*

Single-photon absorptiometry, available for over 25 years and using low-energy photon beams, measures appendicular bone mass at the forearm and heel. The sites are usually immersed in water to make the soft-tissue thickness constant. The photon beam is directed through the forearm of the patient and detected by a scintillation counter on the other side of the arm. The intensity of the transmitted beam is measured at intervals along the radius and ulna to determine the total bone mineral content. The technique is limited because it can only measure peripheral sites and the position of the beam is critical to avoid errors when doing repeated scans.

Dual-photon absorptiometry uses two photon energies, usually derived from gadolinium, and permits distinction between bone and soft tissue; this allows measurement at sites of fragility fractures in the lumbar spine and proximal femur. The radiation dose is small (50–150 mSv) and precision good (1–4 per cent). The disadvantages are a long scanning time and the need to replace the isotope sources. In many places, dual-photon absorptiometry has been superseded by dual-energy X-ray absorptiometry, which uses X-rays as the source for protons. Its advantages are a reduced scanning time, improved resolution, precision, and accuracy.

Quantitative computed tomography allows volume measurements and also permits distinction between cortical and trabecular bone in the vertebrae. Its main disadvantages are cost and high radiation exposure. Ultrasonography is a non-invasive technique currently under investigation; its use and correlation with bone mineral density measured by dual-energy X-ray absorptiometry is currently being assessed and it cannot as yet be recommended for clinical use.

Bone biopsy

Since the advent of non-invasive techniques to measure bone mass, transiliac bone biopsy is no longer essential to establish the diagnosis of osteoporosis. It may be indicated where osteomalacia is suspected on the basis of abnormal biochemical or radiological features. When undertaken, however, the result often indicates osteoporosis rather than osteomalacia. Bone histomorphometry is of use in quantitating rates of bone formation and resorption, but few centres can undertake this and it is usually done as part of clinical research (Malluche and Faugere 1991).

Biochemical markers

Routine biochemical tests are usually normal in osteoporosis. Biochemical markers of skeletal metabolism are available, but their precise role has not been established. Markers of bone formation include serum alkaline phosphatase (particularly the bone isoenzyme), osteocalcin (also known as bone gla protein), and type 1 procollagen propeptides. Fasting urinary calcium and hydroxyproline, and serum tartrate-resistant acid phosphatase, are markers of bone resorption that lack sensitivity. The urinary excretion of the collagen cross-links, pyridinoline and deoxypyridinoline, reflects breakdown of bone and cartilage collagens and appears to be raised in disorders characterized by high bone turnover such as after the menopause and in primary hyperparathyroidism. The biochemical markers may be of help in investigating bone turnover in established osteoporosis by separating individuals with high-turnover from those with low-turnover osteoporosis, and in monitoring the effects of appropriate treatments.

Management

Prevention

Prevention of bone loss appears to be the most effective means of reducing the incidence of fragility fracture. A reduced bone mass in an individual, and therefore the increased risk of fractures, is related to the peak bone mass achieved by that individual, the rate of bone loss with ageing, and, in females, the rate and duration of postmenopausal bone loss. The determinants of peak bone mass include genetic factors, which cannot be manipulated, and nutritional and environmental factors, which may be manipulated to the individual's advantage. For pharmacological intervention, particularly hormone replacement therapy, the identification of the individual at risk will help restrict therapy to those who need it and avoid treating those whose risk for fragility fracture is low. At present the only means of achieving this is through bone mass measurement, and prospective studies suggest that a reduction in bone density by 1 SD is associated with a relative risk for fracture that varies from 1.5 to 3.0 with site-specificity. In other words, bone mineral density in the spine and hip is a better predictor for fracture of the respective site than that in the forearm is for fracture of the spine or hip.

Calcium

The role of calcium supplementation in preventing bone loss remains controversial. Matkovic's study (Matkovic *et al*. 1979) is often cited as an important piece of evidence appearing to indicate that the preservation of cortical bone was greater in women living in a community with a high-calcium diet than in one with a low-calcium diet. The study has been criticized in that the association was apparently related to other differences between the two communities: the community with a high-calcium diet was physically more active than the low-calcium (Kanis 1991). In their comprehensive review on calcium, Kanis and Passmore (1989) suggest that the inverse relation between calcium intake and hip fracture rate around the world indicates that calcium intake cannot account for the marked variation in fracture rates and argues against a role for calcium in preventing fractures. Studies by Heaney *et al*. (1978) indicated that increased dietary calcium intake was capable of restoring calcium balance in pre- and postmenopausal women, but others have failed to record the advantages of calcium supplementation in preventing bone loss or acting as an effective substitute for hormone replacement (Nilas *et al*. 1984; Riis *et al*. 1987). There may be a role for increasing calcium intake in the elderly osteoporotic female in preventing cortical bone loss and reducing the incidence of further vertebral fractures. A meta-analysis (Cummings 1990) indicated that the beneficial effects of calcium were greatest when calcium intake is low; the advantages in other situations were small and require further study. Calcium supplementation of prepubertal children enhances the rate of increase in bone mineral density but it is unclear if this gain translates into increased peak bone mass (Johnston *et al*. 1992). It is likely that the benefit may be lost once the supplements are stopped. Recent studies over 4 years have shown that, in postmenopausal women, calcium supplements compared to placebo lead to a reduced rate of loss of total-body bone mineral density (Reid *et al*. 1993; Reid *et al*. 1995). In the lumbar spine and femoral neck the difference between the two groups occurred predominantly in the first year; in the subsequent years the calcium-treated group lost bone but at a lower rate than controls. Although there were significantly fewer symptomatic fractures in the calcium group, the study was not large enough to provide a definite answer, which can only be given by a much larger, prospective study. At present, therefore, calcium supplementation should be restricted to those with definite osteoporosis and with a poor calcium diet (daily calcium intake of less than 400 mg), as supplementary therapy in any anabolic treatment, malabsorption states, and in elderly people. Prophylactic use cannot be justified and would have considerable cost implications.

Exercise

It is generally accepted that skeletal mass at any site is dependent on the stress to which it is subjected (Rubin and Lanyon 1984) and that strenuous physical activity in adults is associated with a greater bone mass (Nilsson and Westlin 1971). There is also some evidence that physical activity may reduce the rate of bone lost due to menopause, although the exact type of exercise needed is unclear (Smith *et al*. 1984). In general, however, the exercise must be weight-bearing in type. Physical activity may also be of importance in children and leads to moderate increases in bone mass at several sites, including the hip. The resultant increase in peak bone mass could lead to a significant decrease in the incidence of osteoporotic fractures in later years (Slemenda *et al*. 1991).

Hormone replacement

The most effective treatment in preventing postmenopausal bone loss is oestrogen replacement therapy, which has been shown to reduce the risk of bone loss and incidence of fractures, particularly those of the hip. Loss of ovarian function is associated with a rapid rate of bone loss over a 5- to 10-year period, after which it gradually slows and returns to the age-related rate of bone loss (Lindsay *et al*. 1987). There is histological evidence of increased osteoclastic bone resorption associated with a relative reduction in osteoblastic activity after the menopause. The administration of oestrogen is associated with a reduced rate of bone resorption and therefore a decreased rate of bone loss (Kanis *et al*. 1990). How oestrogens achieve this effect is unclear but they appear to have a direct action on osteoblast activity (Eriksen *et al*. 1988) with a secondary effect on osteoclast activity mediated by cytokines (McSheety and Chambers 1986). Unfortunately, replacement of oestrogen alone is associated with an increased risk of endometrial cancer, which may persist even after discontinuing oestrogen replacement (Paganini-Hill *et al*. 1989). The endometrial cancers are not aggressive and the 5-year survival was near to 100 per cent. The addition of progestogen allows the shedding of the endometrium, and minimizes the risk of hyperplasia and subsequent neoplasia. In general, 12 days of progestogen with continuous oestrogen use carries a negligible risk of hyperplasia (Whitehead and Fraser 1987) and a relative risk of endometrial cancer of 0.9 compared with 1.4 in women using oestrogen alone (Persson *et al*. 1989). Thus, in women who have a regular scheduled bleed, there is no need for a routine endometrial examination to detect hyperplasia unless the bleed occurs prematurely.

Use of the oral contraceptive pill, early menarche, and a late menopause are risk factors for breast cancer and suggest an oestrogen-related effect. Most studies suggest that oestrogen used in hormone replacement therapy (**HRT**) does not increase the overall risk of breast cancer (Brinton *et al*. 1986). There is, however, some concern over very long-term treatment with oestrogens, especially over 10 years, when there may be a small increase in risk (Bergkvist *et al*. 1989). One study from Sweden has suggested a relative risk of 1.7 in women using HRT for more than 7 years (Bergkvist *et al*. 1989), but a recent large meta-analysis suggests a relative risk of 1.3 (Steinberg *et al*. 1991). The Royal College of Obstetrics and Gynaecology Study Group concluded that there may be a duration-dependent risk of breast cancer with HRT and that there was no evidence that progestogens protect against that risk. More recent evidence from the Nurses Health Study suggests that the risk of breast cancer is significantly increased amongst women taking HRT, the relative risk being 1.32, which is not appreciably different if progestogen is also added to the treatment. The use of HRT for 5 to 9 years led to a relative risk of breast cancer of 1.46, which was greatest amongst women aged 60 to 64 years. The relative risk of death due to breast cancer was also increased, at 1.45 in women who had taken medication for five or more years (Colditz *et al*. 1995). Women who are concerned about the breast cancer risk should be encouraged to participate in the United Kingdom national mammographic screening programme, which offers 3-yearly screening from 50 years of age.

With regard to hypertension, there is no evidence that HRT elevates blood pressure and in some instances it has been found to lower the diastolic pressure. Although oral contraceptives increase blood clotting factors and risk of pulmonary embolism, there is currently no good evidence that postmenopausal oestrogen replacement therapy increases the risk of thromboembolic disease. An increased risk of deep-vein thrombosis and pulmonary emboli has recently been reported in women currently taking HRT (Daly *et al*. 1996; Grodstein *et al*. 1996*a*; Jick *et al*. 1996). In all three studies, although the relative risk of venous thrombosis was raised to between 2.1 and 3.5, the absolute risks remained low. For example, Daly *et al*. (1996) found an adjusted relative risk of 3.5, but this would yield only one extra case in 5000 users per year.

HRT is associated with decreased mortality from ischaemic heart disease (by 40–50 per cent). A recent prospective study by Stampfer *et al*. (1991) showed a 50 per cent reduction in the risk of major coronary arterial disease or fatal cardiovascular disease, and no increase in the risk of stroke, in women who had ever used oestrogen replacement therapy compared with women who had never used oestrogen. Part of this effect is probably due to the beneficial effects of oestrogen on lipid levels. The addition of a progestogen does not alter the cardioprotective effects of postmenopausal oestrogen (Grodstein *et al*. 1996*b*). After the menopause, levels of high-density lipoprotein (associated with removing precholesterol from the blood) decline while total cholesterol and low-density lipoprotein increase. Oral oestrogen is associated with a rise in the level of the protective high-density lipoprotein–cholesterol fraction and a decreasing low-density fraction as documented by the Lipid Research Clinic's follow-up study (Bush *et al*. 1983). The effects of combined therapy on ischaemic heart disease are unknown. It is possible, but not proven, that some of the beneficial effects of oestrogen may be reduced by the administration of progestogens (Goldman and Tosteson 1991).

Recently, evidence has also been presented that HRT is associated with an increased risk of deep vein thrombosis and/or pulmonary emboli. The relative risk of venous thrombosis appears to be increased two- to threefold in current users of HRT. The absolute risk in current users remains small, with estimates of 16 and 23 excess cases per 100 000 women per year for all venous thromboembolisms and 6 per 100 000 women per year for pulmonary embolism only. In all three studies presented the risk of venous embolism disappeared on cessation of HRT (Daly *et al*. 1996; Grodstein *et al*. 1996*a*; Jick *et al*. 1996).

Treatment with exogenous oestrogen after the menopause results in a significant reduction in bone resorption as reflected in a fall in the fasting urinary calcium:creatinine and hydroxyproline:creatinine ratios (Lindsay *et al*. 1976). The mechanism of the oestrogen effect is unclear, but is likely to be mediated through the oestrogen-sensitive osteoblast releasing growth factors that inhibit the recruitment and differentiation of osteoclasts from their bone marrow precursors. The minimum oral dose of oestradiol required to prevent bone loss is 2.0 mg/ day, and of conjugated oestrogen 0.625 mg /day. For percutaneous delivery, 3 mg of oestradiol gel, or 50 mg oestradiol implant, or at least 50 mg/24 h of transdermal oestrogen will also be effective. If HRT is discontinued the rate of bone loss is similar

to that seen in early years of the menopause. The optimal duration of treatment is unknown, but it should be long-term (from 5 to 10 years) to maximize the benefit to the cardiovascular system and bone without significant risk. Melton (1987) suggests that treatment for 5 years would shift the hip fracture:age curve to the right. Although life expectancy is increased by about 2 years in HRT users, he argued that the shift in the fracture:age curve would still mean that many women would not live beyond the age where the shifted curve is placed (Melton 1987). From findings by Lindsay *et al*. (1987) it is evidently appropriate to start treatment early in the menopause, since it is unlikely that any existing bone loss can be recovered. Although it remains unclear how long the benefits of HRT on bone mass persist after its discontinuation, a Swedish cohort study suggests that the more potent oestrogens gave a 0.37 relative risk of trochanteric fracture in women who had started treatment before the age of 60 years; in contrast the weaker oestrogen did not confer any benefit (Naessen *et al*. 1990). Other data suggest that the use of HRT 14 years after the menopause may still result in reduction of further bone loss and a slight increase in trabecular bone mass in the axial skeleton (Quigley *et al*. 1987; Lindsay and Tomme 1990).

Calcitonin

Calcitonin is a 32-residue peptide hormone produced by the parafollicular cells of the thyroid gland. The hormone binds to high-affinity receptors on osteoclasts, but its precise physiological role in man is uncertain. Preliminary studies suggest that calcitonin may be as effective as oestrogen in abolishing postmenopausal bone loss (Reginster *et al*. 1987). Further studies are necessary to determine optimal dose, route of administration, and long-term effect. If confirmed it may prove an alternative to HRT in individuals in whom oestrogens are contraindicated or unacceptable. At present, calcitonin is given subcutaneously but the development of new formulations means that an effective nasal spray and suppository delivery systems may soon become available.

Treatment of established osteoporosis

For the very elderly individual with osteoporosis-related fractures there is no effective treatment available. However, for postmenopausal women and men aged 50 to 70 years with established disease, available treatments can be grouped into class I agents, which either impair bone resorption and/or reduce activation frequency, or class II agents, which increase bone formation (Table 8).

Class I—impair bone resorption and/or reduce activation frequencies
Hormone replacement therapy
Calcitonin
Bisphosphonates
Anabolic steroids
Calcium
Vitamin D and metabolites
Class II—stimulate bone formation
Sodium fluoride
Intermittent parathyroid injections

Table 8 Potential treatments for established osteoporosis

HRT

As a class I agent, HRT leads to reduced bone turnover and is effective in preventing postmenopausal bone loss. But HRT may also retard bone loss in established osteoporosis: over a 2-year period, a small increase in bone mass may be seen in trabecular rather than cortical bone as formation continues and refilling of the remodelled space occurs. After about 2 years a plateau is achieved and further increases in bone mass are unlikely. A similar plateau for bone mass may occur with other antiresorptive agents such as calcitonin and bisphosphonates. One problem with HRT in older patients is the reluctance to accept the resumption of menstruation. Long-term studies examining the effectiveness of HRT in preventing further vertebral fractures in patients with spinal osteoporosis are not available.

Calcitonin

In patients with vertebral or wrist fractures, treatment with calcitonin leads to a small increase in bone mass over the first 1 to 2 years. The usefulness of this increase in bone mass will become clearer when results become available from prospective studies in progress on the rates of new vertebral fractures. It may be possible to obtain continued increases in bone mass if calcitonin is administered cyclically. At present, synthetic salmon calcitonin is approved for the treatment of postmenopausal osteoporosis but is required to be given parenterally. It is an expensive drug and similar benefits may be achieved by giving lower doses every 2 to 3 days, although this must be proved by clinical trials.

The analgesic effect of calcitonin, probably mediated through b-endorphin release, is sometimes useful in controlling pain resulting from vertebral crush fractures and enables early mobilization of the patient.

Bisphosphonates

The bisphosphonates are potent inhibitors of bone resorption and have been successfully used to inhibit osteoclastic activity in Paget's disease of bone and malignant hypercalcaemia. Disodium etidronate has recently been used in the treatment of established vertebral osteoporosis. In two double-blind, placebo-controlled studies, etidronate, given cyclically in a dose of 400 mg daily for 2 weeks every 3 months for 3 years, modestly but significantly increased spinal bone density and reduced the incidence of further vertebral deformity and fractures (Storm *et al*. 1990; Watts *et al*. 1990). There was no significant change in cortical bone mass. In an open-label follow-up of 37 postmenopausal females with osteoporosis treated for 5 years, a further increase in bone density of 1.4 per cent was observed during the last 2 years of study; the reduction in vertebral fracture rate observed in the earlier part of the study was also maintained (Storm *et al*. 1996). Etidronate has been approved for use in established vertebral osteoporosis in the United Kingdom and most European countries, but not in the United States,

The aminobisphosphonate, alendronate sodium (alendronate), increases bone mineral density in the spine, hip and total body, and reduces the incidence of new morphometric vertebral fractures (Liberman *et al*. 1993) (Fig. 11). The results of a randomized trial involving 2027 women with at least one vertebral fracture at baseline and low bone-mass density of the femoral neck, treated with alendronate or placebo, were recently reported; they showed that the relative risk of sustaining a new morphometric vertebral fracture was 0.33 in the treated compared to the control group (Black *et al*. 1996). In addition, there was a reduction in clinically apparent vertebral fractures as well as of any clinical fracture in the hip and wrist. The reduced risk of hip fracture noted in this study of postmenopausal women dwelling in the community suggests that bisphosphonates may be of value in preventing such fractures in women with low bone-mass density of the hip. However, until a formal analysis of cost-effectiveness is made, the expense of using alendronate to prevent such fractures may appear prohibitive.

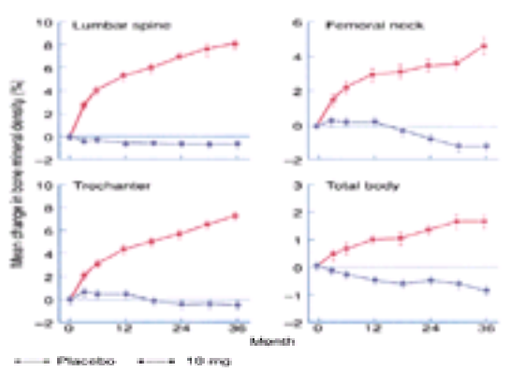

Fig. 11 Changes in bone mineral density from baseline values in women with postmenopausal osteoporosis receiving alendronate 10 mg/day or placebo for 3 years

(after Liberman *et al*. 1993)

In general, bisphosphonates are well tolerated but should be used with caution in patients with impaired renal function. Their absorption is impaired by calcium, iron, magnesium, and aluminium, to which they bind. Some unwanted side-effects of etidronate include hypersensitivity reactions, urticaria, and angio-oedema, but these are uncommon. Etidronate should be used cyclically and not daily as this will lead to impaired normal bone mineralization. In contrast, alendronate, because of its high potency, can be given daily. Although the frequency of upper gastrointestinal side-effects with alendronate was similar to placebo in the randomized trial discussed above, the clinical use of alendronate has been associated with oesophagitis, at times severe enough to warrant admission to hospital, and other upper gastrointestinal symptoms. These symptoms may be more common in those with previous upper gastrointestinal problems and in those taking non-steroidal anti-inflammatory drugs. To some extent, these complications can be avoided by asking the patients to take alendronate with at least 100 ml of water and to avoid lying down during the next 30 min.

Testosterone and anabolic steroids

Hypogonadism in males is a well-established cause of osteoporosis and can be prevented by rendering the individual eugonadal with replacement therapy using testosterone, which increases bone mass by stimulating bone formation. The testosterone ester is usually given intramuscularly every 2 weeks. The newer oral testosterone preparations may also be used, but their effects on bone mass have not been fully evaluated. The use of testosterone in osteoporotic male patients with normal gonadal function cannot be recommended until further data become available showing benefit.

The anabolic steroids, stanozolol and nandrolone denoate, appear to reduce bone resorption as determined by hydroxyproline excretion, and lead to an increase in bone mass in both males and females. The reported increases in bone mass with anabolic steroids may in part be due to measurement artefact: these drugs decrease fat mass and increase lean body mass, which leads to a falsely elevated measure of bone mass. Anabolic steroids also cause mild degrees of masculinization, which is unacceptable to many women, and, in addition, they have adverse effects on plasma lipids, raising doubts about their long-term safety.

Vitamin D and metabolites

It has been proposed that circulating 1,25(OH)D (calcitriol) and calcium absorption are decreased in some, especially elderly, osteoporotic patients. A potential therapeutic role for calcitriol is suggested by its ability to stimulate intestinal calcium absorption, reduce secondary hyperparathyroidism, and abolish PTH-mediated bone resorption. Unfortunately, trials of calcitriol treatment for women with osteoporosis have yielded conflicting results. Some found that the bone density of the spine increased with calcitriol (Gallagher and Goldgar 1990) while others found that it decreased by similar amounts in patients and controls (Ott and Chesnut 1989). In all studies the cohorts have not been large enough to evaluate the effects of calcitriol on the rate of new vertebral fractures. More recently, Tilyard *et al*. (1992) have reported their findings on the occurrence of new vertebral fractures in 622 postmenopausal women with spinal fractures entered into a prospective study of calcitriol on calcium. A threefold reduction in the occurrence of new vertebral fractures or deformity was observed over 3 years in women treated with calcitriol. This effect was evident only in women who had five or fewer vertebral fractures on entry into the study. A reduction in the number of peripheral fractures was also noted in those treated with calcitriol. The dose of calcitriol was 0.25 mg twice a day: it was not associated with any major adverse effects, but concerns about the effect of calcitriol on urinary calcium excretion and renal function remain, since these were not estimated in all patients. In elderly women the addition of 800 units of vitamin D_3 and calcium reduced the number of fractures in comparison to a control group; a significant difference in number was apparent only after 12 to 18 months of the 3-year study (Chapuy *et al*. 1992). The incidence of hip fractures showed a marked increase in the placebo group but remained unchanged in the group treated with vitamin D_3, suggesting that vitamin D_3 prevented the exponential increase in the incidence of hip fractures that takes place in this age group.

Vitamin D deficiency is common in elderly persons, owing to reduced exposure to sunlight, decreased synthesis of vitamin D_3 in the ageing skin, and low dietary intake of vitamin D. Ooms *et al*. (1995) noted that supplementation of the elderly with 400 units of vitamin D_3 daily leads to a slight decrease in secondary hyperparathyroidism and an increase in bone density at the femoral neck. Although Chapuy *et al*. (1992) showed a reduction in the incidence of hip fracture following supplementation with 800 units of vitamin D_3, it is not known whether the benefits were due to the supplemental vitamin D or calcium. Supplementation with 400 units of vitamin D_3 administered to elderly men and women dwelling in the community in Amsterdam did not lead to a decrease in the incidence of hip or peripheral fractures (Lips *et al*. 1996). However, this Dutch population differed in many respects to that studied by Chapuy *et al*. (1992): they were younger, fewer had a raised PTH, and evidence for secondary hyperparathyroidism and vitamin D deficiency was less common. In addition, the dose of vitamin D_3 was 400 units not 800 units as in the French study.

The parenteral administration of vitamin D (150 000 to 300 000 units annually) to elderly individuals did not lead to any reduction in fractures of the leg, but fractures of the arms were reduced by half (Heikinheimo *et al*. 1992).

Sodium fluoride

Sodium fluoride stimulates the proliferation and activity of osteoblasts, leading to an increase in osteoid production and trabecular bone volume. It should be given with substantial calcium supplements to allow mineralization to take place, otherwise osteomalacia will develop.

The drug is rapidly absorbed from the gastrointestinal tract if taken in the fasting state; food will impair absorption. Approximately 60 per cent of the drug accumulates in bone and the rest is excreted by the kidneys. Fluoride attaches to apatite in bone, making it more resistant to resorption. In spinal osteoporosis, moderate doses of sodium fluoride (50 mg/day) reduced the incidence of spinal fracture by 25 per cent after 2 years of treatment (Mamelle *et al*. 1988), but others have found it to be less effective. In recent, randomized, placebo-controlled studies of high-dose sodium fluoride (75 mg daily), increases in axial bone-mineral density were found without any reduction in the incidence of fractures, suggesting that the mechanical strength of the newly formed bones may be reduced (Riggs *et al*. 1990; Kleerekoper and Nelson 1992). These studies have been criticized for using excessive doses of fluoride that may have led to the accumulation of unmineralized osteoid. This issue will only be resolved by further, carefully conducted clinical trials, so that at present fluoride remains an investigational drug.

Although slow-release sodium fluoride reportedly prevented new vertebral fractures and increased bone mineral density in the spine and femoral neck (Pak *et al*. 1995), those trials have been criticized for their design and inability to detect any osteotoxic effects of fluoride (Kleerekoper 1996)

Parathyroid hormones

Animals given daily or alternate-day injections of PTH develop increased amounts of trabecular bone that is biologically normal. In man, daily injections of the 1–34 fragments of PTH, when given alone, increased trabecular bone volume but decreased cortical bone mass; the treatment was abandoned because of the potential disadvantage of increasing the risk of limb fractures. Recent studies using PTH 1–34 in combination with HRT (Reeve *et al*. 1990), calcitriol, or calcitonin demonstrated impressive increases in spinal trabecular bone mass, comparable to that seen with fluoride, but achieved within 12 months as compared to 2 years with sodium fluoride. Side-effects were few and the results suggest the need for a randomized control study of PTH in combination with another antiresorptive agent. At present, therefore, PTH, like sodium fluoride, should be regarded as an investigational drug only.

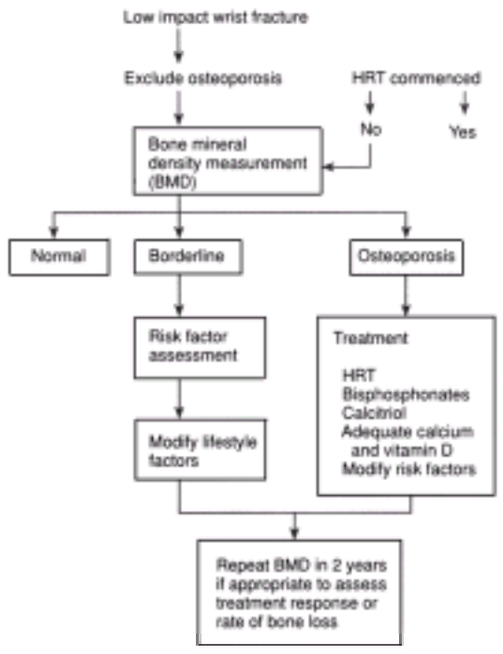
The investigation and management of low-trauma fractures

A low-trauma fracture (i.e., one that follows a fall from standing height or less) should always be investigated to exclude the possibility of osteoporosis. The three most common sites of fracture are the wrist, vertebrae, and hip, and an approach to their management is summarized below.

Wrist fracture

These occur more frequently in younger postmenopausal females than males. The presence of underlying osteoporosis can be confirmed by measuring bone mineral density, although this may not be necessary if the woman elects to go on HRT. If the bone mineral density is consistent with the diagnosis of osteoporosis, treatment suggested in Box 1 should be considered.

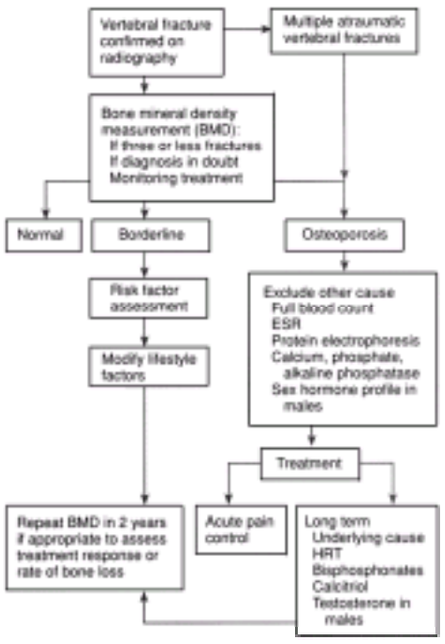
Box 1



Vertebral fracture

Secondary causes such as multiple myeloma and metastases should be excluded where clinically indicated. In those with multiple, atraumatic vertebral fractures, measurement of bone mineral density may be unnecessary, but it should be considered in those with fewer than three vertebral fractures. A repeat measurement of bone mineral density should be considered in those whose baseline density is borderline and where a response to treatment is needed (e.g. when using a bisphosphonate, calcitriol, or calcium and vitamin D) (see Box 2).

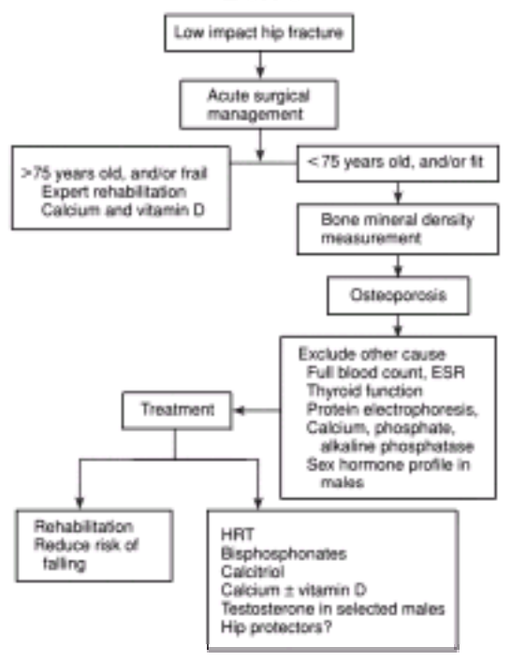
Box 2



Hip fracture

The acute treatment of the hip fracture should follow the Royal College of Physicians guidelines. In the frail elderly person, the future management should consist of adequate vitamin D and calcium. In the younger patient and the independently living elderly person, management with other drugs should be considered as outlined in Box 3. The use of hip protectors remains experimental until their benefit in preventing hip fracture can be demonstrated in the community-dwelling elderly person who falls frequently.

Box 3



Osteomalacia and rickets

Osteomalacia and rickets are characterized by defective mineralization of bone and cartilage leading to an accumulation of unmineralized bone matrix called osteoid. The normal lag between osteoid synthesis and mineralization is prolonged, leading to a decrease in the rate of bone formation. Rickets represents the occurrence of this defect in growing children before the closure of the epiphyses. Unlike osteoporosis, osteomalacia is characterized by a reduction in the ratio of mineralized bone to matrix.

Although osteomalacia can be caused by many disorders, it mostly results either from a primary disorder of vitamin D metabolism or a primary, and non-PTH-related, defect in renal tubular resorption of phosphate (Table 9).

Abnormal vitamin D metabolism
- Reduced bioavailability
  - Nutritional vitamin D deficiency (rare)
  - Inadequate exposure to sunlight
  - Malabsorption states (gastrectomy, coeliac disease, Crohn's disease, pancreatic insufficiency, hepatobiliary disease)
- Defective metabolism
  - Hepatobiliary disease
  - Chronic renal failure
  - Anticonvulsant drugs
  - Vitamin D-dependent rickets type I
  - Oncogenic hypophosphataemic osteomalacia
  - X-linked hypophosphataemia
- Receptor defects
  - Vitamin D-dependent rickets type II

Altered phosphate homeostasis
- Chronic phosphate malabsorption
  - Antacid abuse, malabsorption
- Renal phosphate loss
  - X-linked hypophosphataemia (familial hypophosphatemic rickets)
  - Fanconi syndromes; hereditary forms (Wilson's disease, cystinosis, oculocerebral (Lowe) syndrome, tyrosinaemia), and acquired renal tubular defects (paraproteinaemias, Sjögren's syndrome, systemic lupus erythematosus, monoclonal gammopathies, heavy metal poisoning)
  - Oncogenic hypophosphataemic osteomalacia
- Defective mineralization
  - Aluminium toxicity, bisphosphonates
  - Fibrogenesis imperfecta ossium
  - Hypophosphatasia

Table 9 Classification of osteomalacia

Clinical and laboratory features

The classic symptoms of osteomalacia are generalized bone pain and tenderness, weakness of proximal muscles, and difficulty in walking. However, symptoms may be vague and of insidious onset, making the diagnosis difficult. The bone pain of osteomalacia is dull, poorly localized, and made worse by weight-bearing. It is usually symmetrical and may involve the back, pelvis, thigh, and ribs, often because of the presence of pseudofractures. Compression of the sternum and rib results in pain. Some patients have no pain, particularly in X-linked hypophosphataemic rickets where, in spite of life-long osteomalacia, pain may occur only in middle age.

Muscle weakness, usually proximal, may be of varying severity with only minimal atrophy and no fasciculation. The patient has a waddling gait, and difficulty in climbing stairs and getting out of bed and chair. Muscle biopsy shows no evidence of primary muscle disorder. Proximal weakness is not a feature of X-linked hypophosphataemic rickets.

The features of rickets depend on the age of the child and the underlying syndrome. The child may be hypotonic and apathetic, with growth retardation and delayed walking. Bowing deformities of the long bones will be present when weight-bearing occurs. The epiphyseal plate is widened due to the accumulation of disorganized, unmineralized cartilage, leading to cupping and irregularity at the metaphyseal–epiphyseal junction, usually at the wrist; at the costochondral junction this change gives rise to the 'rachitic rosary'. An indentation may develop at the attachment of the diaphragm to the softened ribs (Harrison's groove). In the neonate and young child the rapid growth of the skull leads to softening of the calvarium (craniotabes), parietal flattening, and frontal bossing. There is delayed dental eruption and enamel defects. Unfortunately, skeletal deformities often persist, even when the histological defect has been corrected, and may require surgical correction.

In osteomalacia and rickets, hypocalcaemia often causes no symptoms, but it sometimes results in paraesthesias, tetanus, cramps, carpopedal spasm, dysarthria, and cardiac arrhythmias. Hypocalcaemia is infrequently severe enough to lead to depression, psychoses, and convulsions.

Radiological features

The radiological features of rickets are most pronounced at the growth plate, where the epiphyses are widened and the calcification border of the metaphysis becomes cup-shaped. The size and density of the ossification centres are reduced, the cortex is indistinct, and there may be bowing of the long bones. In milder forms there may be no diagnostic radiological features.

The pathognomonic radiological feature of osteomalacia is pseudofracture (also known as Looser's zones and Milkman's fracture). Initially the fracture is incomplete, and extends perpendicularly from the cortex with poor callus formation; radiologically it is seen as a radiolucent line. Pseudofractures, often multiple and bilateral, are mainly found in the pubic rami, femoral neck, ribs, clavicles, the outer border of the scapulae, and the metatarsals. They occur in bones subjected to mechanical stress and may have an anatomical relation to entry sites of blood vessels into bone.

Biochemical features

Vitamin D-deficiency osteomalacia is characterized by a low serum calcium and phosphate with elevated serum alkaline phosphatase, increased urinary phosphate excretion, decreased urinary calcium excretion, low circulating levels of 25(OH)D, and a mild elevation of PTH (secondary hyperparathyroidism). Levels of $1,25(OH)_2D$ may be normal or elevated, and therefore unhelpful in the diagnosis of osteomalacia. If the serum calcium and 25(OH)D are normal but the phosphate low, a renal phosphate leak syndrome or end-organ resistance should be suspected. A mild hyperchloraemic acidosis, due to renal bicarbonate loss, may accompany vitamin D deficiency and is a consequence of secondary hyperparathyroidism. Severe hyperchloraemic acidosis suggests a renal tubular disorder, which may be confirmed by failure to acidify the urine after loading with ammonium chloride.

When there is doubt about the occurrence of osteomalacia, the diagnosis can be made by bone biopsy. Specific features of osteomalacia are the presence of excess unmineralized matrix (osteoid) over bone trabeculae, and increased thickness of osteoid. If doubt remains, careful histomorphometry may be needed (Malluche and Faugere 1991). In vitamin D deficiency the biopsy will also show features of hyperparathyroidism, which are usually absent in hypophosphataemic disorders.

Metabolism of vitamin D

The two forms of vitamin D, vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol), derived from plant and animal tissues respectively, undergo identical metabolism in humans and have similar effects on target tissues. The absence of a subscript often implies a reference to both forms of vitamin D (Fig. 12).

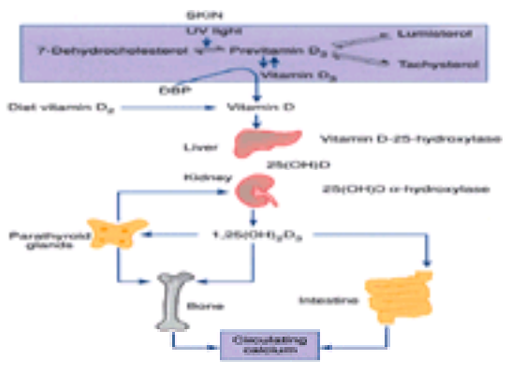


Fig. 12 Schematic representation for metabolism of vitamin D. Previtamin D_3 is formed in the skin and isomerizes to vitamin D_3 or to other biologically inert isomers. Vitamin D-binding protein (DBP) has affinity only for vitamin D_3, which is translocated to the circulation. Vitamin D is then hydroxylated in the liver and kidney to the active metabolite $1,25(OH)_2D$.

Ultraviolet light converts 7-dehydrocholesterol to previtamin D_3. Continued stimulation leads to photoisomerization of previtamin D_3 to two biologically inert products (lumisterol and tachysterol). Previtamin D_3 undergoes thermal isomerization to vitamin D_3, and by binding to vitamin D-binding protein (**DBP**), to which it has a high affinity, it is translocated into the circulation. Dietary vitamin D is absorbed in the jejunum after incorporation into chylomicrons, a process that requires the presence of

bile salts, fatty acids, and monoglycerides.

All forms of vitamin D and their metabolites are transported in the circulation through binding to DBP. The protein has a higher affinity for 25(OH)D than vitamin D or $1,25(OH)_2D_3$. The circulating levels of DBP exceed those of vitamin D and its metabolites, so that all but 1 per cent of these metabolites are present in the free, non-bound form to enter into target cells.

Vitamin D is initially transported to the liver where it is hydroxylated on carbon-25, by vitamin D 25-hydroxylase enzyme, to produce 25(OH)D. The production of 25(OH)D is dependent on the supply of substrate; circulating levels of 25(OH)D reflect an individual's vitamin D status. Only in severe liver disorder is the hepatic production of 25(OH)D impaired, and even then the associated intestinal malabsorption is a contributory factor. From the liver, 25(OH)D, bound to DBP, is transported to the kidney, where it is hydroxylated either to $1a,25(OH)_2D$ (calcitriol) by the renal 25(OH)D 1a-hydroxylase or to $24,25(OH)_2D$. In mammals the principal source of $1a,25(OH)_2D$ is the kidney, except during pregnancy when the placenta can also synthesize it. It is unclear whether other tissues can produce $1a,25(OH)_2D_3$ in normal humans. Granulomatous tissue may possess 1a-hydroxylase activity and this may be the source of the inappropriately high levels of 1,25(OH)D observed in these disorders (Adams *et al*. 1983). Indeed, macrophages activated by lipopolysaccharide or interferon-a, and human T-cell leukaemia-1 virus-infected cord lymphocytes, can also convert 25(OH)D to 1,25(OH)D. The renal 1a-hydroxylase is tightly regulated by PTH, calcium, phosphate, and calcitriol. A high PTH and low calcium stimulate $1,25(OH)_2D$ production, while a raised 1,25(OH)D inhibits calcitriol production but increases the production of $24,25(OH)_2D$.

Calcitriol acts by binding to specific intracellular receptors that occur not only in the target tissues of bone, intestine, kidney, and parathyroid glands but also in mononuclear cells, activated T and B lymphocytes, and skin. Calcitriol stimulates calcium and phosphate absorption in the intestine and increases bone resorption to maintain mineral homeostasis. In bone, however, calcitriol also stimulates the osteoblast and is essential for bone formation, an activity that may also be stimulated by $24,25(OH)_2D$. As mentioned above, receptors for calcitriol are found in tissues that do not have a direct role in mineral homeostasis, including breast cancer cells (Eisman *et al*. 1979), skin keratinocytes and dermal fibroblasts, and haemopoietic cells (Bar-Shavit *et al*. 1983; Bhalla *et al*. 1983). Calcitriol inhibits proliferation and induces differentiation of myeloid cells towards the monocytic lineage (Amento *et al*. 1984; Bhalla *et al*. 1989), perhaps through an early regulation of the c-*myc* gene (Reitsma *et al*. 1983; Kamali *et al*. 1989). *In vivo*, calcitriol, or its 1a analogue, prolong survival of mice inoculated with mouse myeloid leukaemia cells (M1). Calcitriol affects monocyte and T-cell function by influencing the production of cytokines such as IL-1, IL-2, and TNF (Bhalla *et al*. 1986). Since calcitriol can also be synthesized by immune cells it may have an autocrine or paracrine role in the local regulation of immune cell function, but in humans the physiological significance of this needs further elucidated.

Abnormal vitamin D metabolism

Reduced bioavailability

Vitamin D deficiency

Vitamin D deficiency through poor dietary intake is rare unless combined with reduced exposure to sunlight, which occurs especially in elderly people and in the immigrant Asian population of the United Kingdom. Osteomalacia is present in 25 per cent of bone biopsies from elderly patients in the United Kingdom and Scandinavia who have sustained hip fractures, and is likely to be due to insufficient intake of vitamin D and reduced exposure to sunlight. In some countries, dairy products are fortified to prevent nutritional vitamin D deficiency. However, it may still occur in individuals who avoid dairy products and in children who are exclusively breast-fed for prolonged periods.

It is important not to miss a diagnosis of vitamin D-deficiency rickets or osteomalacia, since effective therapy is available and, especially in rickets, limb deformity may be prevented. Bone pain and muscle weakness improve rapidly with replacement therapy, but biochemical and radiological improvements take longer.

The prevention of nutritional vitamin D deficiency is a public-health issue and the deficiency can be eradicated by fortification of certain foods with vitamin D. Simple vitamin D deficiency responds to therapy with oral vitamin D (ergocalciferol) in doses of 2000 to 4000 units (50–100 mg) daily and can be prevented by physiological replacement doses of 200 to 400 units (5–10 mg) daily. In severe vitamin D deficiency it may be better to give a loading dose of 50 000 units (1.25 mg) daily for 1 month followed by physiological replacement. Calcifediol (25(OH)D) can be used instead of vitamin D, where available, and may have fewer problems with accumulation than does vitamin D itself.

Gastrointestinal disorders

Intestinal fat malabsorption due to gastrointestinal, hepatic, or pancreatic disease leads to vitamin D deficiency without the need for other risk factors such as reduced exposure to sunlight. It leads to three distinct types of bone lesions (Rao 1990): (a) increased surface and volume, but not thickness, of osteoid, with normal serum calcium and phosphate but with evidence of secondary hyperparathyroidism—these patients are asymptomatic unless a fracture occurs; (b) increased thickness of osteoid and a prolonged mineralization lag time with reduced concentrations of calcium, phosphate, and elevated alkaline phosphatase—these individuals are symptomatic and have the classical radiological features of osteomalacia; (c) a third group, probably the most common, has low-turnover osteoporosis and is symptomatic only if a fracture occurs. In these disorders and other states of hypovitaminosis it is important to remember that cortical bone loss is irreversible; observe individuals with gastrointestinal disorders regularly to detect vitamin D deficiency. Prevention is best achieved by being aware of the risk and measuring the serum 25(OH)D annually. Treatment of hypovitaminosis D in these situations can be with vitamin D, although larger doses will be needed, or with 25(OH)D or calcitriol. The aim is to keep serum 25(OH)D in the high normal range. In treating established disease, give calcium supplements as well as magnesium if hypomagnesaemia is present.

Defective metabolism

Chronic renal failure

Chronic renal failure leads to reduced production of $1,25(OH)_2D$ and $24,25(OH)_2D$ from 25(OH)D by the kidney. Since a major effect of $1,25(OH)_2D$ on the intestine is to facilitate calcium absorption, in renal failure the intestinal calcium absorption falls, and, in conjunction with skeletal resistance to the calcium-mobilizing action of PTH, leads to hypocalcaemia. The inability of the diseased kidney to excrete phosphate leads to hyperphosphataemia, which aggravates the hypocalcaemia either by decreasing the renal 1a-hydroxylase activity or by impairing the release of calcium from the skeleton. Hypocalcaemia is a large stimulus to the parathyroid glands and leads to parathyroid hyperplasia and secondary hyperparathyroidism. The net result is a complex effect on bone leading to various skeletal disorders described under the term 'renal osteodystrophy'. Patients may have osteitis fibrosa, due to high levels of PTH, osteomalacia, due in part to vitamin D deficiency, or a combination of both. Retention of aluminium, and its deposition at the calcification front, may also play an important part in the development of osteomalacia, which may be refractory to treatment with $1,25(OH)_2D$ (Fig. 13).

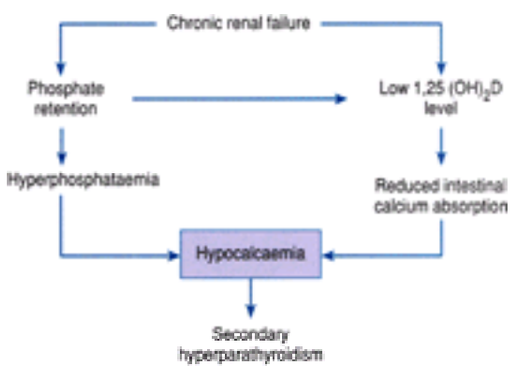

Fig. 13 Pathogenesis of renal bone disease.

Renal osteodystrophy is best managed and prevented by reducing the dietary intake of phosphate, avoiding aluminium-containing phosphate binders, increasing the dietary intake of calcium except when there is marked hyperphosphataemia (because of the risk of extraskeletal calcification), and by supplementation with either $1,25(OH)_2D$ or $1a\text{-}OHD_2$ (alfacalcidol). These treatments usually improve mineral homeostasis, improve clinical symptoms of bone disease, and suppress parathyroid secretion. Occasionally, however, secondary hyperparathyroidism is so severe, with hypercalcaemia, extraskeletal calcification, fractures, and bone pain, that parathyroid surgery may be necessary.

Anticonvulsants

Chronic anticonvulsant therapy induces hepatic microsomal mixed-function oxidases that degrade steroid hormones such as oestrogen and cortisol. Since the hypothalamic–pituitary axis is intact, feedback regulation helps to maintain normal circulating levels of these hormones. Similarly, the chronic use of anticonvulsants leads to increased metabolic conversion of vitamin D and 25(OH)D to biologically inactive metabolites, which are excreted in the urine and bile. Unlike other steroid hormones, feedback regulation is limited and dependent on dietary intake of vitamin D and sunlight exposure. If dietary intake is defective, vitamin D deficiency may result. Anticonvulsants, however, may also affect calcium homeostasis by inhibiting intestinal calcium transport and the bone-resorbing effects of PTH and $1,25(OH)_2D$, and by suppressing osteoblastic and osteoclastic activity. There are significant differences between the various anticonvulsant drugs. Phenobarbitone, a more potent inducer of hepatic microsomal enzymes than phenytoin, does not lead to a low 25(OH)D because increased catabolism is matched by increased formation. Phenytoin does not directly affect vitamin D metabolism but causes bone disease more often than phenobarbitone because it impairs intestinal calcium absorption and reduces the release of calcium from bone, leading to hypocalcaemia and secondary hyperparathyroidism. The net effect is that vitamin D requirements are increased by chronic use of anticonvulsants, especially in those on multiple drugs and in institutional care. Such individuals should be given additional vitamin D, but it is unclear whether all patients taking anticonvulsants should receive prophylactic vitamin treatment.

Vitamin D-dependent rickets type I

This is a rare, autosomal-recessive disease, in which a low or undetectable circulating $1,25\text{-}(OH)_2D$ is the result of defective renal 25(OH)D 1a-hydroxylase activity, and which manifests itself before the age of 2 years with classical features of rickets. Affected children fail to respond to conventional doses of replacement therapy with vitamin D but do so to large doses of vitamin D and 25(OH)D, or to physiological doses of 1,25(OH)D or 1a(OH)D.

Receptor defects

Vitamin D-dependent rickets type II

This is a rare disorder with rickets and/or osteomalacia but with no biochemical evidence of vitamin D deficiency, hypocalcaemia, secondary hyperparathyroidism, high levels of $1,25(OH)_2D$, and failure to respond to large doses of vitamin D or its metabolites. About 70 per cent of the cases reported have alopecia (often complete) and absent eyelashes yet the number and morphology of scalp hair follicles is normal. Alopecia is worse in those resistant to treatment with 1,25(OH)D. Affected patients come from consanguineous marriages and the inheritance is most likely to be autosomal-recessive. The disorder is due to defects in the intracellular interaction of 1,25(OH)D with its receptor. Defects include reduced receptor affinity, abnormal numbers of receptors, and impaired ability of the receptor–hormone complex to bind the DNA. In patients with normal hair a clinical remission can be induced with high doses of vitamin D analogues. A 10-fold higher dose is needed in those with alopecia, but even then only one-half will respond.

Altered phosphate homeostasis

Phosphate depletion

Osteomalacia from chronic phosphate depletion is uncommon and is seen in individuals who consume large amounts of phosphate-binding antacids over a number of years (Dent and Winter 1974). The osteomalacia is clinically, radiologically, and histologically similar to that seen in vitamin D deficiency. Biochemically, however, there are differences in that the serum calcium is normal or even increased, serum phosphate may be low or normal, but urinary phosphate excretion is reduced while urinary calcium excretion may be increased. The concentration of calcitriol is increased and may be responsible for increased absorption of calcium. Treatment consists of phosphate supplementation and avoidance of antacids.

Renal phosphate loss

Hypophosphataemic rickets/osteomalacia may result from hereditary or acquired disorders.

X-linked hypophosphataemic rickets

Also known as familial hypophosphataemic rickets, X-linked hypophosphataemic rickets was first described by Albright *et al*. (1937), who noted that in some patients rickets did not improve with normal doses of vitamin D but did when pharmacological doses of vitamin D were used. The disorder was called vitamin D-resistant rickets and later became known as hypophosphataemic (vitamin D-resistant) rickets when it was noted that it occurred in association with a low serum phosphate. The inheritance is usually X-linked dominant, although autosomal forms also occur. The mutant gene in the disease is located in the distal part of the short arm of the X chromosome (Thakker and O'Riordan 1988).

The disease is fully expressed as rickets and short stature in homozygous males, but the expression of the disease in girls is variable, from none to severe rickets and stunted growth (Fig. 14). A low serum phosphate is found soon after birth, but the disease is only clinically manifest soon after the child begins to walk. Bow legs appear first and there is failure of normal growth. There may be a waddling gait. Skull deformities develop from premature closure of the sutures. Unlike vitamin D-deficiency rickets, in X-linked hypophosphataemic rickets there is no proximal myopathy or dental hypoplasia, but tooth eruption is delayed and tooth development poor, leading to dental abscesses and early dental caries.

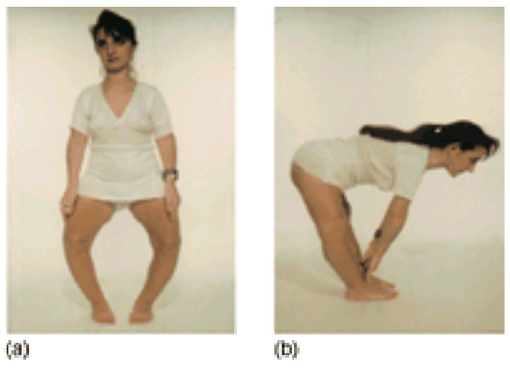

Fig. 14 Twenty-one-year-old girl with X-linked hypophosphataemic rickets. (a) Bowing of the femur and tibia due to previous rickets; (b) lumbar flexion is minimal due to spondylitic changes in the spine.

Radiologically, bone mass is not diminished and may even be above the age-matched normal since there is no secondary hyperparathyroidism. In adults there may be reduced joint mobility, especially at the elbows, shoulders, hip, and spine, due to a widespread enthesopathy (Davies and Stanbury 1981; Polission *et al*. 1985). Spinal enthesopathy may occasionally lead to cord compression. The rigid spine, held straight and with loss of lumbar lordosis, may be confused with ankylosing spondylitis. Indeed, radiographs of the spine may show calcification of the outer fibres of the annulus fibrosus, giving a 'squared-off' appearance to the vertebral bodies, and later complete bridging between vertebrae may lead to a 'bamboo spine'. Ligamentous calcification may obscure the sacroiliac joints, often only in the

upper part (Fig. 15). In the long bones, the cortex appears thickened and the trabeculae are coarse and thickened. Pseudofractures may occur. Degenerative changes develop in weight-bearing joints, probably secondary to the limb deformity.

Fig. 15 X-linked hypophosphataemic rickets. Ligamentous calcification of the upper part of the sacroiliac joints and around the hip joints. There is also bridging of the vertebral interspaces.

Biochemical tests show a low serum phosphate, a normal calcium and PTH, and normal or low levels of $1,25(OH)_2D$. Hypophosphataemia is due to a renal tubular defect, with increased renal loss of phosphate due to lowered renal threshold for phosphate. Renal function is otherwise normal and there are no acidification defects, glycosuria, or aminoaciduria.

It is important to make a correct diagnosis of this disorder as early as possible since proper treatment of the infant will prevent skeletal deformities and allow for normal growth. Although hypophosphataemia is central to the disorder, treatment with phosphate alone leads to secondary hyperparathyroidism and with vitamin D alone to the risk of hypercalcaemia and renal failure. A combination of $1,25(OH)_2D$ and phosphate is most effective, resulting in a return to normal of serum phosphate and healing of rickets. Hypercalciuria should be avoided; serum phosphate, calcium, and urinary calcium should be monitored regularly (Petersen *et al*. 1992).

Metabolic acidosis

A chronic metabolic acidosis may result from Fanconi syndrome or renal tubular acidosis, and may be associated with rickets and osteomalacia. Fanconi syndrome embraces a number of acquired and hereditary disorders in which there are varying combinations of defects of the renal proximal tubule. The proximal tubular abnormality leads to glycosuria, aminoaciduria, hyperphosphaturia and hypophosphataemia, and a systemic acidosis from failure of bicarbonate reabsorption. The hereditary forms are seen most commonly in cystinosis, Wilson's disease, and Lowe syndrome, while the acquired forms are seen in association with multiple myeloma, light-chain nephropathy, amyloidosis, Sjögren syndrome, heavy metal poisoning, and malignancy. The hereditary form can present with rickets, while rickets or osteomalacia may occur in acquired forms. The mechanism for the rickets/osteomalacia is not fully known. The failure of mineralization is a consequence of hypophosphataemia, hypocalcaemia, and metabolic acidosis. In some forms, e.g. Wilson's disease, hepatic damage may lead to low levels of 25(OH)D, while in other forms levels of $1,25(OH)_2D$ are reduced due to the proximal renal tubular defect. Treatment of the bone disease is with phosphate supplements and vitamin D metabolites, especially the 1a(OH)D analogue.

Renal tubular acidosis describes disorders in which there is renal loss of bicarbonate resulting in reduced plasma bicarbonate and a systemic acidosis. The pH of the urine is inappropriately high compared to the metabolic acidosis. Renal tubular acidosis exists as two major forms. In the distal tubular form, known as type I, there is failure to secrete protons so that a large pH gradient between blood and the tubular fluid cannot form. In the proximal tubular type (type II) there is bicarbonate wasting but the ability of the distal tubule to excrete protons is intact. Renal tubular acidosis type II is also often associated with Fanconi syndrome and other proximal tubular defects. The development of rickets and osteomalacia in both forms is due to hypophosphataemia and perhaps failure to synthesize $1,25(OH)_2D$, a consequence of the systemic acidosis. The treatment consists of correcting the acidosis and using vitamin D if the rickets fails to heal.

Oncogenous hypophosphataemic osteomalacia

Some tumours (usually mesenchymal) lead to rickets or osteomalacia characterized by hypophosphataemia with phosphaturia. The bone disease regresses after removal of the tumour. The biochemical defect is characterized by a low maximum tubular reabsorption of phosphate per volume of glomerular filtrate, suggesting renal phosphate wasting, and, in some patients, by low or inappropriately low levels of $1,25(OH)_2D$. While the biochemical abnormalities are similar to those seen in X-linked hypophosphataemic rickets, there are more severe skeletal deformities. Clinical features are predominantly those of bone pain, proximal muscle weakness, sometimes fractures, and, in children, growth retardation (Ryan and Reiss 1984). A similar type of hypophosphataemic osteomalacia may occur in association with fibrous dysplasia and neurofibromatosis. The mechanism responsible for the development of hypophosphataemia is unknown, but the tumour may produce a humoral factor that affects proximal tubular function and leads to phosphate wasting and suppressed production of $1,25(OH)_2D$.

The tumour may be small and difficult to locate, but if found and completely removed the bone disorder reverses. Clinical features may return if there is a recurrence of the tumour. If it is not possible to resect the tumour completely, treatment is aimed at correcting the hypophosphataemic osteomalacia by phosphate and $1,25(OH)_2D_3$ supplements.

Defective mineralization

Aluminium

As discussed above, in chronic renal failure aluminium is deposited in bone and impairs mineralization.

Fibrogenesis imperfecta ossium

This is a rare disorder that affects middle-aged men, who develop generalized bone pain and fractures. Approximately 50 per cent of reported cases have an associated monoclonal gammopathy. Radiologically the bones appear dense with loss of normal trabecular pattern; histologically bone shows an increased amount of thick osteoid, reduced mineralization, and decreased birefringence due to the lack of normal lamellar arrangement of collagen. It has been suggested that the disorder is due to an acquired defect of collagen that impairs normal mineralization in lamellar bone, but collagen synthesis elsewhere is normal. Some clinical but not histological improvement may occur with vitamin D. Melphalan reportedly induced a clinical remission, with some improvement in the histological appearances of bone, in a patient with coexistent monoclonal gammopathy (Stamp *et al*. 1985).

Hypophosphatasia

This is a rare, heritable cause of severe rickets in childhood and recurrent stress fractures in adults, transmitted in an autosomal-recessive manner with an incidence of 1 in 100 000 live births for the severe form. There is a reduction in serum and tissue alkaline phosphatase in association with increased urinary excretion of phosphoethanolamine and increased circulating inorganic pyrophosphate and pyridoxal-5'-phosphate. Infantile forms present before the age of 6 months with growth retardation, rachitic deformities, hypercalcaemia, hypercalciuria, and renal failure. Childhood hypophosphatasia may present with premature loss of deciduous teeth alone or in association with rickets. It may improve spontaneously. Adult hypophosphatasia presents with recurrent stress fractures that heal poorly. Chondrocalcinosis is common and attacks of pyrophosphate arthropathy may occur. The cause for the mineralization defect is unknown but it has been suggested that the accumulation of pyrophosphate, due to failure of alkaline phosphatase to cleave it, leads to deficient skeletal mineralization (Whyte 1989). There is no treatment available for this disorder. Since there is no hypocalcaemia, vitamin D and its metabolites should be avoided; their use may lead to hypercalcaemia and hypercalciuria (Whyte 1989).

5.17.2 Paget's disease of bone

Adrian J. Crisp

Introduction and epidemiology

On 14 November 1876 Sir James Paget gave the first comprehensive account of 'osteitis deformans' to the Medical and Chirurgical Society (Paget 1877). Paget's disease is a chronic disorder characterized by accelerated resorption and production of bone, resulting in deformity and fragility, and, in Paget's phrase, by 'change of size, shape and direction'. A radiological survey in Britain of hospital patients of 55 years and over in 31 towns concluded that 4 to 5 per cent had Paget's disease, with a focus in Lancashire of 7 to 8 per cent (Barker 1984). The male:female ratio is 3:2. About 10 to 30 per cent of patients have a single pagetic lesion (monostotic disease) and the rest polyostotic disease. There have been many reports of the disease affecting more than one family member and of its recurrence in successive generations. The disease is most common in Britain, North America, Australia, and New Zealand but rare in Eire, Scandinavia, Asia, and in non-white races (Barker 1984). This remarkable geographical distribution compels speculation about a genetically determined disorder disseminated by the migration of populations. Paget's disease is not only a cause of bone and joint pain but also of chronic disability; in one study, 42 per cent of middle-aged patients were forced into premature retirement from work by the disease (Harinck *et al*. 1986).

Pathophysiology

Histopathology

The striking histological feature of the disease is the increased number and size of both osteoclasts and osteoclast nuclei, with active bone resorption. There is a compensatory increase in the number and size of osteoblasts, leading to exuberant new bone formation. This considerable increase in bone turnover disrupts the normal lamellar structure of the matrix collagen, with increased intraosseous fibrosis, hypervascularity, and enlarged haversian canals. This bone consists of a variable mixture of immature ('woven') bone and irregular mature lamellar bone (without haversian systems) separated by deeply staining cement lines in the characteristic mosaic pattern of the disease (Fig. 1).

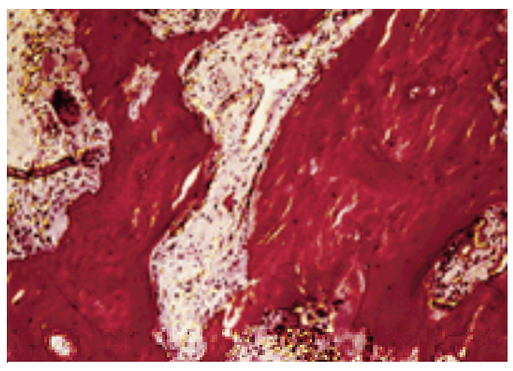

Fig. 1 A section of pagetic bone showing the anarchic architecture and the exaggerated resorption lacunae occupied by multinucleated osteoclasts.

Aetiology

The weight of evidence argues that Paget's disease is caused by a slow-virus infection of bone cells. Polyclonal antibodies reveal paramyxovirus antigens in pagetic osteoclasts compatible with measles and respiratory syncytial virus infections. Studies with monoclonal antibodies implicate measles, simian virus, and human parainfluenza. *In situ* hybridization with DNA probes specific for measles nucleocapsid protein detects measles sequences in osteoclasts, but probes also hybridize with osteoblasts, fibroblasts, and lymphocytes (Basle *et al*. 1987).

Impressive evidence has also come from the demonstration of virus-like particles in osteoclast nuclei (Fig. 2) with a similarity to the measles virus inclusions observed in the brains of patients with subacute sclerosing panencephalitis, a known outcome of measles (Basle *et al*. 1987).

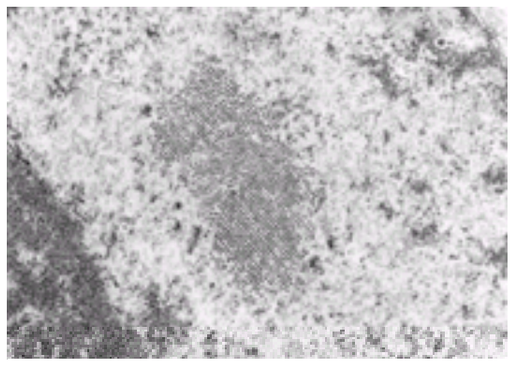

Fig. 2 An electron micrograph of bone tissue from a patient with Paget's disease showing viral microcylindrical elements. (Reproduced with the kind permission of Professor Andre Rebel of Angers, France and of *The Lancet*.)

There is some evidence, based on history of exposure of patients with Paget's disease to dogs in early life, implicating canine distemper, a closely related paramyxovirus (O'Driscoll and Anderson 1985). The same Manchester group has also reported the presence of RNA from canine distemper virus in pagetic bone (Gordon *et al*. 1991). The pattern of disease spread also points to infection, perhaps in early life. Paget's disease is characterized by the concurrent appearance of lesions in one or several bones rather than by the sequential recruitment or spread of new bone involvement in each patient.

However, not all studies have found paramyxovirus particles or RNA in pagetic bone (Ralston *et al*. 1991). There has been no convincing recovery of virus from pagetic cells or pagetic osteosarcoma so far, and it has not been possible to passage the disease to uninfected cell cultures and animals. In addition the antiviral agent, inosiplex, which has successfully treated subacute sclerosing panencephalitis, has been ineffective in Paget's disease in preliminary studies.

Kahn (1990) has suggested that the target cell for viral infection may not be the osteoclast but the osteoblast, which can also contain viral RNA. The structure of the osteoblast is also more deranged in Paget's disease than in any other high-turnover states such as renal hyperparathyroidism. Common progenitor cells give rise to osteoclasts, granulocytes, and monocytes and distribute their progeny widely throughout the circulation; one might then expect that new bone involvement would be 'metastatic' in each patient, which is incorrect. Osteoblasts, which are modified fibroblasts, proliferate locally, and this would be more compatible with the pattern of bone involvement in Paget's disease. We know very little of the molecular basis of Paget's disease. Growth factors are likely to influence the anarchic processes in pagetic bone, which are characterized by bone destruction without respect for the existing architecture and with generous formation of new vessels. Non-transforming growth factors, as well as transforming growth factors secreted by some osteosarcoma cells, are convincing candidates for control of the cellular processes in Paget's disease, which has often been considered a benign tumour of the bone (Krane 1986).

Clinical features (Table 1, Table 2)

	Percentage
Pelvis	72–76
Lumbar spine	33–58
Thoracic spine	24–45
Femur	25–55
Sacrum	29–44
Skull	26–42
Tibia	22–35
Radius	16
Feet	10
Hands	9
Ribs	3

Table 1 Distribution of Paget's disease in the skeleton

Pain
Bone expansion and deformity
Fractures
Heat
Neurological syndromes:
Deafness
Tinnitus
Headache
Spinal cord and root compression
Brainstem/cerebellar compression
Blindness
Other cranial nerve involvement
Malignant osteosarcoma and benign giant-cell tumour
Immobilization hypercalcaemia and hypercalciuria
High-output cardiac failure
Hyperuricaemia and gout
Angioid streaks of retina

Table 2 Clinical features of Paget's disease

Many patients with Paget's disease are unaware of it. Infection may occur in early life and require many years before bone lesions are detectable. The diagnosis is often made incidentally during radiological or biochemical investigations of other systems. The pagetic vertebra seen on a plain abdominal radiograph or a raised serum alkaline phosphatase are very common presenting features. Although long-term prospective studies of outcome in asymptomatic patients with Paget's disease have not been made, perhaps only a minority of patients will eventually develop clinical symptoms or signs clearly attributable to the disease.

Pain

Bone pain

Typically the bone pain of Paget's disease is constant, deep, and boring, sometimes worse at night and at rest. The cause of the pain is not well understood but is likely to be related to increased internal and periosteal blood flow in metabolically active bone increasing intraosseous pressure and stimulating bone pain fibres, which may lie in canaliculi. Long before there is any biochemical evidence of disease control there is often a correlation between pain relief and reduction of bone blood flow, as indicated by thermography, when rapidly acting drugs such as mithramycin (plicamycin) are used (Crisp *et al*. 1989). Compression fractures of verebrae also occur in weakened pagetic bone.

Adjacent joint pain

Bone deformity commonly alters force transmission through the adjacent joint causing premature loss of articular cartilage and secondary osteoarthritis, especially at hip and knee (Fig. 3). Patients can also develop osteoarthritis in an unaffected knee as a result of favouring the contralateral, non-pagetic knee. Metabolically active, hyperaemic, subchondral bone may also be toxic to articular cartilage. Osteoarthritic pain is usually associated with exercise and relieved by rest and sleep. In practice it is often difficult to dissect pagetic bone pain from osteoarthritic pain. Protrusio acetabuli occurs in about one-quarter of hip joints involved by Paget's

disease and sacroiliac joint obliteration occurs rarely (Guyer 1980).

Fig. 3 A patient with Paget's disease of the right femur and tibia causing external rotation of the right leg and secondary osteoarthritis of the knee. A psoriatic patch is also noted on the right knee.

Bone expansion and deformity

Bowing long-bone deformity causes effective inequality of leg length, leading to lumbar scoliosis and accelerated degenerative lumbar spondylosis as well as secondary osteoarthritis. Adaptation to slow, insidious deformity may cause remarkably few symptoms.

Fractures

Pain may arise from incomplete fissure fractures involving only cortex on usually the convex side of a bowed long bone. The pain may settle with rest and medical treatment, but the fissure fracture can extend into a completed fracture. Mild injuries may cause pathological fractures in weakened pagetic bone. In a large series of 180 patients, 15 per cent suffered fractures (Harinck *et al*. 1986). Avulsion fractures, for example, of the patella, can occur after sudden muscular contraction. Non-union may be more common at sites of fracture in pagetic bone.

Heat

Palpation of affected bones near to skin surfaces is often helpful, although bone tenderness is unusual. Auscultation of tibia or skull can sometimes reveal bruits. Temperature may be correlated with both metabolic activity of bone and with bone pain.

Neurological syndromes

Common symptoms of cranial Paget's disease includes non-specific headaches, possibly due to vascular changes in bone and meninges, impaired hearing, and tinnitus. About half the patients with skull involvement will develop deafness, which may be sensineural, conductive, or mixed. Nerve entrapment by the expanded petrous temporal bone is partly responsible, but subtle toxic effects on the inner ear mediated by hypervascularity are also likely. Less commonly the optic nerve and other cranial nerves may be affected with predictable results.

Skull expansion may cause frontal or occipital prominence but if the base of the skull is involved, softened bone may lead to platybasia—the descent of the cranium on to the cervical spine—which may cause dizziness and syncope, owing to kinking of the vertebrobasilar blood vessels, or even cerebellar or brainstem compressive syndromes.

Dysfunction of the spinal cord may rarely result from vertebral expansion and compression but both skull-base and cord dysfunction may follow ill-understood, 'steal' phenomena: increased blood flow in bone 'steals' blood away from neural structures causing ischaemic damage. Hence incipient paraparesis may improve rapidly with intensive medical therapy reducing bone blood flow.

Neoplastic complications

Almost all cases of osteogenic sarcoma in adults arise from pagetic bone but conversely osteosarcoma is a very rare complication of Paget's disease occurring in less than 0.1 per cent of affected patients. The sarcoma is highly malignant and usually rapidly fatal. This diagnosis is worth considering in a patient who develops intense pain in an affected bone, with a progressive lytic lesion and a rising alkaline phosphatase against a background of stable symptoms (Fig. 4). There may be genetic factors: three brothers, who all developed Paget's disease in early life, later died from pagetic osteosarcomas (Brenton *et al*. 1980).

Fig. 4 A radiograph of the right lower leg of a patient with Paget's disease. Just above the ankle joint the markedly lytic region contains an osteosarcoma.

Over 100 cases of the benign giant-cell tumour arising from pagetic bone have been reported. These commonly involve facial bones and mandible, and some cases have been linked by a common family background in Avellino, a small town in Italy (Jacobs *et al*. 1979; Bhambhani *et al*. 1992).

Immobilization, hypercalcaemia, and hypercalciuria

The serum calcium is usually normal but during immobilization for an unrelated illness or orthopaedic surgery, hypercalcaemia and hypercalciuria can occur. Bone formation is inhibited but resorption continues unchecked. Rarely both abnormalities can occur without immobilization, but this can often be traced to coincidental hyperparathyroidism. Hypercalciuria alone is more common, occurring in 21 out of 180 patients, nine of whom described a history of renal calculi (Harinck *et al*. 1986).

Hyperuricaemia

Increased bone-cell turnover might be expected to increase urate synthesis: 13 out of 101 (12.9 per cent) patients without an independent cause had raised urate values. Only three patients suffered from clinical gout (Harinck *et al*. 1986).

High-output cardiac failure

Cardiac index (cardiac output corrected for surface area) is increased in the majority of pagetic patients, especially those with widespread disease. High-output cardiac failure has only rarely been reported when more than one-third of the skeleton is involved.

Other clinical associations

Angioid streaks in the retina caused by disruption of Bruch's membrane may be associated but are also more firmly linked with another condition of abnormal connective tissue, pseudoxanthoma elasticum. Associations with Hashimoto's thyroiditis, Dupuytren's contracture, and chondrocalcinosis have all been proposed but none is firmly based.

Investigations and assessment

Biochemical

Serum alkaline phosphatase

This osteoblastic enzyme, a measure of new bone formation and not resorption, is the most useful and widely available marker and may be elevated by as much as 30 times above the upper limit of the reference range. Analysis of isoenzymes or measurement of alternative liver enzymes help to exclude a significant hepatic contribution to the total alkaline phosphatase. Occasionally, this enzyme is normal with limited Paget's disease but one should not be deterred from treating a painful pagetic lesion by a normal result.

Urine hydroxyproline

Increased osteoclastic bone resorption parallels increased bone formation and may be assessed by assay of urine hydroxyproline excretion, a breakdown product of collagen. Only 20 to 30 per cent of the total hydroxyproline is derived from bone resorption. Ideally the patient should have followed a gelatin (denatured collagen)-free diet for 48 h before the urine collection to exclude a dietary contribution but this is often impractical. The urinary hydroxyproline/creatinine ratio may be determined on a 2-h collection after an overnight fast or on a 24-h specimen.

Urinary pyridinoline collagen cross-links

The recent development of an assay to measure the excretion of bone-specific collagen cross-links offers the prospect of accurate measurement of current osteclastic bone resorption. This is likely to replace measurement of urinary hydroxproline when more widely available (Beardsworth *et al*. 1990).

Serum osteocalcin

Osteocalcin, which is specifically produced by osteoblasts, might in theory be of benefit in the assessment of Paget's disease. However, only one-half of patients with raised alkaline phosphatase have raised osteocalcin and values can be increased by treatment via interactions between parathyroid hormone and 1,25-dihydroxyvitamin D_3. Thus, osteocalcin is unlikely to be a valuable marker of disease activity in Paget's disease.

Serum total acid phosphatase

This osteoclastic enzyme can be raised in active Paget's disease but is of little value. Occasionally metastatic prostatic carcinoma is incorrectly diagnosed in the presence of sclerotic vertebrae and a raised concentration. The two conditions can coexist.

Serum a_2HS glycoprotein

This liver-derived protein is taken up by active bone and levels tend to be lower than normal in active Paget's disease.

Radiological

Plain radiographs

There is a wide variety of appearances in Paget's disease but the key features are lytic areas, especially early in the disease, sclerotic areas, and bone expansion with coarse and disorganized trabecular structures (Fig. 5 and Fig. 6).

Fig. 5 A radiograph of the pelvis showing typical widespread Paget's disease.

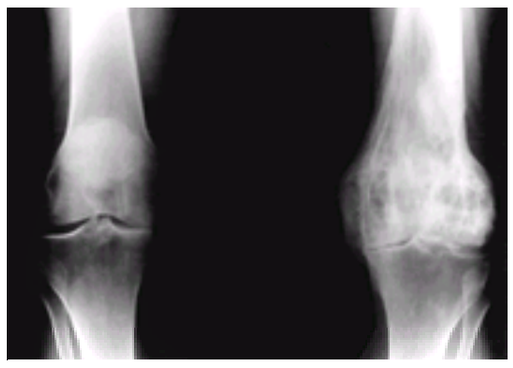

Fig. 6 A radiograph of both knees showing typical pagetic involvement of the left distal femur and worse osteoarthritis of the affected knee when compared with the knee uninvolved by Paget's disease.

Isotope bone scanning

In one study (Meunier *et al*. 1987), scanning demonstrated 8.3 per cent more pagetic sites than did plain radiography and is therefore the most sensitive investigation for defining the extent of lesions (Fig. 7). A scan and then plain radiographs of affected sites should be performed at first diagnosis for future comparisons. The percentage retention of the isotope after 24 h—less than 40 per cent in normal subjects in our laboratory—provides an index of total pagetic bone activity. During aggressive advance of the resorption front, scanning may underestimate disease activity, suggesting active osteoclastic activity with a poor osteoblastic response—a situation comparable with many lytic lesions in multiple myeloma. Quantitative bone scintigraphy comparing the area of increased uptake with the same area on the contralateral (unaffected) side can be very useful in the assessment of the monostotic lesion when alkaline phosphatase is often normal.

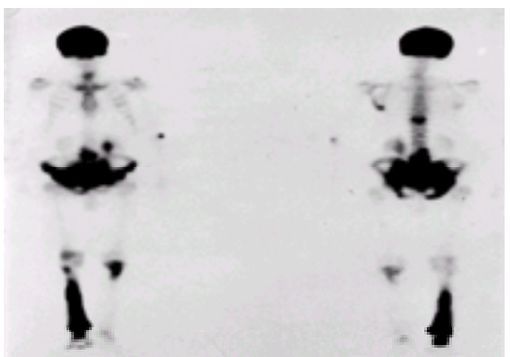

Fig. 7 A scintigram showing a typical pagetic distribution of lesions in skull, vertebrae, pelvis, and both legs.

Thermography

Increased bone and periosseous blood flow is demonstrated effectively in superficial bones and is reduced after effective treatment (Fig. 8). Thermographic improvement and pain reduction seem to be linked (Crisp *et al*. 1989).

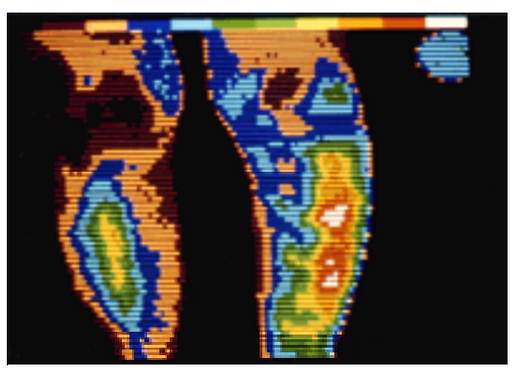

Fig. 8 A thermogram of lower legs in a patient with Paget's disease showing a focus of increased temperature (white and red areas) at the site of active Paget's disease (by kind permission of Dr Brian Hazleman).

Differential diagnosis of Paget's disease

The combination of physical signs, including a warm deformed bone with characteristic radiographs and a raised serum alkaline phosphatase, usually leaves no doubt about the diagnosis of Paget's disease. Consider also:

1. Other causes of raised serum bone alkaline phosphatase:
   a. metastatic bone disease;
   b. osteomalacia;
   c. hyperparathyroidism, with osteitis fibrosa cystica: this may accompany Paget's disease and may be more than coincidental;
   d. idiopathic hyperphosphatasia: characterized by bone deformity in childhood and a probably recessive inheritance—its relationship with adult Paget's disease is not known.
2. Other causes with similar radiographic appearances:
   a. metastatic bone disease; osteolytic and osteoblastic disease, e.g. prostatic secondaries;
   b. fibrous dysplasia;
   c. chronic osteomyelitis;
   d. metaphyseal dysplasia (Engelmann's disease);
   e. sternocostoclavicular hyperostosis.

Treatment

Attitudes towards treating Paget's disease vary considerably from the therapeutic nihilist, who attributes most of the pain to secondary osteoarthritis and considers specific treatment as an expensive superfluity to the tyro who chooses to treat all patients. The criteria of the present author are listed in Table 3. With the advent of safe effective drugs for Paget's disease there is a firm trend towards early, aggressive treatment with the objective of maintaining serum alkaline phosphatase within the normal range. Although remission after treatment is related to the degree of biochemical control (Harinck *et al*. 1987; Kanis and Gray 1987), and there is strong histological evidence that effective suppression promotes more normal bone remodelling, we lack evidence that intensive treatment inhibits the development of long-term complications.

Pain arising from a site of known Paget's disease
Early, potentially deforming disease
Osteolytic lesions especially in weight-bearing bones
Skull disease
Complications:
Progressive neurological syndromes
Fissure fractures (avoid etidronate)
Immobilization hypercalcaemia
High-output cardiac failure
Disease in patients aged under 55 years
Serum alkaline phosphatase and/or urine hydroxyproline concentration more than twice upper limit of normal
Patients likely to undergo joint replacement at involved sites within 6 months

Table 3 Indications for treatment of Paget's disease

Pagetic and related osteoarthritic pain may be reduced by simple analgesics and non-steroidal anti-inflammatory drugs but pure pagetic bone pain often responds poorly to these. Physical treatment to improve muscle function and correct any inequality in leg length with shoe raises may be very helpful. More effective control will be achieved by drugs that suppress bone turnover. All primarily inhibit osteoclast activity, as reflected by an early decrease in urine hydroxyproline excretion followed by a later fall in serum alkaline phosphatase. Intravenous mithramycin (plicamycin), 15 µg/kg per day for 7 to 10 days is highly effective, giving rapid pain relief within 3 days and biochemical improvement, but it has an unacceptable toxicity to bone marrow, liver, and kidneys and is on the verge of obsolescence since the availability of later generation bisphosphonates. It may still be of value for the urgent treatment of acute neurological deterioration, most commonly spinal cord compression, when the rapid control of bone blood flow and perhaps periosteal oedema can lead to impressive improvement.

In most patients the choice of treatment now falls between the bisphosphonates (previously called diphosphonates) and the calcitonins.

The bisphosphonates (Fig. 9)

This family of pyrophosphate analogues share a common P–C–P backbone replacing the P–O–P of pyrophosphate. Side-chain variations confer differing properties but they are all effective for pagetic pain and disease activity. Oral etidronate and more recently oral tiludronate and intravenous pamidronate are licensed for use in Paget's disease in the United Kingdom. There has been additional experience with oral and intravenous clodronate, which is at present licensed only for use in malignant hypercalcaemia.

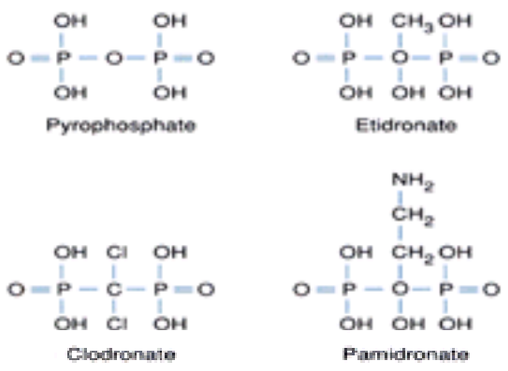

Fig. 9 The structures of pyrophosphate and bisphosphonates in common clinical use.

Calcitonins only partially suppress the disease while treatment continues. Bisphosphonates can achieve prolonged remissions following a course of treatment and are therefore now first choice.

Etidronate disodium

The recommended regimen for oral etidronate is 5 mg/kg per day for up to 6 months, although a month's course of 20 mg/kg per day is probably as effective, without added toxicity (Preston *et al*. 1986; Heath 1987). To achieve maximal gut absorption all oral bisphosphonates should be taken at least 2 h after food. Mild gastrointestinal symptoms and transient increased bone pain are occasional side-effects. Etidronate even at low doses can cause a reversible mineralization defect, which may be minimized by vitamin D supplements, and may increase the risk of fracture. This bisphosphonate is contraindicated for lytic lesions in weight-bearing long bones (Krane 1982). Courses of etidronate should always be followed by a minimum treatment-free period of 3 months to permit recovery of the mineralization defect.

Newer bisphosphonates

The newer bisphosphonates are not completely free of the risk of causing a mineralization defect but the safe therapeutic window is much wider. Clodronate is about 10 times less potent than pamidronate and there has been far less clinical experience with it (Yates *et al*. 1985). Oral tiludronate 400 mg daily for 3 months has been recently licensed for the treatment of Paget's disease in the United Kingdom. Very poor absorption and a high incidence of mild gastrointestinal side-effects with pamidronate effectively limits its use to the intravenous route but absolute compliance with a precise dose is achieved.

The optimal dosage regimen for pamidronate in Paget's disease remains to be determined. Anderson *et al*. (1994) have induced a full biochemical remission (serum alkaline phosphatase falling to normal) in 90 per cent of patients in whom this enzyme was initially raised, with one or more complex courses. Such courses typically induce a remission of about 2 years and Anderson *et al*. claim that a permanent remission can be achieved in 10 to 15 per cent of patients. If the alkaline phosphatase level is below 500 i.u./l they advocate a 30 mg infusion over 2 h followed by three infusions of 60 mg each over 4 h. If the alkaline phosphatase level exceeds 500 i.u./l, six 60 mg infusions are recommended administered at 2-week intervals.

Other groups have argued that a single infusion of a dose large enough to saturate all of the binding sites of bone affected by Paget's disease should achieve as much as complex recurrent regimens (Fig. 10). Watts *et al*. (1993) studied the effect of a single infusion of 105 mg of pamidronate in 14 patients with mean levels of serum alkaline phosphatase about three times the normal upper limit. The alkaline phosphatase level returned to normal (the goal of successful treatment and likely to produce prolonged remission) in 71 per cent of patients with a mean nadir of the enzyme at 5.9 months. Excellent symptomatic control was achieved for 1.5 to 2 years. Four patients received a second infusion of 105 mg of pamidronate, a mean interval of 19 months after the first dose. This resulted in a similar clinical and biochemical response to the first. One patient had a 4-year remission before treatment was required.

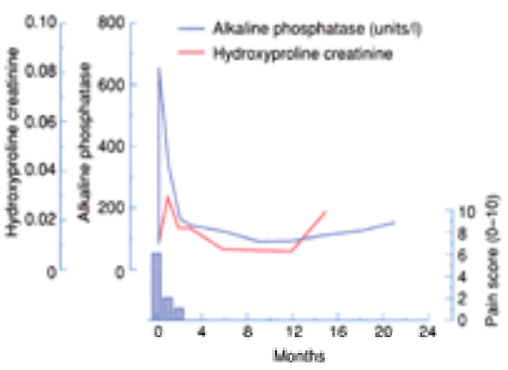

Fig. 10 The effect of a single intravenous infusion of pamidronate (APD) at a dose of 105 mg in one patient with Paget's disease. An early rapid fall in urine hydroxyproline excretion is followed by a slower fall in serum alkaline phosphatase. Pain is abolished after 3 months and the patient is still pain free after 21 months.

Further support for a single dose regimen was reported by Chakravarty *et al*. (1994) who treated 36 patients, with mean levels of serum alkaline phosphatase about four times the normal upper limit, with 60 mg of pamidronate. Alkaline phosphatase levels were returned to normal in 78 per cent of patients at 6 months and 77 per cent of patients at 1 year. The efficacy of the two single-dose regimens using pamidronate at 60 to 105 mg therefore is similar, but is marginally inferior to the complex regimen advocated by Anderson *et al*. (1994) which achieves a normal level in 90 per cent of patients.

The author's current practice is to treat pagetic patients with a single infusion of pamidronate 90 mg over 6 hours. Patients are followed up every 3 months with a clinical assessment and measurement of alkaline phosphatase. If this is supranormal at 6 months, a second infusion of 90 mg is administered. Only a small minority of patients do not achieve normal alkaline phosphatase levels with this regimen. This 'resistant' subgroup is treated with 90 mg infusions every 3 months until remission occurs.

Intravenous pamidronate is usually well tolerated but the following side-effects have been reported: transient pyrexia after the first but not usually after later infusions; mild leucopenia and mild hypocalcaemia; myalgia; transient increased bone pain; acute anterior uveitis, which may recur if the patient is rechallenged (unpublished observation).

The calcitonins

Subcutaneous or intramuscular calcitonin (salmon, porcine, or human) is safe and effective but has many disadvantages. It is so far only widely available by injection. It commonly causes mild side-effects such as nausea, flushing, and diarrhoea. After successful initial treatment, patients may relapse while continuing treatment, because of down-regulation of calcitonin receptors. Early relapse after ceasing treatment is also common, and calcitonin is very expensive.

If salmon calcitonin (salcatonin) is chosen, the starting dose after a 10 i.u. test dose is 50 to 100 i.u. daily reducing to 50 i.u. two or three times weekly once the symptomatic response has been achieved. Patients usually notice decreasing pain after 1 to 2 months but if there has been no response by 3 months, then calcitonin treatment should cease. Effective treatment has been claimed to reverse disease progression and, until the advent of the newer bisphosphonates, calcitonin was the treatment of choice for lytic disease of long bones and fissure fractures. Many patients learn to give their own injections but to condemn them to many years of injections 2 to 3 times weekly is becoming increasingly unacceptable when alternative short courses of bisphosphonates can achieve prolonged clinical and biochemical remissions.

It is possible that new formulations of calcitonin given by nasal spray, for example salmon calcitonin at 200 to 400 i.u. daily, when available might be useful but the typical therapeutic effect is weaker than that of the newer bisphosphonates (Reginster *et al*. 1988).

Surgery

There is still no consensus as to whether patients requiring total hip or knee replacement for joints ravaged by the combination of Paget's disease and osteoarthritis should receive specific medical treatment before surgery. There is some evidence that effective treatment—a newer bisphosphonate or calcitonin rather than the demineralizing etidronate—reduces bone blood flow, improves the quality of bone in which the prosthesis will be sited, and facilitates the adhesion of cement to bone. Certainly orthopaedic surgeons should not be deterred from replacement arthroplasty by the presence of Paget's disease, as the risks of prosthetic loosening are only slightly increased. It would seem logical to time surgery to coincide with a phase of clinical and biochemical pagetic remission induced by medical treatment. Prospective studies are awaited.

5.17.3 Diseases of bone, cartilage, and synovium

P. J. Maddison

In this chapter, a miscellaneous group of disorders affecting components of the joint and periarticular structures is described. They can present a challenge to the clinician in diagnosis and management. There is often a delay in diagnosis causing pain and disability. Frequently this is due to insufficient clinical suspicion, partly because of the rarity of most of these conditions. Their diagnosis generally depends on recognizing a combination of clinical, laboratory, and histological features, but the advent of techniques such as magnetic resonance imaging (**MRI**) facilitates earlier diagnosis. This is particularly important for conditions such as osteonecrosis where the institution of treatment at an earlier stage in the course of the process may prevent joint destruction.

Osteoid osteoma

Skeletal neoplasms are discussed in Chapter 1.2.1.2 and Chapter 5.19.1. Only rarely do they cause problems for the experienced clinician in being mistaken for systemic rheumatic diseases. An exception is hypertrophic osteoarthropathy (Chapter 5.19.1); another is osteoid osteoma. This is a benign osteoid-forming tumour, which can be an elusive cause of bone pain, 'radiculopathy', or 'arthritis' in children and young adults, depending on its site. It is uncommon and accounts for 10 to 12 per cent of benign bone neoplasms (Dahlin and Unni 1986).

The maximum age incidence is in the second and third decades, but this tumour can occur in all age groups, and is two or three times more common in boys than girls. More than two-thirds of the lesions occur in long bones, mostly in the lower extremity and especially involving the femur and tibia. The neck of the femur and the intertrochanteric region are a particularly characteristic location in the femur (Resnick and Niwayama 1988).

The lesion consists of a small core or nidus of cellular, highly vascularized tissue, with an interlacing network of immature bone and osteoid in varying proportions. The nidus is surrounded by a zone of reactive bone, especially in cortical bone. Very rarely, the osteoid osteoma is multifocal with more than one nidus. High levels of prostaglandins are produced within the lesions (Makley and Dunn 1982). Intra-articular lesions, which are rare and arise at the end of a long bone within the insertion of the joint capsule, are accompanied by a synovitis characterized by a hyperplastic synovium and a prominent lymphocytic infiltrate.

Clinical features

Almost without exception the initial symptom is pain. This may be vague and intermittent at first but becomes increasingly intense. Often, though not invariably, it is worse at night, and typically it is relieved by aspirin and other non-steroidal anti-inflammatory drugs. Although pain is usually felt in the region of the bone lesion, the presentation can be much less characteristic and the diagnosis is often delayed for many months. For example pain can sometimes be referred or radicular, accompanied by muscle atrophy and diminished or absent tendon reflexes in the affected limb, thus mimicking a spinal lesion (Kiers *et al*. 1990). Intra-articular lesions can also present a confusing picture, with joint pain, stiffness, effusion, muscle atrophy, and loss of function. Osteoid osteomas that arise in the posterior elements of the spine can present with scoliosis or torticollis.

Diagnosis

A typical lesion (Fig. 1(a)) in the cortex of a long bone is seen on a plain radiograph as a well-defined area of sclerosis, 0.5 to 1.0 cm in diameter, surrounding a radiolucent nidus, which may contain speckled areas of calcification. However, lesions in cancellous bone and neural arch and intra-articular lesions are often difficult to locate with plain radiographs. A bone scan using $^{99}Tc^{m}$ hydroxymethylene diphosphonate is a highly sensitive technique to screen for an osteoid osteoma, as these lesions avidly accumulate isotope (Fig. 1(b)). Helms *et al*. have described the 'double density sign' as characteristic for osteoid osteoma (Helms *et al*. 1984) but it is often not seen and the bone scan is then non-specific for differentiating an osteoid osteoma from lesions such as a stress fracture, synovitis, and a Brodie's abscess. Computed tomography (**CT**) is also valuable for imaging lesions difficult to locate on plain radiographs, especially those in the spine and proximal femur, and for precisely locating the nidus before surgical resection (Swee *et al*. 1979). MRI effectively demonstrates the associated intramedullary and soft tissue changes but the resulting image can lead to diagnostic confusion and CT is generally considered to be the better imaging modality for the diagnosis of osteoid osteoma (Assoun *et al*. 1994).

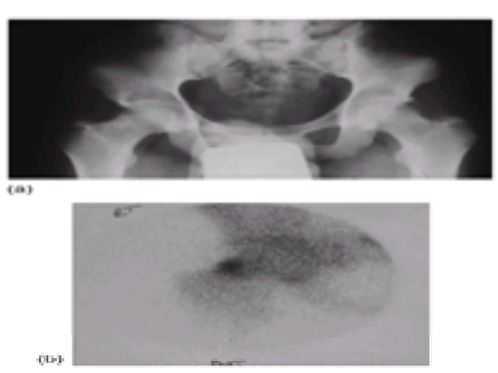

Fig. 1 (a) Plain pelvic radiograph showing an osteoid osteoma of the femoral neck in an 18-year-old male who presented with a 3-month history of progressively worsening pain. (b) Radionuclide bone scan showing increased uptake of isotope by the lesion.

Treatment

Surgery is curative, provided the nidus is excised completely. If this is not achieved, the osteoid osteoma may recur, up to10 years afterwards. Many surgeons use an *en bloc* excision but some use CT- or radioisotope-guided excision of osteomas, mainly of those located in the extremities (Ward *et al*. 1993; Musculo *et al*. 1995). Radiofrequency ablation (Rosenthal *et al*. 1995) or thermocoagulation (De Berg *et al*. 1995) have been reported as promising and less invasive alternatives to surgery in selected patients.

Synovial chondromatosis

This is a disorder of unknown aetiology that affects synovium-lined joints, tendon sheaths, and bursas. It is characterized by chondrometaplasia of the subsynovial connective-tissue cells. The joint cavity becomes filled with a thickened synovium containing pearly-white to blue nodules. Some of these lie free in the joint as loose bodies. The histological appearance is of double-nucleated chondrocytes exhibiting moderate hyperchromasia, arranged in clusters with abundant intervening matrix.

The disorder is uncommon and generally occurs in middle-aged men. It has never been reported before puberty. Most commonly it affects the knee (one-half of cases) or hip, but can also involve other large joints such as the elbow, shoulder, and wrist. Extra-articular involvement of tendons occurs, predominantly in the hands and feet.

Clinically, it resembles pigmented villonodular synovitis (see below). The presenting symptoms are mild, but progressive, pain and locking. Aspirated joint fluid is always yellow or straw-coloured. Plain radiographs (Fig. 2) show small, punctate calcifications outlining the joint margin and sometimes bony erosions due to raised intra-articular pressure. Large osteochondral fragments can be seen but this is not a specific feature. Loss of articular cartilage does not occur. If the cartilaginous nodules are not calcified or ossified, the diagnosis can only be confirmed by arthroscopy.

Fig. 2 Anteroposterior view of the elbow demonstrating multiple osteochondral bodies, regularly shaped and uniform in size. This is typical of synovial chondromatosis. (By courtesy of Dr P. Renton, University College London.)

This is a benign condition. During the active phase it is very slowly progressive but it becomes self-limiting and regression can be observed. In rare cases there is transformation to chondrosarcoma.

Treatment is surgical and most authorities suggest that this should consist of removal of loose bodies and excision of the synovial membrane (Christensen and Poulsen 1975), which can be done via the arthroscope (Coolican and Dandy 1989). Removal of loose bodies without an extensive synovectomy has been reported to give similar results (Shpitzer *et al*. 1990).

Pigmented villonodular synovitis

The term pigmented villonodular synovitis was first coined by Jaffe *et al*. in 1941 to encompass a group of conditions, previously known by a variety of other terms, characterized by exuberant proliferation of synovial cells and mesenchymal supporting tissue affecting joints, tendons, and bursas (Jaffe *et al*. 1941; Flandry and Hughston 1987; Goldman and DiCarlo 1988). In their seminal paper, Jaffe and colleagues emphasized the villous and nodular proliferation, the deposition of iron and fat, and the non-malignant nature of these conditions. The terminology subsequently was expanded to distinguish localized lesions (sharply localized or pedunculated lesions involving tendon sheaths or part of the joint lining) from diffuse lesions of the joint synovial membrane, which, although similar histologically, are more progressive and tend to recur after treatment.

Aetiological factors

The aetiology is unknown and there are still various hypotheses based on different interpretations of the histological changes. Although once considered to be neoplastic, pigmented villonodular synovitis does not behave like a malignancy and does not metastasize. In contrast, a benign neoplastic process of synovial, vascular, or fibrohistiocytic origin is proposed by some (Rao and Vigorita 1984). This view is supported by some cytogenetic evidence of clonality (Ray *et al*. 1990). Most favour a non-neoplastic aetiology; suggestions include a response to blood and blood products from trauma. An epidemiological study (Myers *et al*. 1980), while showing no evidence of a genetic basis for pigmented villonodular synovitis, demonstrated a history of chronic repetitive trauma and repeated haemarthroses in approximately 50 per cent of cases. However, there has been a general failure to reproduce typical histological changes in experimental models with injection of various substances from whole blood to colloidal iron. Furthermore, clinical experience from haemophiliacs and others with bleeding disorders points away from a reaction to trauma and haemorrhage *per se*. A commonly held, but rather unhelpful, view is that pigmented villonodular synovitis is an inflammatory response to an as yet unknown trigger.

Pathology

The striking pathological feature is the proliferation of synovial lining cells at the surface and invading the subsynovial stroma. The result in diffuse pigmented villonodular synovitis is a greatly thickened synovial membrane bristling with big, long villi, which may be interspersed with nodules of various size. The tissue is often stained red-brown from repeated haemorrhage, with mottled areas of yellow-orange from lipid deposition. Histologically (Schumacher *et al*. 1982), there is marked proliferation of surface lining cells, together with an invasion of the subsynovial stroma by large epithelioid histiocytic cells that electron-microscopic studies show to be a mixture of proliferating synovial fibroblasts and type B synovial lining cells. The stroma also contains multinucleate giant cells and lipid-laden macrophages. In addition, there are a few lymphocytes and plasma cells. Capillary hyperplasia resulting in numerous thin-walled vascular channels is another characteristic feature. Haemosiderin is deposited in the lining and epithelioid cells, and in the stroma. Another typical feature is the ability of pigmented villonodular synovitis to invade subchondral bone. This is thought to be through erosion into the osteocartilaginous junction, by extension into vascular foramina, and from the effect of increased intra-articular pressure causing focal osteopenia in the subchondral bone.

Clinical features

Pigmented villonodular synovitis is rare, with an estimated annual incidence of around 1.8 cases/million population (Myers *et al*. 1980). Typically it affects adults of both sexes in their third or fourth decade, but there is a wide age range and cases have been reported in children (Docken 1979) and even infants (Curtin *et al*. 1993). Classically, it presents as a monoarthritis. In 80 per cent of cases the knee is involved, followed in order by the hip, ankle, and shoulder; very rarely, multiple joints are involved and there are case reports of involvement at sites such as the spine (Clark *et al*. 1993) and temporomandibular joint (Franchi *et al*. 1994). The onset is usually insidious, with pain the most common complaint (Flandry *et al*. 1994a); this is mild at first but progressive. Rarely, there may be sudden exacerbation of pain

due to torsion or infarction of a nodule of abnormal tissue. Sometimes there are features of internal derangement, such as locking, especially with localized forms of pigmented villonodular synovitis. Occasionally, an affected knee joint becomes unstable. On examination, there is often swelling and sometimes one or more palpable masses of synovium. There may be local warmth and points of tenderness.

Joint aspiration gives fluid that ranges in colour from yellow or straw, with deep xanthochromia from previous haemorrhage, to brown-stained or frankly bloody. Reports of synovial fluid analysis are sparse but findings point to inflammation and include a slight elevation of protein, reduced glucose, and a low to moderate leucocyte count. The results of other laboratory tests are otherwise normal.

Plain radiographs may be normal or only show the soft tissue outline of synovial swelling, which is made more radiodense by haemosiderin deposition. However, calcification, which occurs in malignant lesions such as synovial sarcoma, is absent. In approximately 50 per cent there are osteoarticular changes corresponding to invasion of bone by the lesion. These include multiple subchondral cysts, which can occur on non-weight-bearing surfaces, and well-demarcated erosions due to increased intra-articular pressure. These changes occur earlier in joints with a tight articular capsule, such as the hip, than in the knee in which a more distensible capsule accommodates a greater degree of soft tissue proliferation. In the knee, bony lesions often develop first in the patellofemoral compartment, where intra-articular soft tissue is more likely to be entrapped (Smith and Pugh 1962). Preservation of joint space is reported to be a typical feature of pigmented villonodular synovitis, but, in fact, loss of joint space can occur as a late feature. Juxta-articular osteoporosis and osteophyte formation are not seen. MRI is very characteristic if there is sufficient haemosiderin and fat deposition in the lesion. Haemosiderin deposition produces a low signal intensity on T_1-weighted images, which decreases even further on T_2-weighted images. In contrast, areas with high fat content have high signal intensity. Consequently, an MRI study demonstrating a multinodular intra-articular lesion with patchy areas having characteristics of fat and haemosiderin deposition is highly suggestive of pigmented villonodular synovitis. However, in practice both false positives and false negatives occur. Techniques such as arthrography and arteriography have been used, but the results are rather non-specific.

Diagnosis

The diagnosis is based on a combination of clinical, radiological, and histological findings and the gross appearance of the lesion. The presence of serosanguinous synovial fluid in a young adult in the absence of a history of recent trauma is highly suggestive of the diagnosis of pigmented villonodular synovitis. The definitive diagnosis, however, often rests on the interpretation of a synovial biopsy. Histological criteria for the diagnosis have not been defined. Although features such as epithelioid cells, multinucleate giant cells, and deposition of fat and haemosiderin are highly characteristic, interpretation of the histological features by a specialist in osteoarticular pathology is required.

Conditions to be considered in the differential diagnosis of pigmented villonodular synovitis include:

1. malignant synovioma;
2. synovial haemangioma;
3. synovial chondromatosis;
4. tuberculous arthritis;
5. amyloidosis;
6. haemophilia;
7. lipoma arborescens.

Treatment

Localized forms of pigmented villonodular synovitis are treated by marginal excision of the lesion and have a good prognosis. The diffuse form, however, tends to be progressive and recurrence is not uncommon. Treatment suggestions are largely based on anecdotal experience, the published series are small, and post-treatment follow-up is limited. A range of techniques, which include radiation, wide synovectomy, synovectomy combined with radiation, arthrodesis, bone grafting, primary arthroplasty, and radiation synovectomy, has been used. No single method has a uniformly high proportion of good results.

The most commonly reported treatment is surgical synovectomy. There are recent reports of good results (Flandry *et al*. 1994b), although in previous series there have been a high percentage of recurrences, with persistent joint pain and stiffness as common sequelae (Johansson *et al*. 1982). The use of radiation therapy as an adjunct does not improve the outcome. Radiation synovectomy using intra-articular yttrium-90 silicate has been reported, with promising results (Franssen *et al*. 1989). There are several advantages over surgical synovectomy including technical simplicity and fewer complications. There is limited experience, however, and not much long-term follow-up. In advanced cases with joint destruction (especially in the hip), it may be necessary to resort to a total arthroplasty.

Chronic focal osteomyelitis (Brodie's abscess)

This usually follows an acute haematogenous infection in an adolescent male (Boriani 1980). Three-quarters of Brodie's abscesses develop in the lower extremity, most often in the tibia. The acute episode of infection may have been successfully treated with antibiotics from a clinical point of view, only to be followed by a focus of chronic infection that can persist for years if not surgically drained.

Typically, the infection occurs in the metaphyseal side of the growth plate, where it remains localized. In rare cases, the infection extends through the growth plate into the epiphysis. Usually it is unifocal but multiple abscesses have been reported. Approximately 80 per cent involve *Staphylococcus aureus*, although almost any organism can be implicated.

Pain is the main complaint, described as aching or boring, and may have been present for months or even years. This is accompanied by localized tenderness and sometimes swelling. Occasionally, the abscess dissects through spongy bone and erodes through the cortex to drain into a joint, or through a sinus to the skin surface. The symptoms and signs of systemic illness that generally accompany acute osteomyelitis are conspicuously absent. Laboratory tests may also be normal, although there can be slight leucocytosis or elevation of the erythrocyte sedimentation rate. Radiographs show a sharply demarcated and irregular area of bone destruction surrounded by sclerosis (Fig. 3). Cultures from the abscess are positive in 50 to 80 per cent of cases.

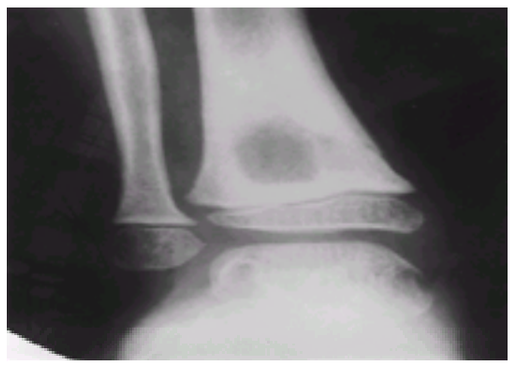

Fig. 3 Anteroposterior view showing a sharply demarcated Brodie's abscess surrounded by reactive sclerosis in the distral diaphysis of the tibia of a child presenting with chronic pain. (By courtesy of Dr P. Renton, University College London.)

Treatment is by surgical drainage and appropriate antibiotics. The prognosis is good.

Osteonecrosis

Osteonecrosis is a major reason for orthopaedic surgery to the hip, particularly in younger patients. There are several synonyms: avascular necrosis, aseptic

necrosis, ischaemic necrosis, steroid necrosis, segmental subchondral infarction. Osteonecrosis at certain sites is associated with eponyms such as Legg–Perthes' disease (hip), Freiberg's disease (metatarsal), and Kienboch's disease (lunate).

In 1860, James Paget described the gross appearance of osteonecrosis in his lectures on surgical pathology (Bullough and DiCarlo 1990). Necrosis of the femoral head was associated with Caisson's disease in 1888, with corticosteroids in 1957 (Pietrogrande and Mastromarino 1957), and the association with systemic lupus erythematosus was reported in 1960 (Dubois and Cozen 1960). Before the 1960s, most reported cases were associated with fracture. The current prevalence of osteonecrosis is difficult to assess because many cases are clinically silent. Different forms of osteonecrosis affect children, young adults, or elderly people. However, most of those with atraumatic osteonecrosis are relatively young, with a peak incidence in the fifth decade of life. One group reports that about 18 per cent of femoral heads removed in total hip-replacement procedures for non-traumatic causes show evidence of osteonecrosis (Bullough and DiCarlo 1990). Approximately 60 per cent are bilateral, women are slightly more affected (1.2:1), and the mean age of presentation is 55 years compared with 67 years for patients with primary osteoarthritis.

Osteonecrosis, like infarction anywhere, results from a reduction or the obliteration of the blood supply to the affected area. Subchondral bone has a limited collateral circulation and the perfusion pressure and blood flow of epiphyses and fatty marrow is low compared with red diaphyseal marrow. Therefore, ends of bones such as the femoral head are more susceptible to ischaemia. Various mechanisms have been implicated (Mankin 1992):

1. interruption of extraosseous arterial blood supply (e.g. trauma, vasculitis);
2. interruption of intraosseous sinusoidal circulation (e.g. nitrogen bubbles, sickled erythrocytes, thrombi, fat emboli);
3. extravascular compression of sinusoidal circulation (e.g. nitrogen bubbles, intramedullary lipocyte hypertrophy, accumulation of Gaucher's or malignant cells).

Often a combination of factors is involved. A final common pathway appears to be increased bone-marrow pressure, which can be demonstrated in the very earliest stages of the process (Zizic *et al*. 1986) and which further contributes to the impaired intraosseous microcirculation and progression of necrosis.

The pathology of osteonecrosis is well defined. The first phase is necrosis of bone and bone marrow. A cut section of bone shows a wedge-shaped necrotic zone in the subchondral region, which is demarcated from the normal bone marrow by a hyperaemic border. Granulation tissue develops and then advances from the margin of the infarct and necrotic bone is resorbed. Behind this, a second front of osteoblasts lays down new bone. If articular stress exceeds the structural integrity of the altered bone, there will be collapse of the articular surface and disruption of the joint.

Aetiological factors (Zizic 1990; Mankin 1992; Chang et al. 1993)

Some of the causes of osteonecrosis are:

1. trauma;
2. sepsis;
3. radiation, thermal, and electrical injury;
4. Caisson's disease;
5. haemoglobinopathies;
6. haemophilia;
7. coagulopathies;
8. Gaucher's disease;
9. alcoholism;
10. Cushing's syndrome;
11. corticosteroid usage;
12. systemic lupus erythematosus;
13. rheumatoid arthritis;
14. systemic sclerosis;
15. vasculitis;
16. organ transplantation (kidney, heart, marrow);
17. chronic dialysis;
18. human immunodeficiency virus infection;
19. pancreatitis;
20. chronic liver disease;
21. hypertriglyceridaemia;
22. pregnancy (especially in the third trimester);
23. (idiopathic).

The major cause is a fracture that interferes with the blood supply to areas such as the femoral or humeral head, talus, and scaphoid. Osteonecrosis is a major complication of intracapsular fracture of the femoral neck, which is accompanied by disruption of the circulation in approximately 20 per cent of cases. Osteonecrosis occurs in 18 per cent of compressed-air workers and 4 per cent of divers; it appears to be the result of the development of intravascular and extravascular nitrogen gas bubbles during decompression, effectively occluding the circulation to sites such as the femoral and humeral heads. Lesions are frequently multiple and bilateral; involvement of the humeral heads is particularly characteristic. In Caisson's disease, for some reason, the subchondral bone of the knee and the ankle are not involved.

Depending on the genotype, sickle cell haemoglobinopathies have a 5 to 14 per cent prevalence of radiographically detectable osteonecrosis. As in Caisson's disease, the femoral and humeral heads are involved.

The two most common causes of non-traumatic osteonecrosis are alcoholism and hypercortisolism, which account for two-thirds of the cases. A feature they have in common is alteration in systemic fat metabolism. Osteonecrosis may be produced as a result of fatty emboli, or of intramedullary lipocyte hypertrophy and consequent intraosseous sinusoidal compression. Osteonecrosis in rheumatoid arthritis and systemic lupus is mostly associated with corticosteroid treatment. However, as in systemic lupus (see below), osteonecrosis is described as a complication of rheumatoid arthritis in the absence of steroids (Wollheim 1984), although there is little information about the prevalence of this. Osteonecrosis has been reported after repeated intra-articular injections of long-acting corticosteroids (Laroche *et al*. 1990).

Osteonecrosis in systemic lupus

This is a relatively common and disabling complication of lupus (Cronin 1988). The prevalence of the symptomatic, radiographic lesion in adults with systemic lupus is reported to be between 5 and 10 per cent. However, asymptomatic lesions detected by MRI are more common and present in up to 35 per cent (Nagasawa *et al*. 1994). Although some become apparent on plain radiographs, present in up to 25 per cent of adult systemic lupus erythematosus patients (Klippel *et al*. 1979) and possibly in even more children (Bergstein *et al*. 1974), in only a minority of lesions is the necrosis extensive enough to cause clinical problems. The major risk factor for osteonecrosis is corticosteroid therapy, but there are reports of the complication before the steroid era (Leventhal and Dorfman 1974). Suggested additional risk factors present in the analysis of some studies, but not in others, include younger age, vasculitis, Raynaud's phenomenon, and leucopenia. Osteonecrosis has been reported in association with antiphospholipid antibodies in patients with the 'primary antiphospholipid syndrome' but others (Alarcon-Segovia *et al*. 1989; Migliaresi *et al*. 1994) have found no correlation between anticardiolipin antibodies and osteonecrosis in their lupus population. It appears that it is the use of large doses of corticosteroids (e.g. prednisolone, 60 mg daily), sustained over a period of months, that is important for the development of osteonecrosis, rather than the duration of corticosteroids or the accumulative dose *per se*. Giving pulses of megadose corticosteroids either once or repeated after intervals of several weeks does not independently predispose to osteonecrosis. A meta-analysis reported by Felson and Anderson suggests that this relationship to dose and duration of corticosteroids applies to patients with a variety of clinical conditions (Felson and Anderson 1987). It is worth remembering that a number of malpractice suits have been brought against physicians for failing to inform patients of this complication of corticosteroids.

The onset of localized pain, particularly in a weight-bearing joint, should give rise to a high index of suspicion. The femoral head is most commonly involved, but other sites include the femoral condyle, tibial plateau, humeral head, talus, scaphoid, and lunate. Simultaneous involvement of multiple sites is not infrequent.

Diagnosis

Pain is the principal symptom. In about two-thirds of the patients it occurs at rest and may be troublesome at night (due to increased intraosseous pressure). It is well established that once radiographic changes occur in osteonecrosis the natural history is generally subchondral bone collapse and severe disability. The Arlet and Ficat classification of osteonecrosis is based on the plain radiographic appearance (Ficat and Arlet 1980), as follows:

Stage I: normal appearance;

Stage II: early changes consisting of diffuse osteoporosis, sclerosis, and cyst formation producing a mottled appearance (Fig. 4(a));

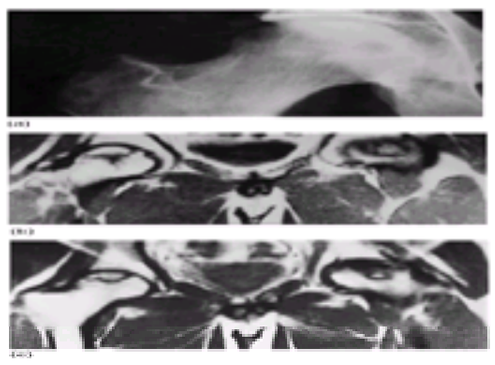

Fig. 4 (a) Early changes of osteonecrosis of the femoral head shown on plain radiograph (Arlet and Ficat stage II). (b) MRI clearly detects osteonecrosis at an early stage in T_1-weighted and (c) T_2-weighted images. (By courtesy of Dr P. Renton, University College London.)

Stage III: subchondral bone collapse (crescent sign) with normal joint space;

Stage IV: abnormal contour of bone with joint-space loss.

This has been extended by Steinberg *et al*. to provide a more sensitive method of following the progress of osteonecrosis in the femoral and humeral heads (Steinberg *et al*. 1984).

In early stages the plain radiograph is normal. The imaging technique currently combining the greatest sensitivity and specificity for the diagnosis of early cases is MRI (Zizic 1990) (Fig. 4(b) and (c)). The presence of a low intensity band on T_1-weighted images is an early specific finding of osteonecrosis and MRI has the advantage of identifying early changes in necrotic bone marrow before other changes in bone have taken place (Halland *et al*. 1993; Sugano *et al*. 1994). If MRI is not available, an isotope bone scan with $^{99}Tc^{m}$ diphosphonate is indicated (Tawn and Watt 1989). This is also helpful in early diagnosis but it is less specific, anatomical resolution is often poor, and false negatives commonly occur, especially when there is bilateral disease. Other methods used for early diagnosis have included CT with multiplanar reconstruction (Sartoris *et al*. 1986). This is reported to be more sensitive than bone scan but the significant radiation exposure makes MRI a more attractive option. Measurement of intramedullary bone pressure and intraosseus venography proposed by Zizic *et al*. is probably also redundant as a routine procedure since the advent of MRI (Zizic *et al*. 1986). However, bone biopsy of the affected site is sometimes necessary, as local infection can be associated with osteonecrosis (Habermann and Friedenthal 1978).

Osteonecrosis at specific sites

Vertebral

This is uncommon but compared with compression fractures of osteoporosis is more often associated with neurological complications (Feldmann *et al*. 1988). This mainly happens in elderly people; the lesions are usually single, and at the thoracolumbar junction. It is not usually associated with malignancy and MRI is helpful in early diagnosis. The intravertebral vacuum cleft is the characteristic feature on the plain radiography.

Keinbock's disease

This describes osteonecrosis of the lunate. It may occur after a fracture but in most cases there is no specific history of this. Often it happens in the dominant hand and is thought to be the result of chronic repetitive trauma. It is associated with a short ulna, which probably reinforces the effects of repeated trauma.

Preiser's disease

This is spontaneous osteonecrosis of the scaphoid, usually affecting the proximal pole. Involvement of the scaphoid is usually post-traumatic and in idiopathic cases the trauma may have been minor and unrecognized.

Hegemann's disease

This describes osteonecrosis of the humeral trochlear. This is rare and happens mainly in preadolescent and adolescent boys, who present with a swollen elbow; this has reduced movement but is not particularly painful. Usually it resolves spontaneously.

Legg–Perthes' disease

This is osteonecrosis of the femoral head, which occurs in children between the age of 4 and 12 years and affects one or both hips. The aetiology is unknown but the condition is associated with increased intraosseous pressure and venous hypertension (Liu and Ho 1991). There may be spontaneous resolution, especially in younger patients, in whom conservative management is indicated.

Osteonecrosis of the femoral condyle

This occurs spontaneously in older people, predominantly affecting the medial condyle.

Kohler's disease

This is the rare involvement of the tarsal navicular, which primarily occurs in male children between the ages of 4 and 10 years. It is usually self-limiting.

Freiberg's disease

This is osteonecrosis of the metatarsal head, usually the second. It mainly affects adolescent females and is usually self-limiting.

Treatment

Advanced osteonecrosis of weight-bearing surfaces, such as the femoral head, leads to secondary osteoarthritis and severe disability. Total joint replacement may be the only solution in such cases. The results are satisfactory, giving a long period of good function. However, one still hesitates to recommend total joint replacement in young people and the failure rate may be higher in operations for osteonecrosis, especially when associated with corticosteroids, than in arthroplasties for other conditions (Cornell *et al*. 1985). Attempts have therefore been made to treat the condition at an earlier stage in order to preserve the integrity of affected bone.

Osteonecrosis of the femoral condyle in elderly people can often be treated conservatively with initial limitation of weight-bearing, non-steroidal anti-inflammatory drugs, hydrotherapy, and muscle strengthening exercises (Motohashi *et al*. 1991).

There is little evidence from retrospective studies that bed rest, modified weight bearing, analgesics, or non-steroidal anti-inflammatory drugs are of much benefit in other cases, at least for osteonecrosis of the hip in adults. Because increased intraosseous pressure is a common feature in early stages, core decompression has been recommended. Encouraging results with prevention of progression in early stages of osteonecrosis of the hip (Hungerford 1989) and the shoulder (Mont *et al*. 1993) have been reported by some groups. However, this is a controversial topic and not all studies have been so encouraging (Learmonth *et al*. 1990). The use of MRI to assess the extent of osteonecrosis may be a way of selecting those most likely to respond to this procedure (Holman *et al*. 1995).

Other ways of preserving the femoral head include bone grafting using a variety of procedures (Rosenwasser *et al*. 1994; Urbaniak *et al*. 1995), the use of electrical stimulation, and sometimes a combination of these (Steinberg *et al*. 1985). In addition, various techniques of osteotomy, such as the transtrochanteric osteotomy of the femoral head, have been used to alter the weight-bearing surface away from the involved area. These techniques are still being refined and evaluated.

Osteochondritis dissecans

Osteochondritis dissecans is usually a solitary lesion of the medial femoral condyle in which a fragment composed of articular cartilage and subchondral bone becomes demarcated from the surrounding bone and cartilage and may form an intra-articular loose body (Green and Banks 1990). Occasionally, it may involve the elbow, hip, and talus. The aetiology is unknown but anomalies of ossification and low-grade trauma appear to be important.

It predominantly affects adolescent males and should be suspected in a child or teenager who, after minor trauma, develops a relatively sudden onset of knee pain followed by mechanical dysfunction. There may be a hereditary component and familial occurrence has been reported (Paes 1989). This is characterized by multiple articular lesions, particularly affecting the hips and knees, and an autosomal dominant inheritance. Sometimes there is associated dwarfism and a generalized epiphyseal abnormality.

Symptoms are mainly pain, reduced joint movement, effusion, and limp. A plain radiograph shows a well-circumscribed, sclerotic lesion demarcated by a radiolucent line from surrounding bone (Fig. 5).

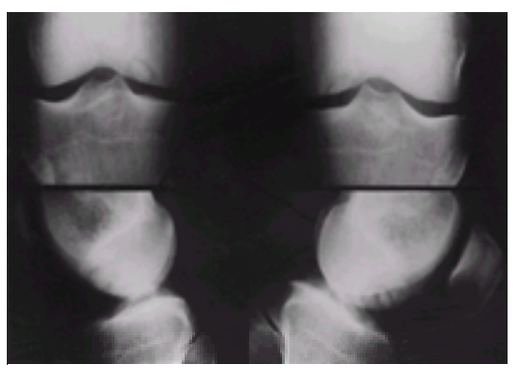

Fig. 5 Anteroposterior and lateral views showing typical lesions of osteochondritis dissecans in both medial femoral condyles. A radiolucent line separates the oval-shaped, *in situ* body from the femoral condyle. (By courtesy of Dr P. Renton, University College London.)

In young patients before skeletal maturity there is a good chance of healing, and treatment is consequently conservative. Once the epiphyses have closed, osteochondritis dissecans is more likely to cause intra-articular loose bodies and subsequent symptoms of internal derangement, and eventually secondary osteoarthritis. Arthroscopy can be helpful in assessing the extent of the lesion. A variety of surgical procedures have been recommended, from drilling of the lesion to promote ingrowth of fibrocartilage to replacement of a large deficit with an osteochondral allograft.

Relapsing polychondritis

This is an uncommon, multisystem disorder of unknown aetiology characterized by episodic and sometimes progressive inflammation of cartilaginous structures and tissues rich in glycosoaminoglycans. The characteristic clinical syndrome, with involvement of the pinna of the ears, nose, larynx and upper airways, joints, heart, blood vessels, inner ear, cornea, and sclera, was first described by Jaksch-Wartenhorse (Jaksch-Wartenhorse 1923). In about 30 per cent of cases it is associated with other systemic rheumatic or autoimmune diseases such as rheumatoid arthritis, systemic lupus, Sjögren's syndrome, thyroiditis, ulcerative colitis, psoriasis, and Behçet's syndrome (Kitridou *et al*. 1987; Tishler *et al*. 1987; Orme *et al*. 1990; Harisdangkul and Johnson 1994).

Aetiology and pathogenesis

The most specific lesion is inflammation of cartilage. This leads to cartilage destruction and fibrosis. The lesion is characterized by a dense inflammatory infiltrate of neutrophils, lymphocytes, macrophages, and plasma cells. Initially this involves the perichondral region. There is loss of proteoglycans, destruction of the collagen matrix, and chondrocyte death. Destroyed cartilage is replaced by granulation tissue and there is subsequent fibrosis (Fig. 6). Cartilage matrix proteins, such as cartilage oligomeric matrix protein (COMP), are released and raised levels are present during disease activity (Saxne and Heinegard 1995).

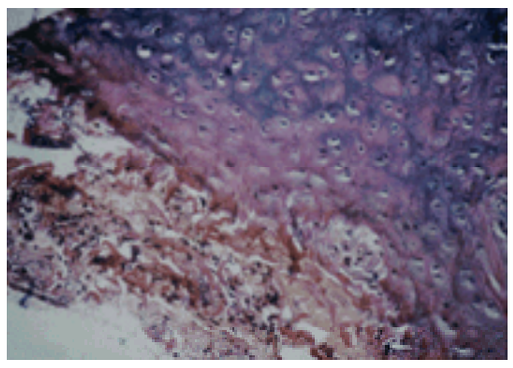

Fig. 6 Acute inflammation of the perichondral region of the external ear with infiltration of neutrophils, mononuclear cells, and plasma cells with destruction of underlying cartilage (haematoxylin and eosin). (By courtesy of Dr A. Balsa, La Paz Hospital, Madrid.)

The cause is unknown but, on the basis of circumstantial evidence, it is thought that there is an immunological pathogenesis. Components of cartilage, such as

collagen, elastin and proteoglycan, express multiple antigenic determinants but these are normally sequestered from the immune system. A breach of the integrity of cartilaginous structures could potentially stimulate an immune response to these constituents. The ubiquitous nature of matrix components such as elastin and proteoglycans could explain the pattern of involvement, which includes respiratory tract cartilage, structures of the eye, and the cardiovascular system.

Antibodies, predominantly IgG, which react specifically with collagens type II, IX, and XI (forming the major fibrillar scaffold in cartilage), can be detected in some but not all patients with relapsing polychondritis (Yang *et al*. 1993). The highest titres are found in the early phase of the disease and the titre may relate to disease activity (Ebringer *et al*. 1981). These antibodies are not disease specific and occur, for example, in rheumatoid arthritis, although possibly they are directed to different epitopes on the collagen molecule (Terato *et al*. 1990). The possibility that humoral factors are involved in the pathogenesis is suggested by the report of polychondritis occurring in the newborn infant of an affected mother and the subsequent recovery of the baby (Arundell and Haserick 1960). Granular deposits of immunoglobulin and complement have been observed at the chondrofibral junction in biopsies from affected ears (Valenzuela *et al*. 1980), suggesting the involvement of immune complexes. Collections of fluid in the middle ear have been reported to be hypocomplementaemic, suggesting complement consumption (McKenna *et al*. 1976). Thus, there is evidence for humoral immune mechanisms being involved in cartilage injury. In addition, earlier reports of cellular immune reactions to proteoglycan and other matrix components (Herman and Dennis 1973) have been supported by the more recent demonstration of cell-mediated immunity to collagens type II, IX, and XI paralleling the humoral response to these structural proteins (Alsalameh *et al*. 1993).

A significant increase in DR4 antigen frequency has been found (Lang *et al*. 1993) but, in contrast to rheumatoid arthritis, there is no predominance of any DR4 subtype.

Clinical features

The disease predominantly affects middle-aged white subjects, with a peak incidence in the fourth to fifth decades, although it has been reported in all races and age groups. The patient typically presents with recurrent swelling and pain of the external ear and/or nose, or with uveitis, or with an arthropathy. The cumulative involvement of various organ systems is summarized in Table 1.

Organ	Percentage involvement
External ear	85
Arthritis	75
Nose	50
Eye	50
Respiratory tract	50
Internal ear	40
Skin	25
Kidney	20
Heart	10
Blood vessels	8
Central nervous system	Rare

Table 1 Extent of organ involvement in relapsing polychondritis

Episodes of inflammation of the cartilaginous portion of one or both ears and the nose are often sudden and last several days. Repeated episodes of protracted inflammation, leading to cartilage destruction, produce deformity such as saddle nose (Fig. 7(a) and Fig. 7 (b)).

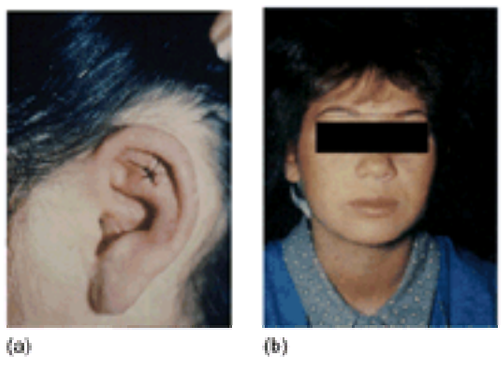

Fig. 7 Clinical features of relapsing polychondritis. (a) Acute inflammation of the external ear. (b) Saddle nose deformity. (By courtesy of Dr A. Balsa, La Paz Hospital, Madrid.)

Joint involvement is also common and occurs independently of other manifestations. The typical clinical picture is episodic, asymmetrical inflammation of both large and small joints, including the parasternal and sacroiliac joints, lasting several days to weeks. Generally it is non-deforming, non-erosive, and seronegative for rheumatoid factor (O'Hanlan *et al*. 1976; Balsa *et al*. 1995). Radiographs have demonstrated narrowing of the joint space without erosion, presumably reflecting the pathological process of loss of hyaline cartilage only (Booth *et al*. 1989). Aspirated synovial fluid is non-inflammatory. Mitchell and Shepard reported that, in addition to non-specific proliferation of lining cells, a unique feature was the presence in the middle and deeper layers of the synovium of large, clear spaces with projecting multinucleate bodies surrounding chondrocytes (Mitchell and Shepard 1972). In contrast to the 'pure' polyarthritis of relapsing polychondritis, the condition can develop against the background of a well-defined, erosive polyarthritis such as rheumatoid arthritis.

A wide range of rather non-specific ocular manifestations occur in relapsing polychondritis. The most common is episcleritis but more severe involvement includes scleritis and peripheral corneal thinning, both of which can lead to perforation, uveitis, retinal vasculitis, and optic neuritis, any of which can lead to blindness (Hoang-Xuan *et al*. 1989). Also reported are palsy of ocular muscles, orbital inflammation, and papilloedema.

The disease affects the respiratory tract in at least one-half of the patients. This can lead to the breakdown of tracheal and bronchial cartilage, with resulting airway collapse during the respiratory cycle (Crockford and Kerr 1988). The larynx and upper trachea are frequently involved first, and symmetrical subglottic narrowing is a common finding. Eventually the process can involve the distal trachea and main bronchi. Symptoms of respiratory tract involvement include dysphonia, cough, stridor, and dyspnoea; this involvement can dominate the clinical picture. During the active phase there may be tenderness over the thyroid cartilage and trachea. Young patients presenting with involvement of the upper respiratory tract early in the course of the disease tend to be rather resistant to treatment and have a poor prognosis (Neilly *et al*. 1985).

Involvement of the inner ear tends to occur later in the course of the disease and leads to vestibular and auditory dysfunction. A wide range of non-specific skin lesions has been reported, including erythema nodosum and leucocytoclastic vasculitis. The MAGIC (mouth and genital ulcers with inflamed cartilage) syndrome describes an overlap with Behçet's syndrome characterized by prominent orogenital ulceration (Orme *et al*. 1990). Renal manifestations have been reported in as many as 20 per cent of cases (Chang-Miller *et al*. 1987). On renal biopsy the predominant lesions are reported to be mesangial proliferation and segmental, necrotizing glomerulonephritis with crescents. Immunofluorescence and electron-microscopic studies show faint deposition of immunoglobulin and complement, and small amounts of electron-dense deposits, respectively, mainly in the mesangium. Patients with renal involvement tend to have more severe disease with extrarenal vasculitis and worse prognosis.

The heart is involved in about 10 per cent of patients. Aortic incompetence, either from dilatation of the aortic root or valvular destruction, is the most common manifestation. It is often severe, progressing even when other aspects of the disease are in remission (Buckley and Ades 1992), and requires valve replacement in at

least a third (Manna *et al*. 1985). Even when valve replacement is successful, there is the possibility of future dehiscence of the prosthetic valve because of continuing inflammation of perivalvular tissues (Lang-Lazdunski *et al*. 1995). Other cardiovascular manifestations include pericarditis, myocarditis, heart block, coronary vasculitis leading to myocardial infarction, and aneurysms of the aorta and other large arteries. Vasculitis involving large and medium-sized arteries may occur independently of cardiac involvement and often carries a poor prognosis. Meningioencephalitis has been reported in association with polychondritis but central nervous system involvement is rare (Hanslik *et al*. 1994)

Laboratory abnormalities are non-specific and for the most part reflect chronic inflammation. Common features are an acute-phase response, anaemia of chronic disease, and thrombocytosis. There may be a moderate leucocytosis. The development of a myelodysplastic syndrome has been reported (Diebold *et al*. 1995). Serological tests demonstrate anti-type II collagen antibodies in up to one-half of patients, circulating immune complexes in the majority, and antinuclear antibodies in approximately 20 per cent. ANCA have been reported in 24 per cent of patients with polychondritis, mainly during the acute phase of the disease, and in some patients in association with vasculitis (Papo *et al*. 1993; Handrock and Gross 1993). Various imaging techniques are useful for assessing complications of the disease. For example plain radiographs of the respiratory tract should include a soft tissue exposure of the neck in the lateral projection to demonstrate the larynx and upper trachea, together with penetrated frontal views of the trachea and major bronchi in the chest (Crockford and Kerr 1988). CT scanning is an accurate method for assessing the upper and lower airways (Mendelson *et al*. 1985; Davis *et al*. 1989) (Fig. 8). The value of MRI in assessing disease involvement, especially of the upper respiratory tract, is also reported (Fornadely *et al*. 1995).

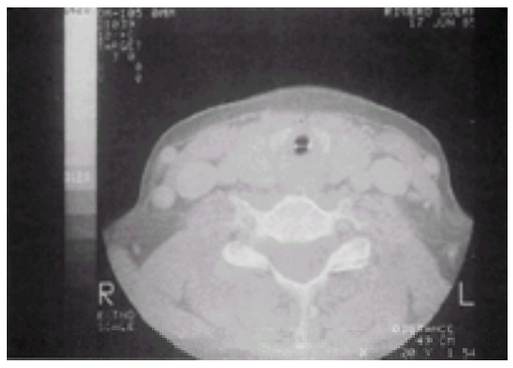

Fig. 8 A CT scan showing cartilage destruction and marked narrowing of the trachea. (By courtesy of Dr A. Balsa, La Paz Hospital, Madrid.)

The clinical course of this disease is highly variable. It is probable that the literature emphasizes the worst end of the spectrum and that many milder cases go unrecognized. It has been suggested that the 5-year and 10-year survival after diagnosis are 74 and 55 per cent (Michet *et al*. 1986). The most common causes of death are infection, cardiac and respiratory involvement, and systemic vasculitis.

Diagnosis

Early diagnosis is important in an attempt to prevent potentially life-threatening complications. There are no universally accepted diagnostic criteria but McAdam *et al*. proposed that the presence of three of the six following clinical features should be diagnostic (McAdam *et al*. 1976):

1. recurrent chondritis of both auricles;
2. non-erosive polyarthritis;
3. chondritis of the nasal cartilage;
4. ocular inflammation including conjunctivitis, keratitis, scleritis/episcleritis, uveitis;
5. involvement of laryngeal and/or tracheal cartilage;
6. cochlear and/or vestibular involvement.

These were modified slightly by Damiani and Levine (Damiani and Levine 1979) to include:

1. three or more of the above criteria;
2. at least one clinical criterion plus histological confirmation;
3. chondritis in two or more separate anatomical locations with a response to treatment.

Treatment

The rarity of relapsing polychondritis, the diversity of its presentation, and the unpredictability of recurrences make it difficult to recommend a particular treatment protocol. There are no controlled trials therefore the following is based on anecdotal experience.

Mild symptoms of joint involvement and inflammation of ear and nose cartilages can sometimes be controlled by non-steroidal anti-inflammatory drugs alone. Dapsone has been reported to be effective for systemic manifestations not controlled with symptomatic treatment alone (Barranco *et al*. 1976). Corticosteroids can be effective in suppressing acute, severe manifestations. High doses (at least 1 mg/kg per day of prednisolone or equivalent) are required. Alternate-day regimens are not recommended but there are reports of bolus parenteral methylprednisolone being effective for manifestations such as acute airways' obstruction (Lipnick and Fink 1991). It appears that corticosteroids are more effective in treating disease in cartilage of the respiratory tract than, for example, involvement of the joints and eyes. Also, there is no evidence that corticosteroids influence long-term outcome, and in some patients the disease undoubtedly progresses despite giving corticosteroids (Kilman 1978).

In severe cases, the addition of an immunosuppressive agent is required to control disease activity and to be steroid sparing. Successful responses have been reported using agents such as azathioprine and cyclophosphamide. The latter is the drug of choice for features such as necrotizing scleritis and systemic vasculitis. In refractory cases there have been anecdotal reports of success with cyclosporin A (Svenson *et al*. 1984) and monoclonal antibodies to CD4 (Van der Lubbe *et al*. 1991).

Additional supportive measures may be needed for those with severe respiratory, cardiac, and renal complications. For example whereas only 14 per cent of patients with this disease present initially with respiratory tract involvement, 80 per cent of these will require tracheostomy. Initially, this is usually for glottic, laryngeal, and subglottic inflammation and oedema producing airways' obstruction (McAdam *et al*. 1976). Later, the indication for tracheostomy is often the collapse of laryngeal or tracheal cartilages. The recent introduction of expandable metal stents represents an important development in managing patients with major airway stenosis and collapse (Shah *et al*. 1995).

5.17.4 Diseases of bone and cartilage in children

Barbara M. Ansell

The developmental skeletal disorders are difficult to classify and depend largely on radiological examination (Poznanski 1974; Wynne-Davies *et al*. 1985; Spranger 1992). Their importance lies in that they can present with musculoskeletal pain, alterations in joint movement and growth disturbances, so it is necessary for paediatricians and rheumatologists to be able to recognize such conditions.

The osteochondrodysplasias

There are more than 160 osteochondrodysplasias, divided into three groups: (i) defects of tubular and flat bone, (ii) disorganized development of cartilagenous and fibrous components of the skeleton, and (iii) idiopathic osteolyses. Features of some of the more common ones which give rise to problems follow.

Achondroplasia

This is the most common form of short-limbed dwarfism. Although inherited as an autosomal dominant trait, many cases represent new mutations. Arms and legs are short and such children usually have hypotonia, and with the head normal in size, may have difficulty in supporting it. There is an increased lumbar lordosis; spinal stenosis may result in neurological complications in adolescence or adult life. Hypochondroplasia resembles achondroplasia but lacks the facial characteristics.

Diatrophic dwarfism

This is characterized not only by short stature but also by cleft palate, thickening of the ear pinnas, severe club feet and thumb deformation, as well as joint dysplasia and scoliosis. It is thought to be inherited as an autosomal recessive trait.

Metatrophic dysplasias

In this, not only are short limbs present at birth and increasing loss of joint mobility, but there is also a kyphoscoliosis which is severe and progressive and cord compression is not uncommon. This disorder is an autosomal dominant one.

Epiphyseal dysplasias

Multiple epiphyseal dysplasia

One of the most common skeletal dysplasias which is inherited as an autosomal dominant trait (Maudsley 1955; Amir *et al*. 1985). It presents in childhood with pain and stiffness in affected limbs and is characterized by shortening and contractures and occasionally scoliosis. It can easily be confused with chronic arthritis (Patroni and Kredich 1985), but absence of inflammatory signs is important in its differentiation. Radiologically there are progressive irregularities of the end plates of the mid-thoracic vertebral bodies, short metacarpals and terminal phalanges and flattening, sclerosis, and fragmentation of the epiphyses of the hips, (Fig. 1) knees and other joints.

Fig. 1 A 10-year-old boy presenting with recurrent hip problems over 1 year; he had mild epiphyseal dysplasia, but fragmentation of the femoral heads is obvious.

Spondyloepiphyseal dysplasia

This is characterized by short stature with a disproportionately short trunk. Epiphyses of the hips and shoulders are the most severely affected early, and there may be platyspondyly.

Three forms are presently recognized—congenita, pseudoachondroplasia and tarda. The congenita form is inherited as an autosomal dominant; it is present at birth and is associated with myopia and retinal detachment (Anderson *et al*. 1990a). The pseudoachondroplasia may be inherited as an autosomal dominant or recessive and presents in early childhood (Hall *et al*. 1987). The patient's stature is short but with a normal face. There is marked irregularity of the epiphyses of the long bones which are late in maturing, and progressive scoliosis (Maroteaux *et al*. 1980). The tarda form may be inherited as an X-linked recessive (Iceton and Horne 1986) or be dominant, but it can be seen as a new mutation in two or three sibs (Szpiro-Tapio *et al*. 1988). There is little difference between these forms clinically as most look the same, however radiological changes may differ and a tentative classification has been suggested by Maroteaux and Spranger (1991).

There are a growing number of mutations in the gene for type II collagen (Col 2 A1), which include point mutations, deletions, insertions and splicing defects (Williams *et al*. 1993; Reginato *et al*. 1994). Unrelated families have been reported with Ang ^{75}Cys or Ang^{519}Cys mutation (Williams *et al*. 1993). Late-onset spondyloepiphyseal dysplasia is associated with precocious osteoarthritis, but in tall patients, has also been shown to be associated with type II procollagen gene (Col 2 A1) mutation in exon 11; recurrent mutations at a few specific sites of Col 2 A1 suggest there may be susceptibility 'hot spots' (Bleasel *et al*. 1995). However, not all cases are associated with primary defects of type II collagen (Anderson *et al*. 1990b).

Late-onset spondoepiphyseal dysplasia usually presents between the age of 3 and 10 years, but can be later, with pain in the knees and fingers followed by deformity and can simulate juvenile arthritis (Lewkonia and Beck-Hansen 1992); such children are noted to tire easily on activity and from an early age tend to find stairs difficult, presumably due to the poor development of the hips (Fig. 2). From time to time there may be acute episodes of pain, sometimes associated with swelling. It is not uncommon to have a family history of 'similar arthritis'. Clinically such children are usually of short stature; initially there is a suggestion of bony enlargement of the finger joints which becomes more obvious as deformity progresses (Fig. 3). This is followed by enlargement of the knee joints, particularly the patellas, with gradual loss of function of knees and hips (Wynne-Davies *et al*. 1982). All the acute phase reactants are normal as is the blood count, there are no immune complexes present; rheumatoid factor, antinuclear antibodies (ANA) and DNA, are negative. Radiological changes are characteristic and diagnostic (Fig. 4 and Fig. 5). Spranger (1983) described this condition as a progressive 'pseudojuvenile rheumatoid arthritis'. Pseudogout has also been noted (Bradley 1987). Spinal stenosis as a sequel is not uncommon, while total replacement arthroplasty of the hips for secondary degenerative changes may be required at an early age (Fig. 6). Hypoplasia of the odontoid process can also predispose the patient to cervical cord injury as a result of minor trauma.

Fig. 2 This girl was described as normal at birth, but at about the age of 3 was noticed to have difficulty climbing up and down stairs; the hip radiographs revealed these poorly developed acetabula and persistence of anteversion of the hips: shortly after this, hand function became impaired and she was diagnosed as spondyloepiphyseal dysplasia.

Fig. 3 This shows the clinical appearance of the hands in another case of spondyloepiphyseal dysplasia commencing at the age of 4. By the age of 12, there is obvious bony enlargement of the proximal interphalangeal joints associated with some loss of movement and slight bony enlargement at terminal interphalangeal joints.

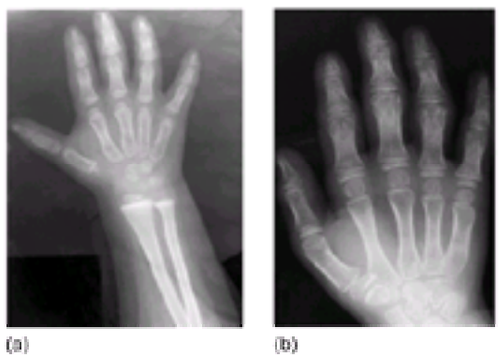

Fig. 4 (a) The initial hand radiograph of the patient in Fig. 2 was regarded as normal, although bony changes are starting in the phalanges. By the time bony enlargement was obvious (b) the radiograph shows marked widening of the phalanges at the proximal and distal interphalangeal joints, as well as alteration in texture and epiphyseal changes.

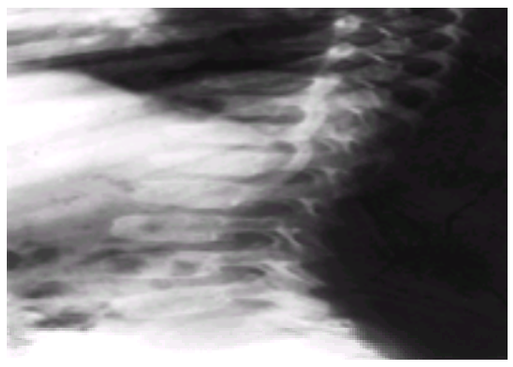

Fig. 5 Lateral radiograph of the spine of a 6-year-old presenting with lumbar lordosis, difficulty in using the hands and limited walking ability. Note the characteristic beaking in vertebral bodies, particularly in the lower thoracic spine, in this child with spondyloepiphyseal dysplasia, which had also affected his father.

Fig. 6 The shape of the femoral heads, and the avascular necrosis and secondary degenerative changes that have occurred by 16 years of age in the patient illustrated in Fig. 2; this was just prior to bilateral total replacement arthroplasties.

Cartilage–hair hypoplasia

This is inherited as an autosomal recessive trait and can usually be diagnosed at birth as these children have achondroplastic features, the hands are short and fat, there is hyperextensibility of the joints with the exception of the elbows and the hair is fine and sparse. Radiographs show widened metaphyses with scalloping, irregular sclerosis and cystic defects (McKusick 1964). These children tend to have a T-cell immunodeficiency which predisposes them to infection (Harris *et al*. 1981; Polmar and Pierce 1986).

Dyggve–Melchior–Clausen syndrome

This appears late in an initially normal child and manifests as dwarfism, claw hands, sternal problems, lumbar lordosis and progressive mental retardation (Dyggve *et al*. 1962; Beighton 1990). Clinically it mimics Morquio's disease, but in addition there is mental retardation. This condition is probably heterogeneous since both autosomal recessive and X-linked recessive forms have been described.

Acro/acromesomelic dysplasia

Trichorhinophalangeal dysplasia

This is characterized by enlargement of the interphalangeal joints in particular (Fig. 7) which may cause confusion with juvenile chronic arthritis (Noltorp *et al*. 1986). Clinically the bulbous nose with hyperplastic nares, large ears, short brittle hair and short stature suggest the correct diagnosis (Gieodron *et al*. 1973). All acute phase reactants are normal and radiographs show cone-shaped epiphyses with short metacarpals and metatarsals and there may be fragmentation of femoral epiphyses. Many families have shown autosomal dominant inheritance. The chromosome 8q deletion is subtle in that only the very narrow 9-positive band 24.12 is missing (Fryns and Van den Berghe 1986; Bühler *et al*. 1987). There are considerable similarities to the Langer–Gieodron syndrome (TRP II) in which exostoses occur as well as mental retardation and in these children 8q 24.13 is deleted as well.

Fig. 7 Trichorhinophalangeal dysplasia; note the bony enlargement of proximal interphalangeal joints together with facies. (By courtesy of Dr Alan Craft, Newcastle.)

Storage diseases

The deficiency of a lysosomal degradative enzyme causes an accumulation of its substrate within the lysosomes of the cell; the tissue distribution of the enzyme deficiency determines its expression. Classification is still not entirely satisfactory.

Mucopolysaccharidoses

These are due to deficiency of enzymes involved in the metabolism of glycosaminoglycans (Table 1) (Beck *et al*. 1986; Whitley 1993). All are autosomal recessive disorders (Stanbury *et al*. 1989). A prominent feature is a progressive skeletal dysplasia affecting particularly the hands, hips and vertebrae. It is important to be aware that all these syndromes can present as joint problems, and the first clue to diagnosis may be a claw hand (Fisher *et al*. 1974), but other problems include stiffness of the shoulders, general stiffening and clumsiness in using joints and occasionally dislocation of the hips. In the more severe types such as Hurler's syndrome, there is a gradual coarsening of the facial features associated with dwarfism, mental retardation and clouding of the cornea. There is no difficulty in diagnosis when the fully developed features of Hurler's syndrome are present, but it may take up to 2 years for these to become obvious; flexion deformities of the fingers allow suspicion early, so that prenatal diagnosis of future sibs can be made.

Type		Urinary excretion	Enzyme deficiency	Gene	Locus
I	Hurler	Dermatan sulphate Heparan sulphate	α-L-Iduronidase	4p	16.3
I	Scheie	Dermatan sulphate	α-L-Iduronidase		
I	Hurler/Scheie	Dermatan sulphate Heparan sulphate			
II	Hunter	Dermatan sulphate Heparan sulphate	Iduronate-, sulphatase	Xq	27.3
II	Hunter/Scheie	Dermatan sulphate Heparan sulphate			
III	Sanfilippo A	Heparan sulphate	Heparan		
	B		α-(N-Acetyl)glucosaminidase		
	C	Heparan sulphate	Acetyl-CoA- α-glucosaminide		
	D	Heparan sulphate	N-Acetyl-glucosamine-6-sulphatase	12q	14
IV	Morquio-Brailsford A	Keratan sulphate Chondroitin-6 sulphate	Galactose-6-sulphatase		
	B		β-Galactosidase		
VI	Maroteaux-Lamy	Dermatan sulphate	N-Acetyl-galactosamine-4-sulphatase		
VII	Sly	Dermatan sulphate Heparan sulphate Chondroitin sulphate	β-Glucuronidase		

Table 1 Mucopolysaccharidoses

The two conditions that warrant special mention are Scheie and the Morquio–Brailsford syndrome, as these children are of normal intelligence and develop symptoms after the age of 2 or 3 years. In Scheie syndrome, where the disease is caused by a deficiency of the enzyme a-L-iduronidase (Scott *et al*. 1990), the stature is well preserved, but there is progressive stiffening of the joints of the hands (Fig. 8), elbows and knees without swelling and pain and with no evidence of inflammatory indices. Urinary excretion of dermatan sulphate is increased. Clouding of the cornea may mimic iridocyclitis. Later carpal tunnel compression and atlantoaxial subluxation can cause problems; cardiac difficulties involving the aortic and mitral valves are also seen (Butman *et al*. 1989).

Fig. 8 Hands of child with Hunter–Scheie syndrome which had progressively stiffened from the age of 1 year.

A phenotype described by Roubicek *et al*. (1985), intermediate between Hurler and Scheie, has the coarse facial features and corneal clouding, skeletal changes are mild to severe, but mental retardation is mild.

In the Hunter–Scheie syndrome, stiffening of the shoulders associated with some degree of dwarfism occurs early as well as moderate skeletal involvement, but intellectual impairment of varying degree does not develop until later.

In the Morquio–Brailsford syndrome, two different enzyme deficiencies have been noted (Table 1), but symptoms and signs are similar. There is progressive musculoskeletal stiffening which usually begins about the age of 3 or 4 years and is associated with dwarfing. The hands tend to enlarge, valgus deformity of the knees gradually develops and the gait becomes stiff and waddling with some kyphosis and protrusion of the sternum. Initially as the joints enlarge they are hypermobile, but later become stiff. Characteristic radiological findings include platyspondyly and odontoid hypoplasia, and dysplastic hips with poorly developed acetabula. Radiologically they are distinct from the various forms of spondyloepiphyseal dysplasia. Progressive cervical spinal cord damage can occur (Lipson 1977). Clouding of the cornea is mild initially, but deafness may be an early problem. Rarely echocardiographic changes occur and aortic regurgitation develops in a proportion (John *et al*. 1990).

All these children need, not only to be protected against unnecessary therapy with long-acting drugs such as gold, penicillamine, or methotrexate, but also to be watched for complications such as carpal tunnel compression (Wraith and Alani 1990), atlantoaxial subluxation (Lipson 1977), and spinal cord compression (Blaw and Langer 1969).

Mucolipidoses

The term mucolipidosis is applied to a group of disorders that are characterized by the intracellular accumulation of both glycosaminoglycans and sphingolipids, but without excess urinary excretion of glycosaminoglycans. Progressive ocular and neurological abnormalities are common to all these disorders, which are autosomal recessive.

Mucolipidosis type I

Isolated neuraminidase deficiency (sialidase) produces a Hurler-like syndrome. The urinary excretion of sialated urinary oligosaccharides is markedly elevated.

Mucolipdosis type II

Sometimes called 'I cell disease', also causes a Hurler-like syndrome with progressive loss of joint movement. There are prominent intracytoplasmic (I) inclusions in lymphocytes and skin fibroblasts. Biochemically there is a deficiency of Glc- *N*-acetylglucosaminyl-phosphotransferase in fibroblasts and leucocytes (Cipolloni *et al*. 1980).

Mucolipidosis type III

This is sometimes known as pseudo-Hurler polydystrophy and is characterized by restriction of joint mobility, which does not become apparent until the second or third year of life. Such patients have presented to us as juvenile arthritis starting with difficulty in raising the shoulders (Fig. 9) and problems with grip (Fig. 10), and atypical carpal tunnel syndrome (Starreveld 1975), or with thickening in the hands and some tightening of the skin mimicking scleroderma. No inflammatory arthritis is present and routine blood tests are all normal. Mentality may be normal or slightly below standard. Radiographic findings are those of a dysotosis multiplex. The condition tends to stabilize in the teens. Ocular features include cloudy cornea, astigmatism, abnormalities of the retina and optic nerve, and visual field defects (Traboulsi and Maumence 1986). Aortic incompetence is not uncommon. The basic defect is in the enzyme that specifically phosphorylates mannose residues of lysosomal glycoproteins. Characteristic inclusions are found in cultured fibroblasts.

Fig. 9 This boy, who proved to have mucolipidosis type III, presented with difficulty in using his hands; he was found to have very limited shoulder movement, contractures at the elbow and the beginning of contractures at the knees, hips and feet.

Fig. 10 Hands of the child from Fig. 9; note the inability to pinch with finger and thumb, and the thickening of the tissues due to deposition.

Sphingolipidoses

Here there is an accumulation of lipid in the cell as a result of specific enzyme deficiencies; only three of the many different sphingolipidoses have musculoskeletal signs and symptoms, notably Farber's lipogranulomatosis, Gaucher's disease, and Fabry's disease.

Farber's lipogranulamatosis

This is due to deficiency of acid ceramidase and is an autosomal recessive sphingolipidosis. Usually it begins in the neonatal period with a hoarse cry and irritability. Painful red masses develop along tendon sheaths and around joints, followed by the development of contractures. Delayed motor development and mental retardation are prominent. Epiglottal and laryngeal swelling cause repeated pulmonary infections, usually leading to death early in life. It has been suggested that there are milder types of this defect, and recent descriptions of older children presenting with joint deformity and some mental retardation are appearing (Jameson *et al.* 1987). These may confuse the rheumatologist.

Gaucher's disease

This results from a deficiency in the enzyme acid glucosidase and is characterized by an accumulation of glucosyl ceramide in reticuloendothelial cells in the bone marrow, spleen, liver, lymph nodes and other internal organs. Three clinical forms are now recognized. The most common, type 1, is the chronic non-neuropathic adult form, more prevalent in Ashkenazi Jews. Type 2 is the infantile or active neuropathic form, and death occurs before the age of 2 years. Type 3 is the juvenile or subacute neuropathic form, which occurs particularly among the Swedish, and is thought to be caused by a single mutation in exon 10 of the glucocerebrosidase gene (Dahl *et al*. 1990). Osteoarticular complaints are an important feature, particularly in type 3, where they may be the earliest manifestation of the disease and result from infiltration of the marrow of the subchondral bone. A common complaint is polyarthralgia affecting the large peripheral joints, pathological fracture of a long bone or compression of a vertebra which gives rise to pain. Severe degenerative hip disease as a result of avascular necrosis and collapse of the femoral head is not uncommon. The most frequent early radiological finding is widening of the distal portion of the femur just above the medial condyle, the Erlenmeyer flask deformity. Similar flaring may be present in the tibia and humerus (Peters *et al*. 1977; Stowens *et al*. 1985).

Fabry's disease (angiokeratoma corporis diffusum)

This is an X-linked recessive disorder characterized by the progressive accumulation of birefringent deposits of triglycosylceramide in the endothelial and smooth muscle cells of blood vessels and in ganglions and perineural cells of the autonomic nervous system. It results from a deficiency of ceramide trihexoside-a-galactosidase and ceramide trihexosidase, the gene for which has been localized to the Xq 22–23 region of the X chromosome (Sakuraba *et al*. 1990). The affected boys have recurrent attacks of fever and a severe arthritis with a burning and tingling pain in the extremities. This is aggravated by hot weather or exercise. The fingers and elbows may become swollen with difficulty in extending the fingers. The typical rash consists of purple papules—angiokeratoma diffusum universale. Ocular signs include opacification of the cornea in a whirl-like configuration. Secondary osteonecrosis may become increasingly important in weight-bearing joints such as the hips. Female heterozygotes may have a milder form of the disease, as did the mother in a case presenting with fever and lymphadenopathy (Mayou *et al*. 1989). Renal, cardiac and cerebral disease tend to cause death in the mid-adult years (Kramer *et al*. 1985; Sakuraba *et al*. 1986; Morgan *et al*. 1990).

Other rare disorders

Multicentric reticulohistiocytosis (see Chapter 5.13.7)

A disease sometimes referred to as 'lipoid dermatoarthritis'. As yet no biochemical abnormality has been defined, but foamy giant cells and histiocytes are found on biopsy of the skin, synovium and mucous membranes. It causes a mutilating, destructive arthropathy with cutaneous nodules often on the face as well as other sites (Zayid and Farroj 1973).

Winchester syndrome

This begins after the age of a few weeks up to one year with swelling of the proximal interphalangeal joints and enlargement of the wrists; later corneal clouding, coarsening of the face, and joint contractures appear (Winchester *et al*. 1969). Patchy thickening of skin with pigmentation are found over the back, flanks and lateral aspects of the arms. Other features are corneal opacities in mid-childhood, retarded growth, carpal-tarsal osteolysis and destruction of the small joints. Increased urinary oligosaccharide excretion is found (Lambert *et al*. 1989; Winter 1989).

Kniest syndrome

This is associated with congenital short limbs, and with a large head, round face and depressed nasal bridge. It is inherited usually as an autosomal dominant disorder, but sporadic cases have been seen (Kim *et al*. 1975). Stiffness of the fingers, dislocation of the hips and kyphoscoliosis develop; later enlargement of the joints and severe contractures occur (Fraya *et al*. 1979). The cartilage has hypertrophic chondrocytes surrounded by a loose matrix that contains large holes

resembling Swiss cheese, hence the name. Other abnormalities, notably cleft palate, vitreo-retinal degeneration and retinal detachment, deafness and hernia are characteristic. Other chondrodysplasias may have a similar appearance (Sconyers *et al*. 1985).

Moore–Federman disease

Small hands with brachydactyly are noted early, followed by contractures of the hand joints (Fig. 11) and dwarfism (Moore and Federman 1965). This may be the same condition as acromicric dysplasia (Winter *et al*. 1989).

Fig. 11 This 7-year-old presented with some difficulty in gripping and possible swelling of the fingers. She was noted to be short. Her grandfather had very similar hands.

Thiemann's disease

This tends to commence at about the age of 10 or 11 years and is characterized by progressive enlargement of the proximal interphalangeal joints of the hands, the interphalangeal joints of the great toe and occasionally other toes, followed by slight flexion of the enlarged joints. Clinically there is bony swelling but no evidence of soft-tissue swelling and the erythrocyte sedimentation rate is normal. Radiologically there is irregularity of the epiphyses of the phalanges. This condition can be familial (Molloy and Hamilton 1978).

Idiopathic acro-osteolysis

Although destruction and disappearance of bone as a primary condition is rare, a number of different types have been described (Brown *et al*. 1976). Hereditary osteolysis is an autosomal dominant; it usually begins about the age of 3 years and affects children of both sexes (Naranjo *et al*. 1992). The bones of the carpus and tarsus (Urlus *et al*. 1993) are particularly affected, and to a lesser extent the hands and feet as well as elbows and knees. It presents with tender, swollen, limited wrists and ankles closely mimicking juvenile chronic arthritis, but there is no obvious synovitis and the erthrocyte sedimentation rate is usually normal (Beals and Bird 1975). Initially the radiographs are normal, but after a time there is porosis of the carpal bones followed by localized destruction (Fig. 12) and finally complete disappearance of the bone. This condition tends to stabilize spontaneously in early adult life. The Haydu–Cheney acro-osteolysis is characterized by facial as well as skeletal hanges. The eyes slope downwards, the philtrum is long and the nostrils anteverted. The skull radiograph shows wormian bones, an elongated pituitary fossa and a thickened cranium with persistent sutures; the classical acro-osteolysis only develops later in childhood. Inheritance is likely to be autosomal dominant, although most cases are sporadic (Macpherson and Pai 1989). Multicentric osteolysis has also been reported as an autosomal recessive trait with symptoms developing between the age of 2 and 5 years (Torg *et al*. 1969).

Fig. 12 This child presented some 3 years earlier with pain and swelling in the wrists and feet; note the tapering of the bases of the metacarpals, and absorption of carpal bones at a different rate on the two sides, together with the early absorption of the ulnar head on the left, due to idiopathic acro-osteolysis.

The Thieffry–Kohler form is similar to idiopathic multicentric osteolysis, but with a facial appearance characterized by frontal bossing, micrognathia, a small mouth and protruding eyes. It is usually inherited as an autosomal dominant trait. The joint manifestations begin in the wrists and ankles, leading to progressive deformity. It is not certain whether the form associated with progressive nephropathy resulting in hypertension and renal failure in early adult life is the same as Thieffry–Kohler (Shurtleff *et al*. 1964; Carnevale *et al*. 1987).

Phantom bone disease (Gorham's disease)

This is a non-hereditary form which occurs usually between the ages of 5 and 10 years (Gorham and Stout 1955). Any bone can be affected and there are usually multiple sites which are asymmetrical in distribution; histologically there is proliferation of thin-walled blood vessels.

Distal osteolysis

Thought to be inherited as an autosomal dominant trait, it is characterized by progressive osteolysis of the phalanges, metatarsals and metacarpals. It tends to occur in children of 8 years and upwards and often heals spontaneously, although sometimes part of a finger or toe may be lost (Elias *et al*. 1978).

Other oddities

Not all children who present with joint deformities can be characterized, for example the patient shown in Fig. 13 and Fig. 14, and all skeletal disorders mimicking arthritis have not been covered here, so cross-reference to other chapters is essential. Readers are also referred to Wynne-Davies *et al*. (1985) and Spranger (1992).

Fig. 13 This boy was first noted to have a left elbow contracture as a baby; this progressed and deformities were noted in the other elbow, wrists, knees, ankles and feet. The only relevant history was that his mother had had mumps during the pregnancy.

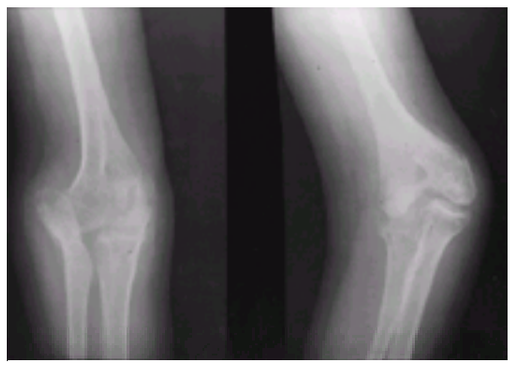

Fig. 14 Unusual bony abnormalities in the elbow radiograph from the patient shown in Fig. 13. The radial head on the left in particular is grossly abnormal.

Arthrogryposis

This is a symptom complex characterized by stiffness and contractures of the joints at birth. It can affect both the upper and lower limbs in about 50 per cent of cases, while in 40 per cent it is only the lower limbs and 10 per cent the upper limbs. Distal joints are often severely affected with the feet showing talipes equinovarus and the wrists severe flexion deformities. These are frequently associated with flexion contractures of the knees and fixed extended elbows (Lloyd-Roberts and Lettin 1970). The normal contours of the joints are lost as are the skin creases over them; there is absence or underdevelopment of surrounding muscles. The rigidity of joints is thought to be due to fibrosis. In addition, there may be congenital defects of the skeleton. The patients that give rise to problems in differentiation from juvenile arthritis are those with isolated limitation of movement, particularly at the hips, knees, or elbows (Fig. 15). It is important to recognize them early as improvement can be achieved by manipulation and splinting, while soft-tissue release of ligaments and tendons around the joints will help fixed deformities, but should be carried out in relatively young patients.

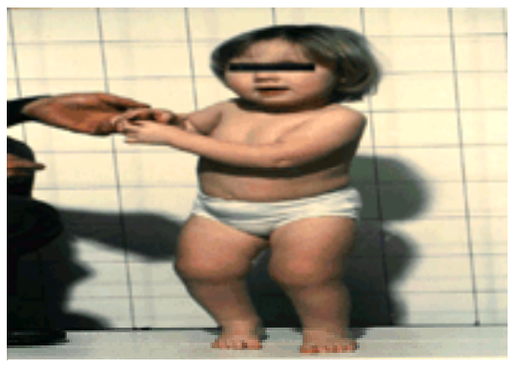

Fig. 15 Although well covered, it was considered that this baby, who had presented with contractures of the hips, knees and ankles at birth, was suffering from a limited form of arthrogryposis.

Kashin–Beck disease

This endemic arthritis with systemic or visceral manifestations has been reported from Eastern Russia, Siberia, Northern China, and Korea and appears to result from eating bread baked from fungus-infected grain (Nesterov 1964). Unknown toxic products cause an epiphyseal and metaphyseal dysplasia of the bones of the interphalangeal, wrist, knee, and ankle joints. This isorder continues to become more severe as long as the child lives in the endemic area eating such products, and will ultimately cause symmetric progressive limitation of movement involving multiple joints. The initial symptoms are in school-aged children and consist of aching and muscle weakness. Laboratory indices of inflammation are absent. The eventual dwarfing, bony dysplasia, and short digits resemble those seen in the lysosomal stores diseases. Experimental animals fed grain infected with *Fusarium* species have been shown to develop a similar form of dysplasia.

Mseleni disease

The population of the Mseleni area of Northern Zululand has a high incidence of a chronic polyarthritis, commencing in childhood or adolescence and characterized by a restriction of movement and limitation of mobility, with the hips, knees, and ankles as the predominant sites of involvement; mild stunting of growth is common (Lockitch *et al*. 1973). The characteristic radiograph abnormalities include irregularities on the surface of the epiphyses, change in shape and, ultimately, progress to osteoarthritis in the hips, often with protrusio acetabulae; short metacarpals and deformity at the distal end of the ulna may also occur. The aetiology is thought to involve a nutritional deficiency or toxin similar to the Kashin–Beck disease.

5.18.1 Intervertebral disc disease and other mechanical disorders of the back

Malcolm I. V. Jayson

Introduction

The primary roles of the human spine are to bear the weight of the upper structures of the body, provide flexibility for movements, and protect the vital structures—in particular the spinal cord and the nerves that emerge through the intervertebral foramina. The stresses associated with a lifetime's use, combined with ageing and degenerative changes and the effects of individual and repeated traumatic episodes, are commonly associated with mechanical problems so that back pain due to structural change of the spine is almost a universal experience. However, although mechanical and degenerative changes of the lumbar spine are common, the correlation with back pain is weak (Lawrence 1977). Some patients have minor evidence of damage to the spine yet experience major problems; others may show degenerative change and yet be symptom free. Moreover, structural changes in the spine are permanent but the symptoms of back pain are commonly transient. Acute episodes of pain are separated by periods in which symptoms are minimal or absent. This complicates our understanding of the pathogenesis of back problems. The remitting course of individual episodes emphasizes the need for controlled studies of various treatment programmes.

Epidemiology

Back pain is an extremely common problem. Recent population studies in Britain show a point prevalence of 14 per cent at any one time (Mason 1994), 39 per cent in the last month (Croft and Jayson 1994), 37 per cent in the last year (Mason 1994), and lifetime prevalence of between 58 per cent (Croft and Jayson 1994) and 80 per cent (Waddell 1987). The peak prevalence is between 45 and 59 years although it is common in the young and in the elderly (Papageorgiou *et al*. 1995). True sciatica appears to be much less frequent. With strict diagnostic criteria, the overall prevalence in studies by Heliovaara *et al*. was estimated to be 5.3 per cent in men and 3.7 per cent in women (Heliovaara *et al*. 1987).

Despite a dramatic increase in recent years in disability due to back problems, there is no clear evidence of an increase in the number of back-related injuries (Troup and Edwards 1985). In a recent survey (Mason 1994), 11 per cent of the population (that is 30 per cent of those with back pain in the last year) reported their activities limited by back pain during the previous 4 weeks; 1.9 per cent of all employed people and 6 per cent of employed people with back pain had lost at least 1 day off in the last month. In Britain in 1993, the total work loss was estimated as approximately 150 000 000 days (Clinical Standards Advisory Group 1994). The prevalence of back disability is increasing rapidly with the number of working days lost now running at some four times the figures for 20 years ago, and similar changes are found in most countries. Cats-Baril and Frymoyer estimated the costs in the United States to be between $25 and 100 billion in 1990 (Cats-Baril and Frymoyer 1991). There is, however, little evidence of increase in the numbers of work-related injuries (Health and Safety Executive 1993). We see a dramatic increase in the morbidity associated with back problems but there does not seem to be any change in the nature of the back injuries. It is likely that social, psychological, and employment problems are playing the major role in this dramatic increase in disability.

There is little difference in the prevalence of back pain and disability between men and women. There is an increased prevalence of low back pain and disability with lower social class; the relationship being stronger in males than females (Walsh *et al*. 1992; Mason 1994). Many patients report the development of back problems in relationship to an accident or injury although commonly this is difficult to evaluate (Mason 1994). Most are work related injuries (Health and Safety Executive 1993) with the highest incidence rate in the construction industry and agricultural sector. There appears to be an association between low back problems and heavy manual work. Videman *et al*. found that vertebral osteophytes were associated with heavy physical work (Videman *et al*. 1990). However, symmetrical disc degeneration was associated with sedentary work. A number of studies have shown an increased lifetime prevalence of back problems in those involved in heavy occupations as compared with light work (Biering-Sorenson 1985; Riihimaki *et al*. 1989) but it is difficult to know whether this is due to the direct effects of overloading the spine or to repeated minor trauma. Mitchell found that people performing heavy manual work had no increase in the number of spells off work with back pain but they were of increased duration (Mitchell 1985). There also appears to be an association between back pain and long-term exposure to driving and vibration (Hulshof and van Zanten 1987).

Epidemiological studies show associations of back pain with neck pain (Porter and Hibbert 1986), chronic musculoskeletal pains (Makela 1993), smoking, psychological distress, and depression (Wright *et al*. 1995).

Structure and function of the lumbosacral spine

The five lumbar and first sacral vertebrae form the principal load carrying structure for the back. Each pair of vertebrae is joined by the intervertebral disc anteriorly and the two apophyseal joints posteriorly. These joints cannot move in isolation and all movements between vertebrae necessarily affects all three. For this reason each pair of vertebrae and the connecting three joints are known as a spinal unit.

The intervertebral disc in the adult consists of a central gelatinous nucleus pulposus surrounded by the tough fibres of annulus fibrosus. The annular fibres spiral obliquely in fascicles between the vertebral rims, lying at about 60° to the spinal axis and interdigitating with each other (Fig. 1). This arrangement makes the intervertebral disc an effective shock absorber which accommodates vertical loads by slight squashing of the disc and bulging of the periphery, and flexion, extension, and lateral flexion movements by alteration of the angles of the crossing fascicles. However, torsion of the lumbar spine is less readily accommodated as twisting of one vertebra on that below means that some collagen fibres of the annulus will be stretched. This is one of the reasons why twisting movements of the lumbar spine are more likely to be associated with annular damage.

Fig. 1 The collagen fibres of the annulus fibrosus spiralling obliquely around the margins of the intervertebral disc. (By courtesy of Dr J.B. Weiss.)

There is a lumbar lordosis that is most marked at L4/5 and L5/S1. The associated increase in pressures in the posterior part of the disc, together with the lower lumbar discs carrying higher loads than the upper discs, account for the greater prevalence of lumbar problems at these sites.

The gel-like nucleus of the normal disc consists of a matrix of water and glycosaminoglycan in a random meshwork of Type II collagen fibres (McDevitt 1988). With ageing and disc degeneration there is alteration of the glycosaminoglycan, with a reduction of its molecular size (Adams and Muir 1976), and the nucleus becomes more fibrous. There is loss of water content, the gel-like character of nucleus is lost, and, as a result, it is no longer able to redistribute pressures in an isotropic fashion. Localized areas of pressure concentration appear and may be associated with focal damage and an increase in proportion of the body load is borne by the annulus fibrosus. The normal annulus primarily consists of Type I collagen fibres at its outer periphery but with a gradual change to Type II fibres at its inner margin with the nucleus (Eyre and Muir 1976). Type I collagen is characteristic of collagens involved in resisting tensile loads, which is the primary function of the outer annulus, whereas the inner annular and nuclear Type II collagen is more typical of cartilage collagen and has to withstand compressive loads. There is clearly an appropriate, functional adaptation of collagen structure within the disc. In degenerative disease this pattern is lost. There is an excess of Type I collagen in both the annulus and nucleus (Herbert *et al*. 1975) interfering with the biomechanical efficiency of the disc. There are alterations in the patterns of degradative enzymes with disc degeneration and herniation (Ng *et al*. 1986) but it is not clear whether these changes play a fundamental role in degeneration of the disc or are secondary to disc damage. Experimental induction of disc prolapse shows that extensive vascular ingrowth is followed by more florid evidence of internal disc disruption (Vernon Roberts 1992). Angiogenic factors associated with the proliferation of new blood vessels are capable of activating degradative enzymes (Weiss and McLaughlin 1993), so providing a possible mechanism for the initiation of disc degeneration.

Measurements of pressures within the intervertebral disc show the increase associated with the upright posture and load bearing (Nachemson 1992). The load on the lumbar spine is increased by contraction of the paravertebral muscles, which stabilize the spine, and reduced by the lumbar lordosis. The design of car seats is largely related to information about the stresses on the disc with varying degrees of lumbar support and back rest inclination.

In contrast to the discs, the apophyseal joints are true synovial joints with fibrous capsules lined by synovium. They lie in an anteroposterior direction although their centres of rotation are behind the disc. Rotation of the lumbar spine is therefore limited and will produce sheer stresses on the disc—again accounting for the risks associated with torsion of the lumbar spine.

Pain is commonly experienced in the back and lower limbs. It may arise from stimulation of the nerve roots or nociceptive receptors (Wyke 1987). These are distributed in:

1. the skin and subcutaneous tissues;
2. the fibrous capsules of the apophyseal and sacroiliac joints;
3. the outer layers of the annulus fibrosus;
4. the longitudinal ligaments of the spine and, in particular, the posterior longitudinal ligaments;
5. the periostium and attached fascias, aponeuroses, and tendons;
6. walls of blood vessels in and around the spine;
7. the dura mata and epidural adipose tissues.

There is a complex anastomotic network of sensory fibres around the vertebral column and, in particular, around the margins of the intervertebral disc, penetrating the outer annulus and encircling blood vessels (Ashton *et al*. 1994). Substance P immunoreactive fibres can be demonstrated in these areas (Coppes *et al*. 1990). As a result, back pain is often diffuse and it can be difficult to locate the source of the problem from the distribution of symptoms.

Afferent impulses pass through the sensory neurones and the dorsal horn ganglion into the spinal cord. Complex neuropharmacological changes involving substance P, vasoactive intestinal peptide, and other neuropeptides are modulated after nociceptive stimulation of the spine (Weinstein 1986). As a result, pain felt in the back and in the lower limbs can arise due to a wide variety of different reasons. These include:

1. radicular pain from direct nerve or nerve root compression;
2. referred pain from damage of nociceptive receptors in the various spinal tissues with referral of symptoms into the lower limb;
3. deafferentation pain resulting from a loss of the afferent connections of the spinal neurones;
4. dysregulatory or reactive pain involving the pathophysiology of the afferent motor system with resulting hypertonus of postural muscles;
5. psychosomatic pain such as pain enhanced by emotion, depression, or social distress.

In addition, recent work suggests central mechanisms by which the perception of pain is modulated. In particular, following nociceptive damage neuromorphological and neurochemical changes occur within the dorsal horn which may be long lasting so the sensation of pain may persist despite the lack of peripheral cause. The cells may be sensitized with increased sensitivity to minor stimulation and the message may spread within the spinal cord so that symptoms are perceived over a wide area (Dubner and Basbaum 1994).

The sympathetic chain runs alongside the vertebral column with multiple anastamosing sympathetic fibres and the peripheral sympathetic system accompanies blood vessels extending into the lower limbs. Many patients with chronic lower limb pain showed evidence of a sympathetic dysfunction syndrome. Most often this follows surgery to the lumbar spine although it can occur in association with mechanical problems (Sachs *et al*. 1993).

Pathological changes in the spine

Herniated intervertebral disc

Nuclear material can burst through the annulus fibrosus displacing and damaging the surrounding structures. Most often this occurs at the level of the L4/5 and L5/S1 intervertebral discs and the prolapse is usually in a posterolateral position, although sometimes it can be much nearer or in the midline. As a result, the prolapse may damage nerve roots in addition to ligaments, periostium, blood vessels, dura, and other tissues. The degrees of herniation are known as protrusion, extrusion, and sequestration according to their extent and whether the herniated material retains contact with the disc. Herniation most often develops after heavy load bearing with the spine in a flexed and twisted position. However, there is evidence that compression of a healthy lumbar disc will usually cause vertebral end plate fracture and that posterior and posterolateral herniation only occur when there is previous disc degeneration and fissure producing weakening of the annulus fibrosus (Jayson *et al*. 1973). The particular stress may have acted solely as the final precipitating cause of the problem.

The herniated material is often surrounded by an area of erythema and oedema. Usually it will gradually heal with fibrosis and shrinkage so that eventually the symptoms will improve. However, the annulus will be damaged and there is considerable risk of recurrent disc herniation and later development of secondary degenerative changes. The herniated material may press directly on nerves or compress the epidural veins producing venous obstruction and ischaemia over the relevant nerve. It may be complicated by thickening of the neural sheaths with perineural and intraneural fibrosis, and in turn by neuronal atrophy (Hoyland *et al*.

1989).

A more central, posterior prolapse can damage the posterior longitudinal ligament, which is innervated by the sinuvertebral nerve, and produce central back pain. A large, central posterior prolapse can compress the cauda equina leading to multiple nerve root damage in the lower limbs and sphincter disturbance.

There seems to be some predisposition towards development of herniation. Pathological studies in cadavers (Jayson and Barks 1973) and magnetic resonance scanning in life (Powell *et al*. 1986) show that when disc degeneration is present there is an increased risk of changes at multiple levels. There may be familial factors predisposing towards the development of this prolapse although no specific immunogenetic pattern has been identified (Postacchini *et al*. 1988). Environmental factors clearly play a part. Moderate amounts of physical activity are good for the back but lack of exercise and excessive spinal loads are both associated with increased risks of back pain, disc herniation, and degenerative disease of the spine (Videman *et al*. 1990).

The classical presentation of a herniated intervertebral disc is the acute onset of back pain followed by radicular pain, numbness, and paraesthesiae in one or other lower limb. The problem may develop after some stress and in particular bending, twisting, and lifting which, when combined, seem to produce the greatest risk. Most patients, however, will give a history of some preceding aching and stiffness in the back over the previous few days.

Clinical pattern

Direct damage to the nerve root will produce pain, numbness, and paraesthesiae as shown in Table 1. A small lateral herniation of the L4/5 disc will commonly affect the L5 nerve and herniation of the L5/S1 disc will affect the S1 root. However, a large prolapse, particularly if it is more central, may affect several nerve roots with widespread neurological symptoms and signs, and perhaps sphincter disturbance. There is considerable overlap in the distributions of the various nerve roots and the symptoms and physical signs only act as approximate guides to which disc has been damaged. In addition, pressure on ligaments and other soft tissues will produce referred pain felt in the buttock and lower limb. This is often confused with radicular symptoms due to nerve root damage. Referred pain is poorly defined and patients commonly have difficulty in describing its distribution. The symptoms of disc herniation are made worse by spinal movements and also by Valsalva manoeuvres such as coughing, sneezing, micturition, and defecation, which raise the cerebrospinal fluid pressure. Examination may show a sciatic scoliosis due to unilateral spasm of the paraspinal muscles. There may be severe limitation of spine movements but often in only one or two directions and in particular movements, including flexion. Palpation of the spine may show local areas of tenderness over the spine or sometimes elsewhere, such as the sacroiliac joints. Straight leg raising is limited with a positive Lasegue's test. The specific neurological signs of nerve root damage should be sought (Table 1).

Root	Superficial paraesthesiae and sensory change	Muscle weakness	Tendon reflex changes
L2	Upper thigh: anterior, medial, and lateral surfaces	Flexion and adduction of hip	None
L3	Anterior surface of lower thigh Anterior and medial surfaces of knee	Adduction of hip; extension of knee	Knee jerk possibly decreased
L4	Anteromedial surface of leg	Extension of knee; dorsiflexion and inversion of foot	Knee jerk decreased
L5	Anterolateral surface of leg, dorsum and medial surface of foot, especially dorsal surface of hallux	Extension and abduction of hip Flexion of knee; dorsiflexion of foot and toes, especially hallux	None
S1	Lateral border and sole of foot, back of heel, and lower calf	Flexion of knee; plantar flexion and eversion of foot	Ankle jerk decreased

Table 1 Principal changes used for identifying the sites of lumbar nerve root lesions (note that this table does not list the total distribution of each root)

Investigations

The blood sedimentation rate, plasma viscosity, and routine haematological and biochemical tests are normal. The cerebrospinal fluid obtained by lumbar puncture is usually normal but when there is a large prolapse with a spinal block the protein may be elevated.

Imaging techniques commonly used include:

Plain radiography

In an acute prolapse the spine is normal except perhaps for a scoliosis. When followed over several years, disc narrowing may develop and later on there may be secondary spondylotic changes.

Radiculography

Water-soluble radio-opaque dye is injected into the subarachnoid space at lumbar puncture. The dye penetrates along the nerve roots and obstruction to flow produced by a prolapse can be clearly identified (Fig. 2).

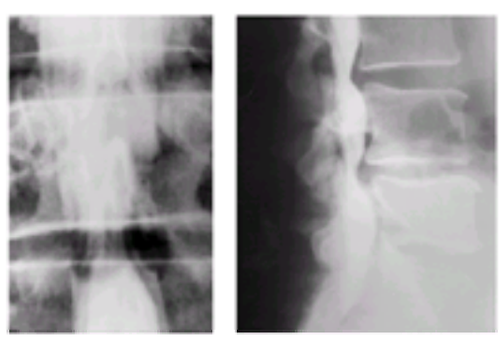

Fig. 2 Radiculogram showing (a) left sided L4/5 disc herniation and (b) smaller disc protrusion at L3/4.

Discography

Direct injections may be made into an intervertebral disc. A normal, healthy disc will accept about 0.5 ml of fluid without producing significant symptoms. Larger volumes will be accepted by herniated discs with reproduction of symptoms. The pain may be relieved by injection of local anaesthetic. The radiographic appearances of disc herniation may be identified (Fig. 3).

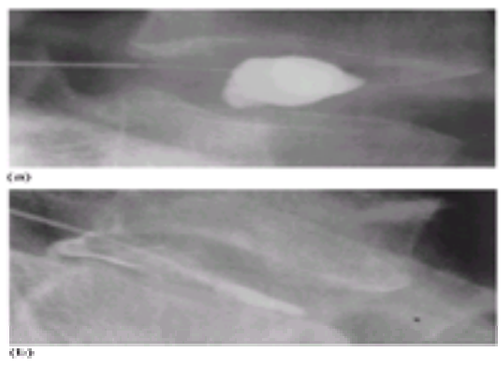

Fig. 3 Discography: (a) normal and (b) disc degeneration with leakage of the dye into the epidural space.

Computed tomography (CT)

Herniation of a disc and the size and extent of nerve root involvement can be determined. This technique is sometimes use to complement radiculography when the details of nerve root damage may be clarified.

Magnetic resonance imaging (MRI)

This technique is becoming the investigation of choice. It has the advantage of avoiding the use of X-rays. It will demonstrate the size and extent of a disc herniation as well as degenerative change in the disc by loss of signal on the T_2 image and reduction of disc height (Fig. 4).

Fig. 4 MRI scan, vertical reconstruction. There is loss of signal at the L3/4, L4/5, and L5/S1 discs indicating disc degeneration with herniation at L4/5 and L5/S1.

Lumbar spondylosis

Degenerative changes in the spine are common. Pathological studies have demonstrated their first appearance to be often around 25 years and they are almost universal in older people. Although patients with severe degrees of spondylosis more commonly develop back pain than those without, the correlation between back pain and radiographic evidence of lumbar spondylosis (Lawrence 1977) and MRI evidence of disc bulging and protrusion (Jensen *et al*. 1994) is poor. Because they are so common it may be better to call these appearances 'ageing change' rather than 'degenerative change' as the latter term conveys a perjorative image to patients and an implication of long-term problems, which is frequently not the case.

There is disorganization of the internal structure of the disc with the loss of the clear distinction between the nucleus pulposus and the annulus fibrosus. Cleft formation within the disc is common. The disc becomes narrowed with osteophytosis around the vertebral margins. Osteoarthritic changes may also develop in the apophyseal joints and it is commonly not clear whether such changes preceded or followed degeneration in the disc. Lumbar spondylosis with osteophytes and often minor degrees of disc herniation can directly impinge upon nerve roots and other structures. More commonly, however, they may contribute towards obstruction of vascular flow and be associated with peri- and intraneural fibrosis and neuronal atrophy (Hoyland *et al*. 1989).

There is no defined clinical pattern associated with lumbar spondylosis. Some patients only suffer postural backache with pain associated with prolonged sitting or standing in a poor posture or aggravated by heavy manual work. Others suffer more severe episodes, often provoked by trivial stress. These acute episodes will usually resolve within a few days but the patient is always at risk of further episodes. The pain may be felt across the back but often spreads into the buttock and the lower limbs. If there is nerve root entrapment there may be the specific radicular symptoms and signs (Table 1). Soft tissue damage can produce referred pain spreading to the limb, which is often not in a well defined distribution.

The radiographic changes include narrowing of disc space, gas in the disc, sclerosis of the vertebral end plates, and marginal osteophytosis (Fig. 5). It is important to remember that these changes are common in the symptom-free population and particularly in older subjects. Their presence, therefore, does not mean they are the source of the symptoms and careful evaluation is always required to ensure there is no other problem in any individual patient.

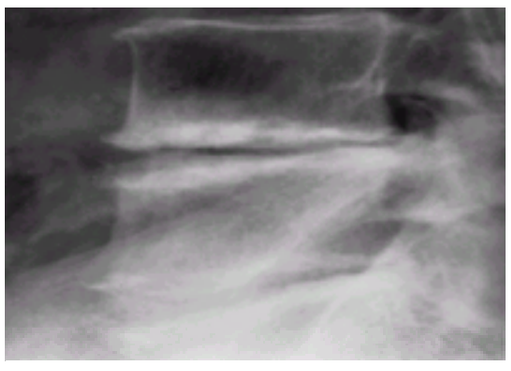

Fig. 5 Lumbar spondylosis at L4/5 and L5/S1.

Internal disc disruption

After trauma, and in particular compressive loads on the spine perhaps associated with the vertebral end plate fracture, there may be degradation of the nucleus pulposus spreading outwards to involve the annulus fibrosus. This may irritate nerve endings in the outer border of the annulus and lead to the development of pain. Loss of disc height may contribution towards venous obstruction and tissue ischaemia (Crock 1992).

The symptoms are felt in the back or referred into the buttock or lower limb. They are aggravated by movement. However, the nerve roots may not be affected in which case there will be no specific neurological signs. In the early stages, plain radiographs may be normal but later there is progressive narrowing of the disc space. Likewise, the myelogram and CT scan may be normal although the MRI scan may show loss of signal in the T_2 image. On discography the radiographs, perhaps supplemented by a CT scan, may show characteristic morphological appearances. Reproduction of the pain by raising the pressure within the individual disc and relief by local anaesthetic is more valuable.

In cases where the disc can be specifically identified as the source of the symptoms, spinal fusion may be helpful (Colhoun *et al*. 1988).

Facet joint syndromes

The apophyseal joints are true synovial joints and commonly develop osteoarthritic changes. Patients may develop pain which arises from osteoarthritic apophyseal joints. The typical picture is of pain in the back spreading into one or other buttock or into the back of the thigh. It is aggravated by extension and on palpation there is marked tenderness over the facet joints. However, each facet joint has a nerve supply arising from several levels and, as a result, the pain often has a widespread distribution making it difficult to identify which specific joint is the source of the symptoms.

Facet joint arthrography can be helpful as it may demonstrate osteoarthritic change and, in particular, if injection of the joint aggravates the symptoms and anaesthetic provides relief, this strongly suggests that the joint is responsible for the development of pain (Fairbank *et al*. 1981). However, the diagnosis is controversial as the correlation between the response to provocative surgical procedures and clinical findings is poor and it remains possible that when symptoms are relieved by anaesthetic it has leaked out from the joint and provided symptomatic relief simply by affecting nerve endings in a widespread distribution.

Spinal stenosis

There is considerable variation in the size and shape of the vertebral canals. In particular, some patients have a canal with a small diameter and with a trefoil shape due to osteoarthritic hypertrophy of the apophyseal joints. The nerve roots may be tightly packed. As a result, there is an increased risk of back problems following any further intrusion into the canal. It is known that patients developing symptoms from a disc protrusion have significantly smaller canal measurements than the normal population (Porter *et al*. 1980). Symptoms due to spinal stenosis may develop in later life as a result of osteophytosis, disc bulging, and ligament thickening intruding into a tight canal space.

There are two principal syndromes associated with spinal stenosis—central stenosis and foraminal stenosis.

Central stenosis—neurogenic claudication

On walking the patients progressively develop discomfort, numbness, paraesthesiae, heaviness, and a dead feeling in the lower limbs that will eventually make them stop. On resting the symptoms gradually ease over a period of 5 to 10 min and the patient may start walking again. The problem is frequently confused with claudication due to a poor arterial blood supply in the lower limbs. As the patients are frequently elderly and may also have an arteriopathy the differential diagnosis may sometimes be difficult. The vertebral canal has slightly greater dimensions when the spine is flexed and many patients describe bending forwards to relieve their pain. Likewise they may find it easier to walk uphill when they lean forwards than downhill when they lean back.

On examination they may stand with the spine, hips, and knees slightly flexed. They can usually bend forwards without problem but extension is absent. Neurological examination is unhelpful.

Plain radiographs may show the evidence of degenerative change but it is difficult to determine the dimensions of the vertebral canal. Myelography can be technically difficult because of the crowding of the nerve roots. CT and MRI scans are most helpful for identifying the extent and severity of the stenosis and measurement of the vertebral canal dimensions may be made (Fig. 6).

Fig. 6 MRI scan showing spinal stenosis, most marked at L3/4 and L4/5, with degenerative disc disease.

Foraminal stenosis—root entrapment syndrome

Narrowing of the intervertebral foramen with nerve root entrapment can give rise to a specific pattern of radicular pain in the lower limb (Porter 1992). This narrowing may be due to bony osteophytosis from the apophyseal joints, posterolateral osteophytes on the vertebral bodies, ossification and hypertrophy of the posterior spinous ligaments, and fibrous proliferation of the nerve root sheaths.

The patient develops a pattern of radicular pain distinct from that of a prolapsed intervertebral disc. In particular, the pain is often severe and unremitting, being present at rest in bed as well as on exercise, although it may be aggravated by physical activity. Back movements may be full and many patients do not show restriction of straight leg raising.

CT (Fig. 7) and MRI scans are most helpful for demonstrating foraminal stenosis. Nerve root sheath injection with local anaesthetic can also be helpful for identifying the site of the pain producing lesion (Dooley *et al*. 1988).

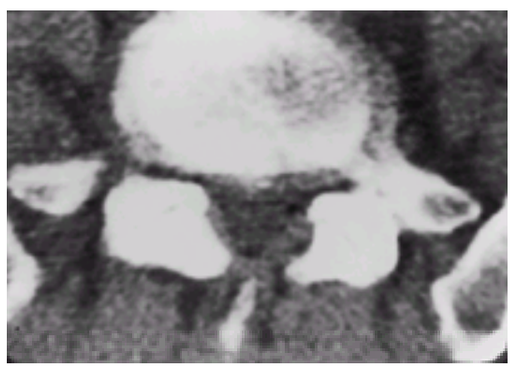

Fig. 7 CT scan showing foraminal stenosis.

Spondylolysis and spondylolisthesis

Defects in the pars interarticularis (spondylolysis) are common and usually not of significance. Spondylolisthesis refers to slipping, usually forwards but occasionally backwards, on the vertebra below. Spondylolisthesis has been classified by Wiltse and Rothman (Wiltse and Rothman 1990) as follows:

1. congential;
2. isthmic:
    a. lytic—stress failure of the pars interarticularis,
    b. an elongated but intact pars secondary to a healed stress fracture,
    c. fracture;
3. degenerative;
4. post-traumatic;
5. pathological—due to destruction of posterior elements;
6. surgical.

Patients may develop pain in the back and in the lower limb aggravated by standing and walking and relieved by rest. Narrowing of the vertebral canal can cause symptoms suggestive of spinal stenosis. The physical findings will depend on the degree of slip and extent of neurological damage. It may be possible to palpate a step on their spine on forward flexion in gross cases.

Postsurgical back pain

Many patients undergo surgery for spinal disorders. A significant proportion fail to respond or develop recurrent back problems. Careful assessment is needed to determine the cause of the problem in each individual case. Problems that may be identified are as follows:

1. the operation was undertaken at the incorrect level;
2. inadequate surgery, perhaps with failure to decompress adequately a nerve root or excise a disc herniation;
3. recurrent disc herniation at the same or another level;
4. secondary or degenerative change, perhaps associated with extensive removal of bone;
5. perineural fibrosis and arachnoiditis (see below);
6. sympathetic dysfunction syndromes (Sachs *et al*. 1993);
7. psychological factors;
8. unrelated pathology.

Perineural fibrosis and arachnoiditis

Abnormal fibrosis may develop in the periradicular tissue (perineural fibrosis) or within the dural sac (arachnoiditis). The former develops most commonly in a florid form in patients who have undergone spine surgery and may be due to retained cotton debris from the surgical swabs and patties (Hoyland *et al*. 1988). However, minor degrees of periradicular fibrosis are common in association with lumbar spondylosis. It is frequently difficult to correlate the presence of epidural fibrosis and the development of back and lower limb symptoms (Cooper *et al*. 1991).

Arachnoiditis was first described following meningitis. It can develop following surgery but is then restricted to the level of the operation. The most widespread forms of arachnoiditis are found in those patients who in the past underwent myelography using oil based radiographic media. There is inflammation around the nerve roots followed by necrosis and adhesions. The pathological changes and clinical features of arachnoiditis have been described by Burton (Burton 1990).

Very severe and widespread pain often is experienced not only in the back and lower limbs but over the whole trunk and even extending into the upper limbs and face. It frequently has a burning and dysaesthetic quality and patients are commonly very distressed. Radiculograms will show a grossly distorted thecal sac (Fig. 8). High resolution MRI scans are most helpful for demonstrating the presence of arachnoiditis (Fig. 9).

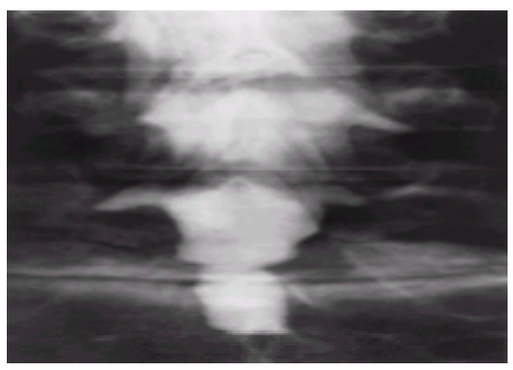

Fig. 8 Radiculogram in a patient with arachnoiditis showing gross distortion of the thecal sac.

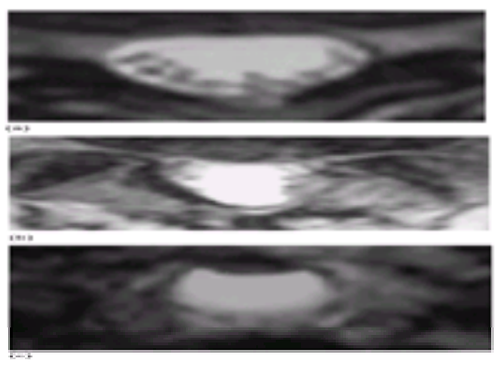

Fig. 9 High resolution MRI scans showing the nerve roots (a) normal, (b) arachnoiditis. The nerve roots are adherent to each other, atrophic, and stuck to the wall of the thecal sac. (c) The nerve roots have atrophied completely and can no longer be seen. Residual Myodil is still present anteriorly.

Non-specific back pain

In many patients it is difficult to define a precise cause for the symptoms. They suffer persistent or recurrent episodes of back pain. Examination may reveal limitation of spine movement but without neurological signs. Radiographs may show varying degrees of lumbar spondylosis but it is difficult to determine.

Within this group many will have localized areas of tenderness over the spine or the sacroiliac joints. Pressure on areas may reproduce the patient's symptoms and

they are sometimes called areas of subluxation or dysfunction by osteopaths and chiropractors although there is no pathological basis for these terms. Collee *et al*. described iliolumbar and greater trochanteric pain syndromes occurring in patients with chronic low back pain (Collee *et al*. 1990). However, no specific pathology has been demonstrated and the cause of the problems remain uncertain.

Hypermobile patients often suffer recurrent back pain. Radiographs may show marked evidence of degenerative change yet these subject retain a remarkably good range of back movements. It is believed that injury of the ligaments and capsule, perhaps associated with small fractures, may be the source of pain in these circumstances.

The fibromyalgia syndrome is also a source of confusion. These patients have multiple tender points, particularly around the shoulder and hip girdles, and this is commonly associated with a poor sleep pattern. Many are depressed and there is an association with migraine and an irritable bowel syndrome. There is no evidence of a specific back pathology, although the fibromyalgia syndrome can complicate other back problems so that patients experience widespread pain (see also Chapter 5.14).

Management

Each patient will require individual assessment. In particular, it is important to distinguish patients with acute, recurrent, and chronic mechanical back pain syndromes.

Acute back pain

Most acute back problems are seen in primary care. Many patients do not seek medical advice and a high proportion will be treated by a physiotherapist, osteopath, or chiropractor. It is generally believed that about 90 per cent of acute episodes settle within 6 weeks (Waddell 1987). However, these estimates may be over optimistic. Croft *et al*. found that of patients consulting their primary care practitioner, 69 per cent had a clear cut new episode of back pain, 20 per cent had an acute exacerbation of a more chronic or persistent complaint, and in 8 per cent the consultation was part of a continuing problem (Croft and Jayson 1994). At 6 months follow-up, 27 per cent had recovered completely, 28 per cent improved, 30 per cent were the same, and 14 per cent had become worse.

In acute back pain the patients should be triaged into those with simple back ache, nerve root pain, and possible serious spinal pathology. Guidelines for classifying these three groups have been published (Clinical Standards Advisory Group 1994).

Simple backache

Clinical criteria

Patients aged 20 to 55 years;

pain in the lumbosacral region, buttock, and thighs;

pain mechanical in nature varying with physical activity and with time;

patient is well.

Blood tests and lumbar spine radiographs are not indicated unless there is doubt about the diagnostic triage.

Such patients should be managed with simple analgesics such as paracetamol (aminocetophen). Occasionally they may require non-steroidal anti-inflammatory drugs. Narcotics should be avoided and never given for more than 2 weeks. Bed rest should only be prescribed if essential and then normally for only 1 to 3 days. This produces less disability than more prolonged periods of bed rest (Deyo *et al*. 1986).

It is always important to provide ergonomic advice on posture while standing, working, sitting, and lifting in order to protect the back against excessive loads.

Early physical activity is encouraged and reduces pain (Malmivaara *et al*. 1995). Indeed, continuing ordinary activities whenever possible seems to produce the best outcome (Malmivaara *et al*. 1995). Patients should be advised that exercise is not harmful and reduces pain, and that physical fitness is beneficial. The patient should be encouraged to return to work as soon as possible. Simple analgesic, or perhaps anti-inflammatory drugs, may be required and narcotics should be avoided if possible. With a regimen such as this, most patients will return to normal function rapidly.

The role of the therapist is restoration of function and encouraging the patient to be mobile. Physical exercise has an important role. The actual type of exercise is relatively unimportant. The benefits seem to lie in the quantity of exercise rather than in its specific nature. A positive attitude to activity and encouragement to return to work as soon as possible is all important. Early identification of psychosocial problems is important as they predict both the development of back pain (Croft, P., Papageorgiou, A.C., Ferry, S., Thomas, P., Jayson, M.I.V., and Silman, A.C., in press) and of acute back pain becoming chronic (Burton *et al*. 1995).

In order to remobilize the patient there is a wide variety of forms of physiotherapy and manual treatments. There is no evidence that heat, cold, ultrasound, or massage provide any benefit other than comfort at the time they are administered. Exercises and physical fitness are important and an incremental aerobic fitness programme of physical reconditioning is advised.

With this programme the vast majority of patients will recover within 6 weeks. If the pain still persists at 6 weeks, the diagnostic triage should be reviewed and investigations such as erythrocyte sedimentaion rate and a radiograph of the lumbar spine should be requested, if specifically indicated. For the patient with persistent back ache an active rehabilitation programme is necessary and at this stage referral may be required for a second opinion, rehabilitation, additional assessment, pain management, and, occasionally, surgery.

Manipulation is practised by physiotherapists, osteopaths, chiropractors, physicians, and surgeons. Although there has been some conflicting evidence from various trials, overall it appears that manipulation accelerates the rate of recovery in recent onset back pain, although not making any long-term difference to the outcome (Twomey and Taylor 1995). There is no evidence distinguishing the effects of manipulation by the various practitioners except that manipulation under general anaesthesia carries significant risk of neurological damage to the cauda equina (Haldeman and Rubinstein 1992).

Nerve root pain

Clinical criteria

Unilateral leg pain greater than back pain with the pain radiating to the feet or toes;

there may be numbness and paraesthesias in the same distribution;

reduced straight leg raising indicating nerve irritation;

motor sensory or reflex changes limited to one nerve root.

The management of such patients is similar to simple backache but undertaken more slowly. The recovery rate is not as good. If they fail to improve within 6 weeks, they may need more detailed assessment. Such patients may require scans and may be considered for surgery.

Possible serious spinal pathology

Clinical criteria

Aged under 20 or over 55 years;

previous trauma;

constant, progressive non-mechanical pain;

gradual onset —morning stiffness, limitation of movements in all directions and peripheral joint involvement, and other features suggesting ankylosing spondylitis or related disorders;

systemically unwell;

widespread neurological signs and cauda equina syndrome;

weight loss;

significant medical history such as previous carcinoma, steroid therapy, etc.

In such circumstances the patient will require intensive and appropriate investigations.

Recurrent back pain

Many patients have recurrent episodes of back pain which may be precipitated by lifting, twisting, and bending. A detailed understanding of the structure and function of the spine and the appropriate ways to protect it in a variety of physical activities combined with simple exercises to increase physical fitness and strengthen the abdominal and paraspinal muscles seem helpful in preventing further recurrences of back problems. The role of the physiotherapist is back education and the training may be formalized as a series of lessons in a 'back school' (Andersson 1992). The results of such training programmes are at least as good and probably better than conventional physiotherapy treatments.

Chronic back pain

Many patients suffer persistent pain in the back which may spread into the lower limbs. They may become very severely and permanently disabled. Many have previously undergone one or more spinal operations. Detailed assessments are required to elucidate the pathogenesis of the pain in individual subjects and to plan a treatment programme.

Chronic back pain may be due to:

1. chronic disc herniation with persistent nerve root damage;
2. severe degenerative change in the intervertebral discs;
3. non-mechanical pathologies such as inflammatory spondylarthropathies, neoplasms, infections, Paget's disease, etc;
4. incomplete discectomy or nerve decompression;
5. recurrent or new disc prolapse;
6. scar tissue forming around the nerves, perhaps as a reaction to surgery. Retained microscopic cotton debris from the swabs and patties used at operations may be of direct relevance here (Hoyland *et al*. 1988);
7. arachnoiditis due to previous oil based myelography (Fig. 8);
8. sympathetic syndromes with referred symptoms felt in the lower limb (Sachs *et al*. 1993);
9. fibromyalgia;
10. psychological factors—these play an important part in many patients, perpetuating the chronic nature of back pain. They include depression, anxiety, and compensation factors. Operant conditioning refers to the psychological reinforcement of pain behaviour and may include not only financial benefits but also sympathy and concern expressed by relatives, friends, medical, and paramedical staff;
11. central nervous system modulation.

Assessment of the chronic back pain patient requires a very careful history and examination. The findings suggestive of a substantial non-organic component to the problem (Waddell *et al*. 1990) include:

1. pain behaviour;
2. pain reproduction on simulated movements of the spine such as pressure on the skull, rotation of the pelvis;
3. restricted straight leg raising on formal testing but unrestricted distracted straight leg raising such as being able to sit up with the lower limbs extended;
4. regional weakness or sensory disturbance in a non-neurological distribution;
5. widespread superficial tenderness over the back.

Adequate management can only be undertaken after a thorough evaluation of each individual patient. This should include a very careful review of the medical history together with physical and psychological assessments. When specific pathologies can be identified they may be amenable to the appropriate therapy. For many patients this is not possible. Forms of treatment which may be beneficial include:

1. The use of appropriate medication—pure analgesics such as paracetamol, or perhaps codeine or its derivatives, or dextropropoxyphene are adequate for most patients. For some, particularly if there is a pain pattern suggestive of a secondary vascular/fibrotic/inflammatory element with pain aggravated by rest, non-steroidal anti-inflammatory drugs could be very helpful. Muscle relaxants, such as chlormezanone and baclofen, may be helpful when there is a major element of muscle spasm. Some patients describe a neuralgic element to the pain with electric shock sensations radiating down the lower limbs. This may be relieved by antiepileptic drugs such as carbamezepine or sodium valproate. Others have widespread, superficial paraesthesiae and tenderness and may respond to tricyclic antidepressant drugs such as amitriptyline. In the spinal stenosis syndrome there is some evidence (Porter and Hibbert 1983) that calcitonin may provide relief, perhaps by altering blood flow dynamics within the vertebral column.
2. Physiotherapy and ergonomic advice—this teaches the patients how to perform tasks within their physical capabilities and helps to give them confidence.
3. Local injections may be helpful for some people. They include:
   a. Trigger point and local injections, usually of steroid and anaesthetic. Although commonly used, the evidence for their value is in doubt. Garvey *et al*. compared lignocaine alone, lignocaine plus steroid, needle insertion with no injection of material, and application of a vapour coolant spray followed by acupressure and found no differences between these treatments (Garvey *et al*. 1989).
   b. Facet joint injections. No study has demonstrated any benefit from this technique.
   c. Epidural injections. There have been a number of controlled studies with conflicting results. My opinion is that the technique is of value for the patient with radicular pain which has failed to resolve completely. Major adverse effects are rare but they are principally associated with dural puncture and intrathecal injection (Bogduk 1995).
   d. Acupuncture. Although some studies suggest that needling has advantages over control treatment, all had major methodological flaws. There do not appear to be any differences in outcome with needling in the Chinese meridians compared with misplaced needling. The TENS machines are an alternative method of providing acupuncture.
4. Acupuncture and transcutaneous electrical nerve stimulation is believed to stimulate large afferent fibres blocking pain transmission through nociceptive small fibres. Despite widespread claims that this is of value, no trial has convincing demonstrated significant advantage to these techniques.
5. Patient education. Failure to provide an explanation of the problems leads to patient dissatisfaction (Deyo and Diehl 1986). The back education programme may be structured as a back school. Although appreciated by the patients, their specific value with regard to outcome is in doubt.
6. Lumbar corsets and belts. The evidence for their efficacy is confused. Many patients come to depend on their corsets and may develop severe restriction of spine movements. My own view is that they should not be in general use.

7. Activity modification. Bed rest should be avoided in chronic back pain. Patients should be encouraged to remain active and undertake a regular exercise programme to improve physical fitness (Frost *et al*. 1995).
8. Further surgery—the results of secondary and subsequent operations tend to be poor. Further surgery should only be contemplated in patients for whom there is a very clearly defined lesion causing symptoms for which there is an adequate surgical solution.
9. Multidisciplinary functional restoration programmes—these programmes are recent developments. Detailed assessment is required. Once the patient accepts that no further specific interventions will help they should enter a programme combining intensive physical activation, counselling for the understanding of pain and related problems, reducing the use of medication and health care, and dealing with depressive symptoms and anxiety together with encouragement to return to normal activities. These programmes are time consuming and expensive but effective in improving function, return to work rates, and work retention (Burke *et al*. 1994). Mayer *et al*. were able to return 87 per cent of patients to work after such a programme in contrast to 41 per cent of controls (Mayer *et al*. 1987).

Conclusion

In recent years, there has been a major increase of interest in the back pain problem. We now have much better understanding of the mechanisms of pathogenesis of various back pain syndromes and the reasons why the problems may persist and become chronic. With this better understanding, targeted therapy appears effective and lends hope of providing better control of this problem in the future.

5.18.2 Cervical pain syndromes

Allan I. Binder

Introduction

The vast majority of patients with neck pain have degenerative or mechanical lesions. 'Cervical spondylosis' is often used to describe neck pain of a mechanical nature, but the term is variably applied to include soft tissue, disc, and degenerative bony lesions (Resnick 1985). Furthermore, the boundary between 'normal' ageing and disease is unclear. The pathology of cervical spondylosis is assumed to be identical to lumbar spondylosis, but this similarity has been questioned (Bland and Boushey 1990). Less research has been performed into cervical than lumbar pain, as severe disability is less common with cervical disease.

This chapter will concentrate on the common mechanical and degenerative pain syndromes that predominantly affect the cervical spine and the principles of their treatment. Other conditions which can cause neck pain will be considered in more detail in the relevant chapters devoted to the particular diseases.

Epidemiology

About 10 per cent of the adult population have neck pain at any one time (Lawrence 1969; Hadler 1985), with symptoms often being associated with specific occupations or sporting activities (Holt 1972). While this prevalence is similar to that of low back pain, to lose time from work is unusual, and under 1 per cent of patients develop neurological deficit. As so many patients with neck pain never seek medical care, the true prevalence of chronic disease is uncertain.

Functional anatomy of the cervical spine

The cervical spine is the most mobile and least stable part of the human spine, consisting of seven vertebrae connected by five intervertebral discs. There are 37 separate articulations (Bland and Boushey 1990), and a complex system of ligaments and muscles, which with the varying shapes of individual vertebrae, and different methods of articulation, are responsible for the myriad movements of the head and neck. Any of these structures can be the source of pain.

The vertebral arteries pass close to the zygapophyseal joints, immediately anterior to the emerging cervical nerve roots. The preganglionic sympathetic nerve fibres run closely adherent to the carotid and vertebral vessels, to synapse with the stellate, middle, and superior cervical ganglia. The postganglionic sympathetic fibres then separate into three directions: some fibres go to the upper limbs to provide autonomic control of circulation, sweating, and proprioception; other fibres re-enter the spinal cord via the intervertebral foramina to synapse in the vestibular apparatus, cerebellum, thalamus, and hypothalamus; and some fibres pass upward with the vertebral and carotid arteries to the brain (Bland and Boushey 1990). Involvement of the vertebral arteries and sympathetic nerves in the degenerative process may explain many of the unusual features associated with disease of the cervical spine.

The lack of room in the spinal canal between C4 and T2 is due to the enlargement of the cord in this region. As degenerative changes are also most frequent and severe between C5 and T1 (Hayashi *et al*. 1988), compression of the cord usually develops at this site. Inflammatory arthropathies in contrast, have a predilection for involvement of the atlantoaxial and upper cervical spine. Minor congenital spinal abnormalities increase the risk of degenerative change (Hensinger 1991), and there is a remarkable similarity in the pattern of degenerative disease in monozygous twins (Palmer *et al*. 1984), possibly reflecting the similarity in the shape of their vertebrae.

The anterior and posterior nerve roots from C4 to T1 exit through the dural root sleeves, and traverse the intervertebral foramina. They then merge to form the brachial plexus (Fig. 1), which lies between the clavicle and first rib, in close proximity to the subclavian vessels. The neurovascular bundle is susceptible to compression at various sites in the thoracic outlet, which lies between the neck and axilla. Cervical nerves have a dermatomal representation (Fig. 2), which explains the radicular pattern of symptoms in the upper limbs caused by impingement on nerve roots.

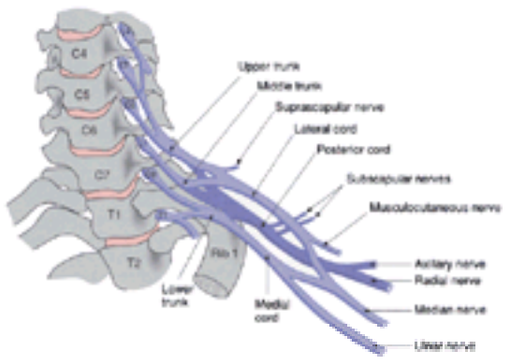

Fig. 1 Diagram showing the nerve roots (C4 to T1) forming the brachial plexus, with the peripheral nerves which arise from the plexus.

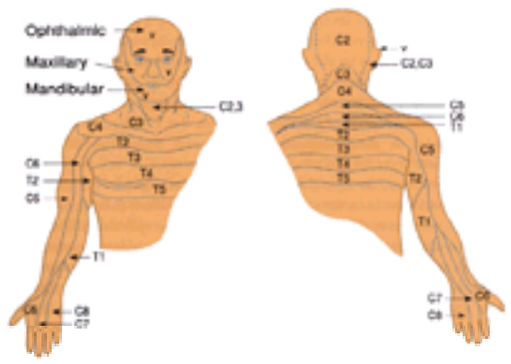

Fig. 2 Dermatomal distribution of the cervical and upper thoracic nerves which reflect the radicular pattern of nerve root lesions.

Aetiology of neck pain

Although 'cervical spondylosis' accounts for most cases of neck pain, there are many other causes of pain which need to be excluded (Table 1). The cervical spine is frequently involved in polymyalgia rheumatica, rheumatoid arthritis, and other arthropathies, and neck pain can result from serious local pathology, such as infection or malignancy. It is also often the site of referral of pain from distant sources (Table 2).

Table 1 Causes of neck pain

Acromioclavicular joint, temporomandibular joint, teeth
Heart — angina pectoris, myocardial infarction
Aorta — aneurysm
Pharynx — infection, tumour
Lung — bronchogenic carcinoma, Pancoast tumour, apical lesion
Abdomen — disease of the gallbladder, stomach, oesophagus (including hiatus hernia) and pancreas
Diaphragm — subphrenic abscess
Central nervous system — migraine, 'tension' headache, tumour, posterior fossa lesion, meningitis, arachnoiditis
Lymph node — cervical lymphadenitis
Shoulder — frozen shoulder, reflex sympathetic dystrophy

Table 2 Sites of referred pain to the neck

Cervical spondylosis

Pathology

With ageing, degenerative change usually develops in the cervical spine (Gore *et al*. 1986). This is readily apparent on radiographs of most adults over the age of 30 years. The term 'cervical spondylosis' refers to this progressive degenerative process, which affects all levels of the cervical spine (Lestini and Wiesel 1989), but with more severe changes at the lower levels (Hayashi *et al*. 1988). There is a sequential change in the intervertebral discs, with osteophytosis of the vertebral bodies and changes in the facet joints and laminal arches. There is a continuum from 'normal' ageing to the overtly pathological state. The correlation between the degree of radiological change and the presence and severity of pain is poor (Van der Donk *et al*. 1991), and hence there is disagreement on the exact definition of cervical spondylosis.

With increase in age, there is a steady decrease in the degree of hydration of the intervertebral discs. Degeneration follows and radiolucent nitrogen-filled spaces (vacuum disc phenomenon) may develop within the disc. When present, these spaces confirm the degenerative nature of the process, and are reassuring, as they exclude a diagnosis of infection (Resnick 1985). With progression of the ageing process, loss of disc height and bony sclerosis follow. Osteophytosis often then develops, with degenerative changes (osteoarthritis) in the nearby zygapophyseal joints and other articulating surfaces. Involvement of the spinal ligaments in the degenerative process can lead to a loss of stability, which is an important factor in causing myelopathy in elderly patients.

Clinical assessment

Detailed history and examination will usually confirm the degenerative nature of the condition or alert one to a need to exclude more serious pathology. Assessment of

the shoulder joints is also necessary to determine if there is coexisting shoulder pathology (Hawkins *et al*. 1990), although cervical pathology itself can cause painful limitation in the range of shoulder flexion and abduction above 90°.

Symptoms

Pain

This is the most common symptom of cervical pathology, and is usually poorly localized to the neck and shoulders when arising from deep structures, such as ligaments, muscles, joints, discs, or bone. The pain can however, be clearly defined and in a dermatomal distribution when caused by irritation of the nerve roots (Fig. 2). Pain arising from structures of the cervical spine is characteristically altered (aggravated or relieved) by their movement. The causes of neck pain are shown in Table 1.

Pain is most often referred to the occiput, nuchal muscles, and superior aspect of the shoulders. Heaviness or aching of the upper limbs also reflects cervical origin, and the pain can closely mimic soft tissue lesions of the shoulder, elbow, and wrist (Gunn and Milbrandt 1976; Murray-Leslie and Wright 1976). Retro-orbital and temporal pain suggest referral from the upper cervical levels (C1 to C3). Temporal pain when associated with tenderness can be misinterpreted as evidence of giant-cell arteritis. Pain can also be referred to the upper thoracic spine and interscapular areas. Some patients, especially with lesions of C6 and C7 complain of anterior chest pain, which closely mimics coronary ischaemia (Brodsky 1985). Pseudoangina of this type is sometimes associated with local tenderness of the chest wall. There is particular diagnostic difficulty in patients with a combination of both coronary insufficiency and cervical spondylosis, as anginal pain is more likely to radiate to the neck in patients with symptomatic cervical spondylosis. Coronary angiography is the key investigation in the assessment of the severity of the cardiac lesion in these cases.

Stiffness

This is a common accompaniment of ageing, degeneration, and many vertebral diseases, and can be reversible or irreversible.

Dizziness

This may occur as a result of involvement of the vertebral arteries, especially in the presence of severe degenerative spinal disease. Atheroma and disturbance of flow in the vertebral vessels may contribute to the development of dizziness in older patients. Vertigo and faintness caused by vertebrobasilar disease is nearly always accompanied by other focal symptoms of transient ischaemia of the brainstem or occipital lobes. In some patients with cervical pathology, tinnitus and gait disturbance (Sudarsky and Ronthal 1983) can occur, as a result of irritation of the sympathetic nerves.

Occipital headache

This is a common manifestation of cervical degenerative disease, especially when the disease affects the upper cervical levels. Occipital neuralgia is another cause of occipital pain in some patients. Edmeads (1988) discussed the controversy over the importance of disease of the cervical spine in the aetiology of non-occipital headache; Wober-Bingol *et al*. (1992) found no link, but Nagasawa *et al*. (1993) found a strong association.

Blurring of vision and diplopia

These symptoms, where associated with neck movement can result from cervical pathology, and have been attributed to irritation of the sympathetic nerve supply to the eye.

Dysphagia

This can be caused by irritation of the cranial or sympathetic nerves, muscular spasm, or compression of the oesophagus by large anterior osteophytes (Sobol and Rigual 1984).

Paraesthesia and sensory loss

Numbness and tingling is usually vague and ill-defined in cervical spondylosis, but can be precise, following the clear segmental dermatomal distribution of nerve entrapment (see Radiculopathy below). The symptoms are often affected by neck movement, or are postural, being worse at night or with specific activities. Lesions of C1 to C3 can cause paraesthesia affecting the face, head, and tongue. Involvement of the C4 root gives symptoms referred to the superior aspect of the shoulder, and C5 to T1 lesions give numbness in the upper limb (see Fig. 2).

Weakness

Mechanical disease of the cervical spine most typically gives a subjective feeling of heaviness or weakness, especially affecting the hands, but without true weakness on formal testing. Objective muscle weakness, wasting, and fasciculation in the absence of systemic upset suggests a radiculopathy, thoracic-outlet syndrome, or neuropathy of the brachial plexus. Abnormality of gait due to spasticity of the lower limbs suggests myelopathy.

Rare manifestations

Unusual features sometimes resulting from pathology of the cervical spine are shown in Table 3. Most of these symptoms result from irritation of the sympathetic nerves, but the clue to their vertebral origin is reproducibility with neck movement.

Visual—blurring, diplopia, retro-orbital pain
Auditory—tinnitus, nerve dealness, earache, poor balance
Intestinal—dysphagia, nausea, vomiting, diarrhoea
Cardiac—'pseudoangina', dyspnoea, palpitations
Respiratory—cough, dyspnoea, sneezing
Central nervous system—syncope, 'drop attacks', vertebro-basilar insufficiency, speech disturbance, migraine

Table 3 Rarer symptoms arising from cervical spine pathology

Signs

Tenderness

When due to degenerative disease, tenderness is poorly localized and of variable severity. It is usually worse in the lower cervical region, and may be associated with muscle spasm. Tender myofascial trigger points are a characteristic feature of the 'fibrositis/fibromyalgia' syndrome (Smythe 1986), but also occur with disease of the facet joints. Exquisite localized tenderness over a vertebral body may suggest osteomyelitis or malignancy, particularly if the patient has features of systemic upset or

abnormality of blood tests such as full blood count, erythrocyte sedimentation rate, C-reactive protein, or protein electrophoresis.

Limitation of movement

This is a feature of ageing and degeneration and may be otherwise asymptomatic or accompanied by pain. Severe irreversible loss of range particularly on lateral flexion and rotation occurs with cervical spondylosis, but is more characteristic of the spondylarthropathies and diffuse idiopathic skeletal hyperostosis (**DISH**). Reversible stiffness, worse in the early morning, is more suggestive of polymyalgia rheumatica or an inflammatory arthropathy than of a degenerative lesion.

Neurological deficit

Neurological abnormalities are characteristic of radiculopathy, but also occurs in thoracic-outlet syndromes and neuropathy of the brachial plexus (see below).

Radiological assessment (see also Chapter 4.9.1)

Routine radiographs of the anteroposterior and lateral spine are sufficient to indicate the severity of bone and disc pathology. A through-mouth view to outline the odontoid peg, when combined with flexion/extension radiographs, will demonstrate existing subluxation. Oblique views of the cervical spine will show the intervertebral foramina, and are useful in patients suspected of having a radiculopathy (Fig. 3). Loss of cervical lordosis on the lateral radiograph in patients with neck pain is usually ascribed to muscle spasm, but this association has been questioned (Helliwell *et al*. 1994).

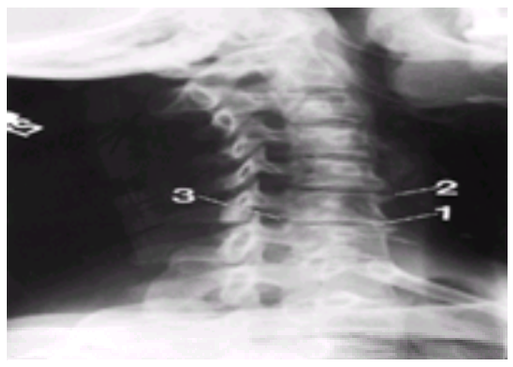

Fig. 3 Oblique radiograph of the cervical spine in a patient with cervical spondylosis, showing the loss of disc height (1), anterior osteophytosis (2), and foraminal narrowing (3).

Myelography, computed tomography (**CT**), and CT-myelography, have greatly improved the radiological assessment of cervical disease, especially at the upper cervical levels, which are hard to visualize on routine radiographs.

Magnetic resonance imaging (**MRI**) is less invasive and equally reliable as CT-myelography for the visualization of cervical abnormalities (Nagata *et al*. 1990), and is the radiological investigation of choice (Kramer *et al*. 1991), giving detailed information about the spinal cord, bones, discs, and soft tissue structures (Fig. 4 and Fig. 5). MRI is particularly valuable in demonstrating congenital abnormalities, cord tumours, demyelination, and disc lesions. Degenerative vertebral changes are well demonstrated, but as they occur normally with ageing, need to be interpreted with care. Asymptomatic people often show important pathological lesions, such as narrowing of the disc space, osteophytosis, or even compression of the spinal cord (Boden *et al*. 1990), and the frequency of abnormal scans in asymptomatic people increases with age. Boden *et al*. (1990) and Lehto *et al*. (1994) have emphasized that decisions about surgery should be based on clinical indications with the support of the MRI findings, and not on radiological data alone. Similar false-positive studies have been described with plain radiography, CT (Wiesel *et al*. 1984), and all other radiological techniques.

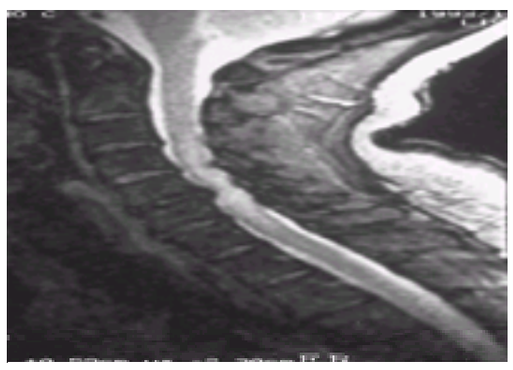

Fig. 4 MRI scan showing loss of height and signal affecting several discs, with multisegmental spondylotic bars. Compression of the cord is noted by protrusion of the C5/6 disc with myelopathic changes in the cord.

Fig. 5 MRI scan showing a cervical disc prolapse at C4/5 with impingement upon the cervical cord and secondary myelopathic changes in the cord itself.

Electrodiagnostic studies

Electromyography, nerve conduction studies, and somatosensory evoked potentials may help in the elucidation of the diagnosis, especially where primary neurological disease or polymyositis need to be differentiated from radiculopathy or myelopathy secondary to degenerative vertebral disease (Dvorak *et al*. 1990). Specific neurophysiological findings have been described in cervical spondylosis associated with myelopathy or radiculopathy (Yiannikas *et al*. 1986), but there is no consensus as to their reliability or diagnostic value, particularly in uncomplicated cervical spondylosis. Magnetic stimulation of the motor cortex (Di Lazzaro *et al*. 1992) and spinal cord evoked potentials (Baba *et al*. 1993a) have more value in the assessment of myelopathic patients, but at best, the electrodiagnostic techniques

only provide supportive evidence to clinical and radiological findings.

Other tests

Other tests such as full blood count, erythrocyte sedimentation rate, C-reactive protein, protein electrophoresis, liver function tests, urate, rheumatoid factor, and bone scan may be necessary to exclude other causes of neck pain (Table 1 and Table 2).

Complications of cervical spondylosis

Cervical myelopathy

The relatively tight fit of the spinal cord in the lower cervical region, as a result of the natural expansion of the cervical cord, accounts for an increased risk of development of a myelopathy at this site.

Myelopathy can develop *de novo*, or can occur in patients with known cervical spondylosis, particularly in the presence of a congenitally narrow spinal canal (Fukui *et al*. 1990). With progressive degeneration and resulting osteophytosis and instability, pressure on the spinal cord can develop.

In elderly patients, myelopathy can result from compression of the spinal cord, disturbed blood supply, or a combination of both factors. Disc protrusion, posterior osteophyte formation, and retrolisthesis (posterior slide) due to ligamentous laxity, contribute to age-associated spondylotic spinal compression (Hayashi *et al*. 1988). Even when the static spinal canal diameter is adequate, many elderly patients show significant and progressive 'dynamic' spinal stenosis (Hayashi *et al*. 1988; Fukui *et al*. 1990), which can be demonstrated (Jinkins *et al*. 1986) by a comparison of flexion and extension CT or MRI scans.

In young patients, a sudden onset of myelopathy or radiculopathy suggests cervical disc prolapse (see below). Cervical myelopathy can also result from vertebral diseases such as osteomyelitis, malignancy, and crystal arthropathy, and intramedullary disease can present with similar symptoms (Table 4.)

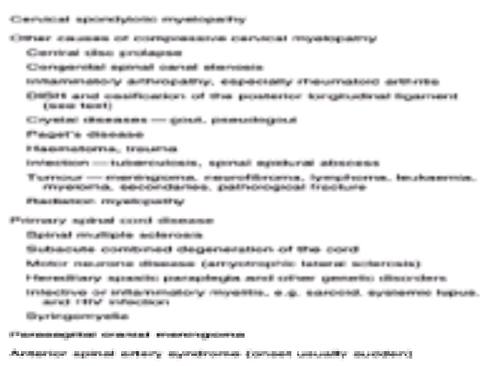

Table 4 Differential diagnosis of cervical myelopathy

Cervical myelopathy typically presents with a slowly progressive disability over a period of weeks or months, although the onset can be sudden, especially when caused by trauma or central disc prolapse. The most common, early manifestations of myelopathy are clumsiness, weakness or dysaesthesia of the hands, or gait disturbance due to upper motor-neurone abnormality in the lower limbs.

Numbness or tingling in the hands is poorly localized, unless radiculopathy is also present. There is usually no gross sensory deficit, but blunting of light touch, pin-prick, and temperature sensation can occur. Stereoanaesthesia, and isolated loss of position sense in the hands, is also sometimes seen, particularly in high cervical lesions. Clumsiness or weakness of the hands may rarely be associated with variable degrees of wasting and evidence of lower motor-neurone abnormality at the level of the lesion. Characteristic features in the legs are of a spastic paraparesis, and in elderly patients, undiagnosed cervical myelopathy is an important case of gait disturbance (Sudarsky and Ronthal 1983).

Tendon reflexes are often reduced in the arms and increased in the legs with up-going plantar responses and ankle clonus, although the balance is dependent on the level of the lesion. Inversion of the supinator jerk (reduced or absent supinator reflex with brisk finger flexion when tapping over the lower radius), with a brisk triceps jerk, suggests involvement of the spinal cord at the C5/6 level. A brisk finger-flexion reflex (on tapping the examiner's own fingers when placed over the flexor surface of the terminal phalanges), and a positive Hoffman's sign (brisk thumb flexion when the distal phalanx of the middle finger is flicked into extension) also suggests hyperreflexia. Sphincter control is usually well maintained in cervical myelopathy complicating cervical spondylosis.

Neck pain may not be a prominent feature of myelopathy, and when present, its mechanism of production is complex and poorly understood. The cervical lesion is often multisegmental (Fig. 4), and in some cases there is a large discrepancy between the sensory level on clinical examination and the true level of cord compression (Simmons *et al*. 1986).

Shooting electric pain down the spine, arms, or legs, or temporary neurological deficit when the head is flexed (Lhermitte phenomenon) may be mentioned by the patient. Great caution (and prior radiography) is necessary when attempting to confirm the presence of this sign, as permanent deterioration in the neurological condition may follow its performance. Lhermitte phenomenon is usually a sign of cervical myelopathy of an inflammatory type (typically multiple sclerosis), but can be due to compressive, or rarely other (e.g. vitamin B_{12} deficiency) causes.

MRI (Fig. 4) is the investigation of choice in patients with suspected myelopathy (Kramer *et al*. 1991; Okada *et al*. 1994), although CT-myelography also has value. The anteroposterior or sagittal diameter of the canal on radiological investigation is a useful indicator of possible myelopathy, and compression of the cord is likely if the diameter at any level is 10 mm or less (Murone 1974). With a diameter above 13 mm, compressive symptoms rarely occur solely on the basis of degenerative disease. Atrophy of the spinal cord on CT-myelography (Jinkins *et al*. 1986), or intrinsic spinal cord damage on MRI (Fig. 4), especially after myelopathic decompression (Nagata *et al*. 1990; Batzdorf and Flannigan 1991; Matsuda *et al*. 1991) are associated with a less favourable outcome.

The most sensitive neurophysiological investigation in the assessment of patients with cervical myelopathy is somatosensory evoked potentials, especially when done in both upper and lower limbs (Yiannikas *et al*. 1986). However, these tests rarely add much to the evaluation, particularly in difficult cases.

Cervical radiculopathy

Nerve root compression as a result of cervical spondylosis usually occurs at the C5 to C7 level with lesions being single or multiple, and uni- or bilateral.

Acute radiculopathy in the young usually follows trauma or lateral prolapse of a disc. In middle-aged and elderly patients, asymptomatic osteophytic encroachment gradually narrows the nerve root foramina until trivial trauma is sufficient to precipitate acute or subacute radiculopathy. Chronic radiculopathy may arise insidiously, or may follow the more acute syndromes. As chronic radicular syndromes are usually due to degenerative disease, they can be associated with myelopathy.

Neurological features follow a segmental distribution in the upper limb (see Fig. 2). Sensory symptoms such as shooting pain, paraesthesia, and hyperaesthesia are more common than motor weakness or a change in the reflexes. Arm weakness, when present, is of a lower motor-neurone type, and may be accompanied by a loss of reflex (biceps and supinator jerk in C5/6 lesions; triceps jerk in C7 lesions).

Radicular pain can be exacerbated by manoeuvres that stretch the affected root, or by an increase in intrathoracic or intra-abdominal pressure, as occurs with coughing, sneezing, or the Valsalva manoeuvre. If sustained shoulder abduction induces a temporary relief in radicular pain, a C6 lesion can be expected (Fast *et al*.

1989). This test has value both diagnostically and as part of a conservative treatment regimen (Farmer and Wisneski 1994).

Oblique cervical radiographs often demonstrate narrowing of the nerve root foramina (Fig. 3) in patients with radiculopathy (Pyhtinen and Laitinen 1993). Electromyography may show abnormalities in patients with clinical signs of root compression, and additional information can sometimes be obtained from studying superficial radial sensory-evoked potentials. However, these techniques are of limited value where symptoms of radiculopathy occur without objective signs (Yiannikas *et al*. 1986).

Cervical radiculopathy (Table 5) can rarely be caused by malignant tumours, such as Pancoast tumour (Vargo and Flood 1990), or nasopharyngeal malignancies, particularly when accompanied by bony infiltration. There is often difficulty in differentiating cervical spondylosis with myelopathy or radiculopathy from primary neurological diseases, such as syringomyelia, motor neurone disease (amyotrophic lateral sclerosis), or tumour, particularly when unrelated osteoarthrosis of the cervical spine coexists (see Table 4 and Table 5).

Cervical spondylotic radiculopathy
Other causes of compressive cervical radiculopathy
Lateral disc prolapse
Inflammatory arthropathy, e.g. rheumatoid arthritis
Trauma, haematoma
Arachnoiditis
Infection
DISH and ossification of the posterior longitudinal ligament (see text)
Tumour—primary, secondary, Pancoast tumour of lung
Brachial plexus and thoracic-outlet syndromes
Peripheral nerve and 'double-crush' syndromes
Complete rotator-cuff tear and reflex sympathetic dystrophy
Motor neurone disease and other primary spinal cord diseases (see Table 4)

Table 5 Differential diagnosis of cervical radiculopathy

Other important mechanical pain syndromes

Cervical disc prolapse

Herniation of a cervical disc is a common cause of neck, shoulder, and arm pain in the younger patient. It typically presents as a sudden onset of neck pain with associated muscle spasm, followed by radicular symptoms and signs in the upper limb. It may follow trivial trauma or awkward movements of the neck, but in many cases there is no obvious cause. Some patients give a history of preceding mechanical cervical pain, and manipulation or chiropractic therapy can precipitate the acute disc prolapse. The lesions almost always affect the lower cervical levels.

Lateral disc protrusion, which is more common, results in radiculopathy affecting the C7 root in 70 per cent of cases, the C6 root in 20 per cent, and the C5 or C8 roots in the remaining 10 per cent of cases (Yoss *et al*. 1957). The site of pain and the neurological features depend on the level of the lesion (Smythe 1994; Nakajima and Hirayama 1995), but the syndromes are often incomplete. Limitation of cervical range is usual, and pain can be aggravated by movement (especially hyperextension), coughing, and sneezing, and relieved by traction on the neck.

Central disc prolapse, if large, causes myelopathy (Fig. 5), and when painless may simulate degenerative syndromes of the spinal cord, such as motor neurone disease or multiple sclerosis (see Table 4). MRI (Vanderburgh and Kelly 1993) or CT-myelography are essential to differentiate disc prolapse or other causes of compressive myelopathy from intrinsic disease of the spinal cord, even when the latter is considered more likely.

Disc prolapse is much less common in the thoracic spine and is difficult to diagnose clinically, unless myelopathy or radiculopathy intervene.

Diffuse idiopathic skeletal hyperostosis (DISH, Forestier's disease, ankylosing hyperostosis)

This common disorder of unknown aetiology is most often diagnosed in middle-aged or elderly white males, who show an ossifying diathesis. Patients develop flowing ossification along the anterior and lateral aspects of the spine, bridging between vertebrae, but with preservation of normal disc heights. The condition affects the thoracic spine most severely, but can also occur in the cervical and lumbar regions. The lesions start at the ligamentous insertions (entheses), with progression of the flowing osteophytes along the ligaments. Similar ossification is also found at entheses along the pelvis and other parts of the skeleton.

Severe limitation of cervical spine movement usually develops without any other symptoms (Boachie-Adjei and Bullough 1987). However, some patients present with pain, myelopathy, and less commonly, radiculopathy. Large anterior osteophytes in the cervical region can also cause dysphagia owing to oesophageal obstruction. If anterior osteophytes due to cervical spondylosis or DISH are suspected as the cause of the dysphagia, barium swallow is the preferred method of initial assessment, as endoscopy carries some risk of inadvertent oesophageal perforation (Kristensen *et al*. 1988). The ossification progresses more rapidly at mobile compared with immobile segments (Suzuki *et al*. 1991).

Ossification of the posterior longitudinal ligament

This is probably a variant of DISH (Hukuda *et al*. 1983), or is closely associated with it (Resnick *et al*. 1978). It is most frequently found in Japanese or other Asian patients, but is occasionally found in all ethnic groups. Like DISH, it occurs most often in middle-aged and elderly males, with a majority of cases producing no symptoms. However, in association with congenital and degenerative vertebral abnormalities, even trivial trauma can precipitate cervical myelopathy or radiculopathy. The ossification can be difficult to detect on plain radiographs, and both MRI (Otake *et al*. 1992; Baba *et al*. 1995) and CT scanning have value where the diagnosis is suspected. Calcification of the ligamentum flavum and posterior longitudinal ligament can also result from calcium pyrophosphate crystal deposition (pseudogout), confirmed on biopsy in patients having surgery for compressive myelopathy (Brown *et al*. 1991; Baba *et al*. 1993b).

Soft tissue syndromes considered to be 'mechanical'

Spasm, postural, and anxiety/tension-related neck pain

Most adults suffer transient neck pain and stiffness, which is attributed to awkward posture of the neck, especially during sleep. The pathology is uncertain and the condition is self-limiting within days. Occupations and hobbies which involve heavy lifting or unusual positions of the neck are a cause of recurrent pain of this type. Anxiety and tension can manifest as episodic or chronic neck pain in susceptible individuals. Poor posture of the cervical and thoracic spine (Griegel-Morris *et al*. 1992), which can cause muscle spasm, and hence traction on the nerve roots, may explain these symptoms. The interaction between cervical spondylosis, tension, and the fibrositis/pain-amplification syndrome needs further clarification.

'Fibrositis/fibromyalgia' and pain-amplification syndrome (see also Chapter 5.14)

'Fibrositis' is a term that has been used for many decades to describe non-specific neck pain. Smythe (1986) defined the diagnosis more precisely, describing a pain-amplification syndrome associated with localized points of myofascial tenderness. This can be confined to the cervical spine (fibrositis), or can be more generalized (fibromyalgia), with the tender points concentrated around the entheses. Patients localize the pain to the posterior and lateral regions of the neck with associated stiffness. Tenderness is noted most specifically anterior to the transverse processes in the lower cervical spine. Sleep disturbance and fatiguability have been described in some cases. There is greater agreement on diagnostic features with the adoption of the American College of Rheumatology Fibromyalgia Classification Criteria (Wolfe *et al*. 1990).

Neck pain associated with tender trigger points is also found as a stress-related phenomenon (Croft *et al*. 1994; Wolfe *et al*. 1995). Poor posture, underlying vertebral degeneration, especially of the facet joints, and pain amplification may be important elements contributing to the severity of pain in these cases. Pain amplification may also explain the disproportionately severe pain in some patients with rheumatoid arthritis and other inflammatory arthropathies. Treatment of fibromyalgia is disappointing (Simms 1994; Wilke 1995), and the level of disability is often similar to rheumatoid arthritis (Martinez *et al*. 1995).

'Whiplash syndrome'

Acute flexion–extension injuries, typically in automobile accidents following rear-end impact, can cause acute neck pain (whiplash injury), even in the absence of bony damage. More severe symptoms are associated with an unprepared occupant, acceleration/deceleration injury, and a rotated or inclined head position (Sturzenegger *et al*. 1994). Although seat belts have reduced the incidence of severe injuries, the frequency of whiplash-type lesions has continued to rise (Bourbeau *et al*. 1993; Galasko *et al*. 1993), often leading to considerable and prolonged disability, complicated by medicolegal difficulties.

Severe cervical pain, spasm, loss of range, and occipital headache, are the most common symptoms, but many patients also complain of widely radiating pain, headache, vertigo, memory loss, poor concentration, fatigue, or neurological symptoms in the upper limbs (Radanov *et al*. 1992). Very occasionally, temporary or permanent quadriplegia may ensue.

The pathology of the condition is unclear, but soft tissue damage, bleeding into the muscles, and zygapophysial joint injury (Barnsley *et al*. 1995) may explain the acute pain and spasm. Traction and microinjury of the cord, and acceleration/deceleration injury to the brain may be responsible for some of the other symptoms. The presence of cervical spondylosis adds to the risks of damage to the spinal cord or emerging nerve roots. Despite the frequency of whiplash injury, there is no objective investigation which if carried out early on, can define the site and severity of the damage and so predict outcome. Technetium isotope scanning (Barton *et al*. 1993), CT (Antinnes *et al*. 1994), and MRI (Jonsson *et al*. 1994; Pettersson *et al*. 1994) are useful in some cases of whiplash, although the correlation with clinical symptoms and signs is often poor.

The management of whiplash immediately after the injury, remains controversial. Rest in a collar is usually advocated, with physiotherapy (see below) being started as soon as the acute spasm has settled. Mealy *et al*. (1986) found significantly better recovery with early active mobilization, and McKinney *et al*. (1989) found similar benefits from a regimen of early exercise at home. However, Pennie and Agambar (1990) were unable to confirm any benefits of early active treatment for whiplash injury in a large series of patients.

Patients need to be warned that recovery may take 18 months or longer. Maimaris *et al*. (1988) and Evans (1992) found a poor outcome to be associated with older age, occipital headache, neck stiffness, referred symptoms, abnormal neurological signs, degenerative changes on radiographs, and symptoms persisting for more than 2 months. Psychosocial factors and personality traits were less important than the physical factors (reflecting severity) mentioned above, in predicting outcome (Radanov *et al*. 1994), and the settlement of litigation was not always associated with rapid recovery (Parmar and Raymakers 1993). Maimaris *et al*. (1988) reported that a third of their patients were symptomatic beyond 2 years, and Watkinson *et al*. (1991) found some symptoms in 86 per cent and intrusive symptoms in 23 per cent of patients reviewed at an average follow-up of 10.8 years. It is uncertain if whiplash injury accelerates the progression of degenerative change in affected patients (Hamer *et al*. 1993), but a point is reached where physical therapy should be stopped, as it is unlikely to result in any further improvement (Hirsch *et al*. 1988).

Treatment of mechanical cervical disease

Most mechanical neck pain is responsive to conservative therapeutic regimens, although surgical intervention is sometimes necessary. Box 1 summarizes the principles of therapy and timing of MRI scanning in patients with uncomplicated acute and chronic mechanical cervical syndromes and those with neurological complications.

Bedrest

This is only necessary in acute lesions, especially with neurological deficit, such as a prolapsed cervical disc, trauma, or when there is a suspicion of infection or malignancy. A hard collar is advisable in these cases, and patients should be watched carefully for a deterioration in neurological status, when urgent neurosurgical intervention may be necessary.

Physiotherapy

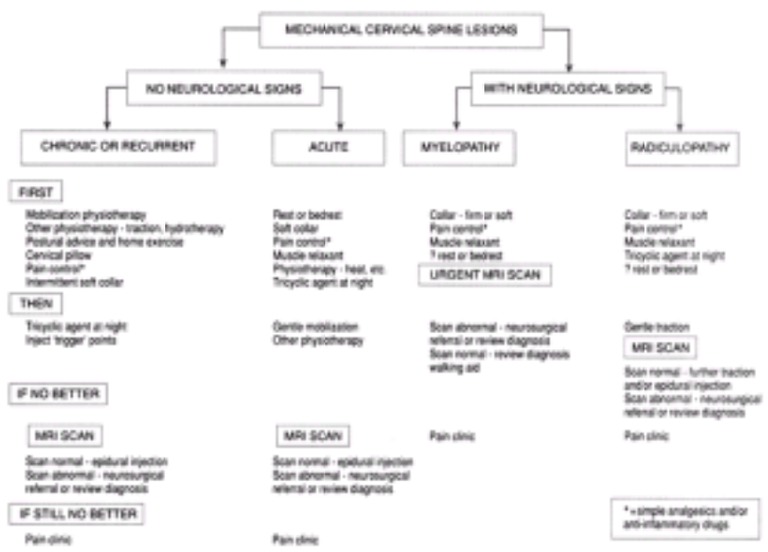
This is the mainstay of treatment of chronic cervical syndromes, and needs to stress the improvement in muscle strength and range of movement, using passive mobilization techniques. Other electrical modalities of treatment may help by giving symptomatic relief to patients, especially where mobilization physiotherapy is contraindicated. Advise on posture and relaxation (such as the Alexander technique), weight reduction, and a home exercise programme are also likely to be beneficial. The avoidance of awkward head positions and lifting heavy weights, especially in occupational or recreational activities, may also prove of value. Dizziness, when due to cervical causes, usually proves unresponsive to physiotherapy and is often a limiting factor to this type of treatment. Transcutaneous electrical nerve stimulation and acupuncture can help reduce pain in some patients. Manipulation by chiropractors is often beneficial (Cassidy *et al*. 1992), but can prove hazardous, especially when radiological examination is not undertaken before treatment (Raskind and North 1990). Dissection of the vertebral arteries and vertebrobasilar strokes (Frisoni and Anzola 1991) are well-recognized complications, for example.

Cervical traction is particularly valuable in patients with radiculopathy, but may also be beneficial in other patients with cervical pathology. It can be used in continuous or intermittent regimens, but whichever regimen is used, great care is necessary, as some patients fail to tolerate this form of treatment or show neurological deterioration as the weight is applied.

Soft collar and cervical or soft pillow

A soft collar can be worn during periods of increased pain, and is especially valuable to facilitate sleep when this is disturbed by pain. Special pillows are also available to provide support for the neck during sleep, although some clinicians prefer to recommend a soft pillow that can be moulded into the appropriate shape to support the neck. Patients should be discouraged from using more than one or two pillows, to prevent undue angulation of the neck which can precipitate symptoms at night and on waking.

Box 1 Principles of treatment of mechanical cervical syndromes and timing of MRI scanning



Drugs

Analgesic tablets should be used during periods of increased pain, but anti-inflammatory and muscle relaxant drugs are only justified in acute situations where pain is particularly severe. Low-dose amitryptiline (10 to 75 mg at night) may alter the pain amplification cycle noted in some patients.

Cervical epidural injection

The injection of depot steroids into the cervical epidural space can maximize pain control in patients in whom serious underlying pathology, such as infection or tumour, or gross neurological deficit have been excluded (Rowlingson and Kirschenbaum 1986). Epidural injections often produce long-lasting improvement in cervical degenerative lesions (Cicala *et al*. 1989), especially in patients with radicular pain (Ferrante *et al*. 1993; Castagnera *et al*. 1994). The injection of local steroid alone, or in combination with local anaesthetic agents, into painful 'trigger' points or near painful facet joints or impinged nerve roots, may also relieve pain and spasm in some cases, although this is less effective than the epidural route (Stav *et al*. 1993).

Surgery

Neurosurgical intervention is only necessary in patients with progressive cervical myelopathy, or rarely with radiculopathy or intractable pain. Even with a prolapsed cervical disc, most patients will recover spontaneously or with conservative measures. Unlike prolapse of a lumbar disc, herniation of a cervical disc is associated with a slower rate of recovery that is more difficult to document with objective measurements. With cervical myelopathy due to degenerative disease, the result of decompressive surgery is often disappointing (Yonenobu *et al*. 1986; Rowland 1992). The rate of progression of the neurological deficit may be slowed by the surgery, but the lost function may not recover. This poor outcome reflects the irreversible nature of the damage to the spinal cord (see Fig. 4 and Fig. 5) and also the compromised vascular supply to the cord in some cases. Some patients show a good initial recovery following surgery, but with relapse some time later (Goto *et al*. 1993). This relapse may reflect recurrence of the original pathology, or scar tissue related to surgery at the site of the initial operation. The likely benefits of further surgery are based on detailed reinvestigation by radiological and other means.

In principle, surgical intervention can be achieved via the anterior and/or posterior routes, with the operative procedure being individually selected on the basis of detailed clinical and radiological assessment. In cases of myelopathy, a multisegmental operation is often necessary to obtain satisfactory results. This multisegmental approach is particularly important where neurological abnormality is associated with DISH or ossification of the posterior longitudinal ligament (Epstein 1993) that have been unresponsive to conservative therapy.

Although many operations using the anterior or posterior approach have been advocated for cervical myelopathy, they are all based on the principles of fusion to prevent excessive motion (especially if only one or two levels are involved), and decompression by laminectomy, laminoplasty, or discectomy.

Surgery is less often necessary for cervical radiculopathy. The principles of treatment are similar to those for myelopathy (Chesnut *et al*. 1992), but decompression can be achieved by foraminotomy and/or partial discectomy.

Pain clinic

Where physical approaches to therapy have been exhausted, the multidisciplinary approach of the pain clinic may assist the patient in learning to cope with the chronic pain. This approach is more often required for low back-pain syndromes, where serious and prolonged disability is more likely.

Neck pain, shoulder pain, and soft tissue lesions in the upper limb

Patients with cervical spondylosis often complain of shoulder pain, and it is important to differentiate neck pain referred to the shoulder (usually the superior aspect) from primary conditions of the shoulder. Many patients have features that suggest both cervical and shoulder lesions, and these can be difficult to separate (Hawkins *et al*. 1990). Treatment may need to be directed at both sites.

The 'double crush' syndrome refers to a combination of both cervical radiculopathy and a peripheral nerve entrapment lesion. The most common peripheral lesion is carpal tunnel syndrome, although the ulnar and radial nerves can also be affected. Elucidation of the peripheral lesion is usually possible using electromyography and nerve conduction studies. Somatosensory evoked potentials and electromyographic sampling of the more proximal muscles may provide evidence of cervical radiculopathy or plexus lesions in addition to the peripheral lesion. Surgical intervention should be directed at the peripheral entrapment lesion before the cervical lesion.

Cervical spondylosis can also mimic epicondylitis and other localized soft tissue lesions in the upper limbs (Gunn and Milbrandt 1976), and there is a well-documented association between cervical spondylosis and these soft tissue lesions (Murray-Leslie and Wright 1976).

Referred pain syndromes

Where appropriate, examination for polymyalgia rheumatica, reflex sympathetic dystrophy, inflammatory arthropathy, infection, malignancy, and even crystal arthropathies may be necessary. Table 2 above shows the sites of origin, and the more common causes of pain referred to the cervical region.

Brachial plexus lesions

Pain of brachial plexus origin is felt in the neck, shoulder, forearm, or hand. Supraclavicular pain is common and may be accompanied by local tenderness, and bony (cervical rib), or pulsatile (aneurysm) swelling at this site. The pain can often be induced by certain manoeuvres or changes in the position of the arm (see below). Table 6 shows the causes of brachial plexus injury.

Trauma — birth and motorcycle injury, surgery, cannulas, or needles
Thoracic-outlet syndrome — e.g. cervical rib
Traction — surgery, e.g. medial sternotomy, rucksack palsy, postanaesthesia
Brachial plexus neuropathy (brachial neuritis):
Infection — viral, bacterial
Toxins — heroin
Injection of foreign serum or vaccine
Systemic illness — lupus, vasculitis, Hodgkin's disease
Familial brachial plexus neuropathy
Idiopathic
Radiotherapy
Tumour — especially Pancoast tumour of lung, breast
Lightning, electric shock

Table 6 Causes of brachial plexus lesions

Thoracic-outlet obstruction

Compression of the distal nerve roots, brachial plexus, subclavian vessels, or the combined neurovascular bundle can occur at various sites between the neck and the axilla (the thoracic outlet). Possible contributing factors are shown in Table 7. 'Cervical ribs', which vary from simple exostoses of the transverse processes of C7 to fully formed extra ribs, are the most common cause of the thoracic-outlet syndrome. As 0.5 per cent of the population have bilateral cervical ribs yet less than 10 per cent ever get symptoms, other factors (Liu *et al*. 1995) must also be important in symptomatic cases. Poor posture and sagging or droopy shoulders (Swift and

Nichols 1984) have been identified as important factors in the development of symptoms, especially in females of early or middle age, in whom the syndrome is most often diagnosed.

Cervical rib
Congenital fibromuscular bands
Congenital abnormality of clavicle or first rib
Interscalenus muscle hypertrophy
Clavipectoral lesions — the 'hyperabduction syndrome'
Old fracture of the first rib or clavicle
Vascular disorders and hyperviscosity syndromes
External compression, e.g. heavy weights, rucksack lesions
Poor posture, sagging or droopy shoulders
Excessive muscle development around shoulders

Table 7 Contributing factors to thoracic-outlet syndrome

The typical symptoms of thoracic-outlet obstruction vary according to the site of compression of the neurovascular bundle (Novak *et al*. 1993). Pain is usually present in the neck, shoulder, or upper arm. Vasomotor abnormalities such as numbness, paraesthesia, coldness, colour change, or Raynaud's phenomenon are characteristic of the lesion and may dominate the picture. Compression of the lower levels of the brachial plexus result in neurological features such as sensory loss in the C8 and T1 dermatomes, with paraesthesia, or weakness in the hand. Some patients show well-defined syndromes due to selective compression of the subclavian vein, artery, or brachial plexus (Wilbourn 1993).

Obliteration of the radial or brachial pulse may be noted, either when the patient takes and holds a full breath with the head tilted back or rotated laterally (Adson Test), or when the arm is abducted and externally rotated while the shoulders are braced (Wright's manoeuvre). Both tests can be noted with thoracic-outlet syndrome, but are not reliable indicators of this condition.

Ten per cent of patients develop serious vascular complications, which can be venous or arterial (Hawkes 1986). Thrombosis of the axillosubclavian vein can present acutely or chronically, sometimes following prolonged exercise. Typical features are pain and swelling of the arm aggravated by exercise, with the diagnosis being confirmed by venography. Compression of the subclavian artery can be followed by post-stenotic dilatation, aneurysm formation, and retrograde thromboembolic phenomena. Claudication, vasomotor phenomena, digital gangrene, and acute limb-threatening ischaemia can occur. Arteriography, and in some cases Doppler ultrasonography are necessary to confirm the arterial abnormality.

Thoracic-outlet syndrome may be difficult to show objectively (Novak *et al*. 1993), and few patients have the diagnosis confirmed (Wilbourn 1993). Radiographs of the cervical spine may demonstrate cervical ribs, congenital bony abnormalities, or old fractures. MRI can also define soft tissue bands and other lesions causing distortion or deviation of nerves and blood vessels in the thoracic-outlet (Panegyres *et al*. 1993). Electromyography and somatosensory evoked potentials may offer some supportive evidence to confirm the diagnosis, or exclude lesions such as cervical radiculopathy, carpal tunnel syndrome, or ulnar neuropathy, which can closely mimic this syndrome. Arteriography and venography are necessary in difficult cases, especially with vascular complications.

Conservative treatment (Walsh 1994) with shoulder-girdle exercises and improved posture often fails to remove all the symptoms, but is all that should be advocated for mild disease, especially where the diagnosis remains in doubt.

Surgical intervention, which is often unsuccessful (Urschel and Razzuk 1986) and carries considerable risks (Marinoni *et al*. 1987), should be avoided (Wilbourn 1991), except in patients with serious vascular or other complications, or in severe cases of proven thoracic-outlet syndrome.

Surgery can be carried out via the supraclavicular or transaxillary routes, or via a combination of both. Operations advocated include resection of the first rib (Martin 1993), resection of the cervical rib, claviculectomy, scalenotomy with soft tissue release, and partial scalenectomy.

Resection of the cervical rib is adequate treatment in patients with predominantly neurological symptoms, but may not be sufficient with serious vascular disease. Therapeutic options for acute venous thrombosis are anticoagulation, fibrinolysis, and thrombectomy, followed by treatment of the thoracic-outlet syndrome, usually by resection of the first rib. For chronic venous obstruction, primary treatment of the actual syndrome may be enough, although some cases also require endovenectomy or venous bypass surgery (Sanders and Haug 1990). Compressive arterial lesions can be treated by rib resection or primary treatment of the syndrome, but once intrinsic arterial damage has developed, aneurysmectomy and arterial reconstruction are necessary. With distal thromboembolic disease, thrombectomy or embolectomy need to be combined with the other measures (Scher *et al*. 1984). Where vasomotor symptoms persist after the initial operation, chemical sympathectomy of the upper thoracic sympathetic chain may be helpful.

Cryptogenic brachial plexus neuropathy (brachial neuritis, neuralgic amyotrophy)

This condition usually develops acutely in healthy adults aged between 25 and 65 years. Some cases follow viral or other infection, injection of serum or vaccine, heroin use, or strenuous exercise. Rare cases are familial. An ache first develops around the shoulder or neck with increasing severity over 1 to 2 weeks. As the acute pain starts to settle, rapid onset of weakness and wasting of the shoulder and upper limb muscles is noted. The pattern of wasting depends on the pattern of injury of the brachial plexus nerves. Sensory loss, paraesthesia, hyperaesthesia, and hyporeflexia may also occur. The pain is exacerbated by use of the affected muscles, which may become totally paralysed. The lesion can be bilateral, and in some cases, is associated with involvement of the phrenic nerve (Walsh *et al*. 1987) or other peripheral and even cranial nerves (Mohanaruban and Fisher 1986). Electromyography of the affected muscles reveals fibrillation potentials and positive waves, in a pattern characteristic of combined damage to nerve roots and peripheral nerves. The electromyographic abnormality is often bilateral, even where this was not clinically apparent.

Although the course is variable, the prognosis for recovery is good. Most recover within 6 months, with 90 per cent showing a complete recovery within 3 years. Recurrences do occur, but are rare.

Brachial plexus neuropathy needs to be differentiated from acute poliomyelitis, rotator cuff tears, extradural malignancy, Pancoast tumour of the lung, thoracic-outlet syndrome, and cervical radiculopathy.

Conclusion

Degenerative lesions in the cervical region cause many varied symptoms, which are not always recognized to be from this source. 'Cervical spondylosis', which is a vague term used to describe a whole range of degenerative and mechanical lesions, causes less disability than similar lesions affecting the lumbar spine, and has therefore been the subject of less study. The more common mechanical syndromes and associated complications and their treatment have been discussed, with consideration being given to other causes of neck pain and neurological deficit in the upper limbs.

5.19.1 Rheumatic diseases and neoplasia

Thomas G. Benedek

Some systemic rheumatic diseases may predispose to the development of malignant neoplasms. Conversely, some malignant neoplasms may present with rheumatic symptoms. Although the pathogenesis of these complex relationships is incompletely understood, recognition of the manifestations is necessary for the efficient diagnostic evaluation of many patients. The relations and conditions considered here may be classified thus:

1. Relation of rheumatic diseases to malignant neoplasms:
   a. rheumatoid arthritis;
   b. spondylarthropathies;
   c. Sjögren's syndrome;
   d. systemic lupus erythematosus;
   e. dermatomyositis/polymyositis;
   f. systemic sclerosis (scleroderma);
   g. polymyalgia rheumatica.
2. Rheumatic manifestations of malignant neoplasms:
   a. skeletal neoplasms;
      i. osseous metastases
      ii. synovial sarcoma
      iii. leukaemia
      iv. paraproteineamic arthropathies
   b. paraneoplastic syndromes;
      i. hypertrophic osteoarthropathy
      ii. oncogenic osteomalacia
      iii. carcinomatous polyarthritis
      iv. carcinomatous neuromyopathy
      v. Eaton–Lambert myasthenic syndrome
      vi. fasciitis syndromes
      vii. paraneoplastic Raynaud's phenomenon.

Relation of rheumatic diseases and neoplasia

Rheumatoid arthritis

The pathogenetic significance of even a high degree of association is difficult to determine and does not prove a causal relationship. This problem is exemplified by questions about the relationship between rheumatoid arthritis and cancer. The mean life expectancy is shortened by rheumatoid arthritis, according to a Finnish study (Myllykangas-Luosujärvi *et al*. 1995), by at least 3 years. The greatest proportional excess of deaths is due to infections but since infections have diminished as a primary cause of death, gastrointestinal diseases have become predominant numerically (Mitchell *et al*. 1986; Wolfe *et al*. 1994; Myllykangas-Luosujärvi *et al*. 1995). Nevertheless, most patients live into the seventh decade, when the incidence of malignancies is highest but the onset of rheumatoid arthritis is relatively infrequent. The length of the latent period before a neoplasm becomes diagnosable is unknown. Thus, a patient who has had rheumatoid arthritis for a few years may have been incubating the neoplasm before rheumatoid arthritis supervened. The best, albeit weak, evidence that neoplasms do not predispose to the occurrence of rheumatoid arthritis, rather than the reverse, is that they do not precede rheumatoid arthritis with unexpected frequency.

Epidemiological problems may include inconsistent diagnostic criteria for rheumatoid arthritis and for specific neoplasms, regional variations in the occurrence both of rheumatoid arthritis and of various neoplasms, and whether the cases of rheumatoid arthritis are entered from hospital rolls, outpatient services, or community surveys. A high degree of association with one subset of neoplasms may be hidden in a broader category. However, the narrower the subset of cancers that is being correlated with the incidence of rheumatoid arthritis, the larger the cohort of rheumatoid cases must be for statistically significant correlations to be obtained. A further confounding consideration is whether a correlation is attributable to a characteristic of the disease or of its treatment.

The best available data regarding the relationships between rheumatoid arthritis and cancer emanate from complementary epidemiological studies in Finland from 1967 to 1973 (Isomäki *et al*. 1978) and in Sweden from 1965 to 1984 (Gridley *et al*. 1993). Comparisons with national incidence data were made in both investigations. The smaller Swedish cohorts included 32.6 per cent as many men and 22.9 per cent as many women with rheumatoid arthritis, but cancer among these was diagnosed in 81.3 per cent as many men and 64.0 per cent as many women. The proportionately larger number of neoplasms in the Swedish cohorts can be attributed to the much longer period of observation (20 years rather than 7). While the total incidence of neoplasms in both investigations approximated the expected, the frequency of some neoplasms exceeded or was less than expected. Unfortunately, the Finnish data do not differentiate among lymphomas or leukaemias. Table 1 shows the neoplasms that deviated from the expected incidence in the Swedish data and asterisks indicate which deviated in the Finnish data. For Hodgkin's disease there was an excess only in men in Sweden and only in women in Finland. This demonstrates uncertainty due to small numbers. Other lymphomas occurred in excess in both investigations. Non-Hodgkin's lymphoma appears to be the most highly associated with rheumatoid arthritis among the lymphoreticular neoplasms (Symmons *et al*. 1984; Porter *et al*. 1991). Thirty-seven of 39 such cases were over the age of 50 and the interval between the onset of rheumatoid arthritis and the diagnosis of the lymphoreticular neoplasm was at least 10 years in two-thirds (Banks *et al*. 1979; Symmons *et al*. 1984). A prospective 10-year Finnish study of 500 men and 500 women with rheumatoid arthritis and age-matched, random control cases substantiated the excess of haemopoietic neoplasia (Laakso *et al*. 1986). Both apparently benign paraproteinaemia and multiple myeloma occur with increased frequency in rheumatoid arthritis (Zawadzki and Benedek 1969; Eriksson 1993). The observation that rheumatoid arthritis patients do not have an increased likelihood of a second primary neoplasm supports the data that rheumatoid arthritis, with the exception of lymphoreticular processes, does not confer an increased susceptibility to neoplasia (Hakulinen 1986).

Table 1 Neoplasms showing an unusual association with rheumatoid arthritis

The data of Isomake *et al*. showed a deficit of gastric and rectal carcinomas in women (Isomäki *et al*. 1978). The Swedish data demonstrated this in both sexes and for colonic carcinoma as well. Laakso *et al*. found more gastrointestinal carcinomas in their rheumatoid arthritis than in control cohorts, but better survival in the former (Laakso *et al*. 1986). Recent studies provide persuasive, albeit inferential, evidence that the deficit of at least colorectal carcinoma in rheumatoid arthritis patients is due to an effect of the chronic consumption of aspirin or other non-steroidal anti-inflammatory prostaglandin-inhibiting drugs (Thun *et al*. 1991). These drugs inhibit the chemical induction of colonic tumours in rodents. Several clinical studies have now shown the same effect, although with a wide difference in the duration of use before the effect becomes definite—possibly a decade or longer (Rosenberg *et al*. 1991; Giovannucci *et al*. 1995). In view of the substantial chronic use of these drugs in rheumatoid arthritis, the deficit of colorectal cancer may here find its explanation. Whether gastric carcinogenesis is similarly influenced and whether the larger rheumatological doses have a more rapidly demonstrable effect than the equivalent of 0.3 g of aspirin every other day have not yet been established.

The possibly carcinogenic effect of drugs used to treat rheumatoid arthritis has been examined more directly. Gold compounds and corticosteroids have not been implicated. However, the greatly increased incidence of lymphoreticular neoplasms in immunosuppressed organ transplant recipients led to concern about a similar risk in rheumatoid arthritis patients since these drugs have come into use in their treatment (Kinlen 1985). At present the implication of methotrexate and azathioprine is doubtful (Silman *et al*. 1988; Stern *et al*. 1982; Kingsmore *et al*. 1992). However, cyclophosphamide has been clearly shown to be carcinogenic in cases of rheumatoid arthritis. In a case–control study of 119 rheumatoid arthritis patients followed for 20 years, a difference in the incidence of malignancies appeared 6 years after cyclophosphamide was begun and persisted irrespective of when it was discontinued. Fifty cancers were found in 37 cyclophosphamide cases versus 26 in 25 matched, non- cyclophosphamide treated cases ($p<0.05$). All nine bladder carcinomas occurred following cyclophosphamide treatment and this was associated with the largest cumulative doses. All lymphoreticular neoplasms occurred during the first decade of observation, while bladder carcinomas were still being found two decades after cyclophosphamide treatment (Baker *et al*. 1987; Radis *et al*. 1995).

Spondylarthropathies

The spondylarthropathies as such do not predispose to the occurrence of leukaemia or solid neoplasms (Smith *et al*. 1977). However, patients whose vertebral column has received therapeutic X-irradiation, as was popular in the 1940s, are at increased risk, particularly for leukaemia. The studies begun by Court-Brown and Doll in Great Britain led to the recognition of this hazard and the eventual discontinuance of this therapy (Court-Brown and Doll 1965). Haemopoiesis may remain depressed in heavily irradiated areas more than a decade after treatment. Leukaemias, particularly the acute myeloid type, have a peak incidence 2.5 years after a course of treatment. Except for chronic lymphocytic leukaemia, these dyscrasias occur more than three times as often as expected following X-ray therapy. The excess risk then diminishes but does not disappear (Darby *et al*. 1987). Apical pulmonary fibrosis, an uncommon complication of ankylosing spondylitis (Rosenow *et al*. 1977), has been reported as the site of primary adenocarcinoma, but only following X-ray therapy (Ahern *et al*. 1982). The risk of solid neoplasms over-all following X-ray therapy is increased slightly and this has been associated with older age at the time of treatment. The occurrence of fibrosarcomas has been associated with X-ray therapy (Edgar and Robinson 1973) but not lymphoreticular neoplasms (Boice 1992).

Sjögren's syndrome

In considering the relationship of Sjögren's syndrome to neoplasia only lymphoreticular proliferation warrants consideration. Three circumstances must be defined:

1. Myoepithelial sialadenitis is the pathological term for the diagnostic alteration in salivary and lacrimal glands that is essential, but not sufficient, to substantiate the clinical diagnosis (Schmid *et al*. 1982).
2. This, in addition, requires findings of xerostomia and/or keratoconjunctivitis sicca (subnormal salivation and/or lacrimation).
3. When these findings occur in the absence of an autoimmune rheumatic disease the designation is Sjögren's disease (or primary Sjögren's syndrome). 'Sjögren's syndrome' (or secondary Sjögren's syndrome) indicates the concurrent presence of a connective tissue disease, most often rheumatoid arthritis or systemic lupus erythematosus.

Sjögren's syndrome is predominantly an ailment of middle-aged women. The mean age at the time of diagnosis of the primary and secondary form is similar (Moutsopoulos *et al*. 1980). Depending on the sites and magnitude of the characteristic proliferation of lymphocytes and epithelial cells, the disease may have various manifestations, but diminished salivary and lacrimal function predominate. The proliferation may remain within lymph nodes or extend extranodally. Because of the range of alterations within lymph nodes and extranodally, the lesions vary from clearly benign, through the potentially premalignant 'pseudolymphoma' phase, to one of the malignant lymphomas (McCurley *et al*. 1990), which usually is of a non-Hodgkin's B-cell type. Hodgkin's disease (Nagai et al., 1993), reticulum cell sarcoma (Hornbaker *et al*. 1966), T-cell lymphoma (Chevalier *et al*. 1991), monoclonal gammopathies (Sugai *et al*. 1985) including cryoglobulinaemia (Tzioufas *et al*. 1986), and angioimmunoblastic lymphadenopathy (Bignon *et al*. 1986) are rare occurrences. Latency between the onset of clinically evident salivary gland enlargement and the diagnosis of malignant lymphoma range from 1.5 to 12 years in the experience of Schmid *et al*. (Schmid *et al*. 1982), and intervals of 20 years are known.

While about 20 per cent of patients with rheumatoid arthritis also have Sjögren's syndrome, the reported prevalence of rheumatoid arthritis among cases of Sjögren's syndrome has varied, depending on the diagnostic criteria and techniques, from 13.4 per cent of a Swedish cohort (Holm 1949) and 14.3 per cent in a Scottish study (Thompson and Eadie 1956) to 58.4 per cent in a Czech investigation (Lenoch *et al*. 1967). Sjögren's syndrome has been described as a complication of all major systemic autoimmune rheumatic diseases but, aside from rheumatoid arthritis, it has been observed frequently enough only in association with systemic lupus erythematosus to conclude whether the association influences neoplasia—it does not.

Lymphocytic lesions are more likely to extend beyond the salivary and lacrimal structures in primary than in secondary Sjögren's syndrome. However, this does not alter the risk of neoplastic change (Moutsopoulos *et al*. 1980). The early diagnosis of the lymphoma is difficult since it results from an evolutionary process in the course of Sjögren's syndrome. Therefore, prevalence figures depend in large measure on the mean duration of disease in the cohort of patients studied. In the three largest published studies lymphomas were detected in a mean of 4.3 per cent of 445 cases of Sjögren's syndrome (Whaley *et al*. 1973; Kassan *et al*. 1978; McCurley *et al*. 1990). This exceeds the frequency in any other population of patients, but whether by as much as 44-fold (Kassan *et al*. 1978) has not been confirmed.

Of 20 patients in whom the routine histopathological diagnosis was myoepithelial sialadenitis, immunohistological techniques showed various evolutionary stages of neoplasia in 12, and three were frankly lymphomatous (Hyjek *et al*. 1988). Refined procedures have shown that many of these neoplasms belong to the monocytoid B-cell type and may be detectable in cases that are considered pseudolymphoma by the usual techniques (Sung *et al*. 1991). Neoplastic transformation may, in a minority of patients, result in either of two contradictory immunochemical processes. In some cases the development of a lymphoma is indicated by a decrease in serum IgM and, if rheumatoid factor has been present, by its decreasing titre. In other cases a monoclonal gammopathy develops which may be indistinguishable from Waldenström's macroglobulinaemia. In most of such cases the monoclonal protein has been IgM k, except in Japan, where an IgA paraproteinaemia appears to be as likely as the IgM type (Sugai *et al*. 1985).

Of 28 patients with Sjögren's syndrome and lymphoma recorded in three American studies (Kassan *et al*. 1978; McCurley *et al*. 1990; Sung *et al*. 1991) seven had rheumatoid arthritis and one lupus erythematosus. Contrary to the female predominance of Sjögren's syndrome, neoplastic change in Sjögren's syndrome does not appear to be sex influenced.

Lymphomas originate in salivary glands infrequently and most of these are non-Hodgkin's B-cell neoplasms—the same type that is most often associated with Sjögren's syndrome. In reviews of 33 salivary gland lymphomas in New York and 40 cases in London, each included four instances of Sjögren's syndrome, an incidence of 11 per cent (Hyman and Wolff 1978; Gleeson *et al*. 1986). A French investigation of 113 cases of non-Hodgkin's lymphoma (86 per cent B-cell, 14 per cent T-cell) found 10 (8.8 per cent) with clinical Sjögren's syndrome. It had preceded the diagnosis of lymphoma in two. Remission of the lymphoma was associated with loss of the salivary gland infiltrate in cases that met only the histopathological criteria of Sjögren's syndrome, but not in those who had clinical Sjögren's syndrome (Janin *et al*. 1992).

In conclusion, the magnitude of the association between either primary or secondary Sjögren's syndrome and the development of any of several malignant lymphomas is uncertain. However, rapid enlargement of salivary glands unaccompanied by signs of inflammation, and/or a changing immunoglobulin pattern, warrants a biopsy which should be examined immunohistochemically.

Systemic lupus erythematosus

Systemic lupus erythematosus (**SLE**) most frequently occurs between the ages of 15 and 35 and in this age group women predominate at least 8:1. Life expectancy for the patient with SLE has increased markedly since the 1950s, in part due to enhanced diagnostic awareness and improved techniques whereby milder cases, which may be expected to have a more chronic course, are being identified, and in part due to improved therapy. While the 4-year survival was about 50 per cent in 1955, the 10-year survival in the 1990s may exceed 80 per cent (Abu-Shakra *et al*. 1995). Since cancer is relatively uncommon in young women, its occurrence in a typical case of SLE may raise the suspicion of a causal relationship. It follows that if there is an association between SLE and neoplasia, more such cases would occur among the recent greater number of long-term survivors, especially since some of the immunosuppressive agents used in treating SLE are potentially carcinogenic.

The possibility of such a relationship is supported in the animal model of SLE. The offspring of matings of NZB and NZW mice manifest characteristics of an autoimmune disease resembling SLE and infrequently develop a lymphoma. Treatment of such mice with the equivalent of therapeutic doses of cyclophosphamide (Walker and Boles 1973) resulted in a high incidence of various neoplasms, and treatment with azathioprine resulted in lymphomas (Casey 1968). Results were strongly dose related.

In a review of 15 cases of solid tumours in cases of SLE, seven had been treated with one of these drugs; the neoplasm was not detected until 12 to 19 years after the diagnosis of SLE in eight, six of whom had received azathioprine or cyclophosphamide (Sulkes and Naparstek 1991). In a Finnish series of 17 cases of neoplasia in SLE, the neoplasm was detected 12 to 30 years after SLE in eight; cytostatic drugs were not considered to have been a contributory factor (Pettersson *et al*. 1992; Sweeney *et al*. 1995). The observation by Sweeney *et al*. that patients in whom a neoplasm develops have a later onset of SLE differs from the reports of others who found the diagnosis of SLE to have been made in 20 of 33 such cases at age 35 or less (Sulkes and Naparstek 1991; Pettersson *et al*. 1992) The prolongation of life has been a factor in the increased concurrence of SLE and neoplasia. However, at present neoplasia in SLE does not exceed the expected incidence (Sweeney *et al*. 1995).

Case reports give the impression that SLE conveys a susceptibility to the development of lymphoreticular neoplasms. The diagnosis of Hodgkin's disease may be obscured by the similarity of symptoms if it develops during the course of SLE (Bhalla *et al*. 1993). However, except for the aforementioned Finnish study, large series of cases of SLE do not support such an association. Four cohorts encompassing 1510 cases of SLE included only six lymphomas among 36 cases of neoplasia (Ropes 1976; Lewis *et al*. 1976; Abu-Shakra *et al*. 1995; Sweeney *et al*. 1995). Furthermore, Razis *et al*. found no instances of SLE among 1269 patients with lymphosarcoma or among 1102 with Hodgkin's disease (Razis *et al*. 1959). Miller found only one instance of SLE among 1893 patients who had a solid tissue neoplasm and one among 264 patients with a lymphoproliferative neoplasm (Miller 1967). Of 29 patients with an autoimmune rheumatic disease and lymphoma only one had SLE (Banks *et al*. 1979). Unless the SLE patient is being treated chronically with a potentially carcinogenic drug, particularly cyclophosphamide, no special surveillance for neoplasia is warranted. A recent report has emphasized the association of SLE and non-Hodgkin's lymphoma (Mellemkjaer *et al*. 1997).

Polymyositis/dermatomyositis

The first two reports of the association of dermatomyositis with cancer were published in 1916. However, whether this association might be more than coincidental initially attracted attention in 1951 when a German dermatologist concluded from a literature review that cancer occurs at least five times as frequently among cases of dermatomyositis as in the general population. The pathogenetic validity of the dermatomyositis–neoplasia association was first questioned in 1975 (Bohan and Peter 1977) and the statistical debate has continued. The only undisputed conclusion is that when the myopathy occurs during childhood it is not associated with neoplasia. The two principal epidemiological questions are:

1. May the apparent association be accounted for entirely by referral and examination biases?
2. Even assuming that the association over all is artefactual, are there hidden subsets of myopathy–neoplasia relationships that have a biological basis?

Most reports have been of individual cases of dermatomyositis and/or polymyositis, or of series of patients who were ill enough to be hospitalized, both of which make extrapolation to the entire spectrum of dermatomyositis/polymyositis cases unreliable. Some recent investigators have sought to avoid 'Berkson's (hospitalization) bias' (Masi and Hochberg 1988). Lyon *et al*. analysed 322 cases that were contributed by American rheumatologists and compared a subset of 104 with a sex-matched sibling (Lyon *et al*. 1989). Only 1.5 per cent of the total cases had had a neoplasm and there was no definite difference in neoplasia between the cases and their siblings. However, only cases that were diagnosed within a 2-year period and assessed in the third year were included. The potential longer-term risk was not addressed.

Although a Swedish investigation was based on patients who had been hospitalized with a diagnosis of dermatomyositis or polymyositis, this was not done as selectively as in most countries and therefore minimized the Berkson bias. A potential weakness was that national cancer incidence data rather than individual matching was used for controls. All cases diagnosed dermatomyositis/polymyositis between 1963 and 1983 were followed through 1987 with the help of a national cancer registry. As in most such cohorts, cancer was more prevalent among cases of dermatomyositis than of polymyositis, but during an average follow-up of 10.4 years all subdivisions demonstrated an increased risk of neoplasia: dermatomyositis male 2.4, female 3.4; polymyositis male 1.8, female 1.7. The risk of a neoplasm within 5 years after the diagnosis of dermatomyositis was: male 4.4, female 4.8 (Sigurgeirsson *et al*. 1992).

Zantos *et al*. analyzed the foregoing (Zantos *et al*. 1994) and two other differently but well controlled smaller studies (Manchul *et al*. 1985; Lakhanpal *et al*. 1986) and concluded that, indeed, both dermatomyositis and polymyositis are associated with an increased risk of cancer. Several studies have found clustering of the diagnosis of dermatomyositis or polymyositis and a neoplasm within a short time frame. Sigurgeirsson *et al*. found both diagnoses to be established within 1 year of each other in one-half of the cases of dermatomyositis and one-third of the cases of polymyositis (Sigurgeirsson *et al*. 1992). Manchul *et al*. found neoplasms in 25 per cent of 71 dermatomyositis/polymyositis cases and in 10 per cent of 142 control cases, half with inflammatory, half with non-inflammatory musculoskeletal diseases (Manchul *et al*. 1985). In eight of the 18 dermatomyositis/polymyositis cases the neoplasm was diagnosed within ±6 months of the myopathy, compared to one of 14 related to the diagnosis of the control cases. Presumably the proximity of some of the diagnoses results from particularly careful examinations stimulated by the belief that the myopathy is a paraneoplastic phenomenon. However, most of these neoplasms are discovered as a result of standard examinations (Plotz *et al*. 1989). The neoplasm which occurs in the dermatomyositis/polymyositis patient reflects the geographic prevalence of the neoplasm rather than a particular affinity to the myopathy. For example 42 per cent of the associated neoplasms in Japan have been gastric carcinomas, versus 8 per cent in the United States; conversely, 8 per cent of dermatomyositis/polymyositis associated neoplasms in Japan have been carcinomas of the breast, versus 17 per cent in the United States (Hidano *et al*. 1986; Callen 1982).

No laboratory tests reliably identify which patient with dermatomyositis/polymyositis is harbouring a neoplasm. The inflammatory and degenerative findings in muscle biopsies are not altered by the presence of a neoplasm, nor are the titres of any of the numerous autoantibodies that may be detectable in this disease helpful (Basset-Sequin *et al*. 1990). Anti-Jo-l and anti-nRNP are the most characteristic (Targoff and Reichlin 1988). Their absence helps to exclude the diagnosis of dermatomyositis/polymyositis. The most consistent biochemical abnormality is elevation of serum creatine phosphokinase, which usually reflects the acuteness of the myopathy, but is not affected by the presence of a neoplasm. It has been suggested that a normal creatine phosphokinase concentration in clinically evident dermatomyositis/polymyositis augurs a poor prognosis (Fudman and Schnitzer 1986). Interpretation must take into consideration that the normal creatine phosphokinase in comparable individuals is about 80 units higher in blacks than in whites (Black *et al*. 1986).

In regard to the association with neoplasia, polymyositis must be differentiated particularly from carcinomatous neuromyopathy (Brain and Adams 1965) and

paraneoplastic endocrine myopathies (Patel *et al*. 1993). Myasthenia gravis, which may coexist with polymyositis (Behan *et al*. 1982), may come into consideration, as well as the rarer Eaton–Lambert myasthenic syndrome (see below), and drug-induced myopathies (Zuckner 1990). Clinically, rapid response to corticosteroid therapy favours the diagnosis of dermatomyositis/polymyositis over the others.

As improved therapy prolongs survival with dermatomyositis/polymyositis, an increase in the number of neoplasm associated cases may be anticipated. Whether this is due to a causal relationship with the myopathy or with the increasingly cancer-prone older age group is uncertain. The conservative conclusion to be drawn from the available epidemiological and clinical data is that when a patient over 45 years of age is seen during the first year of dermatomyositis/polymyositis close surveillance for cancer is justified. Later in the course of the disease more than routine evaluations for cancer are not cost effective.

Diffuse scleroderma and paraneoplastic Raynaud's phenomenon

Diffuse scleroderma (systemic sclerosis) is less common than systemic lupus erythematosus, but probably occurs more frequently than polymyositis. Its peak incidence is in the fifth decade. Small cohorts have not shown an abnormal risk of neoplasia. However, an epidemiological study conducted in metropolitan Pittsburgh (United States) during 1971 to 1982 obtained an excess incidence of 1.8 over regional incidence data. During a mean observation period of 4.3 years, nine women and five men (5.3 per cent) had a malignant neoplasm. A total of 680 patients with systemic sclerosis (78 per cent women) were examined during these 12 years. Twenty-five had a malignancy, 3.6 per cent of women and 4.1 per cent of men (Roumm and Mesdger 1985). Such an excess was confirmed in a study of 248 cases of systemic sclerosis first seen between 1978 and 1992 in Toronto (66 per cent women). Compared to the population of the province of Ontario, systemic sclerosis had an increased cancer risk of 2.1 (Abu-Shakra *et al*. 1993).

It is likely that most neoplasms occur coincidentally with systemic sclerosis, including the few that antedate its development. However, the relationship of carcinomas of the breast and lung with systemic sclerosis requires special comment. The fact that breast cancer is the most common neoplasm among cases of systemic sclerosis can superficially be attributed to the female preponderance of this disease. However, 34 per cent of 90 women with systemic sclerosis and a neoplasm in four studies had breast cancer, about twice the proportion of breast cancer among North American female cancer patients (Duncan and Winkelmann 1979; Lee *et al*. 1983; Roumm and Medsger 1985; Abu-Shakra et al.). Furthermore, while the mean interval between the diagnosis of systemic sclerosis and other neoplasms was about 6 years, the interval for breast cancer was only 2 years (Duncan and Winkelmann 1979; Roumm and Medsger 1985). Of 35 cases where a neoplasm was found within 1 year of the diagnosis of systemic sclerosis, 37 per cent were carcinomas of the breast. This is not entirely attributable to the availability of more sensitive diagnostic methods for cancer of the breast than for cancer of other organs. While the explanation of the relationship remains obscure, the practical conclusion to be drawn from these observations is that women should undergo a careful breast examination at least semi-annually and annual mammography during the first 3 to 5 years after a diagnosis of systemic sclerosis has been made.

The occurrence of carcinoma of the lung in association with systemic sclerosis exhibits three peculiarities:

1. It is consistent with the female susceptibility to systemic sclerosis rather than the male susceptibility for pulmonary carcinoma.
2. Smoking is not implicated in the pathogenesis of these carcinomas.
3. The cancer occurs in cases of long-standing systemic sclerosis in which pulmonary fibrosis has become prominent (Talbott and Barrocas 1980).

Some types of pulmonary fibrosis predispose to carcinogenesis, but the precipitating factors are unidentified. Thus, cryptogenic fibrosing alveolitis is associated with a substantially increased risk of lung cancer (Turner-Warwick 1980), while rheumatoid lung disease is not. The mean duration of systemic sclerosis in 64 patients when lung cancer was diagnosed was 15 years (Talbott and Barrocas 1980). As the most optimistic 5-year survival estimate for patients with systemic sclerosis is only about 70 per cent (Steen 1990), those in whom lung cancer develops tend, contrary to those with breast cancer, to have a relatively benign course of systemic sclerosis. Among 58 patients with systemic sclerosis and lung cancer 60 per cent were less than 60 years of age and 69 per cent were women. The suggestion that alveolar cell carcinoma is peculiarly associated with systemic sclerosis may be attributable to a reporting bias. The histological types of pulmonary carcinomas in systemic sclerosis probably occur in similar proportions to those in other patients (Roumm and Medsger).

While Raynaud's phenomenon is an early manifestation of virtually all cases of systemic sclerosis, it occasionally occurs as a paraneoplastic symptom without other evidence of systemic sclerosis. The preponderance of female cases approaches the 9:1 sex ratio of Raynaud's phenomenon in general. Raynaud's phenomenon appears not to be associated with any particular neoplasm. Onset has been described as virtually concurrent with the diagnosis of the cancer, and no longer than 2 years preceding such a diagnosis. The ischaemia may be unilateral (DeCross and Sahasrabudhe 1992). In some cases it has resolved following resection of the neoplasm. The pathogenetic relationship remains obscure, although in one report cells of a cervical carcinoma were producing interleukin-6, which was suspected to be the vasospastic stimulus (Murashima *et al*. 1992). Raynaud's phenomenon may also be induced by certain antineoplastic drugs: bleomycin, vinblastine, cisplatin (Hansen and Olsen 1989).

Polymyalgia rheumatica

Polymyalgia rheumatica is the rheumatic syndrome that occurs particularly in the most cancer-prone age group. The average age of onset is about 65 years, and the disease begins below the age of 50 in fewer than 5 per cent (Huston *et al*. 1978). There is a female predominance of about 3:2. A survey of 96 patients with polymyalgia rheumatica diagnosed during 10 years in a community in the northern United States included six who had a cancer before and ten in whom the diagnosis of a neoplasm occurred after the onset of polymyalgia rheumatica. The 16 patients encompassed seven different neoplasms (Chuang *et al*. 1982). The largest investigation has been conducted in Norway with 185 cases of polymyalgia rheumatica diagnosed between 1978 and 1983 and followed to 1987. Each was matched with five control subjects. Of the polymyalgia rheumatica cases 14.6 per cent had cancer, as had 14.2 per cent of the controls; the polymyalgia rheumatica cases included 14 different neoplasms. The female preponderance of the neoplasm cases was consistent with the sex ratio of the entire cohort. Thirteen had a neoplasm, found an average of 8.3 years before polymyalgia rheumatica and in 14 a neoplasm was found an average of 4.6 years after the onset of polymyalgia rheumatica (Haga *et al*. 1993). The temporal relationships support the view that these are merely coincidental events.

Neoplasia was more strongly associated with isolated temporal arteritis (24 per cent) than with either isolated polymyalgia rheumatica (11 per cent) or polymyalgia rheumatica with temporal arteritis (10 per cent) (Haga *et al*. 1993). This observation is supported by the finding that there may be a difference between temporal arteritis with and without polymyalgia rheumatica. HLA DR4 occurs significantly less frequently in cases of isolated temporal arteritis than in the presence of polymyalgia rheumatica (Richardson *et al*. 1987). While DR4 appears to be associated with polymyalgia rheumatica as well as with rheumatoid arthritis, whether this is pertinent to neoplasia susceptibility with temporal arteritis warrants further evaluation.

Lymphomas occasionally occur in patients with polymyalgia rheumatica (Kalra and Delamere 1987; Montanaro and Bizzarri 1992). However, the occurrence in series of cases is low enough to indicate coincidence (1 of 96; 2 of 185). Chuang *et al*. found that 18 per cent of their polymyalgia rheumatica cases also met diagnostic criteria for rheumatoid arthritis (Chuang *et al*. 1982). Polymyalgia rheumatica clearly lacks the association with lymphoreticular neoplasia observed in rheumatoid arthritis. Whether the occurrence of monoclonal gammopathy resembles the prevalence in rheumatoid arthritis requires further investigation (Kalra and Delamere 1987).

When a person in the seventh decade or beyond presents with myalgia, proximal muscle weakness, and perhaps also weight loss, both polymyalgia rheumatica and a paraneoplastic neuromyopathy should be considered. Polymyalgia rheumatica symptoms are more likely to predominate in the shoulder girdle and paraneoplastic syndromes in the pelvic girdle, but neither this or any serological findings differentiate reliably. Since carcinomatous neuromyopathy most often results from carcinoma of the lung, it is prudent to include chest radiography in the evaluation of possible polymyalgia rheumatica, but an intensive search for a neoplasm is not ordinarily warranted.

Rheumatic manifestations of malignancy

Skeletal neoplasia

Apart from hypertrophic osteoarthropathy, cancer infrequently produces skeletal symptoms that the careful clinician might mistake for a systemic rheumatic disease. Data about the principal primary neoplasms of bone are summarized in Table 2. At least 95 per cent of malignant neoplasms in bone are metastatic carcinomas. These reflect the age and sex distribution of the primary disease; on average, patients with metastatic carcinoma are about two decades older than patients with musculoskeletal sarcomas. Metastases usually result from haematogenous spread with implantation in the marrow cavity (Galasko 1982). The cortex is affected by neoplastic factors that predominantly stimulate osteoblastic activity, resulting in sclerotic lesions, even in the presence of the osteoclastic activity that causes the more

common lytic lesions (Springfield 1982). Only in myeloma and lymphoma do the lytic lesions not tend to be associated with reactive bone formation. Certain tumour cell lines are predisposed to survive in specific organs. Carcinoma of the prostate, breast, kidney, and thyroid are particularly likely to form metastases in bone. Although bronchogenic carcinoma is less likely to do so, the frequency of this neoplasm places it second only to breast as a source of skeletal metastases. The lumbosacral vertebrae, pelvis, femora, and ribs are the most frequent sites of osseous metastases. A radiographically solitary lesion occurs in fewer than 10 per cent of patients with skeletal metastases. Most solitary lesions once were considered benign. However, scintigraphy has caused this opinion to be revised. Because of its greater sensitivity, a bone scan is mandatory to confirm that a lesion probably is solitary (Merrick and Merrick 1986). Vertebrae are the most common site of metastases which are radiographically undetectable initially and manifested only by local pain (Clain 1965). In cases with normal radiographs in which a scintigram indicates metastases, the lesions generally become evident radiographically within 6 to 18 months. A scintigraphically solitary lesion proves to be metastatic in about one-half of cases (McNeill 1984). Nevertheless, a positive radiograph is occasionally contradicted by a false-negative scintigram.

	Cases	Percentage male	Peak decades (% of cases)	Most frequent sites		Reference
Malignant						
Multiple myeloma	869	60.9	7th (36.8)	6th (26.4)	Multifocal	Kyle (1975)
Osteogenic sarcoma	1274	58.1	2nd(47.2)	3rd (22.6)	Femur Tibia	42.4 18.5
Chondrosarcoma	643	59.6	6th (25.7)	5th (19.8)	Femur Humerus	22.1 11.8
Lymphoma	469	62.3	6th (21.7)	7th (16.1)	Femur Humerus	24.5 8.7
Ewing's tumour	402	57.0	2nd(57.5)	1st (17.9)	Femur Humerus	22.4 11.4
Fibrosarcoma	207	50.7	4th (18.3)	6th (16.3)	Femur Tibia	26.1 15.9
Malignant synovioma	106	60.5	3rd (29.9)	4th (26.6)	Thigh Knee	29.1 18.7
Benign						
Osteochondroma	727	62.9	2nd(49.1)	3rd (16.8)	Femur Humerus	32.9 15.4
Giant cell tumour	425	45.5	3rd (38.8)	4th (23.3)	Femur	30.8

Table 2 Principal age, sex, and site of the commoner neoplasms of bone

A primary or a metastatic neoplasm in a juxta-articular site or in synovium may imitate mono- or oligoarticular arthritis. There may be signs of synovitis, including small non-haemorrhagic effusions without actual invasion of the synovium. Conversely, villonodular synovitis, a benign neoplasm which most often affects the knee, may cause a juxta-articular lytic lesion mimicking a primary bone neoplasm (Jergensen *et al*. 1978). Neoplastic cells in joint effusions do not necessarily indicate invasion of the synovium. Despite its vascularity the synovium rarely is a metastatic site (Newton *et al*. 1984). Metastases, particularly to acral sites, may cause symptoms that mimic rheumatoid arthritis or, if there is a local inflammatory reaction and coincidental hyperuricaemia, gout. Nevertheless, acral metastases are uncommon, presumably because of the small number of tumour cells that reach the extremities of the vasculature. According to a review in 1976, 88 cases of metastases to hand bones had been published, most from pulmonary carcinomas (Uriburu *et al*. 1976). Metastases to the feet may be rarer still, 72 cases having been reported up to 1982, without as great a predominance of a particular organ of origin (Zindrick *et al*. 1982).

Synovial sarcomas are uncommon neoplasms that occur predominantly before the age of 40. Fewer than 8 per cent are diagnosed beyond age 60 (Tillotson *et al*. 1951; Cadman *et al*. 1965). There is a 3:2 male preponderance. The tumour is usually located in periarticular tissue rather than within the joint cavity. The most frequent sites in 550 cases collated from four publications are: knee 22.5 per cent; foot and ankle 21.4 per cent; and thigh 15.8 per cent (Tillotson *et al*. 1951; Cadman *et al*. 1965; Mackenzie 1966; Hajdu *et al*. 1977). A lower extremity is affected in approximately 70 per cent of the patients. However, this neoplasm occasionally occurs far from joints, such as in the hypopharynx or oesophagus (Amble *et al*. 1992).

Histologically this neoplasm may be 'biphasic,' meaning that it contains both epithelial and spindle cells, or 'monophasic,' when virtually only one cell type is present. This does not affect the prognosis. Synovioma acquired its name because of its usual proximity to the synovium. However, ultrastructual and immunochemical studies have failed to find synovial characteristics, so that it probably arises from a primitive mesenchymal precursor cell (Miettinen and Virtanen 1984).

About 60 per cent of the patients present with local pain or tenderness, but signs of inflammation are rare. Radiographically about 30 per cent of synoviomas contain calcifications and 10 per cent show signs of bone invasion. Survival is better correlated with a low prevalence of mitoses in the neoplasm than with small size (less than 5 cm diameter) (Cagle *et al*. 1987; Rööser *et al*. 1989). However, both criteria are more predictive than whether the tumour was resected locally or by amputation.

According to Mayo Clinic data, osteoarticular symptoms occur in about 14 per cent of childhood cases of acute leukaemia and in 4 per cent of adults with a leukaemia (Silverstein and Kelly 1963). Musculoskeletal symptoms in paediatric cases usually are a manifestation of acute lymphocytic leukaemia, while in adults the association is strongest with the chronic myelogenous type. Leukaemia is by far the most frequent malignancy in white children, being somewhat less common among black children. It also is the most frequent cause of neoplastic skeletal symptoms in childhood and adolescence. For example of 13 children, 2 to 14 years of age, who presented for rheumatological evaluation and proved to have a malignancy, 10 had leukaemia and the others soft tissue sarcomas (Schaller 1972). Of 28 consecutive leukaemic children (24 acute lymphocytic leukaemia), 14 had musculoskeletal symptoms, most frequently in the knees (Costello *et al*. 1983).

Musculoskeletal symptoms may be the earliest indication of leukaemia and may precede its discovery by several months. There may be bone pain and/or arthralgia, which tends to be asymmetrical. Synovial effusion is uncommon, with its leucocyte count usually below 20 000/mm ^{3}, and often without morphologically evident leukaemic cells (Holdrinet *et al*. 1989). Such identification has been made immunologically (Harden *et al*. 1984). Articular symptoms more often are due to periarticular infiltration than to synovial involvement. Scinitgraphy is more likely than radiography to detect early lesions, but no abnormality may initially be demonstrable. Radiographic findings include metaphyseal radioluscent bands (mainly in children), diffuse osteopenia (mainly in adults), osteolytic lesions, and periostitis. Analysis of synovial fluid is important because the effusion may have resulted from infection or, less frequently, contain urate or calcium pyrophosphate crystals, each of which requiring other than antileukaemic therapy. Osteoarticular leukaemic symptoms usually respond well to chemotherapy and their recurrence augurs a relapse.

Primary skeletal neoplasms are uncommon in childhood. According to a survey conducted during 1969 to 1971 in the United States, the annual incidence below the age of 15 years was about 5 per million (Young and Miller 1975). Neuroblastomas are the most frequent solid tumours to cause skeletal metastases in children. Metastasis of carcinomas to bone is rare—two of 39 in one series of children. The distribution of metastases is as in adults (Leeson *et al*. 1985).

Among skeletal neoplasms in adults multiple myeloma is most likely to present problems in rheumatological differential diagnosis because:

1. This disease occurs mainly after the age of 55, so that complaints of skeletal pain may initially be minimized as symptoms of degenerative disease of joints or intervertebral discs.
2. Myeloma may present as a polyarthritis, more or less resembling rheumatoid arthritis, in which the shoulders, wrists, and knees are affected most often.

There may be subcutaneous nodules, although usually not in the typical sites of rheumatoid nodules. Symptoms rarely are due to the infiltration of synovium by myeloma cells; the usual cause is deposition of amyloid in the synovium (Gordon *et al*. 1973). The same process and symptoms may result from primary amyloidosis (Cohen and Canoso 1975). Synovial fluid sometimes contains the paraprotein, but synovial biopsy is necessary to confirm the diagnosis of articular amyloidosis. The diagnosis of myeloma must be confirmed by the demonstration of a great excess of immature plasma cells in a bone marrow aspirate or biopsy. In rheumatoid arthritis the marrow usually shows only a slight increase in plasma cells, but a large proportion of these may resemble the immature cells seen in myeloma.

Patients with chronic rheumatoid arthritis are at an increased risk of developing multiple myeloma. However, a misdiagnosis may result from the detection of a monoclonal paraprotein, which is found two to three times as frequently among cases of rheumatoid arthritis than in the general population (Zawadzki and Benedek 1969). The significance of a paraproteinaemia may be difficult to interpret at any one time.

In 1971, 241 patients with a diagnosis of monoclonal paraproteinaemia without evidence of any of the usually associated diseases were placed under surveillance by the Mayo Clinic. After a median period of 22 years, 53 per cent had died without having developed a malignant paraproteinaemia. Multiple myeloma had developed in 39 (16 per cent) after a median of 10 years; amyloidosis had developed in 8 (3 per cent) after a median of 9 years; macroglobulinaemia in 7 (3 per cent) after a median of 8 years; and 5 (2 per cent) developed a malignant lymphoproliferative disease after a median of 10.5 years (Kyle 1993). These data suggest that about a

quarter of cases of 'benign' paraproteinaemia are at risk to develop one of these fatal diseases.

Oncogenic osteomalacia

Osteomalacia is a less frequent cause of tumour-associated skeletal pain than hypertrophic osteoarthropathy. However, since most of the tumours are benign, have no preferential location, and many are small, they may be difficult to find. Hence, symptoms may last for years unexplained. The patient presents with skeletal and/or articular pain, especially affecting the lower extremities, progressive pelvic girdle weakness leading to deterioration of the gait, there may be fractures and, with childhood onset, growth retardation. Symptoms most often begin in the third or fourth decade without a family history of rickets (Ryan and Reiss 1984). Various types of fibromas and haemangiomas are the most common; sarcomas have rarely been associated with this paraneoplastic activity, and carcinomas not at all (Weidner and Cruz 1987). Radiographic findings include pseudofractures (Looser's lines) and thickening of long bones despite osteopenia. Bone scans show scattered areas of increased tracer uptake (Schapira *et al*. 1995). The characteristic biochemical findings are hypophosphataemia, hyperphosphaturia, elevated alkaline phosphatase, normal to slightly subnormal serum calcium, normal serum creatinine and parathormone, and subnormal serum 1,25-dihydroxyvitamin D.

It has been inferred from the biochemical data that an unidentified tumour product interferes with the conversion of 25-hydroxyvitamin D to the active 1,25-dihydroxy compound (Harvey *et al*. 1992). Why this defect does not result in hyperparathyroidism is unknown. The disease is cured symptomatically and biochemically by resection of the tumour. If this is not feasible or until it is located, treatment with phosphate and calcitriol (1–3 µg/day) is beneficial.

Hypertrophic osteoarthropathy

Hypertrophic osteoarthropathy often is referred to as 'pulmonary' because most cases are associated with an intrathoracic disease. Lung cancer now accounts for at least 90 per cent of the cases in the industrialized world. However, extrathoracic circumstances as disparate as non-neoplastic liver disease (Epstein *et al*. 1979) and pregnancy (Borden and Holling 1969) may be associated with the same syndrome. The occurrence of hypertrophic osteoarthropathy in large series of cases of lung cancer has varied widely, perhaps due to inconsistent diagnostic criteria or referral bias. It is more likely to occur in males regardless of age. In the Edinburgh analysis of 4000 cases of primary lung cancer, of whom 90 per cent were men, only one of 49 cases of hypertrophic osteoarthropathy occurred in a woman (LeRoux 1968). At the Mayo Clinic, 10 per cent of 1657 cases of primary lung cancer manifested hypertrophic osteoarthropathy. Women accounted for 19 per cent of those with hypertrophic osteoarthropathy, but 26 per cent of those without this complication (Stenseth *et al*. 1967). Of 1920 cases of lung cancer seen in Cleveland (United States), hypertrophic osteoarthropathy was found in only 0.8 per cent (Segal and MacKenzie 1982), and among 200 cases in London it was found in 4 per cent (Yacoub 1965). Hypertrophic osteoarthropathy is less than one-third as likely to occur with pulmonary metastases as with primary lung cancer (Stenseth *et al*. 1967), but sarcomatous metastases are more likely than carcinomatous metastases to induce hypertrophic osteoarthropathy. Of 38 children (mean age 13) with neoplastic hypertrophic osteoarthropathy 79 per cent were boys, 37 per cent had an osteogenic sarcoma, 34 per cent a nasopharyngeal carcinoma, and 16 per cent had Hodgkin's disease (Staalman and Umans 1993).

Calculated from a sex, age, and race-specific cohort analysis of the prevalence of lung cancer in the United States during 1983 to 1986, and assuming a 6 to 9 per cent incidence of hypertrophic osteoarthropathy, the following frequency per 100 000 would be anticipated in each 55 to 64-year age group: white male 15 to 22; black male 25 to 28; white female 8 to 11; black female 9 to 13. Because of the lower female incidence of hypertrophic osteoarthropathy these figures should be reduced by at least one-third for women. For the 45 to 54-year age group the figures would be about 40 per cent of the foregoing (Devesa *et al*. 1989).

The most apparent but least specific sign of hypertrophic osteoarthropathy is digital clubbing. This begins with subungual oedema and hyperaemia, followed by proliferation of connective tissue. About 80 per cent of such individuals have some form of pleuropulmonary disease, but only about 20 per cent of cases of clubbing have lung cancer. Chronic clubbing does not predispose to the development of hypertrophic osteoarthropathy (Coury 1960).

Patients usually complain of arthralgia, especially of the knees, ankles, or wrists. However, on examination the pain typically is periarticular. Some patients have true joint pain and tenderness, and perhaps small effusions and morning stiffness. Hence, such a patient may be misdiagnosed as having rheumatoid arthritis. The erythrocyte sedimentation rate in this situation is elevated, but rheumatoid factor, with rare exceptions, is absent. Symptoms usually may be controlled with non-steroidal anti-inflammatory drugs (Schumacher 1976).

Skeletal metastases from lung cancer occur more frequently than hypertrophic osteoarthropathy and tend to produce less symmetrical symptoms. The simultaneous occurrence of hypertrophic osteoarthropathy and bony metastases is rare. The greater diagnostic problem occurs because symptoms of hypertrophic osteoarthropathy often precede the discovery of an intrathoracic neoplasm by a few months, and possibly by two or more years. Despite the frequency of rheumatoid arthritis in middle-aged women, the possibility that this disease is being mimicked by hypertrophic osteoarthropathy should be considered when a woman who has risk factors for lung cancer is being evaluated.

Radiographically, signs of periostitis with subperiosteal new bone formation along the distal and/or proximal fourths of long bones, predominantly on the extensor surfaces, is diagnostic. The most commonly and prominently affected sites are the distal and proximal portions of the tibia and fibula, and distal femur (Ali *et al*. 1980). Because the periosteal reaction is so hyperaemic, bone scanning with $^{99}Tc^{m}$-diphosphonate has proven to be diagnostically more sensitive than radiography. This technique, contrary to radiography, has demonstrated rather frequent involvement of the scapula and skull.

The occurrence of hypertrophic osteoarthropathy is influenced by the size, location, and cell type of the primary pulmonary neoplasm. The mean tumour mass in cases of hypertrophic osteoarthropathy is about twice as large as in those without hypertrophic osteoarthropathy (Stenseth *et al*. 1967). The influence of location is especially perplexing. Location in the periphery of a lung increases the chance that hypertrophic osteoarthropathy will develop, while invasion of the pleura appears not to exert this influence. The association of hypertrophic osteoarthropathy with malignant mesothelioma is also unusual, while the neoplasm with which hypertrophic osteoarthropathy is most highly associated is benign mesothelioma—35 per cent (Briselli *et al*. 1981). In contradistinction to other paraneoplastic manifestations of lung cancer, which are particularly associated with the small-cell type, hypertrophic osteoarthropathy occurs least often in this relationship.

The immediate pathophysiology of hypertrophic osteoarthropathy consists of increased blood flow in the bones and adjacent connective tissues of the legs and forearms, facilitated by the development of arteriovenous shunts (Rutherford *et al*. 1969). The same syndrome occurs in dogs, especially secondary to thoracic sarcomas (Nolling *et al*. 1963). No comprehensive explanation of the syndrome has been proved. Most of the pathogenetic hypotheses were thoroughly reviewed by Shneerson (Shneerson 1981). Impetus for a neurogenic explanation evolved from the discovery that peripheral vagotomy on the side of the neoplasm may, even without its removal, abruptly stop the pain bilaterally, followed by gradual resolution of the periosteal reaction and clubbing. Analgesia begins within a week of surgery in about three-quarters of cases, probably due to collapse of the arteriovenous anastomoses (Nolling *et al*. 1963; Stenseth *et al*. 1967; Rutherford *et al*. 1969). However, the gradual response of hypertrophic osteoarthropathy to radiation therapy of the neoplasm and the bilaterality of the syndrome suggest a humoral rather than a neurogenic mechanism. The heterogeneity of its causes proves that hypertrophic osteoarthropathy is not mediated by a uniquely neoplastic product. Gynaecomastia, which is an undoubtedly humoral manifestation that may occur in hypertrophic osteoarthropathy, is not correlated with increased serum oestrogen concentration or another identified hormone. A substance resembling growth hormone has recently been considered as a potential humoral incitor of hypertrophic osteoarthropathy (Gosney *et al*. 1990). A persuasive explanation for many, but not all, characteristics of hypertrophic osteoarthropathy has been made for platelet embolization with release of platelet-derived growth factor. This substance, among other functions, stimulates mesenchymal cell growth, increases vascular permeability, and attracts smooth muscle cells and fibroblasts (Dickinson 1993).

A combined neurohumoral pathogenesis of hypertrophic osteoarthropathy seems most plausible. Only a neural mechanism could explain the abrupt diminution of peripheral blood flow and associated analgesia that usually follows vagotomy, while the symmetrical osteogenesis is best explained by the action of one or perhaps several as yet unidentified humours.

Carcinomatous polyarthritis

Carcinomatous non-metastatic polyarthritis must be distinguished from hypertrophic osteoarthropathy, rheumatoid arthritis, and polymyalgia rheumatica. The syndrome is not associated predominantly with intrathoracic neoplasms and both sexes are equally at risk. Most cases occur above the age of 60, when the onset of polymyalgia rheumatica but not of rheumatoid arthritis is expected. Onset of the arthritis may be insidious or abrupt, but the symptoms are less likely to be symmetrical than in definite rheumatoid arthritis, and rheumatoid nodules do not develop (Pines *et al*. 1984). Pain is felt in large and small joints, rather than being periarticular as in hypertrophic osteoarthropathy. Deformities rarely develop. Symptoms are more likely than those of hypertrophic osteoarthropathy to precede the diagnosis of a neoplasm which, nevertheless, is usually made within a year of the beginning of articular complaints. On the contrary, the diagnosis of polymyalgia rheumatica and a neoplasm usually occurs several years apart. Immune complexes have rarely been detected in carcinomatous polyarthritis (Awerbuch and Brooks 1981; Bradley and

Pinals 1983).

Arthritic symptoms as well as serological abnormalities rapidly resolve following resection or successful radiation therapy of the neoplasm (Gottlieb *et al*. 1979; Simon and Ford 1980). Recurrence of the neoplasm may be indicated by recurrence of the arthritis (Egelmeijer and MacFarlane 1992). If the neoplasm persists, the clinical course of the arthropathy does not necessarily mirror the progress of the neoplasm. Symptomatic response to treatment with non-steroidal anti-inflammatory drugs or corticosteroids is similar to that in rheumatoid arthritis.

Carcinomatous neuropathy

In individual cancer patients it may be difficult to determine whether the development of weakness is due to inanition or is a specific paraneoplastic manifestation. When to suspect cancer in a patient with unexplained weakness and perhaps some muscle wasting is equally problematical. In a prospective study of 100 persons over 65 years of age who had no identified cancer but whose gait was impaired by largely unexplained weakness of the legs, eight cases of carcinoma were detected during 18 months of observation (Newman and Gugino 1964).

According to Shy and Silverstein, carcinomatous neuromyopathy is a 'clinical syndrome of symmetrical muscular weakness and wasting, associated with decrease of the appropriate myotactic reflexes. Either a myopathic or a combination of myopathic and neuropathic lesion. ... is found pathologically' (Shy and Silverstein 1965). At least initially, weakness is out of proportion to alteration of muscle mass. Pelvic girdle muscles are most affected, so that gait disturbances, particularly on ascending stairs, may be the first symptom.

The syndrome occurs most frequently in association with small-cell carcinoma of the lung, followed by other pulmonary, gastric, and ovarian carcinomas. Because of the male preponderance of lung cancer, non-myasthenic carcinomatous neuromyopathy occurs more commonly in men (Croft and Wilkinson 1965); on examination of 1465 carcinoma patients they made this diagnosis in 15.0 per cent of men and 11.6 per cent of women with lung cancer, 7.4 per cent of men and 12.5 per cent of women with gastric carcinoma, and 16.4 per cent of cases of ovarian carcinoma. No consistent relationship between the occurrence of the myopathy and either the age of the patient or known duration of the neoplasm has been determined. Compared to 'neuromyopathy' Eaton–Lambert syndrome is rare (probably less than 1:40). Autonomic dysfunctions, such as dry mouth and postural hypotension, are common findings with small-cell carcinoma and not a reliable diagnostic clue to Eaton–Lambert syndrome (Elrington *et al*. 1991). Differentiation between 'cachectic' and 'neuromyopathic' clinical findings may be uncertain. Hawley *et al*., in a prospective study of 71 patients with small-cell lung cancer, were impressed by a greater preservation of strength relative to the severity of weight loss (Hawley *et al*. 1980). The myopathy also was less severe than that found in a group of alcoholic men matched by age and weight loss.

Both histopathological and electrophysiological abnormalities are demonstrable in the absence of clinical neuromuscular findings. In a study of 100 consecutive patients with lung cancer who were assessed with muscle biopsies, 15 (mainly small-cell) had signs of proximal myopathy, while 18 (mainly non-small-cell) had cachectic (diffuse) myopathy. However, 99 patients had abnormal histological findings. Most consistent (74 cases) was atrophy of type-2 (large mean diameter, phosphorylase-rich) nerve fibres (Gomm *et al*. 1990). Contrary to some investigators, no microvascular abnormalities, such as atrophy of terminal arteriovenous anastomoses (Scelsi and Pinelli 1977) were detected. In some cases there is only scattered, non-specific atrophy or necrosis of muscle fibres with lymphocytic infiltrates.

Paul *et al*. compared the electromyographic findings of 195 non-diabetic cancer patients below the age of 65 years with 50 age-matched controls (Paul *et al*. 1978). Muscle wasting was better correlated with myographic abnormalities than with slowed nerve conduction, and both types of abnormality were more prevalent among patients with diffuse muscle wasting, most of whom presumably had a cachectic myopathy, than in those whose wasting predominantly affected the proximal musculature. Retarded conduction velocity was equally prevalent in patients with carcinomas of the lungs and of other organs, but other abnormalities were twice as frequent among cases of lung cancer. The cause of the various abnormalities and of their variability remain obscure. Treatment is non-specific until the neoplasm is found and then is focused on the neoplasm.

Rarely a more aggressive myopathy occurs. In this, weakness progresses within a few weeks and affects virtually all muscles, despite preservation of tendon reflexes. It is not associated with a particular type of carcinoma. There is extensive necrosis of terminal intramuscular nerve fibres and of muscle fibres, with consequent elevation of the serum creatine phosphokinase (Vosskämper *et al*. 1989).

Eaton–Lambert myasthenic syndrome

The Eaton–Lambert myasthenic syndrome was differentiated from myasthenia gravis in 1957. In early descriptions it was associated almost exclusively with small-cell carcinoma of the lung. The association with this neoplasm has been confirmed but it has become recognized that nearly one-half of cases occur in the absence of a neoplasm. The latter cases have brought the sex ratio from strongly male to 1:1 (Pascuzzi and Kim 1990; McEvoy 1994). Eaton–Lambert syndrome occurs in about 3 per cent of cases of small-cell carcinoma and rarely in other pulmonary or extrapulmonary neoplasms (O'Neill *et al*. 1988).

The most common presenting finding is weakness of the pelvic girdle musculature, initially revealed by an altered gait. Autonomical functions may be affected, manifested most often by dryness of the mouth and/or orthostatic hypotension (Khurana *et al*. 1988). The main differential diagnosis is with myasthenia gravis. While one can be fairly confident that no carcinoma is impending if none has been found after 3 years of Eaton–Lambert syndrome, one must consider that myasthenia gravis is also associated with an increased incidence of neoplasia, albeit less so. In contrast to Eaton–Lambert syndrome, at least half of these cancers are found after myasthenia gravis has been present for longer than 3 years. Most patients with either syndrome who are found to have cancer are between 55 and 65 years of age (Papatestas *et al*. 1971). One simple differentiating symptom from myasthenia gravis is that extraocular muscles typically are not affected in Eaton–Lambert syndrome.

If Eaton–Lambert syndrome is associated with a carcinoma, there rarely is more than a 2-year interval between the onset of muscular symptoms and discovery of the neoplasm. In the 21 patients with small-cell lung cancer of O'Neill *et al*. the tumour was diagnosed within 1 year of the syndrome's onset in 16 (O'Neill *et al*. 1988). The maximum interval between the onset of Eaton–Lambert syndrome and detection of the neoplasm has been less than 4 years and in such cases the association may be coincidental. The age distribution is wider in the absence of neoplasia but the neuromuscular manifestations are the same.

The simplest screening test for Eaton–Lambert syndrome consists of evoking a single muscle action potential with an electromyograph before and after voluntary effort. The potential should at least double, and may increase 17-fold. Repetitive stimulation of a nerve at a tetanic rate also results in increase of the action potential, while in myasthenia gravis the potential gradually diminishes. There are also pharmacological differences. Neostigmine and other anticholine esterases improve strength in myasthenia gravis, but have little effect in Eaton–Lambert syndrome. Consequently, in Eaton–Lambert syndrome a test dose of edrophonium fails to elicit a definite response as it does for myasthenia gravis (Brown and Johns 1974).

Both conditions result from a defect in the neuromuscular transmission of nerve impulses. In myasthenia gravis acetyl choline reaches the motor endplates in normal increments, but the sensitivity of its receptors on the endplates and contiguous muscle cell membrane is diminished. Each receptor site can accept two molecules of acetyl choline. Release of the quanta of acetyl choline in the depolarization phase of the electric potential is mediated by the influx of calcium ions into the presynaptic membrane. In Eaton–Lambert syndrome an inadequate amount of acetyl choline is released due to a complex mechanism which, at least in part, is an antibody blockade of the calcium phase (Leys *et al*. 1991; Maselli 1994). Injection of the IgG serum fraction from patients with Eaton–Lambert syndrome into mice may temporarily reduce their muscle action potential. This has been interpreted to indicate that there is an autoantibody which, when transferred in sufficient concentration, can block neuromuscular transmission (Lambert and Lennon 1988). Such an antibody appears to be more prevalent in non-neoplastic cases of Eaton–Lambert syndrome than in the presence of small-cell carcinoma (Leys *et al*. 1991). How this antibody (or antibodies) is generated remains obscure. It appears unlikely that this mechanism is related to the generation of other pathogenic autoantibodies. The occurrence of Eaton–Lambert syndrome has been reported in association with rheumatoid arthritis (Peris *et al*. 1990), systemic lupus erythematosus (Hughes and Katirji 1986), and Sjögren's syndrome (Tsuchiya *et al*. 1993), but is so rare as to be presumed coincidental.

Treatments endeavour to regain the effectiveness of acetyl choline. Plasmapheresis produces transient clinical improvement, although more gradually in Eaton–Lambert syndrome than in myasthenia gravis. Therefore, Newsom-Davis and Murray speculated that improved strength in Eaton–Lambert syndrome results from newly synthesized acetyl choline rather than from removal of blocking antibody (Newsom-Davis and Murray 1984). Resection of the carcinoma may result in neuromuscular improvement. Corticosteroid therapy may be beneficial, but the effect develops more gradually than in myasthenia gravis, possibly over months. The first relatively specific medication for Eaton–Lambert syndrome was guanidine, 20 to 30 mg/kg per day orally; it facilitates the release of acetyl choline. However, there is risk of bone marrow depression and other toxicities (Henriksson *et al*. 1977). 3,4-diaminopyridine enhances acetyl choline release by prolonging the action potential

and calcium influx. In dosages from 15 to 100 mg/day it is at present the most efficient medication. Its main, infrequent, side-effect is seizures (McEvoy 1994). In the absence of a fatal neoplasm Eaton–Lambert syndrome is a chronic disease.

Fasciitis syndromes

Several varieties of non-infectious fasciitis have been described in recent years: eosinophilic fasciitis (1974); palmar fasciitis (1982); fasciitis–panniculitis (1992). The main pathological difference between eosinophilic fasciitis and fasciitis–panniculitis seems to be the lack of an eosinophilic infiltrate in the latter. The strongest clue that the neoplasms described in a minority of cases of eosinophilic fasciitis and fasciitis–panniculitis are not merely coincidental events is that they have almost exclusively been haematological (Lakhanpal *et al*. 1988; Naschitz *et al*. 1994).

Medsger *et al*. described a 'palmar fasciitis-arthritis syndrome' associated with ovarian carcinoma (Medsger *et al*. 1982). This may be the neoplasia induced variant of reflex sympathetic dystrophy, which it resembles. Cases published as 'shoulder-hand syndrome associated with cancer' probably have been instances of the same process (Michaels and Sorber 1984). However, there are differences from typical reflex sympathetic dystrophy: palmar fasciitis is always bilateral, may involve the lower extremities, and tends to advance to severe disability more rapidly. The skin of the hands becomes so tense that a misdiagnosis of scleroderma may be made. Involvement of the plantar fascia has also been reported. The shoulders are affected consistently, but the arthritis may also involve extremity joints. Most patients have been women above the age of 55, and about half of the neoplasms have been ovarian carcinomas (Pfinsgraff *et al*. 1986). The syndrome develops a few weeks to a year before discovery of the neoplasm and may first occur with a recurrence (Mesdger *et al*. 1982). Treatment of the neoplasm usually does not alleviate the syndrome.

5.19.2 Algodystrophy (reflex sympathetic dystrophy syndrome)

Geoffrey O. Littlejohn

Introduction

Algodystrophy is an important pain syndrome characterized by variable dysfunction of musculoskeletal, skin, and vascular systems. The most characteristic feature is persistent pain, and this plus the associated disability, may have profound psychosocial effects. Moreover, the clinical features may be recalcitrant to medical intervention. Algodystrophy presents in a variety of clinical states and may be mild and short-lived or severe and prolonged. It is important to recognize the syndrome in the early and often incomplete phase if currently available therapeutic approaches are to be most effective.

Nomenclature

Algodystrophy is a chronic pain syndrome. Pain is the dominant symptom and, although the clinical features are characteristic and reproducible, the exact cause of the problem is unclear. Algodystrophy may occur in a variety of clinical conditions, affect different regions of the body to a greater or lesser extent, and the clinical manifestations vary around the central core features. As such there are a large number of descriptive names that are synonyms for algodystrophy. Reflex sympathetic dystrophy syndrome is the most appropriate alternative. Even so, this term is only used in a descriptive sense and does not imply specific underlying mechanisms (Janig *et al*. 1991). Table 1 summarizes some of the synonyms for algodystrophy. Some prefer to use the original nomenclature in situations where the precipitating cause is obvious: for instance, the syndrome is often called causalgia when it follows injury to a peripheral nerve, or Sudeck's atrophy where it follows wrist fracture. The term algodystrophy, derived from the Greek *algos* meaning pain and 'dystrophy' meaning a disorder related to poor nourishment, best encapsulates the principal clinical features and serves to remind us of the essential nature of the syndrome.

Reflex sympathetic dystrophy syndrome
Causalgia
Shoulder–hand syndrome
Sudeck's atrophy
Transient osteoporosis
Regional migratory osteoporosis
Post-traumatic painful osteoporosis
Complex regional pain syndrome

Table 1 Selected alternative terms for algodystrophy

The distinctive but varied clinical features of algodystrophy have provided classic clinical descriptions for over 100 years. Indeed, Hunter was one of the earliest to allude to this condition (Hunter 1843). By the middle of the nineteenth century, formal clinical descriptions were available in the context of traumatic lesions of peripheral nerves. Mitchell *et al*. (1864) described the deep burning pain of causalgia but also emphasized other features such as 'the skin affected in these cases was deep red or mottled, or red and pale in patches, ... the surface of all the affected part was glossy and shining as though it had been skilfully varnished ..., in some form, pain has been invariably attendant upon the disease state of skin which we have tried to describe. ... In the great mass of cases, it has been of that peculiar burning character of which we have spoken, ... in other instances, there was associated with this, acute or aching pain which extended beyond the disease tissues.' With the advent of radiology the clinical manifestations were greatly expanded as the breadth of the syndrome was recognized (Doury *et al*. 1981).

More recently the putative role of the sympathetic nervous system in this syndrome has been incorporated through use of the terms sympathetic-maintained (or mediated) pain and sympathetically independent pain (Roberts 1986). These subgroups are differentiated on the response of the pain to sympathetic blockade (Campbell *et al*. 1992). In a further development the term complex regional pain syndrome has been proposed, based entirely on clinical features (Merskey and Bogduk 1994)

Epidemiology

Algodystrophy is a common rheumatological disorder. It has been seen in all races and geographical regions. It affects both sexes and may occur at any age. Historically the published records have concentrated on the elderly patient who has sustained trauma, for instance a Colles' fracture, but over the last decade the occurrence of algodystrophy in children, particularly adolescent girls, has been well characterized (Silber and Majd 1988; Cicuttini and Littlejohn 1989; Sherry *et al*. 1991). In the adolescent, girls are affected far more than boys and in the adult, men seem to be affected more than women. The most frequent age group affected is between 40 and 60 years of age.

As with many rheumatic diseases the 'classical case' is easily characterized and recognized but occurs far less commonly than *formes frustes*. Minor variants tend to be less troublesome or may be regarded, in some instances, as part of the initiating cause. For example, minor algodystrophy following trauma may be regarded as a part of the normal response to injury. Minor forms may also occur in other painful, peripheral rheumatic disorders such as inflammatory arthritis and thus be hidden with the clinical features of the inflammation itself. A true estimate of the prevalence of the condition is thus extremely hard to provide.

In its classical form, 1 in 200 people presenting to a trauma unit will develop algodystrophy (Plewes 1956), but in other traumatic states up to 1 in 20 will develop it (Kozin 1986). Before the intensive mobilization of patients with myocardial ischaemia or hemiplegia became acceptable, between 5 and 20 per cent of such patients developed algodystrophy (Davis 1977). In a study of 109 unselected patients with Colles' fracture, 25 per cent had two or more features of algodystrophy at 9 weeks, while at 6 months 62 per cent showed some residual abnormalities (Atkins *et al*. 1989). It is likely that the prevalence of algodystrophy will always be underestimated

because of its minor variants. In order to identify mild or early forms of algodystrophy, it should be anticipated where there are triggering events known to be associated with the syndrome.

Clinical features

Like other chronic pain syndromes the chief complaint and that which draws the syndrome to the attention of the medical practitioner is pain. This not only manifests as spontaneous, often burning, pain but also as a pain amplification state. Here otherwise innocuous stimuli produce pain (allodynia) and there is increased pain perception to a given painful stimulus (hyperalgesia). Hyperpathia, where there is delayed overreaction particularly to a normal repetitive cutaneous stimulus, is also found. The pain will usually occur some days to weeks after a triggering factor, if present, and will generally be constant. Although burning pain is a characteristic of the syndrome, more commonly the pain is described as a deep, dull aching sensation. Paroxysms of pain may occur, lasting for seconds. The pain may disturb sleep, and even any slight movement that mechanically stimulates the sensitized region will produce worsening of the symptom. The patient may report the use of cold, wet compresses to relieve the discomfort.

Typically the syndrome principally involves the distal part of a limb; for instance, a hand and lower forearm region (Fig. 1) or a foot and lower leg. With time, in the majority, much less apparent but definitely abnormal clinical features occur in the opposite limb. The syndrome may involve one digit or rarely all four limbs. Shortly after the onset of pain, swelling, the second most common feature, occurs (Blumberg *et al*. 1994). This may be intermittent in the early stages and is usually associated with a change in the texture of the overlying skin, producing the reticular or lividoid appearance over the involved part (Fig. 2). Palmar erythema may be noted. Early in the course the involved region is warmer than the surrounding region. Varying degrees of sweating may occur but are not essential to the diagnosis. There may be piloerection.

Fig. 1 Reflex sympathetic dystrophy syndrome of the left hand in a 21-year-old man after trauma, showing diffuse swelling, cutaneous blood-flow change, and dystrophic skin changes. One of the earliest reported pictures of this condition (from Otis (1877), by courtesy of Dr R.L. Travers).

Fig. 2 Diffuse swelling of lower right forearm and hand in a 13-year-old girl with reflex sympathetic dystrophy syndrome. There is extreme hyperalgesia. Note flexed wrist and hand posture and skin discoloration. (By courtesy of Dr R. Allan, Royal Children's Hospital, Melbourne, Australia.)

Examination confirms the presence of a decreased pain threshold, particularly to mechanical stimuli, leading to abnormal tenderness as the principal clinical finding. Early in the course the hyperalgesia tends to be periarticular, but later regions well away from joints and particularly those over bone also become exquisitely tender. This distribution is non-(neuro-) anatomical and found over a wide region of the involved parts. For instance, if the principal involvement is in the mid- tarsal region of the foot, one would usually find tenderness on palpation of a metatarsophalangeal joint and regions of the lower leg, as well as in intervening areas. Mild oedema may be noted, either pitting or not. Early on, joint movement in the region will be restricted by pain but with care it be demonstrated that the range of motion is often near normal, despite the initial impression (Fig. 3). There may be a prominent motor component with tremor, weakness, or muscle tightness.

Fig. 3 Right lower leg and foot in a 15-year-old female patient with reflex dystrophy syndrome showing skin discoloration, regional swelling, and inability to extend the right ankle (a) and the adoption of a plantar flexion (b) assumed in order to reduce pain. The lower third of the leg, including the foot was extremely hyperalgesic. (By courtesy of Dr R. Allan, Royal Children's Hospital, Melbourne, Australia.)

Triggering events

A number of well-characterized events may precede algodystrophy. It is best to regard these events as triggers rather than as causative because of the wide variety of different associations. Table 2 summarizes the important disorders associated with algodystrophy.

	Approximate frequency of association (%)
Trauma	50
Idiopathic	25
Disorders of the nervous system	
Central conditions

Table 2 Selected disorders associated with algodystrophy

In most series, depending on the criteria for classifying algodystrophy, trauma will be identified as a trigger in around half of subjects (Doury *et al*. 1981; Kozin 1986). In many instances it is likely that a prior traumatic episode will have been recalled by the patient after the development of algodystrophy rather than the event being a true trigger. However, major and even minor, apparently trivial, traumas, particularly to a distal part of a limb, have been clearly linked to the development of the syndrome. In about one-half of cases the trauma will have led to bone fracture and indeed many accounts of the syndrome come from observations made on peripheral fractures, such as Colles' fracture at the wrist. Other important traumatic triggers include simple sprains, strains, contusions, or jarring injuries, particularly to the distal part of the limbs. Surgical procedures, particularly of limb joints, such as arthroscopy, can induce algodystrophy (Small 1993). Other triggering traumas include peripheral burns and frost-bite. Trauma to articular more than diaphyseal regions predisposes to this syndrome (Fontaine *et al*. 1957). Although trauma is a common trigger, in the context of the large number of traumatic events found in any community, the subsequent development of algodystrophy affects less than 1 per cent of all such events. Perhaps a common thread among injuries that result in algodystrophy is the individual's reaction to pain and the frightening nature of the injury, be it major or apparently trivial.

A variety of disorders of the nervous system may act as triggers. These include conditions resulting in hemiplegia and other central diseases, including cerebral tumour, meningitis, or syringomyelia, among others. Peripheral nerve injury is the classical cause of causalgia but other peripheral nerve disturbances such as those caused by *herpes zoster*, nerve-root impingement, or peripheral neuropathy may result in this syndrome. Pain arising from a visceral or deep somatic structure, such as myocardial ischaemia in the former instance and mechanical pain from the cervical spine in the latter, may be associated. Pain arising from a peripheral origin, such as that seen in inflammatory arthritis or after deep venous thrombosis, may provoke the syndrome. Certain medications, particularly barbiturates and isoniazid, have been reported as triggers.

There are a variety of other conditions that may be linked with algodystrophy. These include pregnancy (with particular involvement of the hip), metastatic tumours, acrodermatitis continua, and prolonged immobilization of a peripheral limb (Schwartzman and McLellan 1987). The suggestion that there is an increased prevalence of diabetes and hypertriglyceridaemia in this group of patients (Amor *et al*. 1980) has been refuted by others (Eurly 1992).

At least 25 per cent of cases have no easily identifiable trigger. Here the search for central factors or psychological susceptibility is often made. In children it is common to find an unresolved stress or an unsatisfactory psychosocial state in the background (Sherry and Weisman 1988). In adults, this is more difficult to identify clearly. A small percentage of patients developing algodystrophy will have a defined psychiatric condition, such as major depression, or a chronic anxiety state, but many more are likely to have abnormal reactions to psychosocial stresses. These factors may be difficult to identify accurately but there is often a strong clinical impression that they are playing an important part in the triggering or expression of the syndrome. However, in many patients, no such factors can be identified. There is no definite evidence that particular personality traits predispose a person to develop algodystrophy (Bruehl and Carlson 1992; Lynch 1992).

Course

In most instances the clinical features persist, fluctuate, or gradually resolve according to the natural history or treatment intervention, without further sequelae. In some patients there is a dystrophic phase, usually some months after the start of the problem. Here the limb becomes cool, and cutaneous pallor or cyanosis replace the previous erythema. There is decreased growth of dermal appendages, such as hair, and the nails become brittle. Skin and subcutaneous tissues may atrophy. Increased sweating becomes more prominent and the pain persists and often worsens. There may be dysaesthesia (painful, abnormal skin sensation) in a non-anatomical distribution. Radiological evaluation will show change in the mineral content of bone in the area. Joints become tighter, this time due to contracture of surrounding structures. After several months there may be an atrophic phase. Pain usually decreases at this stage but can remain intractable in some. There may be marked atrophy of subcutaneous tissue, such as to cause tapering of digits, and flexion contractures of peripheral joints become prominent. The limb is characterized by vasoconstriction and coolness and the skin is cyanotic, smooth, and glossy. Hair growth can be increased or decreased.

While the clinical features of algodystrophy are easy to recognize, there are, as mentioned above, more patients who have variations or incomplete forms than have the typical condition. Variants are particularly common in children where the painful limb is usually cool and slightly swollen from the outset and the syndrome does not tend to go through the classical phases, often resolving much more quickly than in an adult.

Traditionally the disorder has been staged according to observations by Steinbrocker and Argyros (1958), where stage 1 comprises the 'acute' clinical features with pain, tenderness, swelling, and vasomotor and pseudomotor changes predominating. With time, stage 2 will supervene and this is dominated by dystrophic features and will last for several months. Stage 3 comprises atrophic changes and may be long lasting. In extreme cases this classification is of use but in the average situation most patients do not progress beyond stage 1 or early stage 2. Perhaps this is because of early intervention or perhaps we are now diagnosing the condition in its milder and incomplete forms more often. Many patients also have features derived from different components, and investigations and clinical features often do not correlate, irrespective of the chosen staging. The success of treatment does not depend on the patient's clinical stage except that profound stage 3 changes are difficult to reverse.

Classification

There is no validated classification for diagnosis in the clinical setting or for research purposes because of the polymorphic nature of algodystrophy. The classification of Kozin *et al*. (1981) is often very useful clinically. Here, definite algodystrophy is present when there is pain and tenderness in an extremity, swelling of that extremity, and vasomotor or pseudomotor changes. Dystrophic change may also be present. Probable algodystrophy consists of pain and tenderness, together with vasomotor and pseudomotor changes or swelling; possible algodystrophy comprises vasomotor or pseudomotor changes; and doubtful algodystrophy is considered where there is pain and tenderness out of keeping with any preceding injury or other organic disease process.

Regions involved

Several common areas of involvement have been defined (Doury *et al*. 1981). The arm may be involved in a unipolar fashion, with either shoulder (frozen shoulder) or hand being affected. Involvement of the shoulder is associated with marked retraction of the joint capsule, restricted range of motion, and pain persisting for several months. On resolution of the syndrome, loss of range of motion of the shoulder is common, although usually not clinically significant. Peripheral involvement may include a single digit (Laukaitis *et al*. 1989), a few metacarpal rays (Lequesne *et al*. 1977), or more typically the whole hand and lower forearm may be involved. Bipolar forms include the shoulder–hand syndrome. Up to 25 per cent of upper-limb involvement is bilateral, the changes in the opposite side often being more evident after investigation (Kozin *et al*. 1976).

Leg involvement, although more common, is less dramatic than that of the arm.. Here the features are usually confined to a part of the limb such as the foot, knee, or hip. Bipolar and bilateral involvement are less common than in the arm. Involvement of the knee, either of the whole or of part, including the patella, has only more recently been characterized (Tietjen 1986; Coughlan *et al*. 1987).

Algodystrophy of the hip is less commonly recognized because the hip joint is deeply positioned and there is a lack of the cutaneous features that are more common in peripheral and superficial sites. The duration of symptoms in this region is shorter, possibly because early mobilization is easier. Some (for example, Lakhanpal *et*

al. 1987) suggest that this variant is distinct enough to be termed transient regional osteoporosis. Absence of precipitating trauma, good outcome, and a propensity for recurrent episodes and involvement of multiple regions is characteristic of this variant. Signs of cutaneous or vascular change are uncommon. Algodystrophy may also affect the spine and occasionally other areas of the skeleton.

Investigations

Laboratory investigations

There is no abnormality of acute-phase reactants nor of standard biochemical markers in algodystrophy. In some patients with early disease, 24-h urinary hydroxyproline excretion may be increased, reflecting bone demineralization (Doury 1988).

Imaging

The principal contribution to diagnosis remains clinical. However, a number of radiological and nuclear medicine techniques may show characteristic abnormalities. As there is no specific 'gold standard' for diagnostic criteria it is difficult to establish the clinical usefulness of these investigations. The main problem arises from the many variations of the syndrome, and most studies have considered only severe algodystrophy in evaluating investigations, thus producing a distorted view of their clinical utility. Table 3 summarizes selected investigations.

Investigation	Changes	Usefulness
Plain radiography	Patchy osteopenia early; diffuse late	Moderate predictive value
Fine-detail radiography	Diffuse and periarticular osteopenia common	80% abnormal
	Cortical bone resorption	
	Juxta-articular/subchondral erosion	
Dual-photon absorptiometry	Loss of up to 30% of bone mass	Unknown
Dual-X-ray absorptiometry	Bone loss shown	Unknown
Magnetic resonance imaging	Regional/diffuse bone loss	Unknown, probably low
Scintigraphy	Abnormal in early, pool, or late phases	High specificity
Thermography	Change in cutaneous temperature	Unknown

Table 3 Investigations in algodystrophy

Sudeck (1900) first showed the value of radiology in this condition. Plain radiographic changes reflect bone demineralization; these may take several weeks to months to appear after the onset of the syndrome. These changes persist longer than other clinical features on resolution. Some patients never have radiological changes and others have only subtle changes. It is essential that good technique and meticulous examination of radiographs, with comparison of the affected side to the other side, be performed. Characteristically children have far less radiological changes than adults, with only the minority showing demineralization. Patchy osteopenia may be seen in the early stages and diffuse changes characterize the later stages. Typically in the hip or knee, changes are most obvious in the subchondral region where loss of subchondral bone and preservation of subchondral plate will produce a significant finding. Severe juxta-articular changes might include erosions. However, the joint space is never affected. The sensitivity and specificity of radiological appearances are around 70 per cent for well-defined algodystrophy (Kozin *et al*. 1981). Plain radiography is an essential investigation but has only moderate predictive value for diagnosis. Fine-detailed radiography better shows the demineralization, which is accentuated around epiphyseal regions, reflecting hyperaemia at this site. Subperiosteal, endosteal, and intracortical bone resorption together with juxta-articular and subchondral erosions, are observed frequently with this technique (Genant *et al*. 1975; Griffiths and Virtama 1988).

Magnetic resonance imaging (MRI) may also show changes characteristic of bone loss (Fig. 4). For instance, in the hip, low intensity signal on T_1-weighted images and high intensity on T_2-weighted images may be seen. The clinical usefulness of this technique and absorptiometry, which also may reflect bone loss, is yet to be established.

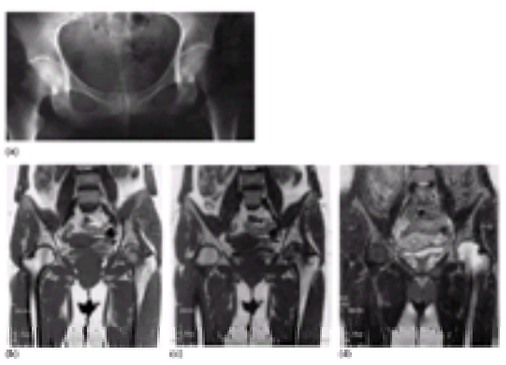

Fig. 4 (a)–(d) A 31-year-old female patient with transient regional osteoporosis of the left hip. Plain films (a) indicate regional osteoporosis of the left femoral head. MRI scan (b,c,d) shows changes of diffuse osteopenia in the left femoral head, compared with normal changes on the right side. (By courtesy of Dr John Stuckey, Victorian Imaging Group, Melbourne, Australia.)

Scintigraphic studies using technetium have a high specificity but a similar sensitivity to that of plain radiographs (Fig. 5). Typically a three-phase study (Kozin *et al*. 1976) is made, with the early phase showing regional blood flow over the first 2 to 3 min, the second phase showing the blood-pool image, and the third phase (some 2 to 4 h later) showing the standard bone-uptake findings. While any of these three phases may be abnormal it is more common to find increased flow (early phase) and uptake (late phase) in around 80 per cent of abnormal studies. Diminished flow and uptake are more commonly seen in children and adolescents than in adults (Silber and Majd 1988; Goldsmith *et al*. 1989). Scintigraphy appears more accurate if symptoms have been present for less than 6 months or if the patient is older than 50 years (Werner *et al*. 1989). Multiple investigations are often needed (Fig. 6).

Fig. 5 A 28-year-old female patient with diffuse increase in isotopic uptake of right foot and lower end of right tibia, in a foot which was diffusely swollen and extremely hyperalgesic. The reflex sympathetic dystrophy in this case was associated with Reiter's disease initially affecting the right ankle. Inflammatory arthritis, trauma, or

other pain stimuli may associate with the onset of reflex sympathetic dystrophy.

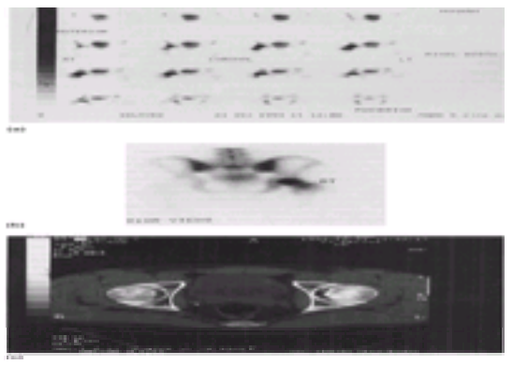

Fig. 6 A 39-year-old male with 4 months of pain from right hip. The nuclear scan (a and b) with spectroscopy reveals marked increase in isotopic uptake in the right femoral head and neck. The CT scan (c) shows osteopenia. Femoral head biopsy showed osteopenia of the neck and head of femur. The diagnosis was transient regional osteoporosis of the femoral head. (By courtesy of Dr John Stuckey, Victorian Imaging Group, Melbourne, Australia.)

Thermography may show changes in regional cutaneous temperatures compared with the unaffected side (Perelman *et al*. 1987). Typically there is an early increased or, particularly in children, decreased cutaneous heat emission. Critical evaluation of this technique is required before it can be usefully applied clinically (Fig. 7).

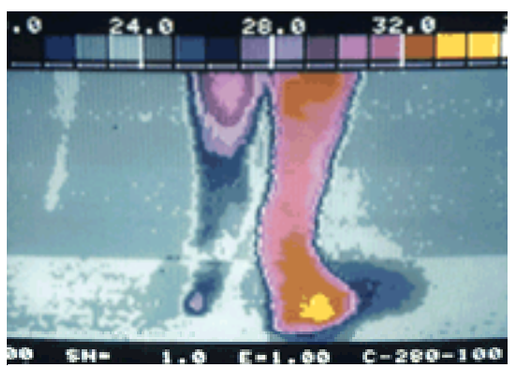

Fig. 7 Thermogram indicating lowered skin temperature (blue colours, compared with normal temperatures pink-red) of right leg and foot in a 15-year-old female patient with reflex dystrophy syndrome. (By courtesy of Dr R. Allan, Royal Children's Hospital, Melbourne, Australia.)

Histopathological changes

Synovial biopsies of joints in the region of algodystrophy will often show low-grade synovitis characterized by proliferation of synovial cells and small blood vessels, together with a mild chronic perivascular infiltrate. There have only been limited studies on the bone demineralization, periarticular fibrosis, and dermal atrophy (Arlet *et al*. 1978; Doury *et al*. 1981).

Diagnosis

The diagnosis of algodystrophy is based on the clinical features. A high degree of clinical suspicion is required, particularly in early diagnosis. Focal disease may mimic inflammatory or infectious arthritis or bone disease, trauma, or osteonecrosis. Characteristic clinical features, elimination of other causes for such symptoms, and appropriate imaging will usually allow for a clinically robust diagnosis. The most important thing in diagnosis is to think of the possibility of algodystrophy.

Pathophysiology

Algodystrophy is caused by a regional change in function of the pain system. This involves both peripheral and central mechanisms in a complex manner. The cause for this pain syndrome is poorly understood. However, many of the clinical features reflect change in function of various components of the peripheral nervous system. Many fibre types with different functions appear to contribute in varying degrees to the syndrome.

Table 4 summarizes the principal clinical characteristics of the syndrome and possible causative mechanisms. Input from two afferent fibre types, the small diameter, non-myelinated C-fibres and the large, myelinated A-b-fibres, together with change in function of sympathetic efferents, appear the likely mediators of many of the peripheral features. Sympathetic activity, through release of noradrenaline and the inflammatory prostaglandins, may sensitize peripheral nociceptors, thus decreasing threshold to peripheral mechanical and chemical stimuli. This may result in the hyperalgesia. It has been suggested that a $_1$-adrenergic receptors may become expressed on such nociceptors, particularly in a post-injury situation, and that these receptors will respond to sympathetic fibre release of noradrenaline (Campbell *et al*. 1988). Subsequent release of proinflammatory neuropeptides, such as substance P, by activated C-fibres would contribute to regional neurogenic inflammation with increase in blood flow and oedema. The associated synovitis may be due to this mechanism. Levine *et al*. (1984) have demonstrated that substance P contributes to experimental synovitis and this system is further modulated by alteration of sympathetic input. Periarticular osteoporosis may relate to the hyperaemia in the epiphyseal vessels in particular, or to neuropeptide effects on bone mineral metabolism. Allodynia is likely to reflect abnormality within the large myelinated afferent fibre system, as blocking these fibres by local anaesthetics will abolish this finding in other situations (Meyer *et al*. 1972; Roberts 1986).

TABLE cellSpacing=0 cellPadding=0 align=left border=0 hspace="10" vspace="5">

Characteristic	Mechanism
Pain	
Spontaneous	Sensitized peripheral/central nociceptors
Allodynia	Large myelinated fibre input to sensitized dorsal horn transmission neurones
Hyperalgesia	C-fibre sensitization in periphery+sensitized 2nd order neurones
Movement pain	Large myelinated fibre input to sensitized dorsal horn transmission neurones
Swelling	Neuropeptides from C-fibres; sympathetic effects on post-capillary venules
Bone change	Hyperaemia secondary to neuropeptide release; sympathetic effects
Synovitis	Neuropeptides
Dystrophy	Unknown neurological mechanism; mechanical effects

Table 4 Pathophysiological mechanisms in algodystrophy

In sophisticated tests, sympathetic efferents can be shown to have abnormal activity in the majority of patients with this syndrome. Many patients, though not all, do respond to sympathetic blockade, highlighting the role of sympathetic activity. The interaction between the products of the sympathetic nervous system and the peripheral nociceptors is also highlighted by the knowledge that injection of noradrenaline will exacerbate pain and this is blocked by intravenous administration of the a_1-adrenergic antagonist, phentolamine. The phentolamine test can be used diagnostically to help predict patients who have a large sympathetically maintained component to their syndrome and those who are likely to benefit from sympathetic blockade (Arner 1991; Campbell *et al*. 1992).

The cause for these functional changes in the peripheral pain system is still unclear. Livingstone (1943) suggested that there was a persisting peripheral afferent stimulus which led to abnormal activation of internuncial neurones situated in the dorsal horn at the relevant level. Efferent sympathetic activity was felt to follow that sequence. The realization that the majority of patients with algodystrophy do not have an identifiable persisting afferent stimulus in the region of pain, has led to an appreciation that a functional change within the dorsal horn itself is the most important cause for the syndrome. This functional dorsal horn abnormality is usually triggered by minor trauma, often in an emotional context. This was accounted for by Lankford and Thompson's theory (Lankford and Thompson 1977).

Roberts (1986) has suggested that initial activation of the unmyelinated C-fibre nociceptors, through unknown mechanisms, leads to sensitization of wide dynamic range neurones in the dorsal horn. Such neurones receive not only nociceptive input but input from other sources, including low-threshold, large myelinated afferents that otherwise serve functions such as proprioception. Input from these fibres resulting, say, from change in joint position or movement will impinge on the sensitized neurone with wide dynamic range in the dorsal horn and this input will be perceived as pain (allodynia). Central sensitization mechanisms mediated by excitatory amino acids and their interaction with the *N*-methyl-D-aspartate receptor, as well as the neuropeptides, are relevant to this process (Schwartzman 1993).

With activation of the system, automatic reflex changes at a segmental level lead to both muscle change and stimulation of the sympathetic system. The former may result in various neuromuscular features that can accompany algodystrophy, such as dystonia or other movement disorders (Schwartzman and Kerrigan 1990). The latter will affect functions in peripheral tissues and may result in a number of the dystrophic features of the syndrome. In addition, the cycle is completed whereby sympathetic efferent activity maintains peripheral fibre sensitization, which in turn feeds back into the dorsal horn system initiating further sympathetic activity. Such neurogenic reflexes are usually bilaterally represented, explaining the bilateral findings in many patients with algodystrophy.

The reason for change in function of these interactions in the dorsal horn is unclear. It seems naïve to explain such intense pain syndromes on purely segmental and peripheral pathophysiological changes. The complex and hierarchical nature of the pain system includes essential connections to the higher centres including the cortex. Important descending influences from higher centres impinge on the dorsal horn and modulate many components of the pain system. Thus central events which might include a variety of cortical and psychological factors may further influence this system. These might include the stress of pain itself and its effects on the central nervous system and the hypothalamic–pituitary axis, the patient's beliefs, mood, emotions, and even their quality of sleep. A change in any of these factors may affect the homeostatic mechanisms involved in pain control and sensitization phenomena in the dorsal horn. It is through such mechanisms that the emotional and affective components of the painful stimulus modify the peripheral reception and processing of further information relating to pain (Harvey 1987).

Algodystrophy shares many features with fibromyalgia syndrome, another common chronic pain syndrome (Bengtsson and Bengtsson 1988; Vaeroy *et al*. 1989). When this syndrome is localized a significant component of patients' symptoms relate to sympathetic-maintained pain (Fig. 8). Other features shared between the two syndromes are allodynia, hyperalgesia, and dermatographia. Table 5 compares selected features of these syndromes.

Fig. 8 A 28-year-old female with reflex sympathetic dystrophy syndrome of right lower leg from knee to foot. This area was extremely hyperalgesic compared with the left side. Signs of overt swelling, colour change, or other change 'sympathetic' features were lacking, as can be the case. This patient later developed a regional pain syndrome involving low back and all of the right leg. This illustrates the spectrum of reflex sympathetic dystrophy syndrome in that not all patients have the classic features.

Syndrome	Nociceptor	Mechanoreceptor	Sympathetic nervous system	Motor
Algodystrophy	++	++	+++	+
Fibromyalgia	++	+	+	+
Dystonia				+++

+ to +++ indicates range of qualitative changes.

Table 5 Abnormalities in different pain syndromes and dystonia

Other factors that may be important in the pathophysiology have been variously reviewed (Doury *et al*. 1981; Carlson and Jacobs 1986; Escobar 1986; Fields 1987; Kozin 1994; Janig 1996).

Management

Algodystrophy must been seen as a pain syndrome if an effective treatment programme is to be provided. This involves treating the whole patient and not just the obviously abnormal area of complaint in the periphery.

Preventive strategies include the recognition of situations that are likely to provoke the syndrome. Thus early mobilization after myocardial infarction, cerebrovascular accident, hand surgery, or mild peripheral injury is essential. Appropriate reassurance and direction in the handling of patients in any post-traumatic setting, particularly in emotionally charged, work-related events is essential.

Many authorities indicate that prognosis for full recovery relates inversely to the duration of symptoms before the onset of treatment; however, others feel that the syndrome can reverse, to a large extent, at any time (Kozin *et al*. 1987).

In milder forms of algodystrophy the principles of management (Table 6) include adequate pain relief, reassurance, and explanation. A positive approach in regard to outcome is appropriate and necessary. Careful explanation is required to ensure that the holistic concept of a chronic pain state is understood by the patient, according to their level of understanding. This is essential; it leads to a co-operative management plan that has the patient as the key person in the team. This

syndrome is not well served by the adoption of the 'injury' model where a powerful external 'treater' is required to give the 'curative' treatment. Such well-intentioned approaches often lead to a more dense ingraining of the syndrome, probably through blocking of positive benefits that would come from modulation of the central pathways on to the dorsal horn. Similarly, certain systems of compensation and other medicolegal events appear to inhibit resolution of the syndrome.

Accurate, early diagnosis
Explanation, reassurance
Adequate analgesia (medication, transcutaneous electrical stimulation)
Prevention of dystrophic change—exercise, movement
Attention to sleep disturbance
Attend to pain behaviour, psychosocial stresses, including compensation, litigation issues
Transient interruption of sympathetic activity
Skilled pain management/psychological counselling
Other

Table 6 Principles of management of algodystrophy

Counselling the patient, attending to the associated anxiety, and correcting any sleep disturbance, often through the use of low-dose tricyclic medication, are beneficial and prevent further amplification of the syndrome.

Useful treatments in milder algodystrophy, particularly in children, are exercise programmes which might include hydrotherapy. Activation of muscles and mechanoreceptors probably inhibits the activated dorsal-horn pain system on a local, segmental basis.

Numerous other treatment programmes have been suggested for the more severe or persistent types of algodystrophy. Some find systemic corticosteroids to be beneficial, even when the syndrome has been long-lasting (Kozin *et al*. 1981; Christensen *et al*. 1982). A typical course might commence at around 50 mg of prednisolone a day in divided doses and decrease to zero over 3 to 4 weeks. Subsequent courses may be needed. Some have advocated calcitonin, for example, 100 to 160 IU/day over 10 to 14 days, which has been shown to have benefits over placebo (Gobelet *et al*. 1986; Gobelet *et al*. 1992).

Interruption of the sympathetic efferent system to the region through various techniques has proved beneficial to many patients. Typically, a regional sympathetic ganglion block is made, using up to five short-acting sympathetic blocks, on a daily or alternate-day basis. If pain relief results, the patient is started on a more vigorous physiotherapy or exercise programme. Such approaches may result in 40 per cent of patients having a better result after 3-years follow-up; however, the majority have a less useful outcome (Wang *et al*. 1985).

Regional sympathetic blocks compare favourably with ganglion blockade (Bonnelli *et al*. 1983). These may be achieved using the Bier technique, whereby occlusion of venous outflow to the region, usually the lower arm or leg, is followed by intravenous installation of guanethidine or another similar agent. The exact mechanism of action of sympathetic modulation is unclear. Peripheral nerve blocks in the axilla will also modify afferent nerve transmission and may be useful. Again these procedures often need to be repeated to achieve sustained results (Schwartzman and McLellan 1987).

Surgical sympathectomy is only done if there is definite, but short-lived, improvement with the previous procedures.

Many other approaches have been used; these range from epidural opioids to cutaneous clonidine patches. Controlled studies are lacking for most of these approaches (Dotson 1993). The large variety of therapies emphasizes the difficulty in treating established algodystrophy. My approach to management is as follows:

1. *Young patient, any severity, any duration*:

   Always

   a. accurate diagnosis, explanation, reassurance as to expected good outcome;
   b. identification and management of psychosocial stressors especially family, school, or other;
   c. establishment of a regular activity programme—walking, bicycle riding, swimming, etc.
   d. resumption of all previous activities, especially those related to school;
   e. careful supervision of programme and close liaison with parents, especially the mother if a female patient.

   Often

   a. transcutaneous nerve stimulation to help pain control and allow entry into activity programme;
   b. hydrotherapy if limb sensitivity to movement is extreme. An empathetic physiotherapist is often the most powerful tool in this programme.

   Sometimes

   a. tricyclic medication to correct sleep disturbance and increase the pain threshold;
   b. a clinical psychologist to help manage pain and consider psychosocial background dynamics;
   c. regional temporary sympathetic/ganglion blocks;
   d. other approaches.
2. Adult patient, mild severity, and duration:

   Always

   a. accurate diagnosis, explanation, reassurance as to probable good outcome;
   b. identification and management of any obvious psychosocial stressors including work-related or legal issues;
   c. establishment of regular activity programme using involved limb;
   d. planned return to all previous activities currently abandoned due to pain;
   e. careful supervision of the programme with attention to the 'blocks' to progress that often occur.

   Often

   a. supervision of the physical programme by a physiotherapist with use of transcutaneous nerve stimulation, hydrotherapy, and similar tactics to control pain and encourage activity;
   b. short-term use of tricyclic medication.

   Sometimes

   a. pain-management counselling by clinical psychologist or similar skilled person;
   b. regional temporary sympathetic/ganglion blocks;
   c. other approaches, such as short-course corticosteroids.
3. Adult patient, moderate/severe, prolonged duration:

Always

a. use all the above approaches, sometimes sequentially and sometimes concomitantly;
b. put emphasis on pain-management counselling early in programme, with frequent use of interventions to block efferent sympathetic outflow, and/or corticosteroids;
c. stay with the patient—suboptimal therapeutic responses require longer-term support.

Prognosis

The outcome for patients with algodystrophy is quite varied. Minor forms seem to have an excellent outcome and children with the condition are expected to regain normal function and lose their pain. Some adults with severe forms of the condition may have protracted chronic pain states, significant dystrophic tissue change and longer-term disability. Pain usually eases over time even in those patients.

Summary

Algodystrophy is a common and significant musculoskeletal condition that results from a complex neurophysiological change in the pain transmission pathways. The syndrome is characteristic and reproducible but many variants occur clinically. The best treatment is through early recognition and management along principles used in other chronic pain syndromes, but with particular attention to the characteristic increase in sympathetic-maintained pain.

5.19.3 Rheumatic complications of drugs and toxins

Robert M. Bernstein

Congratulations if you have reached this chapter or happened upon it by chance. The author felt obliged to meet you here, because Francis Bacon held 'every man a debtor to his profession.' Bacon was also of the opinion that 'books must follow sciences, and not sciences books', but often books follow books: they contain not truth but copies of bad maps, so it is up to the student to read the scientific literature directly as well as learn by exploration and experience.

This chapter deals briefly with rheumatological presentations of adverse drug reactions and poisoning; more extensive reviews are available (Shoenfeld and Isenberg 1989; Kahn 1991). With so much public whim and paranoia it is easy to close our minds in defence of what we do, particularly when it comes to prescribing strange chemicals or eating them. Assessment of a potential reaction should involve clinical observation during therapy, after withdrawal of the drug, and, if possible, upon rechallenge; where the reaction is subjective rechallenge should be blinded.

Immunological reactions

A long list of drugs can trigger autoimmune diseases in many ways similar to their idiopathic counterparts (Table 1). These serve as important models for the study of idiopathic disease. Apart from anaphylaxis, which is immediate, and rashes, which often occur early in treatment, most of these reactions develop gradually after an appreciable exposure to the drug (Perry 1973). Some reactions are rare, but others may affect over 10 per cent of patients with sufficient drug exposure. Factors influencing susceptibility include cumulative dose, renal and hepatic function, genetic polymorphisms influencing drug metabolism (particularly acetylation and sulphoxidation), sex, and immunological response (HLA-DR type and complement null alleles). Grounds for imputing an immunological mechanism include infiltration with lymphocytes (hepatitis, myositis) and the presence of autoantibodies (haemolytic anaemia, myasthenia gravis, lupus, Goodpasture's syndrome, pemphigus). The autoantibodies are usually similar to those arising in the relevant idiopathic autoimmune condition (Table 1), but generally occur much more frequently than any clinical expression of disease. Thus, hydralazine induces antinuclear antibodies in up to 60 per cent of patients but the lupus syndrome in only 2 to 10 per cent, and Coombs' antibody need not cause haemolysis.

Syndrome	Autoantibody specificity
Lupus	Histones, Single-stranded DNA, Poly (ADP-ribose), Mitochondria (venocuran-induced) Myeloperoxidase
Myositis	Nuclear
Myasthenia gravis	Acetylcholine receptor
Scleroderma	None recognized*
Haemolytic anaemia	I antigen of red cell
Thrombocytopenia	Platelet membrane
Pemphigus	Skin basement membrane
Goodpasture's syndrome	Kidney basement membrane

*Topoisomerase I in silica mimics

Table 1 Drug-induced autoimmune syndromes and autoantibodies

Drug-induced lupus

Starting with observations by Perry in the 1950s on a late toxic reaction to hydralazine therapy (Perry 1973) and then similar observations with procainamide, many drugs have been reported to induce systemic lupus erythematosus or a lupus-like syndrome (Table 2). To implicate a drug with certainty the syndrome should remit after drug withdrawal and recur on rechallenge, but often there are just a few case reports and sometimes the connection is doubtful since idiopathic lupus may have been developing at the time. In particular, oestrogens and sulphonamides may exacerbate or bring on idiopathic systemic lupus erythematosus, and hair dyes containing aromatic amines have been implicated in a cluster of cases of systemic lupus erythematosus and scleroderma in a small town in Georgia (Freni-Titulaer *et al*. 1988). Minocycline, a semisynthetic tetracycline used for a variety of infections, and for treatment of acne vulgaris, has been reported to induce a lupus-like syndrome (Gough *et al*. 1996).

Definite	Hydralazine Isoniazid Procainamide
Probable	Penicillamine Sulphasalazine Acebutalol Labetalol Methyldopa Captopril Phenytoin Carbamazepine Chlorpromazine Lithium Propylthiouracyl Quinidine Psoralen/ultraviolet A (PUVA) Venocuran Minocycline

For a more comprehensive list see Slinger (1988).

Table 2 Drugs reported to induce a lupus syndrome

Clinical features

The clinical features of drug-induced lupus are shown in Table 3, with data on idiopathic systemic lupus erythematosus for comparison. Common, early manifestations (after several months of drug exposure) are arthralgia, aching, malaise, and elevated erythrocyte sedimentation rate. Arthritis, rash, lymphadenopathy, pleurisy and pleural effusion, pericardial effusion and hepatosplenomegaly occur less often, and Raynaud's phenomenon, central nervous system involvement, and renal disease are rare.

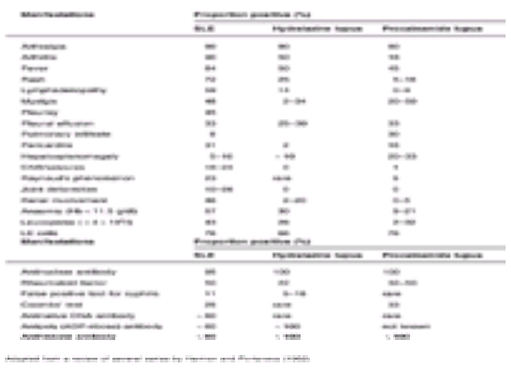

Table 3 Clinical and laboratory manifestations of idiopathic systemic lupus erythematosus and drug-induced lupus

Drug-induced lupus is clearly distinguished from idiopathic systemic lupus erythematosus by the dearth of renal, central nervous system, and Raynaud's involvement, the lower frequency of rash, a narrower autoantibody profile, the rarity of hypocomplementaemia, and a different HLA background (Table 3 and Table 4). However, these are not all necessarily fundamental differences, since drug-induced lupus is usually curtailed within the first couple of years of clinical expression by withdrawal of the drug or (if misdiagnosed) by treatment with corticosteroid. A few cases do go on to cutaneous vasculitis (Bernstein *et al*. 1980) and may progress to glomerulonephritis. After stopping the drug, clinical features generally improve within days or weeks and resolve within months of stopping the offending drug; the antinuclear antibody titre wanes over a year or two (Mansilla-Tinoco *et al*. 1982).

	Hydralazine-treated controls	Hydralazine lupus	Odds ratio
Mean hydralazine intake	65 g	150 g	
Female	31%	81%	9.9
White	63%	96%	8.2
Slow acetylator	55	96	8.2
HLA-DR4	25%	72%	8.1
C4 null	43%*	76%	4.3

Based on Batchelor et al. (1980), Mansilla-Tinoco et al. (1982), and Speirs et al. (1989).
*Healthy controls not hydralazine treated.

Table 4 Risk factors for hydralazine lupus

Antibody profile

The antinuclear antibody profile in drug-induced lupus is much narrower than in idiopathic systemic lupus erythematosus. Antibodies to extractable nuclear antigens are rare, and to cardiolipin and native DNA uncommon. The characteristic antinuclear antibody is of homogenous pattern and high titre—the sort producing the LE cell phenomenon. The specificity of these antibodies is for histones and poly(ADP-ribose), sometimes for single-stranded DNA, but only rarely for native double-stranded DNA (Hobbs *et al*. 1987). Serial measurement of DNA binding may show a slight rise and then a fall on drug withdrawal but this usually remains within the normal range of DNA binding (which laboratories set quite high to exclude the modest levels of anti-DNA antibody seen in quite a wide range of autoimmune conditions). Antihistone antibody titres rise much higher in drug-induced lupus than in idiopathic systemic lupus erythematosus, whereas levels of antibody to poly(ADP-ribose) are similar. Antibodies to myeloperoxidase (anti-MPO), giving a pANCA pattern of immunofluorescence on alcohol-fixed neutrophils, have also been reported in drug-induced lupus (Nässberger *et al*. 1990). The presence of autoantibodies is not *per se* a reason to discontinue treatment.

Risk factors

Dose and metabolism

The risk factors for developing hydralazine induced lupus are fairly clear (Table 4). A modest dose must be taken for a year or two or a large dose for several months, and almost always the patient is a 'slow acetylator'. Drug acetylation occurs immediately after absorption on first pass through the liver, and we know that administration of acetylprocainamide (itself an effective antiarrhythmic drug) never leads to the lupus syndrome even though a little of the dose is deacetylated (Woosley *et al*. 1978). The antinuclear antibody frequency rises faster in slow than fast acetylators. Indeed, it was thought for a time that acetylation of dietary toxins might be relevant to the genesis of idiopathic systemic lupus erythematosus but this is not the case.

Sex and race

As in idiopathic systemic lupus erythematosus, females are more at risk than men (though drugs like hydralazine and procainamide are used more often in men), but, in contrast to idiopathic systemic lupus erythematosus, Perry observed that black patients are highly resistant to the development of hydralazine lupus.

Major histocompatibility complex

Hydralazine lupus is associated with HLA-DR4 (Batchelor *et al*. 1980) and with null alleles of the complement component C4 (Speirs *et al*. 1989). HLA-DR4 and C4B null are known to be in linkage disequilibrium, just as in idiopathic systemic lupus erythematosus the HLA-DR2 and -DR3 associations may reflect the frequency of haplotypes containing C4A null alleles together with these DR antigens.

Pathogenesis

Complement dysfunction induced by drugs

Serum complement levels are usually normal in drug-induced lupus, but the drug may interfere with its function. In immune complex disease, complement is important in the solubilization of immune complexes and in their removal on the CR1 receptor of red cells (Schifferli *et al*. 1986). Indeed, many patients with idiopathic systemic lupus erythematosus have a null allele of C4 or occasionally C2, and homozygous deficiency of any of the early components of complement often leads to systemic lupus erythematosus. Reidenberg made the point that pharmacological rather than small immunizing doses are required for a drug to induce and maintain the lupus syndrome (Reidenberg 1981). One pharmacological mechanism demonstrated *in vitro* is that several lupus-inducing drugs block the transient activated form of C4. Inhibition of C4 activity is seen with hydralazine, isoniazid, penicillamine, and the hydroxylamine form of procainamide but not acetylprocainamide (Sim *et al*. 1984). Despite these findings, hydralazine does not exacerbate idiopathic systemic lupus erythematosus *in vivo*, and it has to be determined whether inhibition of C4A or C4B is more important.

Modulation of lymphocyte function

Drugs inducing autoimmune disease may also have a pharmacological action on lymphocytes. T lymphocytes from patients treated with methyldopa show reduced suppression of lymphocyte responsiveness to phytohaemagglutinin and immunoglobulin synthesis. Conversely, procainamide may have an inhibitory effect on T-cell responses to mitogens. Lymphocytotoxic antibodies are frequently induced by procainamide and hydralazine therapy, but their functional significance is unclear since they kill best below body temperature and can be found whether or not the lupus syndrome has developed (Bluestein *et al*. 1979).

Induction of autoantibodies

Autoantibodies are necessary for the genesis of drug-induced lupus (though not sufficient, whatever the titre, class, or complement-fixing ability), and much thought has been given to how drugs might induce autoantibodies. The specificity of the response rules out a general polyclonal B-cell activation, nor can tissue damage be blamed since there is no inflammation when the antibodies first appear.

The favoured explanation (Table 5) is that the drug interacts directly with the autoantigen. Hydralazine and procainamide bind to chromatin, and this may alter the autoantigen so as to overcome T-cell tolerance and thereby release autoreactive B cells from suppression. The fine specificity of autoantibodies in drug-induced lupus is in keeping with this model; histones and poly(ADP-ribose) are components of the nucleosome (unit of chromatin structure) and the histone epitopes recognized are those exposed on the surface of the nucleosome (Craft *et al*. 1987). This pattern of immune response can be imitated by immunization of rabbits with whole nucleosomes, whereas naked histones induce antibodies to epitopes that are normally buried.

1. Binding of drug to autoantigen, so overcoming T-cell tolerance
2. Antidrug antibody shows fortuitous cross-reaction with auto-antigen.
3. Anti-idiotype to antidrug antibody mimics the drug and binds to its receptor (the autoantigen)

The autoantigen might be on the cell membrane or released from dead cells.

Table 5 Models for the induction of autoantibodies by drugs

Alternative models involve antidrug antibodies that are cross-reactive either directly (rheumatic fever model) or through an anti-idiotype response (Table 5). These options demand fortuitous cross-reaction with one epitope on the autoantigen, followed by a spreading induction of autoantibodies to other epitopes.

Drug-induced myositis

Toxic myopathies occur occasionally with various drugs including clofibrate, emetine, chloroquine, e-aminocaproic acid, vincristine, lithium, amphotericin B, salbutamol, colchicine, and nitroxoline (Le Quintrec and Le Quintrec 1991). A true drug-induced myositis is seen occasionally with D-penicillamine and also reported with penicillin, sulphonamides, procainamide, hydralazine, phenytoin, propylthiouracil, phenylbutazone, cimetidine, and tamoxifen. In penicillamine therapy for rheumatoid arthritis, the frequency of myositis is 0.2 to 1.2 per cent rather than the expected coincidence of less than 0.001 per cent. Most cases of drug-induced myositis are antinuclear-antibody positive, and there seems to be a high frequency of dysphagia and muscle weakness but little myalgia. Myositis is mediated mainly by T cells, and in a case associated with cimetidine therapy there was a marked increase in the proportion of cytotoxic/suppressor T cells in the peripheral blood similar to the inflammatory infiltrate in muscle.

Drug-induced myasthenia gravis

Rheumatoid arthritis and idiopathic myasthenia gravis are weakly associated, but in 1975 Bucknall *et al*. described four cases of myasthenia gravis developing during penicillamine therapy and remitting after treatment was discontinued (Bucknall *et al*. 1975). This reaction may occur in up to 1 per cent of rheumatoid arthritis patients after several months of penicillamine therapy at daily doses of 500 mg or more. Antibodies to the acetylcholine receptor are found in all cases but their specificity is restricted to the human receptor. HLA typing shows more BW35 and DR1 and less B8 and DR3 than in idiopathic myasthenia gravis, and less DR4 than in rheumatoid arthritis controls (Dawkins *et al*. 1981).

Drug-induced scleroderma

Scleroderma-like disease with the typical microvascular and fibrotic changes can follow exposure to a variety of drugs and chemicals. The drugs include bleomycin, 5-hydroxytryptophan, carbidopa, pentazocine, penicillamine, phytonadione, diethyopropion, and mazindol (appetite suppressants), and intravenous cocaine abuse. In bleomycin-induced scleroderma, there is increased collagen synthesis by dermal fibroblasts *in vitro* and administration of bleomycin to rats produces skin thickening with increased collagen synthesis (Rush *et al*. 1984; Bourgeois and Aeschlimann 1991).

Chemicals inducing scleroderma-like disease

Just as there are chemical causes of cirrhosis and pulmonary fibrosis, there are chemicals other than drugs that induce a scleroderma-like disease. These include silicone implants, vinyl chloride, and the outbreak of 'Spanish oil disease'.

Silicone implants

Silicones are polymers mainly of dimethylsiloxane (chains of alternating silicon and oxygen atoms with two methyl groups attached to each Si atom). The silicone forms a liquid, gel, or rubber-like material (elastomer) depending on the number of cross-links between the polymer chains. Being fairly inert within the body, silicone is used to lubricate syringes and has been incorporated in intraoccular lenses, ventriculoperitoneal shunts, and heart valves, as well as forming breast implants and artificial testicles.

Breast implants consists of silicone gel, and sometimes a space for saline, enclosed within a silicone rubber envelope. Implants are used chiefly for breast augmentation and reconstruction after surgery for breast cancer. In animals, injection of gel can induce local chronic inflammatory reactions and unsightly local reactions can occur in humans after direct injection of gel and occasionally after rupture of an implant. Augmentation of the breasts with silicone became popular from

the 1960s but is now being squeezed out by the lawyers.

Miners exposed to inhalation of crystalline silica have an increased risk of scleroderma (Erasmus 1957), but the question of scleroderma and other chronic illness as a response to silicone polymers is now a contentious issue.

Anecdotal reports of rheumatic symptoms arising after silicone injection or implantation have been published since the 1960s (Kamugai *et al*. 1984) and in a welter since medicolegal interest arose (Sanchez-Guerrero *et al*. 1994). Most are vague complaints, to which the controversial term human adjuvant disease has been applied (because silicone is not itself immunogenic but appeared to have adjuvant activity). Only a minority of cases have involved a clear cut autoimmune rheumatic disease and these have been indistinguishable on clinical and serological grounds from idiopathic cases.

There is no good epidemiological evidence for an increased frequency of autoimmune rheumatic diseases in relation to silicone although the overall community prevalence of scleroderma may have increased in the past 50 years (Sanchez-Guerrero *et al*. 1994).

Despite the lack of scientific evidence, some patients may wish to have their implants removed for peace of mind. If the manufacturers survive bankruptcy, their settlement offer may reward those with common complaints like fatigue, widespread aching, paraesthesia, and the like. We must guard against this windfall making our patients feel worse.

Vinyl chloride disease

Workers exposed to vinyl chloride for prolonged periods in the manufacture of polyvinylchloride may develop an illness characterized by breathlessness, Raynaud's phenomenon, and contracture of the hands with thickening of the skin. Deposits of complement and fibrinogen are present in blood vessel walls (emphasizing that, like systemic sclerosis, this is a disease of the microvasculature as well as fibrosis), but anticentromere and anti-Scl-70 antibodies are not found. It is suggested that HLA-DR5 influences susceptibility and DR3 influences the severity of vinyl chloride disease (Black *et al*. 1983).

Spanish oil disease (see also Chapter 5.8)

The sale of contaminated rape-seed oil as cooking oil to about 20 000 people in the Madrid area led to a 'toxic oil syndrome' with an initial acute phase of fever, rash, gastrointestinal upset, neurological disturbance, acute interstitial pneumonia, and sometimes death. Many recovered, but several hundred went on to develop hardened, thickened skin, Raynaud's phenomenon, dysphagia, pulmonary hypertension, alopecia, dry eyes, dry mouth, arthritis, and flexion contractures. Autoantibodies were not a feature, but there was microvascular damage with endothelial proliferation and infiltration of vessel walls by lymphocytes and macrophages (Spurzem and Lockey 1984).

Eosinophilia–myalgia syndrome (see also Chapter 5.9.1)

First reported to the Centers for Disease Control in November 1989, almost 1500 cases had been notified 4 months later and it was clear that the ingestion of tryptophan as a health-food supplement was responsible. The amino acid all came from one manufacturer and a contaminant in the manufacturing process has been implicated. Long-term follow-up is underway but new cases have ceased occurring. The syndrome is characterized by the abrupt onset of malaise, myalgia, weakness, contractures, induration of fascia, morphoea-like lesions, and blood eosinophilia ($1–30\times10^{9}$/l). Neuromyopathy is frequent and cardiac abnormalities have been seen, with some deaths. The histological findings resemble eosinophilic fasciitis with an interstitial and perivascular inflammatory infiltrate (Le Quintrec and Le Quintrec 1991).

Serum sickness and hypersensitivity vasculitis

Serum sickness is an immune-complex disease. First seen following the injection of antiserum for the treatment of bacterial infections such as diphtheria and tetanus, it now occurs rarely with some drugs, particularly penicillin, sulphonamides, penicillamine, and thiouracil. The first indication is usually fever, appearing 7 to 12 days after the beginning of treatment, followed by urticaria, joint pains, and occasionally glomerulonephritis or myocarditis (Rich 1942); this may progress to vasculitis.

Hypersensitivity or leucocytoclastic vasculitis is characterized by an infiltrate of dead or dying polymorphonuclear white cells in the walls of small blood vessels. There is often no obvious cause but in some cases drugs have been implicated, particularly sulphonamides, penicillin, thiouracil, iodides, organic arsenicals, oestrogens, and hydantoins (Dubost *et al*. 1991). For more on vasculitis see Chapter 5.11.1, Chapter 5.11.2, Chapter 5.11.3 and Chapter 5.11.4.

Food and arthritis

Despite much folklore and several books, there is little convincing evidence that immune reactions to what we eat have any bearing on the pathogenesis of arthritis or the autoimmune rheumatic diseases (Walport *et al*. 1982). Anecdotal reports of food allergy have involved foods such as wheat, eggs, beef, and pork, and one diet recommends avoiding 'acidic' foods. Features often associated with arthritis in 'allergic' cases are migraine headaches, rhinitis, and gastrointestinal symptoms. After 50 years of open study, double-blind trials of diet are now in progress. It is possible that a diet of fish oil alters prostaglandin synthesis in a way that reduces the intensity of inflammation.

Specific syndromes occasionally associated with food allergy include palindromic rheumatism (reports of provocation by nitrates and menthol), vasculitis (various foodstuffs and in one case a particular brand of beer), hydrarthrosis of the knees (a case induced by English walnuts), and seronegative rheumatoid arthritis (a case exacerbated by milk and cheese). Most of these studies involved withdrawal of the foodstuff and rechallenge in open fashion.

Could rheumatoid arthritis be caused or exacerbated by absorption of antigens from the bowel? Pigs develop arthritis and nodules if fed a diet high in fish protein, and the onset of arthritis is associated with increased isolation of *Clostridium perfringens* from the gut flora. Arthritis is commoner in people with selective IgA deficiency, again highlighting mucosal defence. After intestinal bypass (once in favour as a treatment for morbid obesity) arthritis, often accompanied by features of Behçet's syndrome, may develop, and radiolabelled fragments of *E. coli* administered by mouth have been demonstrated in joints.

Metabolic reactions to drugs and toxins

Drugs and toxins causing gout

The relationship of alcohol to gout is complex in that many who drink well also eat well (with a high intake of purines), but it does seem that a high alcohol intake stimulates endogenous urate synthesis while high doses of alcohol temporarily reduce urate excretion (Scott 1991).

Lead rather than alcohol may have been responsible for the frequency of 'saturnine' gout in Georgian times when pewter was in fashion (lead-induced renal tubular damage leading to reduced excretion of uric acid). Nowadays, thiazide and loop diuretics are a common cause of hyperuricaemia, and gout is well recognized not just in bucolic men but in elderly women; the average increase in serum urate is about 70 µmol/l.

Salicylates have a uricosuric effect at higher doses but at low dose (with a low urine salicylate concentration) the excretion of uric acid is actually inhibited. Even the uricosuric agent probenecid has this paradoxical effect if given at a tiny dose. Among non-steroidal anti-inflammatory drugs, azapropazone has the most clinically useful uricosuric effect.

Hyperuricaemia, through an effect on the kidney, can also occur with pyrazinamide, ethambutol, and cyclosporin. Increased production of urate is caused by nicotinic acid and various cytotoxic agents, including vincristine, busulphan, thiotepa, cytarabine, 6-mercaptopurine, chlorambucil, cyclophosphamide, and the like. Increased tissue destruction leads to the release of purines and their metabolism to uric acid; this pathway can be blocked by the xanthine oxidase inhibitor allopurinol but with the warning that allopurinol increases the bioavailability of the azathioprine metabolite 6-mercoptopurine.

Fluoride and bone pain

In certain areas of India very high levels of fluoride in water lead to increased bone density and hyperostosis that goes on to cause widespread nerve root entrapment. Ingestion of moderate amounts of fluoride, as sometimes used in the treatment of osteoporosis, can cause severe pain in the legs, felt mainly around the joints. This lower limb pain occurs in up to 25 per cent of patients and remits when fluoride therapy is stopped or the dose reduced (Reeve 1990); microfractures may be the cause (Laroche and Mazieres 1991; Rooney *et al*. 1991).

Rheumatological effects of retinoids, quinolones, and proton pump inhibitors

Retinoids are derivatives of Vitamin A used in the treatment of severe acne. Chronic administration whether as a food fad or as dermatological treatment can cause arthralgias, arthritis, bone pain, hypercalcaemia, and periosteal new bone formation. Hyperostosis of the appendicular skeleton can occur, especially in children, and premature closure of the epiphyses has been reported (Kaplan and Haettich 1991).

Quinoline antibiotics include nalidixic acid and ciprofloxacin; very rarely these cause arthralgias and tenosynovitis in children, while puppies and the young of other susceptible species show surface blistering of the articular cartilage (Ribard and Kahn 1991).

Omeprazole and lansoprazole may cause arthralgias in occasional patients.

Transplant arthropathy

A painful, self-limiting, pseudoinflammatory arthropathy of lower limb joints can occur a few months after organ transplantation. There are clinical, radiological, and scintigraphic similarities to reflex sympathetic dystrophy. Knees or ankles are affected most often, but hip and wrist involvement has been seen. The clinical features are joint pain and tenderness and there may be effusion, periarticular oedema, and erythema. Blood tests for inflammation and autoantibodies are unhelpful; joint fluid cytology is non-inflammatory and does not reveal crystals. Radiographs show no specific abnormality, but isotope bone scans show greatly increased uptake on both sides of the joint (as well as in clinically unaffected joints sometimes). Avascular necrosis does not develop and spontaneous resolution after several months is the rule. This arthropathy has been recognized since the widespread adoption of cyclosporin for immunosuppression in organ transplantation. Cyclosporin levels have often been high when the arthropathy began and resolution tends to follow a reduction in cyclosporin levels. For instance, in our series of eight cases, mean cyclosporin levels were 458 mg/l at onset and 175 mg/l at resolution (Jones and Bernstein 1994).

Toxicity of antirheumatic treatment

Simple analgesics

Simple analgesics such as phenacetin, though probably not paracetamol, can cause renal papillary necrosis; this is commoner in hot climates where the urine is likely to be concentrated. Analgesics have a narrow safety range: eight tablets of paracetamol daily are safe, yet 30 tablets can ruin the liver.

Non-steroidal anti-inflammatory drugs

Gastrointestinal damage

Non-steroidal anti-inflammatory drugs commonly irritate the gastrointestinal tract (Henry *et al*. 1996), possibly through inhibition of prostaglandins which are important in protecting the mucosa and in the cellular mechanism for mending mucosal breaches. Endoscopy studies have shown up to 20 per cent of patients have ulcers and a further 30 per cent minor gastroduodenal lesions at any one time, and the risk of an acute bleed, perforation, or death rises from under 0.1 per cent in middle life to about 2.5 per cent in the elderly (Beardon *et al*. 1989). The synthetic prostaglandin E_1 misoprostol reduces non-steroidal anti-inflammatory-induced damage in the stomach, duodenum, and small intestine by about 75 per cent, whereas H_2-antagonists are protective only in the duodenum. Selective inhibitors of the inducible cyclooxygenase (COX-2) are likely to prove safer anti-inflammatory drugs.

Renal, haematological, and skin reactions

Non-steroidal anti-inflammatory drugs can reduce renal blood flow causing a tendency to hypertension and renal insufficiency (especially in the presence of hypovolaemia or pre-existing renal damage). Only sulindac is said to spare the kidneys. Other complications of non-steroidal anti-inflammatory drugs therapy include thrombocytopenia caused by increased platelet destruction, aplastic anaemia, and thrombocytopenia with phenylbutazone (now restricted in the United Kingdom to the hospital treatment of ankylosing spondylitis). Rashes are uncommon and occur most often with fenbufen.

Effects on cartilage

Shortly after the introduction of indomethacin there were reports of accelerated osteoarthritis of the hip, and in a clinical study of osteoarthritis of the hip, deterioration to the end-point of joint replacement was rather faster in patients treated with a strong inhibitor of prostaglandin synthesis (indomethacin) than with a weak inhibitor (azapropazone) (Rashad *et al*. 1989). Experimental data suggest various ways in which non-steroidal anti-inflammatory drugs might damage or even protect articular cartilage, and new chondroprotective agents are being sought by the pharmaceutical industry.

Disease-modifying, second-line therapy

Ocular toxicity from the deposition of antimalarial drugs such as chloroquine is well known. Rashes are common with most of the second-line drugs but with gold and penicillamine there is a particular risk of exfoliative dermatitis. Gold and penicillamine also cause membranous glomerulonephritis with nephrotic syndrome and, rarely, renal failure, while bone marrow toxicity with leucopenia, thrombocytopenia, or occasionally aplastic anaemia can occur with gold, penicillamine, sulphasalazine, and cytotoxic agents such as methotrexate, azathioprine, and cyclophosphamide; though onset can be abrupt, it is often gradual, so regular monitoring of the blood count and urine is recommended. Gold can also cause, rarely, pneumonitis and, not uncommonly, a 'post-injection flare' of arthritis (Rooney *et al*. 1991).

Penicillamine

Penicillamine used in the treatment of rheumatoid arthritis and Wilson's disease can trigger the whole range of drug-induced autoimmune reactions (membranous glomerulonephritis presenting as nephrotic syndrome, Goodpasture's syndrome, myasthenia gravis, polymyositis, pemphigus, lupus, and scleroderma), accompanied by the appropriate autoantibody (to kidney or skin basement membrane, acetylcholine receptor, double-stranded DNA, and so on). Susceptibility to at least some of these reactions is increased by the HLA antigen DR3 and by slow sulphoxidation of penicillamine (Emery *et al*. 1984).

Corticosteroids

Corticosteroid therapy (Geusens and Dequeker 1991) reduces resistance to infection whether administration is systemic or intra-articular, and this must be borne in mind in all sick patients on steroids. A hot, red joint following a steroid injection may be infected or (more often, one hopes) a gout-like reaction to particles in the steroid preparation responsive to non-steroidal anti-inflammatory drug therapy. Repeated steroid injections can lead to avascular necrosis. In the shoulder there is the added risk of rotator cuff degeneration, so injections there should be limited to a few.

Osteonecrosis (avascular necrosis) is also a serious complication of systemic steroid therapy, affecting usually one or both hips but sometimes other joints such as knees and shoulders. It may occur in 5 per cent or more of patients on long-term steroid therapy, and there is a particular risk with high-dose intravenous steroids used in the treatment of transplant rejection and sometimes for connective tissue diseases.

Osteoporosis is a concern with systemic corticosteroid therapy. In younger women treated with prednisolone at doses of 5 to 7.5 mg/day there was no bone loss detectable by dual photon absorptiometry over a 1 year period, but exacerbation of bone loss after the menopause is more of a problem. Calcium supplements may

help and female hormone replacement therapy or three monthly cycles of calcium for 11 weeks followed by a diphosphonate for 2 weeks encourages deposition of calcium on remaining bone trabeculas (Reeve 1990). More effective diphosphonates will be available shortly.

Monoclonal antibody and recombinant protein therapies

The next edition of this textbook will be full of optimism for the treatment of autoimmune diseases and arthritis by new methods. This paragraph is reserved for a host of adverse reactions—such as serum sickness (from mouse Fab), infection (as with steroids), enhanced autoimmunity (reported with interferons), and novel phenomena as yet undreamt of—that may arise from these new therapies, and also for debate with taxpayers who must pay for the therapies, as science brings home the bacon.

6.1 Surgery in adults

Justin Cobb and C. B. D. Lavy

Introduction

The surgeon is an indispensable member of the team involved in the treatment of a patient with arthritis. He or she should be available not only as a technician to perform operations but ideally should also be involved in the decision making processes in the management of the patient, such as the timing of surgery, the order in which affected joints should be treated, and of course the procedures undertaken. Most large units have combined clinics where the experience of rheumatologist, surgeon, physiotherapist, occupational therapist, and patient can be shared. In patients with polyarthritis, where several joints are likely to need surgery, a valuable relationship between patient and surgeon can be developed—a relationship which gives the patient trust and confidence and gives the surgeon a greater understanding of the patient's specific needs than can be gained by a single meeting.

This chapter will firstly list the options available to the surgeon dealing with rheumatic disease. Secondly, it will cover specific pre- and postoperative considerations that must be addressed by the surgeon. The third and largest part of the chapter will focus on specific anatomical regions in detail, outlining the procedures most commonly used. Operating theatre technique will not be covered. For this the reader is referred to specific operative texts, some of which are included in the references.

Surgical technique

The armamentarium of surgical treatment of arthritis includes the following procedures:

1. arthroscopy and arthroscopic debridement;
2. synovectomy;
3. soft tissue release, realignment, or repair;
4. tendon transfer;
5. osteotomy;
6. excision arthroplasty;
7. prosthetic arthroplasty;
8. arthrodesis and stabilization.

Not all the above are relevant in every anatomical region but they are listed here for completeness. The particular techniques that are commonly used will be outlined under individual joints and regions below.

Special considerations in planning surgery in rheumatic diseases

When to operate

It is difficult to give specific guidelines as to when surgery should be considered for a particular joint as no joint can be considered in isolation from the other joints in the same limb or the other limbs, the patient his or herself, and the patient's position in his or her family and community. However, with all the above in mind, the two factors that most affect the decision to proceed with surgery are pain and loss of function. If the patient's pain cannot be adequately controlled by conservative means and their life, or more particularly their sleep, is being affected then surgery should be considered (Seyfer 1993). Similarly if the patient's function is being significantly impaired by joint destruction or deformity then surgery to reconstruct or replace the joint should be considered.

Prophylactic surgery has a limited place in the treatment of rheumatic diseases. Synovectomy is certainly of use in incipient tendon rupture. It has also been performed in an effort to prevent deterioration of inflammatory arthritis; however, no long-term study has shown significant slowing of joint destruction. Prophylactic surgery also has a role in stabilizing the potentially unstable spine.

Which joint to operate on first

The order of surgery in patients who have several joints that will benefit from surgery is a common problem in polyarthritic conditions such as rheumatoid arthritis. In deciding which joints to start with there are no hard and fast rules but there are several considerations that must be taken into account. Firstly, when surgery to upper and lower limbs is being considered the lower limb is usually done first as this restores important independent mobility. Rehabilitation following such surgery, however, often requires the use of crutches and if the arm function is so poor that even gutter crutches cannot be used, then surgery to the upper limb may have to precede that to the lower limb. Secondly, when two joints in a limb are equally affected it is usual to operate on the proximal joint before the distal joint. This helps to reduce pain and improve the proximal stability in the limb before surgery to the distal joint. Where two joints in a limb are both equally affected, for example the hip and the knee, it may be found that surgery to the hip so improves lower limb function that surgery to the knee is no longer needed. Similarly, surgery to the shoulder may dramatically reduce pain and functional demand on the elbow so that pain is improved and surgery to the elbow is not needed. In other patients the opposite may be found—surgery is so successful in relieving pain in the most painful joint that the patient's attention now turns to a less affected joint, one that previously had not troubled them much which now becomes the focus of their attention.

The final consideration in the order of surgery is the concept of surgical success. When a number of procedures are likely to be necessary it is often helpful to the patient's morale to start with a procedure that carries a high statistical likelihood of success. An example of this is excision of the distal ulna and synovectomy of the wrist.

Patient's consent and preparation

Patients must be adequately consented for surgery. This includes not only understanding the operation and its important complications but also the nature of the rehabilitation process involved which may be long. It is helpful if the physiotherapist and occupational therapist both meet the patient beforehand. It can also be of help for the patient to meet others who have had similar surgery.

Anaesthetic considerations

Patients with rheumatic diseases often have associated medical conditions that must be considered during surgery (Skues and Welchew 1993). For example in rheumatoid arthritis cervical spine instability means that great care must be taken with endotrachial incubation and, if in doubt, fibreoptic intubation used. With some rheumatic diseases temporomandibular joint function is also limited and cricoarytenoid cartilages can be involved—both also causing airway difficulties. Patients with chronic inflammatory disorders are also often anaemic and some require preoperative transfusion. Pulmonary, cardiovascular, and renal complications in rheumatic diseases can also affect anaesthesia. These are discussed elsewhere.

Drugs affecting surgery

Patients who have been on steroids or antimetabolic drugs may have thin, delicate skin that tears or bruises easily. Great care must therefore be taken during surgery and in positioning and handling the anaesthetized patient. Skin may also be sensitive to the adhesive compound used in some dressings. Steroids and antimetabolic drugs may also reduce the patient's resistance to infection and also delay wound healing, although they are not in themselves contradictions to surgery. Specific medical complication to steroids and other disease-modifying agents will be considered elsewhere.

Positioning the patient

Often joint stiffness and restriction of movement will not allow normal positioning to be used. For example shoulder and elbow stiffness may not allow the hand to be flat on a table beside the patient. A degree of flexibility on the part of the surgeon is therefore needed. Great care must always be taken of the anaesthetized patient to ensure that joints are not over stressed. This is especially the case with rheumatoid arthritis where the soft tissues and bones are fragile. Care must also be taken at pressure points to avoid skin necrosis, bruising, and damage to peripheral nerves.

Surgical treatment in specific anatomical regions

Shoulder

The shoulder is commonly involved in inflammatory arthritis with clinical features of pain in 47 per cent (Laine *et al*. 1954). Petersson reports radiographic changes in the shoulders in 83 per cent of patients with rheumatoid arthritis (Petersson 1986). There is, however, little correlation between clinical signs and symptoms and radiographic appearance and it is not uncommon for a grossly destroyed shoulder joint to present with few symptoms.

The shoulder comprises four main anatomical areas; the sternoclavicular joint, the acromioclavicular joint, the subacromial region, and the glenohumeral joint. Pain arising from the sternoclavicular joint is usually easy to diagnose as it is localized to the sternoclavicular region. However, it is more difficult to be specific about the anatomical origin of pain and tenderness in the area around the shoulder itself. Physical signs can point to one of the three sites as the origin of the pain but most surgeons rely on the additional diagnostic information given by local anaesthetic tests. One per cent lignocaine is injected sequentially into the subacromial space, the acromioclavicular joint, the region of the biceps tendon, and the glenohumeral joint until the pain is abolished. Many patients will have some involvement at more than one, or indeed all, of these sites (Johnston and Kelly 1990).

Sternoclavicular joint

If conservative measures such as injection of steroids cannot control the pain arising from this joint then synovectomy can be considered or a limited excision of the medial end of the clavicle can be performed, keeping the excision medial to the costoclaviclar ligaments. Care must be taken to avoid instability by preserving as much of the capsule as possible. The surgeon should also be cautious as the immediate posterior relation of the left joint is the innominate vein.

Acromioclavicular joint

This joint is involved in 70 per cent of rheumatoid shoulders. If pain becomes severe and cannot be controlled by conservative treatment or injection, the distal end can be excised lateral to the coracoclavicular ligaments which provide stability.

Subacromial region

Pain commonly arises from this region due to subacromial impingement which may be associated with inflammation in the subacromial bursa or a partial or complete rotator cuff tear. If pain from this area is abolished by local anaesthetic injection yet not controlled by steroid injection, then a subacromial decompression can be performed. This can be done as an open operation or, where the expertise exists, as an arthroscopic procedure using a powered burr. Rotator cuff repair is usually unrewarding in late rheumatoid arthritis because of the atrophied nature of the supraspinatus tendon.

Glenohumeral joint

This is involved in more than two-thirds of patients with rheumatoid arthritis (Ennevaara 1967). In early cases synovectomy can be performed either as an open procedure or arthroscopically (Bennett and Gerber 1994). Ogilvie-Harris, and Wiley had good results in nine out of eleven patients having this procedure arthroscopically (Ogilvie-Harris and Wiley 1986). In moderate to severe bony destruction a double osteotomy, as described by Benjamin, can be performed (Benjamin *et al*. 1979). This comprises an osteotomy of the humerus at the surgical neck and a similar osteotomy of the scapula at the glenoid neck. The mechanism of action of this procedure is poorly understood but it has been shown to have good result in terms of pain relief and increased movement in 25 out of 29 patients in Benjamin's series and in 29 out of 32 patients in Jaffe and Learmonth's series (Benjamin 1987; Jaffe and Learmonth 1989).

Joint replacement

Arthroplasty of the shoulder has not been as successful as in the knee or the hip in terms of pain relief or restoration of range of movement. This has been due to poor bone stock in which to anchor prostheses and poor quality soft tissues, especially the rotator cuff. Despite these difficulties, shoulder replacement is a useful therapeutic tool in rheumatoid arthritis giving pain relief in over 90 per cent of patients (Friedman *et al*. 1989).

Early shoulder replacements were constrained, for example the Stanmore shoulder, which had a plastic glenoid cup holding a humeral head fully captive (Lettin *et al*. 1982), or the Kessel shoulder which had the ball joint the other way around (Kessel and Bayley 1988). More recent total shoulder replacements such as the Neer (Neer *et al*. 1982), the Global, or the Copeland have an anatomically shaped humeral head which can articulate with the patient's own glenoid if this is not severely damaged, or with a prosthetic glenoid which is usually cemented in place. The range of movement following total shoulder replacement depends largely on the state of the rotator cuff. Where the rotator cuff is intact the reconstruction of the anatomical contours of the shoulder joint following arthroplasty can give a very good range of movement with abduction to over 90°. In severe bony destruction, however, there is often virtually no rotator cuff remaining and range of movement is minimally increased by surgery. Indeed the main benefit of the procedure is pain relief.

Arthrodesis

The success of arthroplasty means that arthrodesis is hardly ever indicated in rheumatic diseases. Even in rare cases where because of infection total shoulder replacements need to be removed a stable fibrous pseudoarthrosis usually gives a better functional result than an arthrodesis.

Elbow

Extra-articular procedures commonly performed around the elbow in rheumatoid arthritis include removal of nodules and transposition of the ulnar nerve. Rheumatoid nodules are common around the elbow and they may become painful, unsightly, or ulcerated. Ulnar nerve dysfunction may be motor or sensory and can result both from mechanical and pressure factors due to the presence of swollen and inflamed synovium and a deforming joint. Ischaemic factors also have a role. Ulnar nerve function may be improved by a simple release or, if it is clearly tight, then transposition anterior to the medial epicondyle is recommended.

Synovectomy

Synovectomy of the elbow joint itself is difficult as surgical access to all parts of the intact joint requires several incisions; however, it gives some benefit at least in the short term when there is gross swelling. Porter reported relief of pain and return of function in 12 out of 16 patients over a 5-year period (Porter *et al*. 1974). Arthroscopic synovectomy is a new tool that has to be performed with care as the radial and median nerves are closely related to the anterior capsule.

Excision of radial head

When the radial side of the joint is giving rise to the majority of symptoms, excision of the radial head can be performed at the same time as synovectomy (Copeland and Taylor 1979). This is an excellent procedure in terms of pain relief. Stability of the joint should be considered but is seldom significantly compromised in low demand patients. Silastic replacement of the radial head has not proved universally successful.

Arthroplasty

When there is severe pain in the presence of destructive changes in the elbow joint, both in rheumatoid arthritis and in osteoarthritis, arthroplasty can be performed. The simplest and oldest comprises excision arthroplasty which relieves pain but has unreliable stability. Inter position arthroplasty using silicon or metal had limited popularity (Coates *et al*. 1991) but most surgeons now use a form of total joint replacement. The available options are a simple hinge such as the Stanmore replacement, a semiconstrained hinge such as the GSB (Fig. 1), or a minimally constrained surface replacement such as the Souter (Souter 1990; Pritchard 1991). The increased stability of a hinge has been sited as increasing the risk of loosening by increasing forces at the prosthesis–bone interface. However, in up to 12-year follow-up GSB elbows continue to be considered excellent by 90 per cent of patients.

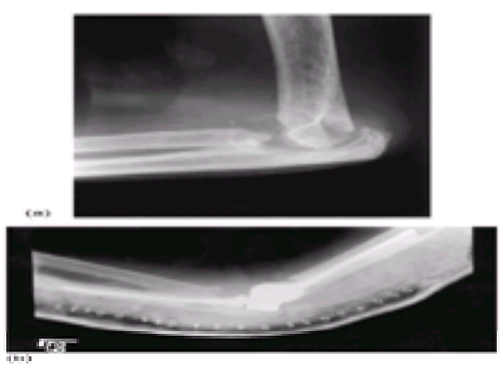

Fig. 1 Rheumatoid elbow (a) pre- and (b) postarthroplasty using a GSB semiconstrained hinge prosthesis.

Wrist

Osteoarthritis

Osteoarthritis of the of the wrist is not common and is usually post-traumatic, following either fracture of the distal radius or carpal bones, especially the scaphoid. When pain cannot be controlled, conservatively surgery should be considered. Joint replacement, as described below for rheumatoid arthritis, is an option in very low demand patients. Excision of the proximal carpal row can be performed where the disease is confined to this region. The space previously occupied by the excised proximal row becomes a pseudoarthrosis, relieving pain at the expense of some stability. Limited carpal fusions can also be performed particularly when the osteoarthritis is confined to the radial side of the wrist. This procedure does not have a high rate of success but if pain persists or recurs it can be revised to a complete wrist fusion.

Rheumatoid arthritis

Rheumatoid arthritis can affect the wrist joint as well as the flexor and extensor tendons and surgery to the tendons, such as synovectomy or transfer of the extensor tendons, is often combined with surgery to the wrist; however, in this text we will consider them separately. Rheumatoid arthritis can affect the radioulnar as well as the radiocarpal joints and often it is this joint that gives much of the pain, both from instability and from impingement on the carpus. Treatment by excision of distal 10 to 15 mm of the ulnar is very effective in terms of relief of pain and also removes an unsightly lump (Posner and Ambrose 1991; Clawson *et al*. 1991). When the pain is also arising from the radiocarpal joint, the surgical options are fusion or arthroplasty. Limited wrist fusion such as the Chamay technique (Chamay *et al*. 1983), which uses graft from the distal ulnar to fuse the radius to the lunate, are of use when there is good bone stock remaining but in most late cases there is such distortion of the normal anatomy that complete arthrodesis is performed.

The commonest method used involves insertion of a Rush pin (Fig. 2) or a Steinmann pin down the third metacarpal and across the wrist. This can be supplemented with a staple to improve stability. The position of stabilization is slight radial deviation and dorsiflexion. However, if both wrists are to be fused then perineal toilet is often improved if one is fused in slight flexion.

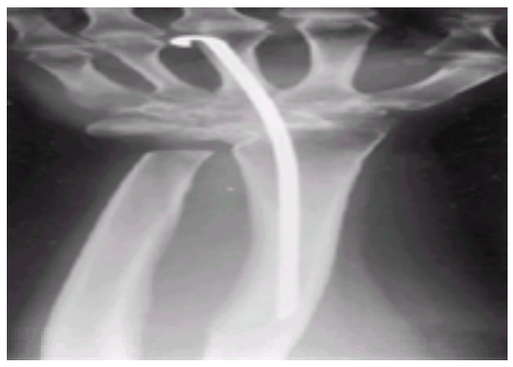

Fig. 2 Rheumatoid wrist following fusion using an intramedullary Rush in.

Joint replacement

The Swanson design silastic prosthesis is the most popular form of arthroplasty in Britain. The proximal carpal row is excised and the prosthesis fills the gap with one stem that fits into the distal radius and one that fits into a hole made through the capitate into the third metacarpal. Metal grommets can be used to protect the prosthesis from the sharp edges of the bone. This procedure gives good results in terms of relief of pain in low demand patients (Jolly 1993) but range of movement is usually limited to an arc of 40 to 50°. There are other designs of wrist replacement, such as the Meuli ball and socket joint which is popular in continental Europe. Where both wrists are involved in rheumatoid arthritis, many surgeons fuse the dominant wrist which is likely to take more force and confine arthroplasty to the non-dominant side.

Surgery to extensor tendons

In early disease, synovectomy of the extensor tendons is often combined with surgery to the wrist. The tendons are exposed by reflecting a flap of the dorsal extensor retinaculum, then after synovectomy the flap is replaced deep to the extensor tendons thus protecting them from the wrist joint. Synovectomy relieves pain and swelling and also reduces the risk of rupture.

The most common tendons to be ruptured are the extensor pollicis longus and the extensor digiti minima. The former is commonly treated by transfer of the extensor indicis proprius tendon from the index finger, which conveniently has two extensor tendons, and the remaining extensor indicis communes is adequate to extend the index. Treatment of rupture of extensor digiti minimi is usually by joining the distal end of the tendon to the extensor tendon of the ring finger. Realignment of the extensor tendons can be performed in rheumatoid arthritis. This commonly occurs at the level of the metacarpophalangeal joints where all the tendons tend to shift in an ulnar direction but also at the wrist where the extensor carpi ulnaris can migrate in a volar direction around the ulnar head.

Surgery to the flexor tendons

Synovitis also occurs around the flexor tendon in the synovial sheaths at the wrist and the fingers. When this interferes with function because of pain or by restricting flexion, synovectomy can be performed to improve movement and reduce the risk of rupture. In late cases rupture can occur. Surgical treatment of such rupture is complex and involves tendon grafting, often with a staged procedure. In mild cases of synovitis, triggering can occur around the neck of the flexor sheath. This is treated by simple division of the tight neck of the sheath. A limited synovectomy can also be performed.

Carpal tunnel syndrome

Median nerve compression is common in rheumatoid arthritis and can be relieved by carpal tunnel release. This is easily performed as a day case procedure under local anaesthetic. Endoscopic carpal tunnel release is popular in Europe and in the United States but because of early reports of nerve injury it has had a cautious reception so far in the United Kingdom.

Hand

Surgery to the fingers in rheumatoid arthritis

Boutonniere or Swan neck deformity can be corrected surgically by soft tissue procedures provided the joints are passively mobile. Once fixed deformity of the proximal interphalangeal (PIP) joints occurs, correction is much harder and surgical improvement may only be achieved by fusion in a position of function or arthroplasty using a silastic replacement joint. The position of fusion is usually 45 to 90° of flexion but depends on the range of movement at the metacarpophalangeal joints.

Surgery to the thumb in rheumatoid arthritis

Rheumatoid arthritis commonly causes a Z-deformity of the thumb and can cause instability of either the metacarpophalangeal or interphalangeal joint. Such instabilities are seldom helped bysoft tissue procedures and a fusion is usually necessary (Toledano *et al*. 1992).

Surgery to the metacarpophalangeal joints

When rheumatoid arthritis involves the metacarpophalangeal joint there is often a tendency to subluxation of these joints in an ulnar and volar direction. In early cases this can be treated with synovectomy and soft tissue realignment (Wynn Parry and Stanley 1993). This does slightly decrease range of movement but improves function because of decreased pain and increased power. In late cases where there is bony destruction of the metacarpal head, metacarpophalangeal joint replacement using Swanson silastic prostheses may be necessary (Fig. 3). This is always performed in conjunction with soft tissue release and realignment. Such reconstructive surgery, however, should only be done in order to improve function in the hand and should not be performed purely to improve the cosmetic appearance of a deformed rheumatoid hand. The postoperative care of metacarpophalangeal joint replacement and soft tissue realignment is extensive and involves the close co-operation of a hand therapist with experience in splinting as well as physical exercise techniques (Stanley 1992).

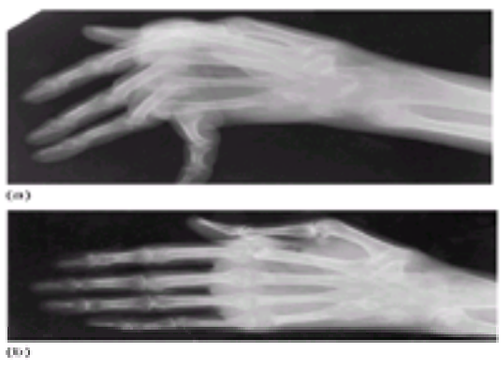

Fig. 3 Rheumatoid hand (a) before and (b) after silastic metacarpophalangeal joint replacements.

Cervical spine

Rheumatoid arthritis can affect all the synovial joints in the cervical spine including the bursa between the odontoid process and the transverse ligament. This can result not only in destruction of joints but also in attenuation of ligaments and consequent instability of the cervical spine (Heywood *et al*. 1988). The commonest site for involvement in the cervical spine are:

1. atlantoaxial subluxation or anterior subluxation of C1 on C2;
2. atlantaoccipital impaction, also known as cranial settling;
3. subluxation of the cervical vertebras below C2.

Surgery is not indicated in all cases of cervical instability but it is very important that instability is fully investigated with flexion and extension radiographs, a full neurological examination, and, where there are any neurological signs, a magnetic resonance imaging scan. Neurological impairment can be caused not only by the mechanical effect of the instability but also by pressure from proliferation of soft tissues.

The nature of surgery indicated depends on the pathology demonstrated. If there is progressive instability then prophylactic stabilization can be performed to prevent later deterioration. There are several methods of stabilization of the cervical spine including bone grafting and fixation with plates or preformed wire rectangles or

loops (Ranawat *et al*. 1979; Ransford *et al*. 1986). Stabilization is also indicated when there is intermittent or persistent neurological deficit. In these cases it may also be necessary to decompress the spinal cord or nerve roots (Johnston and Kelly 1990).

Foot and ankle

In the foot, as in other areas, meticulous attention to the history and clinical signs is essential. Pain may arise from impingement or entrapment of tendons or nerves, or from joints that are unstable not just destroyed. The judicious use of soft tissue procedures, selective arthrodeses, and joint arthroplasty may maintain fore- and hindfoot function for some years. When destruction and deformity have progressed, it is still usually possible to salvage a painless, albeit flat, foot by forefoot arthroplasty and triple arthrodesis of the hindfoot.

Synovectomy and soft tissue procedures

While little is published regarding synovectomy alone in the foot, there is some evidence that early synovectomy may delay deterioration in the ankle as in other joints (Hecker *et al*. 1982; Kvien *et al*. 1987; Mohing *et al*. 1982). Pain around the lateral malleolus in the valgus hindfoot may be due to impingement of the lateral malleolus, or to peroneal tendon entrapment. Injection of the tendon sheath is a simple diagnostic and therapeutic procedure that may give relief for some years. A conservative approach to the foot and ankle may also include early decompression of the tibialis posterior tendon and other medial structures to prevent rupture and subsequent deformity (Cracchiolo 1984).

Excision arthroplasty

Damage to the foot, and especially the forefoot, occurs very early in rheumatoid arthritis. A painful and deformed forefoot with hallux valgus, dorsal dislocation of the lesser metatarsophalangeal joints together with significant synovitis is the rule. The buttonholing of the metatarsal heads through the plantar fascia makes walking exquisitely painful. The surgical goal is a foot that is comfortable for slow pedestrian life, as part of the management of a systemic condition. Forefoot arthroplasty is the procedure of choice: the metatarsal heads are resected, allowing the hammering toes to drop down into the plane of the foot. The hallux valgus may be corrected by excising the metatarsal head or the base of the proximal phalanx (Fowler 1959; Gainor *et al*. 1988; Kates *et al*. 1967).

Arthrodesis

Isolated painful destruction of the ankle joint in rheumatoid arthritis is best treated by arthrodesis (Fig. 4). Several methods of internal fixation are available (Dent *et al*. 1993; Holt *et al*. 1991; Iwata *et al*. 1980; Moran *et al*. 1991). These have a lower complication rate and are better tolerated than the traditional method using Charnley external fixation clamps which have a significant infection rate (Moeckel *et al*. 1991).

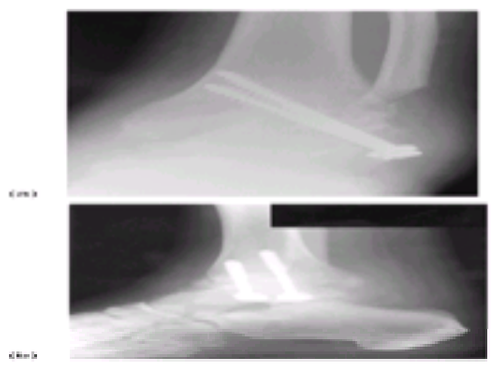

Fig. 4 Anterioposterior (a) and lateral (b) radiographs showing an ankle joint arthrodesed using parallel screws. The subtalar joint is normal.

More commonly the significant valgus deformity of the hindfoot is accompanied by pantalar arthritis. In these circumstances triple or pantalar arthrodesis is the treatment of choice (Vahvanen 1967). In the badly damaged hindfoot, a nail may be inserted from the sole up into the tibia, with or without the use of bone graft. A painless ankylosis can usually be obtained (Stone and Helal 1991). Talonavicular joint destruction with valgus deformity should also be corrected early and before the forefoot, if symptomatic: it may reduce symptoms in the foot by reducing the valgus shearing forces (Cracchiolo 1984).

Joint replacement

While ankle joint replacement is technically possible, the clinical results are disappointing compared to fusion (Jensen and Kroner 1992; Stauffer 1977; Wagner 1982). It may offer some early advantage in elderly patients with low physical demands, but these benefits are outweighed by the complication rate and difficulty in salvage (McGuire *et al*. 1988).

Prosthetic replacement of the first metatarsophalangeal joint has its advocates but the long-term results are not good enough to justify the additional complications (Hasselo *et al*. 1987).

Knee

Synovectomy

Arthroscopic synovectomy can effectively abolish the pain and stiffness in knees with a florid synovitis that is refractory to conservative measures (Ogilvie-Harris and Basinski 1991). It has considerable advantages over open synovectomy, in terms of hospital stay and morbidity, while the results of the two methods appear comparable with both groups regaining an average of 75° of movement (Matsui *et al*. 1989). This improvement is maintained for about 5 years although in that time the radiographic appearances continue to deteriorate (Paus and Dale 1993), but even at 14 years 67 per cent have remained in remission from the inflammatory element of their condition (Ishikawa *et al*. 1986). Simpler arthroscopic lavage and debridement may provide temporary relief but nothing more than this.

Joint replacement

The stiff and painful knees of the inflammatory arthropathies are best treated by total knee replacement. Double osteotomies were used in the past with varying effects, but excision of the entire articular surface and a thorough synovectomy is possible during total knee replacement reducing the rate of reactivation following the operation (Low *et al*. 1994). There is a considerable biological advantage to this removal of all antigenic stimulation as well as the great advantage of excellent mechanical function.

Prosthetic design

The current designs allow only the joint to be resurfaced with a minimum of bone resected. The great advantage this has over the hinge replacements, such as the Stanmore, is that of bone stock preservation. By resecting as little bone as possible, the prosthesis loads the juxta-articular cancellous bone, preventing stress shielding and subsequent bone loss. Ligaments may be spared if present. In rheumatoid arthritis where they are invariably absent, their absence may be accommodated by constraining the knee with a moulded polyethylene insert (Fig. 5). This will give the stability needed for a normal gait without the problems of loosening, fracture, and massive loss of bone stock encountered by the hinge knees of the 1970s and 1980s.

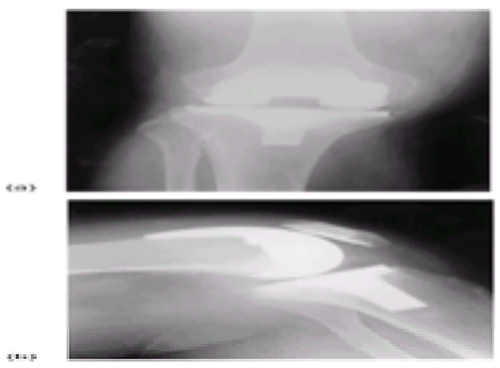

Fig. 5 Anterioposterior (a) and lateral (b) radiographs showing a cemented total condylar knee replacement. The patella has been resurfaced.

The present condylar type knee replacements have had significant problems with excessive wear of the tibial and patellar insert followed by secondary loosening. Many prostheses have been withdrawn from use following relatively unsuccessful trials (Kim and Oh 1995) and their failure rates vary considerably (Knutson *et al*. 1994).

Cemented or uncemented

There is little to choose between cemented and uncemented in total knee replacement at present although loosening seems slightly less in the tibial component if cemented (Knutson *et al*. 1994).

Outcome studies

Total knee replacement has evolved over the last three decades into a procedure that rivals total hip replacement for reliability and safety. In the Swedish knee arthroplasty register, which holds the records of over 30 000 knee replacements since 1976, the revision rate at 5 years has fallen from 10 per cent to 3 per cent (Knutson *et al*. 1994). Despite the softened bone and often deformed joints, the success rate in rheumatoid arthritis is just as gratifying as in osteoarthritis, with no significant difference in outcome (Briggs and Augenstein 1995; Hsu *et al*. 1995).

Complications

Aseptic loosening

This remains the principle problem in the long term. Poor surgical technique resulting in malalignment of the prosthesis is a significant cause of early loosening (Harvey *et al*. 1995).

Other knees loosen after excessive wear of the tibial insert. This leads to eccentric movement and abnormal loading. Early designs of replacement prevented normal joint motion and the constraints themselves caused the abnormal loads and early failure (Rickhuss *et al*. 1994). All knee replacements now allow some rotation as well as unlimited flexion, and this freedom from constraints has been a major factor in preventing early failure. The results of revision knee replacements were very disappointing when the initial prosthesis was a hinge type joint. The huge loss of bone stock led to rapid loosening once again, and many patients in the end faced excision arthroplasty or amputation (Ahlberg and Lunden 1981). Today, the more conservative joint resurfacing procedures have a lower revision rate and last longer so while the annual revision rate is still rising, the percentage of operations that are revisions has actually fallen over the last decade.

Arthrodesis

Joint replacement has a good track record now and the operation of knee fusion is only indicated as a salvage procedure in osteoarthritis affecting few joints. If properly performed, the mechanical function of the individual can be excellent (Behr *et al*. 1985; Figgie *et al*. 1987). If many joints are affected, the impact of knee fusion is so mechanically serious that this should not be considered.

Excision arthroplasty

Failed revision arthroplasty may occasionally result in a flail leg without a functioning joint but with so little bone stock that an arthrodesis would be difficult or impossible. This is a procedure for a very low level of activity and only really appropriate if many other joints are involved and repeated infection or poor soft tissue cover cause revision surgery to fail (Adam *et al*. 1994).

Hip

When the hip has been damaged by an inflammatory arthropathy, the principal surgical intervention is joint replacement. Arthroscopy and arthroscopically assisted synovectomy are technically difficult and of limited benefit. Corrective osteotomies around the hip are rarely appropriate, as the primary pathology is not mechanical. The possible beneficial effects of osteotomy in inflammatory arthropathy, which are poorly understood and inconsistent, been superseded by the more reliable effects of joint replacement.

Synovectomy

Synovitis in the hip although present in up to 40 per cent of patients as shown on ultrasound, does not correlate well with clinical findings. Many of the joint with florid synovitis on ultrasound will have few hip symptoms while other symptomatic hips have little synovial thickening (Eberhardt *et al*. 1995). The hip itself is not simply accessible for open surgery and carries with it a high risk of avascular necrosis of the femoral head. Open synovectomy requiring hip dislocation has been reported in younger patients with some success (Albright *et al*. 1975) but is not common practice. Arthroscopically assisted synovectomy has also been reported (Gondolph-Zink *et al*. 1988) but this is a difficult procedure with limited application.

Joint replacement

Total hip replacement has specific problems related to each of the inflammatory arthropathies, and their biological manifestations. Ankylosing spondylitis causes progressive ankylosis that may continue after the operation, while rheumatoid arthritis sufferers will usually have very poor bone stock and may have eroded the acetabulum. While these specific problems may make the technical aspects of the replacement demanding, the procedure is as successful for patients with rheumatoid arthritis as those with osteoarthritis. Despite being a major operation, involving pain and 10 days in hospital, joint replacement remains the most important intervention in a rheumatoid patient's disease process and, by their perception, well ahead of methotrexate and early aggressive management (Fries 1988).

Prosthetic design

Numerous designs of prosthesis exist, with little to recommend one over another. None has performed as well as John Charnley's original design (Wroblewski 1986) but several others have a proven record such as the Exeter (Fowler *et al*. 1988).

Cemented or uncemented?

Aseptic loosening remains the major cause of failure in total hip replacement. Improvements in cementing technique have reduced the rate at which early signs of loosening now appear, but the erosion of bone by the loosening process remains a concern. Various surface treatments have been used to attempt to stabilize the

prosthesis-bone interface without the use of polymethyl-methacrylate. Extensive use of porous surfaces coating the prostheses have failed to demonstrate any advantage over cement in terms of overall survival and symptom control. There may, however, be some improvement in bone stock, with less loss of bone mass owing to stress shielding. Hydroxyapaptite coating has been available for 8 years and seems very promising (Fig. 6). There may be a significant improvement in bone mass in the uncemented hydroxyapaptite coated group, making the revision a more successful operation, but this is not yet proven. The uses of a cemented stem and an uncemented cup, a 'hybrid' hip replacement, is another acceptable compromise.

Fig. 6 A hip 1 year after hydroxyapatite-coated, uncemented total hip replacement. Radiolucent lines are visible indicating solid fixation.

Biomaterials

Polyethylene wear particles from the artificial joint have been implicated in the loosening process. Small particles excite an inflammatory reaction causing erosion of bone, visible on radiographs as radiolucent lines. Improvements in the density of the polyethylene and the smoothness of the cobalt-chrome alloy femoral head have reduced this. Ceramic bearings have theoretically superior wear characteristics and should further reduce the volume of particulate debris. Long-term clinical results are not available.

Outcome

Rheumatoid arthritis sufferers consider joint replacement to be the most successful and significant intervention in their disease, being rated above any of the pharmacological therapies. Total hip replacements is certainly reliable and durable; 96 per cent of Charnley cemented total hip replacements were reported as being good to excellent at 15 to 21 years (Wroblewski 1986) in Charnley's own unit, while at the Mayo clinic 79 per cent were good or excellent at 15 years (Kavanagh *et al*. 1989). The Exeter hip has also a good record with 5.5 per cent needing revision at 13.5 years (Fowler *et al*. 1988).

In rheumatoid arthritis the reduction in bone density seems to be offset by the low level of exercise and most authors find the outlook worse for those patients with rheumatoid arthritis. One single-arm study showed a 91 per cent chance of the hip still functioning well at 11 years in rheumatoid arthritis (Severt *et al*. 1991).

Complications of total hip replacement

Infection

The systemic administration of prophylactic antibiotics, together with ultra clean air theatres have made the infection rate in primary hip replacement very low with figures of less than 1 per cent. However, in rheumatoid arthritis the rate is higher, at around 3 per cent (Severt *et al*. 1991), owing to immunocompromise and poor skin healing. The infected total hip replacement can often be salvaged by extensive debridement, and one or two stage revision followed by long-term antibiotics. In the long term however, repeated infection will lead to an excision arthroplasty.

Aseptic loosening

Hips may loosen for a number of reasons:

1. excessive wear leading to eccentric motion of the head and thus high peakloads;
2. stress shielding of the bone leading to resorption of the proximal bone and loss of bone stiffness;
3. faulty technique;
4. aggressive granulomatous reaction.

If the interface between the implant and bone is not solid, progressive motion will cause slow resorption of bone and an increasing zone of soft tissue between the implant and the bone. The painful total hip replacement should be revised early rather than left for as long as possible, as the enlarging radiolucent line around a prosthesis on radiographs represents resorption of bone and thus progressive weakening of the remaining bone stock. The results of revision surgery are fair: most people are helped considerably but the life expectancy of the revised hip is less than for the primary total hip replacement. A 10 per cent failure rate at 5 years would be average (Lord *et al*. 1988).

For this reason, cementless revisions with porous ingrowth or hydroxyapaptite coating is being tried in many centres. Bone graft may be needed, either in the shape of cancellous chips from the pelvis or allograft from femoral heads harvested during primary total hip replacements. These are used to augment the failing bone stock of either proximal femur or acetabulum. Inevitably, if the process of joint replacement is started young, and the patient has an oligoarthropathy, with a relatively active lifestyle, then repeated revisions will culminate in excision arthroplasty. Without a hip joint an otherwise fit person will walk with two sticks, but a typical polyarthritic rheumatoid arthritis sufferer will become comfortable but wheelchair bound.

Arthrodesis

Arthrodesis of the hip is the operation of choice in active young people with a single very painful and stiff joint. It will give good service for 20 years and may be revised safely. It does not have a role in polyarticular disease, where the change in biomechanics increases the stress to the knee joint unacceptably.

Excision arthroplasty

Excision arthroplasty of the hip is not necessary in uncomplicated IA. While it will give considerable relief of pain and will not deteriorate, it is only indicated where infection or very poor bone stock make further reconstructive attempts unwise. While the range of motion is excellent, the power is minimal and walking without two sticks is difficult, even for an otherwise fit young person with no other mechanical disability.

6.2 Surgery in children

Malcolm Swann

Introduction

Surgery now has a firmly established place in the management of juvenile chronic arthritis and in the rheumatic diseases of childhood (Arden and Ansell 1978; Swann 1983a; Rydholm 1990). This chapter is principally concerned with surgery of juvenile chronic arthritis and includes the scope and indications, problems and outcome. The number of children being offered surgical relief varies considerably not only between different countries but between different units within a country (Granberry and Brewer 1978). Much will depend on the attitude of the rheumatologist about seeking such help. It will then depend upon the immediate availability of an orthopaedic surgeon with an expert team conversant with the particularly challenging problems that this condition presents. Experience drawn from the Medical Research Council unit at the Canadian Red Cross Hospital at Taplow and at Wexham Park Hospital, Slough (England) forms the basis for the conclusion drawn here (Ansell and Swann 1983). There are some 5000 patients with juvenile chronic arthritis on the records and of these, 10 per cent have had a surgical procedure and many of them multiple procedures. In this surgically treated group, half have seropositive arthritis.

Surgery should be seen as complementing the other forms of treatment. Thus all the patients must have full exposure to conservative treatment including medication, physiotherapy, and splintage. At some stage it may become evident that these methods are failing and that further help must be sought. The clinician has a difficult task in managing this condition, whose cause is unknown and whose natural course is unpredictable both in the patient in general and in the individual joints. There are no markers to indicate when the disease will undergo remission or finally burn out. The problem is compounded by the unpredictable response to medication, which in itself may have side-effects; by physiotherapy, which can be painful if inappropriate; and by structural changes, which cannot be overcome by conservative means. For instance, splints need to be moulded, comfortable, and changed frequently if there is any alteration in a position. Thus, in our present state of knowledge, some problems cannot be surmounted by conservative means alone and surgical intervention will be required.

Many centres lack the specific expertise and team required for the disciplined and perhaps intensive approach that is necessary to overcome the many problems in treating these children. Failure of this vigilant guidance and its application, and in some cases failure of compliance by the patient (or their parents) may also result in unsuccessful therapy, with the establishment of loss of movement and deformity. Surgical help may be required in such cases in order to recover lost ground. There can be no doubt that the management of juvenile chronic arthritis is best supervised in special centres (Woo *et al*. 1990).

The main reasons for undertaking orthopaedic surgery are relief of pain, correction of deformity, and to overcome loss of motion. The last of these reasons applies not only to the individual joints but to the patient as a whole. These principles apply in particular to the surgical management of juvenile chronic arthritis. There are, however, two principles on which this surgical practice is based. First, the patients must have the opportunity to undergo corrective procedures early in the course of the disease in order to prevent the development of deformity and loss of movement. No surgeon would wish to be presented with a patient in a wheelchair who he or she is seeing for the first time with no options but to advise the total replacement of a destroyed joint. Second, the selection of a particular operative procedure is based on a thorough understanding of the cause of deformity, lack of movement and pain. A more detailed analysis of this will be made later but an example is a misshapen overgrown patella, stuck by fibrous adhesions to the underlying femoral condyle. Here there is deformity and loss of movement where medication, physiotherapy, and splintage may be fruitlessly and painfully applied until the adhesions are ultimately divided by operation.

The first of these principles can only be applied if the surgeon is invited to see the patient early in the course of the disease. Ideally, joint consultation should take place in the outpatients department, and on ward rounds so that cases can be presented and discussed, and a plan of management drawn up. The team must include an experienced physiotherapist, an occupational therapist, and nursing staff and others to reflect the special needs of children with arthritis. The second of these principles can only be applied after full investigation and appreciation of the precise anatomical, physiological, and pathological changes that have occurred (Swann 1987).

Contraction, contracture, and spasm

A number of loose descriptive phrases used in the clinical assessment of patients are often misleading. Muscle spasm is associated with any painful condition in the musculoskeletal condition and in essence serves to prevent movement that is painful, holding the joint in a position of comfort and maximum capacity. There is a contraction of the muscles but there is not a contracture. If the pain can be relieved by anaesthetic or other means, the affected joint will be seen to have a full range of movement. A contracture of muscles does occur after its denervation, when there is true replacement of muscle by fibrosis, or in conditions such as arthrogryphosis. The replacement of muscle with fibrous tissues does not occur in arthritis. There is, however, shortening of the muscle fibres and in established cases, it may take some while for these to be stretched out completely by appropriate treatment, including physiotherapy. However, contracture does occur in the periarticular tissues, such as in the capsule and ligaments, and is particularly noticeable in seronegative arthritis. This reaction may be so severe that it appears to be part of the primary pathology of the disease. The two states are interrelated, for a continuation of muscle spasm, either voluntary or involuntary, will allow a periarticular contracture to become established, with the shortening of the muscles and tissues on the concave side compounded by the wasting and stretching of the muscles and tissues on the convex side. The latter is particularly noticeable in relation to the quadriceps muscles at the knee.

If one considers a knee the clinical record may state, 'flexion range 30 to 90 degrees' or alternatively, 'flexion contracture 30 degrees'. This reading may be totally misleading as it takes no account of the pathology causing the loss of movement; nor is there usually standardization of the conditions under which such a record is made. The issue of the cause of a flexion contracture has been discussed and it should also be appreciated that a knee with a true range of movement under anaesthetic of, say, 30 to 90° has both an extension contracture as well as a flexion contracture, that is, it will neither bend fully nor straighten. If, however, the loss of movement is because of other causes such as pain, for example, the range will depend on many factors including the disease activity, and the level of analgesia and medication at the time (joints being noticeably stiffer on the morning that alternate-day steroids are due), and not least the confidence and co-operation of the patient.

Surgical intervention fits into this picture as being absolutely indicated in the presence of an established, true contracture.

Selection of surgical methods

This can be decided after a thorough analysis of the specific cause of the problem that is being addressed. Thus we need to examine the issues as to why a particular joint may be painful, why it is deformed and why it loses movement (Fig. 1). In order to appreciate this an understanding of the pathology is required in terms of both the intra- and periarticular aspects. There is also a clear distinction between loss of movement and stiffness. It is thus not only the arthritic process within the joint but its effect on lack of mobility, muscle wasting, osteoporosis, general debility of the patient, and many other factors that determine the outcome.

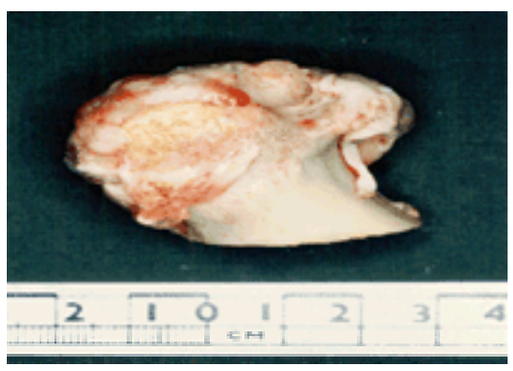

Fig. 1 The femoral head of a 14-year-old patient with juvenile chronic arthritis removed at the time of arthroplasty.

In general the cause of deformity, loss of movement, and pain follows a particular pattern. Pain in a joint is often associated with effusion so the patient will derive comfort in holding the position of maximum capacity, while attempts at movement are countered by muscle spasm. In time, a contracture of the periarticular tissues with shortening of the muscles on the concave side and lengthening of the muscles on the convex side of the joint occurs. Intra- and periarticular ligaments are affected and may be destroyed or fibrosed and together with intra-articular destruction of a joint surface, subluxation is often observed. Meanwhile this direct damage to the joint leads to loss of cartilage, and bone destruction and collapse, and this is sometimes accompanied by avascular necrosis and finally fibrous ankylosis and bone ankylosis. The greatest tendency to contracture is seen in the patients with seronegative arthritis, particularly those with the so-called dry-type arthritis. Loss of movement in a joint means that some areas of articular cartilage are never normally opposed and are thus denied the intermittent compression necessary for their normal nutrition. At the same time, opposed surfaces held under continuous pressure will also lack the normal stimulation to nutrition and in both cases degeneration of the hyaline cartilage follows (Salter and Field 1960).

These patients not only suffer a generalized retardation of growth but also suffer local defects of growth. Hypertrophy, irregular growth, or premature fusion of an epiphysis occur and are probably the result of the local increased blood supply. Frequently these children are unable to walk because of the pain caused by polyarthritis or because of their constitutional illness. This lack of activity contributes to the failure of joints, particularly of the hip, to develop properly. Bone porosis and muscle weakness add to the problem.

A range of surgical treatment is available and designed to tackle the problem at various stages of this pathological process (Fig. 2). Thus conservative measures including medication, splintage, and physiotherapy are adequate in the mildly affected, soft-tissue operations are indicated at the stage of early contractures, and operations on bones and joints (where even an arthroplasty may be recommended) in those more severely affected.

Fig. 2 Photograph of a 14-year-old boy who developed systemic-onset juvenile arthritis aged 6 years. Note the flexion of hips, flexion and valgus deformity of the knees, femoral internal rotation and tibial external rotation, and varus deformity of the feet. The cause of these deformities is analysed in the text. Some upper-limb problems are also apparent. He has since had bilateral soft-tissue releases of the hips followed later by total hip replacements, bilateral supracondylar osteotomies of the femurs, and a wedge tarsectomy.

Any synovial joint can be affected by inflammatory change but it is the knee and hip that are most commonly affected. Emphasis on the surgical management will therefore be directed to these two main joints but the principles outlined apply to other sites.

The hip

Cause of deformity

All the components that cause pain, loss of movement, and deformity are seen when the hip is affected. Pain and swelling of the joint lead to early flexion deformity and some adduction, with restricted movement. The psoas and adductor muscles are particularly dominant in this respect. In time erosion, destruction, sometimes subluxation, and often necrosis of the femoral head are identified and sometimes growth disturbance (Hastings *et al*. 1994). The persistent spasm and increased vascularity lead to a disturbance of normal growth. The capital epiphysis fuses early and there is some broadening and shortening of the femoral neck, while unequal forces may alternatively induce a marked valgus and anteversion. The greater trochanter grows at a normal or accelerated pace and the lesser trochanter is frequently overgrown because of traction from the psoas muscle. The femoral shaft becomes excessively bowed and the lumen of the medullary cavity has its greatest diameter in the sagittal plane.

The attitude assumed by the hip in early-onset arthritis is therefore dominated not only by the joint destruction and lack of proper use but also by the growth derangement brought about by the epiphyses. If there is anteversion of the femoral neck the femoral head tends to sublux anteriorly out of the socket and this leads to the patient assuming a flexed hip position, particularly when standing, in order to ensure stability and comfort. The valgus anteverted neck also means that the abductor lever is reduced and a Trendelenburg or waddling gait will occur.

The clinician must be alert to these causative factors when dealing with a flexion deformity of the hip because if the joint cannot be straightened it must be determined whether this is because of the spasm of the muscles, a soft-tissue contracture, or an abnormality of the bone development. Likewise the factors causing a limp must be sought.

A hip joint unaffected itself by disease can develop deformity secondary to a fixed flexed knee below or a scoliotic spine above, and with the chronicity of this illness

such a hip may develop a fixed deformity itself.

Specimens of femoral heads removed at operation have shown definite evidence of repair by fibrocartilage in patients whose disease is controlled or quiescent. It is therefore important that the hip is maintained in a congruous position with uninhibited motion so that there is adequate moulding if attempts at repair are to be successful.

Surgical management

This is best considered in three stages dependent on the degree of the problem:

Stage 1: hips in which there is almost a full range of movement under anaesthesia and with minimum radiological change.

Stage 2: hips in which there is still some fixed deformity and restriction of full movement under anaesthesia and in which radiographs, arthrograms, computerized tomographic (CT) scans, magnetic resonance imaging (MRI) or ultrasonography confirm the presence of a joint space.

Stage 3: hips lacking movement under anaesthesia with persistent deformity and advanced radiological change.

Stage 1

The establishment of fixed deformities and loss of movement can be aggressively countered at this stage by a well-supervised conservative regimen. These children are admitted to the hospital for full evaluation of their problem. Medication includes analgesics and possibly an intra-articular steroid injection. Skin traction is applied, with the pull toward abduction, and maintained for 24 h a day interspersed with physiotherapy. When the condition permits, prone lying for part of each day may help reduce flexion deformity of the hip. However, it should be appreciated that in a hip which has an effusion, attempts at extension may actually increase the intra-articular pressure and thus the pain. There is some evidence to suggest that a rise of intra-articular pressure will also lead to avascular necrosis (Soto-Hall 1964). Early surgical decompression of these hips is therefore indicated before attempts at extension using traction or prone lying. This will be discussed later. When the hips are affected the knee in particular needs to be watched and may require splints to prevent concomitant flexion. As the patients begin to improve, hydrotherapy should be instituted daily in addition to the traction. Sitting, such as in a wheelchair, is forbidden. When the pain abates, walking with aids can start progressively, with traction maintained at night.

Stage 2

When there is an established flexion contracture, movement is limited even under anaesthesia, and the joint space can be demonstrated, then the situation can be improved by a soft-tissue release operation (Mogensen *et al*. 1983). While complete release operations may sometimes be necessary (Alvarez *et al*. 1992; Witt and McCullough 1994), the tightness of the adductors and psoas is the main obstacle to correction (Swann and Ansell 1986). An open adductor tenotomy can be done and through the same incision the psoas tendon can easily be reached and divided at its attachment to the lesser trochanter.

After the operation the hips are again put on traction in abduction and extension, and the regimen, continued as described for stage 1 except that hydrotherapy, of necessity, is delayed until the wounds are healed. Experience of this procedure in over 100 cases has produced gratifying results that include lessening of the flexion contracture (Fig. 3), an increase in the total range of movement, and a very dramatic relief of pain, probably due to decompression of the joint. Radiographs have shown an improvement in terms of a decreased osteoporosis, a clearer definition of the joint line, and some widening of the joint space in more than half the patients (Fig. 4). The longer-term results at 3 years and more have been shown to mirror the activity of the subsequent disease. Nevertheless, by improving the movement and function of the joint a congruous, contained femoral head may be possible with some repair, so if the disease activity abates a serviceable hip remains. In those cases where the continuing disease activity results in a less favourable outcome a period of relief from pain is usually enjoyed and the structural anatomy is in a better position for hip arthroplasty at a later state.

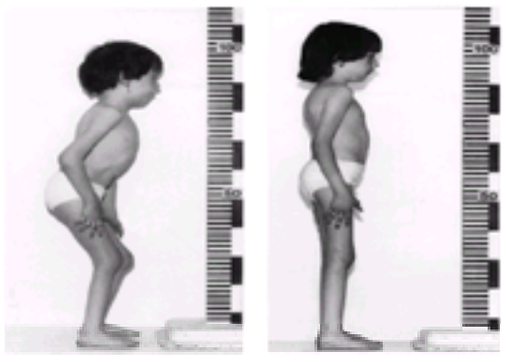

Fig. 3 This patient developed pauciarthritis aged 15 months, which subsequently extended. (a) At age 3 years: appearance after a full regimen of medication, physiotherapy, and splintage; she had active disease in both hips and knees with persistent flexion deformities at these joints. (b) After soft-tissue release of both hips and both knees a few months later—the posterolateral knee scar can just be seen.

Fig. 4 This patient developed a severe systemic disease followed by polyarthritis aged 4 years. (a) Radiographs of the hips when the patient was aged 13 during an active phase of the disease and immediately before soft-tissue release; there is a marked flexion contracture. (b) The same hips 3 years later following the soft-tissue release: the disease had also become quiescent but the operation permitted mobility to be regained and some healing has occurred; these hips have remained painless and the patient is now 29 years old and walks without a limp.

The role of osteotomy to correct deformity is limited, but occasionally muscle imbalance, joint effusion, and an increased valgus of the femoral neck lead to anterolateral subluxation of the hip and theoretically a varus osteotomy is indicated under these circumstances. However, the porosity of bone will often preclude internal fixation and external immobilization will lead to intractable stiffness. An osteotomy can occasionally be used in a patient whose disease is no longer active and in whom there is good bone stock. Care must be exercised before proceeding with a containment osteotomy because sometimes a coxa magna precludes the femoral head being fully restored to the acetabulum. This containment may also be prevented if there is a mass of thickened synovial tissue in the acetabular floor—a situation which may be identified by MRI. In addition, care in alignment of the shaft is essential to allow the possibility of total arthroplasty at a later date.

Stage 3

Total hip arthroplasty may be indicated in a patient with a severely destroyed joint who may be condemned to a painful existence in a wheelchair. Some of the patients have had to have custom-made prostheses to fit their mini skeletons (Fig. 5). These are time-consuming procedures because of the bleeding and the frailness of the bone, and our long-term studies have shown they carry, as expected, a higher rate of infection and prosthetic loosening than in other conditions (Learmonth *et al*. 1989; Williams and McCullough 1993). A current review of 96 hip replacements with a follow-up of 6 to 18 years (average 10 years) revealed that 25 per cent had failed, and the appearance of translucent lines and hip migration even in the asymptomatic patient suggests that this rate will rise with time (Witt *et al*. 1991). Of the 42 children reviewed in 1986 following total hip replacement (Ruddlesdin *et al*. 1986), four have since died of amyloid disease. Nevertheless, those who have reached late teenage or early adulthood have clearly been transformed by being physically able to integrate better with the community in terms of work, pleasure, and social contact. All the patients and their parents, save one, felt the operation had been worthwhile, despite those that had failed and the need for a revision arthroplasty in a large number of cases. However, modern techniques including the use of bone grafting, have enhanced the success of these more difficult procedures. I feel that despite the overall high failure rate the operation remains well worthwhile in carefully selected cases as the only alternative to a painful wheelchair existence.

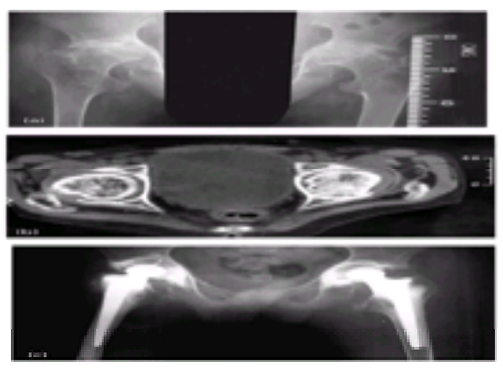

Fig. 5 This patient developed systemic-onset juvenile chronic arthritis aged 7 years. He also suffers from diabetes and myasthenia gravis. (a) Hips at age 16 immediately before surgery: the patient was unable to walk because of the painful disability; note the severe acetabular erosion and the overgrowth of the lesser trochanters; the sunken hips prevent proper abductor function. (b) A CT scan of the same patient used to define the pelvic bone stock available for anchoring the acetabular component of a total hip replacement; note the thin medial wall. (c) The postoperative appearance: note this patient has subsequently had both his knees replaced (see Fig. 6).

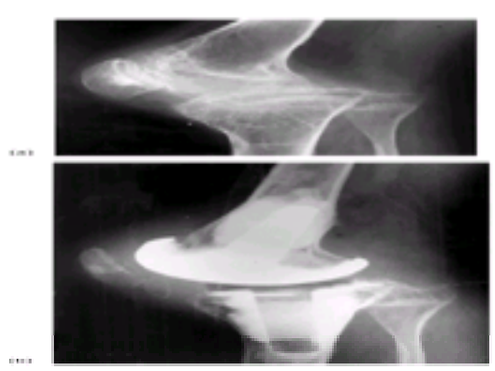

Fig. 6 The same patient as depicted in Fig. 5; after hip arthroplasty further deterioration occurred in both knees. (a) Preoperative radiograph at age 16 years: note the severe degree of osteoporosis, overgrowth of the patella, posterior subluxation of the tibia, and the marked depression of the tibial plateau. An anteroposterior view showed the knee to be in a marked valgus position as a result of the collapse of the lateral tibial plateau but also an overgrowth of the medial femoral condyle. (b) Total knee replacement using an Attenborough prosthesis. The small size, destroyed surface, and osteoporosis are best suited to an unrestrained, stemmed prosthesis with cement. Some newer designs of total condylar replacement are proving satisfactory after adolescence when the disease has become inactive. This patient has now regained mobility having lost the flexion contractures in both hips and both knees, and in each case has a flexion range of 90° or more.

The knee

Cause of deformity

The knee is frequently affected early in several of the subgroups of juvenile arthritis, possibly because of its large synovial surface. When this becomes inflamed the joint is flexed into a position of comfort and maximum capacity, and hamstring spasm will prevent it straightening. The stretched quadriceps muscle rapidly wastes and this may also be a reflex phenomenon associated with the effusion within the joint. This weakness of the quadriceps adds to the inability of the patient actively to straighten the knee. The periarticular structures undergo fibrosis and it is important to note that this includes the broad expanse of the quadriceps expansion on each side because this in turn will limit flexion. The joint thus develops a flexion contracture and an inability to flex so that it loses movement early, i.e. an extension contracture.

These effects combine to lead to a characteristic posterior subluxation of the tibia. The articular cartilage becomes eroded with continuing activity but because this is particularly thick in the younger child, the erosion must be well advanced before significant joint narrowing can be seen. Marked effects are imposed on the growth of the bone because of the hyperaemia and venous hypertension. There is an overgrowth produced by the epiphyseal plate and in patients with only one knee affected, characteristically in pauciarthritis, the limb grows longer than its fellow. The medial side of the femoral growth plate appears to have a propensity to be stimulated in the greatest manner and this is one of the causes of a valgus deformity (see Fig. 2). Valgus may also be related to collapse of the lateral side of the joint, and this may be in response to forces of the adducted hip above and possibly a varus foot below. A complex state develops in these patients, leading to a rotation deformity. Anteversion of the femoral neck produces internal rotation deformity of the femur, which is clinically evident by the squinting patellae. Secondary external rotation of the tibia at the knee plus some torsion of the tibia itself may then begin to develop to keep the axis of the ankle in line with the direction of progress (see Fig. 2). In addition, when a foot affected by the disease has painful articulations and is held in eversion and valgus when the patient walks, this will also induce a torsional force on the tibia. Finally, an iliotibial band contracture causes flexion and external rotation of the knee and contributes to this complex mechanism of deformity. Lateral subluxation of the patella may follow, which in itself may require surgical correction because the line of pull of the quadriceps has thus become mechanically inefficient.

The patella itself often develops overgrowth into a misshapen and mechanically unacceptable form, whilst closure of the patellofemoral joint by fibrous ankylosis may be a cause of a fixed deformity that will certainly require surgical release.

Management

In terms of surgical treatment it is helpful to consider the knee in three stages, depending on the extent of the pathology present.

Stage 1: A knee in which there is a full range of movement under anaesthetic and minimal changes on radiographs.

Stage 2: Knees with some restriction of movement and slight deformity that cannot be corrected under anaesthetic but where a joint space is still present.

Stage 3: Gross loss of movement with a severe deformity and marked radiographic changes.

An overall appraisal of the other joints affected, particularly in the same limb, must be made before beginning treatment. Correcting the flexed deformity of the knee if the ipsilateral hip exhibits a similar problem is useless and probably the hip should be dealt with first. When planning surgery it has to be decided whether the deformity can be corrected by a soft-tissue operation and thus increase the total range of movement, or by osteotomy, leaving the range of movement unchanged. The former is ideal but can only be achieved when the disease activity is controlled and the joint destruction is minimal. an osteotomy realigns the limb by producing a secondary deformity that masks the first. However limited the movement in a knee, it must be possible to extend it. The patient can then stand in comfort, wear a calliper if necessary, avoid quadriceps fatigue, and prevent the induction of a secondary deformity of the hip.

When fixed flexion is considerable, several complications of treatment must be recognized. First, as the leg is extended, traction will occur on the popliteal artery and nerves, and may lead to a vascular embarrassment or neurological damage. Second, passive conservative treatment using traction or plaster may lead to problems such as subluxation of the knee, supracondylar fracture of porotic bone, or anterior compression across the joint when the posterior capsule is unyielding and acts as a hinge at the back. This compression itself may cause necrosis of the cartilage and subarticular microfracture. If the method employed requires prolonged immobilization, further disuse porosis will occur and the articular surface will suffer, as hyaline cartilage requires intermittent compression to maintain effective nutrition.

Treatment

Stage 1

The patient is examined under a general anaesthetic and if this reveals a normal range of movement and no fixed deformity, physiotherapy and rest splints are indicated. If pain is severe, slow correction by reversed dynamic slings is used if the deformity does not exceed 25° but these must not be applied under anaesthetic. Medication can be helpfully reinforced by intra-articular steroid injections (Earley *et al*. 1988). Synovectomy is indicated where there is permanent thickening and effusion in the knee, often leading to overgrowth of the limb. Synovectomy, however, has a limited role in polyarthritis because the patients who might benefit most are often too sick for surgery because of systemic disease. It should be therapeutic rather than prophylactic in a disease whose future progress in an individual patient and an individual joint is unpredictable. Arthroscopic synovectomy is the method of choice if the joint can be distended (Vilkki *et al*. 1991).

Stage 2

Soft-tissue release of the posterior structures may result in an immediate correction of a flexion deformity or be used as a prelude to further serial plasters or reversed dynamic traction (see Fig. 3). It is a satisfactory procedure when there is no concomitant valgus deformity. The operation involves lengthening of the hamstring muscles and division of the posterior capsule of the knee joint right across its axis and around on either side (Clarke *et al*. 1988). It is a difficult procedure and if the tibia is found to be subluxed the contracted cruciate ligament may need to be divided. After the surgery, plaster is applied for 3 days, following which it is bivalved and movement encouraged to overcome the tendency to postoperative stiffness. The plaster shells are kept as rest splints and used for early walking until strength is regained.

If the deformity is fixed and bone destruction is more advanced, then a supracondylar osteotomy is an appropriate procedure, and can be used to correct valgus at the same time. The operation is done through a short medial incision and the porosity of the bone often precludes internal fixation so that a plaster cylinder or similar external splint is applied and weight bearing encouraged at the outset. The plaster is removed as early as possible, usually at about 4 weeks to obviate stiffness. A calliper or alternative support is advised for immediate use as a night splint to maintain correction. The bone can be expected to unite satisfactorily and the position of the leg is maintained in correct alignment by direct inspection. Intensive physiotherapy is required to prevent postoperative stiffness. It is occasionally necessary to repeat the osteotomy if the forces that necessitated it in the first place continue to act, particularly if there is an exceptional increase in growth of the patient.

Epiphyseal stapling has occasionally been used to correct valgus of the knee and some surgeons use this method to arrest excessive longitudinal growth, particularly in cases of pauciarthritis (Rydholm *et al*. 1987).

Stage 3

These knees are often totally adherent, with fibrous adhesions not only between the main articular surfaces but in particular between the patella and the femoral condyle. They are usually associated also with considerable periarticular contracture. For this reason, access to the knee is difficult through an arthroscope as the joint cannot be distended with fluid in the normal fashion in order to get a clear view. Some of these patients can benefit from an extensive surgical approach that divides the adhesions, followed by an immediate postoperative regimen using the continuous passive-motion machine under adequate analgesic cover. However, many joints are clearly so badly destroyed that nothing short of total knee replacement is indicated (Fig. 6). Technological design and improvements in techniques have now produced a generation of knee prostheses that can be manufactured in a smaller size and are suitable for these juvenile patients. The experience being gained with these is encouraging and for any child who has a severely painful joint with deformity and destruction that precludes any other form of treatment, this method must be considered. The indications are similar to those suggested for a hip prosthesis.

The foot and ankle

Studies have shown (Ansell and Wood 1976) that within 1 year of onset of the disease, the ankle joint was affected in 40 per cent of cases, the subtalar and midtarsal in 27 per cent, and the metatarsophalangeal in 9 per cent. At the 15-year follow-up only 0.9 per cent of children felt that the foot was the most limiting factor. The early onset of the disease in the foot leads to growth abnormalities that present clinical features often requiring surgical remedy. The multiple and complex synovial articulations fall prey to the severity and duration of the disease. Problems present as elsewhere, with pain, deformity, and loss of function. Pain is associated with active disease but it must be appreciated that a deformity causing pressure or stiffness may throw abnormal strains on other, possibly unaffected joints. Foot problems may also arise secondarily to those of the knee. Finally, inflamed synovial sheaths or bursae may require attention.

Management

This is best considered under the headings of the forefoot, the hindfoot, and the ankle (Ansell and Swann 1996).

The forefoot

The main indication for surgical intervention in the foot is pain. Deformity *per se* is not an indication to operate unless it is causing pain or loss of function, and many foot problems can be dealt with by simple conservative means, including special shoes, orthoses, splints, or even a calliper. However, when the problem cannot be controlled by these simpler means or if the older patient is reluctant to wear a surgical shoe or an orthosis, surgery is indicated. Specific examples where surgical intervention will, however, be required as a primary source of relief to the patient include significant toe deformities produced by epiphyseal abnormalities, and severe metatarsalgia with clawing of the toes associated with disruption and dislocation of the metatarsophalangeal joints, as seen in seropositive disease. In these patients, severe hallux valgus deformity may occur, which will require a metatarsal osteotomy for realignment of the great toe. The reader should be aware that overall excellent results can be obtained by careful selection of patients for surgery, particularly for instance where a local pressure point in the forefoot or toes is the source of severe pain. The operations include surgical trimming of a bony prominence or irregularity, straightening of the toes, and excision arthroplasty of the metatarsophalangeal joints (Fowler 1959).

The hindfoot

This includes the subtalar, talonavicular, and calcaneocuboid joints. No set pattern of deformity is seen here but the deviation may be into either varus or valgus. Whichever way they go, both the heel and the forefoot usually diverge in the same direction, setting up abnormal foot imprints and consequently secondary strain-pressure areas and callosities. Valgus deformity can be produced by a spasm of the peroneal muscles and this can be a presenting feature of juvenile chronic arthritis, where it is labelled a peroneal spastic flat foot. Valgus is also caused by some collapse of the foot to spare the painful articulations affected by disease, or secondarily to compensate deformity at the knee. Loss of joint congruity and fixation by joint adhesion or contracture will later prevent passive correction. A varus

deformity is particularly disabling because the patient walks on the outer border of the foot (see Fig. 2). Not infrequently this is associated with a valgus deformity of the knee and as such may be partly compensatory, accentuated by taking a full load of body weight. This combined deformity may seriously affect the patient's gait.

The indications for treatment are pain and deformity: however, a deformity that is painless but interfering with the child's gait should be corrected. In the majority of patients, conservative treatment suffices in as much as one is able to obtain a good correction of the deformity, but it is necessary to do this under a general anaesthetic. At the same time an intra-articular injection of triamcinolone is given into the dominantly affected joint and, if the exact location is not clear, it is put into the sinus tarsi. After this, the foot is put into a corrective, plaster-of-Paris walking cast for 4 weeks; the plaster is then removed and the position maintained with a calliper (Mavidrou *et al*. 1991).

Surgical management

In some patients where passive correction even under anaesthetic is not possible, some form of surgical correction will be indicated. In principle this consists of the removal of bone wedges to correct alignment of the foot and fusion of painful joints, in particular the talonavicular joint, which is often the predominant cause of trouble. Realignment of the heel in the presence of a good triple joint can be achieved by an osteotomy of the os calcis.

The ankle joint

The ankle joint itself may undergo erosive disease or be secondarily affected by avascular necrosis of the talus. It may also become mechanically stressed when normal movement is lost at the subtalar or midtarsal joints.

There is sometimes difficulty in identifying the source of pain in the hindfoot region, especially in differentiating between the ankle joint and the subtalar joint. Clinical examination and radiographs may help in identifying the joint at fault. However, the solution is complicated by the fact that a radiologically destroyed and stiff subtalar joint may itself be relatively painless but throw strain on an ankle joint that is not the site of primary disease. It is therefore recommended that a conservative approach is taken for as long as possible, including the use of gentle examination and repositioning of the foot under anaesthetic, injection of triamcinolone, and immobilization in plaster for 4 weeks. If these measures fail and it is necessary to proceed further the surgical options consist of arthroplasty or arthrodesis of the ankle joint.

Soft-tissue lesions around the foot

Tenosynovitis may induce pain, swelling, and spasm; in particular the sheath of the tibialis posterior is most commonly affected. The paratenon and bursae associated with the Achilles tendon are involved in patients with ankylosing spondylitis. Local injections of steroid into the inflamed tendon sheath are helpful but if this method fails, surgical synovectomy may have to be considered.

Intensive conservative treatment of feet affected by disease should preclude the need for surgery in the majority of cases. Nevertheless, conservative treatment may be instituted too late or fail to control the condition, particularly in persistently active disease. Surgery may then have some part to play in correcting the deformity, which is painful and retards walking. With rare exceptions it should only be employed when growth has ceased.

The upper limb

The most common problems that will need to be considered by the surgeon in juvenile chronic arthritis are those in the lower limb, and these have therefore been addressed at some length. However, the principles of surgery in the hip, knee, and foot are also invoked in the management of the upper limb and a short summary of the position with regard to the shoulder, elbow, hand and wrist follows.

The shoulder joint

This tends to be involved in those patients who have severe, generalized disease with prolonged activity. Its onset is often insidious and the patient is usually more concerned with the arthritis that affects the weight-bearing joints. It is when other joints in the upper limb, such as the elbow or wrist, are involved that the patient will become aware of the shoulder.

Shoulder problems are often exacerbated by the need to use crutches, and earlier and more satisfactory relief of problems in the leg joints have been helpful in this respect. There is very little conservative treatment that is effective for the shoulder, although it is worth trying an intra-articular steroid injection. If both shoulders are seriously affected, then everyday tasks such as dressing and feeding become well-nigh impossible and under these circumstances surgical relief may be sought. On the whole, synovectomy is ineffective, although if there is a very big subacromial bursa this can be excised. Osteotomy of the shoulder has an amazingly good outcome in terms of pain relief. This results in better use of the shoulder and scapula, although the actual movement in the glenohumeral joint itself may not be demonstrably increased. Arthrodesis is rarely indicated in a disease where stiffness itself is a problem. However, the present generation of shoulder arthroplasties is showing promise and some surgeons with an interest in this joint are reporting good results.

The elbow joint

This joint is more frequently involved than the shoulder, 45 per cent of the patients in a 15-year follow-up having problems. Assuming a failure of conservative treatment there are a number of surgical procedures that have a significant place in the management of this joint. Recurrent attacks of pain and swelling may derive benefit from a synovectomy; if the radial head is damaged and growth has reached maturity, it too can be removed. Arthrodesis is impractical but arthroplasty has a significant place. After excision of the bone ends, either an interposition of skin or fascia or a prosthetic replacement if enough bone stock is available are both very successful in relieving pain and improving movement and function.

The wrist and hand

These have a multitude of synovial joints so it is to be expected that most patients suffering from juvenile chronic arthritis in one of its forms should at some time have at least one of these joints involved (Harrison 1978). If the synovial sheaths of the flexor and extensor tendons are also included, few patients will escape some manifestation, and if the many growth plates and epiphyseal centres are involved, then the stage can be set for severe disability. Probably nowhere else is better rewarded by early splinting and physiotherapy to prevent deformity and stiffness. There are, however, indications where surgery can be helpful in this condition, but for the most part it is advised that this should be undertaken by a hand surgeon who is conversant with this minefield of problems. Indeed, the systemic illness of a child may militate against surgical intervention and when tendon sheaths are affected their involvement may also regress as the disease itself comes under control. We have found that the use of corticosteroids in persistent disease of the synovial sheath has been particularly helpful; intrathecal injections of hydrocortisone are given under general anaesthesia because they are painful. Occasionally, patients with a persistent thickening from proliferative synovitis in a limited field may benefit from a simple synovectomy followed by rapid mobilization. Extensive synovectomy of the flexor sheaths is never undertaken because it can lead to intractable stiffness. However, limited excision of the synovium of the dorsal sheaths, particularly in seropositive arthritis, does have some place, particularly where there is a danger of tendon rupture. The problems presented by a trigger finger or carpal tunnel compression are dealt with in the conventional fashion with the use of local steroid or, failing response, surgical decompression.

Wrist and carpal joints

There is often early destruction and deformity from epiphyseal involvement at these sites and the outcome is dictated by the degree of disease, age of onset, and the particular extraneous forces about the joint. A flexion deformity may occur early, and forward subluxation and ulnar deviation of the wrist must be countered by vigorous splinting and exercises. If stiffness does occur, one must ensure that it does so in a good position. Subluxation of the distal ulna often causes a painful swelling with some risk of tendon rupture; provided that the distal growth plates are closed, ulna styloidectomy may be indicated. For the severely damaged wrist and carpus, the choice will lie between arthrodesis and arthroplasty. Arthrodesis is well tried and, if indications are right, it can be most successful, mimicking that which nature often attempts. However, careful appraisal of the whole position of the arm must be made, as in some patients who already have stiff shoulders and elbows the retention of a small amount of movement, particularly in radial deviation, may make a disproportionate difference to their quest for independence.

Finger joints

The metacarpophalangeal joints when affected particularly in seropositive arthritis may benefit from synovectomy. If totally destroyed, and there is ulnar drift, a realignment procedure is worth undertaking with the use of some form of arthroplasty. When the problem is as severe in the interphalangeal joints, stabilization is again worthwhile, using a silastic implant.

The spine

The cervical spine is affected in both seropositive and seronegative juvenile arthritis (Swann 1983b), the dorsal spine exhibits crush fractures when steroids have been exhibited, and the lumbar spine takes the brunt of ankylosing spondylitis.

Patients with seronegative juvenile chronic arthritis may present with a painful torticollis and if this is neglected the patient will be left with a permanent disability with the head tilted rigidly on one side. These patients should be given a general anaesthetic, if necessary, in order to relieve the spasm, and whilst the head and neck are held straight a firm collar is applied. This is taken off for daily exercise and then reapplied, for although it will not prevent fusion occurring it does permit it to take place in a more satisfactory position. Seropositive arthritis, on the other hand, leads to instability and it is particularly at the atlantoaxial level where the subluxation or dislocation may occur. There is an absolute indication for surgical fusion at this level if there is a neurological involvement or severe pain or both.

It is of particular importance that the anaesthetist should be aware of these problems in the cervical spine in both types of disease. The rigidity of the neck, associated with a small airway, may make intubation difficult or impossible by conventional means. Subluxation or dislocation at the atlantoaxial level will equally be a hazard because attempts at intubation may lead to cord damage. It is essential that an up-to-date radiograph should be available immediately before the patient is given a general anaesthetic. The use of the fibreoptic laryngoscope and other airway techniques have obviated the worries that existed previously; many patients who are having lower limb surgery can be managed well with spinal or epidural anaesthesia (Smith 1990).

Scoliosis

Structural scoliosis occurs more commonly in patients with juvenile chronic arthritis than in the normal population (Ross *et al*. 1987). This may arise from the postural curves associated with asymmetrical involvement of the lower limb joints causing pelvic tilting. Timely surgical relief of the primary cause in the lower limbs has led to a lessening of the spinal curve. Asymmetrical involvement of the apophyseal joints may also contribute to this problem. In patients with scoliosis, careful appraisal of the underlying pathology should be made, but if there is a need, conventional methods of correction and stabilization can be used.

Fractures

The limited activity of these patients and their inability to participate in sport protects them largely from this problem. Nevertheless they are prone to pathological fractures because of their osteoporosis and the stiffness of their joints. This is particularly so with supracondylar fractures of the knee and underlines the inadvisability of manipulating the joints under anaesthetic. Examination under anaesthetic is permissible but must be attended by the utmost care.

After fractures, immobilization of the cast must be maintained for the minimal time consistent with union to prevent additional stiffness of the adjacent joint. The degree of osteoporosis usually precludes internal fixation of the fragments.

A number of patients have suffered crush fractures of the spine, particularly if they are on corticosteroids. No special treatment is indicated and recovery with remarkable reformation of the vertebrae can be expected.

Summary

All synovial joints are vulnerable to the deformity and functional loss that can occur in juvenile chronic arthritis. The principles outlined in this chapter should be applied intensively in this polyarthritic condition. The prognosis in terms of complete remission for many sufferers makes the treatment all the more demanding and worthwhile so that they may grow into physically functional adults.

6.3 Rehabilitation of adults

Lynne Turner-Stokes

Introduction

Arthritis produces a wide spectrum of disability. Some aspects, such as deformity or florid synovitis of the hands, are clearly visible. Others, for example variable fatigue, are less so, and can lead to real social handicap as they are likely to be unsympathetically received by friends and family.

Until recently, 'rehabilitation' to the average rheumatologist meant wax baths and wheelchairs. In the last decade, the development of a multiprofessional approach to rehabilitation has transformed the way we think about disability. The purpose of this chapter is to describe that multiprofessional approach, as applied to the management of inflammatory joint disease.

Epidemiology

Epidemiological surveys in the United Kingdom (Harris 1971; Badley *et al*. 1978) have shown that the largest single group of impaired people have locomotor disease, amounting to one-third of the total impaired and to 40 per cent in the elderly population.

In a population of 100 000 people over 1000 will have rheumatoid arthritis, of whom 120 will be severely handicapped and 25 will be chair- or bed-bound. The same population will have 300 or more patients with severe osteoarthritis, of whom 50 will be totally immobile (Clarke *et al*. 1987)

Impairment, disability, and handicap

In the past, terms such as disability and handicap have been loosely applied. For the purpose of this chapter I shall use the *International classification of impairments, disabilities and handicaps (ICIDH)* (World Health Organization 1980). In essence, 'impairment' refers to the symptoms and signs of arthritis, 'disability' is the resulting loss of function, and 'handicap' is the disadvantage experienced as a result of that disability.

Handicap is determined largely by social and environmental factors, and by the individual's expectations and aspirations. Thus the same level of impairment may lead to very different degrees of handicap in different individuals. For example, relatively mild arthritis in the hands may be devastating to the concert pianist but of little consequence to the cross-country runner, while similarly mild arthritis of the knees could have the opposite impact.

As health professionals, we tend to measure what we can alter. Doctors traditionally measure impairment, while therapists measure functional loss or disability. Patients and their families tend to be more concerned with handicap, but until recently, very little effort has gone into measurement of handicap or quality of life.

Handicap is only indirectly affected by reducing disability. The main limiting factors are social and environmental—housing, education, employment for example—and are largely beyond the control of healthcare workers.

In the United States the Americans with Disabilities Act now ensures that all public buildings must be fully accessible to disabled people, and an individual cannot be excluded from employment because of disability alone. In the United Kingdom and Europe we still fall a long way behind, but if we are to be the best advocates for our patients, we must measure these aspects and continue to apply pressure to improve the lot of our disabled patients.

Measurement of disability

If we are to manage disability effectively, it is essential that we measure it in order to be able to assess the outcome of our endeavours. There are two main types of measure for disability, specific and generic. Generic measures take a global view of disability and record it in a standardized manner that allows comparison. It is essential to collect generic information to allow comparison of different programmes, populations, and practices, but we must also realize that these scores often show little relevance to how individual patients function in their own environment. To assess this, we require specific measurements.

For example, incontinence is a major cause of disability and handicap, something we all dread. Stiffness, immobility, and poor dexterity combine to make it a common problem for patients with arthritis, many of whom are middle-aged to elderly women with a degree of urinary urgency and frequency. If we want to know whether a patient can get to the toilet in time, it matters not how long it takes them to walk a standard 10 m, or undo three standard buttons on a standard garment. What matters is how long it takes them to get to their toilet from their usual chair in the daytime, or from their bed at night, and once in the toilet, how long it takes them to undress and position themselves appropriately to pass urine without spillage (Turner-Stokes and Frank 1992). The presence or absence of a downstairs toilet, or a commode in the bedroom, may make the critical difference between continence and incontinence.

Measurement of disability therefore requires a combination of specific and generic measures. No one instrument will suffice. A large number of disability scores have been produced, some well validated, others not. It is important to select a scale that is set at the right level. The Barthel score, for example, is used widely for patients with neurological disability. It has pronounced floor and ceiling effects and, although reliably scored between different observers, it is relatively unresponsive to

change, which makes it unsuitable for assessing functional outcome in most patients with arthritis.

Some instruments require an independent observer, others have been developed for self-completion. One of the most widely used functional scores is the Stanford Health Assessment Questionnaire, which was developed in the United States, but has subsequently been translated into English practice and validated for self-completion by Kirwan and Reeback (1986). If routinely completed by patients while they wait for a clinic appointment, Health Assessment Questionnaire scores can provide a useful serial record of disability and its change with time.

Measurement of handicap and quality of life

As mentioned earlier, disability is not the only outcome measure that should be recorded. Handicap and quality of life are more important to the patient and their family, but more often than not we have no indication of whether our treatment is having any impact at all in these areas (see also Chapter 1.1.5).

An abbreviated list of potentially useful generic scales is given in Table 1. The London Handicap Scale was developed for stroke patients, and the Community Integration Questionnaire for patients with brain injury, but both collect information in a standardized way that is potentially useful for patients with arthritis.

Modality to be measured	Instrument	Reference
Impairment	Ritchie index	Ritchie *et al.* (1968)
Disability	Health Assessment Questionnaire (HAQ)	Kirwan and Reeback (1986)
	Functional Independent Measure (FIM)	Hamerman *et al.* (1993)
Handicap	London Handicap Scale	Harwood *et al.* (1994)
	Community Integration Questionnaire	Willer *et al.* (1994)
Quality of Life	SF-36	Garratt *et al.* (1993)
	General Health Questionnaire	Goldberg and Hillier (1979)
	Nottingham Health Profile	Hunt *et al.* (1981)
Depression	Beck depression score	Beck *et al.* (1979)
Anxiety	Spielberger score	Spielberger *et al.* (1970)

	Multi-dimensional pain inventory	Kerns *et al.* (1985)

Table 1 Modalities and examples of available measures for assessing patients with arthritis

A number of instruments have been developed to assess quality of life in relation to health, including the General Health Questionnaire, the Nottingham Health Profile, the Sickness Impact Profile, and the SF-36. The SF-36 in particular has been designed for ease of use and is gaining popularity. It could potentially provide useful information on quality of life for patients with arthritis and their families. However, as yet it has not been validated for use with disabled patients or their carers, so any information obtained should be treated with caution.

Patients in the early stages of arthritis may not be significantly disabled other than by pain, and standard disability scores may not be suitable. Alternatives such as the Multidimensional Pain Inventory may be useful, not only for measuring the impact of their symptoms but also the extent to which they use positive coping strategies to combat them.

These are just a few of the scales that have been developed. None of them is perfect and they all have somewhat different emphasis. When selecting an instrument, careful examination of all of the items included will indicate which is the most relevant to the population under study. Although some scales apply weighting to different items, so that they perform as interval scales, it should be remembered that most measures provide ordinal data, which should not be submitted to simple mathematical manipulation such as summing or averaging. Rasch analysis is a method of applying a mathematical model to ordinal data, so that they behave as interval data. Its role is currently being explored in this area, but it is too early to say if this will prove useful. Whichever instrument is used, it should be applied only with reference to the original manual, and careful thought should be given to the mode of analysis employed.

Functional anatomy and disability in arthritis

The hand

Functional dexterity of the hand is more advanced in man than in any other species, and it is our ability to manipulate objects in our environment that has allowed us to capitalize on our large cerebral capacity. The two major functions of the hand are the power grip the precision or pincer grip. If these are limited by weakness or pain, the hand rapidly becomes non-functional. Opposition, required for the pincer grip, is often lost, but patients will learn to oppose the side of the thumb, which provides adequate function.

Rupture of extensor tendons is commonly regarded as a rheumatological emergency, but surgical repair is necessary not so much to provide active extension as to prevent the dropped fingers getting in the way of hand function. The importance of hand function cannot be overstressed. Patients and their medical attendants often crave cosmesis, but cosmetic repair undertaken at the expense of function is almost universally disastrous.

The wrist

The wrist provides a mechanism to extend the range of activity of the hand, and a fulcrum to stabilize the grip. Some 30°of wrist extension is required for optimal power grip, and if function is limited by painful wrists, arthrodesis may be considered. Careful attention should be paid, however, to the position of arthrodesis. To be able to wipe their own bottom, a patient requires at least 30° of wrist flexion, so if bilateral arthrodesis is undertaken, one wrist should be in flexion and one in extension. If one wrist has spontaneously fused, its position must be considered when fusing the other.

The elbow and shoulder

These joints are often restricted in rheumatoid arthritis but, in functional terms, it is their combined range that is important. Is it sufficient to allow the hand to reach to the mouth for feeding, to the back of the head for grooming, and to the perineum for maintaining personal hygiene?

Flexion deformities of the elbow are usually well documented but restriction of 20 to 30° is functionally unimportant on its own. Meanwhile, the radioulnar joints are often forgotten, but they allow supination and pronation, which are essential to optimal hand function.

The spine

Involvement of the cervical spine may result in subluxation and dislocation, which is not only a source of painful disability and disturbed sleep, but may result in cord compression. Patients with atlantoaxial subluxation must be taught to protect the neck from sudden movements, for example when motoring or using public transport.

The hip

Hip restriction results in immobility and stiffness that can be severely limiting. Climbing stairs, getting in and out of the bath, and sitting comfortably on the toilet all require hip flexion. For young women, abduction as well as flexion is required for sexual intercourse and childbirth.

The knee

The locking mechanism of the knee, which allows us to stand for long periods without using much muscle power, requires not only full extension but also rotation in

the last 5 to 10°. Failure to achieve this severely limits standing, and flexion deformities of 20° or more make walking extremely difficult.

The ankle and foot

The true ankle joint allows plantar and dorsiflexion, and the subtalar joint, abduction and adduction. Restriction of the subtalar joints make walking on rough ground difficult.

Metatarsalgia, which is often a hallmark of rheumatoid arthritis, results from dropped metatarsal heads. If, as a doctor, you do only one thing for a patient, education about appropriate footwear early in the course of disease is probably the greatest contribution you can make to maintaining mobility (see ' Footwear' below).

Systemic disease

In addition to specific joint problems the effects of systemic disease itself can be severely limiting. Fatigue, anaemia, muscle wasting all take their toll, quite apart from morning stiffness, which may require the patient to get up several hours earlier to prepare for work or get the family off to school, for example. General advice on sensible eating, exercise, and sleeping patterns is important and should not be overlooked.

Psychological reaction (seeChapter 1.1.6)

Traditionally last on the list, the psychological impact of arthritis should in reality come first. Few of us can readily imagine what it is like to live with constant pain. Response to pain can vary enormously between patients. We are all familiar with the 'typus robustus' who denies pain despite gross destructive disease, while others are totally incapacitated but have relatively minor visible signs.

A variety of psychological and social factors may interact to sensitize or desensitize patients to the effects of pain. Depression, altered body image with poor self-esteem, altered sexuality, role reversal in marriage, as well as intellect, comprehension, and expectations, will all affect a patient's perception of pain and disability. The standard 15-min medical outpatient appointment in the United Kingdom National Health Service does not allow for sensible appraisal of these factors even though it is they, and not drugs or blood tests, that will ultimately determine outcome.

Medical and social models of rehabilitation

Many areas of medicine are currently going through a period of substantial change and rehabilitation is no exception. The days are gone when the doctor reigned supreme over the patient's care and wrote detailed prescriptions of exactly what physiotherapy should entail, usually based on very little understanding. Instead we have interdisciplinary teams made up of highly trained professionals, each of whom brings specialist knowledge of their own field to the group. In most cases, gone too are the days when the patient was expected simply to be a passive recipient of therapy. It is essential that any programme remains as far as possible within the patient's control. Since it will ultimately be their responsibility to maintain progress by themselves it is important to engage then from the start and failure to do so is the single most important cause of failure to demonstrate long-term benefits of therapy.

There is currently much debate in the United Kingdom over whether rehabilitation services should be provided in the hospital or community setting. This is the wrong question. Services should clearly be provided in both settings. The question should be how to identify the most suitable service for a given individual and how to ensure that they have access to it. Some patients are ill and require rehabilitation in the context of their medical management. Others are not ill and reasonably demand the right to exercise choice over the services they wish to use. The medical and social models of rehabilitation are not, therefore, mutually exclusive, it is more a question of 'horses for courses' (appropriateness).

The principles of rehabilitation

Whichever model of rehabilitation is adopted, the principles are essentially the same. Rehabilitation has been defined in many different terms, but ultimately it involves restoring an individual to their maximal functional independence. It consists of two main parts:

1. restitution: restoring lost function by minimizing impairment;
2. substitution: compensation for residual functional loss by using alternative techniques, aids, or appliances.

In practice these two approaches are often applied simultaneously and a problem-orientated approach will combine restorative therapy, teaching compensatory techniques, and the use of a variety of aids and appliances. The important components of rehabilitation for patients with arthritis can be summarized as in Table 2.

Table 2 Important components of rehabilitation for patients with arthritis

Problem-orientated approach and the interdisciplinary team

The interdisciplinary team

Members of the interdisciplinary team are highly trained professionals in their own right and each brings a specialist knowledge of their own field to the group. Some of the professions that may be included in the rheumatological interdisciplinary team are listed in Table 3.

Doctor
Nurse
Physiotherapist
Occupational therapist
Psychologist
Counsellor
Orthotist
Dietitian
Chiropodist
Social worker
Rehabilitation engineer

Table 3 Professions included in a rheumatological interdisciplinary team

The key to good rehabilitation is teamwork (Fig. 1) and this requires coordination and a team leader. The doctor may not necessarily be that leader—having good medical skills is not synonymous with having team management skills—but is nevertheless an essential part of the team. Interdisciplinary team management allows individual members of the team to refer to any other, without going back through the coordinator. Opinion and action are thus obtained more quickly, and are more likely to be relevant to the original question.

Fig. 1 An effective interdisciplinary team requires a coordinated approach both with, and away from, the patient. (a) A doctor, physiotherapist, and occupational therapist join forces to splint a hand in order to meet both therapeutic and functional requirements; (b) the key to coordinated therapy is integrated timetabling.

The problem-orientated approach

Rather than members working individually within their own professional boundaries, the well-coordinated interdisciplinary team provides a unified, problem-orientated approach. The individual problems that limit a patient's independence are identified and tackled systematically by achieving a series of staged goals set by the patient and therapists together. If at all possible, goals should be set, together with a date at which they will be reviewed. This helps to focus both patient and therapists on exactly what has to be done. It is immediately clear when progress is not being made, so that the reasons for this can be explored. It is essential that objectives and treatment are functionally relevant to the patient in their normal environment, and very often this will involve the active participation of the carer as well.

Contents of the rehabilitation programme

Exercise

Although some textbooks in circulation still have 'bed rest' at the top of their list of management, it is now almost universally accepted that bed rest is bad for patients with arthritis, resulting in flexion contractures, osteopenia, and muscle wasting. Instead it is recognized that active use and weight bearing through joints maintains bone and muscle strength. Nevertheless, patients must be taught to apply these principles sensibly. An exercise programme should contain the four elements listed in Table 4. Wherever possible, exercise should be put in a social context, taking advantage of local leisure facilities that patients can have access to outside the hospital environment. Once again, advice on appropriate footwear for exercise is an essential part of the programme.

To maintain:	Type of exercise	For example:
Muscle strength	Isometric exercise to build up muscle bulk and strength	Quadriceps drill But the programme must be tailored to the age and fitness of the patient
Joint mobility	Active exercise to maintain joint range	Pendular and wall-climbing exercises for the shoulder
Limbering up	Programme of daily exercises to combat early morning stiffness	Working the hands in a basin of warm water
Cardiovascular fitness	Physical stamina, cardiac and respiratory function	Swimming, cycling, walking, dancing

Table 4 The main components of an exercise programme

Education

Education of the patient and family is vital to the continued success of the rehabilitation process. They need to know what to expect from the disease, what to expect from rehabilitation, what they can do to maximize benefit, and what they must do to avoid exacerbating the condition. Education must begin one-to-one, although it can be continued in group sessions, with the help of leaflets and audio- and videotapes to digest at home. Introduction to patient support and self-care groups can also be extremely helpful, not only for obtaining advice and information, but for the comfort of knowing they are not alone in their suffering.

Joint protection

Trauma exacerbates inflammatory arthritis, whereas careful use of muscle and joints can reduce pain and fatigue. The main objectives of a joint protection programme are therefore to reduce pain, prevent damage and deformity, and conserve energy. The principles are outlined in Table 5.

1. Use the strongest and largest joints possible to accomplish a task
2. Spread the load of carrying/lifting over several joints
3. Use each joint in its most stable functional position
4. Maintain joint mobility and function
5. Avoid maintaining a joint in one position for a long time—especially in positions that exacerbate deformity, e.g. avoid sleeping with a pillow under the knees
6. Avoid excessive activity
7. Pace activity: punctuate periods of activity with regular rest periods

Table 5 The principles of joint protection

Energy conservation

While bed rest is to be avoided, fatigue is one of the major causes of disability in arthritis. In order to avoid the inappropriate blitzing the housework and then retiring to bed for 2 days, patients need to be taught to pace their activities and to conserve their energy where possible. Some practical examples of ways to save energy are given in Table 6.

(a) *Personal care*
Dress sitting down
Avoid back-fastening or tight-fitting clothes
Shower rather than bathing if possible
Avoid low chairs

(b) *Domestic*
Reorganize the kitchen so that all frequently used equipment is readily to hand
Do all activities in sitting where possible, using a perch stool
Avoid lifting and carrying—move heavy objects using a trolley
Use both hands
Use a jug to fill the kettle, rather than lifting the kettle itself
Steam or microwave vegetables to avoid lifting heavy pans
Soak pans immediately after cooking
Use duvets on the beds instead of blankets
Plan domestic chores sensibly, for example:
Complete upstairs tasks and then the downstairs ones to avoid frequent trips up and down the stairs
Intersperse heavier tasks with lighter ones
Use modern labour-saving devices whenever possible

Table 6 Practical example of ways to conserve energy

It is not always necessary to prescribe special equipment. Some examples of standard modern labour-saving devices that may be helpful for patients with arthritis are listed in Table 7. These are relatively inexpensive, readily come by, and more often acceptable to patients than having a house full of special adaptations that advertise their disability to every visitor.

Food processor, blender
Electric tin-opener
Portable telephone
Remote control for television, video, hi-fi etc.
Dishwasher
Front-loading automatic washer/dryer
Computer/word-processor
Automatic car—power steering

Table 7 Standard modern labour-saving devices that may be helpful for patients with arthritis

Community-orientated supervision

Whatever techniques are instituted in hospital, follow-up into the home is necessary to ensure that advice given is appropriate. It is common experience that specific advice given on joint protection and energy conservation changes when the patient is seen in their own environment. Time-consuming though a home visit may be, it will save time in the long run.

Likewise, exercises will only be continued if they are functionally appropriate, and this too is much easier to gauge in the context of the home environment. Reassessment at home every 2 to 3 months allows plans to be made in the context of the normal environment and avoids painful, slow, and unreliable ambulance journeys to hospital.

Home assessment is also vital in considering the need for structural changes or adaptations. Some areas to consider are given in Table 8, but first some basic information is needed about mobility and transfers.

Access
Can they get in and out of the house through the front or back door?
Can they move from room to room inside the house?
If living on more than one level, can they get up and downstairs:
If not, could a stairlift or through-floor lift be installed?
How will they get to the toilet by day and during the night?
Can they get to washing/showering facilities?
Inside the home
Is furniture suitable and conveniently placed?
Remove potential hazards, e.g. slip rugs
Are plugs and switches at reachable height?
Security
Can they control their own front door?
How will they summon help in an emergency?
Kitchen
Are frequently used items stored conveniently?
Are work surfaces at a suitable height?
Can they use the basic equipment?
Bathroom and lavatory
Can they get into the shower or bath?
Is any special equipment needed such as:
Bathing aids
Raised toilet seat
Rails, tap handles?
Bedroom
Height of bed—can they get in and out of it?
Is the mattress suitable—are they at risk of pressure sores?
Is the mattress needed for bedbound patients?

Table 8 Some areas to consider in assessment of the home environment

Mobility, transfers, and stairs

Is the patient in a wheelchair? If so, consider (i) whether ramps are needed, (ii) are the door frames wide enough to pass through without trapping their fingers, and (iii) is there room to manoeuvre. Are they able to transfer themselves from the wheelchair independently; if so, do they need equipment such as grab rails or a sliding board? If on their feet, can they manage stairs? If so, do they need one rail or two? Note: if a walking stick is used, only one hand is free to hold a rail to go upstairs, but a rail is needed on the opposite side coming down unless they are able to use the walking stick in the opposite hand.

Environmental control

For severely disabled people who live alone, the use of a computer to control the home environment has now become commonplace, but the availability of this facility is often forgotten. Its use requires neither dexterity nor high-powered cognitive function, and, using scanning software and an appropriate on–off switch, almost any movement that is under reliable voluntary control may be used to operate an environmental control unit (Fig. 2). A sample of available switch types is given in Table 9,

and the sort of functions they may be used to control in Table 10.

Fig. 2 An environmental control unit may be used with a range of single switches and operated by almost any movement that is under reliable voluntary control. Remote control by radio waves or infrared avoids the need for fixed wiring. (a) A wheelchair-mounted Steeper FOX system; (b) the Steeper Persona.

Switch type	Movement that operates it
Plate switch	Pressure from hand or foot
Button switch	Pressure from thumb or finger
Chin or head switch	Pressure from chin or head
Eye blink	Movement of eyelid
Suck-and-puff	Sucking and blowing
Tongue plate	Touch of tongue on palate plate

Table 9 Some types of on–off switch that may be used for controlling an environmental control unit

Alarm
Intercom
Control of front-door lock
Telephone
Opening/closing curtains
Control of electric sockets for heaters/fans/lights
Control of radio/television
Communication aid
Computer

Table 10 Common functions that may be controlled by an environmental control unit

Psychosocial aspects

Despite the best endeavours of a multiprofessional team, the functional outcome from rehabilitation of patients with arthritis remains dependent on psychosocial factors, which include:

1. personality: coping style, self-esteem and motivation;
2. section of community: class, intellect, and education;
3. patient's reaction to disability: e.g. depression, denial;
4. family's reaction: sympathy, overprotection, anger;
5. supportive network: family, friends, workmates;
6. environment, housing, transport;
7. financial security, employment.

Active psychological support is essential to allow patients and families to work through the changes that have occurred in their lives and to re-establish their relationships on a positive basis.

Cognitive behavioural rehabilitation techniques have been used extensively in patients with chronic pain. They involve teaching them how to use coping strategies to increase their activity despite the pain and regain control over their lives. The approach is shown to be beneficial not only in increasing activity levels but also in reducing depression and anxiety. More recently the approach has been successfully applied to patents with arthritis (O'Leary *et al*. 1988) but it is essential that it is introduced in the early stages of disease. It is also essential to involve the family and carers because they must be prepared to stand back and allow the patient to regain control of his or her own life.

Sexual problems

Sexual problems are extremely common when one member of the partnership has arthritis and may arise from a number of factors listed in Table 11.

Altered body image in the face of physical deformity
Joint restriction—limiting usual positioning for sexual intercourse, in particular the missionary position
Fatigue and loss of libido
Poor cardiovascular fitness—inability to sustain activity for long enough to achieve orgasm
Hand deformity—impeding foreplay and fitting of contraceptive devices
Fear of pain leading to frigidity and impotence

Table 11 Factors that may contribute to sexual dysfunction in patients with arthritis

Young patients with arthritis often encounter difficulties with forming relationships because of the above problems and also due to lack of access to dances, clubs, and other traditional courting scenes.

It is important to remember that sexual problems are not confined to marriage, heterosexuality or to the under-60s. Patients often have to be given the right to talk about it, but a busy clinic is not the time or the place. A number of organizations provide trained sexual counselling specifically for people with disabilities (for example, in the United Kingdom, SPOD, is the Association to Aid the Sexual and Personal Relationships of People with a Disability). The wise physician will keep to hand the telephone number of their local service.

Aids and appliances

In general, aids help to compensate for either pain and weakness or for lack of joint range. Some aids that are particularly useful to patients with arthritis are listed in Table 12 and illustrated in Fig. 3. However, they must be carefully chosen with specific needs in mind. Articles must be lightweight, strong and reliable, cheap, and acceptable to the patient and family.

Fig. 3 Some aids that may be useful to a patient with arthritis. (a) Thick-handled utensils; (b) rubber grip-pad; (c) kettle rocker-stand; (d) angled chopping knife; (e) plug with grip-handle; (f) Easi-reach device; (g) ejector chair.

To compensate for weakness or pain

Thick-handled utensils—require less effort to grip

Key turners and other easy-to-grip devices

Lever tap handles

To compensate for lack of joint range

Long-handled utensils—extend effective reach

Raised chair, toilet seat—easier to stand up from

Velcro fasteners on clothes—require less dexterity than zips and buttons

Table 12 Aids that are likely to be useful to the patient with arthritis

Orthoses

An orthosis is a device worn outside the body that aids function, protects, or prevents pain. One easy way to waste money is to provide orthoses that patients never wear. Worse, an inappropriately prescribed orthosis can actually enhance damage and deformity.

In order to avoid this great care must be paid in prescription to ensure that:

1. the device is well fitting and does the right job;
2. the patient is able to put it on and take it off easily;
3. both patient and carers know how, when, and why to use it;
4. the device is acceptable to the patient.

Because of these factors it is vital that the orthosis be checked after fitting and reviewed at each prescription. 'Stabilized' prescriptions that replicate the device when it wears out should only be signed when a trained orthotist is available to supervise subsequent fittings and has the experience and authority to alter the specifications in accordance with need. Unless this is so, each orthosis should be prescribed and checked by a suitable experienced physician—which by and large does not include junior medical staff.

Splints and orthoses have a special role in childhood arthritis. Some forms of juvenile arthritis are likely to remit by the time the time the child reaches adulthood. Splints form a vital part of management in preventing deformity so that when synovitis does resolve the joint still has optimal range and function. Hand splints (working and resting), knee splints, and shoe raises should be regularly reviewed to ensure this outcome as the child grows.

Adults tends to be less tolerant of non-functional splints, usually not having parents at home to bully them into wearing splints for certain parts of the day or night. Therefore, in adult arthritis, the emphasis on splint wearing is to increase function by stabilizing the joint and reducing pain more than preventing deformity.

Orthoses may be custom-made or provided ready-made or 'off the shelf'.

Off-the-shelf orthoses

Commonly prescribed items in rheumatology include the following.

Futura wrist splints

These stabilize the wrist in 30° extension and in theory act as a working splint. In practice they either fail to support the wrist adequately or the extensor bar effectively prevents useful function. Many physicians do not realize that the extensor bar is malleable and should be specifically adjusted when the splint is prescribed to ensure a good fit.

Cervical collars

Soft collars

Soft collars can be used to support the neck relieving painful muscle spasm, especially at night.

Hard collars

For patients with cervical subluxation, a hard collar is recommended while motoring or using public transport, to avoid dislocation with sudden jarring movements. In practice, they are so uncomfortable that patients rarely comply with this advice; a soft collar may be less protective but at least it is more likely to be worn.

Knee braces

Lightweight SK knee braces (Fig. 4(a)) are often prescribed for unstable knees, but are rarely able to provide adequate support. A range of more sophisticated devices is now available, which can be adjusted to allow a defined range of flexion and extension as well as providing mediolateral support. These heavier braces are more supportive, but many patients who need to use them will then need help getting them on and off.

Fig. 4 'Off-the-shelf' orthoses: (a) lightweight SK knee brace; (b) ankle–foot orthosis.

Ankle–foot orthoses

Ankle–foot orthoses (Fig. 4(b)) provide dorsiflexion at the ankle, for example where foot drop results from vasculitic nerve damage. The orthosis fits inside the shoes and usually requires a shoe that is one size larger than normal. Although ankle–foot orthoses are available off the shelf, if one is to be worn for any length of time a custom-made one that is moulded to the foot is more satisfactory.

Custom-made orthoses

In general, custom-made orthoses (principally splints) are more satisfactory if someone of sufficient experience is available to make them. Splints can help to reduce deformity or increase function by:

1. stabilization of a joint;
2. reducing pain by immobilization;
3. maintaining passive joint range;
4. functional positioning during activity;
5. protection leading to greater confidence in use.

Working splints are designed to be used during functional activity, for example cock-up wrist splints that leave the fingers free and support the wrist in 30° extension. Dynamic splints have a moving part that allows either free movement or movement against resistance provided by a spring or a piece of elastic. These may be used for example to correct flexion contractures. Resting splints hold the joint or limb in an optimal position and many be used to combat pain or prevent deformity. For example, paddle splints help to maintain finger extension, but because they render the hand useless, they are usually worn at night.

Footwear

Advice on appropriate footwear may be the single most useful thing you can provide for patients. Patients with arthritis should not wear silly shoes, except on very special occasions, and all sloppy slippers should be thrown away.

Appropriate footwear has the following characteristics:

1. adequate width and height to accommodate the toes;
2. soft rubber sole and padded insole to provide shock absorption for the metatarsal heads;
3. arch-support insole and strong medial side of shoe to prevent valgus deformity of the ankle and spread weight evenly across the weight-bearing areas of the foot.

Trainers or sneakers provide all of these features and are often acceptable to younger patients. Older women may prefer a leather casual, but Ecco and Roehide are two shoe manufacturers whose lines include all of the above features. In the United Kingdom, their products are obtainable in some high-street shoe shops, e.g. Clark's and K Shoes.

Alternatively, an arch support insole may be fitted into an existing pair of strong shoes (Fig. 5(a)), but this will tend to be bulky and reduce the depth of the shoe so that the toes may rub on the leather upper. This is particularly a problem with flexion deformities of the toes and may lead to callous formation and ulceration over the interphalangeal joints. Extra-depth shoes can be prescribed to combat this problem and are available off the shelf in styles that are not readily distinguishable from ordinary footwear (Fig. 5(b)).

Fig. 5 Footwear: (a) arch-support insoles with built-in metatarsal pads; (b) extra-depth shoes may be needed to accommodate arch supports.

Metatarsal pads are often prescribed but are rarely of any help as they fail to support the weight-bearing surface of the foot. The standard arch-support insole provided by most orthotics departments is made of expanded polystyrene. Some have three little discs in the metatarsal areas, which are designed to cushion the metatarsal heads but more often than not merely exacerbate metatarsalgia. Sorbithané is a highly shock-absorbent material and arch-support insoles made of Sorbithane are available in many sports shops. Although more expensive, they are generally much more satisfactory and worth the initial outlay as they are resilient and can be moved from shoe to shoe.

Mobility

Although doctors spend much of their time and effort trying to relieve pain, when patients are asked which aspect of their arthritis affects them the most, their reply is most commonly 'immobility' (Chamberlain and Buchanan 1978). The major problem is mobility outside. Public transport is often totally inaccessible, and community transport systems for disabled people are limited. Unless they have a car, immobility can severely limit a patients ability to lead a normal life.

Walking aids

The choice of a walking aid must take into account a number of factors including the extent of involvement of lower and upper limbs, and the terrain to be negotiated. Often a patient may require a variety of walking aids to use under different circumstances.

A walking stick can provide confidence as well a mechanical advantage if it is the right length and the patient is taught to use it correctly—usually held in the opposite hand to the affected lower limb. Attention should be paid to the comfort of the handle for patients with hand involvement—a moulded Fischer handle helps to spread the weight evenly in the presence of hand deformity (Fig. 6).

Fig. 6 Walking aids: a moulded Fischer handle (a) helps to distributed the weight more evenly across the hand than with a standard walking stick (b).

Elbow crutches give a firmer base and a gutter crutch allows patients with severe involvement of the hand and elbow to bear weight on the forearm. It should be remembered, however, that bilateral use of sticks or crutches effectively impedes carrying anything other than a bag slung over the shoulder and the width of the base of a two-crutch user is wider than that of a wheelchair. Walking frames provide a more stable alternative (Fig. 7), although some patients feel that they carry a greater stigma of disability, and they cannot give support while going up and down stairs.

Fig. 7 A gutter rollator walking frame provides stability without putting pressure on the hands.

Any walking aid that is prescribed should be fitted and checked by an experienced physiotherapist, who will ensure that it is the most suitable aid, correctly adjusted, and in safe working order. The physiotherapist will also instruct the patient in its use and maintenance; in particular, ferrules should be checked regularly for wear.

Wheelchairs

Wheelchairs may be regarded as admission of defeat but in reality they can increase mobility, broaden horizons, and conserve energy for more productive use. Attendant-operated (8L) chairs have small wheels that can be difficult to negotiate over kerbs. The larger wheels on a 9L self-propelling chair (Fig. 8) make it easier to push, and therefore it is usually recommended even though most patients with rheumatoid arthritis who require a wheelchair will be unable to self-propel over any distance because of shoulder involvement.

Fig. 8 The large wheels on a self-propelling 9L wheelchair make it easier for an attendant to push; most patients with rheumatoid arthritis are unable to propel much

because of shoulder problems.

Electric wheelchairs allow independent mobility for the severely disabled patient (Fig. 9) but a smooth proportional control is essential as jerky movement is not only painful but also dangerous if there is risk of cervical subluxation.

Fig. 9 An electric wheelchair allows independent mobility for severely disabled patients; a smooth proportional control is important where there is risk of cervical subluxation.

Patients who spend any length of time in a wheelchair are at risk of pressure sores. They require appropriate cushioning and may also need a special seating package, which should be prescribed by a specialist clinic, to correct their position.

Driving for disabled motorists

A number of adaptations are available for patients who drive, or are regularly driven in a family car. Swivel seats can facilitate getting in and out of the vehicle (Fig. 10). Wide-angled mirrors offer a panoramic rear view without having to turn the head. Headrests are essential to protect patients from rear-shunt whiplash injuries, whether or not they have atlantoaxial subluxation. In the majority of cases, automatic gear shift and powered steering may suffice, but a range of adapted controls is available, and is rapidly becoming more sophisticated (Fig. 11). If considered as potential users of adapted cars, patients should be professionally assessed at a specialist centre such as, in the United Kingdom, Banstead Mobility Centre. Patients unable to walk more than 100 yards (approx. 90 m) may be entitled to a disabled parking permit—known in the United Kingdom as the 'orange badge'—to facilitate convenient parking. This may be applied for through the local authority.

Fig. 10 Swivel seats facilitate getting in and out of a car.

Fig. 11 The range of devices for controlling a car is becoming more sophisticated. (a) A complex mechanical control system; (b) its modern electronic counterpart.

Social factors

While healthcare workers may not have direct influence over factors such as housing, finance, employment, and education, they may be the best advocate that a patient has to help them achieve at least a minimum standard of living. Many patients with arthritis are young, most are cognitively intact and should have good employment prospects given appropriate retraining. Failing that, patients need to be prepared for increased hours of leisure time. Contrary to the views of some doctors, rehabilitation does not end with being able to wash, dress, and make a cup of tea.

6.4 Rehabilitation of children

Renate Häfner and Marianne Spamer

Introduction

Inflammatory arthritis is the most commonly seen feature in rheumatic disorders of children and adolescents. It occurs most often as idiopathic arthritis with different subtypes (systemic, polyarthritis, oligoarthritis, etc.) but may also be a symptom of an underlying disease such as systemic lupus erythematosus, sarcoidosis, or Behçet's syndrome. Rehabilitation follows the same principles as for all arthritic disorders. The therapy offered must give careful consideration to the child's age and developmental status, the pattern of joint involvement, and the individual disease course.

Some autoimmune rheumatic diseases such as juvenile dermatomyositis where muscular involvement is predominant or skin fibrosis, such as scleroderma, can lead to functional impairment and joint contractures without the presence of an overt arthritis. Patients with these conditions benefit from different therapy protocols.

Aims of rehabilitation—a multidisciplinary team approach

The different aspects of rehabilitation require the co-operation of several health-care professionals who work together to improve the child's function, independence, and self-esteem. This includes caring for the whole family and overseeing integration into the community. The team is usually guided and co-ordinated by a paediatric rheumatologist. It includes a physiotherapist, occupational therapist, social worker, and psychologist. The team members co-operate with each other and interact with community and school staff (Table 1).

Achievements	Team members
Improved joint function and mobility (proper joint positioning, correction of deformities)	Physictherapist, occupational therapist
Self-care and independence	Occupational therapist
Integration into school	Social worker, occupational therapist, school staff (teacher, school nurse)
Guidance of the whole family	Social worker, psychologist
Promoting self-esteem	All team members

Table 1 Achievements of a multidisciplinary health-care team; the paediatric rheumatologist co-ordinates all team activities

The physiotherapist works together with the occupational therapist to improve function of individual joints as well as general mobility. They are also responsible for correction of joint deformity, which often requires individual splinting. Increased mobility forms the basis for greater independence. Children with marked impairment benefit from additional self-care support by an experienced occupational therapist. Most children can learn to master daily activities like hair washing, combing, dressing, feeding, and going to the toilet without extra help. However, they may need some specially adapted equipment. Instructions for joint protection should always be part of the therapy programme.

The child's rheumatic disease always has an impact on the whole family. Physiotherapy, doctor's visits, transportation to school, and other activities are time-consuming. Financial hardship in such families is common. Siblings may feel neglected and parents are usually overburdened with the extra tasks and worries, so rehabilitation must include care for the whole family, which is where the social worker has an important part to play. The social worker gives advice on financial entitlements, may help organize transportation, and assist with individual social problems. A psychologist can be helpful to handle conflict situations.

A very important aspect of rehabilitation involves integrating the child into school life. To achieve this, it is necessary for several health-care professionals to co-ordinate contact with teachers and other school staff to highlight the child's needs and help organize school life with the minimum of disruption for all concerned.

Perhaps the team's most important role is psychological—to create the highest possible level of integration so that children cease to see themselves as sick and different and acquire a sense of belonging.

Rehabilitation of chronic arthritis

Management of arthritis in children requires a wide-ranging knowledge of how functional impairment and deformities develop in individuals. The therapist must always keep in mind the progress of deformity and try to thwart this vicious circle as early as possible. It is much more beneficial to prevent deformities than to treat them.

Development of joint deformities

Inflammatory arthritis is very painful. Pain in children with arthritis, however, is often neglected as small children in particular rarely complain of painful joints. It is therefore important to note non-verbal expressions of pain (Scott *et al*. 1977; Melvin 1989; Altenbockum *et al*. 1993; Truckenbrodt 1993). Unfortunately children

rapidly adapt to painful arthritis with a reflex pain-relieving positioning of the affected joint. This is always a malposition which in turn produces a muscular imbalance. Those muscles which draw the joint into the relieving position become hypertonic, and the antagonists become weak (Altenbockum *et al*. 1993; Truckenbrodt 1993. If caught at an early stage the deformity can still be corrected passively. If inflammation and pain persist the incorrect position becomes permanent and a normal part of daily activities. The deformity usually increases during physical activity. Finally neither active nor passive correction is possible; a fixed deformity has developed. Incorrect weight distribution on the joints favours arthritic destruction which increases pain and deformity; hence, the vicious circle. At this stage a complete restoration of joint function is nearly impossible. Unaffected neighbouring joints can develop secondary deformities through compensatory over- or misloading. If neighbouring joints are also affected, primary and secondary deformities combine.

Principles of physiotherapy

It is the aim of all therapeutic approaches to keep or restore joint function and alignment as much as possible and achieve a normal pattern of mobility (Jarvis 1980; Erlandson 1989; Melvin 1989; Altenbockum *et al*. 1993). Even slight restrictions of joint function must be taken seriously and treated. In this regard it is important to appreciate that children have a greater joint mobility than adults. Joint function which is normal in adults may already be impaired in a child and must be treated accordingly.

As a precondition for effective physiotherapy the child must relax during treatment, as fear and pain increase muscle tone and intensify the reflex pain-relieving position. A relationship of trust between child and therapist is of the utmost importance in achieving the most beneficial environment and results.

Physiotherapy starts with passive-assisted movement of the joint which is non-weight-bearing. This manoeuvre is carried out with the utmost care within the pain-free range of movement and the best possible corrected axis. Thus even acutely inflamed and painful joints can be treated and protected from functional impairment. Careful movement reduces pain and improves mobility through relaxation of the hypertonic muscle groups.

Next the hypertonic and shortened muscle groups, which keep the joint in its incorrect position, must be stretched together with the other shortened joint structures. This procedure requires a relief position, and joint protection must be considered. Strong leverage to the joint should be avoided and positions such as hand prop, heel posture, or squatting are contraindicated as they increase intra-articular pressure. Stretching must be maintained over a long period of time to become effective. Individual splints may be used to maintain the corrected position. However, active stretching procedures such as hold–relax techniques should be restricted to non-inflamed joints, since they produce high intra-articular pressure.

A further step to extend mobility involves activation of the muscle groups which counteract the deformity. The child learns first with support by the therapist, and then on his or her own to rectify the incorrect position by tensing specific muscles.

Finally, the child must learn to integrate the regained mobility into daily life, overcoming the pathological patterns of movement. Muscular co-ordination is first trained by slow, consciously controlled movements. Frequent repetition of simple actions helps to integrate these into daily activities. In the beginning the therapist will need to support and correct the joint movements. Later more complex and faster movements can be achieved unaided. It is important, however, to adapt the training to the child's abilities. If the patient is overburdened by movements that are too complex, he or she will fall back into the unphysiological pattern of motion. This can lead to deterioration in the function of the involved joints.

Some therapists recommend strengthening of the weak muscles as a first step to overcome weakness and joint deformities (Jarvis 1980; Erlandson 1989; Melvin 1989). In our experience, however, this is ineffective as long as inflammation persists, joint alignment has not been regained adequately, and the child is still accustomed to a pathological pattern of motion. If, however, all these conditions have been restored, training of muscle co-ordination will simultaneously increase muscular power. Forced strengthening of individual muscle groups is rarely necessary and exercises to combat resistance should be discouraged since they increase pressure on the joints (Altenbockum *et al*. 1993).

The cervical spine

Involvement of the cervical spine mostly affects children with systemic onset arthritis and in those with seronegative polyarthritis, rarely in pauciarticular disease. The typical pain-relieving position is in mild flexion with restricted extension. All other movements are also impaired. Cervical spine involvement is easily detected when the child is asked to look up or around. Extensive eye movements compensate for the restricted extension and rotation (Fig. 1). Neck pain can be especially severe in children with systemic disease. It is induced by playing, writing, or working in a sitting position with the head slightly flexed. The cervical spine tends to early ankylosis in juvenile arthritis. Radiographic lesions usually start at the C2/C3 level and progress downwards. Fusion of the whole cervical spine can develop (Fig. 2). Atlantoaxial subluxation is rare in children (Ansell and Kent 1977).

Fig. 1 Child with systemic onset disease and involvement of the cervical spine. Impaired extension is compensated by upward movement of the eyes.

Fig. 2 Spinal ankylosis in a child with systemic juvenile chronic arthritis.

Therapy

Treatment of the cervical spine requires extreme caution and should be carried out in a relief position, preferably with the child lying on his or her back. Careful passive movement in all directions with slight traction can relieve pain and improve function. The dorsolateral neck muscles can be stretched by moving the shoulder girdle while the cervical spine remains in a fixed position. However, if spinal ankylosis has already developed no manipulation should be attempted.

A soft collar relieves pain and muscular tension of the cervical spine. It should be worn during long sedentary periods and as soon as pain starts. Children with severe neck problems may need to wear a collar all day. To aid comfortable sleep, pillows with a neck pad are helpful (Jarvis 1980; Erlandson 1989; Melvin 1989).

The temporomandibular joints

These joints are often neglected since they are mainly affected in children with polyarthritis where many other joint problems predominate. However, the sequelae of temporomandibular joint involvement can have severe impact on the child's well-being. If these joints become affected in early life significant growth disturbance of the mandible can occur (Bache 1964; Stabrun *et al*. 1988; Melvin 1989). This micrognathia creates malocclusion and disturbs the facial appearance. Restricted mouth opening together with impaired extension of the cervical spine can cause problems if intubation becomes necessary.

Movement of the temporomandibular joint comprises a caudal and ventral gliding of the mandibular condyle to permit mouth opening. Arthritis leads to pain and restriction of both movements, and opening the mouth and lateral displacement of the jaw become impaired (Bache 1964; Melvin 1989) (Fig. 3).

Fig. 3 Asymmetric involvement of the left temporomandibular joint. Lateral movement of the jaw is normal to the right (a) but markedly impaired to the left side (b).

Therapy

Cautious traction with the therapist's thumbs on the dorsal dental rows can mobilize the caudal–ventral motion of the jaw (Fig. 4). Mobilizing grips from outside the mouth are rarely possible since the temporomandibular joint area is very painful and effective therapy would require significant pressure. Active or actively supported exercises with ventral and lateral moving of the jaw are indicated to improve function. Temporomandibular joint involvement needs close collaboration with the dentist or orthodontist since dental or jaw regulation may be required to improve function and occlusion.

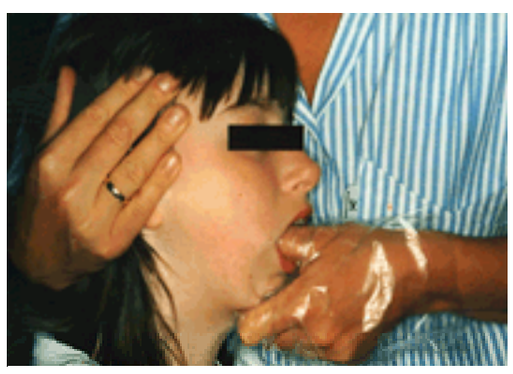

Fig. 4 Mobilization of the caudal–ventral motion of the jaw.

The shoulder

Arthritis of the shoulder occurs mainly in children with polyarticular disease. Since synovitis is difficult to detect and pain is usually greater in other joints it is easily overlooked.

Shoulder involvement impairs elevation and abduction. These movements involve a caudal gliding of the humeral head which is restricted in arthritis. Early co-operation of the shoulder blade during elevation and abduction compensates for impaired range of motion. The pain-relieving position of the glenohumeral joint tends towards adduction and internal rotation. The muscles for external rotation, abduction, and elevation become weak. Joints of the shoulder girdle, such as the acromioclavicular and the sternoclavicular joint, can also be affected. Their position of comfort comprises elevation and protraction of the shoulder girdle.

Therapy

Mobilization of the restricted external rotation, elevation, and abduction comes first (Fig. 5). Manipulation of the caudal gliding of the humeral head is helpful as well as stretching of the tense adductor and internal rotator muscles. Postisometric relaxation can also improve range of motion (Melvin 1989). When adequate shoulder mobility has been achieved muscular activation becomes possible which concentrates on the weak scapular muscles, the external rotators, and abductors. The scapular muscles must be activated towards a caudal and dorsal movement of the shoulder blade.

Fig. 5 Passive-assistive moving of the shoulder towards external rotation.

Exercises in a sling suspension are beneficial for shoulder involvement. They enable active mobilization while the arm is protected from gravity to eliminate joint

stress. The child can swing the arm into elevation and retroversion while lying on the side and into horizontal abduction and adduction while sitting upright.

The elbow

Synovitis of the elbow joint first impairs extension. A flexion contracture up to 30° may develop unnoticed since it hardly interferes with normal activities. Further contracture, however, significantly reduces arm length and can eventually lead to problems with dressing, toilet care, and other daily tasks (Erlandson 1989; Melvin 1989). Severe elbow involvement may also impair flexion which then mainly interferes with eating, combing, and facial care.

Forearm rotation favours pronation as a position of comfort while supination is usually restricted.

Therapy

Mobilization is directed towards the restricted function, usually extension and supination. Since synovial tissue tends to fill the fossa olecrani, moving the elbow may be very painful. Manual traction vertical to the forearm can relieve pain and improve extension, while stretching of the flexor and pronator muscles is important to restore function. Postisometric relaxation of the flexor muscles may also improve extension. Plaster splints which are used for about half an hour after manual stretching help to maintain the improvement.

The hand

In polyarthritis symmetrical involvement of wrist and finger joints occurs in over 90 per cent of patients. In oligoarthritis (or pauciarticular disease) asymmetric wrist involvement affects about 10 to 20 per cent, while single finger joints or digits may also be implicated (Melvin 1989; Altenbockum *et al*. 1993). The typical pain-relieving position of the wrist in children is flexion and ulnar deviation (Table 2) (Chaplin *et al*. 1969; Granberry and Mangum 1980; Findley *et al*. 1983; Erlandson 1989; Melvin 1989; Altenbockum *et al*. 1993). The extensors weaken while the flexor carpi ulnaris muscle becomes hypertonic. First active and later also passive dorsal wrist extension is limited. Secondary hyperextension of the metacarpophalangeal joints may occur (Fig. 6). To compensate for ulnar wrist deviation the metacarpophalangeal joints often drift radially even when they are not affected. The result is a juvenile hand scoliosis often described as 'Z deformity' (Fig. 7), in contrast to adult hand deformity with radial deviation of the wrist and ulnar drift of the fingers (Granberry and Mangum 1980; Altenbockum *et al*. 1993). Occasionally, and particularly in older children with disease positive for rheumatoid factor, an adult-type hand deformity can develop. Finally, the disturbed muscular balance together with loosening of capsule and ligaments results in a volar subluxation of the carpus (Table 2).

Fig. 6 Arthritis of the wrist joint with a typical malposition in flexion. Impaired extension is compensated by hyperextension in the metacarpophalangeal joints.

Fig. 7 Juvenile hand scoliosis with ulnar deviation of the wrist and compensatory radial drift of the fingers.

	No. of wrists affected (%)
Ulnar deviation	142 (59)
Juvenile hand scoliosis	82 (34)
Volar subluxation carpus	164 (68)

Study from the Children's Hospital for Rheumatic Diseases, Garmisch-Partenkirchen. 133 children with 239 involved wrist joints.

Table 2 Deformities of the wrist in juvenile chronic arthritis

Involvement of finger joints can lead to swan-neck or boutonnière deformities. A few children with polyarthritis develop the same malposition in all fingers. Often, however, combinations occur in the same hand. Swan-neck deformity develops mainly in index and middle fingers, boutonnière deformity in the fourth and fifth finger (Altenbockum *et al*. 1993). The thumb tends towards opposition and adduction in its saddle joint and flexion deformity in the metacarpophalangeal joint. A compensatory hyperextension often develops in the interphalangeal joint (Fig. 8).

Fig. 8 Multiple finger deformities in a patient with juvenile polyarthritis: subluxation and adduction of the thumb at the metacarpophalangeal joint with hyperextension of the interphalangeal joint; swan-neck deformity of the index and middle fingers; and boutonnière deformity of the fourth and fifth fingers.

Flexortenosynovitis of the fingers is a common feature in juvenile arthritis. It can be very painful and may result in the adoption of a pain-relieving position with all three finger joints in flexion (Melvin 1989; Altenbockum *et al*. 1993). Due to impaired tendon gliding active, flexion and extension are often reduced although passive movement is still possible (Fig. 9). Finally shortening of the finger flexors develops with a significant impairment of hand function.

Fig. 9 Flexortenosynovitis of the middle finger. Active flexion is markedly impaired (a) while passive flexion is still complete (b).

Therapy

Treatment of the wrist must include restoration of passive and later active dorsal extension as well as radial abduction. The therapist's grip during passive-assistive movement should support the carpus and correct the hand axis. Slow movements which take account of the pain threshold reduce tension of the flexor carpi ulnaris muscle and enable careful stretching (Fig. 10). When joint inflammation has subsided, activation of the extensor muscles becomes part of the programme. Since abduction of the thumb counteracts ulnar wrist deviation it is important to relearn and practise spreading the thumb. It is also important that the children become aware of the physiological course of movement with the therapist's assistance. He or she must correct inappropriate movements such as hyperextension of the fingers or flexion of the elbow that compensate for impaired dorsal extension.

Fig. 10 Cautious passive-assistive moving of the wrist in a small child with polyarthritis.

For small children play activities can help restore active wrist extension. For instance wiping shaving cream over a mirror or painting a sun on the palm and volar side of the fingers. The child is then asked to let the sun shine by raising the hand and spreading and extending the fingers (Fig. 11). Children also like to throw small balls; here the therapist must control the movement to prevent compensation by other joints, especially the elbow (Fig. 12).

Fig. 11 A child demonstrates full range wrist extension and spreading of fingers by letting the sun shine.

Fig. 12 A boy trains active wrist extension by throwing balls. The therapist assists to prevent elbow movement.

Therapy of affected finger joints must take account of individual deviation. In swan-neck deformity it is important to mobilize impaired extension of the metacarpophalangeal joints and then continue with flexion of the proximal interphalangeal joints (Fig. 13). Muscular co-ordination of the extensor digitorum longus with the flexor digitorum superficialis muscle must be trained to achieve a physiological grip. In boutonnière deformity the often hyperextended metacarpophalangeal joints must be mobilized towards flexion. In a further step, stretching of the flexor digitorum superficialis muscle improves proximal interphalangeal flexion contracture.

Fig. 13 Treatment of swan-neck deformity. Mobilization of extension at the metacarpophalangeal joint (a) is followed by flexion at the proximal interphalangeal joint (b).

Flexotenosynovitis is treated by stretching of the flexors which, unfortunately, must exceed the pain threshold in order to be effective. The impaired flexion must also be trained. In treatment of flexortenosynovitis both passive and active movements are necessary to prevent adhesion of the tendons. To reduce pain, cold applications prior to physiotherapy are helpful (Jarvis 1980; Melvin 1989; Altenbockum *et al*. 1993).

Hand orthoses

Therapy of wrist and finger deformities benefits from individual orthoses. The wrist joint can be stabilized by a working splint to prevent or correct flexion position, ulnar (or radial) drift, and carpal subluxation (Chaplin *et al*. 1969; Granberry and Mangum 1980; Jarvis 1980; Findley *et al*. 1983; Erlandson 1989; Melvin 1989; Altenbockum *et al*. 1993) (Fig. 14). These splints should be worn most of the day and especially during manual activities since all active work with the hand increases the deviation. Stabilization of the carpus will improve power transfer in the finger–hand area and will also protect the inflamed joint structures from over- and misloading

Fig. 14 Benefit of working splints. The malposition in flexion and ulnar deviation (a) is corrected with a stabilizing splint (b).

Resting splints are indicated for finger deformities. They should be worn for several hours during the night and contribute to a careful passive stretching of shortened muscles and joint structures (Fig. 15).

Fig. 15 Individual resting splint for a hand with combined finger deformities (see Fig. 8). The thumb rests in abduction; swan-neck deformity of the second and third fingers is corrected with extension at the metacarpophalangeal joint allowing flexion of proximal interphalangeal joints. Boutonnière deformity of the fourth and fifth finger requires proximal interphalangeal extension.

The hip

Hip disease often becomes a major problem in children with chronic arthritis. Frequency of hip involvement differs among the subgroups and varies with time (Fig. 16). It is most common in seronegative polyarthritis at onset and as the disease progresses. In systemic disease about one-fifth of these children start with hip arthritis which increases with follow-up. These patients also run a high risk of hip destruction (Fig. 17). Hip problems can also arise in patients with HLA B27-related arthritis or juvenile spondylitis.

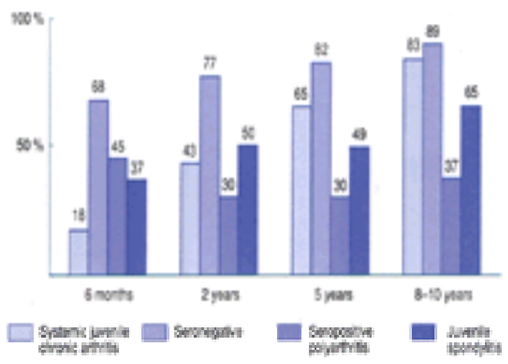

Fig. 16 Frequency of hip involvement in juvenile chronic arthritis within the first 6 months from onset and during follow-up. (Numbers derived from patient studies of the Children's Hospital for Rheumatic Diseases in Garmisch-Partenkirchen).

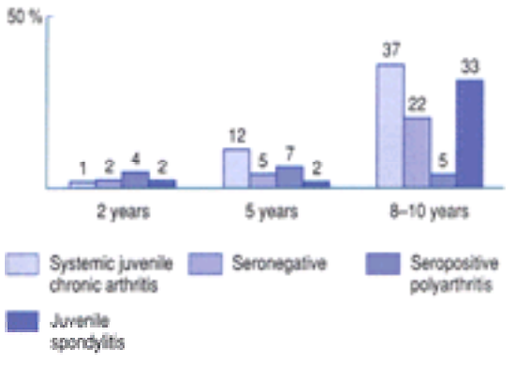

Fig. 17 Development of hip destruction in the subgroups of juvenile chronic arthritis (the same patients as in Fig. 16). The figure demonstrates the percentage of significant destructive lesions in children with hip involvement during follow-up.

Hip mobility in children exceeds that of adults. Young children with free hip function can bend their hips until the knee reaches the belly and external rotation may reach 90°.

The first sign of hip involvement is pain during full range flexion with adduction (Fig. 18). Later full extension, flexion, and inner rotation in 90° flexion become painful. When the children stand or walk they usually deviate into adduction and inner rotation. The abductor and external rotator muscles become weak while adductor and internal rotators as well as flexor muscles tend to shorten. Severe hip involvement is characterized by flexion, adduction, and inner rotation contractures (Swann 1978a; Melvin 1989). In such patients flexion position is compensated for by an increased lumbar lordosis as well as knee flexion (Swann 1978a; Erlandson 1989; Melvin 1989).

Fig. 18 Combined movement of flexion and adduction which is painful early in the course of hip involvement.

Therapy

Arthritis of the hip can be very painful especially in children with systemic disease. In acute stages only careful passive moving and mild traction is tolerated. This, however, should be done as often as possible to prevent contractures. If pain interferes with a full hip extension it is important to position the child in bed, supporting the upper legs and knees by pillows in a mild flexion to allow the muscles to relax. Regular, cautious passive extension, however, is compulsory to prevent flexion contractures.

When pain subsides stretching should be done, concentrating on mainly the flexors and probably the adductor muscles. Later on, active exercises of extensor and abductor muscles is important to improve the range of movement of the joint.

Exercises in a sling suspension are indicated to mobilize the joint. Continuous or intermittent traction for 1 or 2 h a day may relieve pain and contracture. Periods of lying in a prone position are beneficial to increase hip extension (Ansell 1978; Swann 1978a; Jarvis 1980; Melvin 1989; Lloyd and Aldrich 1993; Hayem *et al*. 1994). It is, however, important that the child does not compensate for impaired hip extension with an increased lumbar lordosis when lying prone.

Weight-bearing exercises for children with hip arthritis is controversial (Lloyd and Aldrich 1993). Some therapists encourage ambulation to restore the joint structures and support joint congruity (Bernstein *et al*. 1977; Ansell 1978; Melvin 1989; Lloyd and Aldrich 1993; Hayem *et al*. 1994). Absence of weight bearing may interfere with a normal development of the femur and acetabulum in young children. Valgus deformity and lateralization of the femoral head and acetabular underdevelopment are often seen in children with onset of hip disease at an early age (Bernstein *et al*. 1977; Ansell 1978; Blane *et al*. 1987).

Conversely, weight bearing increases joint stress enormously and can promote hip destruction. Therefore, partial weight bearing is a compromise for children with hip arthritis (Rombouts and Rombouts-Lindemans 1971; Ansell 1978; Jarvis 1980; Garcia-Morteo *et al*. 1981). Depending on the child's age and the condition of the other joints we recommend crutches, bicycles, tricycles, or scooters with a saddle (Fig. 19) for mobility. Wheelchair use is to be avoided since sitting increases flexion

contractures of hips and knees (Ansell 1978; Swann 1978a; Melvin 1989).

Fig. 19 Special vehicle for children with involvement of the lower limbs to avoid weight bearing.

Children have a good potential for restoration of joint cartilage and bone (Rombouts and Rombouts-Lindemans 1971; Bernstein *et al*. 1977; Melvin 1989) (Fig. 20). In our experience walking is not necessary for repairing damage to cartilage or bone and may even delay it due to increased stress on the joints. We therefore prefer partial weight bearing and regular, continuous moving of the hips in a relief position. Such children benefit from using a sling suspension at home for daily exercises (Fig. 21).

Fig. 20 Remodelling of hip joint destruction in a child with seronegative polyarthritis.

Fig. 21 Sling suspension for home exercises.

The knee

In all forms of juvenile arthritis the knee is most frequently involved. However, destructive lesions are less prominent compared with joints such as the wrist or hip. Deformities, however, can develop rapidly.

The typical pain-relieving position is flexion of the knee joint which is stabilized by an increased tension of the hamstring muscles (Swann 1978a; Jarvis 1980; Erlandson 1989; Melvin 1989; Altenbockum *et al*. 1993). The quadriceps muscle becomes hypotonic. Knee flexion contractures can develop into a very severe problem in young children. Each surgical procedure, even a small biopsy or arthroscopy, produces deterioration and should therefore be avoided in children under 5 years of age.

Flexion position of the knee enables rotatory movements to be made. Predominant activity of the biceps femoris muscle in childhood arthritis results in an outer rotation of the lower leg that is often compensated for by inner rotation of the hip joint, which then gives the impression of a valgus position of the knee but is really a pseudovalgus deformity (Altenbockum *et al*. 1993) (Fig. 22). Small children are particularly prone to develop a true valgus position which exceeds the physiological valgus for that age (Swann 1978a; Erlandson 1989; Melvin 1989; Altenbockum *et al*. 1993). It is caused by increased tension of the iliotibial band with ensuing instability of capsule and ligaments. Permanent knee flexion with dominant activity of the hamstring muscles favours dorsal subluxation of the tibia.

Fig. 22 Pseudovalgus deformity in a child with arthritis of the left knee. Flexion contracture with inner rotation of the leg gives the impression of a valgus position.

All these knee deformities are especially noticeable in young children. In a study of 63 patients with early-onset oligoarthritis who had 73 affected knee joints we have

seen flexion contracture and quadriceps atrophy in almost all. About 60 per cent also showed outer rotation of the lower leg and tibial subluxation (Table 3).

	No. of knees affected (%)
Flexion contracture	73 (100)
Outer rotation, lower leg	39 (53)
Subluxation tibia	40 (55)

Study of 63 children with early onset oligoarthritis. 73 involved knees.

Table 3 Deformities of the knee in juvenile chronic arthritis

Asymmetric knee involvement often results in a discrepancy in leg length due to increased growth at the affected knee joint.

Therapy

The first step in treatment of the knee should be to consider how to achieve full extension as well as the physiological hyperextension. When sitting with knee joints stretched the child should be able to lift the heel.

When treating a knee flexion contracture it is especially important that the therapist is careful to respect the pain threshold, for only if the child is totally relaxed does it become possible to stretch the hypertonic hamstrings, in particular the biceps femoris muscle.

Once there is improvement of passive extension the quadriceps muscle can be mobilized. A playful trick helps small children to find the right muscle: a face drawn on the child's knee with the mouth in the skin fold above the patella will start to smile when the quadriceps tenses.

A more difficult way to activate the quadriceps is when children throw balloons which have been put on their feet. Fast muscular co-ordination is best trained by letting the child kick about in the air or in water. However, the therapist must watch how far the full active extension is integrated in the course of movement. When muscular balance between hamstrings and quadriceps muscle has been restored the physiological movement pattern alone builds up muscle strength without extra power training (Altenbockum *et al*. 1993).

Gait training for affected knee joints must ensure a correct heel strike with fully extended knees and knee flexion during the swing phase.

Additional aids

Stretching of the hamstring muscles can be supported by splints (Ansell 1978; Swann 1978a; Jarvis 1980; Erlandson 1989; Melvin 1989; Altenbockum *et al*. 1993). They are put in place after physiotherapy in the best position of maximum extension.

As for hip treatment, arthritis of the knee also benefits from partial weight bearing (Swann 1978a; Jarvis 1980; Melvin 1989; Altenbockum *et al*. 1993). It reduces stress to the joint, enables relaxation of the hypertonic muscles, and helps to avoid the wrong pattern of motion during walking.

A leg length discrepancy must be corrected by a combined sole and heel lift, otherwise pelvic tilting and scoliosis of the spine can develop. The increased leg length also promotes fixed knee flexion of the affected knee.

The foot

The numerous foot joints and variety in the pattern of joint involvement usually lead to a combination of different axial deformities and in most patients the gait becomes disturbed (Swann 1978b; Rana 1982; Gschwend and Ivosevic-Radovanovic 1986; Lechner *et al*. 1987; Erlandson 1989; Melvin 1989; Altenbockum *et al*. 1993; Truckenbrodt *et al*. 1994). A mild dorsal extension is the typical position of comfort when the ankle or talonavicular joint is inflamed (Melvin 1989; Altenbockum *et al*. 1993) (Fig. 23). The muscular imbalance includes a hypertonic tibialis anterior and a weak triceps surae and peroneus longus muscle. A rheumatic heel foot can develop. Plantar flexion and especially cranial movement of the heel become impaired (Lechner *et al*. 1987; Melvin 1989; Altenbockum *et al*. 1993; Truckenbrodt *et al*. 1994); this is compensated by an increased flexion of the first metatarsophalangeal joint (Fig. 24). The ball of the big toe, normally a major weight-bearing area, is spared and atrophies. During walking, body weight is transferred from the heel over the lateral rim to the distal phalanx of the big toe (Altenbockum *et al*. 1993; Truckenbrodt *et al*. 1994) (Fig. 25).

Fig. 23 Pain-relieving position with the feet in neutral or mild dorsal extension in a child with arthritis of both ankles.

Fig. 24 Rheumatic heel foot: impaired plantar flexion is compensated by flexion of the big toe.

Fig. 25 Loading phase of a heel foot: the weight is shifted from the heel over the lateral rim to the distal phalanx of the big toe; the ball area is spared.

Young children in particular have a physiological tendency towards pes valgoplanus and develop this type of deformity (Swann 1978b; Melvin 1989; Altenbockum *et al*. 1993; Truckenbrodt *et al*. 1994). During walking, impaired mobility is compensated by an outward turning of the leg and rolling over the medial rim (Fig. 26). This incorrect weight distribution increases the valgus deviation and flattening of the longitudinal arch. The forefoot seems to stand in pronation. However, if the heel is corrected into neutral position a supination of the forefoot becomes obvious (Fig. 27). Pronation is always impaired.

Fig. 26 Pes valgoplanus with outer rotation of the leg and rolling over the medial rim.

Fig. 27 Pes valgoplanus with erecting of the heel into neutral position. The forefoot stands in supination.

A rheumatic pes cavus develops less often and is seen mainly in older children with involvement of the distal intertarsal joints. These patients react with a reflex tension of the plantar muscles for pain relief (Fig. 28). Heightening of the longitudinal arch occurs together with an increased loading of the ball area. This often induces flattening of the transversal arch and claw toes. When medial intertarsal joints are especially painful, the weight is shifted to the outer rim and the heel glides into a varus position (Swann 1978b; Rana 1982; Gschwend and Ivosevic-Radovanovic 1986; Melvin 1989; Altenbockum *et al*. 1993; Truckenbrodt *et al*. 1994).

Fig. 28 Rheumatic pes cavus with tension of the plantar muscles.

The three major deformities of the foot can develop alone or in combination. Usually one malposition predominates. In a study of 123 children with foot involvement we have seen pes valgoplanus as the dominant deviation, especially in young children with early-onset oligoarthritis. In the other subgroups heel foot and pes valgoplanus occurred with about the same frequency, while pes cavus was seen less often (Fig. 29).

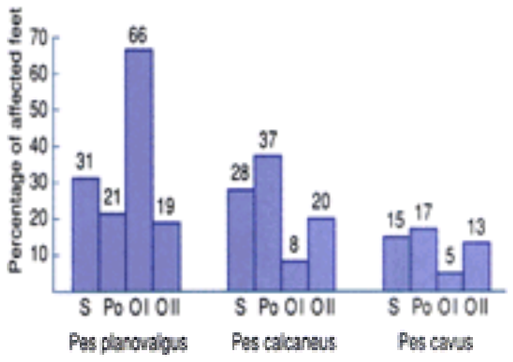

Fig. 29 Frequency of pes valgoplanus, pes calcaneus (heel foot), and pes cavus among the subgroups of juvenile chronic arthritis. (Study from the Children's Hospital for Rheumatic Diseases, Garmisch-Partenkirchen; 123 children, 246 feet). S, systemic juvenile chronic arthritis; Po, seronegative polyarthritis; O I, early onset oligoarthritis; O II, HLA B27-associated oligoarthritis

Other foot deformities concern the forefoot and toes. Arthritis of the first metatarsophalangeal joint often results in a hallux flexus to relieve the painful area of the big toe ball. This deviation resembles the heel foot where a secondary hallux flexus can develop. A compensatory hyperextension of the interphalangeal joint may occur. A hallux valgus is seen mainly in children with polyarthritis and involvement of the metatarsophalangeal joints. These patients also tend to develop claw or hammer toes (Rana 1982; Gschwend and Ivosevic-Radovanovic 1986; Melvin 1989; Altenbockum *et al*. 1993). Forefoot adduction often occurs together with hallux flexus or as a compensatory deviation from arthritis of the knee or ankle joint (Gschwend and Ivosevic-Radovanovic 1986; Melvin 1989; Altenbockum *et al*. 1993) (Fig. 30).

Fig. 30 Forefoot adduction and hallux flexus in a child with arthritis of both knees and ankles.

An equinus position of the foot is very rare in children with chronic arthritis and develops only in patients who have been immobilized in a wheelchair for a lengthy period (Gschwend and Ivosevic-Radovanovic 1986; Melvin 1989).

Therapy

The first step must be to obtain mobility of each of the affected foot and toe joints. To achieve better plantar flexion in the ankle joint the therapist must concentrate in particular on cranial movement of the calcaneus (Fig. 31). Mobilizing forefoot pronation provides a strong fixation of the heel. It is also important to restore extension of the first metatarsophalangeal joint, which is necessary for the physiological loading of the big toe ball. To regain muscular balance the tibialis anterior muscle must be stretched and the triceps surae and peroneus longus muscles be activated.

Fig. 31 Mobilization of plantar flexion with cranial moving of the calcaneus.

In a further procedure the combined movement of forefoot pronation with extension of the big toe must be trained (Fig. 32). This can be achieved with another game, painting the big toe ball to use as a stamp for printing patterns on a sheet of paper.

Fig. 32 Training of active toe extension together with forefoot pronation. The child is asked to push against the therapist's thumb.

To remedy the effects of foot involvement, intensive gait training is always necessary (Jarvis 1980; Lechner *et al*. 1987; Melvin 1989; Altenbockum *et al*. 1993; Truckenbrodt *et al*. 1994). A precise heel strike followed by rolling over the big and small toe ball with extended toes is needed. The push-off with plantar flexion of the ankle and extension of the toes is very important to train. The therapist must correct the wrong pattern and assist the re-education of each phase of a normal gait (Fig.

33).

Fig. 33 Gait training with assistance to relearn each single phase of the gait cycle.

Additional aids

Most children with foot involvement require insoles. They should correct the deviation as long as they are adjustable without pain under full weight bearing. Otherwise the insoles must primarily relieve the inflamed joints. It may even be necesssary to support a deviation until the pain-relieving position has improved.

For stabilization of the upper foot, shoes which extend over the ankle are useful. Soft soles lower the transfer of foot-strikes during walking and relieve all joints of the lower extremity. Severe foot deformities may require custom-made orthopaedic footwear. Partial weight bearing is also recommended for children with inflamed foot joints.

The sacroiliac joint

Sacroiliits can develop in children with HLA B27-related oligoarthritis or juvenile spondylitis. In a series of 71 juvenile patients with sacroiliits we detected radiographic changes of the sacroiliac joints between 1 month and 9 years after onset of peripheral arthritis. Only 33 of these patients complained of back pain, which was localized to the sacroiliac joint alone in 4 of them. Fifteen suffered from pain in the sacroiliac joints as well as the lumbar spine and 14 complained only of lumbar spine problems (Häfner 1987).

Since sacroiliitis can develop insidiously without any or only minor pain it is often overlooked. However, careful examination of these patients can detect the typical incorrect positioning even in the early stages. Physiologically the pelvis is positioned in a slight forward tilt, which means that the sacroiliac joints receive oblique pressure forces from the vertically oriented spine. Patients with sacroiliitis avoid such painful forces by raising the pelvis into a vertical position. However, this diminishes the physiological lumbar curve and contributes to lumbar tenderness, which is often a first symptom of sacroiliac involvement.

Therapy

For proper positioning it is important to maintain or restore the pelvic tilt and the lumbar lordosis. If the sacroiliac joints are painful, correct positioning may only be possible in a relief position. When inflammation and pain subside the patient must learn to maintain the correct position during sitting, standing, or walking. Since pain often blocks all movement of the sacroiliac joint, careful manipulation may help restore the physiological function. However, such manipulation may induce progressive pain during acute phases, in which case it should be postponed until the inflammation subsides, when movement can once more be tolerated. Some patients benefit from a tight pelvic belt which stabilizes the sacroiliac area.

Movement and training of the spinal muscles are always indicated to prevent or reduce secondary spine problems caused by sacroiliitis. They are also important prophylactic steps to prevent further spinal involvement, which may otherwise start in a number of these patients during early adulthood.

Juvenile dermatomyositis (see Chapter 5.9.2)

The acute stage of dermatomyositis is characterized by muscle weakness which can be severe enough to render the child immobile. About two-thirds of such patients also complain of muscular pain, with the trunk musculature usually being more severely affected than the peripheral muscles.

The chronic stage of the disease is exacerbated by progressive joint stiffness due to muscular scarring and shortening together with calcification of the skin and subcutaneous tissue.

Joint deformities follow a characteristic pattern. The wrist tends towards dorsal extension with flexed fingers while volar flexion of the wrist is impaired (Häfner and Truckenbrodt 1989) (Fig. 34). This is in contrast to chronic arthritis where extension is usually more limited and wrist flexion is the typical relief position. Elbows, hips, and knees are at high risk of developing flexion contractures. The ankle deviates into an equinus position. Contraction of the lower extremities is promoted by use of a wheelchair. Unfortunately during the acute stage when muscle weakness interferes with walking, children are often placed in wheelchairs and without adequate treatment they remain wheelchair-bound due to progessive muscular wasting and contraction.

Fig. 34 Range of motion of the wrist in a child with dermatomyositis. Dorsal extension is complete (a) but flexion is severely impaired (b).

Therapy

During the acute phase the main therapy is concentrated on prophylactic treatment of muscle contraction. It includes proper positioning with hips and knees stretched for comfort and the ankle in a neutral position. If pain interferes with optimum positioning, flexed hips and knees must be supported with pillows to relieve muscular tension. Cautious passive movement towards extension becomes very important. Lying prone may help to prevent hip flexion contracture, and sitting with bended hips and knees must be restricted to short periods. Misguided use of the wheelchair can exacerbate the loss of movement.

Careful activated exercises of those muscles which tend to lose tension is very important, otherwise the child will forget what muscular contraction feels like. Muscle

strengthening, however, is not advisable since it can increase muscular damage. Active moving should be encouraged as far as the patient can tolerate without experiencing muscle fatigue.

As soon as joint contractures appear gentle stretching of the muscles is indicated. Use of a plaster cast for a few hours every day helps reduce contractures. Exercises in a sling suspension enable careful active movement with relief from gravity. A further beneficial procedure is hydrotherapy, especially for those children with severe impairment who enjoy the unusual experience of mobility that becomes possible through weight release in warm water.

Childhood scleroderma (see Chapter 5.8.1)

Systemic sclerosis is a very rare disorder in childhood and the paediatric rheumatologist is more often confronted with localized forms of scleroderma. These appear as morphea with round or oval-shaped lesions or in linear form. Fibrotic induration of skin and subcutaneous tissues can impair function depending on the extent of sclerosis. Individual problems arise according to the particular site of damage. Lesions on the face are mainly a cosmetic problem but can have severe psychological impact. Linear forms which cross a joint result in restricted mobility and can be especially disastrous if an entire extremity is involved. In such cases deformities and growth disruption can combine to produce a severe handicap (Fig. 35).

Fig. 35 Widespread localized scleroderma of the right leg with growth disturbance and deformity.

Therapy

The effect of medical intervention in childhood scleroderma is limited so that emphasis should be placed on physiotherapy and physical modalities. The main aspect of treatment aims to prevent or improve contraction. Careful manual stretching of the sclerotic structures is thought to be beneficial but should not exceed the patient's tolerance. Resting splints help to maintain joint position over a prolonged period. Exercises in a sling suspension as well as hydrotherapy in a warm pool represent two possibilities for maintaining or improving mobility without stressing the joints and neighbouring structures.

A beneficial effect can also be expected from manual lymphatic drainage. This process reduces tissue oedema which often dominates in the early phase. Connective tissue massage improves the peripheral blood flow and may contribute to healing of 'rat-bite' necrosis as well as Raynaud's phenomenon in systemic sclerosis (Földi 1991).

Widespread localized forms which involve the whole leg require special shoes with a heel and sole lift to adjust for deformities and growth disturbances.

Parental involvement

For children with chronic progressive disease a regular, often daily, therapy programme is necessary. The best way to guarantee effective treatment at home is to integrate parents into the therapy programme. They must be informed about how joint deformities can develop and learn the principles of physiotherapy. With adequate training most parents are able to undertake the task of daily exercises at home. They must also understand and learn to use the different orthoses and splints as well as the principles of everyday joint protection. Most parents are eager to participate in therapy if they realize that their active role can decisively improve the prognosis for the child's arthritis.

Problems with home therapy usually arise if progressive disease means treatment must be maintained over a prolonged period. In particular where patients suffer frequent relapse or continuous deterioration, general pessimism tends to reduce motivation. Parents and child may feel so discouraged that they abandon therapy. It is important to give them positive encouragement frequently, always acknowledge small achievements, and to assure parents that it is worth maintaining the same state or even accepting a reduction in the rate of progression in severe progressive diseases.

Regular exercises at home are usually necessary for an optimal outcome. It is, however, important that the therapeutic team relieves the family during times of acute stress and accepts temporary interruptions of the treatment routine. The schedule should always take account of holidays and leave enough space for fun and play.

Parental education should also include advice on appropriate leisure activities. Certain sports activities can lead to joint deterioration. On the other hand, sport is an important part of leisure activities in most families. It may be helpful if parents learn to give priority to sports which increase mobility without joint stress such as swimming or cycling, both activities which can have a therapeutic effect for children with rheumatic diseases. Depending on joint involvement and disease activity further sports may be acceptable: table tennis, gymnastics, horse riding, or cross-country skiing can usually be recommended for children with mild disease. Sports requiring a high level of exertion like tennis, skiing, or football should be reserved for patients in remission.

The child with arthritis who cannot participate in sports should be encouraged to gain self-esteem and stimulation in other fields. Parents should be encouraged to help compensate for their child's low level of physical activity with musical education, handicrafts, or playing games at home. Friends can be asked to visit and be integrated into leisure acitvities, which are adapted to the child's capability. This promotes the patient's social development and gives him or her the chance to feel equal in a healthy competition.

Joint protection and adapted devices

Joint protection training is an important task in the therapeutic regimen. The child with arthritis must learn how to reduce stress to the joints in daily activities. Effective joint protection relieves pain and can improve the inflammatory process. Principles of joint protection include:

1. proper positioning of joints to avoid deformities;
2. use of several instead of single joints;
3. transfer of a load from small to large joints or from involved to unaffected areas;
4. avoiding prolonged activity or positioning;
5. planning of rest breaks.

The child will assimilate these principles best if they are demonstrated during work or play. The occupational therapist first watches the patient during an activity and then corrects the incorrect joint position into a proper protective one (Fig. 36). The therapist must also explain the advantages of distributing a load on to stronger or larger areas, for example from the fingers to the palm, or how to use both hands instead of one.

Fig. 36 The occupational therapist corrects a child's hand position during clay crafting.

Joint protection may be supported by use of adapted devices. They help to reduce pain, preserve the proper joint position, minimize joint stress in daily activities, and increase the child's independence. In practice such equipment is prescribed less often for children than adults, since children feel embarrassed to use such appliances and devices with their peers and prefer to use alternative techniques to perform a task or even to ask for help.

Aid appliances, however, may become important for handicapped adolescents who wish to become independent. The most frequently prescribed appliances for children and adolescents include aids for walking and self-care items as well as play and school equipment.

We recommend partial weight release for children with arthritis of the lower extremities. Usually age-appropriate vehicles like tricycles or bicycles are sufficient, but some children may need special aids such as crutches or scooters with a saddle (see Fig. 19).

Self-care equipment should be restricted to severely handicapped patients since most children with arthritis can learn to perform daily tasks without special equipment. Sock cones are sometimes indicated for children with impaired hip and knee flexion, as well as dressing, combing, or hygiene articles with lengthened handles when shoulder elevation and elbow flexion are impaired. Since appliances designed to help adults are often inappropriate for children because they are not adapted to the child's size and reach, the occupational therapist must ensure that any such equipment is adapted for the individual child.

Some equipment for adults may be helpful for children and adolescents as well. Figure 37 and Figure 38 demonstrate the advantage of pot holders and adapted knives for proper wrist positioning. Spring-style scissors and foam material to thicken pencils relieve joint stress during crafting or drawing. Such devices are easy to handle and will be accepted within the peer group.

Fig. 37 Lifting pots with a regular pot holder urges the wrist into ulnar deviation (a). A second pot holder transfers the weight from one to both hands and guarantees proper wrist positioning (b).

Fig. 38 Cutting with a regular knife increases ulnar wrist deviation (a). The malposition is corrected by use of an adapted knife (b).

Integration into school

Most children with rheumatic diseases can and should be integrated into mainstream schools. Classes for the physically handicapped are not the solution since they only serve to increase the child's sense of being abnormal.

Doctors, social workers, and occupational therapists must communicate with educators and school nurses to find appropriate solutions and compromises for a practicable school life.

Problems start with transportation for those children who cannot walk or cycle to school. School buses which pick up the child at home are the best solution but not always available. A car pool with other families may relieve parents of the daily task of driving their child to and from school.

If teachers are informed early enough it is often possible to adapt the timetable to accommodate the child's needs. Less academic subjects could start in the early morning so that children with morning pain and stiffness can arrive later without missing too much. If physical education occurs at the end of the school day those children who are unable to participate can leave early and use the time for home work or physiotherapy. Classes with a handicapped child should preferably be allocated classrooms on the ground floor and moving between classes should be reduced to a minimum.

Keeping an extra set of books at home will save the child from having to carry heavy school bags and for necessary items backpacks should be preferred.

Children with arthritis of the hands may have a major problem with writing. Writing with splints is desirable to avoid ulnar deviation of the wrist but the changed position requires extra training during occupational therapy. Pressure to the finger joints can be avoided if children learn to write holding the pen between index and

middle finger and with the thumb in the opposed position. A thickened pencil also relieves joint stress (Fig. 39).

Fig. 39 Relief to finger joint pressure during writing occurs with an altered writing position (a) or a thickened pen handle (b).

Despite all these aids extended periods of writing may become painful and the child should receive extra time for class work to include rest periods. It is also helpful if the child is allowed to use a typewriter, computer, or dictaphone whenever possible.

Proper positioning during class and whilst doing homework is of the utmost importance, especially for children with back or neck problems. The solution consists of a chair adapted to the child's size, an inclined writing board or bookstand to avoid neck and back flexion, and a slanting cushion to tilt the pelvis and keep the spine erect (Fig. 40).

Fig. 40 Proper positioning during school or homework with an inclined bookstand and a slanting cushion.

All these arrangements can usually be accommodated in a mainstream school if educators are informed and willing to integrate a child with arthritis. The child's classmates receive practical education in social interaction and their support promotes the handicapped child's self-esteem and position in the community.

Guidance for the whole family

Arthritis in a child always has an impact on the whole family. Time-consuming demands, financial loss, and restriction of common activities alter the family's lifestyle; family members become resentful of their personal limitations and added responsibilities, siblings feel neglected and feel that their problems are of less importance or ignored altogether.

This situation requires guidance of the whole family, a task which all the team members may have to help resolve. Diagnosis of a chronic illness is usually devastating and adjustment to the new situation takes time, so it is vital that the health-care team help the families adapt to the altered situation. In the beginning thorough information together with hope for a favourable outcome are important to motivate each family member. Feelings of blame and guilt must be addressed and resolved to guarantee open communication within the family. Practical advice on how to overcome obstacles in daily life and adapt to a new schedule is most helpful.

If disease activity persists over months or years it becomes necessary to guide families towards a lifestyle which is as close to normal as possible.

Overprotection of the ill child and neglect of siblings is a common and understandable parental reaction, but should be avoided by early intervention of educators, psychologists, or other team members. The ill child must learn to cope with frustrations and healthy siblings need support for their problems too.

On the other hand a child with chronic arthritis does need special attention. Pain and physical limitations often exceed what can be tolerated for appropriate social interaction. Regression, aggression, or other behavioural disturbances can result. Parents are often overburdened trying to cope with such problems and should receive early professional advice.

Co-operation within the family facilitates a positive adjustment and parents should be encouraged to share responsibility for all disease-related activities. In many families mothers are left alone to cope with most of the tasks, so fathers must be stimulated to participate in the therapy routine, attend doctors appointments, and help with educational problems. Siblings may also become involved in caring for the ill child. If they receive appropriate recognition for this extra demand they can develop a strong feeling of self-esteem.

Health professionals cannot attend to all the needs of the family and some problems will remain. To deal with these, team members should encourage parents to join in family support groups as exchange of views among families with similar problems can be most helpful. Experienced parents can support families whose child has only recently been diagnosed. The health-care team must, however, be aware of negative influences and uncertainty among the group. This situation can best be avoided if health professionals become regularly involved in support group meetings.

Helping children cope with their disease

Chronic diseases elicit different emotions in different children. Young children usually feel most disturbed by restrictions on their physical activity. In this age group normal motor activity is strongly related to psychosocial development, a process which is endangered in children with rheumatic diseases.

For older children and adolescents the disease has most impact on their social life, as this age group is strongly influenced by peer pressure. The rheumatic disease with its restrictions and special demands does not fit into the life concept of the peer group. Youngsters therefore tend to deny the illness and its consequences.

Different methods of adjustment do exist. Where adjustment is negative children experience their illness as punishment or threat. Emotions of guilt, fear, or helplessness develop, which may result in regression or aggression. A positive adjustment is one in which the child accepts certain limitations but concentrates on personal strengths.

The health-care team together with family, school staff, and friends must encourage such positive adjustment. The children should experience as little limitation on their activities as possible. While treatment discipline is necessary, it should always leave enough time for play and hobbies. Friends and peers should be integrated

into leisure activities. Healthy competition, which is important for the child's development, must be directed towards activities within the child's capabilities. Success at school or competence in music, crafts, games, etc. promote the child's self-esteem.

Loving care is beneficial and especially important during painful relapses and other times of crisis. Overprotectiveness, however, can be devastating and hinder the child's psychosocial development, and children should always be encouraged to become independent. This includes personal care as well as control over medical care and treatment. As they grow up children can learn to determine treatment times and share responsibility for medication, doctor's appointments, etc. Parents are often reluctant to encourage independence and self-care as they fear loss of control over their child's life or tend to underestimate his or her capabilities. Health professionals can mediate between parents and child in this situation and actively support the child's struggle for independence.

Children who experienced pain and physical restrictions from a long-standing rheumatic disease but learned to cope with it often develop a more mature personality compared with others of their age group. Overcoming obstacles which their friends couldn't even dream of can be a source for more self-reliance and positive self-esteem. The adolescent may be earlier and better qualified for an independent life despite some physical limitations. Parents and health-care team members must recognize the child's struggle for freedom and facilitate appropriate self-determination and self-support.

6.5 Corticosteroid injection therapy

Allan I. Binder

Introduction

The injection of local anaesthetic and corticosteroid agents into joints or soft tissue structures constitutes one of the most effective therapeutic options for the treatment of localized painful lesions of articular and soft tissue structures. The value of this form of treatment is widely appreciated (Bamji *et al*. 1990), leading to some concern with regard to the adequacy of the skills and experience of general practitioners and other health-care workers (Phelan *et al*. 1992) who increasingly perform these injections.

This chapter will outline the basic principles of steroid injection therapy, with the technique and special considerations for the more common conditions where it is employed. Sports-related and spinal use is more specialized and will not be considered in detail. The majority of injections can be performed in the clinic, ward, or, if necessary, in the patient's home, using an aseptic no-touch technique.

Effect of steroid on joints and soft tissue structures

Systemic corticosteroid agents have potent anti-inflammatory effects which result in an improvement in pain, stiffness, and systemic illness in patients with active inflammatory arthropathy. They may also significantly reduce the rate of joint damage in early rheumatoid arthritis (Kirwan *et al*. 1995). However, the limiting factor for prolonged systemic steroid therapy is the considerable risk of side-effects such as osteoporosis, reduced resistance to infection, deficient wound healing, accelerated atherosclerosis, and the suppressive effect on the hypothalamic–pituitary–adrenal axis, which can persist for up to a year after corticosteroid therapy has been withdrawn. Atlantoaxial subluxation is also more common in rheumatoid patients treated with systemic steroids.

Local steroid injected into a joint aims to achieve a sustained concentration of the drug in the synovial fluid and to provide the maximum anti-inflammatory effect locally whilst minimizing absorption into the plasma with its attendant risk of systemic side-effects. After injection, the corticosteroid passes from the synovial fluid into the synovial cells, before being gradually released into the circulation to be cleared. There are many steroid agents available and the localized effects depend on the potency, solubility, and dose of the particular agent used.

Hydrocortisone acetate is short acting, has a weak anti-inflammatory effect, is fairly soluble, and is completely absorbed from the joint within hours. The synthetic corticosteroids, such as methylprednisolone acetate, prednisolone acetate, and triamcinolone acetonide, are much more potent and less soluble and hence remain localized in the joint for several weeks (Gray *et al*. 1981). Triamcinolone hexacetonide is the most insoluble steroid, and has the slowest absorption, lowest plasma levels (Derendorf *et al*. 1986), and longest action (Bird *et al*. 1979) of the drugs available.

The benefit of local steroid injection can be observed by the profound reduction in inflammatory change and decrease in the expression of genes that play a role in articular destruction (collagenase, tissue inhibitors of metelloproteinases, complement, and HLA-DR), seen in histological tissue samples following local steroid injection (Firestein *et al*. 1991). Local steroid also leads to an improvement in the relationship between synovial fluid and serum levels of hyaluronan, restoring it towards normal (Pitsillides *et al*. 1994). Corticosteroid crystals which are found in joints immediately after steroid injection, and even a week later, are distinctive, being both intra and extracellular when visualized by polarized light and electron microscopy (Gordon and Schumacher 1979).

The systemic absorption of corticosteroid after local joint injection, may be sufficient to reduce inflammation in non-injected joints, and suppress the hypothalamic–pituitary–adrenal axis for up to 4 weeks after a single dose of a long-acting steroid (Bird *et al*. 1979). However, serious systemic side-effects are rare after a single injection, except in patients with brittle diabetes, infection, or where emergency surgery becomes necessary.

Outside the joints, local steroid injection may also produce beneficial effects in acute or chronic lesions, even where an inflammatory component is difficult to confirm. The injection of local steroid into soft tissue structures produces a characteristic histological picture, with circumscribed deposits of acellular finely granular material that stains faintly with haematoxylineosin. In some cases a mild to moderate reaction of histiocytes, fibroblasts, and lymphocytes may be noted round the edges. Small elongated spaces are usually evident, with occasional weakly birifringent (positive or negative) crystals that have an identical shape and size to the empty spaces (Balogh 1986). There is little data on the absorption of steroid from tendon sheaths, bursas, or other soft tissue structures, although methylprednisolone has been shown to produce measurable plasma levels for a mean of 16 days after soft tissue injection (Mattila 1983). Not all the effects of local steroid on soft tissue structures are beneficial, with impairment in the healing of damaged ligaments (Wiggins *et al*. 1994) and atrophy of up to 40 per cent of skin and subcutaneous tissue thickness, following a single injection of steroid (Gomez *et al*. 1982).

Indications for local steroid injection

Joint puncture permits the aspiration of fluid for microbiological, crystal, and, occasionally, biochemical assessment, and should always precede steroid injection where infection, haemarthrosis, or crystal arthropathy is suspected. The colour, smell, turbidity, and viscosity of the aspirated fluid may help differentiate inflammatory arthropathy from crystal-related or non-inflammatory disease. However, a heavy concentration of polymorphs (pyoarthrosis) is equally likely with acute rheumatoid, infection, or gout. Conventional light and polarized microscopy and, in some cases, microbiological culture of the synovial fluid may be necessary before steroid can be safely injected. Soft tissue lesions, such as olecranon bursitis, are also amenable to aspiration, with fluid from these lesions being subjected to analysis similar to synovial fluid, before steroid is injected.

Local anaesthetic and/or steroid injection also has value as a diagnostic tool where the source of the pain is uncertain. For example the abolition of a 'painful arc' on

abduction, as a result of local anaesthetic injected with the steroid, confirms the diagnosis of rotator cuff tendinitis.

However, the main use of local steroid injection is for treatment of inflammatory and non-inflammatory conditions of joints or soft tissues, whether they are acute or chronic. The main anatomical structures with examples of common conditions amenable to local corticosteroid injection are shown in Table 1. Even acute gout and pseudogout will respond to steroid injection (Gray *et al*. 1981), although this therapy is not usually necessary or always feasible. The treatment of osteoarthritic joints with steroid injection is more controversial (Dieppe 1991), although the presence of an effusion increases the likelihood of short-term reduction in pain (Gaffney *et al*. 1995) in these cases.

Structure	Examples of diseases amenable to injection
Joints	Rheumatoid and other inflammatory arthropathies
Entheses	Tennis and golfers elbow, rotator cuff tendinitis
Tendon sheath	De Quervain's tenosynovitis, trigger finger
Bursae	Trochanteric, olecranon bursitis
Ligaments / muscles	Strains, sprains, sports injuries
Nerve compression	Carpal and tarsal tunnel syndrome
Nodules/ganglia	Rheumatoid arthritis, trauma
Trigger points	Cervical, lumbar
Epidural	Nerve root compression

Table 1 Indications for local steroid injection

Contraindications to local injection

There are some absolute and other relative contraindications to steroid injection therapy as shown in Table 2. Any suspicion of sepsis within the affected joint, on the same limb, or systemically precludes steroid injection, until infection has been excluded or adequately treated. Steroid injection is best avoided in joints previously affected by septic arthritis, as local defence mechanisms within the joint are suspect. Monoarthritis of unknown cause should always be regarded with suspicion and steroid injection delayed, until either a diagnosis is made or at least until infection has been excluded.

Absolute contraindication
Septic arthritis, septicaemia, active sepsis in locality, tuberculosis
Febrile patient, cause unknown
Serious allergy to local anaesthetic, steroid, or previous local injection
Sickle cell disease
Relative contraindication
Monoarthritis of unknown cause
Neutropenia, thrombocytopenia
Anticoagulants or bleeding diathesis

Table 2 Contraindications to local steroid injection

Septic arthritis is particularly easy to overlook in rheumatoid patients who are frail and elderly or being treated with systemic steroid or other immunosuppressive drugs. In these patients infection is often polyarticular, mimicking an exacerbation of the inflammatory disease. Although *Staphylococcus aureus* is the most common infecting organism, patients may not present with fever, weight loss, or other features usually associated with systemic infection (Kraft *et al*. 1985). A mild rise in neutrophil count and a high sedimentation rate may also fail to differentiate infective from inflammatory causes, although an exceptionally high C-reactive protein level is more suggestive of infection. While systemic ill health can be a prominent feature in septic arthritis, it can also occur in patients with rheumatoid arthritis without infection (systemic rheumatoid), and steroids should not be given by any route until infection, including tuberculosis, has been sought and if necessary treated.

Patients need to be asked about previous allergic reactions to local anaesthetic agents (e.g. with dental treatment), steroids, or local injections. An exacerbation of the pain for 24 to 48 h following a previous steroid injection does not suggest allergy but rather a crystal-related phenomenon (Berger and Yount 1990). Neutropenia, thrombocytopenia, and clotting abnormalities constitute relative contraindications to local steroid injection. If patients are on anticoagulants, these should be stopped for at least 24 h before the steroid injection. With other clotting abnormalities or blood dyscrasias, haematological advice should be sought, and appropriate preparations made to reduce the risk of bleeding following the injection. While haemophilic arthropathy has been successfully treated with cautious steroid injection (Shupak *et al*. 1988), this therapy should be avoided in sickle cell disease (Gladman and Bombardier 1987) as a sickle crisis may be precipitated by the procedure.

Potential dangers and side-effects

Local steroid injections are extremely safe, provided that the indication is appropriate, there are no contraindications, and a careful aseptic technique is used. Some side-effects apply to all injections (Table 3), while others are site-specific, and will be discussed below. While the exacerbation of pain for up to 48 h following the injection suggests a crystal-related phenomenon (Berger and Yount 1990), pain persisting beyond this time requires assessment for infection or other complications. Infection following steroid injection constitutes the most important side-effect, although it is very rare, with an estimated sepsis rate of 1 in 14 000 to 50 000 injections (Gray *et al*. 1981). Chronic debilitating illness such as severe diabetes mellitus or rheumatoid (Ostensson and Geborek 1991), or factors like drug abuse and alcoholism (Haslock *et al*. 1995), which suppress general immunity can predispose patients to infection. Postinjection sepsis may result from contamination of the injection equipment (Nakashima *et al*. 1987) or skin, haematogenous spread (Von Essen and Savolainen 1989), or reactivation of a previous infection. Accelerated joint destruction will also follow the injection of steroid into an undiagnosed septic joint.

Exacerbation of pain for 24–48 h (crystal related)
Septic arthritis
Accelerated destruction of an unsuspected septic joint
Subcutaneous tissue atrophy
Depigmentation
Transient facial flushing
Anaphylaxis
Peripheral nerve injury
Tendon rupture
Avascular necrosis, Charcot joint
Loss of diabetic control
Reactivation of tuberculosis
Cartilage damage
Soft tissue calcification

Table 3 Side-effects attributed to local steroid injection

Subcutaneous tissue atrophy (Fig. 1) or depigmentation (Fig. 2) are more likely if excessively large or repeated doses of long-acting steroid are given. While tendon rupture (Fig. 3) or facial flushing is encountered fairly often, other side-effects (Table 3) are rare. The importance of local injection in the development of avascular necrosis or a Charcot joint (Parikh *et al*. 1993) remains uncertain.

Fig. 1 Subcutaneous tissue atrophy following steroid injection of De Quervain's tenosynovitis lesion.

Fig. 2 Depigmentation following steroid injection of De Quervain's tenosynovitis lesion.

Fig. 3 Rupture of the long head of the biceps tendon following anterior shoulder injection.

Method of steroid injection

The method of injection of local steroid into painful joints and soft tissue structures is similar, although the exact technique may depend on the local anatomy, the size and depth of the lesion concerned, and the need to aspirate fluid before injection. The broad principles of injection therapy will be outlined first with locally determined modification in techniques being considered under the individual conditions.

As the success of local injection therapy depends on the accurate placement of the injected steroid (Jones *et al*. 1993), detailed knowledge of the anatomy at the site of injection is important. Consistency in the choice of equipment (needles and syringes) and adequacy of relaxation of the patient, and especially of the limb to be injected, further improves the feel, and hence reliability, of the injection. While the injection of large fluid-filled joints is relatively easy, other injections may require considerable skill and experience.

There is no single 'correct' method of performing steroid injection and most skilled operators develop their own unique style (Haslock *et al*. 1995), based on training, experience, and the equipment available. Irrespective of the individual variation in method, this should always be based on a consistent, safe, aseptic, 'no-touch' technique. The method presented reflects the author's own practice.

Equipment

Table 4 summarizes the equipment needed for routine steroid injection. Single-dose ampoules of steroid and local anaesthetic agents should always be used to eliminate any possibility of cross infection.

Steroid preparations (individual ampoules)
- short acting — hydrocortisone acetate 25 mg/ml
- long acting — methylprednisolone acetate 40 mg/ml
  - methylprednisolone acetate 40 mg/ml, lignocaine 10 mg/ml
  - triamcinolone hexacetonide 20 mg/ml
  - triamcinolone acetonide 40 mg/ml

Single-dose 1% lignocaine ampoules for injection

Refrigerant spray

Sealed isopropyl alcohol swabs

Other
- sealed single-use needles — 25G, 23G, 21G and 19G
- single-use syringes
- sterile cottonwool
- elasticplast, crepe bandages

Table 4 Equipment required for local steroid injection

Steroid agents

Hydrocortisone acetate is the only frequently used, short-acting agent (Gray *et al*. 1981) and is especially useful for superficial lesions, where there is a risk of subcutaneous atrophy or depigmentation, or in lesions (such as Achilles tendinitis) where tendon rupture may occur. Although there are many long-acting steroid agents available (Table 4), familiarity with one or two agents is adequate, as the differences between agents is not great. Methylprednisolone acetate has the advantage of being available alone or premixed with lignocaine, permitting greater flexibility in the adjustment of both steroid dosage and fluid volume when injected at different sites. Triamcinolone is also widely used as the acetonide or hexacetonide salts. In most circumstances, the long acting steroid agents are superior to hydrocortisone (Blyth *et al*. 1994), leading to a more sustained clinical improvement.

The dosage of steroid used varies according to the lesion injected. For most joint and soft tissue lesions, 25 mg of hydrocortisone, 40 mg of methylprednisolone or triamcinolone acetonide, or 20 mg of triamcinolone hexacetonide is adequate. Large joints, like the knee, may require double and very small joints or lesions half this dose.

Local anaesthesia

Local anaesthesia of the skin can be achieved by the use of a refrigerant spray such as ethyl chloride. Freezing numbs the skin rapidly and is especially useful in the hand and other sensitive parts of the body, or in patients requiring frequent injections. The skin is sprayed only until it turns white to achieve anaesthesia, as beyond this point a painful burn may ensue.

Lignocaine 1 per cent mixes well without flocculation with most steroid agents, and is usually introduced in combination with the steroid. Where the injection is technically difficult or fluid aspiration is to precede injection, the lignocaine is introduced first. The volume of local anaesthetic agent injected will vary according to the size of the joint or lesion being injected. While the use of lignocaine may reduce the immediate postinjection pain in tennis elbow or other soft tissue lesions (Haslock *et al*. 1995), the rationale for routine use in large joint injection is less clear cut (Kirwan *et al*. 1984).

Other equipment

Sealed isopropyl alcohol swabs or other alcohol-based agents provide a safe and cost effective method of achieving skin cleansing. Iodine, chlorhexidine in spirit, and other cleansers increase the cost of the procedure but offer no advantage over the sealed alcohol-based swabs (Cawley and Morris 1992) and can increase the risk of infection (Nakashima *et al*. 1987).

While a 2 or 5 ml sterile syringe is adequate for most steroid injections, 10 ml and 20 ml syringes are required for fluid aspiration. The choice of needle for any given site is also important. Most medium sized joints and soft tissue lesions can be injected with a 23G (blue) needle. A larger 21G (green) needle is used for larger joints, especially where aspiration is required, and for deep soft tissue lesions such as those round the buttocks and thighs. Where the synovial effusion is large or the fluid is thick, fibrinous, or purulent a 19G (white) needle may be needed for successful aspiration. Small hand and foot joints and superficial soft tissue lesions are best injected with a fine 25G (orange) needle.

Preparation

The method of preparation for joint aspiration and steroid injection is shown in Table 5.

Exclude contraindications or allergy
Explain the procedure before starting
Position patient so patient and limb are relaxed
Wash hands and dry carefully
Prepare injection immediately before use
  To aspirate: lignocaine and steroid separate
  To inject: lignocaine and steroid mixture
Mix steroid thoroughly before preparation and before injection
Use single-dose ampoules
Draw up the drugs yourself!
Change needle before injecting
Keep needle covered before use

Table 5 Preparation for steroid injection

The patient must be as relaxed as possible, as tension in surrounding muscles can make the injection difficult or even impossible. Where patient anxiety is a particular concern, most injections can be carried out with the patient lying supine with the head comfortably supported on pillows. This position facilitates the treatment of vasovagal attacks if they occur. The presence of a nurse helps to reassure and position the patient but the nurse must be dissuaded from drawing up the drugs or shaking them out on to a tray or table before the operator is ready. The procedure should be described to the patient in detail before starting the injection, to reduce the risk of air-borne infection. At the same time, the patient can be assessed for sepsis, allergy, or other contraindications to the injection.

Simple hand washing is adequate for the procedure if a no-touch technique is to be employed, and should precede preparation of the injection. Careful hand drying will prevent water running down the needle. While gloves are now recommended for joint aspiration (American College of Rheumatology Council on Rheumatological Care 1992), less than 50 per cent of American (Yood 993) and 10 per cent of British rheumatologists (Haslock *et al*. 1995) currently heed this advice. The injection is prepared with a combination of steroid and local anaesthetic in the same syringe, in most cases. Where the injection is likely to be difficult or where aspiration is to precede injection, the two agents are drawn up separately, the lignocaine being in a larger syringe. As the steroid preparations are crystalline, they need to be thoroughly mixed before being drawn up and again before injection. The needle should ideally be changed following preparation to maintain sharpness, and must remain covered until the injection is given to reduce the risk of infection.

Injection technique

A method for aspiration and/or steroid injection is summarized in Table 6. Talking should be kept to a minimum during the procedure. The exact site for injection is carefully marked with a blunt-pointed object such as a thumbnail or ball-point pen with the point retracted. This mark should only be made once careful positioning of the patient has been achieved, and needs to remain visible even after skin cleansing to permit a no-touch aseptic technique to be used.

Mark exact point of needle insertion with a blunt object
Use no-touch technique
Cleanse injection site with 2–3 alcohol swabs
Use refrigerant spray for skin anaesthesia
Fleswab injection site
Insert needle without touching the metal
For aspiration: keep needle stationary as fluid is tapped, then change syringe and inject steroid
For injection: pull back plunger before injecting
Remove needle carefully and check for bleeding
Use elastoplast if no allergy; crepe bandage after knee aspiration
Dispose of all needles and syringes safely and avoid needlestick injury
Rest or splint joint after injection if possible
Re-emphasize possible side-effects and benefits

Table 6 Technique for steroid injection

Only one or two joints should be injected per session, with the same joint being injected no more than three or four times a year. Patients should be warned of possible side-effects such as a temporary exacerbation of pain or destabilization of diabetic control following the injection. The patients should also be told about the possible beneficial effects of the absorbed steroid on systemic symptoms or other inflamed joints.

Postinjection

The injected part should, where possible, be rested for 24 to 48 h after injection (Neustadt 1992; Chakravarty *et al*. 1994), although admission for absolute bed rest is neither cost-effective nor practical. Splinting the injected joint may also prolong the duration that the steroid remains localized at that site (Dixon and Graber 1983). Where a large effusion has been drained, as from a knee, a crepe bandage should be firmly applied to provide support and take up the slack in the tissues stretched by the effusion. The maximum improvement usually develops in 2 to 4 weeks, and may last many months.

Joint and soft tissue lesions

The most common lesions amenable to steroid injection will be considered on a regional basis (Table 7), describing the method of injection, choice of steroid agent, volume of injection, and particular differences at each site. Several monographs are available outlining joint injection techniques (Dixon and Graber 1983; Doherty *et al*. 1992).

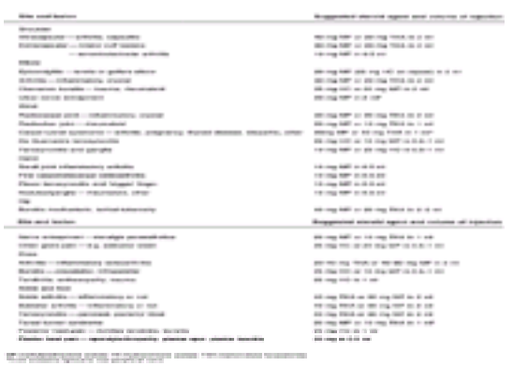

Table 7 Lesions amenable to injection with suggested steroid agent and volume of injection

The painful shoulder

Shoulder pain usually arises from soft tissue lesions, although arthropathies affecting the glenohumeral, acromioclavicular, and sternoclavicular joints also occur, with most lesions being amenable to steroid injection (Table 7). As shoulder structures arise from the C5 dermatome, pain is felt in the upper arm, maximally at the point of insertion of the deltoid muscle. Only the acromioclavicular joint arises from C4, and hence pain radiates to the neck and needs to be differentiated from cervical lesions. Shoulder pain can also result from polymyalgia rheumatica, or can be the site of referred pain from cervical, thoracic, or intra-abdominal pathology.

Injection therapy is much more cost-effective than physiotherapy (Dacre *et al*. 1989) for shoulder lesions but the site of steroid injection needs to be based on anatomical pathology rather than the localization of tender or trigger points (Hollingworth *et al*. 1983). Some studies have failed to confirm the benefit of injection therapy (Adebajo *et al*. 1990) but this may reflect difficulties in placement of the injection (Hollingworth *et al*. 1983).

Glenohumeral joint

This joint communicates with the tendon sheath of the long head of the biceps tendon, but not with the subacromial bursa unless rupture of the rotator cuff has occurred. Aspiration and or injection of the glenohumeral joint can be achieved using the anterior or posterior route, as both provide good access to the joint, although the posterior route is technically easier.

Anterior route (Fig. 4)

Fig. 4 Injection of the shoulder joint via the anterior route.

This route gives more reliable access in patients with adhesive capsulitis and is better suited for aspiration of large shoulder effusions. With the patient lying supine, the arm is rotated to identify the coracoid process and joint line anteriorly, and acromium posteriorly. Laying the arm across the abdomen to result in partial internal rotation of the shoulder, the injection is made just lateral to the coracoid in the line of the joint margin, with the needle directed towards the acromium. If correctly sited, the injection can be given without resistance.

Posterior route (Fig. 5)

Fig. 5 Injection of the shoulder joint via the posterior route.

This is especially useful where the cause of the pain is uncertain or the operator lacks skill in injection procedure. With the patient seated across the couch and approached from behind, the thumb is used to identify the spine of the scapula which is followed laterally until it bends forward as the acromium. The point just below the acromium is marked. The forefinger is then used to palpate the coracoid process in front, rotating the shoulder if necessary to locate it. The needle is inserted under the acromium and gently advanced without resistance with the needle pointing towards the outer side of the coracoid process. More superficial injection is used to treat cuff lesions.

Subacromial bursa—lateral approach (Fig. 6)

Fig. 6 Injection of the subacromial bursa via the lateral route.

Injection into the bursa is particularly useful for rotator cuff lesions, especially when accompanied by a painful arc on abduction. Although subacromial bursitis is rarely a primary diagnosis, it is frequently secondarily affected by pathological processes arising in the rotator cuff and other nearby structures. The subacromial space is very large, being in continuity with the subdeltoid space and also, with cuff rupture, the glenohumeral joint.

To inject the subacromial space, the patient should be seated and approached from the lateral aspect with the arm hanging vertically down, to use gravity to help enlarge the gap between the acromium above and the humeral head below. This gap is palpated, marked, and the needle advanced into the space, directed medially and slightly posteriorly. A relatively large volume of local anaesthetic (2–10 ml) is mixed with the steroid in view of the large capacity of the space being injected. The local anaesthetic rapidly abolishes the 'painful arc', which both helps confirm the diagnosis of a rotator cuff lesion and the correct siting of the injection. The benefit of this injection is particularly dramatic in patients with acute calcific tendinitis, where the pain is so acute that patients often present as an emergency.

While steroid injection to the glenohumeral joint or subacromial bursa often ameliorates the pain associated with adhesive capsulitis (frozen shoulder), it has less effect on the recovery of range of movement (Rizk *et al*. 1991). Arthrographic capsular distension, which ruptures the capsule, when combined with steroid injection, may lead to earlier recovery in range (Rizk *et al*. 1994) in adhesive capsulitis. However, a home exercise regimen which encourages hourly wall climbing to increase abduction and forward flexion, achieves a satisfactory rate of recovery in most patients with frozen shoulder.

Individual rotator cuff tendons

The individual rotator cuff tendons can also be injected with appropriate expertise (Cyriax 1984). The supraspinatus (superior) and subscapularis (inferior) tendons are anterior, and the infraspinatus tendon posterior, to the joint. Pain on resisted shoulder abduction, internal, and external rotation respectively, helps to identify the rotator cuff tendons involved. These injections are especially useful in patients in whom a 'painful arc' is absent, and hence where subacromial injection may be unsuccessful. Bicipital tendinitis is difficult to distinguish from rotator cuff tendinitis, but often coexists with it. While steroid injection via the anterior route may reduce pain from this source, rupture of the long head of biceps may follow the injection (Fig. 3).

Acromioclavicular joint

The acromioclavicular joint, which is on the anterosuperior aspect of the shoulder, is located by following the clavicle laterally until the joint is reached. Local tenderness confirms joint involvement. The joint is injected from the anterior or superior route, but only accepts 0.5 ml of fluid. Care is necessary to avoid deep injection as a pneumothorax can result from apical lung penetration.

Elbow

Elbow pain is extremely common and usually results from epicondylitis. Care is necessary to exclude pain referred from the cervical spine, brachial plexus, or shoulder, which can closely mimic primary elbow pathology. Most elbow lesions (Table 7) are injected from the lateral side, with the patient sitting in a relaxed manner and with the elbow resting on the examination table at an angle of 90°. Only medial epicondylitis and ulnar entrapment neuropathy require a greater angle and appropriate positioning to permit access to the medial aspect of the elbow.

Epicondylitis

Epicondylitis can result from trauma, lifting heavy weights, or repetitive power rotation movements. It is particularly difficult to cure when it is occupation or sport related.

Lateral epicondylitis (tennis elbow) (Fig. 7)

Fig. 7 Injection of a tennis elbow lesion.

In tennis elbow, localized tenderness is found either just distal to the lateral epicondyle or over the radial head. Pain is exacerbated by wrist dorsiflexion against resistance, especially when the elbow is extended and the hand prone. Grip strength is also reduced with the arm held in a similar position. While supination and pronation may be painful, there is no significant loss of elbow range.

Local steroid injection is directed to the site of maximum tenderness, with the injection aimed at 45°, to end near the insertion of the common extensor tendon to bone. A fair amount of pressure is needed to inject at this site, so care should be taken to ensure the needle is firmly attached to the syringe.

Medial epicondylitis (golfer's elbow)

Golfer's elbow causes tenderness very similar to tennis elbow but it is localized to the region of the medial epicondyle. Pain is usually noted on resisted palmar flexion of the wrist against resistance with the hand held supine.

Injection is again directed at the site of maximum tenderness, near the common flexor tendon insertion to bone. Care is necessary to avoid injury to the ulnar nerve which lies in a groove just behind the medial epicondyle.

There is no agreement with regard to the steroid agent of choice to inject tennis and golfer's elbow lesions. While triamcinolone is more effective than hydrocortisone (Price *et al*. 1991), it is more likely to lead to atrophy of the subcutaneous tissue. Both temporary postinjection exacerbation of pain and early relapse of symptoms are common following injection therapy (Dijs *et al*. 1990; Price *et al*. 1991), irrespective of the type of steroid used. The most logical approach is to use a long-acting steroid for the first injection, and hydrocortisone for further injections or for treatment of relapses, but with no more than three injections being given to treat the same lesion. Further injections can lead to long-lasting or irreversible atrophy which may amplify the pain from trivial knocks. Healing of epicondylitis lesions is often slow and diffuse forearm ache may precede recovery.

Elbow joint

The elbow joint is commonly involved in inflammatory arthropathies, causing swelling and painful limitation of elbow movements. The joint is injected using either the posterior or anterolateral route.

Posterior approach (Fig. 8)

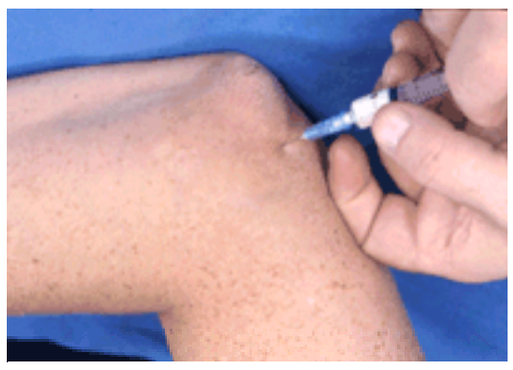

Fig. 8 Injection of the elbow joint via the posterior approach.

This route is easier to use before gross deformity has developed. The posterior joint line can be identified by placement of the thumb on the lateral epicondyle and third finger on the olecranon. The paraolecranon groove between the two fingers identifies the joint line, which runs between the two heads of the triceps tendon. Injection into the joint is just above and slightly lateral to the olecranon, where a bulge can be felt in the presence of a joint effusion.

Anterolateral approach

The thumb is used to palpate the head of the radius at the radiohumeral part of the elbow joint, best identified by rotating the forearm while palpating. An effusion may be evident at this site as a result of synovial extension around the radial head. Once the joint line is identified, the injection is made tangentially just under the capsule, not attempting to reach the centre of the joint.

Olecranon bursitis

Olecranon bursitis can result from infection, trauma, rheumatoid arthritis, or gout. Once infection has been excluded, the bursa can be aspirated and injected with steroid (Smith *et al*. 1989). However, secondary infection (Canoso and Sheckman 1979), chronic local pain, or skin atrophy (Weinstein *et al*. 1984) may follow the injection.

Ulnar nerve entrapment

The ulnar nerve lies in the groove just behind the medial epicondyle, and can be impinged on by local pressure, trauma, or inflammatory synovial tissue. In many cases the cause is unknown. Patients present with pain on the medial side of the elbow, paraesthesia of the ulnar digits, and occasionally sensory or motor abnormalities in the hand. A positive Tinel sign, elicited by local percussion over the nerve behind the medial epicondyle, suggests the diagnosis, which can be confirmed by electromyography. Steroid injection at this site may reduce the symptoms, especially when the lesion has an inflammatory cause, but care is necessary to avoid injury to the nerve during the procedure.

Wrist

Although the wrist and surrounding structures are often involved in the inflammatory arthropathies, there are many other common, non-inflammatory wrist lesions (Table 7), which are amenable to steroid injection therapy. Rheumatoid arthritis has a particular predilection for involvement of the distal radio-ulnar joint near the

ulnar styloid, which is normally separated from the rest of the wrist joint by the triangular fibrocartilage. Radio-ulnar disease, if severe, may lead to attrition and rupture of the fourth and fifth extensor tendons as they pass over the joint. It is also important to differentiate true wrist (radiocarpal) joint involvement from overlying tenosynovitis. Injection around the wrist and hand is best carried out with both the patient and doctor seated, and with the limb resting on the examination couch.

Wrist (radiocarpal) joint (Fig. 9)

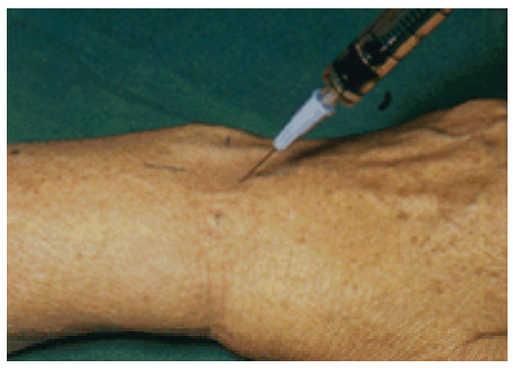

Fig. 9 Injection of the wrist joint.

Injection of the wrist is carried out with the hand held palm down and the joint opened up by palmar flexion over a pillow or similar object. The joint margin is felt as a triangular gap between the lower end of the radius and the lunate and scaphoid bones. The needle is inserted into the joint pointing in a proximal direction at an angle of about 60°. Immobilization of the wrist may prolong the beneficial effects of the injection (Dixon and Graber 1983).

The distal radio-ulnar joint

This joint is identified by gently supinating and pronating the forearm with a finger over the ulnar styloid. Once the joint line is located, it can be injected in a similar manner to the wrist but with the needle inserted almost tangentially into the radio-ulnar joint.

Carpal tunnel syndrome (Fig. 10)

Fig. 10 Injection of carpal tunnel syndrome to the ulnar side of the palmaris longus tendon.

Carpal tunnel syndrome results from median nerve compression in the carpal tunnel of the wrist. Patients present with intermittent or persistent pain and paraesthesia in the thumb, index, and middle fingers, characteristically waking the patient at night. A positive Tinel sign, elicited by local percussion over the median nerve at the wrist, help confirm the diagnosis. Untreated, the lesion can lead to wasting of the muscles of the thenar eminence. Carpal tunnel syndrome can be mimicked by cervical spine or brachial plexus lesions, and electromyography, although not infallible, may assist diagnosis in difficult cases. Even once the diagnosis has been confirmed, a cause, such as inflammatory arthropathy, previous trauma, thyroid disease, or pregnancy should be sought.

The injection is carried out just medial to the midline of the ventral aspect of the wrist, in the first crease, at the junction to the hand. If the palmaris longus tendon is present, it overlies the median nerve and injection should be just medial and parallel to it. A fine 25G needle is inserted, just medial to the midline or palmaris longus tendon, to a depth of 1 cm, directing the needle towards the palm. If the needle is correctly positioned, there should be no resistance, pain, or paraesthesia during the procedure.

Care is necessary to avoid damage to the nerve, which can cause persistent pain and paraesthesia (McConnell and Bush 1990; Frederick *et al*. 1992). Local anaesthetic agents should also be used sparingly to avoid unpleasant, though temporary, paralysis of the median nerve. Long-acting steroid preparations should be used for carpal tunnel injection therapy, as the aim of the injection is to atrophy the soft tissue structures around the nerve. A wrist splint, especially if used at night, may also hasten recovery (Kulick *et al*. 1986). In idiopathic lesions, especially affecting women under the age of 40 years, steroid injection is less likely to be successful (Weiss *et al*. 1994b) and earlier surgery should be considered. The presence of thenar muscle wasting, persistent sensory loss, or a lack of response to steroid injection, is associated with a less favourable outcome even following surgical decompression (Green 1984; Kulick *et al*. 1986).

De Quervain's tenosynovitis (Fig. 11)

Fig. 11 Injection of De Quervain's tenosynovitis.

Stenosing tenosynovitis of the extensor pollicus brevis and abductor pollicus longus (De Quervain's tenosynovitis) is a common condition which is often occupational and related to repeated minor trauma. It causes pain on gripping especially with use of the thumb. Tenderness is noted in the 'snuffbox' area of the wrist where palpable crepitus may be found. Pain can be increased by ulnar deviation of the wrist against resistance after placing the patients thumb in the palm (Finkelstein's

test), with the arm held in the midprone position.

The injection for this lesion is given at the point of maximum tenderness, using a fine-bore needle which is inserted tangentially along the tendon sheath. When correctly sited, the injection can be given without resistance. If there is doubt with regard to placement of the needle, the syringe can be disconnected and movement of the needle will mirror movement of the thumb, if the needle is correctly sited in the tendon sheath.

Local steroid injections (Weiss *et al*. 1994a) are more likely to be effective in acute lesions, and should be combined with a splint and modification of the activities which caused the lesion. Although long-acting steroids are more effective (Anderson *et al*. 1991), hydrocortisone is the preferred steroid agent as it is less likely to cause complications such as subcutaneous atrophy or depigmentation (Fig. 1 and Fig. 2), especially after repeated injection. Dark skinned patients need to be warned that these cosmetic complications may follow the injection.

Extensor and flexor tenosynovitis

These lesions, if troublesome, can be treated by aspiration and local steroid injection, although recurrence is common and surgical excision is more likely to lead to a permanent cure (Wright *et al*. 1994).

Hand

The hand structures amenable to steroid injection are shown in Table 7.

The small joints in the hands

These joints are frequently involved in inflammatory arthropathies and all are amenable to steroid injection to reduce pain and swelling. However, the injections are painful and it is only possible to inject one or two joints per session, unless general or regional anaesthesia is used. The presence of a joint effusion simplifies the procedure and distortion of the normal anatomy makes it considerably more difficult.

The technique of steroid injection is similar for all the small hand joints and can be performed with the patient seated with the hand palm down across the table or examination bench. The joint margin on the lateral or medial side of the joint is identified by gently flexing and extending the digit. The superior part of the joint line is marked, with the joint flexed to an angle of 45°. By distracting the finger with one hand, it is injected with the other hand, using the superolateral or superomedial approach to avoid injury to the neurovascular structures. The joint will only accept 0.5 to 1 ml of injected fluid, which should contain a combination of long-acting steroid and local anaesthetic. Splintage of the joint may prolong the effect of the injection.

Metacarpophalangeal joint (Fig. 12)

Fig. 12 Injection of the metacarpophalangeal joint.

The joint line, which is located about 1 cm distal to, and not at, the crest of the knuckle, is identified by passive movement of the finger. After marking the joint line, the patients finger is distracted as the joint is injected, tangentially under the extensor expansion.

Proximal (Fig. 13) and distal interphalangeal joint

Fig. 13 Injection of the proximal interphalangeal joint.

Injection is also carried out by distracting the joint as the steroid is injected tangentially under the extensor expansion (Evans 1984). The distal joints are technically more difficult to inject unless an effusion is present, as occurs in psoriatic and other seronegative spondylarthropathies.

First carpometacarpal joint (Fig. 14)

Fig. 14 Injection of the first carpometacarpal joint.

This joint is characteristically affected in primary generalized osteoarthritis and non-inflammatory arthropathies. Patients complain of pain at the base of the thumb on gripping, and tenderness and 'squaring' of the thumb base is noted. For injection, the hand is rested on the couch in the midprone position, with the joint line being identified laterally. By applying pressure on the thumb the joint can be distracted, and the injection facilitated. The patient needs to relax the thumb as the needle is angled slightly distally to enter the joint. Different approaches to the joint may be necessary once gross distortion of the joint has occurred. Despite the degenerative nature of the problem, the response to local steroid injection is often good, although patients need to be warned that a temporary increase in the pain may precede recovery. Patient should also be provided with a thumb pillar splint to protect the joint against further damage.

Flexor tenosynovitis and 'trigger' fingers (Fig. 15)

Fig. 15 Injection of second flexor tendon sheath of the hand.

Flexor tenosynovitis is a common cause of poor hand function in inflammatory arthropathies, lupus, or diabetes mellitus but it can also result from trauma or be idiopathic. Nodules may form within the tendon sheaths, making it difficult for the tendon to move freely past the anatomical constrictions, thus leading to 'triggering' of the digit. The nodules can be palpated either attached to the tendon in the pad of tissue adjacent to the proximal phalanx or in the palm opposite the distal palmar crease. They can also occur at the base of the thumb.

Although the tendon nodules can be injected directly, it is more effective to inject the affected tendon sheath. The injection is made with the patient seated with the hand resting palm up on the couch. The needle is advanced tangentially along the tendon sheath in a proximal direction, using a fine-bore needle. Similar injection is possible for thumb tendon nodules.

Steroid injection improves over two-thirds of patients with flexor tenosynovitis (Anderson and Kaye 1991; Lambert *et al*. 1992), and success rates rival surgical intervention (Kraemer *et al*. 1990). Rupture of tendons may rarely follow steroid injection at this site (Tonkin and Stern 1991).

Hip region

Although hip pathology is common, many patients referred with hip problems have pain arising from soft tissue lesions around the hip. The extreme depth of the hip joint and technical difficulty associated with anatomical derangement or osteophyte formation, preclude hip injection as a routine outpatient procedure. Aspiration and, if appropriate, steroid injection, needs to be carried out by an orthopaedic surgeon in theatre or, better, by a radiologist under suitable radiological screening.
Although the hip joint itself is not routinely injected, there are many soft tissue lesions around the hip which are amenable to steroid injection in an outpatient setting (Table 7).

Trochanteric bursa (Fig. 16)

Fig. 16 Injection of trochanteric bursitis.

Patients presenting with hip pain often have pain and local tenderness maximally around the greater trochanter of the femur. It is difficult to differentiate bursitis overlying the greater trochanter from enthesopathy of the muscles inserting at this site. Trochanteric bursitis is usually a non-inflammatory lesion (Ege-Rasmussen and Fano 1985) but is also a common cause of hip pain in rheumatoid patients (Raman and Haslock 1982).

To inject the lesion, the patient is positioned with the painful thigh uppermost and flexed, and the lower leg kept extended. By rotating the affected hip, the prominence of the greater trochanter with its associated tenderness is located, marked, and injected at right angles to the skin. The injection site can be very deep seated in patients with obese thighs, and a longer (5.08 cm) 21G needle may be needed to reach the bursa. While steroid injection therapy has a high success rate in both inflammatory and mechanical lesions, postural advice and review of gait by a physiotherapist is necessary to prevent recurrence of the lesion.

Meralgia paraesthetica

This lesion is an entrapment neuropathy of the lateral cutaneous nerve of the thigh as it traverses the deep fascia, about 10 cm below and medial to the anterior superior iliac spine. Clearly demarcated blunting of pinprick or hyperaesthesia may be found over the anterolateral aspect of the thigh, with tenderness localized to the point where the nerve penetrates the fascia (10 cm below the anterior superior iliac spine). If this point is found, infiltration with steroid and local anaesthetic may abolish the symptoms.

Ischial tuberosity

The ischial tuberosities, located deep in the medial side of the buttocks, have overlying bursas which can become inflamed and cause pain on sitting, especially on a

bicycle seat. These lesions are amenable to infiltration of steroid and local anaesthetic with the patient lying on the lateral side facing away from the examiner. The tender point is identified and injected using a long 21G needle.

Obscure groin pain

Groin pain is common as a result of sport or other injuries. Enthesopathy of the adductor longus tendon, inquinal ligament, and other structures, if identified (Ashby 1994), can be treated with local steroid injection.

Knee

Knee lesions amenable to steroid injection are shown in Table 7.

Knee joint

A knee effusion is a common presenting feature in both inflammatory and non-inflammatory arthropathies, and can seriously impair quadriceps function (Geborek *et al*. 1990). Where the cause of the effusion is uncertain, aspiration of synovial fluid for microbiological and crystal assessment should precede steroid injection.

While there are many approaches to knee aspiration and injection, the most common technique is to use the retropatellar route, via either the medial or lateral approaches. With the patient lying supine, the knee should be extended and the quadriceps muscle relaxed. In the presence of fixed flexion contracture of the knee, support under the knee is necessary to encourage quadriceps relaxation.

Lateral retropatellar approach (Fig. 17)

Fig. 17 Injection of the knee joint via the lateral retropatellar approach.

The joint line is marked between the upper and middle third of the patella, with the needle advanced tangentially between the patella and femoral condyle. By pushing on the medial aspect of the patella, the gap between the patella and femur can be increased, facilitating joint penetration. Aspiration as the needle is inserted will reveal fluid as soon as the joint capsule is entered, so reducing the risk of cartilage injury.

Medial retropatellar approach

The site of joint entry is just below the midline of the patella, with the needle advanced tangentially towards the suprapatellar pouch. Aspiration as the needle is introduced will again prevent cartilage injury.

Irrespective of the approach, a 21G or larger-bore needle is used, to remove as much of the inflammatory fluid and debris as possible, before steroid is injected. The introduction of lignocaine before aspiration and 'milking' the fluid towards the needle with controlled pressure from the other hand will facilitate the procedure. Given the large capacity of the joint and synovial surface area, effusions can be massive. The fluid should be viewed and, if purulent, examined in the laboratory to exclude infection before the steroid is injected.

Long-acting steroid agents are more effective than hydrocortisone (Blyth *et al*. 1994), with a relatively large dose of steroid being necessary; 40 to 80 mg of methylprednisolone or triamcinolone acetonide, or 20 to 40 mg of triamcinolone hexacetonide are needed, depending on the size of the effusion. With such a large capacity and synovial surface area, significant absorption of steroid into the circulation can be anticipated and patients need to be informed of both potential benefits to other inflamed joints and possible risks, such as destabilization of diabetic control, following the injection.

A bandage should be firmly applied to support the knee following injection if a large effusion is drained. Bed rest for 24 h following the injection prolongs the beneficial effects (Chakravarty *et al*. 1994), although routine admission to hospital following injection is not cost-effective.

Popliteal (Baker's) cyst

Patients with a knee effusion may develop a popliteal (Baker's) cyst as a result of a one-way valve between the knee joint and semimembranosus or gastrocnemius bursae. The fluid is resorbed from the bursa, leaving a gelatinous material which cannot be aspirated. The cyst can gradually increase in size or can rupture into the calf muscle mimicking a deep vein thrombosis. Ultrasound of the back of the knee and calf or arthrography of the knee joint can demonstrate the cyst, and if present, rupture into the calf muscle.

If a Bakers cyst requires treatment, the knee joint proper should be aspirated and injected as described above. Attempts to inject the cyst directly could result in damage to the neurovascular structures at the back of the knee. For a ruptured Baker's cyst, a below knee support stocking should be used to facilitate sealing of the capsular rupture, following steroid injection into the knee joint proper.

Osteoarthritis of the knee

Some patients with osteoarthritis of the knee have an effusion which might benefit from aspiration and steroid injection, although the improvement is usually short lived (Schnitzer 1993; Gaffney *et al*. 1995). Infiltration of steroid around the patella (Sambrook *et al*. 1989) or other tender trigger spots around the knee, also provides symptomatic relief in some patients, although steroid injection for osteoarthritic joints remains controversial (Dieppe 1991).

Other knee lesions

Non-infected prepatellar bursitis, painful collateral ligaments, and other painful trigger spots around the knee may be amenable to local steroid injection, which is given at the point of maximum tenderness. If an infected prepatellar or other superficial bursa is aspirated, care is necessary to avoid entry into the knee joint as septic arthritis may ensue. Rupture of the patellar ligament may follow steroid injection near the tendon insertion (Alexeeff 1986).

Ankle and hindfoot

The main causes of ankle and heel pain are shown in Table 7. The tendon sheaths around the ankle often communicate with the ankle joint and can be involved in inflammatory or other pathological processes. Most ankle and hindfoot lesions can be injected with the patient lying supine on the couch.

Ankle joint (Fig. 18)

Fig. 18 Injection of the ankle joint.

The ankle joint is located by dorsiflexing the foot to stretch the tibialis anterior ligament and so make it visible. The joint margin which lies between the tibia and talus is then palpated just lateral to the tendon. After marking the injection site, the needle is inserted almost horizontal to the foot, curving over the talus. If an effusion is present, the joint can be aspirated before steroid is injected.

Tendon sheaths

Injection of steroid along swollen and inflamed tendon sheathes is possible behind the medial malleolus (posterior tibial tendon), or lateral malleolus (peroneal tendon), with marked reduction in pain and swelling following successful injection.

Posterior subtalar joint

This joint is commonly involved in inflammatory and degenerative conditions of the ankle and hindfoot, and leads to an increasing valgus deformity below the ankle. The joint often communicates with the ankle joint, but can be injected directly from behind the lateral malleolus, with the patient lying prone on the couch. The needle is angled in the direction of the first metatarsal joint (Beaudet and Dixon 1981).

Tarsal tunnel syndrome

Entrapment of the posterior tibial nerve by the flexor retinaculum can occur behind and below the medial malleolus. Patients present with burning, tingling, and numbness in the distribution of the nerve, most prominently in the toes and distal part of the sole. Tenderness with a positive Tinel sign elicited by percussion over the nerve near the medial malleolus will confirm the diagnosis. Injection under the flexor retinaculum between the calcaneum and medial malleolus may relieve the symptoms.

Posterior heel pain

Achilles tendinitis includes several lesions such as an enthesopathy at the insertion of the tendon, typical of the spondylarthropathies, and also bursitis and peritendinitis which affect the tendon at a distance from its insertion. All these lesions can result from inflammatory disease, or follow sports or other injuries. Rheumatoid nodules, gouty tophi, and xanthomata can also develop along the Achilles tendon. Partial tendon rupture or core necrosis of the Achilles tendon cannot be clinically distinguished from Achilles tendinitis.

The enthesopathy lesion is diffuse and not readily amenable to injection therapy. While steroid injection is feasible with peritendinitis or bursitis, it is not always successful (DaCruz *et al*. 1988), and is only justified once partial tendon rupture has been excluded, using ultrasound or other radiological investigations. Even if partial tendon rupture is not found, patients need to be warned of the risk of tendon rupture following steroid injection (Galloway *et al*. 1992). Short-acting steroid agents lessen the risk of rupture, especially if patients avoid exercise for a few weeks following the injection.

Inferior heel pain (Fig. 19)

Fig. 19 Injection of plantar fasciitis and plantar heel pain.

A plantar (calcaneal) spur is a common finding on routine radiographs of the heel. These spurs may be asymptomatic or can cause pain under the heel. While most spurs are idiopathic in origin, they are also common in the spondylarthropathies. These lesions can be associated with more diffuse pain radiating up the arch of the foot (plantar fasciitis), especially in patients with reduction in the longitudinal arch of the foot.

Pain under the heel and plantar fasciitis can usually be improved by the use of a cushioned insole, although a local steroid injection under the heel may be indicated for resistant cases. If an injection is needed, the thick skin of the sole should be avoided, with injection being made from the medial side after careful localization of the point of maximum tenderness. The needle is inserted tangentially through the softer skin, so the point of the needle is under the point of maximum tenderness near the bony spur. A cushioned insole should also be provided following injection but recurrence of pain is common. In patients with plantar fasciitis, rupture of the calcaneal origin of the plantar spur may follow steroid injection, with recurrence of pain of a different type after a symptom-free period (Sellman 1994). With very large plantar spurs, surgical excision is necessary.

Forefoot

Metatarsophalangeal joints (Fig. 20)

Fig. 20 Injection of the first metatarsophalangeal joint.

Forefoot pain is extremely common in inflammatory and degenerative arthropathies, and steroid injection therapy is often very effective in reducing pain (Helfland 1973) especially in the period before serious deformity has developed. The lateral metatarsophalangeal joints are located by moving the toe between thumb and forefinger. Once the joint line is found and marked, the joint is injected through the dorsum of the toe with the needle entering tangentially from the lateral side, passing under the extensor tendon which overlies the dorsum of the joint. The first metatarsophalangeal joint is sometimes easier to enter from the medial side, using a similar technique to the other joints. The foot joints need to be injected with particular care, as the risk of infection is greater than at other sites.

Other lesions amenable to steroid injection

While many other lesions can be treated with steroid injection, they often require greater expertise. The temporomandibular joint (Ahlqvist and Legrell 1993), sacroiliac joint (Maugars *et al*. 1992), coccyx (Wray *et al*. 1991) and painful trigger-points in the spine (Garvey *et al*. 1989), and many sports injuries are examples of other lesions which may benefit from steroid injection. Subcutaneous rheumatoid nodules (Ching *et al*. 1992) and ganglia can be shrunk by intralesional steroid injection, although this is not widely practised. Steroid injection has particular importance in juvenile chronic arthritis (Evans *et al*. 1991; Honkanen *et al*. 1993) in an effort to limit growth-related deformities, particularly in weight-bearing joints (Eich *et al*. 1994).

Conclusion

Local steroid injection is one of the most useful therapeutic modalities for the amelioration of pain arising from joint and soft tissue structures. While considerable latitude exists with regard to the precise technique employed, the method must be based on a safe and accurate aseptic no-touch technique. A method of joint injection has been described, with consideration of the most frequently used injections described on a regional basis.

6.6 Sports medicine

Mark Harries

Introduction

This chapter provides a basis for understanding the essential metabolic processes involved in muscle movement and how these translate to human performance. The adaptive responses of the cardiorespiratory and musculoskeletal systems to exercise are also explained. The chapter concludes with a description of the consequences of overreaching these adaptive processes.

Fundamentals of metabolism

The energy for muscular activity derives from a cycle of chemical reactions in which ingested carbon-based fuels are burned with oxygen liberating carbon dioxide. This forms carbonic acid in the tissues which dissociates to bicarbonate and hydrogen ions; a reaction that is catalysed by carbonic anhydrase. Carbonic acid is in dynamic equilibrium with its dissociation products and with CO_2. The high solubility of CO_2 compared with O_2 (more than 20 times as great), coupled with the wide distribution of carbonic anhydrase in the tissues, means that the rate at which CO_2 is mopped up and voided from the lungs can always keep pace with its rate of production. In other words, CO_2 can never accumulate, even during extremes of exertion.

The tendency is always toward a metabolic acidosis, but this is completely overwhelmed by the capacity of the tissues to absorb CO_2 and the capacity of the lungs to dispose of it. The equivalent loss of hydrogen ions by the lung compared with the kidney is in the order of 250:1 and so even during moderate exercise, pH does not change. However, as exercise levels increase, lactate begins to accumulate and the subsequent metabolic acidosis stimulates ventilation with the result that arterial CO_2 may actually fall (Fig. 1).

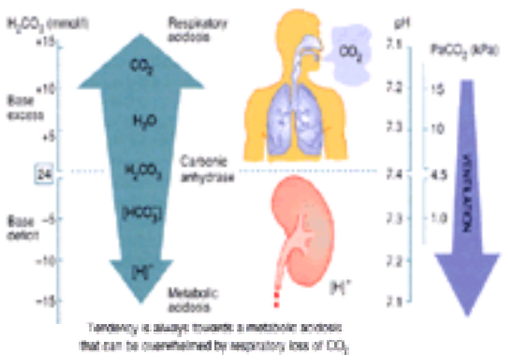

Fig. 1 Metabolism: an acid generator. Oxidation of carbon-based fuels causes a metabolic acidosis due to the conversion in the tissues of CO_2 to carbonic acid by carbonic anhydrase. This tendency is overwhelmed by the capacity of the tissue to absorb CO_2 and the capacity of the lungs to dispose of it. The ratio of the loss of hydrogen ions via the lungs and kidney is of the order of 250:1. Thus, CO_2 can never accumulate, and during moderate levels of exercise, arterial pH does not change. Tendency is always to towards a metabolic acidosis that can be overwhelmed by respiratory losses of CO_2.

How muscle uses its fuel

Energy for movement comes from the hydrolysis of adenosine triphosphate (**ATP**) forming adenosine diphosphate (**ADP**) and liberating 7.6 kcal/mol of ATP. Only around 40 per cent of the energy yield goes into creating tension between molecules of actin and myosin. All is eventually lost as heat. Though the store of ATP is small (only around 10 mmol/kg wet muscle weight), turnover is very rapid and is virtually inexhaustible during sustained moderate exercise. The two principal fuels for ATP synthesis are glucose and long-chain fatty acids: these are available directly fom the diet, or can be liberated from stores—glucose from glycogen in muscle or liver and fatty acids from triglycerides stored in fat cells.

Glycolysis and b-oxidation

The metabolism of both glucose and fatty acids to acetyl coA is an aerobic process. Glycolysis of 1 mol of glucose to form acetyl coA yields 2 mol of ATP (3 mol if the starting point is glycogen). Long-chain fatty acids are metabolized to acetyl coA by b-oxidation, each pair of carbon atoms cleaved from the chain yielding 5 mol of ATP and 1 mol of acetyl coA. Thus, b-oxidation of 1 mol of palmitic acid ($CH_3.(CH_2)_{14}.CO_2H$), would generate 35 mol (5 × 7) of ATP and 8 mol of acetyl coA (Fig. 2).

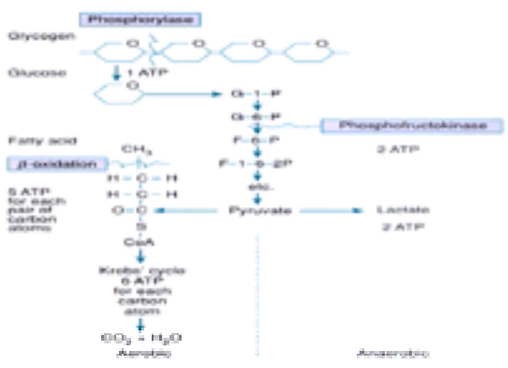

Fig. 2 Glycolysis and b-oxidation. 'Fat burns in a carbohydrate flame'; trained athletes have a greater dependence on fat as a fuel source than the untrained, thereby conserving carbohydrate stores (glycogen). The greatest energy yield comes from mitochondrial respiration. Higher energy demands are met with a switch to anaerobic metabolism and the production of lactate. The rate at which lactate is metabolized is exceeded by its rate of production at around 4 mmol/l. Higher levels can be tolerated, but only for short periods of time. Inherited deficiency of muscle phosphorylase or phosphofructokinse limits performance by restricting glycolysis.

Glycogen accumulates in muscle and liver.

The rest of the oxidative process takes place within the mitochondria in the citric acid (Krebs') cycle and is the source of the greatest metabolic energy yield. Acetyl coA donates two carbon atoms to each turn of the cycle. An *aide mémoire* is that 6 mol of ATP is generated for each carbon atom of the fuel source, such that 1 mol of glucose ($C_6H_{12}O_6$) yields 36 mol of ATP (giving a total of 38 mol when considering the 2 mol generated from glycolysis, or 39 mol if the starting point is glycogen). One mole of palmitic acid ($C_{16}H_{32}O_2$) gives 96 mol of ATP which, when the 33 mol generated from b-oxidation are added, provides a total yield of 129 mol of ATP.

During aerobic exercise, glucose is the preferred fuel, with a gradual switch to fatty acids as glycogen stores are depleted. This rather complex picture is encompassed by the adage 'fat always burns in a carbohydrate flame'. A feature of training is a greater dependence on fatty acids than in the untrained state resulting in a more efficient use of glycogen, which is in limited supply in comparison with the vast stores of fat.

Anaerobic metabolism

For higher energy demands, glucose becomes the exclusive fuel and is metabolized anaerobically with the production of lactate. The energy cost of doing this is enormous, with only 2 mol of ATP generated for each mole of glucose consumed (about 38 mol are produced by aerobic glycolysis). Anaerobic metabolism cannot be sustained because lactate production soon exceeds its rate of metabolism, a point reached when plasma lactate rises beyond a threshold level of 4 mmol/l. When this anaerobic threshold is attained, trained athletes are able to exercise closer to their maximal aerobic capacity (max $\dot{V}O_2$) than sedentary people. In the short term they are also able to tolerate much higher plasma lactates, which may reach 15 to 20 mmol/l in power athletes such as sprinters.

Dietary considerations for energy sources

It follows from the above that glucose is the principal fuel for heavy exercise and fat for low-intensity endurance work. This is reflected in the dietary advice given to the majority of athletes engaged in aerobic sports. Carbohydrate should form 60 per cent of the diet with protein comprising 15 per cent and the rest being fat. The greater the glycogen store, the longer glucose can be burned before fat stores are utilized. This is of great importance in events such as the marathon, triathlon, and cross-country skiing. The concentration of muscle glycogen is in the range 60 to 150 mmol glucosyl units/kg wet weight. Trained athletes can increase this by gorging carbohydrate foods in the few days before competition (Coyle 1991). Simple sugars eaten in such quantities are unpalatable and starch-containing foods such as pasta or potatoes are preferred. It is now accepted that the abundance of phosphocreatine stores is also important in sustaining force during muscle contraction. Ingestion of around 20 g of creatine per day will add to whole body creatine.

Inherited disorders of glycolysis

Deficiency either of muscle phosphorylase (McArdle's syndrome) or phosphofructokinase (Tarui's disease) causes a failure of glycolysis, with the result that glycogen cannot be accessed and instead accumulates in muscle and liver. Of the two, Tarui's disease is much the rarer (Haller and Lewis 1991). Both defects share an autosomally recessive mode of inheritance and so there is often evidence of consanguinity. Both are more common in boys but neither is sex linked. The clinical presentation is that of excessive fatigue on exertion associated with muscle pain, raised serum levels of creatine kinase and blilirubin, and sometimes myoglobinuria. Symptoms may not appear until the second or even third decade of life. Glycogen storage disease type II, deficiency of a $_1$-glucosidase (known variously as acid maltase deficiency or Pompe's disease), presents with respiratory failure as late as the mid-forties. The diagnosis is made on periodic acid–Schiff staining of the muscle biopsy, which shows massive accumulations of glycogen (Fig. 3). Since glycolysis is blocked, pyruvate is never synthesized and there is failure to generate lactate, or in other words, there is a relative incapacity for anaerobic power. The principal fuel then becomes fatty acids, with a slower energy yield, hence fatigue on anything but light work rates.

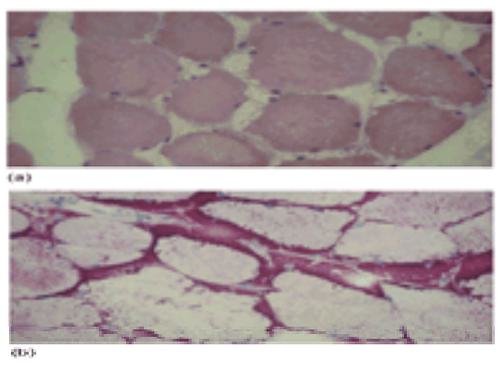

Fig. 3 Inherited disorders of glycolysis. A 17-year-old Royal Naval recruit complained of fatigue and muscle stiffness on exercise although he had been a good sportsman while at school. An exercise test was terminated early due to exhaustion. Samples taken throughout showed that his blood lactate failed to rise. Glycogen in muscle stains pink with periodic acid–Schiff reagent and normally shows as just a few granules around each muscle fibre (a). By contrast, the biopsy sample of the recruit (b) is full of glycogen, which is unavailable for glycolysis due to an inherited deficiency of myophosphorylase (McArdle's syndrome).

Limitations to aerobic work rates

During vigorous exercise, muscle burns all the oxygen available to it. Further demands are met by a switch to anaerobic metabolism with its concomitant limitations imposed by lactic acidosis. The principal factor containing aerobic capacity involves the rate at which oxygen can be delivered, which is itself dependent on three factors: haemoglobin concentration, minute ventilation (pulmonary output), and cardiac output.

The importance of haemoglobin concentration

In the laboratory, the oxygen combining power of haemoglobin is quantified at 1.39 ml of oxygen for each gram of haemoglobin; but in vivo, haemoglobin passing though the lungs picks up only around 1.306 ml/g of haemoglobin. A shift in haemoglobin concentration within the normal range, say from 11 to 18 g/dl, would increase oxygen delivery by a factor of 1.6. It has been well documented that raising haemoglobin beyond the normal range translates directly to an increase in maximal oxygen consumption and an improved performance (Brien and Simon 1987).

Altitude training gives rise only to modest increases in haemoglobin—1 to 2 g/dl at most. For a bigger advantage illicit means have been sought. At the 1984 Olympic Games in Los Angeles, the American cycling team came from nowhere, and contrary to expectations and form, swept the board. Some months later it was revealed that seven of the successful team members had received a transfusion of blood the night prior to competition (Klein 1985). Erythropoietin is now being used with the same ends in mind and has the added advantage that it is virtually undetectable. Paradoxically, highly trained athletes may have a haemoglobin at or below the lower limit of normal: this reflects an increase in plasma volume due to heavy training and is not a true anaemia. If serum ferritin levels are normal, no treatment is indicated in these cases.

Minute ventilation and aerobic performance

While exercising at the maximum sustainable ventilatory capacity (**MSVC**), ventilation can be increased still further for short periods to reach maximum voluntary ventilation (**MVV**). The MSVC is found to be 55 to 80 per cent of MVV (Freedman 1970) or, put another way, assuming that the lungs are normal, the capacity to increase ventilation is so great that the key factor that most limits aerobic performance is likely to be the cardiac output rather than minute ventilation.

Pulmonary conditions limiting ventilatory capacity

The relationship between maximum aerobic capacity (max VO_2) and MSVC is roughly linear: the higher the max VO_2 the higher the ventilatory capacity. This holds true whether VO_2 and MSVC are measured in absolute terms (l/min), or independently of body size (ml/kg per min) (Fig. 4). Minute ventilation is the product of the respiratory rate and breath volume. While exercising at maximum aerobic capacity, respiratory rates are remarkably consistent. Young men take around 60 breaths and women 55 breaths a minute. Given a respiratory rate of 60/min, breath volume clearly cannot exceed the forced expiratory volume (**FEV_1**). Elite oarsmen access only around 50 per cent of FEV_1 each breath compared with middle-distance runners who reach around 60 per cent of FEV_1. This accords well with the formula used to estimate ventilatory capacity from FEV_1 (MSVC = [FEV_1 × 30] + 23). Hence it follows that any condition of the lung in which FEV_1 is significantly reduced will have an impact on aerobic capacity by reducing minute ventilation.

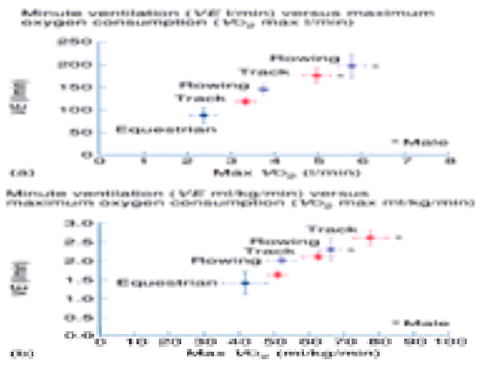

Fig. 4 The importance of high ventilatory capacity. Minute ventilation (VE) at maximum oxygen consumption (max VO_2) is measured in 120 Olympic class athletes grouped according to their sport. The relationship between ventilation and oxygen consumption is linear, whether measured in absolute terms or corrected for body weight. The higher the oxygen consumption, the higher must be the minute ventilation. The highest values are recorded in men, with track athletes at the top according to body weight. Equestrian competitors engage in a more sedentary sport and represent values closer to those which would be expected in normal fit individuals in their mid-twenties.

Asthma

Although chronic bronchitis and emphysema are diseases that reduce ventilatory capacity, they are diseases of older people. Asthma, on the other hand, occurs at all ages and is also much commoner, accounting for around 20 per cent of complaints concerning underperformance received from athletes attending the British Olympic Medical Centre.

The most important feature of asthma for the sportsman is that it worsens during exercise and therefore impacts both on performance and on training. Treatment is highly effective and, therefore, a reproducible diagnostic test is important. However, there is no agreed protocol for exercise testing, although certain ingredients appear to be important. Running in the open air is a more potent stimulus to bronchial constriction than exercising on a cycle or treadmill ergometer. The reasons for this are complex and related in part to climatic conditions. Cold dry air causes more bronchial constriction than warm moist air. The exercise must be rigorous, enough to raise the heart rate to around 80 per cent of the maximum that can be achieved (approximately 220 minus age in years). The duration of the test is also important. It should last at least 3 min but not much longer than 5 min.

Normal subjects may show a short-lived bronchial dilatation on stopping, but a fall in FEV_1 or peak flow of more than 15 per cent occurring 5 to 10 min after exercise is a positive test. Treatment is with an inhaled steroid such as budesonide turbohaler 200 µg twice daily (Fig. 5) (Harries 1994).

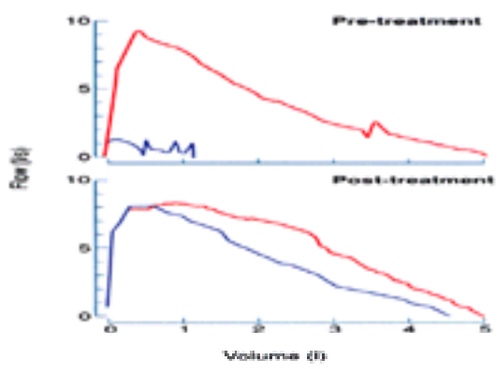

Fig. 5 Exercise-induced asthma. This example of severe bronchial constriction induced by exercise was recorded in an athlete with a clear history of sleep disturbance due to wheeze and tightness in the chest. Flow is plotted against the volume in a forced expiratory manoeuvre from full inspiration to full expiration. Two expiratory efforts are shown; one measured before exercise (red line) and the second around 5 min after a 3-min run (blue line). Peak flow measured 9 l/s before exercise and less than 1 l/s afterwards, representing a fall of more than 80 per cent. Oscillations in flow during expiration are caused by coughing. The athlete was give prednisolone at 30 mg daily for 2 weeks, then continued on beclomethasone dry powder at 400 µg twice daily. One month later the exercise test was repeated under identical conditions (post-treatment). There was no change in peak flow, but more important, pretest FEV_1 had risen 20 per cent from 4.03 to 5.3 l. The exercise test was still marginally abnormal with a small fall in FEV_1 post-exercise and a larger fall in mid-expiratory flow. However, the athlete was sufficiently improved to win a medal at a major international competition just 2 months later.

Anatomical and physiological adaptations to exercise

Elite athletes differ markedly in their physical make-up to sedentary individuals. Whether or not these differences are inherited, or are the result of training, has been the subject of much debate. However, recent evidence suggests that genetic factors are the more important in determining athletic prowess (Bouchard *et al*. 1992).

Adaptations of muscle

The relationship between muscle size and strength is poor. Increase in size reflects fibre hypertrophy and fibre numbers remain unchanged. The greatest hypertrophy results from high-intensity isometric exercise in which muscle is required to contract against a resistance. Strength, on the other hand, may be due in part to fibre recruitment; in other words to an increase in the number of fibres that are available for contractile activity.

Training improves fibre recruitment and chronic endurance training favours the transformation of fast-twitch glycolytic (type IIb) to slow-twitch (type 1) fibres (Dudley *et al*. 1982). Muscle biopsy samples show that capillary density and enzyme activity both increase through training. The mitochondria also appear to increase in number, although this finding may reflect mitochondrial hypertrophy and folding rather than any absolute increase (i.e. it is an artificial observation, reflecting only the cross-section of the biopsy specimen). The net result is an improvement in oxidative potential of muscle with an increase in maximal oxygen consumption in the order of 15 to 25 per cent over time.

Cardiac adaptations

Echocardiography shows that both ventricular dilatation and hypertrophy occur with training. The greatest dilatation is seen in rowers and cyclists, who also show the greatest degree of cardiac hypertrophy; a finding that runs counter to the expectation that strength athletes should develop the most hypertrophy.

Dilatation results in the greatest increase in heart size, such that the cardiac silhouette can be found to occupy more than half the transverse diameter of the chest when observed on a chest radiograph. The diameter of the left ventricle at the end of diastole may reach 7 cm (compared with the normal size of around 5.7 cm). Although this represents only a 10 to 15 per cent increase in diameter, it translates to a 30 per cent increase in stroke volume. A large stroke volume means that adequate cardiac output can be maintained with a lower heart rate. A slow resting pulse is therefore a constant feature of training.

Hypertrophy of the septum and left ventricular wall also occurs but contributes very little to overall change in heart size. Normal wall and septal thickness is from 7 to 11 mm, ranging up to 13 mm in cyclists and rowers. A thickness beyond 16 mm is considered abnormal, particularly if chamber size is not also increased (Pelliccia *et al*. 1991). Disproportionate hypertrophy of the septum with respect to the left ventricular wall may give rise to obstruction of the outflow tract during heavy exercise (see obstructive cardiomyopathy below).

The electrocardiogram is often grossly abnormal with widespread T-wave inversion across the lateral chest leads as far as V4. Multiple nodal (supraventricular) ectopic beats are also common. Both abnormalities tend to correct on exertion. Unfortunately this may also be true of myocardial ischaemia. The resting electrocardiogram, especially recordings made at night, may show bradyarrhythmias with sinoatrial block (Ector *et al*. 1984).

Skeletal adaptations to exercise

Bone density increases in response to exercise in all subjects except amenorrhoeal women. Rise in mineral content is greatest in bone subject to the most stress, such as the femur of runners, the lumbar spine of rowers, and the radius of gymnasts and racket players (Wolman *et al*. 1990). Women who train intensively develop amenorrhoea. The result is a loss in bone density exactly analogous to that which occurs following the menopause. The earliest changes are seen in bone with the highest rate of turnover, and appear first in the trabecular bone of the lumbar spine. Bone loss is detectable after as few as 6 months of amenorrhoea. Losses great enough to result in pathological fracture are usually only seen in women with an associated eating disorder such as anorexia nervosa. Treatment is with oestrogen in the form of hormone replacement therapy (Drinkwater *et al*. 1984; Wolman *et al*. 1991).

Clinical syndromes associated with overexertion

The health benefits of taking regular exercise are beyond dispute. The risk of osteoporotic fracture later in life is reduced (Heinonen *et al*. 1996). Furthermore, there is now direct evidence of a reduced risk of acute myocardial infarction in men and exercise is a major factor in controlling obesity and diabetes (Helmrich *et al*. 1991; Lakke *et al*. 1994), although evidence that exercise benefits hypertension is less strong (Blumenthal *et al*. 1991). Nevertheless, in the United States of America it is recommended that 'every adult should accumulate 30 min or more of moderate-intensity physical activity on most, preferably all, days of the week' (Anonymous 1995).

Sudden death

Although rare, sudden death is almost always due to a cardiac cause. It is assumed that the terminal event is ventricular fibrillation, and limited forensic evidence often reveals an underlying abnormality, such as coronary atheroma or a congenital abnormality of the coronary tree. Even moderate levels of exercise have been implicated; for instance, 12 deaths occurred over 6 years among the joggers of Rhode Island, all but one of these were found to be due to coronary artery disease, with the mortality estimated to be seven times the expected mortality in a sedentary population (Thompson *et al*. 1992). With the rising popularity of veteran events, it is clear that coronary artery disease in sport is going to pose an ever-increasing problem.

Hypertrophic obstructive cardiomyopathy

Obstructive cardiomyopathy, also known as muscular subaortic stenosis, is an absolute contraindication to strenuous dynamic or static activity, because it is a condition that may lead to sudden unexpected death from ventricular fibrillation at a young age. The outflow tract of the left ventricle becomes obstructed in systole by the interventricular septum, which is disproportionately hypertrophied with respect to the ventricular wall. The ratio of the thickness of the septum to the ventricular wall, which is normally 1.3:1, exceeds 1.5:1 (Fagard *et al*. 1984). Death occurs, often in the second decade of life, during the course of vigorous physical activity. Faintness or syncope occurring immediately following exercise is one of the few symptoms, providing an early indication for urgent investigation. The electrocardiogram is unhelpful because T-wave changes suggesting left ventricular hypertrophy are often seen in normal highly trained individuals. The diagnosis is made by echocardiography (Stewart Hillis *et al*. 1994).

The condition is inherited as an autosomal dominant, so all first-degree relatives should be screened. There was once a vogue for treatment with surgery which involved shaving the septum, but medical treatment aimed at suppressing the ventricular arrhythmias is now more established. The drug of choice has been amiodorone, though inhibitors of angiotensin-converting enzyme are currently being assessed.

Both aortic and pulmonary stenosis also cause outflow tract obstruction which may have the same effects as hypertrophic obstructive cardiomyopathy during vigorous exertion. On the other hand, tricuspid and pulmonary regurgitation are very common in the highly trained athlete, occurring in over 90 per cent. The murmurs produced may be difficult to distinguish clinically and expert advice should be sought.

Hyperpyrexia (heat stroke)

During extremes of exercise, rectal temperature may reach 41°C. Heat loss by radiation through peripheral vasodilatation is limited and further losses can only be achieved by evaporating sweat. Once these homeostatic mechanisms are rendered ineffective, such as in a very humid environment or with sweat failure, core temperature rises unchecked. Heat stroke is rare amongst experienced athletes except where there has been stimulant abuse. The usual clinical setting is one of an undertrained individual, competing for the first time and with inadequate fluid intake (Clowes and O'Donnell 1974). A similar picture is also seen in people who have taken amphetamine (speed) or MDMA (Ecstasy) tablets and who have been dancing to exhaustion.

Confusion or coma is the rule with a clinical presentation very similar to septicaemic shock. The skin may be clammy and cold, contrasting with the high rectal temperature. Grand mal seizures occur with decerebrate posturing. Rhabdomyolysis develops early with the creatine kinase often reaching over 100 000 U/l. Paradoxically in the face of dehydration, serum sodium may be low, sometimes below 110 mmol/l. Disseminated intravascular coagulation, renal failure, and liver failure may occur within 24 h (Sutton 1994). Rapid intravenous infusion can be life-saving with an initial infusion of 4 l of saline given in the first hour. Broad-spectrum antibiotics effective against Gram-negative organisms should also be given.

Immune deficiency

There is some evidence that those suffering fatigue syndrome due to overtraining seem to develop frequent infections of the upper respiratory tract. Furthermore, the infecting agent occasionally proves to be unusual (such as *Toxoplasma gondii*). These and other observations have led to the suggestion that overtraining leads to an immunosuppressed state (Khansari *et al*. 1990). Some support for this concept is obtained from studies of plasma glutamine levels. Glutamine is an essential fuel for lymphocytes: it is synthesized by muscle and is found to be low in chronic fatigue states (Newsholme *et al*. 1991).

Drugs to avoid

Amphetamine-like substances and drugs with a-adrenergic (stimulant) actions are all banned. These include isoprenaline, adrenaline, noradrenaline, and phenylpropanolamine. For example, adrenaline may not be given by local injection mixed with an analgesic such as lignocaine. Over-the-counter cold cures often contain one, or more, of these agents.

Selection of an analgesic or anti-inflammatory agent that will not fall foul of the International Olympic Committee's (**IOC**) list of banned substances is made more

difficult by the fact that not only do the rules change from time to time, they also lack consistency. For example, opiate analgesics and pentazocine are banned, but codeine and dihydrocodeine have recently been reinstated: yet dextropropoxyphane remains a banned substance! Corticosteroids may not be given by parenteral injection, which effectively outlaws all depot preparations, but hydrocortisone may be given by intra-articular injection or into soft tissue injuries such as a tennis elbow. At the time of writing, the position of systemically acting corticosteroids is under review by the IOC's Medical Commission.

Such is the state of confusion that some sporting bodies, particularly those not affiliated to the IOC, are beginning to go their own way. That said, there is broad agreement that drugs such as anabolic steroids and amphetamine should be avoided, if only because there is no clinical indication for taking them. However, a blanket ban on so many other medicaments, particularly those that are therapeutically useful, is crude and unworkable.

6.7 Sports injuries

J. R. Jenner and M. Shirley Emerson

Introduction

Regular aerobic exercise has been shown to have a beneficial effect on several aspects of health including:

1. reducing the risk of cardiovascular disease, particularly coronary artery disease and hypertension;
2. reducing the incidence of osteoporosis;
3. helping with weight loss by increasing the metabolic rate;
4. inducing a feeling of general well-being and reducing depression (Report of the Royal College of Physicians 1991).

As a result of these findings, the government has actively encouraged the general population to participate in sporting activities. Unfortunately, one side-effect of sport is injury. If these injuries are not treated promptly and appropriately, the injury may become recurrent or chronic.

Different sports have different rates of injury and different injury profiles (Fig. 1) but the fundamental principles underlying the treatment of acute injuries, as well as their rehabilitation, apply across sports. The major cause of injury in sport is acute trauma to soft tissues such as muscle, tendon, or ligaments. Chronic sporting injuries result from either adverse body mechanics, resulting in excess strain, or overuse, leading to fatigue. Children and teenagers with immature or rapidly growing musculoskeletal systems are prone to injuries not encountered in the adult and these injuries deserve special mention.

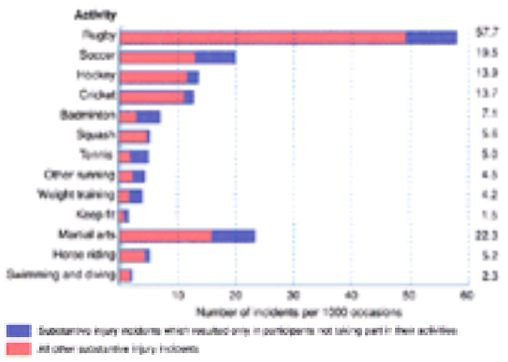

Fig. 1 New substantive injury incident rates by activity in a random sample of 17 564 people aged between 16 and 45 in England and Wales (Nicholl *et al*. 1991)

Injury prevention

Prevention of injury involves several strategies.

Modification of the environment

Many accidents are due to poor surfaces and inadequate equipment. Uneven pitches, collapsing gymnastic equipment, and worn landing mats have all been shown to contribute to injury. These injuries are definitely preventable. Approximately 10 per cent of sports injuries in the United Kingdom are due to collisions with the 'furniture' of the playing field or pitch (Nicholl *et al*. 1991; Coleman *et al*. 1996; Wyatt *et al*. 1996).

Education and behaviour modification

1. Changes in the rules of some games may be necessary to reduce injury levels. Banning the dangerous practices of 'spearing' in American football has resulted in a reduction in the number of injuries producing permanent cervical quadriplegia (Torg *et al*. 1985).
2. Good referees are needed to prevent deliberate fouls, which often lead to injury.
3. Continuing player education is also important to persuade players to obey the rules and not to indulge in 'sport rage'.
4. Trained coaches should have a good knowledge of exercise physiology and be able to advise on good techniques, diet, and to help players avoid overuse injuries through improved training techniques.
5. Matching of young players in team games should be done by size and not by age.
6. Relevant protective equipment should be used. Mouth guards have been shown to reduce the number of dental and oral injuries but many players do not like using them (Jennings 1990). Protective goggles in squash and shin pads in football are examples of the equipment that can reduce injury.

Personal strategies

1. Training to build up muscle strength and endurance. Many injuries occur during the second half of a game, when fatigued muscles do not respond quickly to new situations. This is seen particularly in weekend athletes who do no other training.
2. Warm up and cool down. There are differing opinions on the benefit of warm ups and much of the evidence is anecdotal but the majority of athletes and coaches

are in favour of some mobility exercises and gentle exercise to raise the heart rate and body temperature. After an intense effort, continuing light exercise does seem to allow an enhanced rate of removal of lactic acid and also prevents blood 'pooling' in the lower limbs. Improving flexibility both before and after exercises is reported to reduce injury levels but there is little hard evidence to support this.

3. Diet. There is overwhelming evidence as to the importance of adequate carbohydrate intake while competing and training to maintain and replace muscle glycogen. Carbohydrate should provide 50 to 60 per cent of the calorie intake and the athlete may need to take some of this as a carbohydrate drink (Costill and Hargreaves 1992). Cyclists on the *Tour de France* need to consume about 7000 calories/day and this would be impossible to eat as solid food.
4. Hydration. Most athletes are now aware of the importance of adequate rehydration but children need to be encouraged to drink as part of the game. Immediate postexercise replacement of fluid and carbohydrate, within the first hour, has been shown to restore rapidly muscle glycogen. Reduced glycogen levels lead to muscle fatigue and injury and reduced muscle glycogen is associated with a reduction in muscle and plasma glutamine levels.
5. Avoiding overtraining. Many athletes and sports players are convinced that 'more is better' and are not prepared to incorporate rest and recovery into their schedule. The overtraining syndrome produces symptoms of fatigue, sleeplessness, and loss of appetite (Budgett 1995). Intense and prolonged exercise has also been shown to produce immune system depression for 6 to 20 h after exercise (Newsholme 1994). This may explain why an athlete is more susceptible to injury and illness, including opportunistic infections such as toxoplasmosis and why injuries may take longer to heal.

Acute injuries

Acute management

Trauma results in bleeding. Blood in the extra vascular space is an extreme irritant causing an acute inflammatory response with swelling, an increase in pressure, and, if this pressure becomes great enough, tissue necrosis occurs (Fig. 2). Acute treatment of soft tissue trauma is aimed at limiting the bleeding and its subsequent deleterious affect (Fig. 3). This is achieved by:

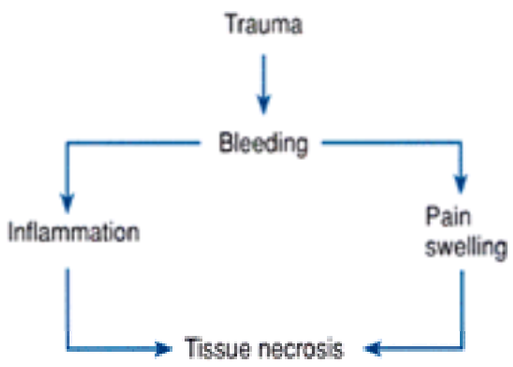

Fig. 2 Flow chart of sequence of events after soft tissue trauma.

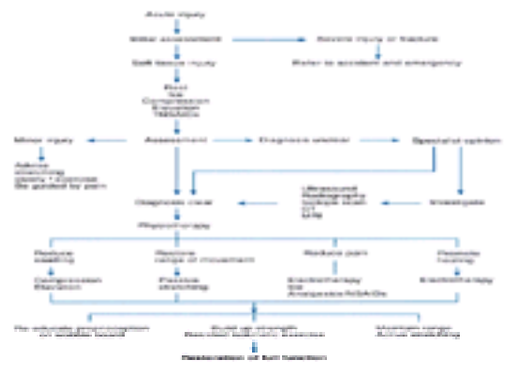

Fig. 3 Flow chart for the treatment of soft tissue injuries after acute injury.

1. rest
2. ice
3. compression
4. elevation
5. non-steroidal anti-inflammatory agent.

This treatment is often given the mnemonic of RICE or NICER.

Rest

Rest is the fundamental treatment for an acute injury. It is essential to limit the trauma and to minimize the bleeding. Once an injury has been sustained, the injured player must immediately leave the field of play. This allows an immediate assessment of the injury to be made and for prompt first aid measures to be instituted. This early assessment can be vital as injuries such as ruptured cruciate ligaments can quickly be masked by bleeding and effusions in the knee and delay an accurate diagnosis.

Ice

Ice has become the traditional agent to help stop bleeding and reduce pain. The mechanism by which ice influences the underlying vasculature is complex. While superficial skin blood flow is reduced, there is an initial short period of increased blood flow in the underlying tissues followed by alternating vasospasm and dilatation. It has been suggested that this 'pumping' action may be beneficial in removing oedema from the muscles.

Compression

Compression is probably the most effective means of limiting bleeding. The application of a firm bandage such as 'Tubigrip' over the whole of a limb may be helpful where direct pressure is difficult or inappropriate. It is important that pressure is not applied so tightly that it interferes with arterial or venous blood flow and therefore cause further damage.

Elevation

Tissue injury causes an acute inflammatory response followed by the development of oedema. The increased tissue pressure can reduce blood flow, increase pain, and delay healing. Swelling can be reduced by elevating the injured limb or, in the case of an injured leg, just by lying down.

Non-steroidal anti-inflammatory drugs

The treatment of soft tissue injury with non-steroidal anti-inflammatory drugs is controversial. Oral non-steroidal anti-inflammatory drugs will reduce pain and

inflammation but probably only have a marginal beneficial effect on the healing process. They also have significant potential side-effects. If prescribed for acute soft tissue injuries, non-steroidal anti-inflammatory drugs are best prescribed for no more than 2 to 3 days after the injury. Topical non-steroidal anti-inflammatory drugs have a lower side-effect profile and exert a small beneficial effect in soft-tissue injuries, helping with an early return to sport.

Haematomas

Muscle haematoma may be due to either extrinsic or intrinsic injury (Table 1). After injury, there is disruption of the muscle fibres and capillaries with associated bleeding. The torn ends retract from the injury leaving it filled with blood.

	Extrinsic	Intrinsic
Mechanism	Direct trauma or compression	Overstretching or overload
Pathology	Muscle compressed against bone	Sudden contraction of a muscle against resistance
Cause	Contact sports	Stretching or sprinting

Table 1 Muscle haematoma

An intact muscle sheath results in an intramuscular haematoma—a swelling within the muscle—causing pain and a considerable amount of disability which resolves slowly over many weeks. An intermuscular haematoma results when there is a tear in the fascial sheath or there is a tearing of vessels between the muscle fascicles. In this situation the blood disperses by gravity, to some distance away from the injury and, although the appearance is quite spectacular with considerable bruising, these injuries tend to recovery within 2 to 3 weeks (Fig. 4).

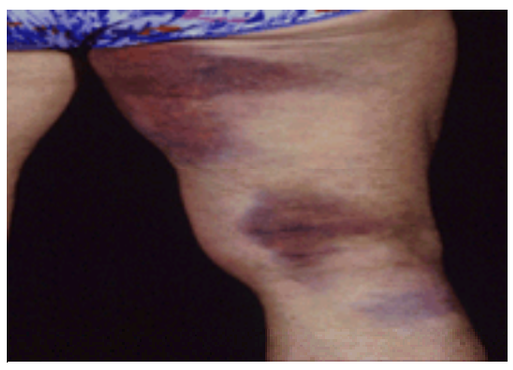

Fig. 4 Dramatic bruising in posterior thigh of rugby player caused by sprinting.

Symptoms depend to some degree on the type of injury. In a compression injury such as a rugby tackle, when the quadriceps muscle is compressed against the femur, the bleeding may be slow allowing the player to continue and only after the game does the increased swelling and accompanying pain and disability become apparent. An overstretching injury is sudden and acutely painful immediately. The commonest presentation is seen in sprinters who overstretch suddenly and tear hamstring muscles. Here the sudden acute pain feels like a blow on the back of the leg and may be severe enough for the athlete to fall to the ground. The diagnosis is usually fairly straightforward. Patients with a severe intramuscular haematoma of the hamstrings often present with a flexion deformity. There is some evidence that the greater the loss of flexion, the longer the time required for healing and return to sport (Renstrom 1988).

The clinical appearances and history are usually diagnostic. The presence of an intramuscular haematoma can be confirmed and treatment monitored by ultrasound.

Rehabilitation

Except in the most severe haematomas, early mobilization is indicated as it:

1. speeds the return of muscle strength;
2. improves the orientation of regenerating muscle fibres;
3. encourages recapillarization;
4. prevents disuse atrophy.

After 48 h of rest and ice, a rehabilitation programme should begin. This should initially consist of gentle stretching with the aim of restoring a full range of joint movement. The physiotherapist may also use various modalities of electrotherapy, such as pulsed magnetic energy, to assist healing. Stretching and strengthening programmes for all the muscle groups of the involved limb are essential, as some injuries may be due to a pre-existing lack of elasticity either in the injured muscle or its antagonist. The importance of balance between the muscle groups in the prevention of injury has been recognized and may be measured using an isokinetic machine, both for assessment and muscle retraining.

Cardiovascular fitness can be maintained by cycling (real bike or exercise bike), swimming, and running in water using a specially designed 'wet vest' to keep the athlete upright. Apart from the physical benefits of this exercise, being active in this way helps to maintain the sanity of the injured athlete. Many committed athletes become anxious and even depressed if exercise is not permitted.

Return to sport

A muscle haematoma can be considered to be completely healed when there is full and pain free muscle contraction. An intermuscular haematoma will usually resolve in 2 to 4 weeks. An intramuscular haematoma may take 8 weeks or more to completely heal, but there is a great variation depending on the site and severity of the injury. Before returning to competition, a further programme of sport-specific training must be carried out. This includes sprints, rapid deceleration, twists, and sharp turns. Co-ordination and proprioception are impaired by injury and the athlete must relearn specific techniques with the help of a coach.

Myositis ossificans

A severe crush injury may be followed by the development of heterotopic ossification or myositis ossificans. This is more likely to occur if the injury is aggravated by continuing activity and further bruising. Applications of heat and vigorous massage all appear to irritate an already irritable muscle, although the exact cause of the calcification is not clear. Suspicions are raised if the patient is unable to achieve full contraction of the affected muscle. The calcification may be seen on radiographs and ultrasound.

Various treatments apart from rest have been used, including high doses of indomethacin and diphosphonates (DeLee and Drez 1994), but with doubtful efficacy. The use of a calcium channel blocker—Diltiazem—may offer a safer alternative (Palmieri *et al*. 1995). Most cases resolve symptomatically over a period of 3 months, although the calcification may persist radiologically. Intervention is rarely required unless mobility or persistent flexion deformity persists for over 6 months.

Muscle ruptures

Muscles may rupture and, although the defects look dramatic (Fig. 5), they rarely need surgical repair unless the rupture is complete.

Fig. 5 Partial rupture of pectoralis major resulting from pulling against resistance in a rugby maul.

Chronic injuries

The vast majority of chronic sports injuries are to the lower limb, predominantly affecting the knee. A description of the majority of these injuries and their treatment can be found in other sections of this book, particularly the section on soft tissue rheumatism (Chapter 5.14). In this section a few of the commonest problems encountered in a sports injury clinic are described—further information can be found in specialist textbooks (Lachmann and Jenner 1994; Harries *et al*. 1994). A careful history is important for diagnosis, particularly to ascertain if there has been overuse or a sudden unaccustomed use of the lower limbs. Type and age of footwear as well as training surface must be enquired after, as well as taking a full history of the pain problem.

Examination must always start with the spine and include the whole upper or lower limb. Leg length inequality of more than 1 cm should be noted. Chronic lower limb sporting injuries are frequently associated with the 'malicious malalignment syndrome' with a broad pelvis, patellas that look towards each other, internal tibial torsion, and flat or hyperpronated feet. Examination should include the joints, soft tissues, and neurological system as well as skin and circulation. The examination is completed by inspecting the running shoes for signs of wear.

Correcting leg length inequality with a simple insole may resolve back problems. Simple shock absorbing insoles may also help many chronic overuse problems. The use of more elaborate insoles to correct hyperpronation and other foot problems are also popular but their success is unpredictable.

Stress fractures

In 1855, a German military physician, called Breihaupt, was the first to describe fractures of the foot bones in new recruits, not caused by direct trauma but by the stress of marching. Stress fractures can occur in any loaded bone and are seen most commonly in lower limbs, particularly in the tibia and metatarsals but they also occur in the upper limb, such as in the ribs of rowers and the arms of gymnasts (Fig. 6) (Matheson *et al*. 1987).

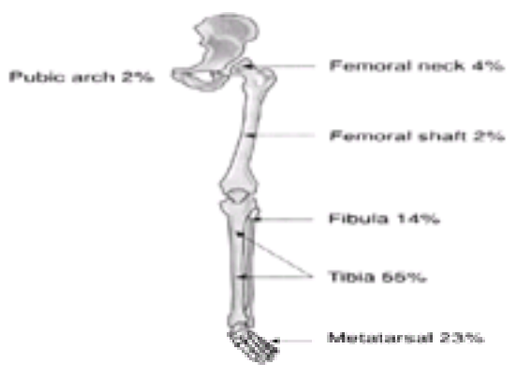

Fig. 6 Percentage of stress fractures occurring at different sites in the lower limb.

Stress fractures occur when bone fails to adapt to new or unusual loading. Normally, microdamage stimulates new bone where needed. When microdamage outpaces the development of new bone, a stress fracture results. Foot biomechanics may influence the development of stress fractures, such as rigid, poorly adapting feet or conversely hypermobile feet. Running on hard surfaces using 'collapsed' running shoes or racing flats certainly has an influence. Women appear to be at greater risk of developing a stress fracture. In a survey of 218 consecutive patients presenting with a stress fracture to our sports injury clinic almost half were women, although women only accounted for a quarter of all the patients seen in the clinic (Fig. 7). Some of the fractures may be due to an inadequate calorie and calcium intake in sports where leanness is favoured, especially if low food intake results in amenorrhoea and secondary osteoporosis. These factors do not entirely account for the high incidences in women.

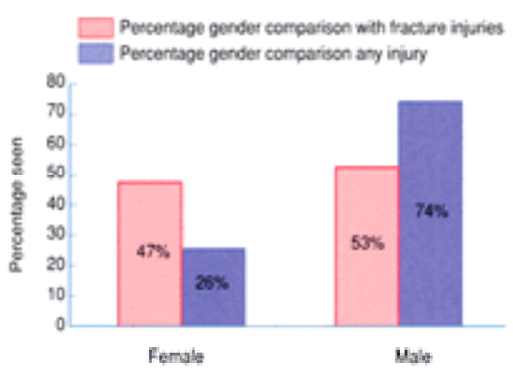

Fig. 7 Comparison of the incidence of stress fractures and all injuries between females and males attending a sports injury clinic.

Clinical features

In vigorous sports, such as high jumping and gymnastics, the onset of pain is sudden and acute, completely preventing the continuation of the activity. In other less explosive sports, such as long distance running, the onset maybe insidious over several days or even weeks, with pain present at first only during exercise and weight bearing but eventually aching at rest and during the night. The site of the pain is very localized and local pressure produces exquisite pain over the fracture, causing the patient rapidly to pull the injured limb away. A stress fracture may be diagnosed on these clinical grounds, but in order to persuade an exercise-addicted athlete to rest there is frequently a need for some corroboration.

Radiographs are not very helpful as they do not show the injury until it is healing and maybe not even then. Bone scans are extremely sensitive and can differentiate between osteitis of the tibia and a stress fracture. Although not absolutely necessary for diagnosis, a positive scan does help to convince the athlete of the nature of his problem and need for rest (Fig. 8).

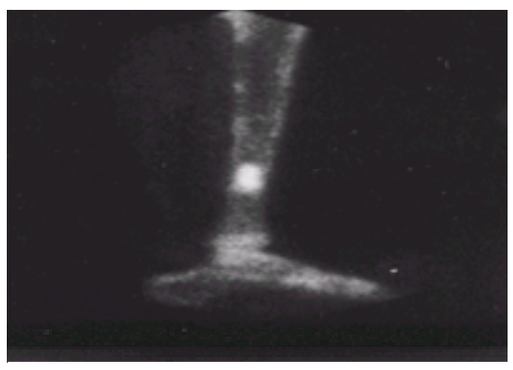

Fig. 8 Tc-99m bone scan showing high focal uptake typical of a stress fracture of the tibia.

Although the majority of stress fractures respond to conservative measures, stress fractures of the femoral neck have the potential for serious complications, including avascular necrosis and persistent non-union, and may need a surgical assessment (Fullerton and Snowdy 1988). These present with vague groin pain, pain in the anterior thigh and the knee, and are most commonly seen in long distance runners.

Management

Reduction of weight bearing is essential, usually with the help of elbow crutches. Modification of activity should continue until symptoms are absent. This can take 6 to 8 weeks and during this time the athlete can do some form of non or partial weight-bearing exercise, such as swimming, water walking, and cycling. Sport can be resumed when there is no pain on weight bearing and must be gradually increased. A stretching and strengthening programme should be carried out.

Using this regime, the majority of athletes will be able to return to sport in 6 to 8 weeks. Problems arise when the athlete is not prepared to rest. Under these circumstances the fracture can continue to cause problems for several months and sometime the only way to prevent continuing disability is to apply a plaster of Paris case and insist on no weight bearing. If not properly dealt with, a stress fracture can persist for 6 months or more.

Anterior knee pain

A patient presenting with poorly localized anterior knee pain, without any history of trauma, is a very common occurrence in a sports injury clinic. The patient is often teenage and a sports enthusiast, playing or training on a daily basis. However, older patients responding to advice to increase their exercise also present with this problem.

Aetiology

Patellofemoral joint stability depends on many factors (Table 2). Any of these factors can cause an imbalance of the patellofemoral joint. It has long been assumed that patellofemoral pain was caused by abnormal patella tracking but all of these anatomical variations are common in the general population and only cause problems when the patellofemoral joint is subjected to chronic overload by repetitive overuse and obvious eccentric contraction strains as in deep squats (Thomee *et al*. 1995).

Torsional deformities of tibia/femur (winking or frog eye patella)
High or lateral patella
Weak or absent vastus medialis obliquus
Tight muscles on the lateral aspect — vastus lateralis and iliotibial band
Increased quadriceps angle
Excessive foot pronation
Weak ankle dorsiflexors
Reduced range of motion at the ankle
Tight hamstrings

Table 2 Factors predisposing to patellofemoral pain syndrome

Clinical features

The patient complains of generalized anterior knee pain and may exhibit the 'grab' sign—holding the whole of the front of the knee. There is no history of trauma but more of a gradual increase in pain over several weeks, often affecting both knees. The pain is made worse by activity, either during sport or going up and down stairs. Sitting with the knee in flexion causes acute discomfort, such as sitting in a cinema, giving the so-called 'movie sign' (Insall 1982). The knee may feel unstable or 'give way'; this is due to reflex quadriceps inhibition rather than a true instability. Clicking and crepitus is common. There is pain and sometimes crepitus if the patella is compressed and moved proximally and distally. There is usually some tenderness along the very anterior joint line and at the attachment of the medial and lateral retinacula. Patella inhibition is elicited by holding the patella at the proximal pole and flexing the knee to about 20°. Straightening the leg causes pain and the patient stops the movement.

Patella subluxation, which can present with similar symptoms, is excluded by the patella apprehension test. The patella is usually very mobile and pushing it sideways produces great anxiety. Treatment is aimed at stabilizing the patella with appropriate quadriceps exercises.

Management

The patient, and often parents, need to be reassured that this complaint is common and does not mean indefinite incapacity. Radiographs may be required to exclude

any more serious pathology, especially if the problem affects one knee only. In mild cases, some reduction of the level of activity is all that is necessary—the patient decides what is tolerable. Activities not causing pain, such as swimming, can be substituted to maintain fitness. Local applications of ice after exercise and a course of non-steroidal anti-inflammatory drugs can hasten recovery.

Rehabilitation

When the acute symptoms have been alleviated, a strengthening and stretching programme involving hamstring and quadriceps is begun under the care of a sports-orientated physiotherapist. The treatment involves selectively strengthening the vastus medialis obliquus, while at the same time reducing the pull of the vastus lateralis. Strengthening of the quadriceps as a whole has been replaced by work only on vastus medialis obliquus (Shelton 1991). There is also some evidence that patellofemoral dysfunction may be related to abnormal timing in the firing of the various quadriceps components (McConnell 1986; Voigt 1991). Muscle re-education using biofeedback techniques during various exercises can be used where the patient is taught to fire the vastus medialis obliquus earlier and more efficiently. McConnell also developed external support for the patella by means of taping. Using these methods, while working on strengthening techniques, often provides immediate and fairly long-lasting relief.

Although the vast majority of patients will improve using these measures, it is important that they understand this is not a cure. Adolescent sufferers may well improve with the passage of time, as some of the imbalance may be associated with growth spurts. If there are persistent anatomical features, the patient will have to be prepared to continue the muscle strengthening exercises indefinitely in order to control their pain. Ten per cent of patients do not improve with the above measures; some may be prepared to modify their lifestyles but others may request surgery. Various surgical options are available, the most common being lateral release (Table 3).

Stage 1	*2–3 weeks*
Reduce symptoms by cutting down activity. No exercise involving deep squats. Relieve the pain with ice and non-steroidal anti-inflammatory drugs.	
Stage 2	*3–4 weeks*
With help of physiotherapist, strengthening exercises for vastus medialis obliquus. Flexibility of hamstrings, quadriceps, iliotibial band, gastrocnemius–soleus complex.	
Stage 3	
Gradual return to sport and then full training	
Stage 4	
Maintenance exercises for vastus medialis obliquus, at least 3 times weekly.	

Table 3 Rehabilitation programme for patellofemoral pain syndrome

Anterior shin pain induced by exercise ('shin splints')

Chronic pain in the shins induced by exercise (commonly known as 'shin splints') is a frequent occurrence in sportsmen and women but is rarely seen in any other group of patients. This syndrome embraces a variety of conditions:

1. stress fracture of the tibia or fibula;
2. fasciitis of tibialis posterior;
3. compartment syndrome;
4. popliteal artery stenosis;
5. referred pain from the spine (cord claudication);
6. peripheral vascular disease (intermittent claudication).

Fasciitis of tibialis posterior

Hyperpronation of the feet is often seen in association with other common malalignment problems. This problem puts extra stress on the tibialis posterior muscle which is responsible for inversion of the foot and inserts onto the posterior aspect of the tibia and fibula. The tendon of the muscle runs behind the medial malleolus and the flat hyperpronated foot is easily overstretched by repetitive activity resulting in a traction injury at the fascial insertion along the posterior border of the tibia.

Patients complain of pain in the shins which starts after starting to run. Often they can run through the pain only for it to return with great severity on ceasing activity. The pain often takes days to wear off. Examination reveals diffuse tenderness along the medial border of the tibia. The diagnosis may be confirmed with a bone scan.

Treatment is difficult. Rest is vital and is followed by a gradual return to sport with appropriate footwear. Orthotic supports to correct the hyperpronation and to provide shock absorption can be tried.

Compartment syndrome

Acute swelling of muscles within a muscle compartment leading to muscle ischaemia and even necrosis is a well recognized complication of acute trauma. The chronic form of this condition is less well known and occurs almost exclusively in endurance sports such as long distance running. As the muscles are exercised they swell within a tight fascial compartment raising the pressure sufficiently to reduce tissue perfusion. There are four separate compartments in the lower limb (Table 4). Compartment syndrome commonly follows a sudden increase in training. Symptoms are absent at rest but pain in the shin commences at a variable time after the onset of exercise and invariably increases until exercise is stopped or moderated. If the limb is rested the pain usually wears off within a few hours. Examination is often unremarkable although highly-developed calf muscles that feel tense at rest may be noted. A Tc 99 bone scan will exclude a stress fracture or fasciitis. Pressure studies can be performed by inserting catheters into each compartment and measuring the pressure rises. This is an invasive investigation and only available at specialist centres. A promising alternative is isotope scanning employing a technetium isotope Tc-99m-methylisobutylisonitrile (MIBI) which is used routinely to detect cardiac ischaemia and can be modified to look at peripheral muscle ischaemia. If the symptoms do not settle with rest, the appropriate compartments can be released by a surgical fasciotomy (Miles *et al*. 1992) (Fig. 9).

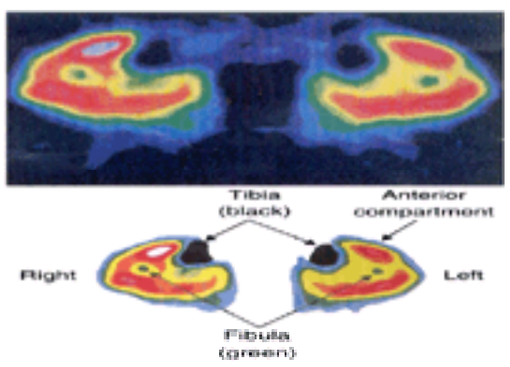

Fig. 9 Methylisobutylisonitrile emission tomogram of mid calf after exercise showing reduction in uptake in left anterior compartment compared with an annotated drawing below.

Compartment	Muscle
Anterior	Tibialis Anterior
Posterior	Gastrocnemius/soleus
Deep posterior	Tibialis posterior
Lateral	Peronei

Table 4 Compartments of the lower limb

Popliteal artery entrapment

Rarely, similar symptoms can be caused by entrapment of the popliteal artery by a fibrous band or hypertrophied head of gastrocnemius. Arteriography may be required to confirm the diagnosis.

Children and sport

Children are prone to similar injuries to adults but should not be regarded as 'little adults' as their physiology and anatomy are very different, resulting in injuries not encountered in the adult:

1. They take shorter, more shallow breaths and need more oxygen for their activity than an adult.
2. They also have lower glycogen levels and essential muscle enzymes and waste more energy.
3. Children perceive exercises as less fatiguing than adults and can almost exercise to destruction, but they also have the capacity to recover very quickly.
4. Muscle, tendon, and ligaments are stronger than bone until bony maturity is reached at 18 to 21 years.
5. Bones are still growing with active apophyses and epiphyses which can be the site of pathology.
6. Growth occurs in spurts, resulting in tight muscles and loss of flexibility making adolescents particularly prone to injury.

Avulsion fractures

Tendons, ligaments, and muscles, especially trained muscles, are stronger than bone and more so at the epiphyseal junctions. Sudden, intense loading of a muscle does not produce a muscle tear as in an adult but is more likely to cause an avulsion fracture where the bony attachment of the muscle or ligament is torn away. Common sites for avulsion fractures are the growth zones around the pelvis, including the attachments at the ischial tuberosity and the attachments of rectus femoris and sartorius. The less severe injuries can sometimes present only as a pain in the groin, with loss of function of the appropriate muscle. These injuries do not show up on radiographs and a bone scan is necessary. The usual treatment is rest followed by physiotherapy treatment, with an emphasis on restoring strength to the injured muscle. Healing may take up to 6 months.

Overuse injuries of the apophysis

In children and adolescents the muscle tendon attachment to bone or the apophysis presents as a 'high-risk' area for overuse injuries (Renstrom 1988). Overuse caused a traction apophysitis and occurs at various sites (Table 5).

Eponym	Site of injury
Osgood–Schlatters	Tibial tubercle
Sinding–Larsen, Johannason	Lower pole of patella
Severs disease	Achilles tendon attachment to calcaneum

Table 5 Sites of apophysitis

Osgood–Schlatter disease follows overloading of the patellar tendon at its attachment to the tibial tubercle. Very active boys, between the ages of 14 to 16 years and girls at a slightly younger age, present with swelling, pain, and acute tenderness over the tibial tubercle. These children are usually playing not only for the school, but taking part in other competitive sports on most days of the week.

The treatment of all the apophyseal overuse injuries is by modifying activity, playing only to a bearable level of discomfort, and using ice before and after exercise. Most respond to this regime but this may take several months and some persist until growing has ceased.

Osteochondritis

This is a collection of conditions affecting various sites of uncertain aetiology and is thought to be due to avascular necrosis of bone and subsequent flattening of the affected bones (Fig. 10; Table 6).

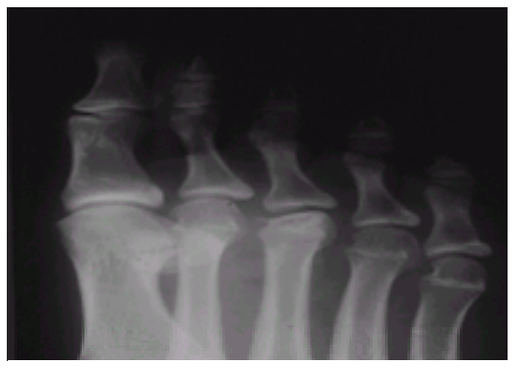

Fig. 10 Freiberg's disease showing flattening of the head of the 3rd metatarsal.

Name	Site
Perthes' disease	Hip
Scheuermann's disease	Vertebral ring epiphysis
Kohler's disease	Navicular bone
Freiburg's disease	2nd or 3rd metatarsal
Panner's disease	Elbow capitellum

Table 6 Sites of osteochondritis

Perthes' disease and the potentially disastrous unrelated hip problem of slipped femoral epiphysis may present with a limp and a painful knee. This can cause diagnostic problems as the child may present following an injury, drawing attention away from the real source of the problem. When faced with this history a radiograph is mandatory, as both conditions require urgent orthopaedic referral.

Scheuermann's disease mainly affects the thoracic vertebrae and because the anterior border of the vertebrae are subjected to deforming forces a kyphosis occurs. Often this is asymptomatic, although there may be some discomfort after hard exercise. In mild cases, flexibility exercises for the hip flexors and hamstrings and abdominal strengthening are sufficient until the disease ends spontaneously. Increasing kyphosis demands more serious intervention.

Osteochondritis dissecans

Osteochondritis dissecans is a disease of unknown aetiology, occurring in young people between the ages of 12 and 16 years. There is destruction and subsequent disintegration of cartilage and bone. Popular theories are trauma or continuous repetitive damage (Fairbanks 1993), ischaemia, and genetic factors. In the United States, the condition is seen as one of the entities in 'little league elbow', seen in young baseball pitchers.

The knee is a common presenting site and the history is of a diffuse knee ache, made worse by activity and accompanied by occasional effusion. When a fragment of bone becomes loose in the joint the patient may present with an episode of locking and effusion. The diagnosis can be confirmed by radiography. Surgical replacement of the loose fragment can give excellent results (Fig. 11).
