Oxford textbook of rheumatology 2nd ed. edition: By by David Isenberg (Editor), et al Oxford University Press;

Sorry, no front pic! By OkdoKeY

Oxford Textbook of Rheumatology

Contents

Volume 1

6 Intervention, rehabilitation, and sports medicine

Mark Harries

6.7 Sports injuries
J. R. Jenner and M. Shirley Emerson

Contributors list

D. ADU
Consultant Renal Physician, Queen Elizabeth Hospital, Birmingham, UK
5.11.3 Classical polyarteritis nodosa, microscopic polyarteritis, and Churg-Strauss syndrome

SANJIV N. AMIN
Consultant Rheumatologist, Bombay Hospital, India
5.3.7 Mycobacterial diseases

ANDREW A. AMIS
Reader in Orthopaedic Biomechanics, Imperial College London, UK
2.7 Biomechanics of articulations and derangements in disease

BERNARD P. AMOR
Professor of Rheumatology, Hôpital Cochin, University of Paris V, France
5.5.5 Reactive arthropathy, Reiter's syndrome, and enteric arthropathy in adults

JANICE R. ANDERSON
Consultant Neuropathologist, Addenbrooke's Hospital, Cambridge, UK
4.10 Histopathology

BARBARA M. ANSELL
Consultant Rheumatologist, Windsor, Berkshire, UK
5.4.3 Juvenile rheumatoid arthritis (rheumatoid factor positive polyarthritis)

BARBARA M. ANSELL
Consultant Rheumatologist, Windsor, Berkshire, UK
5.17.4 Diseases of bone and cartilage in children

PAUL A. BACON
Arthritis and Rheumatism Council Professor of Rheumatology and Head of Department of Rheumatology, University of Birmingham Medical School, UK
5.11.3 Classical polyarteritis nodosa, microscopic polyarteritis, and Churg-Strauss syndrome

ROSAMONDE E. BANKS
ICRF Cancer Medicine Research Unit, St James's University Hospital, Leeds, UK
4.1 Acute phase response

ROSAMONDE E. BANKS
ICRF Cancer Medicine Research Unit, St James's University Hospital, Leeds, UK
4.3 Biochemistry

JOHN I. BALL
Nuffield Professor of Clinical Medicine, Nuffield Department of Clinical Medicine, University of Oxford; Consultant Physician, John Radcliffe Hospital, Oxford, UK
3.3 Specific immune responses

THOMAS G. BENEDEK
Professor of Medicine, University of Pittsburgh School of Medicine, Pennsylvania, USA
5.19.1 Rheumatic diseases and neoplasia

ROBERT M. BERNSTEIN
Consultant Rheumatologist, Manchester Royal Infirmary, UK
5.19.3 Rheumatic complications of drugs and toxins

A. K. BHALLA
Consultant Rheumatologist, Royal National Hospital for Rheumatic Diseases, Bath, Avon, UK
5.17.1 Osteoporosis and osteomalacia

ALLAN I. BINDER
Consultant Rheumatologist, Lister Hospital, North Hertfordshire NHS Trust, Stevenage, Hertfordshire, UK
1.3.9 An anaesthetic perspective

ALLAN I. BINDER
Consultant Rheumatologist, Lister Hospital, North Hertfordshire NHS Trust, Stevenage, Hertfordshire, UK
5.18.2 Cervical pain syndromes

ALLAN I. BINDER
Consultant Rheumatologist, Lister Hospital, North Hertfordshire NHS Trust, Stevenage, Hertfordshire, UK
6.5 Corticosteroid injection therapy

HOWARD A. BIRD
Reader in Rheumatology, University of Leeds, UK
4.1 Acute phase response

HOWARD A. BIRD
Reader in Rheumatology, University of Leeds, UK
4.3 Biochemistry

CAROL M. BLACK
Professor of Rheumatology, Academic Unit of Rheumatology and Connective Tissue Diseases, Royal Free Hospital Medical School, London, UK
5.8 Scleroderma and related disorders in adults and children

DAVID R. BLAKE
Arthritis and Rheumatism Council Professor of Rheumatology and Consultant Physician, St Bartholomew's and Royal London Hospital School of Medicine and Dentistry, Queen Mary and Westfield College, University of London, UK
2.5 The physiology of the joint and its disturbance in inflammation

TOMÁS S. BOCANEGRA
Senior Director, Arthritis Clinical Group, Clinical Research, G.D. Searle & Co., Skokie, Illinois, USA
5.3.9 Parasitic involvement

EMILIO BOUZA

Professor and Chief of the Division of Clinical Microbiology and Infectious Diseases, Hospital General Universitario 'Gregorio Maranon', Madrid, Spain
5.3.3 Osteomyelitis and associated conditions

S. J. BOWMAN
Senior Lecturer in Rheumatology, University of Birmingham, UK
3.3 Specific immune responses

BARRY BRESNIHAN
Professor of Rheumatology, University College Dublin, and Consultant Rheumatologist, St Vincent's Hospital, Dublin, Ireland
5.13.5 Sarcoidosis

PETER BROOKS
Professor of Medicine, University of New South Wales, St Vincent's Hospital, Sydney, Australia
3.5.1 Non-steroidal anti-inflammatory drugs

CAROLYN P. CACHO
Assistant Professor of Medicine, Case Western Reserve School of Medicine, Cleveland, Ohio, USA
1.3.11 The kidney

ANDREI CALIN
Consultant Rheumatologist, Royal National Hospital for Rheumatic Diseases, Bath, Avon, UK
5.5.1 Spondylarthropathy, undifferentiatated spondylarthritis, and overlap

ANDREI CALIN
Consultant Rheumatologist, Royal National Hospital for Rheumatic Diseases, Bath, Avon, UK
5.5.3 Ankylosing spondylitis

EVAN CALKINS
Emeritus Professor of Medicine, School of Medicine and Biomedical Sciences, State University of New York at Buffalo; Senior Physician and Coordinator, Geriatric Programs, Health Care Plan, Buffalo,New York, USA
1.1.3 The geriatric age group

JEFFREY P. CALLEN
Professor of Medicine (Dermatology); Chief, Division of Dermatology, University of Louisville School of Medicine, Kentucky, USA
5.13.3 Panniculitis

JEFFREY P. CALLEN
Professor of Medicine (Dermatology); Chief, Division of Dermatology, University of Louisville School of Medicine, Kentucky, USA
5.13.4 Neutrophilic dermatoses

T. E. CAWSTON
Professor of Rheumatology, The Medical School, University of Newcastle upon Tyne, UK
5.15 Osteoarthritis

JUSTIN COBB
Consultant Orthopaedic Surgeon, University College Hospital, London, UK
6.1 Surgery in adults

ADRIAN J. CRISP
Consultant Rheumatologist, Addenbrooke's Hospital, Cambridge, UK
5.17.2 Paget's disease of bone

CHAD DEAL
Associate Professor of Medicine, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA
1.3.7 The endocrine system

A. M. DENMAN
Consultant Rheumatologist and Clinical Immunologist, Northwick Park Hospital, Harrow, Middlesex, UK
3.5.2 Antirheumatic drugs

A. M. DENMAN
Consultant Rheumatologist and Clinical Immunologist, Northwick Park Hospital, Harrow, Middlesex, UK
3.5.3 Therapeutic immunomodulation

CHRISTOPHER P. DENTON
Clinical Research Fellow, Academic Unit of Rheumatology, Royal Free Hospital, London, UK
5.8 Scleroderma and related disorders in adults and children

STANLEY C. DERESINSKI
Clinical Professor of Medicine, Stanford University; Director, AIDS Health Services; Associate Chief of Infectious Diseases, Santa Clara Valley Medical Center, San Jose, California, USA
5.3.10 Fungal arthritis

KOMAL B. DESAI
Children's Mercy Hospital, Kansas City, Missouri, USA
5.3.2 Pyogenic arthritis in children

MICHAEL J. DILLON
Consultant Physician and Senior Clinical Nephrologist, The Hospital for Sick Children, London, UK
5.11.8 Primary vasculitis in children

MICHAEL DOHERTY
Professor of Rheumatology, Nottingham University Medical School, UK
5.15 Osteoarthritis

FRANCES DORMON
Consultant in Anaesthetics and Intensive Care, Lister Hospital, Stevenage, Hertfordshire, UK
1.3.9 An anaesthetic perspective

GORDON W. DUFF
Lord Florey Professor of Molecular Medicine, Royal Hallamshire Hospital, Sheffield, UK
3.1 Cells and mediators

ALISON A. EDDY
Associate Professor of Pediatrics, The Hospital for Sick Children, University of Toronto, Ontario, USA

5.7.2 Systemic lupus erythematosus in children

ERKKI EEROLA
Head of Laboratory, Department of Medical Microbiology, Turku University, Finland
1.3.6 The gastrointestinal system

MICHAEL EHRENFELD
Clinical Senior Lecturer, Sackler School of Medicine, Tel Aviv University; Consultant Rheumatologist, Rheumatic Disease Unit, Sheba Medical Center, Tel Hashomer, Israel
1.3.8 Oncology and haematology

M. SHIRLEY EMERSON
Clinical Assistant, Peter Wilson Sports Injury Clinic, Addenbrooke's Hospital, Cambridge, UK
6.7 Sports injuries

PAUL EMERY
ARC Professor of Rheumatology and Rheumatologist, Leeds General Infirmary and St James's University Hospital, Leeds, UK
4.2 Haematology

ADEL G. FAM
Professor of Medicine and Head, Division of Rheumatology, Sunnybrook Health Science Centre, University of Toronto, Ontario, Canada
1.2.2.1 The upper limbs in adults

MARC FELDMANN
Head of Cytokine and Immunology Unit, Kennedy Institute of Rheumatology and Professor of Cellular Immunology, Charing Cross and Westminster Medical School, London, UK
5.4.1 Immunopathogenesis of rheumatoid arthritis

I. T. FERGUSON
Consultant Neurologist, Southmead Hospital, Bristol, UK
1.3.3 Neurological complications

ØYSTEIN FØRRE
Professor and Head, Centre for Rheumatic and Autoimmune Connective Tissue Disease, The National Hospital, Oslo University, Norway
4.7 Gene marker analysis

ANDREW O. FRANK
Consultant Physician in Rheumatology and Rehabilitation, Northwick Park Hospital, Harrow, Middlesex, UK
1.2.1.1 Spinal problems in adults

PATRICIA A. FRASER
Assistant Professor of Medicine, Harvard Medical School; Director of Pediatric Rheumatology, Brigham and Women's Hospital, Boston, Massachusetts, USA
5.1.2 Epidemiology of rheumatic diseases in selected non-European populations

CHARLES S.B. GALASKO
Professor of Orthopaedic Surgery, University of Manchester; Consultant Orthopaedic Surgeon, Manchester Children's Hospitals NHS Trust; Consultant Orthopaedic Surgeon, Salford Royal Hospitals NHS Trust, UK
1.2.1.2 Spinal problems in children

PATRICK J. GALLAGHER
Reader in Pathology, Southampton University Hospitals, UK
4.10 Histopathology

ALLAN GIBOFSKY
Professor, Departments of Medicine and Public Health, Cornell University Medical College, New York, USA
5.3.12 Rheumatic fever

DAFNA D. GLADMAN
Professor of Medicine, University of Toronto, Ontario, Canada
5.5.4 Psoriatic arthritis

DAVID N. GLASS
Professor of Pediatrics and Director, Division of Rheumatology, Children's Hospital Medical Center, Cincinnati, Ohio, USA
5.2 Nosology of the chronic inflammatory rheumatic diseases

ELIZABETH M. GRAHAM
Consultant Medical Ophthalmologist, St Thomas's Hospital and The Hospital for Sick Children, London, UK
1.3.10 The eye

CLIVE E.H. GRATTAN
Consultant Dermatologist, West Norwich Hospital, Norfolk, UK
5.11.4 Small vessel vasculitis

IAN D. GRIFFITHS
Consultant Rheumatologist, Freeman Hospital and Senior Clinical Lecturer, University of Newcastle upon Tyne, UK
1.2.3 Extra-articular features of rheumatic diseases

BRIDGET GRIFFITHS
Lecturer, Department of Rheumatology, University of Leeds, UK
4.2 Haematology

WOLFGANG L. GROSS
Professor of Internal Medicine and Rheumatology; Director, Department of Rheumatology, University of Lubeck and Clinic for Rheumatology in Bad Bramstedt, Germany
5.11.2 Wegener's granulomatosis

RENATE HÄFNER
Paediatric Rheumatologist, Rheuma-Kinderklinik, Garmisch-Partenkirchen, Germany
6.4 Rehabilitation of children

VEDAT HAMURYUDAN
Associate Professor of Medicine, Division of Rheumatology, Cerrahpa Ş a Medical Faculty, University of Istanbul, Turkey
5.11.7 Behçet's syndrome

TIM HARDINGHAM

Professor of Biochemistry, School of Biological Sciences, University of Manchester, UK
2.3 Articular cartilage

MARK HARRIES
Consultant Physician, Northwick Park and St Mark's NHS Trust; Honorary Clinical Director, British Olympic Medical Centre, Northwick Park Hospital, Harrow, Middlesex, UK
6.6 Sports medicine

DORIAN O. HASKARD
Sir John McMichael Professor of Cardiovascular Medicine, Royal Postgraduate Medical School and Honorary Consultant Physician, Hammersmith Hospital, London, UK
3.2 Lymphocyte traffic in inflammation

BRIAN HAZLEMAN
Consultant Rheumatologist, Addenbrooke's Hospital, Cambridge, UK
5.14 Soft-tissue rheumatism

SIMON HELFGOTT
Assistant Professor of Medicine, Harvard Medical School and Brigham and Women's Hospital, Boston, Massachusetts, USA
1.3.12 Psychiatric issues in rheumatology

PETER HOLLINGWORTH
Consultant Rheumatologist, Southmead Hospital, Bristol, UK
1.3.3 Neurological complications

ANGELA C. HORSFALL
Senior Research Fellow, Charing Cross Medical School and Honorary Senior Scientist, Kennedy Institute, London, UK
5.7.1 Systemic lupus erythematosus in adults

J. LAWRENCE HOUK
Professor of Clinical Medicine, University of Cincinnati Medical Center, Ohio, USA
4.6 Joint fluid

G. R.V. HUGHES
Head of the Lupus Arthritis Research Unit, Rayne Institute, St Thomas's Hospital, London, UK
5.7.3 The antiphospholipid antibody syndrome

GUNNAR HUSBY
Professor, Oslo Sanitetsforening Rheumatism Hospital, The National Hospital, University of Oslo, Norway
5.13.1 Amyloidosis

DAVID A. ISENBERG
Professor of Rheumatology, University College London, UK
1.3.5 The respiratory system

DAVID A. ISENBERG
Professor of Rheumatology, University College London, UK
5.7.1 Systemic lupus erythematosus in adults

SILVIU ITESCU
Assistant Professor of Surgical Science; Director, Transplantation Immunology, Department of Surgery, Columbia University College of Physicians and Surgeons, New York, USA
5.3.6 HIV infection

MARY ANNE JACKSON
Professor of Pediatrics, University of Missouri School of Medicine and Pediatrician in Infectious Diseases, Children's Mercy Hospital, Kansas City, Missouri, USA
5.3.2 Pyogenic arthritis in children

MALCOLM I.V. JAYSON
Professor of Rheumatology, Rheumatic Diseases Centre, University of Manchester, UK
5.18.1 Intervertebral disc disease and other mechanical disorders of the back

J. R. JENNER
Consultant in Rheumatology, Addenbrooke's NHS Trust, Cambridge, UK
6.7 Sports injuries

VICTORIA A. JOLLIFFE
Senior Registrar, West Norwich Hospital, Norfolk, UK
5.11.4 Small vessel vasculitis

ADRIAN JONES
Consultant Rheumatologist, Nottingham City Hospital, UK
5.15 Osteoarthritis

D. A. JONES
Professor of Sport and Exercise Sciences, University of Birmingham, UK
2.6 Skeletal muscle damage

GARY M. KAMMER
Professor of Internal Medicine/Rheumatology, The Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, North Carolina, USA
1.3.11 The kidney

WALTER F. KEAN
Clinical Professor of Medicine (Rheumatology) and Head, Service of Rheumatology, McMaster University Medical Centre, Hamilton, Ontario, Canada
1.3.1.1 Pregnancy

WALTER F. KEAN
Clinical Professor of Medicine (Rheumatology) and Head, Service of Rheumatology, McMaster University Medical Centre, Hamilton, Ontario, Canada
1.3.1.2 Antirheumatic drugs in pregnancy and lactation

CAROL A. KEMPER
Clinical Assistant Professor of Medicine, Stanford University; Co-director, AIDS Health Services, Santa Clara Valley Medical Center, San Jose, California, USA
5.3.10 Fungal arthritis

MUNTHER A. KHAMASHTA

Deputy Director, Lupus Arthritis Research Unit, The Rayne Institute; Honorary Senior Lecturer, St Thomas's Hospital, UMDS, London, UK
5.7.3 The antiphospholipid antibody syndrome

PNINA LANGEVITZ
Senior Lecturer in Medicine, Tel Aviv University Medical School; Head of Rheumatic Disease Unit, Sheba Medical Center, Tel Hashomer, Israel
5.13.2 Familial Mediterranean fever

C. B. D. LAVY
Associate Professor, University of Malawi School of Medicine and Honorary Consultant, University College London Hospitals, UK
6.1 Surgery in adults

RONALD M. LAXER
Associate Professor of Pediatrics and Medicine, University of Toronto; Head, Division of Rheumatology, The Hospital for Sick Children, Toronto, Ontario, Canada
5.6.2 Systemic-onset juvenile chronic arthritis

ALISON M. LEAK
Consultant Rheumatologist, Thanet General Hospital, Margate, Kent, UK
1.3.10 The eye

KENG HONG LEONG
Consultant Rheumatologist, Department of Rheumatology and Immunology, Tan Tock Seng Hospital, Singapore
5.13.8 Hyperlipidaemias

MATTHEW H. LIANG
Professor of Medicine, Harvard Medical School, and Professor of Health Policy and Mangement, Harvard School of Public Health, Boston, Massachusetts, USA
1.1.5 Outcomes assessment in rheumatology

GEOFFREY O. LITTLEJOHN
Associate Professor of Medicine and Director of Rheumatology, Monash Medical Centre, Melbourne, Australia
5.19.2 Algodystrophy (reflex sympthetic dystrophy syndrome)

AVI LIVNEH
Senior Physician, Sheba Medical Center and Senior Lecturer, Sackler Faculty of Medicine, Tel Aviv University, Israel
5.13.2 Familial Mediterranean fever

DANIEL J. LOVELL
Associate Professor of Pediatrics, Children's Hospital Medical Center, University of Cincinnati Medical Center, Ohio, USA
1.1.7 Growth and skeletal maturation

C. R. LOVELL
Consultant Dermatologist, Royal United Hospital, Bath, Avon, UK
1.3.2 The skin

MICHAEL E. LUGGEN
Associate Professor of Clinical Medicine, University of Cincinnati Medical Center, Ohio, USA
1.3.4 The cardiovascular system

P. J. MADDISON
Consultant Rheumatologist, Gwynedd Hospitals NHS Trusts, Bangor, UK
1.3.2 The skin

P. J. MADDISON
Consultant Rheumatologist, Gwynedd hospitals NHS Trusts, Bangor, UK
4.5 Autoantibody profile

P. J. MADDISON
Consultant Rheumatologist, Gwynedd hospitals NHS Trusts, Bangor, UK
5.13.7 Multicentric reticulohistiocytosis

P. J. MADDISON
Consultant Rheumatologist, Gwynedd hospitals NHS Trusts, Bangor, UK
5.17.3 Diseases of bone, cartilage, and synovium

RAVINDER N. MAINI
Director, Kennedy Institute of Rheumatology; Head and Professor of Rheumatology, Charing Cross and Westminster Medical School; Consultant Physician, Charing Cross Hospital, London, UK
5.4.1 Immunopathogenesis of rheumatoid arthritis

PAUL MAPP
Research Fellow, Bone and Joint Research Unit, The London Hospital Medical College, UK
2.5 The physiology of the joint and its disturbance in inflammation

NEIL JOHN McHUGH
Consultant Senior Lecturer in Rheumatology, Royal National Hospital for Rheumatic Diseases, Bath, Avon, UK
5.12 Overlap syndromes in adults and children

NEIL JOHN MCHUGH
Consultant Senior Lecturer in Rheumatology, Royal National Hospital for Rheumatic Diseases, Bath, Avon, UK
5.13.8 Hyperlipidaemias

ELIZABETH D. MELLINS
Associate Professor of Pediatrics, Stanford University Medical Center, California, USA
5.6.1 Pauciarticular-onset juvenile chronic arthritis

MARC L. MILLER
Clinical Associate Professor of Medicine, Unversity of Vermont School of Medicine, USA
5.3.1 Pyogenic arthritis in adults

H. M. MOUTSOPOULOS
Professor and Chairman, Department of Pathophysiology, Medical School, University of Athens, Greece
5.10 Sjögren's syndrome

PATRICIA MUÑOZ
Assistant Professor in Clinical Microbiology and Infectious Diseases, Hospital General Maranón, Universidad Complutense, Madrid, Spain

5.3.3 Osteomyelitis and associated conditions

STANLEY J. NAIDES
Associate Professor, Division of Rheumatology, Department of Internal Medicine, University of Iowa College of Medicine, and Clinical Investigator, Veterans Affairs Medical Center, Iowa City, USA
5.3.5 Viral arthritis

BARBARA S. NEPOM
Research Associate Member, Virginia Mason Research Center, and Research Associate Professor, Department of Pediatrics, University of Washington School of Medicine, Washington, USA
5.6.1 Pauciarticular-onset juvenile chronic arthritis

S. P. NEWMAN
Professor of Health Psychology, University College London Medical School, London, UK
1.1.6 Psychological aspects of rheumatic disease

LAUREN M. PACHMAN
Professor of Pediatrics and Head, Division of Pediatric Immunology/Rheumatology, Northwestern University Medical School, Chicago, Illinois, USA
5.9.2 Polymyositis and dermatomyositis in children

ELISABETH PAICE
Consultant Rheumatologist, Whittington Hospital, London, UK
1.1.4 Principles of examination

G. S. PANAYI
Arthritis and Rheumatism Council Professor of Rheumatology, United Medical and Dental Schools of Guy's and St Thomas' Hospitals, London, UK
5.11.5 Polymyalgia rheumatica

E. PASCUAL
Professor of Rheumatology, University of Alicante School of Medicine, Spain
5.3.8 Brucellar arthritis

MURRAY H. PASSO
Associate Professor of Clinical Pediatrics, University of Cincinnati College of Medicine, Children's Hospital Medical Center, Ohio, USA
5.5.2 Spondylarthropathies in childhood

REIJO PELTONEN
Specialist in Infectious Diseases, Department of Medicine, Turku University Central Hospital, Finland
1.3.6 The gastrointestinal system

JOHN S. PERCY
Professor of Medicine, University of Alberta, Edmonton, Canada
1.1.1 The adult patient

ROSS E. PETTY
Professor of Pediatrics, University of British Columbia, Vancouver, Canada
1.1.2 Children and adolescents

RAFAL PLOSKI
Research Fellow, Centre for Rheumatic and Autoimmune Connective Tissue Disease, The National Hospital, Oslo University, Norway
4.7 Gene marker analysis

F. MICHAEL POPE
Head of Medical Research Council Connective Tissue Genetics Group, Addenbrooke's Hospital, Cambridge, UK
2.2 Molecular abnormalities of collagen and connective tissue

MORDECHAI PRAS
Professor of Medicine, Faculty of Medicine, Tel Aviv University, Israel
5.13.2 Familial Mediterranean fever

ANNE-MARIE PRIEUR
Consultant Paediatrician, Unite Fonctionnelle de Rhumatologie Pediatrique, Hôpital Necker-Enfants Malades, Paris, France
5.6.3 Rheumatoid factor- negative polyarthritis in children ('seronegative polyarthritis')

ANNE-MARIE PRIEUR
Consultant Paediatrician, Unite Fonctionnelle de Rhumatologie Pediatrique, Hôpital Necker-Enfants Malades, Paris, France
5.13.6 The chronic, infantile, neurological, cutaneous, and articular syndrome (CINCA)

J.-F QUIGNODON
Paediatric Radiologist, Hôpital des Enfants Malades, Paris, France
4.9.2 Imaging in children

DANIEL W. RAHN
Professor and Vice Chairman, Department of Medicine, Medical College of Georgia, Augusta, USA
5.3.4 Lyme disease

J. RECKLESS
Consultant Physician, Royal United Hospital, Bath, and Honorary Senior Lecturer in Biochemistry and in the Postgraduate Medical School, University of Bath, UK
5.13.8 Hyperlipidaemias

PETER RENTON
Consultant Radiologist, University College Hospital and The Royal National Orthopaedic Hospital, London, UK
4.9.1 Imaging in adults

CHARLES RICHARDSON
Faculty of Medicine and Dentistry, University of Birmingham, UK
4.2 Haematology

MALCOLM P. ROGERS
Associate Professor of Psychiatry, Harvard Medical School and Attending Psychiatrist, Division of Psychiatry, Brigham and Women's Hospital, Boston, Massachusetts, USA
1.3.12 Psychiatric issues in rheumatology

ANN K. ROSENTHAL
Assistant Professor of Medicine, Division of Rheumatology, Medical College of Wisconsin, Milwaukee, USA

5.16 Crystal arthropathies

JOAN M. ROUND
Honorary Research Fellow, School of Sport and Exercise Sciences, University of Birmingham, UK
2.6 Skeletal muscle damage

ANTHONY S. RUSSELL
Professor of Medicine, University of Alberta, Edmonton, Canada
1.1.1 The adult patient

OLIVER SANGHA
Harvard Medical School, Brigham and Women's Hospital, Boston, Massachusetts, USA
1.1.5 Outcomes assessment in rheumatology

HANS-GEORG SCHAIBLE
Professor of Physiology, University of Würzburg, Germany
2.8 The neurophysiology of pain

RAYFEL SCHNEIDER
Assistant Professor of Pediatrics, University of Toronto; Staff Rheumatologist, The Hospital for Sick Children, Toronto, Ontario, Canada
5.6.2 Systemic-onset juvenile chronic arthritis

DAVID G.I. SCOTT
Department of Rheumatology, Norfolk and Norwich Hospital, UK
5.11.1 Classification of vasculitis

DAVID G.I. SCOTT
Department of Rheumatology, Norfolk and Norwich Hospital, UK
5.11.6 Large vessel vasculitis

GEOFFREY SCOTT
Consultant Microbiologist, University College London Hospitals, London, UK
4.4 Microbiology and diagnostic serology

G. H. SEBAG
Paediatric Radiologist, Hôpital Robert Debré, Université Saint Louis, Paris, France
4.9.2 Imaging in children

DAVID D. SHERRY
Director, Pediatric Rheumatology, Children's Hospital and Medical Center, Seattle; Associate Professor of Pediatrics, University of Washington, USA
5.6.1 Pauciarticular-onset juvenile chronic arthritis

YEHUDA SHOENFELD
Professor and Head, Department of Medicine 'B', Chaim Sheba Medical Center, Tel-Hashomer, Israel
1.3.8 Oncology and Haematology

ALAN J. SILMAN
ARC Professor of Rheumatic Disease Epidemiology, University of Manchester, UK
5.1.1 Epidemiology and the rheumatic diseases

EARL D. SILVERMAN
Associate Professor of Pediatrics and Immunology, Division of Rheumatology, Hospital for Sick Children, University of Toronto, Canada
5.7.2 Systemic lupus erythematosus in children

ROBERT W. SIMMS
Director, Boston City Hospital Arthritis Clinic; Associate Professor of Medicine, Boston University School of Medicine, Massachusetts, USA
1.2.2.2 The lower limbs in adults

ROGER SMITH
Consultant Physician, Nuffield Orthopaedic Centre, Oxford, UK
2.4 Bone in health and disease

ENRIQUE ROBERTO SORIANO
Consultant Rheumatologist, Hospital Italiano de Buenos Aires, Argentina
5.12 Overlap syndromes in adults and children

TAUNTON R. SOUTHWOOD
Senior Lecturer and Consultant in Paediatric Rheumatology, Department of Rheumatology, University of Birmingham, UK
5.5.2 Spondylarthropathies in childhood

MARIANNE SPAMER
Physiotherapist, Rheuma-Kinderklinik, Garmisch-Partenkirchen, Germany
6.4 Rehabilitation of children

STEPHEN G. SPIRO
Consultant Physician, University College London Hospitals Trust, UK
1.3.5 The respiratory system

CLIFF. R. STEVENS
Head of Vascular Biology, Bone and Joint Research Unit, St Bartholomew's and The Royal London Hospital School of Medicine and Dentistry, London, UK
2.5 The physiology of the joint and its disturbance in inflammation

GEROLD STUCKI
Lecturer, Department of Rheumatology and Physical Medicine, University of Zurich, Switzerland
1.1.5 Outcomes assessment in rheumatology

MALCOLM SWANN
Consultant Orthopaedic Surgeon
6.2 Surgery in in children

IRA N. TARGOFF
Associate Professor of Medicine, University of Oklahoma Health Sciences Center; Staff Physician, Department of Veterans Affairs Medical Center and Assistant Member, Oklahoma Medical Research Foundation, Oklahoma City, USA
5.9.1 Polymyositis and dermatomyositis in adults

DOUGLAS THOMPSON
Principal Biochemist, Leeds General Infirmary, UK
4.1 Acute phase response

DOUGLAS THOMPSON
Principal Biochemist, Leeds General Infirmary, UK
4.3 Biochemistry

ANTOINE A. TOUBERT
Laboratoire d'Immunogénétique Humaine, INSERM U396, Hôpital Saint-Louis, Paris, France
5.5.5 Reactive arthropathy, Reiter's syndrome, and enteric arthropathy in adults

LYNNE TURNER-STOKES
Director, Regional Rehabilitation Unit, Northwick Park Hospital, London, UK
6.3 Rehabilitation of adults

ATHANASIOS G. TZIOUFAS
Consultant Rheumatologist, Department of Pathophysiology, Medical School, University of Athens, Greece
5.10 Sjögren's syndrome

ANTHONY UNSWORTH
Professor of Engineering and Director of the Centre for Biomedical Engineering, University of Durham, UK
2.7 Biomechanics of articulations and derangements in disease

W. B. VAN DEN BERG
Professor of Experimental Rheumatology and Head, Rheumatology Research Laboratory, University of Nijmegen, The Netherlands
3.4 Animal models of arthritis

MARK J. WALPORT
Professor of Medicine, Royal Postgraduate Medical School, Hammersmith Hospital, London, UK
3.1 Cells and mediators

W. WATSON BUCHANAN
Emeritus Professor of Medicine, McMaster University Faculty of Health Sciences, Sir William Osler Health Institute, Hamilton, Ontario, Canada
1.3.1.1 Pregnancy

W. WATSON BUCHANAN
Emeritus Professor of Medicine, McMaster University Faculty of Health Sciences, Sir William Osler Health Institute, Hamilton, Ontario, Canada
1.3.1.2 Antirheumatic drugs in pregnancy and lactation

RICHARD A. WATTS
Consultant Rheumatologist, Ipswich NHS Trust, UK
5.11.1 Classification of vasculitis

RICHARD A. WATTS
Consultant Rheumatologist, Ipswich NHS Trust, UK
5.11.6 Large vessel vasculitis

A. D. B. WEBSTER
Senior Lecturer, MRC Immunodeficiency Research Group, Royal Free Hospital Medical School, London, UK
5.3.11 Immunodeficiency

LAURA F. WEXLER
Professor of Medicine, University of Cincinnati Medical Center, Ohio, USA
1.3.4 The cardiovascular system

FRANCES B. WHEELER
The Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, North Carolina, USA
1.3.11 The kidney

JOHN T. WHICHER
Professor, Research School of Medicine, University of Leeds, UK
4.1 Acute phase response

JOHN T. WHICHER
Professor, Research School of Medicine, University of Leeds, UK
4.3 Biochemistry

PATIENCE H. WHITE
Associate Professor of Pediatrics and Medicine, George Washington University; Chairman, Pediatric and Adult Rheumatology, Children's National Medical Center, Washington DC, USA
1.2.2.3 The arm and leg in children

BRYAN D. WILLIAMS
Professor of Rheumatology, University Hospital of Wales, Cardiff, UK
4.8 Immune complex detection

ROBERT WINCHESTER
Professor of Medicine and Pediatrics, College of Physicians and Surgeons, Columbia University, New York City, USA
5.3.6 HIV infection

JAY B. WISH
Professor of Medicine, Case Western Reserve University; Medical Director, Hemodialysis Services, University Hospitals of Cleveland, Ohio, USA
1.3.11 The kidney

FRANK A. WOLLHEIM
Professor of Rheumatology, Lund University, Sweden
5.4.2 Rheumatoid arthritis-the clinical picture

PATRICIA WOO
Professor of Paediatric Rheumatology, University College London, UK
1.1.7 Growth and skeletal maturation

PATRICIA WOO

Professor of Paediatric Rheumatology, University College London, UK
2.1 Molecular genetics and its relevance in rheumatology

PATRICIA WOO
Professor of Paediatric Rheumatology, University College London, UK
5.2 Nosology of the chronic inflammatory rheumatic diseases

B. P. WORDSWORTH
Clinical Reader in Rheumatology, Nuffield Department of Clinical Medicine, Oxford University, UK
3.3 Specific immune responses

HASAN YAZICI
Professor of Medicine and Chief, Division of heumatology, Cerrahpa§a Medical Faculty, University of Istanbul, Turkey
5.11.7 Behçet's syndrome

PIERRE YOUINOU
Professor of Immunology, Brest University Medical School, France
5.10 Sjögren's syndrome

ADAM YOUNG
Consultant Rheumatologist, City Hospital, St Albans, Hertfordshire, UK
4.11 Electrophysiology

SEBAHATTIN YURDAKUL
Professor of Medicine, Division of Rheumatology, Cerrahpa§a Medical Faculty, University of Istanbul, Turkey
5.11.7 Behçet's syndrome

JOHN B. ZABRISKIE
Associate Professor and Head, Laboratory of Clinical Microbiology/Immunology, Rockefeller University, New York, USA
5.3.12 Rheumatic fever

DEBORAH ZEMER
Sheba Medical Center, Tell Hashomer, Israel
5.13.2 Familial Mediterranean fever

Dose schedules are being continually revised and new side-effects recognized. Oxford University Press makes no representation, express or implied, that the drug dosages in this book are correct. For these reasons the reader is strongly urged to consult the pharmaceutical company's printed instructions before administering any of the drugs recommended in this book.

Preface to the Second Edition

Four years ago, in 1993, the first edition of this textbook was published to considerable acclaim. The many rapid developments in the basic science of rheumatology, imaging of joints, bones, and soft tissues, and exciting advances in treatment for some of the previously most intractable rheumatic diseases, have persuaded us that a second edition is timely and will contain sufficient new material both to stimulate and inform the reader.

The second edition has benefited, we believe, from the rearrangement of some chapters, the expansion of many others which have been brought up to date, and the addition of several completely new chapters. Our contributors have also been asked to provide expanded reference lists to facilitate access to the original sources. This approach ensures freshness of ideas and style, which is complemented by the improved quantity and quality of the colour figures. We also wished to make this a textbook to which rheumatologists could refer as a guide to their management of both the common and more unusual rheumatic conditions. To facilitate this aim, algorithms of optimal treatment are provided in the clinical chapters with additional practical management suggestions, including a section on joint and soft tissue injection.

The textbook has been designed as an attractive and informative manual for rheumatology trainees, full-time clinicians, and academic rheumatologists. We have encouraged our authors to express their opinions freely, to bring areas of dispute into the open, and to present a balanced view overall. As in the first edition; this volume places special emphasis upon the perspective of the age of the patient when dealing with the presentation of various rheumatic conditions, and a number of chapters focus on paediatric rheumatology. Another important emphasis in this edition is on the overlap of rheumatology with other subspecialties. This is provided by a series of chapters co-authored by rheumatologists and colleagues with expertise in a wide range of related conditions.

It has been both a challenge and a pleasure for us to edit the second edition which we hope will build on the clarity and standards of production of the first.

Preface to the First Edition

These are exciting times for the study of rheumatology. Current research, incorporated in this textbook and integral to the editors' enthusiasm for their project, continuously increases our knowledge of the molecular basis of many of the rheumatic diseases. These advances more than justify a new textbook written to complement the successful *Oxford Textbook of Medicine*. As with the other volumes in this series, it is designed to be comprehensive and sufficient for both the trainee and the general physician who require up-to-date information.

The book begins with the variations in presentation of rheumatic symptoms at different ages. There follow chapters dealing with those syndromes, which are not easy to classify and which may be best considered as regional. Although the aetiology of these syndromes is still incomplete they are such a significant part of practice that they demand comprehensive cover. Special emphasis has been placed on back symptomatology both in children and in adults as this problem represents an especially large part of rheumatological practice. Chapters in the third part of Section 1 then discuss rheumatic disease in relation not only to general (internal) medicine but also to other specialties, including psychiatry, anaesthesia, obstetrics, and ophthalmology. The text provides both a comprehensive account of these extensive and pervasive interactions and more focused discussions, either on an area of particular interest to the authors or of special clinical interest; hence the variety of approaches ranges from the general view to the in-depth analysis of a specialist topic.

The next two sections, dealing primarily with basic science, include conceptual advances of relevance to rheumatology and provide an understanding of the rationale for newer therapies being introduced into clinical practice. We have not attempted to replace basic science textbooks; rather we have indicated good reviews on specific topics, concentrating in our volume on how the different areas interact within the context of rheumatic diseases. For example, genetic abnormalities of collagen are described in relation to diseases of cartilage and bone. The joint is treated as a functional unit, and its physiological and biomechanical disturbances are described in the context of a variety of diseases. Parts of the immune system currently thought to be important in the pathogenesis of chronic inflammation are highlighted in some detail. The sections finish with a review of available and innovative ways of controlling inflammation.

Volume 1 concludes with discussion of clinical laboratory practices. Considerable advances have been made in developing laboratory and imaging techniques for clinical assessment. In this section, guidance is given on the selection of appropriate investigations as well as an indication of future developments.

Volume 2 contains the necessary systematic and comprehensive review of the rheumatic diseases. We have tried to encompass rheumatic diseases met throughout the world together with their epidemiological and environmental influences. To this end, authors have been selected who have appropriate clinical experience and established reputations in teaching and research. Colour has been used in this volume to enhance the clinical descriptions while the authors provide a personal as well as an informative approach to management. The final section deals with the important aspects of surgery and rehabilitation. A comprehensive review of surgical techniques has not been attempted. Rather, the major principles have been established to enable appropriate referral as well as the early recognition of complications of surgery.

Throughout the text, considerable emphasis is placed on the age of presentation, thus ensuring that a paediatrician faced with a rheumatological problem is well catered for. Referencing has been selective rather than exhaustive; with the knowledge that computer searches are widely available, we feel that the space may be better used for clinical description.

No project of this magnitude is complete without acknowledgements. We would like to thank the staff of Oxford University Press for their unfailing help. Thanks are also due to our staff, Sheena Stewart, Carolyn Keith Haun, Louise Kittredge, Geraldine Brown, Ann Maitland, and Kate Young for their invaluable assistance in preparing the text.

1.1.1 The adult patient

Anthony S. Russell and John S. Percy

Introduction

In rheumatology, as in other subspecialties, the very core of any medical practice is the consultation, during which the physician gives advice to the patient about diagnostic and therapeutic procedures. The physician must recognize that the patient may believe that he or she has come 'for a blood test' or 'for an X-ray' or 'for treatment'. What the patient has come for, in fact, is advice, which may incorporate some if not all of the patient's expectations. This chapter explores the special problems the rheumatologist meets in attempting to fulfil these expectations.

In locomotor disease, it is not uncommon to meet patients who bring what can best be described as a loosely tied bundle of complaints that they wish to transfer to the doctor for instant solution. Trying to help, they may often have diagnostic suggestions, which they believe will ease this task. These suggestions may be of diverse origins and doubtful practicality based on folklore or superstition, often compounded by information from the communications media. The physician, a pragmatist by training and experience, should use these suggestions judiciously to direct the patient along the correct diagnostic and therapeutic pathway.

The experienced rheumatologist often makes a diagnostic and therapeutic management plan by an intuitive process in the first moments of meeting the patient. Dissection of this intuitive exercise is difficult. But, nevertheless, central to this process is the differentiation of systemic from local disease and serious from minor illness. Systemic disease is suggested by the patient looking ill, weight loss, dyspnoea, fever, neuropathy, lymphadenopathy, splenomegaly, rash, anaemia, raised erythrocyte sedimentation rate or C-reactive protein, and abnormal urinalysis.

The interview and examination that follow the initial contact serve to confirm or deny the initial impression. Any surprises that may arise have to be integrated by a feedback mechanism into the continuing process of assessment. For example the discovery of significant weight loss in a patient who sounded as though he had a rotator cuff syndrome will cause reflection and reassessment. Indeed, this is the mechanism by which physicians develop their clinical expertise and continue to learn (Schon 1987). One important purpose of the interview and physical examination, apart from identification of specific problems, is to gain the patient's confidence and thereby encourage compliance with the suggested investigations and treatment. The patient needs to know that the physician is considering all possibilities and is making a thorough assessment, not only of the presenting complaints, but also of the patient's overall physical and mental state. The difference in emphasis of the approach used in children and in elderly people will be discussed in Chapter 1.1.2 and Chapter 1.1.3.

Before the history and physical examination

The process of evaluation begins even before the patients begin to give their history. After reading the physician's referral letter and any accompanying documentation, our own initial assessment begins in the waiting room (Table 1).

Clinical problem	Possible diagnosis
Painful foot, elderly lady on diuretics	Gout
Young, sexually active; hot swollen joint	Gonococcal arthritis
Headache with diffuse aches and pains in an elderly person	Polymyalgia rheumatica
Antinuclear antibody-positive, but no symptoms	Referring physician's dilemma, not the patient's
On allopurinol with a high uric acid but no arthritis	Not gout
Postpubertal male with low back pain	Ankylosing spondylitis
Woman, 6 weeks postpartum; small joint arthritis	Rubella vaccination; rheumatoid arthritis

NB: intuitive diagnoses must be constantly subject to reflection and reassessment.

Table 1 Preconsultation intuitive observations

Many important signs may be noticed when asking for the patient. An accompanying friend or relative may respond, leading a disabled or reluctant patient forward and apparently wishing to take charge of the proceedings. Observation of such interpersonal reactions forms a significant part of the assessment. We also see whether the patient rises from a chair with difficulty, owing to weakness or stiffness, and how he or she walks towards us. Is a walking aid being used? If so, does it seem to be needed? On introduction, with a normal handshake, is there a flinch? Does the gait change in the walk from the waiting to the examining room? What is the patient's general demeanour. Even before the history taking begins, areas of focus will have already been defined in an intuitive manner. These will subsequently be organized in a systematic manner.

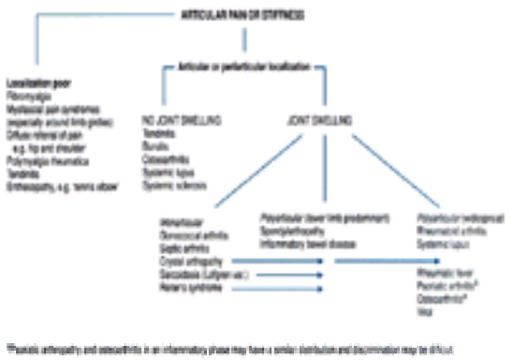
History

When taking the history, the physician should, in due course, attempt to focus the patient's complaints into a differential diagnostic scheme. It is obviously important to determine where the complaints are situated. Are they localized or generalized, episodic, constant, or progressive? Is there any diurnal variation and what, if any, are the aggravating or alleviating factors? In many conditions it is often possible to establish a fairly firm diagnosis from the history alone and, when symptoms are episodic, such a working diagnosis will have to suffice until the patient is seen during a symptomatic period. A 'wait and see' approach is not uncommon in rheumatology but the rationale must be carefully explained to the patient. Thus, the described pattern of joint involvement and characteristic symptoms will often allow the diagnosis of acute gout or palindromic rheumatism to be made with confidence, awaiting objective confirmation during the next episode.

Specific symptoms to be asked for include arthralgias, myalgias, joint swelling, morning stiffness, Raynaud's phenomenon, and skin rashes and paraesthesias.

If there is suspicion of a systemic disease, a full systematic medical inquiry must be embarked upon and any significant symptoms noted. Figure 1 shows what we believe to be the key points in our own intuitive diagnostic process. This becomes modified by the statistics of disease likelihood in our practice (Table 2). Even if the problem appears to be localized, one must be conscious of the fact that systemic diseases (rheumatic and non-rheumatic) often present with local symptoms, for

example carpal tunnel syndrome in rheumatoid arthritis and hypothyroidism (Table 3).



[a]Psoriatic arthropathy and osteoarthritis in an inflammatory phase may have a similar distribution and discrimination may be difficult.

Fig. 1 Aspects of differential diagnosis in rheumatology.

	University (%)	Private practice (%)
Rheumatoid arthritis	14.7	16.9
Degenerative arthritis	17.0	6.6
Ankylosing spondylitis	6.0	2.8
Crystalline arthropathy	3.8	4.1
Septic arthritis	0.7	0.5
Systemic lupus erythematosus	2.8	4.3
Other connective tissue diseases	3.1	—
Juvenile arthritis	0.5	—
Other[a]	51.7	64.7

[b]Largely periarticular disorders but includes fibromyalgia.

Table 2 Distribution of rheumatic diseases as seen in a university clinic and in a busy private practice [a]

Symptom/sign	Illness
Weight loss/bone pain	Multiple myeloma
Carpal tunnel syndrome	Acromegaly Hypothyroidism Amyloid
Bone pain	Secondary tumour
Vasculitis (polyarteritis nodosa)	Hepatitis
Stiffness and difficulty in walking	Parkinson's disease
Chronic synovitis with bowel problems	Inflammatory bowel disease
Stiff fingers, shoulder pain	Diabetic cheiroarthropathy

Table 3 Primarily non-rheumatic illnesses presenting in the rheumatology clinic

Pain and stiffness

The majority of adult patients seeking a rheumatological consultation complain of pain and/or stiffness. The pain is usually localized descriptively to their joints, muscles, or bones and the clinician has to determine whether this localization is correct.

It is important to bear in mind that patients are not usually familiar with anatomy and physiology, and that it is often impossible, for example, to elucidate an anatomically correct description of pain and paraesthesias due to compression of the median nerve from a patient with pain in the hand and forearm. Similarly, patients may complain of pain in the hip 'right in the joint' and when asked to indicate the site of the pain, they will point to the greater trochanter or gluteal region, not the groin.

Nevertheless, if a patient presents with a somewhat localized problem (e.g. forearm pain with use), close attention to the anatomical peculiarities of the region and the relevant symptoms and signs will generally provide a clear diagnosis. Localized problems may be multifocal, suggesting a generalized disorder, but a careful examination (e.g. for bursitis and for tendinitis) after the history will help in this distinction. It is important to be wary of the diagnosis of diffuse or even focal osteoarthritis as the cause of symptoms, even when there may be supporting radiographic evidence. Although this condition may be present, it may not be the predominant cause of symptoms (Table 4).

Diagnosis	Clinical pointer
Periarticular shoulder pain	Referred to deltoid insertion
Tennis and golfer's elbow	Diffuse forearm pain on grip-ping
Carpal tunnel	Nocturnal paraesthesiae, often diffuse
Flexor tenosynovitis	Triggering and/or finger pain on gripping (pulp-pinch sign positive)
de Quervain's tenosynovitis	Positive Finkelstein test
Mechanical back pain	Tenderness over gluteals and sacroiliac ligaments frequent
Spondylitic back pain	Morning sacroiliac or gluteal tenderness; morning stiffness marked
Trochanteric bursitis	Nocturnal pain when lying on that side; focal, point tenderness
Hip synovitis	Usually groin and outer thigh pain, occasionally elsewhere
Anserine bursitis	Often nocturnal medial knee pain if knees are touching; localized tenderness

Other, less localized syndromes, e.g. calcified bursitis, pleural basitis, infrapatellar bursitis, should be immediately apparent on examination of the painful area.

Table 4 Clinical pointers in syndromes where pain is poorly localized

Pain is defined by the patient's subjective description. The clinician's task is to attempt to characterize this in terms that are in common medical usage. As indicated, the starting point for an assessment of pain is to describe localization. The quality, intensity, duration, and type of onset, as well as provoking, aggravating, or alleviating factors must be determined, together with the presence of a diurnal variation. However, such technical terms are usually best avoided with the patient. Important and revealing questions are 'What brings on the pain?', 'What can you do to relieve it?' Having become familiar with the customary responses to such questions the rheumatologist is more alert to the patient who seems unable or even unwilling to describe the problem clearly. It is often helpful to try and reproduce the symptoms by manipulation or pressure, particularly when the patient appears unable to pinpoint the location without help. Thus, forearm pain on gripping tightly

may help distinguish the tender origin of the common extensor in a patient with tennis elbow from a similarly tender trigger point found in fibromyalgia.

While the spread of pain outside the usual limits may reflect intensity, this rarely proves a problem with a superficial pain, which is commonly well localized; thus gout or septic arthritis may be associated with severe pain but the origin is obvious. A glomus tumour of the nail bed may cause considerable proximal radiation of pain but examination should localize the source. To locate the source of pain of deeper or visceral origin may be much more difficult because of the phenomenon of 'referral'. Some patterns of referred pain are precise and well known, for example shoulder pain from a diaphragmatic lesion or gallbladder; arm and/or neck pain from myocardial ischaemia. Others are more variable. Thus, the presence of sciatica may reflect nerve-root compression from a lumbar disc but much more commonly represents a referred distribution of pain from one or more regions around the lumbar spine. Experiments involving threads left temporarily after surgery around painful sensory structures or involving injection of hypertonic saline into ligaments and facetal joint structures have shown referral of pain from the lumbar spine into gluteal areas, to the posterior thigh, and even down the calf (Kellgren 1977). Involvement of the upper half of the lumbar spine tends to be referred to the anterior thigh. The only way to distinguish clearly true sciatica from such referred pain is on the basis of neurological signs, as associated symptoms (e.g. a cough or sneeze impulse) may be found with either. Sometimes the pain may be remarkably well localized but again at a point distant from the exciting lesion; thus interscapular pain may be seen with postural/mechanical problems in the cervical spine, and anterior chest pain in relation to inflammation involving the mid-dorsal spine. Sometimes relatively focal or diffuse tenderness may be associated with such referred pain syndromes. Pain referral may prove confusing to the physician but it is also often difficult to explain to a patient with, for example, pain well localized to the deltoid insertion that it is coming from a pericapsular lesion of the shoulder joint. Equally, deep visceral pain, such as a penetrating duodenal ulcer, may of course be referred to skeletal structures. Because of potentially similar patterns of pain referral a differentiation between skeletal and true visceral pain may have to be made on grounds other than the location of the discomfort.

Quality of pain

Skeletal pain may be caused by a variety of problems ranging from ischaemia, inflammation, and nerve entrapment to central factors that lead to a perception of pain where no evident external causes exist. Quite apart from aggravating or relieving factors, the quality of the pain may provide diagnostic pointers. Thus, a burning pain in the feet, especially at night, may suggest a neuropathy. The pain of rheumatoid arthritis is usually steady and aching not agonizing, excruciating, or terrifying. Such descriptions in a patient with rheumatoid arthritis would suggest an alternative explanation, for example, sepsis, fracture, nerve entrapment, or non-organic causes. Chronic pain syndromes are well recognized but their underlying nature remains controversial. Because of overlapping and insufficient criteria a single individual may be designated by one physician as having a myofascial pain, by another as referred pain with secondary depression, and by a third as a non-organic, that is central, pain syndrome. The descriptions used by patients with central pain tend to be extreme and we find that to have patients complete instruments such as the McGill pain questionnaire is helpful as a teaching aid in illustrating to students the range of terms used. Table 5 illustrates some of the terms from that questionnaire which distinguish between central and peripheral pain syndromes. Similar expressions are chosen by patients with fibromyalgia, which is one reason for its earlier name of 'pain magnification syndrome', but also by those with causalgia, reflex sympathetic dystrophy, and occasionally even periarticular shoulder pain. In addition, some individuals or groups of individuals tend to use these extreme terms out of a sense of frustration or anxiety, or because of ethnic convention (Zborowski 1952), and risk being labelled as neurotic because of them, when the presence of organic disease may be missed. The reality of such pain of central origin has often been dramatically demonstrated by the stage hypnotist with a variety of forms of posthypnotic suggestion. The severe quality of the rare thalamic pain syndrome is also well recognized. It is notable that Mark *et al*. observed with stereotactic thalamic surgery that in some, pain sensation could be abolished without loss of the unpleasant emotional effect and in others the emotional effect may disappear and yet the pain remain without its unpleasant qualities (Mark *et al*. 1960). Some of our current pharmacotherapeutic approaches reflect these findings. Therapy that is less conventional may have even more dramatic affects. Organic pain—for example hot metal or hand immersion at 4°C for 45 min—can be blocked both from consciousness and from detection by electroencephalography during some forms of meditation. The block appears to be below the level of the cortex (Davidson and Goleman 1977). While the various central pain syndromes may respond to narcotic analgesics, this is an inappropriate approach both because it decreases the production of endorphins and because it is likely to cement the abnormal pain-behaviour patterns. Some of these patients have post-traumatic pain syndromes with associated medicolegal implications. In any event, as a group they form a large proportion of patients in many rheumatological practices. It is clear that we urgently need better criteria both for diagnosis and classification of pain syndromes, as well as better approaches to treatment.

TABLE cellSpacing=0 cellPadding=0 align=left border=0 hspace="10" vspace="5">

Organic	Non-organic
Pounding	Flickering
Jumping	Shooting
Pricking	Lancinating
Sharp	Lacerating
Pinching	Crushing
Hot	Searing
Tender	Splitting

Spreading	Piercing
Annoying	Unbearable
Tiring	Exhausting
Fearful	Terrifying
Tight	Tearing

Table 5 Terms from the McGill pain scale that help distinguish between organic and non-organic pain syndromes

Stiffness

Stiffness is an important symptom in rheumatological disease. Typically, patients with rheumatoid arthritis complain of peripheral joint stiffness present for more than 30 min after awakening and recurring after periods of immobility. Patients with peripheral joint osteoarthritis may also have morning stiffness. This is usually of shorter duration but may also recur after rest. Peripheral stiffness may reflect non-articular inflammation and can be marked, as in plantar fasciitis, but is unusual with lesions around the shoulder. Stiffness for less than 5 min is generally of minor significance but could represent, for example, flat feet. Mechanical disorders of the lumbar spine may be associated with morning stiffness of short duration (less than 15 min) whereas patients with ankylosing spondylitis may say that their stiffness persists for several hours. Stiffness present for many hours, and even 'all day', in the absence of gross physical findings usually points to a functional condition such as fibromyalgia.

Is there a history of joint swelling or not?

The cardinal observation made by rheumatologists is that of joint swelling but patients can be amazingly unreliable, in being able to describe a joint swelling that does not exist and has not existed. This is most notorious in fibromyalgia and it is critical to be able to distinguish arthralgias, which may include a variety of lesions of bursas, tendons, and tendon sheaths, from true arthritis (i.e. a swollen joint observed by a competent physician). It is, therefore, a critical part of the subsequent examination to confirm the presence or absence of joint swelling (see below).

Comment

In addition to focusing on differential diagnosis, the history and presentation of symptoms should give the first indication of how patients should be advised to manage their problem(s). Some people will often make light of what is obviously severe rheumatoid arthritis whereas in another circumstance a patient with fibromyalgia will say that they are unable to carry out mundane tasks because of 'knives twisting in the muscles'. The physician's task is to ameliorate the diseases and to provide advice that will allow both types of patient to carry on with normal lives. The stoical patient may elicit a more sympathetic response from the physician but complaints from a medically trivial condition are no less valid or worthy of being taken seriously.

Physical examination

The physician recognizes disease entities from the physical findings in addition to symptoms and needs to integrate these two sets of data. Pain may be localized to joints, the spine, soft tissue, muscle, or bone. If it is localized in joints, can swelling be observed? If so, is the swelling severely inflammatory, moderately inflammatory, or non-inflammatory? This issue of joint swelling and its nature is one of the most critical aspects of the rheumatological examination and is reflected in the importance of teaching proper techniques for the 'wipe' or 'bulge' test in the knee, the proper palpation of the interphalangeal joints, metatarsophalangeal joints, etc. It is perhaps

due to inability to assess swelling in the hip joint that the assessment of the range of motion is most important in this joint. The pattern of joint involvement is very important: is it monoarticular, polyarticular, symmetrical, asymmetrical, widespread, or restricted to lower extremities? Is there a surrounding cellulitis? Severe monoarticular arthritis with or without surrounding cellulitis suggests a crystal-induced arthritis, septic arthritis, sometimes Reiter's syndrome, gonococcal arthritis, or the Löfgren variant of sarcoidosis. These conditions may affect more than one joint, in which case the distribution is usually asymmetrical and, in gout, may involve contiguous joints of the same limbs. Widespread inflammatory joint swelling of moderate or severe degree may be seen in rheumatoid arthritis, psoriatic arthritis, polyarticular crystal-deposit disease, systemic lupus erythematosus, and other diffuse diseases of connective tissue; systemic conditions such as Whipple's disease may also present in this fashion. Joint swelling, without much evidence of inflammation, usually indicates osteoarthritis, which may involve distal and proximal finger joints—a classical feature of this predominantly female familial condition. Involvement of the metacarpophalangeal joints, especially if seen with chondrocalcinosis, should suggest the possibility of previously unrecognized haemochromatosis in the family, and premature osteoarthritis in a variety of joints makes one also consider conditions such as alcaptonuria, Wilson's disease, or epiphyseal dysplasias.

During the course of the examination, fairly obvious findings may give substantial clues to the diagnosis. The facial rash of systemic lupus erythematosus, the scaling skin lesions accompanying psoriatic arthritis, and the specific lesion associated with Lyme arthritis are examples that readily come to mind and are discussed further in Chapter 5.3.4.

Tests

Think hard before you order them, inappropriate testing causes more problems than it solves.

Many of the tests that are available (see Section 4) are often abnormal in a range of rheumatic and non-rheumatic diseases and so, for example, the commonly used rheumatoid factor and antinuclear antibody tests are rarely sufficient in themselves to arrive at a precise diagnosis. Clinical experience teaches that the results of laboratory tests must be interpreted with caution and with continual reference to the clinical presentation. This is not because the tests used in the rheumatology subspecialty are less reliable than those of other disciplines but they are less specific and, more importantly, as many of these diseases are uncommon, the history and physical examination remain pre-eminent. Most of us would request a recent full blood picture and urinalysis on every patient, regardless of diagnosis. The erythrocyte sedimentation rate is still used by many despite the recognized pitfalls of false positive and negative results. It nevertheless remains difficult to support a diagnosis of polymyalgia rheumatics, for example, with a relatively normal sedimentation rate; on the other hand, it is comfortably reassuring to see a normal result in a patient in whom we have found no evidence of inflammatory disease. Selective lymphopenia of less than 1000/ml is the poor man's indication of systemic lupus or a recent virus infection. Thrombocytosis is common in active rheumatoid arthritis and the vasculitides.

As with other tests, it is important to know why the test is being ordered and what influence the result will have on diagnosis and management. A test for rheumatoid factor may be ordered in a patient with clinically obvious nodular rheumatoid arthritis not for diagnosis but for better definition of the condition. A serum uric acid level is of no value in the diagnosis of gout; there are simply too many non-gout individuals with raised levels and too many normal levels seen even during the acute attack to make this helpful. It is, nevertheless, an effective way to monitor compliance with hypouricaemic therapy. In a patient with mechanical back symptoms it is clear that a raised uric acid or a positive rheumatoid factor, for example, are not going to influence diagnostic considerations; they should, therefore, not have been ordered.

A consideration of pre- and post-test probabilities is critical. A positive fluorescent antinuclear antibody (FANA) test is about 97 per cent specific and 99 per cent sensitive for systemic lupus erythematosus. These figures sound, and are, excellent but it remains true that as systemic lupus has a prevalence of around 0.1 per cent of the population or even less, there are, in a given population, more normal people positive for antinuclear antibody than there are lupus patients. Thus, despite a 97 per cent specificity, the majority of individuals with a positive antinuclear antibody in a randomly screened population will not have systemic lupus. On the other hand, if a patient with photosensitivity, leucopenia, and an abnormal urinary sediment has a positive antinuclear antibody, one can be virtually certain that the diagnosis is systemic lupus. Using Bayes' theorem, it has often been calculated that if the pretest probability, that is the clinical likelihood, of a given patient having systemic lupus is over 50 per cent, a positive antinuclear antibody will increase this likelihood to a near certainty. If one orders the test 'as a screen' in a patient who has no clinical evidence of lupus, for example a tennis elbow, where the pretest likelihood of lupus is minimal, then a positive test will have no real import on this probability, perhaps increasing it to about 2 per cent, that is still 50:1 against the diagnosis of systemic lupus erythematosus. This would surely argue against ever doing the test as a screen. In the management of diffuse disease of connective tissue it is important to establish the broad category of the disease which is being treated but the precise subcategory may be therapeutically unimportant. For example a serological diagnosis of mixed connective tissue disease (MCTD) should not prevent routine monitoring of the urinalysis and aggressive treatment of any renal or any other end organ involvement which may occur. 'Anti-ENA' antibody tests (antibodies to extractable nuclear antigen) are unfortunately often performed routinely in patients with a positive FANA. Their role should surely be to try and help delineate clinical subtypes of disease where this information will be of help, either therapeutically or prognostically.

Sometimes laboratory tests may be helpful in reducing the need for more invasive procedures. Thus, a positive test for antineutrophil cytoplasmic antibodies in a patient with features of Wegener's granulomatosis may make a biopsy unnecessary. Similarly, anti-Jo-1 antibodies in a patient with muscle weakness and elevated enzymes may not only help avoid a biopsy but give potentially important prognostic information.

If a young male complains of nocturnal low back pain with stiffness lasting more than one hour in the morning with a restricted range of flexion in the lumbar spine, would testing for HLA-B27 be at all helpful? Under normal circumstances it would not. One would check the pelvic radiograph—it would be very uncommon, even in early ankylosing spondylitis, to see normal sacroiliac joints. Although, as routine interpretation is notoriously unreliable it is a good idea to develop the expertise to review these personally. In the late teens and early twenties and, of course, in children, the radiographs can be difficult to interpret and here HLA-B27 typing may be helpful. In a relative of a HLA-B27 ankylosing spondylitis proband, a negative HLA-B27 test indicates that any back symptoms are very unlikely to be ankylosing spondylitis related, just as a positive test in this context, even with normal radiographs, may suggest a forme fruste of the disease.

Problems of interpretation of the findings also abound in radiography. Mild asymptomatic radiographic changes are frequent, especially in the lumbar spine but also in the knee. It is all too easy to ascribe symptoms to these changes when examination would reveal an anserine bursitis or a similar localized, readily treatable problem. A more critical problem has arisen because of 'false positive' findings, for example of disc protrusion, seen with computed tomography scans of the lumbar spine and even more so with magnetic resonance imaging. Thus, a high proportion of asymptomatic subjects will have one or more abnormalities evident. This means that little reliance can be placed on these findings in symptomatic subjects unless the findings clearly fit with an anatomical lesion predictable with reasonable probability from the clinical examination. Even in a time of no financial constraints these investigations become useful in the management of patients with back pain only if it is important to clearly delineate either the nature of the pathological process or the extent and location of a lesion, for example prior to a surgical intervention or, more questionably, for medicolegal requirements.

It is tempting for an inexperienced physician to place more weight on the printed test results than on clinical judgement; all rheumatologists see too many patients with minor problems where a consultation has been stimulated by an incorrectly ordered test having proved positive. Thus, from a diagnostic perspective, tests are ordered where they can help support or deny the clinically derived diagnostic impression. A further indication would be to follow a patient's progress. Thus, in the treatment of patients with rheumatoid arthritis progression of erosive changes may, by themselves, influence therapeutic decisions. Bone mineral density measurements may be helpful in the diagnosis of demineralization. They will be indicated primarily when the results will be influential in helping the patient or physician reach a therapeutic decision. Thus, if the patient, for various reasons, is to be started on oestrogen therapy anyway there is little or no point in ordering the test. A 'baseline' measurement may be intellectually satisfying but as a failure to respond to oestrogen must be extraordinarily rare, repeated studies make little economic sense.

A management plan and the individual patient

It is clear that any management plan depends on the underlying disease process and the extent of its progression in the individual patient. There is now a clear consensus that the earlier remittive therapy is instituted in rheumatoid arthritis, the more likely it is to be successful. Thus, we would argue that at least all seropositive patients should be started on a remittive agent as soon as the diagnosis is made without subjecting the patient to a demonstration of the inefficacy of non-steroidal anti-inflammatory drugs alone. Similarly, the longer lupus nephritis has gone untreated, the more refractory it seems to be to treatment, which hastens our decision to add cytotoxic therapy to the management of this condition (Table 6).

How compliant	Decisions about parenteral versus oral therapies
Geographic	Are there problems of access to clinic; can the patient attend for a weekly series of gold shots or must visits be more intermittent?
Age of the patient	Is this a child, adult, or elderly person? Are there drug dose problems, drug interactions, or accompanying illnesses? A stroke might make postoperative rehabilitation difficult, deferring, for example, an otherwise indicated arthroplasty
Psychological status	Could the patient tolerate the complications of therapy, e.g. nausea with methotrexate or rash with gold?
Upper gastrointestinal problems, peptic ulceration	Difficulty taking non-steroidal anti-inflammatory drugs

Table 6 Fitting the management plan to the patient

In elderly patients, or those with impaired renal function from other causes, we check the serum creatinine before and either 2 or 7 days after the institution of therapy with non-steroidal anti-inflammatory drugs, depending on the drug half-life. Similarly, in elderly patients or in those who have had significant gastrointestinal haemorrhage or perforation, we would often combine use of such non-steroids with gastric protection. In rheumatoid arthritis this is a further argument in favour of the early use of remittive agents. In localized but painful conditions such as tendinitis and bursitis it is more economical for the patient to be treated with local steroid injections where appropriate rather than by oral non-steroidal drugs, although it may be less convenient for the physician. The expected treatment benefits should not be outweighed by difficulties in complying with the suggested therapeutic programme. For example geographical considerations may be important in the decision whether to use a parenteral or oral remittive agent in rheumatoid arthritis. It is obviously most important that the relative risks and benefits of treatment be most carefully explained to the patient, with supporting written information provided. Except in life-threatening or rapidly crippling conditions it is wise to allow the patient a waiting period for discussion with family members and the referring physician rather than to try to persuade a reluctant patient to accept your suggestions. One phrase we find useful in this circumstance is 'If I or one of my family members had your disease, and another rheumatologist were to suggest this course of treatment, I would have no hesitation in accepting it'.

In any management plan for patients with rheumatological disease a careful assessment must be made of the relative architectural, mechanical, and inflammatory components. All of these must be seen in the context of the patient's general health. Generally speaking, architectural problems may benefit from surgical solutions and secondary mechanical problems, such as muscle weakness, are susceptible to physical therapy. In rheumatoid arthritis, seriously disabling problems in the feet and ankles can be prevented by the provision of adequate transverse and longitudinal supports for the metatarsal arches, combined with suitable footwear. Surgery does not necessarily pose any increased risk in elderly patients, if risk factors such as electrolyte imbalance, heart failure, or arrhythmia can be corrected or treated. It is most important to determine that surgical correction of the musculoskeletal problem, in, for example, a painful unstable knee, will improve the patient's quality of life. There may be little point in giving a patient a perfectly stable, painless joint if exercise distance cannot be significantly increased due to cardiac, respiratory, or peripheral vascular problems. Under these circumstances it would be more practical simply to provide an external brace. Similarly, age can be an important consideration in any plan for staged orthopaedic surgery accompanied by the necessary long periods of rehabilitation between procedures. Such a treatment plan, which may extend over several months or years, may be entirely sensible for a patient in their 40s or 50s whose life expectancy is 20 or 30 years. It could hardly be thought to improve the overall quality of life for someone of 80 whose life expectancy is much less.

If someone's life expectancy is very short because of, say, terminal malignant disease, we may choose to prescribe steroids for their rheumatoid arthritis, but we have on occasion been surprised at the length of the terminal illness, which has allowed serious steroid complications to arise.

Conclusions

Finally, it should be remembered that the ability to recognize a seriously ill patient before a specific diagnosis is as important for rheumatologists as for all other physicians. While this remains part of the art of medicine, it is also a reason for the triggering of appropriate perceptive questions, even to patients who may at first sight appear to have minor disease.

1.1.2 Children and adolescents

Ross E. Petty

Introduction

Musculoskeletal complaints in childhood are common, but usually short-lived, and most are ultimately inconsequential (Apley 1976). It may be difficult, however, to differentiate definitively such problems from those associated with long-term illness. An appreciation of the spectrum of rheumatic disorders in childhood, their frequency, and the age-related factors that may affect their presentation or course is essential for the physician caring for children or adolescents. A full discussion of childhood rheumatic diseases is beyond the scope of this chapter and summaries of many of the important entities are provided in later chapters or in other sources (Cassidy and Petty 1995; Southwood and Malleson 1993).

Rheumatic diseases in childhood differ considerably from those in adults. In some instances the diseases themselves are unique to the young; in all instances, age-related factors are important determinants of clinical presentation, differential diagnosis, and management. It is the purpose of this chapter to consider some aspects of the epidemiology of childhood rheumatic diseases and the clinical characteristics of the growing child that may affect the presentation, diagnosis, and management of such diseases.

Epidemiology

An understanding of the relative frequencies of the rheumatic diseases in childhood, and their distribution through the age range, facilitates their recognition and diagnosis. There is a paucity of valid data on the incidence and prevalence of rheumatic diseases in childhood. This is due, in part, to the absence of definitive diagnostic criteria for these diseases, or to the existence of competing criteria.

Definitions and criteria

There are two major sets of criteria for the diagnosis of chronic childhood arthritis, those of the American College of Rheumatology (**ACR**) (Brewer *et al*. 1977) and those of the European League Against Rheumatism (**EULAR**) (Table 1) (European League Against Rheumatism 1977). The major difference between the two is the inclusion of the seronegative spondylarthropathies in the EULAR definition of juvenile chronic arthritis, and their exclusion from the ACR definition of juvenile rheumatoid arthritis. The EULAR classification restricts the term juvenile rheumatoid arthritis to children with IgM rheumatoid factor. There is little doubt that the IgM rheumatoid factor-positive girl with polyarthritis resembles the adult with seropositive rheumatoid arthritis; the other arthritides defined by the ACR criteria (oligoarticular-onset and systemic-onset juvenile rheumatoid arthritis) are clinically distinct. Oligoarticular-onset arthritis is essentially a uniquely childhood disease. Systemic-onset disease may have an adult counterpart, so-called adult-onset Still's disease (Elkon *et al*. 1982).

	ACR Criteria: JRA[a]	EULAR Criteria: JCA[b]
Age at onset	Under 16 years	Under 16 years
Duration	6 weeks or more	3 months or more
Onset types	JRA: Pauciarticular, <4 joints Polyarticular, >4 joints	Still's disease: Pauciarticular, <5 joints Polyarticular, >4 joints (rheumatoid factor negative)
	Systemic arthritis with characteristic fever	Systemic arthritis with characteristic fever
Other groups	None	JRA: rheumatoid factor positive polyarthritis Ankylosing spondylitis Psoriatic arthritis
Exclusions	Other types of arthritis	

[a]JRA, Juvenile rheumatoid arthritis (Brewer *et al*. 1977)
[b]JCA, Juvenile chronic arthritis (EULAR 1977)

Table 1 Comparison of the ACR and EULAR criteria for the diagnosis of chronic arthritis of childhood

Recently, a third approach to classification of childhood arthritis has been proposed by a committee of the International League Against Rheumatism (**ILAR**) in co-operation with the World Health Organization (**WHO**) (Fink 1995). This classification (Table 2) is proposed in the hope that it will allow the identification of homogeneous groups of patients suitable for genetic, immunological, and epidemiological study. It recognizes that some children will not be classifiable at the present time and it is designed to be revised after testing and validation. It is recommended that at present this classification be reserved for use in research settings and that the ACR or EULAR criteria be retained until proof of the validity of the ILAR/WHO approach has been shown. For consistency with the other chapters in this book, the EULAR terminology for chronic arthritis occurring in children will be used throughout this chapter except where specifically indicated.

Oligoarthritis (<5 joints affected during first 6 months of disease)

Polyarthritis (>4 affected during first 6 months of disease)
- Rheumatoid factor negative
- Rheumatoid factor positive

Extended oligoarthritis (oligoarticular onset but accumulation of >4 affected joints during first year of illness)

Systemic arthritis (arthritis with typical fever, rash) (definite if arthritis is present, probable in the absence of arthritis)

Psoriatic arthritis (arthritis with psoriasis, or arthritis with a family history of psoriasis, and dactylitis or nail abnormalities)

Enthesitis-related arthritis (arthritis with enthesitis)

(Fink 1995)

Table 2 Proposed WHO/ILAR classification of arthritides of childhood

Two other sets of criteria deserve mention. The criteria for the seronegative enthesitis and arthritis (SEA) syndrome (Table 3) (Rosenberg and Petty 1982) identify children who, although they do not currently fulfil criteria for the diagnosis of ankylosing spondylitis, are likely to do so in the future (Cabral *et al*. 1992a; Burgos-Vargas and Clark 1989). These criteria facilitate differentiation of such children from those with other types of arthritis. The so-called 'Vancouver criteria' (Southwood *et al*. 1989) were developed to facilitate the early identification of children who have or will develop psoriatic arthritis (Table 4). Although both of these sets of criteria have gained widespread use, they have not been formally validated.

Age less than 16 years

Seronegativity (absence of rheumatoid factor and antinuclear antibody)

Enthesitis

Arthritis or arthralgia

(Rosenberg and Petty 1982)

Table 3 Criteria for the diagnosis of seronegative enthesopathy, arthropathy (SEA) syndrome

Definite psoriatic arthritis:
- arthritis with typical psoriatic rash, or
- arthritis with three of four criteria:
  - dactylitis
  - nail pitting or onycholysis
  - psoriasis-like rash (atypical in location or form)
  - family history of psoriasis (first or second degree relatives)

Probable psoriatic arthritis:
- arthritis with two of four criteria

(Southwood *et al*. 1989)

Table 4 'Vancouver criteria' proposed for the diagnosis of juvenile psoriatic arthritis

The only other diagnostic criteria that have been developed for childhood rheumatic diseases are those for acute rheumatic fever (Special Writing Group of the American Heart Association 1992) (Table 5) and those for Kawasaki disease (Table 6) (Sekiguchi *et al*. 1985). The application of the criteria for Kawasaki disease has been useful in identifying most children who have this childhood vasculitis but the criteria lack the benefit of rigorous evaluation and could include children with other exanthematous illnesses. Furthermore, their strict application would exclude children whose later disease course indicates that they had Kawasaki disease.

Major manifestations	Minor manifestations
Carditis	Fever
Polyarthritis	Arthralgia
Chorea	Previous rheumatic carditis
Subcutaneous nodules	Prolonged PR interval
Erythema marginatum	Increased erythrocyte sedimentation rate or C-reactive protein

Diagnosis requires the presence of two major criteria, or one major and two minor criteria, and evidence of a preceding streptococcal infection (Special Writing Group of the American Heart Association 1992)

Table 5 Criteria for the diagnosis of acute rheumatic fever

Fever	duration 5 days or more
Conjunctivitis	bilateral, bulbar, non-suppurative
Lymph node enlargement	cervical, non-purulent, >1.5 cm
Rash	polymorphous, no vesicles or crusts
Changes in lips and mucosa	dry, red, vertically cracked lips, or strawberry tongue, or diffuse oropharyngeal erythema
Changes in extremities	erythema of palms or soles, or indurative oedema of hands, feet, or desquamation of tips of fingers

Diagnosis requires the presence of five of six criteria. Recommendations of the Japan Mucocutaneous Lymph Node Syndrome Research Committee 1984 (Sekiguchi *et al*. 1985)

Table 6 Criteria for the diagnosis of Kawasaki disease

Criteria for the diagnosis of other chronic rheumatic diseases of childhood either do not exist, have been adopted in whole or part from criteria for the classification of diseases in adults, as for systemic lupus erythematosus (Tan *et al*. 1982) or dermatomyositis (Bohan and Peter 1975), or have not been validated in clinical practice.

Frequencies of childhood rheumatic diseases

It is frequently perceived that rheumatic diseases are rare in childhood and adolescence. As a result, consideration of such a diagnosis may be inappropriately delayed. In fact, a significant fraction of adults with rheumatic diseases have onset of their disease in childhood (Table 7). Thus, up to one-fifth of all patients with systemic lupus erythematosus or dermatomyositis/polymyositis have onset of their disease before age 17 years. Onset of disease in childhood occurs in from 5 to 10 per cent of individuals with one of the more common chronic arthropathies such as ankylosing spondylitis and rheumatoid arthritis. It is likely that these estimates represent minima because, particularly in the diseases such as oligoarticular-onset juvenile chronic arthritis, many children have remission of their disease in childhood.

Adult rheumatic disease	Annual rate per 100 000	Percentage with childhood onset
Spondylarthropathies	130–1000	10
Rheumatoid arthritis (juvenile)	40	5
Systemic lupus erythematosus	6	18
Dermatomyositis/polymyositis	0.8	20
Scleroderma	0.4	3
Vasculitides	0.2	10
Gout	20	0

Table 7 Incidences of connective tissue diseases

Some rheumatic diseases occur almost exclusively in those under 16 years of age. Included in this category are oligoarticular-onset juvenile chronic arthritis with uveitis, systemic-onset juvenile chronic arthritis, acute rheumatic fever, and, among the vasculitides, Henoch-Schönlein purpura and Kawasaki disease. In contrast, certain rheumatic diseases almost never occur in childhood. Included in this group are gout, calcium pyrophosphate-deposition disease, polymyalgia rheumata, and primary osteoarthritis.

The actual frequencies of each of the types of arthritis in a community is difficult to ascertain. A study from Finland (Table 8) (Kunnamo *et al*. 1986) indicates that acute, presumably postviral arthritis of the hip or knee accounts for three-quarters of all children with arthritis; chronic childhood arthritis accounts for approximately one-fifth. Children with other rheumatic diseases were not included in this study. The overall impression is, however, that the annual incidence of significant joint inflammation or infection involves approximately 1 in 1000 children and that chronic arthritis occurs in 1 in 5000 children per year.

Diagnostic group	Percentage of total	Incidence per 100 000 children
Transient synovitis of the hip	47.8	51.9
Acute transient synovitis	23.5	25.8
Juvenile chronic arthritis	16.8	18.2
Septic arthritis	6.2	6.7
Reactive arthritis	5.0	5.4

Adapted from Kunnamo *et al*. (1986)

Table 8 Incidence of arthritis in children in a Finnish community

The composition of paediatric rheumatology clinic populations has been described in a study by Rosenberg (Rosenberg 1990), and in national registries of children seen in paediatric rheumatology clinics (Bowyer *et al*. 1996; Malleson *et al*. 1996; Symmons *et al*. 1996). In Rosenberg's study, 46 per cent of children with an identifiable rheumatic disease had juvenile rheumatoid arthritis (ACR criteria), 31 per cent had a spondylarthropathy, 18 per cent had a connective tissue disease (systemic lupus erythematosus, dermatomyositis, Henoch-Schönlein purpura, Kawasaki disease, other vasculitis), and 5 per cent had a variety of other conditions. From these data, an annual incidence of juvenile rheumatoid arthritis of 8 in 100 000 and a prevalence of 40 in 100 000 were estimated.

Age at presentation

Many of the rheumatic diseases of childhood have characteristic ages at onset, (Fig. 1) and consideration of the age of the child at the onset of symptoms can be of value in diagnosis. For this purpose, four age groups can be considered. Three rare syndromes make their appearance in the neonatal period; neonatal lupus syndromes, neonatal-onset multisystem inflammatory disease—NOMID (also called chronic infantile neurological cutaneous and articular syndrome—CINCA), and infantile sarcoidosis. In addition, septic arthritis may occur in the neonate. In early childhood (from 1 to 4 years), oligoarticular-onset juvenile chronic arthritis, juvenile psoriatic arthritis, Kawasaki disease, and septic arthritis are most frequent. In midchildhood (7 to 11 years), polyarticular-onset juvenile chronic arthritis and ankylosing spondylitis begin to be seen and juvenile dermatomyositis, Henoch-Schönlein purpura, and polyarteritis nodosa have their peak frequencies. In late childhood and the teenage years, juvenile ankylosing spondylitis (in boys) and systemic lupus erythematosus (in girls) show a marked increase and the rare vasculitis syndromes, such as Wegener's granulomatosis and Takayasu's arteritis, occur.

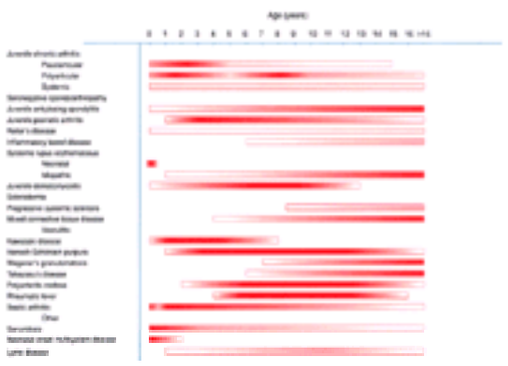

Fig. 1 Characteristic ages of onset of rheumatic diseases of childhood.

Influence of gender

Consideration of the sex of the child may be of help in formulating the differential diagnosis (Fig. 2). The most striking differential sex ratios are seen in the predominance of juvenile ankylosing spondylitis in boys and of systemic lupus erythematosus in girls. In systemic lupus the sex ratio is closer to unity in the very young, however (Cassidy *et al*. 1977). Oligoarticular juvenile chronic arthritis, especially when accompanied by uveitis, is much more common in girls than in boys, whereas systemic-onset juvenile chronic arthritis occurs with equal frequency in both sexes. In general, the spondylarthropathies and the vasculitides are more common in boys than girls.

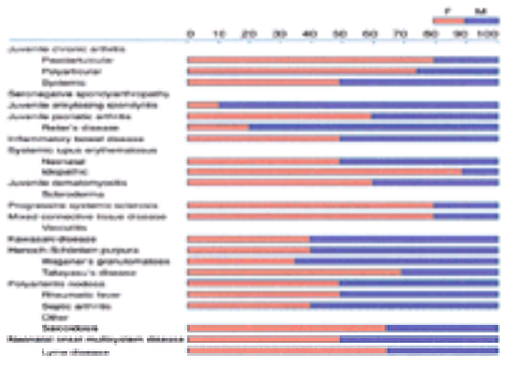

Fig. 2 Sex differences in rheumatological diseases of childhood.

Growth and development

Important age-related characteristics of the patient affect the physician's approach to rheumatic diseases in childhood. Some of the most important are briefly discussed below.

Psychosocial and educational considerations

Chronic illness can have a major impact on the quality of life of the child and the family (Quirk and Young 1990). It is often useful for the health-care team to meet with the family as a whole to acknowledge this fact and to educate other family members about the health problem faced by the child. The physician must establish a professional relationship not only with the child but also with the parents, who usually provide most of the information needed to make a diagnosis, and upon whom implementation of treatment depends. Equally importantly, the physician must recognize the primacy of the patient, even the very young patient, and every reasonable attempt must be made to incorporate the child into the process of obtaining a history and explaining the findings of the physical examination and laboratory investigations. Throughout childhood the roles of child and parent change, and the adolescent must be expected to assume increasing responsibility for attendance at medical appointments, taking prescribed drugs, and complying with prescribed exercise programmes. The older teenager should be given the opportunity to visit the physician without the parent.

The school is one of the child's most important environments; it is to the child what the workplace is to the adult. Attention to school performance, both academic and social, is critical to the development of a complete picture of the child's health, and in children with functional musculoskeletal or abdominal pain it is often the key to understanding the cause of the distress. The co-operation of the teachers and counsellors in facilitating compliance with medications that are taken during school hours, in modifying physical education programmes, and in ensuring the optimal participation of the child with a rheumatic disease in all classroom activities is a vital component of the child's long-term management.

A comprehensive team approach will help address the broad areas of concern to the older child and adolescent, including self-esteem, sexuality, and educational and vocational goals. The timing of transition from a paediatric to an adult health-care setting varies with patient, physician, and availability of appropriate facilities. In general, children are seen in paediatric clinics until they complete secondary education, enter college or university, or join the work-force. A transition clinic in which the expertise of both paediatric and adult rheumatologists are available is an ideal way to facilitate successful entry into the adult medical care setting. From the psychosocial aspect, a 21-year-old patient with a 15-year history of a chronic disease is very different from a 21-year-old patient in whom a similar disease has just begun. Little is known about the best ways to provide care for adults with childhood onset of chronic illnesses. The transition clinic concept will help provide this much needed information.

Motor development

Recognition of the range of normal motor development in the young child is essential for interpretation of findings on physical examination and functional assessment. The major motor milestones are shown in Table 9. Delay in such achievement may occur in a child with any chronic disease, and may be accentuated in the child with disease affecting the musculoskeletal system, the function of which is the basis for the estimation of developmental stages. Although developmental delay is common in chronically ill children, milestones are eventually achieved. There is considerable normal variation in the age at which individual developmental milestones are achieved and the ages in Table 9 should be used as guidelines only (Vaughan and Litt 1992).

Age (months)	Milestone achieved by this age
7	Sits independently
10	Crawls
12	Cruises, walks with one hand held
15	Walks alone; crawls up stairs
18	Runs stiffly; walks up stairs with one hand held
24	Runs well; walks up and down stairs one step at a time
30	Jumps
36	Walks up stairs alternative feet; rides tricycle
48	Hops on one foot
60	Skips

Table 9 Gross motor developmental milestones

Physical growth

Chronic inflammatory disease of the musculoskeletal system, and sometimes the side-effects of its therapy, have profound effects on physical growth. Careful documentation of height and weight should be made at each encounter and compared to growth curves for healthy children of the same sex and age (Fig. 3 and Fig. 4) (Tanner and Whitehouse 1976). In so doing, it is important to consider the parents' height and weight. Sequential measurements ensure not only that the child's height and weight are appropriate for age and sex, but also that the velocity of growth is normal. A growth curve of a child with severe polyarticular juvenile chronic arthritis is shown in Fig. 5. When the disease was controlled, growth velocity increased and a final height close to the expected value was achieved. This is not always the case, however, and severe stunting may result from disease or from prolonged, high dosage of glucocorticoids. Growth failure becomes a serious issue for the adolescent whose peers are growing at a normal rate. Attempts to accelerate growth by giving nutritional supplements or growth hormone have met with limited

success, and feasibility and cost often preclude their use (Butenandt 1979).

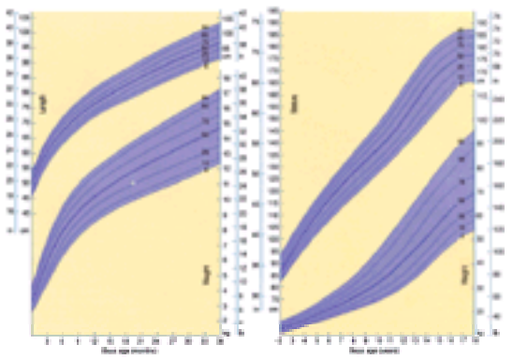

Fig. 3 Physical growth in boys. (a) From birth to 36 months. (b) From 2 to 18 years. Adapted from National Center for Health Statistics Growth Charts (USA) 1986.

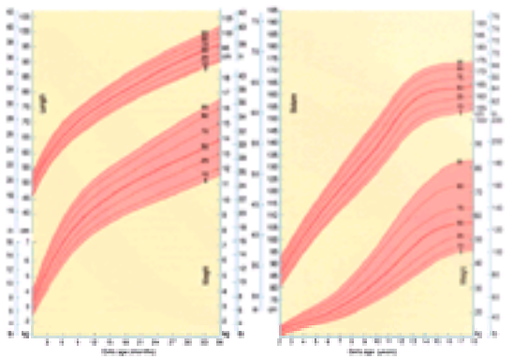

Fig. 4 Physical growth in girls. (a) From birth to 36 months. (b) From 2 to 18 years. Adapted from National Center for Health Statistics Growth Charts (USA) 1976.

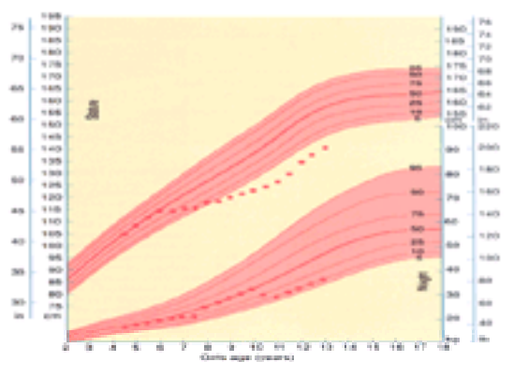

Fig. 5 Growth record of child with polyarticular juvenile chronic arthritis of onset age 5.5 years and severe active disease until age 8 years. The disease was controlled with corticosteroids age 8 to 10 years. The disease was in remission age 11 to 13 years.

Sexual maturation

Delay in sexual maturation in the child with a chronic rheumatic disease is usually a manifestation of inflammatory disease, rather than as an intrinsic abnormality of sexual development. It is useful to document the stages of development of secondary sexual characteristics as shown in Table 10 and Table 11. In boys the genitalia may reach Tanner Stage 2 at any time after the age of 9 years, but need not do so until 14 or 15 years of age. Complete genital maturity (Tanner Stage 5) may occur before the age of 13, but may not occur until 18 years of age (Marshall and Tanner 1986). Axillary hair develops approximately a year after the appearance of pubic hair, and facial hair begins to grow in males a year after the appearance of axillary hair. Menarche, the time of the first menstrual period, occurs at approximately 12.5 to 13 years of age, followed, after a year or more, by the development of the breasts and appearance of pubic and axillary hair (Marshall and Tanner 1986). Delay or irregularity of menstruation is characteristic of adolescent girls who have active inflammatory disease (Fraser *et al*. 1988).

Stage	Pubic hair	Penis	Testes
1	None	Preadolescent	Preadolescent
2	Scant, long, straight	Slight enlargement	Slight enlargement
3	Darker, starts to curl	Longer	Larger
4	Coarse, curly	Broader, glans enlarges	Larger, scrotum darker
5	Adult, spreads to thighs	Adult	Adult

Table 10 Sexual maturation in adolescent boys

Stage	Pubic hair	Breasts
1	Preadolescent	Preadolescent
2	Scant, straight, medial margin of labia	Small mound; areolar diameter increased
3	Darker, starts to curl	Breasts and areolas enlarged; no contour separation
4	Coarse, curly	Areola and papilla form secondary mound
5	Adult; spreads to thighs	Mature, nipple projects; areola part of breast contour

Table 11 Sexual maturation in adolescent girls

In addition to indicating the presence of chronic inflammatory disease, delay in sexual maturation is sometimes a source of severe, often unexpressed, anxiety for the adolescent. The physician or nurse should raise these issues with the adolescent patient if they do not initiate the discussion. The adolescent should understand the reason for the delay in sexual development, and be assured that it is almost certain that normal sexual development will eventually occur. Concerns about fertility, and in girls, the ability to deliver a baby should also be recognized and discussed, sometimes with the advice of an obstetrician. Questions of inheritance of the rheumatic disease are often raised and require answers as permitted by the limited information available.

Diagnostic approach

History

In paediatric rheumatology, perhaps more than in most other branches of medicine, the history and physical examination are the foundations of the diagnostic approach; the laboratory provides limited help. It is important to obtain the historical information from both the care-giver (parent or other adult) and the child. Second-hand historical information, even if provided by the mother, may be less reliable than direct information from the care-giver. Important, too, is information offered by the child. Even a young child may be capable of giving a more accurate history of the symptom than the parent. It is, after all, the child, not the parent, who has the disease. The process of getting historical information from the child may be a time-consuming one, but the reward is often worth the time invested.

Physical examination

Rheumatic diseases are systemic disorders, and the physical examination must include a general physical examination as well as an examination of the musculoskeletal system. In order to gain the most information from the physical examination, the child should be as comfortable as possible. The child's modesty and dignity should be preserved at all times and appropriate examination gowns, shorts, and private changing space provided. The child's permission to examine him or her should be sought informally. Reassurance should be given that the physician will not persist if examination causes pain, and, if possible, examination of the painful area should be left to the end. The experienced physician will identify the 'examinable moment' when the child has gained sufficient confidence in the examiner and acceptance of the environment that useful, trauma-free examination is possible. In small children, examination may begin by observing the child at play or moving about the room. Examination of the joints may begin with the child in the mother's lap. As the child gains confidence in the procedure, the general and musculoskeletal examinations can be completed on the examining table.

Evaluation of the musculoskeletal system must take into account age-related variations from normal, some of which are commented on below.

Range of motion

In full-term new-borns, the elbows, knees, and hips do not fully extend. In the young child, and even the adolescent, hyperextension at the knees and elbows is often greater than in the adult. In other ways, however, normal adult range is achieved by approximately 3 or 4 years of age. Asymmetry of range at any age should be considered to be abnormal.

Muscle strength

Evaluation of muscle strength in the child is difficult. Not only are there obvious age-related differences in muscle strength, but it may be difficult to gain the child's co-operation in order to examine individual muscle groups. In very young children, the examiner must rely on function rather than strength *per se*. Myometry can be used in older children, but repeated evaluation by the same well-trained examiner (usually a physiotherapist), using a standard muscle grading system, is probably the best way of evaluating muscle strength over time.

Gait development

Cruising (walking while holding on to a hand or to furniture) develops by 12 months of age, and independent walking should occur by 15 months. Until the age of 3 years, the child has a gait pattern that differs from that in an adult; the rate of walking is faster, the stance is more broad-based in relation to pelvic width, the knee may not be fully extended, and the ankle may be plantar flexed at foot-strike (Sutherland *et al*. 1980). The ability to climb stairs one at a time develops at about 2 years of age; by 3 years of age the child can usually go up and down stairs, alternating feet. Walking on tiptoe is not abnormal for a child who has just begun to walk. This pattern should disappear by the age of 2 years, however. If it persists beyond this age, causes such as spasticity, muscle weakness, or tethered cord should be considered.

Structural variations from normal

The appearance of flat feet is usually normal in the young child. The distribution of fat and the paucity of muscle development in the infant and young child cause the feet to look flat. This appearance is common in children up to about 5 or 6 years of age. In the absence of symptoms, no investigation or treatment are indicated.

The alignment of a child's legs is a frequent source of parental concern, and age-dependent characteristics should be identified (Salenius and Vankka 1975). From birth until 2 years of age, it is normal to have symmetrical genu varus. From 2 to 5 years of age, mild genu valgum may occur. At no time should the degree of valgus or varus exceed 10°, and it should be bilaterally symmetrical. Age-related normal ranges of varus and valgus are shown in Fig. 6.

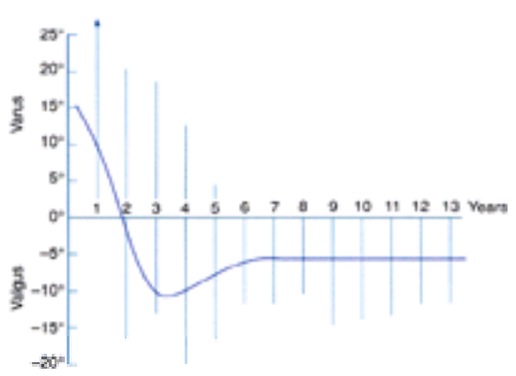

Fig. 6 The femoral–tibial angle (measurement of varus and vulgus at the knee) in normal children. Vertical lines indicate range. Solid line indicates mean (Salenius and Vankka 1975).

Functional assessment

Age-related, functional assessment can be ascertained with some knowledge of developmental stages, and can be documented more precisely with tools developed specifically for this purpose. The development of the juvenile arthritis functional assessment scale (JAFAR) (Lovell *et al*. 1989) has permitted a semiquantitative approach to the measurement of disability in children with chronic arthritis. This assessment can be administered in a few minutes in the outpatient setting.

Laboratory investigations

Laboratory evaluation of the child with a rheumatic disease serves three functions; to provide or exclude evidence of inflammation, to provide evidence of diagnostic significance, and to exclude non-rheumatic diseases (Table 12).

Indicators of inflammation
White blood-cell count, differential, platelet count, erythrocyte sedimentation rate
Tests of diagnostic significance
Antinuclear antibody
Antinuclear antibody specificities if antinuclear antibody is present
Muscle enzymes (if dermatomyositis is suspected)
Antineutrophil cytoplasmic antibodies (if vasculitis is suspected)

Table 12 Laboratory evaluation of the child with musculoskeletal pain or a suspected rheumatic disease

In screening for evidence of inflammation, the white blood cell count and differential, haemoglobin, platelet count, and the erythrocyte sedimentation rate usually suffice. In most instances of chronic inflammatory disease one or more of these is abnormal, although children with monoarticular juvenile chronic arthritis may have normal test results. Discordance between the white blood-cell count or the platelet count and the erythrocyte sedimentation rate (i.e. a low platelet count with an elevated sedimentation rate) may be suggestive of an underlying malignancy such as leukaemia or neuroblastoma. In some disorders, such as Kawasaki disease, platelet counts may exceed one million. Decreased albumin is consistent with inflammation of many causes but if it is marked, and articular disease is mild or moderate, inflammatory bowel disease should be considered. In the child with a fever of unknown origin and an elevated sedimentation rate, but no abnormalities detected on physical examination, inflammatory bowel disease, polyarteritis nodosa, or occult malignancy should be considered.

Tests that have diagnostic specificity are few in number. Although antinuclear antibody is present in many children with a wide variety of rheumatic disease, it occurs in non-rheumatic disease as well (Cabral *et al*. 1992b), but it is absent in children with the seronegative spondylarthropathies. If clinically indicated, the antigenic specificity of the antinuclear antibody should be determined; thus, for example, antinuclear antibody directed to double-stranded DNA strongly suggests a diagnosis of systemic lupus erythematosus.

Studies of the sensitivity and specificity of testing for rheumatoid factor in the child have shown unequivocally that it has little value as a diagnostic test (Eichenfield *et al*. 1986). Rheumatoid factor is usually absent in children with rheumatic disease, except in those with polyarticular juvenile rheumatoid arthritis where its presence is required for diagnosis by the EULAR classification (although not by the ACR criteria), and where it is associated especially with the presence of nodules and erosions.

Some laboratory investigations are useful in excluding rather than diagnosing disease. An unequivocally normal white blood-cell count, differential platelet count, and erythrocyte sedimentation rate make the possibility of an inflammatory, infectious, or malignant disease very unlikely. A normal radiograph of the bones and soft tissues of a symptomatic joint effectively excludes major trauma, and if the symptom is of long standing, inflammation or infection as well. A normal technetium bone scan virtually excludes primary bone or joint disease in a child with undiagnosed musculoskeletal pain.

Specific approaches

Pattern recognition

Using knowledge of the relative frequencies of individual rheumatic diseases, the age of the child at onset of symptoms, and the sex of the child, coupled with the pattern of joint involvement and the character of extra-articular signs and symptoms, it is possible to make some informed guesses about the likely diagnosis of a specific rheumatic disease. Certain patterns of these clinical characteristics are illustrated below.

1. Acute onset of large joint monoarthritis in a young girl should be considered to be oligoarticular-onset juvenile chronic arthritis unless there is evidence of infection.
2. At any age and in either sex, a pattern of scattered, asymmetrical, large and small oligoarthritis or limited polyarthritis suggests the possibility of juvenile psoriatic arthritis.
3. Oligoarthritis of large joints of the lower extremity in an older boy suggests a seronegative spondylarthropathy, most likely ankylosing spondylitis.
4. The presence of enthesitis with arthritis indicates the likely presence of seronegative enthesitis and arthritis syndrome (Rosenberg and Petty 1982), and the probable later development of ankylosing spondylitis (Cabral *et al*. 1992a; Burgos-Vargas and Clark 1989).
5. The onset of polyarthritis in a teenage girl should suggest the possibility of systemic lupus erythematosus as well as polyarticular juvenile chronic arthritis.
6. Isolated hip joint arthritis may be caused by toxic synovitis, Legg–Perthes' disease, a slipped capital femoral epiphysis, or less likely, by chronic inflammatory arthritis, probably ankylosing spondylitis.
7. An older child or young adolescent male with low back pain may have ankylosing spondylitis but mechanical causes, infection, or malignancy are more likely.

The child with limb pain

The causes of limb pain vary with the age of the child. The very young child may not complain of or admit to having pain, but may instead alter the manner in which he or she uses a limb. Pain in the preambulatory child may be first noticed when the child is being held, dressed, or bathed. The child may be observed to refuse to use one arm or leg, or may regress in major motor milestones. For example the child capable of standing may cease to do so. The child who is an established walker may, for no apparent reason, cease walking or develop a limp or other alteration of gait (Table 13). Until fine motor movement of the hands has developed, it may be difficult to notice the functional effects of arthritis in the joints of the hands and fingers. Preference for the use of the right or left hand before the age of 2 to 4 years, when preferential use of one or other hand normally develops, suggests the possibility of an abnormality of the underused hand.

Location of pain	Cause of pain
Back	Trauma, spondylolysis or spondylolisthesis Inflammation (discitis, spondylitis) Infection (osteomyelitis) Tumours (osteoid osteoma, malignancy)
Sacroiliac joint	Trauma Septic sacroiliitis Inflammatory sacroiliitis
Hip	Transient synovitis, Legg–Perthes' disease, slipped capital femoral epiphysis Chronic synovitis (juvenile chronic arthritis) Painful muscles (dermatomyositis) Congenital dysplasia or dislocation
Knee	Hypermobility, patellar dislocation Osgood–Schlatter disease Inflammatory enthesitis Osteochondritis dissecans, torn meniscus or cartilage Chronic synovitis (juvenile chronic arthritis)
Ankle and foot	Hypermobility, trauma (including stress fracture and footwear problems) Enthesitis, chronic synovitis (juvenile chronic arthritis)

Table 13 Painful conditions that may cause a limp

The history of the onset of the pain is important. The presence of an identifiable time of onset may suggest trauma or infection; chronic arthritis most frequently has a very insidious onset, especially in the very young child. Diurnal variation in symptoms is significant, but in the infant or young child this may be difficult to identify. Precipitating or alleviating factors should be noted. The presence of associated systemic symptoms, such as fever, weight loss, rash, upper respiratory tract infection, or diarrhoeal illness, should be noted.

Limb pain may originate in bone, joint, or soft tissues. Localization of the source of the pain to one of these tissues permits appropriate investigations. Young children often localize pain poorly and the physician must carefully identify the area of discomfort by palpation and observation. The child may not admit to pain but will withdraw the limb or appear anxious when the affected part is examined. Observation of the child's facial expression during examination is very important, as is the parent's interpretation of the child's response. Leg pain may be referred from the back to the thigh, from the sacroiliac joint to the buttocks, or from the hip to the knee. Pain in the absence of tenderness suggests that it may be referred from another site.

Quantification of pain in children often requires the use of non-verbal cues. The child's behaviour is the most important indicator of the presence or absence of pain. Visual tools to assess pain such as that shown in Fig. 7 may be useful, especially in following change over time (McGrath and Unruh 1987).

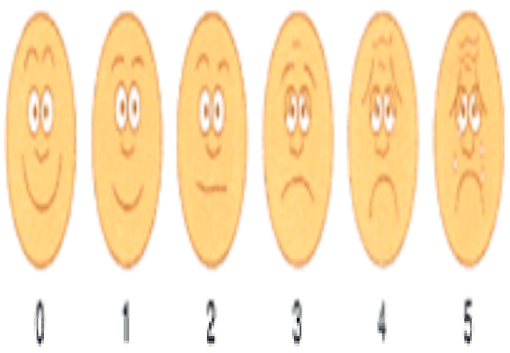

Fig. 7 Pain assessment in children—faces rating scale.

The child with back pain

Back pain is an uncommon complaint, particularly in young children, and should always be thoroughly investigated as its underlying cause may require prompt, specific therapy. Significant causes of back pain in children and adolescents are outlined in Table 14. Common causes of back pain in adults, such as overuse, disc prolapse, or degenerative joint disease, are rare to non-existent in children. In childhood, the important causes of back pain include infection (discitis, osteomyelitis), tumours (benign, such as osteoid osteoma, or malignant), mechanical causes (such as spondylolysis and spondylolisthesis, idiopathic adolescent scoliosis—Scheuermann's disease), and inflammatory causes (such as ankylosing spondylitis). The age relationships and usual sites of back pain in childhood are outlined in Table 15. Pain associated with pyelonephritis and glomerulonephritis, and osteoporosis secondary to glucocorticoid use should also be considered.

Pain in the back
- Acute trauma:
  - fracture/dislocation/haematoma
  - spondylolysis/spondylolisthesis
- Tumour:
  - benign (osteoid osteoma)
  - malignant (reticulum cell sarcoma, metastatic neuroblastoma, leukaemia, lymphoma)
- Infection:
  - discitis
  - vertebral osteomyelitis
- Osteoporosis
- Scheuermann's disease (painful adolescent kyphosis)
- Fibromyalgia

Pain in the sacroiliac joints
- Septic sacroiliitis
- Spondylarthropathy

Pain in the pelvis
- Osteomyelitis
- Tumour (usually osteogenic sarcoma or Ewing's tumour)

Table 14 Back pain in children and adolescents

Cause of back pain	Peak age (years)	Usual site of pain
Discitis	1–3	L4–5 or L3–4
Osteomyelitis	<12	Any site
Scheuermann's disease	13–17	Lower thoracic
Osteoid osteoma	10–30	Any site
Spondylolysis	10–20	L5–S1
Metastatic neuroblastoma	<10	Multiple
Inflammatory sacroiliitis	>12	Unilateral or bilateral
Osteogenic sarcoma	10–20	Ilium
Ewing's tumour	10–20	Ilium

Table 15 Age relationship of causes of back pain in children

Trauma

Trauma is seldom the cause of persisting joint pain or swelling in a child, and the diagnosis of sprain in a young child is usually incorrect. Children of all ages are subject to physical abuse, which may include injuries resulting in musculoskeletal pain. It is estimated that 30 per cent of fractures in children under the age of 3 years are the result of non-accidental injury (Holter and Friedman 1968), and that under the age of 1 year more than half of fractures result from child abuse (McClelland and Heiple 1982). It may be difficult to differentiate fractures secondary to child abuse from those secondary to accidents or to diseases such as osteogenesis imperfecta. However, the characteristic pattern of multiple fractures of different ages, especially involving the posterior ribs, femur, and skull, in combination with skin lesions (bruises, abrasions, burns) strongly suggests the diagnosis. Attention to the problem will help prevent recurrence of the abuse, and allow appropriate intervention which may include taking the child into care.

Monoarticular arthritis

Among the presentations of arthritis in childhood, monoarticular arthritis is particularly problematic. In a child with acute onset of monoarthritis, the initial differential diagnosis includes infection (septic arthritis and/or osteomyelitis), trauma (accidental or non-accidental), and malignancy (especially leukaemia and neuroblastoma). Chronic monoarthritis may represent oligoarticular juvenile chronic arthritis, a seronegative spondylarthropathy, or juvenile psoriatic arthritis. Additionally, a number of uncommon disorders may mimic chronic monoarticular inflammatory arthritis. These include intra-articular haemangiomas, osteochondritis dissecans (especially at

the knee), synovial chondromatosis, lipomatosis arborescens, villonodular synovitis, osteoid osteomas, and discoid meniscus.

In arthritis in the joints of a leg, an altered gait is a common presentation. A limp (asymmetry of gait) may results from structural asymmetry, muscle weakness, or pain. Painful causes of limps are given in Table 14 (Hensinger 1986; Petty 1994). Pain and stiffness are seldom complained of as such in very young children. Instead, non-use, altered use, or irritability are the chief manifestations.

Localized growth disturbances are characteristic of the effect of joint inflammation in the child whose epiphyses have not yet fused. In general, the bones adjacent to an inflamed joint grow more rapidly, and in consequence, the affected digit or limb is longer. If this occurs in a single knee, an inequality of leg length results.

The child with fever of unknown origin

Fever of unknown origin in a child frequently results in consultation with the paediatric rheumatologist with the question: 'Could this girl have one of the rheumatic diseases?' The answer to the question is often 'Yes, she could', but elucidation of the cause may be difficult.

The child who has a history of weeks or even months of fever without demonstration of a cause should be evaluated first to exclude the possibility of occult infection or malignancy (especially leukaemia or lymphoma). Complete blood count, bone marrow biopsy, chest radiograph, and abdominal ultrasonography are appropriate initial investigations. A technetium bone scan and gallium scan may also be indicated. Occult infection, especially osteomyelitis, should be ruled out by radiographs and bone scans. Bacterial endocarditis should be excluded by blood cultures and echocardiography.

The onset of systemic juvenile chronic arthritis may be characterized by fever and rash before the development of joint disease. It is very unusual, however, for arthritis to lag more than a few weeks behind the onset of the systemic features of this disease, and a diagnosis of systemic-onset juvenile chronic arthritis in the absence of arthritis should always be tentative. The presence of pleural or pericardial effusions, splenomegaly, anaemia, leucocytosis, and elevated erythrocyte sedimentation rate, together with a quotidian fever and characteristic evanescent macular rash, would support the possibility of this diagnosis.

Fever with weight loss, with or without gastrointestinal disturbances, erythema nodosum, or arthralgia, suggests the possibility of inflammatory bowel disease. In such instances there may be anaemia, leucocytosis, hypoalbuminaemia, and marked elevation of the erythrocyte sedimentation rate. Definitive diagnosis requires biopsy of the gastrointestinal tract.

Children with vasculitis may have only fever and elevation of indicators of inflammation without objective physical signs. Indirect evidence of vasculitis may be obtained by demonstration of antibody to neutrophil cytoplasm (ANCA), high levels of von Willebrand factor (factor VIII-related antigen), abnormalities on Doppler ultrasonography of large arteries, or with other imaging techniques such as magnetic resonance arteriography or contrast arteriography. Evidence of coronary arteritis in children with Kawasaki disease is shown by electrocardiograph and echocardiograph. Hypertension or haematuria may indicate the presence of renal arterial or glomerular disease. Deficiencies in peripheral pulses suggests the possibility of Takayasu's arteritis. In polyarteritis, the presence of a painful subcutaneous nodule, characteristically in the calf or sole of the foot, provides the opportunity for definitive excisional biopsy.

The child with muscle weakness

Muscle weakness is common in children with inflammatory musculoskeletal disease, although its detection and quantitation may be difficult because of age-related differences in normal muscle strength. As a result, it is often necessary to rely on a history of regression of major motor developmental stages. Thus the child who was an established walker may, because of weakness, stop walking, or ask to be carried. Observation of the child at play, of the manner in which he or she gets up from sitting and lying positions, and of the ability to stand on tiptoes, heels, and squat and recover from a squat all provide useful clues to the presence of muscle weakness. The child with weakness of trunk muscles, as might be seen in dermatomyositis, may have to roll over on to the side or abdomen in order to assume a sitting position from a supine position. The child with weakness of the hip girdle may be unwilling to squat, and unable to stand upright after a squat without exhibiting Gower's sign. Observation of the gait for a wide base or Trendelenburg sign may suggest weakness of the hip girdle. It may be difficult to pick up the young child with weakness of the shoulder girdle because of the instability of the upper trunk. The presence of head lag when lifting the child from the supine to sitting position suggests weakness of neck flexors. With experience and patience, the physician or physiotherapist can demonstrate muscle weakness of a grade or more by formal testing in the child over 3 or 4 years of age. Assessment of muscle strength should also include a neurological examination. Prolonged muscle weakness without muscle wasting is unlikely to be the result of organic disease.

The symmetry of muscle weakness provides an important diagnostic clue. Asymmetric weakness is not likely to result from an inflammatory myositis such as dermatomyositis, or from a primary myopathy. Weakness of one limb or muscle group is most likely to reflect a peripheral neuropathic lesion or inflammation in a major joint such as hip, knee, or ankle. Sacroiliitis can cause severe weakness of the proximal thigh and wasting of muscle. Osteoid osteoma can produce a similar effect. Symmetrical proximal weakness accompanied by muscle tenderness strongly suggests dermatomyositis, and the presence of classical cutaneous changes and elevated muscle enzymes would confirm that diagnosis and differentiate it clinically from primary myopathies.

Summary

The child with a rheumatic disease is often a diagnostic and therapeutic challenge. An effective approach to diagnosis requires a careful history, and a physical examination that takes into account normal age-related variations, which may otherwise be misleading. Treatment requires recognition that the child is rapidly growing and changing physically, psychologically, and socially. It requires recognition of the child's place as a member of a family and the impact of chronic disease on all family members. Problems related to psychosocial and educational development, challenges in school, and the possibility of limitations on employment necessitate management by a well co-ordinated team of health professionals. Attention to these features of care are all the more important because, with few exceptions, rheumatic diseases of childhood are as yet incurable, although in many instances effective control is possible and the child is able to lead a happy fulfilling childhood and adulthood.

1.1.3 The geriatric age group

Evan Calkins

Rheumatological practice among older patients is substantially different from that with persons at midlife with regard to the array of diseases, the physiological and psychological characteristics of the patients, treatment goals, and the approach to management. This chapter will first outline, briefly, aspects of the biology of ageing that underlie these differences. Second, it will consider implications of the biology of ageing on rheumatological practice in a general sense—the geriatric perspective. Third, it will review how the process of ageing influences the characteristics of some of the specific rheumatological entities and their diagnosis and management.

The biology of ageing

Ageing is a continuous, life-long process, involving sequential changes in cells, organs, and the entire organism. Rapid changes occur during early developmental life and extend through youth and adolescence. Most functions achieve their peak by the time the person reaches his/her mid-twenties. From that point on, with very few exceptions, the physiological capacity of a given organ undergoes a pattern of progressive decline, illustrated schematically in Fig. 1, gradually approaching the minimal level required for maintenance of life.

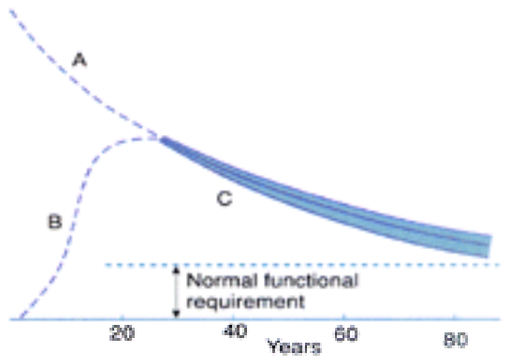

Fig. 1 Schematic depiction of the lifetime curve of physiological function and structure of many components of the body. Some start in embryonic life at negligible levels, others at high levels. Rapid changes occur in childhood and youth. Most functions reach their peak in the mid-twenties. This is followed by a gradual decline, approaching, in time, the minimal requirement for life, indicated by the dotted line. (Reprinted, with permission, from Katz *et al*. 1986.)

Figure 2 illustrates this concept by depicting the progressive structural changes occurring in the Meissner corpuscle (Cauna 1964). This is the nerve ending, located on the finger tips, which permits one to feel in one's pocket and differentiate a 1p from a 5p coin, or a dime from a penny. Numerous changes occur during embryonic development and the early years of childhood. Later changes evolve much more slowly, but they are progressive and, apparently, inexorable. One can hypothesize that, by the time one reaches the age of 40, it is difficult to distinguish a pound coin from a 10p, or a penny from a dime. Two or three decades later, the person has trouble differentiating a coin from a button.

Fig. 2 Changes in the Meissner corpuscle from embryonic life to old age. Changes occur rapidly during early development. They evolve more slowly as one ages, to a state of hypertrophy and, later, to an atrophic rudiment. (Reprinted, with permission, from Cauna 1964.)

Figure 3 depicts a more serious change—the sequential decrease in creatinine clearance as a person ages (Rowe *et al*. 1976). More recent studies have raised the question: do these changes reflect the process of ageing, itself, or the presence of intercurrent disease (Evans and Williams 1992; Lindeman *et al*. 1985). The fact that the decline occurs in approximately two-thirds of individuals, but not all, suggest that it is not a mandatory component of ageing. Still, the change is present in the

majority of older people, even in the presence of normal values for blood urea nitrogen and serum creatinine, and must be kept in mind as one prescribes drugs that are excreted by the kidney.

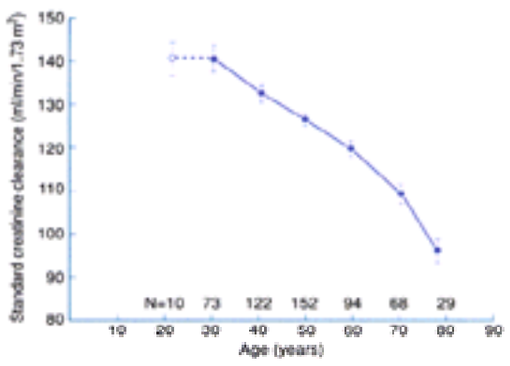

Fig. 3 The relationship of standard true creatinine clearance with age. Reprinted with permission from Rowe, J.W. *et al*. (1976). The effect of age on creatinine clearance in man: a cross sectional and longitudinal study. *Journal of Gerontology*, **31**, 155–63. Note: subsequent authors have shown that these changes occur in two-thirds of patients, but not all, and question whether they are due to age or age-related disease (Rowe *et al*. 1976).

Figure 4 depicts plasma levels of amylobarbitone sodium 4 and 24 h after administration to two groups of patients, one group aged between 20 and 40 years and the other over 65 years (Irvine *et al*. 1974). The data illustrates not only the increased plasma levels achieved in many older patients but also the variability of the response. Despite their superficially similar appearance, older people are more different, one from another, than younger individuals. This is a cardinal principle of geriatric medicine that should be kept in mind by all physicians who treat older persons.

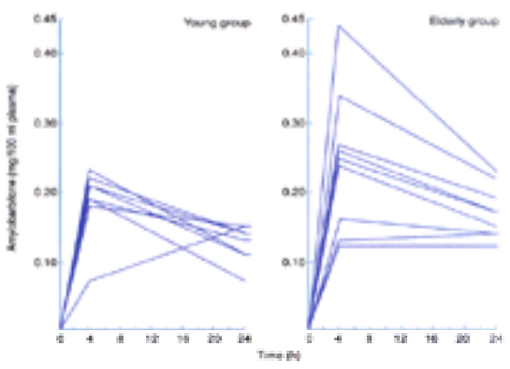

Fig. 4 Plasma levels of amylobarbitone sodium 4 and 24 h after oral administration of a standard dose to groups of subjects age 20–40 years (left panel) and over age 65 years (right panel). The drug is detoxified in the liver. Older persons show far greater variability than young subjects. (Reproduced from Irvine *et al*. 1974, with permission.)

Figure 5 was derived from a study with small animals (mice) but illustrates another important concomitant of the ageing process—the loss of homeostatic ability (Finch *et al*. 1969). In his PhD thesis project, Finch compared rectal temperatures of young and old mice following immersion in a bucket of ice water. The young mice responded by vigorous shivering and equally vigorous thrashing about and were able to sustain their body temperature. The old mice were able to muster only a feeble response and sustained deep hypothermia. Hypothermia is a common occurrence among old people, who have a reduced capacity to respond to external demands of many sorts, including infection and physical trauma, and have difficulty in sustaining homeostasis in the face of these demands. This is due, in part, to the decreased reserve capacity in the function of most organs as the person ages and also to attrition of neuroreceptors.

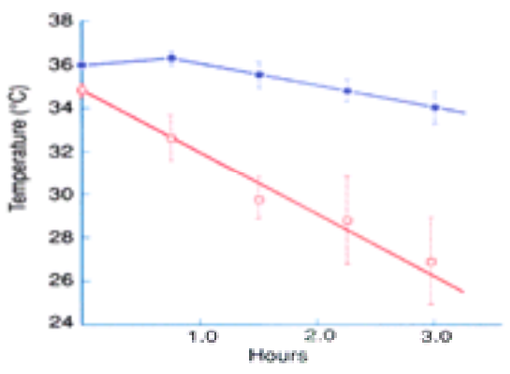

Fig. 5 The effect of age on colon temperature of mice during 3-h exposure to cold (9 to 10 °C). Seven mice per age group. Young adult mice (10 months old); senescent mice (30 months old).(Reproduced from Finch *et al*. 1969, with permission.)

While the general direction of the curve depicted in Fig. 1 is the same for different body components, the shape varies. For example muscle strength declines only gradually during the period between 24 and 40 years of age, and then begins a more rapid decline (Pendergast *et al*. 1993). Further, there is considerable individual variation within what is regarded as normal. Genetic variation may result in significant shifts in the curve in some individuals, resulting in premature death. Similarly, health habits, such as a lifetime pattern of smoking or exposure to industrial toxins, may result in more rapid declines. Temporary reversal of a downward slope may also occur but only with the greatest difficulty. For example vigorous exercise, such as achieved by marathon runners, will result in a substantial increase in the metabolic efficiency of skeletal muscle (Heath *et al*. 1981). However, once the new functional level has been achieved, progressive age-related declines still occur, despite whatever effort the runner may undertake. Although by appropriate preventative measures the decline in physiological function can be delayed to a certain point, no means has yet been achieved to add significantly to the time when declining function crosses the minimum requirement for life, leading to death (Strehler 1975).

Some age-related changes are easy to detect—greying hair, wrinkles, and decreased agility. Careful anthropometric and analytical studies have shown progressive changes in the dimension of many body components (Rossman 1977). These may be as trivial as broadening of the nose or lengthening of the ears, or significant, as in approximate doubling of total body fat, decrease in total body water, and an even greater decrease in body cell solids and bone mineral. Decreases in height are experienced by most men and women, averaging 4.9 cm in women and 2.9 cm in men. Although these losses are related primarily to decreased spinal length, there are also aged-related decreases in leg length. Narrowing of the shoulders and widening of the pelvis are also seen. Bennett, Wayne, and Bauer described progressive degenerative and proliferative changes in the articular surfaces of the knee, as persons age from the second to ninth decade (Bennett *et al*. 1942). McFarland and Dieppe pointed out that many older persons with osteoarthritis of the hands exhibit ulnar drift at the metacarpophalangeal joints, resembling the changes seen in rheumatoid arthritis (McFarland and Dieppe 1983).

While many of these changes are easily observed, the extent of a person's age-related physiological changes and decreased reserve capacity is often not apparent.

Most older people go to great lengths to conceal their disabilities from their friends, family, and society as a whole and also from their physicians. One of the reasons for this is the fear that they will be regarded as senile and a candidate for admission to a nursing home. It is only as the older person faces additional demands, such as an acute infection, that this lack of physiological reserve becomes apparent. As the organ system initially involved begins to fail, additional compensatory burdens are placed on other organ systems which may, already, be functioning at maximal capacity. This leads, in many instances, to a cascade of organ failure and to what is suddenly perceived as multisystem disease.

Taken together these losses add up to what can well be described as frailty, an almost universal characteristic of very old patients (in their 90s and older) and of many people in their 70s and 80s. This term refers not only to the decreased physiological reserve of many organs, but also, more specifically, to decreased muscle strength, balance, and overall functional capacity and to increased likelihood of falls.

An additional factor contributing to these age-related changes and, we are learning, the cause of many, is the decreased physical activity that almost always accompanies the ageing process. Inactivity itself contributes substantially to decline in function of muscles, bones, and other organs (Buchner and Wagner 1992). While cardiovascular deconditioning is the best example of this, we are just beginning to appreciate its widespread effects. For example it has recently been shown that the propensity of an older person to develop gastropathy, secondary to non-steroidal anti-inflammatory drugs, is increased in persons who are physically inactive and can be decreased as the result of physical exercise (Pahor *et al*. 1994a; Pahor *et al*. 1994b). Exercise is the most important means, to date, by which a person can influence his or her functional capacity and general fitness and, by this means, attenuate or even reverse some of the aspects of frailty of old age.

Reflecting, in part, the concepts of multiple organ failure referred to above, most persons age 75 years and older suffer from multiple chronic diseases. Gruenburg has pointed out that medical science has succeeded, at least for the time being, in preventing or treating many of the acute life threatening illnesses, such as serious infection, but has, as yet, had limited success in preventing or curing many of the chronic diseases such as osteoarthritis or macular degeneration of the eye—diseases which do not kill but linger on to collect, in multiples, as one ages (Gruenburg 1977). The presence of multiple diseases in most patients aged 75 years and older has major implications for diagnosis and treatment.

The geriatric perspective

How do these physiological changes accompanying ageing affect the practice of rheumatology? I have selected 10 areas for mention.

Age-related frequency of diseases

The influence of age, sex, and race on the incidence and frequency of specific diseases is a topic of increasing interest (Beeson 1994). These considerations are particularly relevant in the field of rheumatology. Table 1 lists some of the most common musculoskeletal and rheumatic diseases with regard to their age of onset. As the result of these age-specific relationships, the sort of patients one sees in a geriatric rheumatology consulting practice is quite different from that encountered with younger persons. Reiter's disease, Still's disease, and ankylosing spondylitis are not seen as new onset disease among older people. By contrast, osteoarthritis, polymyalgia rheumatica, giant cell arteritis, Sjögren's syndrome, and calcium pyrophosphate deposition disease occur almost exclusively in the older population. Equally important in clinical practice is the fact that musculoskeletal symptoms occurring in older persons may reflect a wide variety of conditions, many of them with serious implications, which are not usually regarded as falling within the constellation of rheumatic disease. Examples include carcinomatosis, multiple myeloma, hyperthyroidism, myxoedema, and a variety of neurological entities including Parkinson's disease and Alzheimer's disease. Differential diagnosis requires a broad understanding of many aspects of clinical medicine, including ones which fall outside the frame of reference of traditional rheumatology.

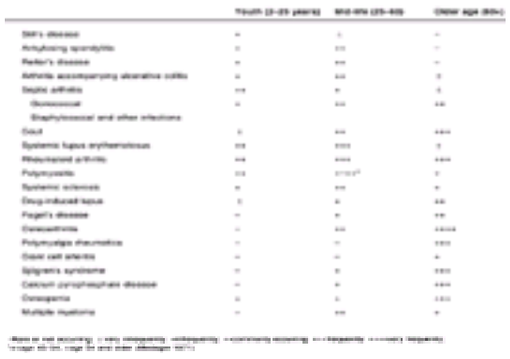

Table 1 Frequency of representative musculoskeletal diseases at various stage of life

The most frequent source of musculoskeletal complaints, in person age 70 to 79 years, is back pain, present in one study from Sweden (Bergstrom *et al*. 1986a; Bergstrom *et al*. 1986b), in 48, 55, and 32 per cent of women age 70, 75, and 79 years, respectively, and in 32, 20, and 28 per cent of men at similar ages. In a study from Iowa, United States, (Lavsky-Schulan *et al*. 1985), 25 per cent of woman and 20 per cent of men, age 75 to 79, were reported as having experienced severe back pain—78 per cent of these women and 68 per cent of these men had sought the help of physicians; 44 per cent of the women and 82 per cent of the men had obtained chiropractic care; 29 per cent of the total group had been hospitalized at least once for their back pain and 8 per cent of the woman and 2 per cent of men had undergone back surgery. Clearly, back pain emerges as one of the most significant aspects of geriatric/rheumatological practice.

The next most frequent musculoskeletal condition, in this age group, is osteoarthritis (Lawrence *et al*. 1989). In the Swedish study mentioned above, at age 70 years 12 per cent of the sample (19 per cent of the men and 6 per cent of the women) were judged, on clinical grounds, to have osteoarthritis of the knees. Surprisingly, these figures declined among those who survived to age 75 and 79 years (5 per cent and 6 per cent respectfully). Radiographic changes, consistent with the diagnosis of osteoarthritis of the knees, were present in 20 per cent of the patients at 70 years of age (26 per cent of women and 15 per cent of men), but in only 14 per cent of those who survived to age 75 years and 13 per cent of those who survived to age 79 years. Since it seems highly unlikely that the radiological changes are reversible, this unexpected finding suggests the possibility that osteoarthritis, or concomitant conditions of which it is a marker, may be associated with a decreased life span. In view of the effect osteoarthritis has on a person's physical function and the benefits of exercise on overall health, the association is not totally illogical. A recent study has lent added support to this hypothesis (Cerhan *et al*. 1995).

In the Swedish study, the frequency of symptoms of rheumatoid arthritis, either present or as a sequel to earlier onset disease, were evidenced in 7 per cent of the 537 patients age 79 years. In three women (0.9 per cent of the total group) and three men (1.5 per cent) the disease had begun within the previous 4 years, that is after age 75 years. Almost identical frequencies were derived from the clinical examination of a subset of these patients. The fact that rheumatoid arthritis is an age-related disease afflicting an increasing percentage of patients at least up to age 79 years, with new-onset disease occurring as late as age 75 to 79, seems well established (Mikkelsen *et al*. 1967; Linos *et al*. 1980).

Multiple diseases

The symptoms of rheumatic diseases are, themselves, relatively non-specific. When a person suffers from a single disease the product of these symptoms gains specificity and one reaches the correct diagnosis relatively easily. When a person has multiple diseases, several of which may be characterized by certain of these non-specific manifestations, or none, the pattern provides a special challenge to the careful clinician. For example because a patient presents with the classic stigmata of long-standing rheumatoid arthritis does not necessarily mean that the symptoms of which the patient currently complains are due to that disorder. An example was a 65-year-old man with long-standing, deforming rheumatoid arthritis who was referred to the author by a primary care physician because of failure to respond to gold. History indicated the presence of severe constitutional symptoms, with sweats and weight loss, which the primary care physician had attributed to increased activity of the rheumatoid process. However, the patient did not complain of morning stiffness and, on physical examination, the joints did not display the extent of active synovitis one would have expected in a patient with constitutional symptoms of that degree. Further studies disclosed the presence of Hodgkin's disease. Another example was a 62-year-old man with extensive radiological evidence of cervical spondylosis and numbness and tingling in the upper extremities. Further work-up disclosed the presence of pernicious anaemia with significant improvement in the neurological manifestations following administration of vitamin B_{12}. For this reason, in an older patient referred for a musculoskeletal disorder it is important to conduct a complete history and physical examination, to explore the

possibility that the symptoms may not reflect the musculoskeletal disease which is initially apparent but may be due to a less obvious concomitant disorder. The examination should include a rectal examination for carcinoma of the prostate, breast examination, and neurological examination.

Use of drugs

The use of drugs in older patients with rheumatic diseases holds promise of great benefit but also great hazard due to the omnipresent threat of adverse drug reactions, often serious and sometimes fatal (Girdwood 1974; Beers and Ouslander 1989; Griffin 1991). Fries *et al*. have stated, with regard to the non-steroidal antirheumatic drugs (non-steroidal anti-inflammatory drugs), 'gastropathy associated with non-steroidal anti-inflammatory drug use probably represents the most frequent drug side-effect in the United States' (Fries *et al*. 1989). Reasons for the increased side-effects of drugs in older patients include changes in pharmacokinetics, pharmacodynamics, and the issue of drug interaction—the effect that one drug may have on the pharmacokinetics of a second, simultaneously-administered agent (Furst 1988; Montamat *et al*. 1989; Feely and Coakley 1990; Gurwitz and Avorn 1991). In the field of rheumatology, the increasing tendency to prescribe multiple antirheumatic and anti-inflammatory drugs to a given patient provides the potential for serious interactions of this sort. These problems become compounded in the person who suffers, simultaneously, from a range of additional chronic diseases, including, perhaps, hypertension, diabetes mellitus, gout, deep venous thrombosis, peptic ulcer disease, and a urinary tract infection.

Several guidelines may prove helpful (Table 2). A careful drug history should be obtained in all older patients, identifying drugs prescribed by each of the different physicians the patient is seeing, and also over-the-counter medications. It is important to limit, to a minimum, the number of drugs a patient is expected to take. In some patients carefully designed exercise, local heat or cold, patient education, and, perhaps, a local injection will avoid utilization of a systemic agent. Few patients can adhere, accurately, to the requirements for taking more than three or four different drugs at one time. Many older persons, especially those who are seeing several different physicians at the same time, will be expected to comply with instructions to take eight or nine drugs, each according to its own time schedule! Simplifying the number of drugs will make life much easier for the patient, decrease the chance of non-compliance or a compliance error, and decrease the likelihood of an adverse drug reaction.

Obtain a list of all current medications, including over the counter preparations, and document any adverse reactions that may have occurred.
Limit the number of drugs. Use non-pharmacological treatment when appropriate
Identify mode of excretion, detoxification, and drug interactions of all drugs you use.
Reduce dosage for older patients. Start treatment with even lower dosage. Instruct patients about possible side-effects.
Obtain appropriate pretreatment laboratory data to assess risk of therapy and provide baseline for identification of possible future toxicity.
Define specific goals for each drug used. Discontinue drug if goal is not achieved.
If toxic effects to drug A ensue, it is better to shift to another agent (B), than to add a drug to offset the toxic effects of drug A.

Table 2 Guidelines for safe administration of drugs in older patients

A physician should be fully informed concerning the mode of excretion or catabolism of each drug he or she is prescribing, and also the potential for interactions. It is wise to limit the number of different drugs a given physician selects to include in his or her therapeutic armamentarium, and to select for a given patient agents with a maximal ratio of benefit to risk, especially in patients who are physiologically compromised in the first place.

Start treatment with a low dose. For most older patients, the maintenance dose will be lower than it would be for younger individuals. At the onset of therapy it is well to prescribe the first few doses at an even lower level, perhaps one-quarter or one-half of the expected maintenance dose. The patient should be instructed to discontinue the drug immediately and telephone the office if side-effects ensue. Base-line laboratory data, relevant to the area in which problems might occur, should be obtained prior to starting a new drug. These values should be repeated at appropriate intervals.

For any drug, the risk of adverse effects varies with each individual patient. The definition of patients at increased risk, in response to a number of agents, is becoming clearer. For example for non-steroidal anti-inflammatory drugs there is a growing consensus that the chance of gastropathy is significantly enhanced if the patient has a history of previous peptic ulcer, previous upper gastrointestinal bleeding of any cause, and in patients with multiple chronic diseases (Llewellyn and Pritchard 1988; Janssen *et al*. 1994). Care should be taken in prescribing warfarin for patients with a predilection for falling.

It is useful to define the specific goal one hopes to be achieved through use of a given agent. If toxic effects ensue, it is much better to shift to a different agent than to add yet another drug, designed to decrease the severity of the adverse drug effects. The entire drug and treatment programme should be reviewed periodically. Drugs that have not been proven to be effective should be discontinued.

Laboratory data

Carefully selected laboratory data is an essential part of pharmacological therapy for three reasons:

1. by helping to assess the risk of toxicity in given patients;
2. to identify persons in whom the drug should not be used;
3. in monitoring patients for potential side-effects.

Laboratory data also constitutes an important component of diagnosis. A great deal of data on this topic is provided elsewhere in this book. Because of the possibility that a given patient may have several, simultaneous, unrelated clinical disorders, a carefully selected group of laboratory determinations should be carried out on all new patients with arthritis, except, perhaps, in its most localized form. While the list will vary in different clinics, Table 3 reflects our policy in this regard.

Obtain always or almost always
Complete blood cell count and differential
Biochemical screen, including blood urea nitrogen, creatinine, glucose, electrolytes, calcium, phosphorus, alkaline phosphatase, uric acid, albumin, total serum protein, and liver enzymes
Urinalysis
Radiograph of hands and other involved joints
Obtain if appropriate
Antinuclear antibody (ANA) screen
If ANA screen is positive, obtain ANA titre, with pattern, anti-dsDNA, and other antinuclear and anticytoplasmic antibodies as appropriate
Rheumatoid factor
Chest radiograph
T_4 thyroid-stimulating hormone
Synovial fluid examination for culture, crystals, and cell count
Other diagnostic studies: Schirmer's test, electromyography, bone scan, MRI, CT scan, arthroscopy, dual energy X-ray absorptiometry, biopsy of skin, muscle, kidney, lacrimal gland, etc.

Table 3 Baseline laboratory studies in the diagnosis of musculoskeletal disease

Established values for most blood chemistries and special studies conducted in rheumatology are the same for older persons as for younger individuals. This is not true, however, for the erythrocyte sedimentation rate, which will often exhibit values of 25 to 30 mm/1 h in an older person without demonstrable rheumatic or inflammatory disease (Fig. 6). Similarly, both the rheumatoid factor and antinuclear antibody test, in low dilution, will be exhibited by many apparently normal older

persons in the absence of any demonstrable inflammatory or rheumatic disease (Hallgren *et al*. 1973).

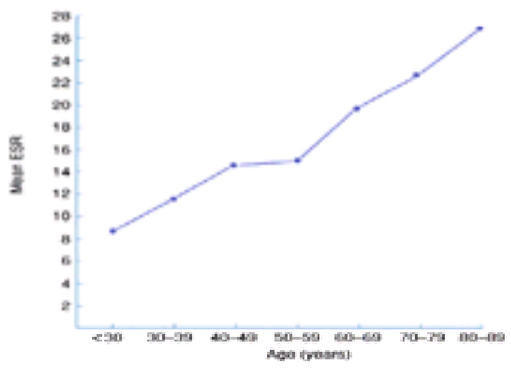

Fig. 6 Increase in mean erythrocyte sedimentation rate with advancing age. Wintrobe method, measured in millimetres per hour. (Reproduced from Hayes and Stinson 1976, with permission.)

Exercise

As noted earlier, muscle function undergoes a progressive, age-related decline. Conspicuous among the changes accompanying this decline are alterations in length–tension relationships (Pendergast *et al*. 1993). In youth, muscles act something like elastic bands—the more one stretches them, the greater the resistance. As one ages, however, this relationship changes and maximum strength or resistance is achieved somewhat short of the point of the maximum length. This results in an effective shortening of the muscle, contributing to the muscle aches experienced by many older people, especially those with arthritis (Fisher *et al*. 1991*b*).

Muscle exercises are of two sorts, aerobic and anaerobic. Aerobic exercises, often recommended to patients in later life, consist primarily of flexibility exercises. These provide entertainment and some improvement in flexibility and balance, but do nothing to improve strength. Anaerobic exercises, however, involving vigorous muscle contraction against resistance, do result in increased strength and in an alteration of the strength–tension relationship toward normal. Exercises of this sort can be conducted, safely, under supervision, among older persons, even those in their late 90s, and result in significant increases in strength (Fisher *et al*. 1991*a*; Fiaterone and Evans 1993; Pyka *et al*. 1994). Unfortunately, if the exercise is confined to a relatively short period, 3 to 6 months for example, the strength will usually return to its original level over ensuing months. To be effective, therefore, a somewhat less intensive programme of continued exercise should be maintained.

These considerations have significant relevance to the field of rheumatology. Arthritis, either generalized or localized to a given joint such as a knee or hip, almost inevitably leads to decreased overall physical activity, with significant consequences in terms of overall muscle strength, cardiovascular function, the likelihood of falls, and other components of frailty. However, these declines in muscle function in patients with osteoarthritis have the capacity to be reversed by well designed anaerobic exercise (Fisher *et al*. 1991*b*).

Since exercise is maximally effective at the specific muscle length at which it is conducted, it should be carried out at several different muscle lengths for the greatest benefit. For example the attachment of the quadriceps muscle is such that it is at its greatest length when the hip is fully extended (i.e. the patient is lying flat). Therefore, quadriceps strengthening exercises should be carried out with the patient both in the sitting and lying position with, ideally, an intermediate position added. A given programme of exercise will result in a slight increase in muscle aching, analogous to that experienced by normal people after a 'workout'. The exercise should not be conducted to the point of actual pain, which is not only uncomfortable for the patient but actually inhibits muscle function and the effectiveness of the programme.

Unfortunately, exercises of this sort are extremely boring. Few patients will actually carry them out by themselves at home. We have found that a series of exercise classes, including approximately 12 patients at a time, and combining exercise with patient education and social support, are enthusiastically received by many patients. Twenty classes, 1 1/4 h each, conducted over the course of 10 weeks, have led to significant enhancement in overall function, balance, and psychological well being (Gunther, J., Brown, D., Karuza, J., and Calkins, E., in press).

Diseases of the joints and muscles not only yield pain and functional limitation, they also assume importance because they tend to limit the ability of the person to participate in normal physical activities such as housework, chores, climbing stairs, and sports. Thus, by appropriate treatment of musculoskeletal problems which inhibit these normal patterns of exercise, the rheumatologist can make an important contribution to the patient's overall health, happiness, and, possibly, longevity.

Prevention

One of the characteristics of frailty or fragility is that it is easier to prevent damage than to repair it. This is particularly true for the geriatric population (German and Fried 1989). Despite progressive functional losses in many organ systems, many people, age 80 years and older, are able to function quite well until some relatively minor episode—an attack of influenza or a fall—triggers a cascade of events with high probability of leading to the need for extensive (and expensive) medical care, losses of functional capacity, increased need for support services, possible institutionalization, and, in some, death.

Thus, a significant portion of the attention given to medical care of older people should be devoted to careful consideration of the full range of measures that will decrease the likelihood of intercurrent illness and accidents, such as falls. In addition to exercises, these measures include use of a cane as an aid to balance as well as to ease pain in affected joints, avoidance of drugs (such as the benzodiazepines) which are known to predispose to falls, and appropriate safety measures at home, such as avoidance of throw rugs and provision of good illumination on stairs. Assurance that these measures are being properly addressed is an appropriate component of rheumatological practice with older patients.

The best current example of the importance of prevention in the field of musculoskeletal disease is osteoporosis (Odell and Heath 1993). In an article entitled 'Health of the nation and osteoporosis', Dixon (Dixon 1992) pointed out that prevention of osteoporosis ideally fulfils the three basic criteria for prioritizing preventive care:

1. the burden of unprevented disease is great;
2. opportunities for prevention exist;
3. practical targets can be set.

In 1989, a report of The Royal College of Surgeons pointed out that patients with hip fractures occupied 20 per cent of orthopaedic beds; 80 per cent were woman over 65 years. The direct hospital costs were £160m at 1977 to 88 prices. Approximately 20 per cent of patients with hip fractures are dead in 6 months and, of the remainder, approximately half lose independence. Patients who are thin, smokers, with a family history of severe osteoporosis, and minimal calcium intake during adolescence are at greatest risk. Initiation of oestrogen replacement at the earliest indication of menopause, especially in high risk patients, is highly effective in preventing this bone loss. Supplementation of calcium intake, to 1500 mg/day, together with small amounts of vitamin D (400 international units either daily or 3 times a week) further contributes to maintenance of bone mineralization. Exercise, especially of a weight bearing variety, will also contribute to retaining calcium in the bones and, possibly, some degree of increased mineral content.

The opportunity to address late-life osteoporosis has recently received an important impetus through two developments. The first is the wide availability of equipment for dual-energy X-ray absorbtiometry, which provides an excellent, relatively low cost means of assessing the mineral content of both vertebral and long bones. In addition to assisting in the identification of early osteoporosis, this technique provides the first readily available means of following the course of patients and determining the effectiveness of a given regimen.

The second advance is the increased appreciation of the effectiveness of two agents in actually reversing osteoporosis—calcitonin and the bisphosphonates. The latter are proving to be the most practical. These agents are synthetic analogues of inorganic pyrophosphate. Like pyrophosphate, they have a high affinity for hydroxyapatite but are resistant to metabolism by endogenous phosphatase. They act both by inhibiting bone resorption and also by inhibiting bone mineralization.

The agent whose use initially demonstrated the potential benefit of this form of therapy, etidronate, exhibits both actions at approximately the same dosage. In clinical practice, the inhibitory effect on bone mineralization is decreased, however, by the administration of the drug in a cyclical fashion, for 2 weeks every 4 months (Watts *et al*. 1990; Harris *et al*. 1993). Even so, there is some evidence suggesting that after 2 years of therapy the effect of the drug on diminishing mineralization of bone may become apparent. It is questionable whether use of the drug should be continued for periods of 3 years or more.

A more recently developed agent, alendronate, is about 1000 times more potent, in terms of inhibiting bone resorption, than etidronate and provides effective inhibition of bone resorption at doses that do not affect mineralization. The agent can be taken daily, on a continuous basis. It is recommended to be taken in a dose of 10 mg/day, one-half hour before breakfast. This avoids the complexity of cyclical therapy and provides the potential opportunity for continuous usage over a long period of time. A recent, large-scale, controlled study showed that daily administration of the drug increased the bone mass of the spine, hip, and total body and reduced the risk of vertebral fractures, the progression of vertebral deformities, and the height loss in both men and women with osteoporosis (Liebermann *et al*. 1995). Although experience has not yet been gained in long-term use of this drug, initial reports suggest that this agent, and others currently being developed, have a high likelihood of yielding a major impact on the frequency and consequences of osteoporosis (Sambrook 1995). It has been shown that administration of etidronate will prevent the loss of bone mineral density in patients receiving long-term prednisone therapy (Mulder and Struys 1994), and one would anticipate that alendronate would also be effective in this regard.

The one period in life when bones readily absorb dietary calcium lies during the 3 or 4 years immediately following puberty (Lloyd *et al*. 1993). There is a direct association between calcium intake of children during this period and the bone mineral mass which they will carry the rest of their lives. As Dixon has observed, 'good bones last a lifetime' (Dixon 1992). It is, therefore, recommended that all children receive diets, appropriately supplemented, which will yield an intake of approximately 1500 mg of calcium daily. This is one of several examples of the fact that patterns of life during childhood have a direct relationship to the way one responds to the challenge of ageing.

Psychological factors

The most common and, probably, most devastating loss, often but not always associated with advanced age, is that of cognitive capacity. The extent of this loss is not readily identified. Older patients are very good at concealing it. Physicians seldom include objective assessment of cognitive capacity as part of their physical examination and frequently overlook losses which have a significant effect on the person's ability to comply with medication regimens and rehabilitation guidelines. Assessments of cognitive capacity can easily be performed through a series of simple questions requiring not more than 10 min (Folstein *et al*. 1975). While Alzheimer's disease and multi-infarct dementia are the most common causes of cognitive loss at this age, there are a number of other causes, some of which are reversible, at least on a short-term basis (Rabins *et al*. 1984). These include depression, delirium, (often secondary to infection or inappropriate medication), hyperthyroidism or myxoedema, hypercalcaemia, and vitamin B12 deficiency. Depression has been shown to be present in approximately 20 per cent of patients in an ambulatory care practice (Blazer 1989). It, too, is often overlooked by physicians. Good objective means of assessment have been designed (Burnam *et al*. 1988) but are rarely put into effective use in a primary care practice. The pain and limitation of musculoskeletal diseases, often preventing patients from participating in life-long activities and interests, produce, in many patients, a sense of discouragement and depression. For this reason it is important that the rheumatologist become skilled in differentiating these symptoms from those of true depression, which is readily amenable to appropriate pharmacological therapy. Chronic anxiety and, not infrequently, panic attacks are other psychological problems experienced by older patients, frequently overlooked by physicians, and readily amenable to appropriate therapy (Lindesay *et al*. 1989; Brown *et al*. 1991).

Older patients also experience serious social losses. These include loss of a job, decreased income, death of friends, possible death of a spouse, children moving away, and possible relocation from the house one has occupied for 40 or 50 years. Despite these losses, essentially all older patients adhere, fiercely, to two goals: ability to live independently in the community and retention of a measure of control. They are aided by two assets—experience and social skills they have acquired since childhood. It is fascinating to see how different people use these two resources to fend off or compensate for the often staggering social and physical losses, sometimes maintaining their proud independence into their early 90s. Others, endowed with a less flexible, resourceful, and determined psychological makeup, crumple at an early age in the face of far less formidable losses and obstacles.

It should be clear from earlier portions of this chapter that the way one responds to the challenge of musculoskeletal disease has a great deal to do with the outcome. Therefore, attention to the psychological and social aspects of a patient emerge as major considerations in a rheumatological practice with older people.

Nutrition

Maintenance of adequate nutrition, in terms of intake of protein, calories, vitamins, calcium, and trace metals is an important component of the ability to maintain independence (Morley *et al*. 1986; Lipsitz 1992). While protein calorie malnutrition is seldom included among the discharge diagnoses of hospitalized patients, it is present, to a significant degree, in a high percentage of hospitalized persons, especially older people, and is a major factor contributing to their inability to respond to acute illness, especially infection (Bienia *et al*. 1982).

Systematic observation of the patient's weight is an important component of ambulatory care practice. A loss of weight, of 8 to 10 per cent over the course of 6 months, is an indication of serious disease or inadequate food intake and should stimulate thorough assessment. While losses of this sort may reflect coincidental chronic illness, older people with rheumatic diseases, especially those living alone, may face difficulties in gaining access to the grocery store, transporting food to their homes, proper preparation of meals, and the process of eating itself. Meals on Wheels and similar programmes assist substantially by providing one good meal a day and a small amount of social support.

Environmental considerations

In addition to efforts to improve the patient's functional capacity, the ability to maintain independence can be enhanced through appropriate attention to the availability and usefulness of the wide range of functional aids that are currently available. These include various types of wheelchairs, canes, and other devices to assist ambulation, and special equipment to aid in eating, dressing, hearing, seeing, and attending to personal needs (Wasson *et al*. 1990). Modification of the physical environment by elevated toilet seats, appropriate ramps, and introduction of community-based resources for social support are also important. While few physicians have the time to assume direct responsibility for instructing patients concerning the use of these resources, the physician, in our culture, is the person to whom the patient turns as the ultimate source of help. Physicians should be aware of the importance of these aspects of care and assume some responsibility for seeing that these needs are met.

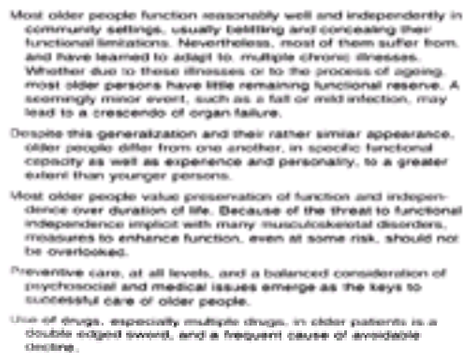
Organizing comprehensive care for the older patient with a rheumatic disease

Thus, the goal of therapy in persons of advanced age, especially 80 years and older, is substantially different from that in a younger person or someone at midlife. In a 30-year-old person with early rheumatoid arthritis, for example, the goal is to do everything one can to achieve a remission, avoiding, if possible, long-term commitment to an agent such as continuing prednisone therapy, which would have a deleterious impact over the decades to come. In a person age 80 years with a similar disease, the goal is to restore the person, in the shortest possible period of time, to the previously established lifestyle. This may involve, for example, early institution of low-dose prednisone therapy, with relatively little concern as to the effect of this agent over the course of a decade or more to come. For a person whose ability to continue independent life is compromised by a painful hip with serious limitation in motion, one might, in consultation with the patient and family, recommend a joint replacement, realizing that the operative risk, in a person of this age, will be significantly enhanced.

Thus, for older persons with arthritis, the programme of management transcends what is, traditionally, the province and training of the physician. It can only be carried out through a team approach—an interdisciplinary pattern of management in which various aspects of care and support are entrusted to people with special skills and experience (Halstead 1976; Rubenstein *et al*. 1994). An approach of this sort is utilized in many, probably most, centres for comprehensive care of patients with arthritis, and is essential in geriatrics. It involves recognition by the physician that he or she can not be the sole provider of health care nor even, necessarily, the 'person in charge'. This approach to management involves interdisciplinary skills rarely if ever taught in medical school or fellowship training. To be effective, it also requires a comprehensive assessment of the range of problems confronted by an individual patient. This has led to the development of a variety of assessment instruments or tools, which have become essential component of geriatric care (Lawton and Broady 1969; Katz *et al*. 1970; Reuben and Siu 1990; McHorney *et al*. 1994).

Finally, and particularly important, is the topic of patient education (Winfield 1989). As Wood has pointed out 'We cannot expect major reduction in the scale of problems for which some help from the health and social services will be needed. The strategic goal should be towards policies of enablement, seeking ways of

maximizing the ability of old people to handle their own health and other problems' (Wood 1992). Measures to achieve this objective, through patient education and mutual support groups, become important components of comprehensive rheumatological practice. Information concerning various aspects of arthritis, appropriate for patients and families, is included in the publication *Arthritis today*, available from the Arthritis Foundation, 1314 Spring Street NW, Atlanta, GA 30309, telephone (404) 872–7100. Other national organizations may provide similar support. Important points to remember regarding special characteristics of older patients and their management are summarized in Table 4.



Most older people function reasonably well and independently in community settings, usually belittling and concealing their functional limitations. Nevertheless, most of them suffer from, and have learned to adapt to, multiple chronic illnesses. Whether due to these illnesses or to the process of ageing, most older persons have little remaining functional reserve. A seemingly minor event, such as a fall or mild infection, may lead to a crescendo of organ failure.

Despite this generalization and their rather similar appearance, older people differ from one another, in specific functional capacity as well as experience and personality, to a greater extent than younger persons.

Most older people value preservation of function and independence over duration of life. Because of the threat to functional independence implicit with many musculoskeletal disorders, measures to enhance function, even at some risk, should not be overlooked.

Preventive care, at all levels, and a balanced consideration of psychosocial and medical issues emerge as the keys to successful care of older people.

Use of drugs, especially multiple drugs, in older patients is a double-edged sword, and a frequent cause of avoidable distress.

Table 4 Important points to remember: Special characteristics of older patients

The geriatric perspective on specific rheumatic diseases

Osteoarthritis

Osteoarthritis is a typical geriatric disorder. Although changes in histological appearance of cartilage and adjacent bone can be seen as early as the third decade, clinical manifestations rarely appear before the fifth or sixth decade. Details concerning the epidemiology, pathology, and clinical manifestations of osteoarthritis are presented elsewhere in this book. Numerous studies have described the physical and biochemical changes of cartilage associated with ageing and with osteoarthritis. Unfortunately, except for elucidating a few genetically controlled abnormalities, these studies have, to date, produced relatively little information concerning the pathogenesis and means of prevention of common forms of osteoarthritis. In this author's opinion, much more attention needs to be paid to the role of stresses on joints, secondary to the way people, especially children, use their legs. Studies on effectiveness of measures to correct abnormal gait in children, through orthotics and other means, on the development of osteoarthritis in late life are difficult to carry out, due to the element of time, but might pay important dividends. Such studies would be consistent with a theme I have tried to present in this chapter—that ageing is a life-long process and that patterns established during childhood have a great deal to do with the way people respond to the challenge of ageing.

Clinical aspects

One of the striking features of this disorder, of particular relevance in practice with older patients, is the lack of concordance between radiological findings and clinical symptomatology. Many patients with severe radiological changes indicative of osteoarthritis of the spine, for example, exhibit no symptoms. Conversely, other patients will complain of severe disabling back pain without radiological evidence of osteoarthritis or any other identifiable structural disorder.

The reasons for this lack of concordance are not fully understood. There are wide discrepancies in pain perception among individual persons (Lichtenberg *et al*. 1986). While this undoubtedly reflects, to some degree, physiological differences, it is inescapable that the major differences are psychological in nature. Musculoskeletal symptoms are strongly influenced by psychological factors such as attitudes towards pain and disability and the sense of control over one's disease (Keefe *et al*. 1987). Failure to recognize this aspect of rheumatological practice and to respond to it appropriately accounts for a considerable measure of the frustration experienced by many primary care physicians in attempting to treat patients with osteoarthritis.

The lack of concordance between radiological evidence of osteoarthritis and symptoms is important for another reason. The existence of radiological evidence of osteoarthritis, whether in the neck, spine, hips, or knees, and pain generally referable to that area should not be taken as evidence that the pain is due to the osteoarthritis rather than a concomitant problem of an entirely different sort, such as carcinoma of the pancreas or prostate, multiple myeloma, dissecting aortic aneurysm, or a fracture of an adjacent bone.

In older patients with osteoarthritis there is a general agreement that acetaminophen in good doses is the safest agent for relief of pain and is effective in many patients. Two 650 mg tablets three times a day can be tolerated by most patients. Higher doses may result in a 'spaced out' sensation. The possibility of nephrotoxicity has recently been emphasized. This is much more likely to be seen in patients with already-established renal disease than in otherwise normal persons. Serum estimations of creatinine and blood urea nitrogen should be obtained during long-term treatment with acetophenetidin. The hazards accompanying use of the non-steroidal anti-inflammatory drugs in older patients has already been discussed. These drugs should be used with the greatest caution or omitted altogether in patients who present high risk for toxic side-effects. Because of the hazards of addiction, codeine and other narcotics should not be used in patients with osteoarthritis or other chronic forms of arthritis, except under unusual circumstances and for short periods of time. Although propoxyphene has been widely criticized and is regarded, by some, as inappropriate for use in older persons, we have found that 75 mg of propoxyphene once daily, perhaps in the evening, in addition to acetaminophen or aspirin, is helpful in many older patients. Higher doses of propoxyphene may be necessary in some patients.

The concepts concerning design and implementation of exercise programmes, discussed earlier, are particularly applicable and effective in patients with osteoarthritis. So, too, are earlier statements on the use of assistive aids, environmental support, the issue of multiple disease, and the concepts of interdisciplinary team care. Details on surgical management are presented elsewhere in this book.

Rheumatoid arthritis

As pointed out earlier, very few demographic studies on the incidence or characteristics of rheumatoid arthritis in persons 70 years of age and older are available, and the studies that have begun to appear contain little information on the clinical characteristics of patients in this age group. Therefore, our understanding of the clinical features of this disease in older persons is based on observations of patients who present themselves or are referred to the rheumatologist's office or hospital, and are subject to wide variations in patient selection. Persons with this disorder fall into two general categories—those whose disease commenced many years before and now present with sequelae of the disease and previous modes of therapy, and those with new onset disease. Little information is available concerning the characteristics of persons in the former group. One gains the impression that far fewer of them exists than one would have anticipated from incidence rates over the decades, consistent with other data concerning the negative impact of rheumatoid arthritis, or its treatment, on life expectancy (Allebeck 1982; Pincus and Callahan 1986).

A number of clinical studies have suggested that new onset disease, in older persons, is different from that in people at midlife (Deal *et al*. 1985; Healey 1986). Approximately two-thirds of the cases exhibit a gradual onset, occurring over the course of weeks or months, and constitutional manifestations are mild. In a smaller group of patients the arthritis develops much more rapidly, often over the course of a few days. These patients may experience severe constitutional symptoms, including fever and even chills. They appear to have a greater chance for spontaneous remission than do patients in the gradual-onset group. Although many older persons with new onset rheumatoid arthritis will have a positive titre for rheumatoid factor, one must bear in mind that rheumatoid factor in low titre will be seen in many older persons without any evidence of rheumatic or inflammatory disease (Hallgren *et al*. 1973). In our experience, the number of older persons with new onset disease who exhibit the clinical features of seropositive rheumatoid arthritis is rather small.

In view of the extensive coverage of the pathogenesis, course, manifestations, and treatment of rheumatoid arthritis in other sections of this volume, this discussion will focus on selected areas of special relevance in the older patient.

Differential diagnosis of rheumatoid arthritis and osteoarthritis

This differential has been presented, for years, to entering medical students as one of the pedestals of rheumatology. Among older people, however, the differential is far less easy. It is also important in that antirheumatic therapy, such as methotrexate or low dose prednisone, appropriate for use in patients with rheumatoid arthritis, is not indicated in osteoarthritis and will be of little value. For this reason, uncertainty concerning this diagnosis is one of the chief reasons for referrals from the primary care physician to the geriatric rheumatologist. Table 5 summarizes points that we have found to be helpful.

	Rheumatoid arthritis	Osteoarthritis
Most helpful		
Time of major symptoms	Morning	Evening
Duration of morning stiffness	2–3 h—all day	1 h or less
Radiographic changes (special joints)	Look for 'double line' (synovial thickening)	Look for fuzziness of cartilage (calcium pyrophosphate deposition disease)
Synovial fluid		
White cell count	2000–25 000	100–4000
Turbidity	Slight or moderate	Fluid clear or slightly turbid
Viscosity	Watery	Viscid
Mucin clot*	Poor clot	Good clot
Calcium pyrophosphate crystals	Rarely present	May be present
Less helpful		
Distribution of joints involved, present of synovial thickening, tenderness, or effusion, rapidity of onset of acute involvement		

*Obtained by dropping a few drops of synovial fluid into dilute vinegar or dilute acetic acid

Table 5 Differential diagnosis of rheumatoid arthritis and osteoarthritis in an older patient

Speed of onset

In theory, this should be a fundamental part of the differentiation. Osteoarthritis is a chronic disease with, usually, a gradual onset while, especially in older persons, rheumatoid arthritis may exhibit a rapid onset, over the course of 1 week. However, older patients with osteoarthritis will often exhibit sudden onset of swelling, tenderness, and effusion in a given joint, especially a knee, following relatively minor trauma. In some instances this will be due to haemarthrosis due to the 'nipping' of a synovial lip by an osteoarthritic spur.

Distribution of involved joints

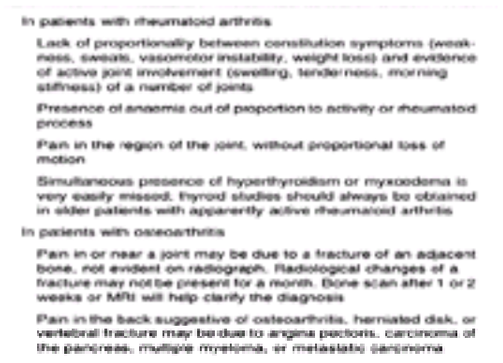
This differential, too, may be blurred. Osteoarthritis frequently involves the proximal interphalangeal joints and this may over-shadow changes in the distal interphalangeal joints. Occasionally, involvement will be seen in the metacarpophalangeal joints as well, even including a mild ulnar drift (MacFarlane and Dieppe 1983). While synovial thickening, accompanied by warmth and tenderness, is a characteristic feature of rheumatoid arthritis, these changes are often seen in patients with osteoarthritis, especially in the knees. It has been speculated that this may reflect immunological reaction to breakdown products of cartilage. Alternatively, this may be due to calcium pyrophosphate deposition disease, a frequent concomitant of osteoarthritis.

The time of day when symptoms are most severe, and the presence or absence of morning stiffness, are both useful in differentiating these entities. Further help can be derived from the radiograph. The differential points are exhibited with special clarity in hand films, due to the multiplicity of joints and the closeness of the joints to the radiographic film. The bony and cartilage changes of the two disorders are described elsewhere in this book. Older patients with rheumatoid arthritis will frequently exhibit radiological changes of osteoarthritis as well, either as a simultaneous, coincidental disease or secondary to the rheumatoid process. Soft tissue changes may also be of assistance. If one carefully examines a film with the aid of a bright light, one is often able to detect, adjacent to a proximal interphalangeal joint, a 'double line' indicating the presence of fusiform synovial thickening characteristic of rheumatoid arthritis. One should also look carefully for evidence of calcium pyrophosinate deposition disease, a common concomitant of osteoarthritis but not of rheumatoid arthritis.

Synovial fluid analysis remains an important component of differential diagnosis. There will be patients in whom the diagnosis of rheumatoid arthritis or osteoarthritis is so clear that fluid analysis will not be necessary. However, at least one analysis should be conducted on all patients in whom fluid is available. Details concerning synovial fluid examination and its use in differential diagnosis are presented elsewhere in this book. Attention should be paid to appearance, viscosity, cell count, culture, and a search for crystals. If a single joint shows evidence of greater inflammation than is present in other joints, one should suspect the presence of septic arthritis. Many patients with osteoarthritis have underlying or concomitant calcium pyrophosphate deposition disease. Therapy with colchicine, although not as an effective as in gout, is helpful in some patients. Treatment of either rheumatoid arthritis or osteoarthritis is by no means easy. To attempt it in the absence of a clear diagnosis is difficult, and every effort should be made to establish the diagnosis.

Treatment of the older patient with rheumatoid arthritis

In patients with rheumatoid arthritis, as in those with osteoarthritis, it is important to search for the possible presence of concomitant disease. Key questions that should be asked in this regard are outlined in Table 6.



In patients with rheumatoid arthritis
Lack of proportionality between constitution symptoms (weakness, sweats, vasomotor instability, weight loss) and evidence of active joint involvement (swelling, tenderness, morning stiffness) of a number of joints
Presence of anaemia out of proportion to activity or rheumatoid process
Pain in the region of the joint, without proportional loss of motion
Simultaneous presence of hyperthyroidism or myxoedema is very easily missed. thyroid studies should always be obtained in older patients with apparently active rheumatoid arthritis
In patients with osteoarthritis
Pain in or near a joint may be due to a fracture of an adjacent bone, not evident on radiograph. Radiological changes of a fracture may not be present for a month. Bone scan after 1 or 2 weeks or MRI will help clarify the diagnosis
Pain in the back suggestive of osteoarthritis, herniated disk, or vertebral fracture may be due to angina pectoris, carcinoma of the pancreas, multiple myeloma, or metastatic carcinoma

Table 6 Clues to the presence of concomitant disease complicating rheumatoid arthritis or osteoarthritis

The physician should be particularly attentive to non-pharmacological therapy (Podgorski and Edmonds 1985). Use of any drug in older persons is fraught with greater risk than in those at midlife. Non-pharmacological therapy has few complications and, if carefully supervised by the physician, is remarkably effective. By involving a commitment on the part of the patient, non-pharmacological therapy can contribute, substantially, to the sense of control a patient has over his or her disease.

Rheumatoid arthritis is a constitutional illness. Patients should get sufficient rest to avoid fatigue. The physician should spell this out in detail. For example, the patient might rest in bed for 2 h after lunch, undertake light activities at home during the rest of the day, but be given permission to undertake one activity outside the home, such as a shopping trip or going out to dinner with friends. The concept of rest also includes use of appropriate splints for actively involved joints, always accompanied by periods of range of motion exercises.

In the older patient with rheumatoid arthritis who fails to respond to a comprehensive programme of rest, exercises, and salicylates or non-steroidal anti-inflammatory drugs, methotrexate (Wolfe and Cathey 1991) and low doses of prednisone are, in our view, the agents of choice. Methotrexate is particularly effective in patients who exhibit marked synovial thickening. Prior to initiating treatment, a complete blood cell count, liver function tests, and a chest radiograph must be obtained. The

complete blood cell count should be repeated every month; liver function tests every 3 months. An initial dose of 7.5 mg of methotrexate per week may be increased to 15 mg if necessary. Patients may experience bothersome upper gastrointestinal symptoms, which subside with decreased dosage. If gastrointestinal symptoms persist, or the patient does not achieve a satisfactory response, methotrexate may be administered intramuscularly at the same dosage levels. The dosage should be decreased, in any case, once an initial response has been achieved. All patients receiving methotrexate should also be given folic acid, 1 mg daily or 5 mg each week. This will not inhibit the effectiveness of the methotrexate.

In contrast to use of low-dose prednisone in patients with lupus erythematosus or giant cell arteritis, the initial dose in patients with rheumatoid arthritis should be fairly close to what would be an appropriate maintenance level in that particular patient, that is approximately 8 mg/day, given in the morning. The dose should be titrated against symptomatic response in 1 mg aliquots so as to achieve a reasonably satisfactory response at a minimal dosage level. Concomitant calcium and vitamin D should be given and, for patients at high risk for the development of osteoporosis, etidronate or better, alendronate. Methotrexate may be given simultaneously with prednisone.

I have not included sulfasalazine, plaquenil, or penicillamine in this list. The reason is that, in my view, these agents are less effective than methotrexate or low-dose prednisone. In the older patient, delay in initiating full rehabilitation brings the serious hazard of social isolation, discouragement, and the development of decubitus ulcers and other sequelae of inanition. The benefit/hazard ratio of either methotrexate or prednisone in proper doses, accompanied by a full, well-organized, conservative programme, will, in my view, be greater than that associated with the other agents.

Polymyalgia rheumatica and temporal arthritis

Polymyalgia rheumatica and temporal arthritis are among the entities that generate a reasonable flow of consultations from the primary care physician to the rheumatologist. Three aspects account for most of these consultations. The first is the fact that a considerable number of patients, perhaps half of those referred to me in my own consultation practice, with classic clinical characteristics of polymyalgia rheumatica including rapid response to low-dose prednisone, turn out, after follow-up for a year or so, to have either seronegative rheumatoid arthritis or, less frequently, systemic lupus erythematosus. Dixon has pointed out the diagnostic importance of the precise timing of the initial response to prednisone (Dixon 1978). Patients with seronegative rheumatoid arthritis, masquerading as polymyalgia rheumatica, will exhibit a good clinical response to prednisone, in a dose of 10 or 15 mg/day, but this usually occurs on the second or third day after therapy; patients with polymyalgia rheumatica typically manifest this improvement on the first day after starting prednisone. The nature of this response, together with the discordance between the constitutional symptoms, especially muscle stiffness and weakness and objective evidence of inflammation of the peripheral joints, in patients with polymyalgia rheumatica, provide good grounds for initial differentiation. However, even in these patients, by the end of a year or so of prednisone therapy, a number will begin to exhibit sufficient involvement of the peripheral joints, including proximal interphalangeal and/or metacarpophalangeal joints, accompanied by early radiological changes, to justify the diagnosis of seronegative rheumatoid arthritis. Healey and Sheets have emphasized the close relationship of these two entities (Healey and Sheets 1988). A problem is created by the fact that, by the time a year has gone by, one is fairly well committed to long-term prednisone therapy in a patient in whom one might not have selected this treatment if the correct diagnosis had been made at the outset. An alternative approach, that of treating patients with polymyalgia rheumatica with a non-steroidal antirheumatic drug from the onset, would avoid this problem. However, not all patients will respond and there is the added hazard of the toxic effect of non-steroidal anti-inflammatory drugs in older patients.

A second problem, occurring in patients in whom the diagnosis of polymyalgia rheumatica was correctly made, is inability to withdraw steroid therapy after 1 or even 2 years without a significant flair up of the symptoms of polymyalgia. This occurs in approximately one-third to one-half of the patients who are referred to me with this condition. For these patients, a very small dose of prednisone, perhaps 2 or 3 mg/day, often proves to be effective and a long-term commitment at this dosage level seems unavoidable. It has been suggested that this problem would be less apt to occur if the initial dose were established at the lowest possible effective level, perhaps 8 to 9 mg/day.

A third problem is presented by the patient who has temporal arteritis suppressed by the initial high doses of prednisone, in whom the symptoms recur as the prednisone dose is decreased to a level of, perhaps, 30 mg/day. In these patients, addition of methotrexate, 7.5 to 15 mg/week, may permit further reduction of prednisone dosage. There are also patients in whom it is possible to lower the dose of prednisone to 8 or 9 mg/day, while further decreases are accompanied by flair up of the manifestations of temporal arteritis and continued therapy at this dosage level is unavoidable.

Remitting seronegative symmetrical synovitis with pitting oedema syndrome (RS $_3$ PE)

McCarty *et al*. have described a syndrome which they have termed remitting seronegative symmetrical synovitis with pitting (o)edema, the first letters of which form the abbreviated title RS$_3$ PE syndrome (McCarty *et al*. 1985). Occurring in men twice as frequently as in women, with an average age of 75 years, the syndrome is characterized by the sudden onset, sometimes within hours, of a symmetrical polysynovitis manifested in extreme cases by tenderness and swelling of the peripheral joints, especially wrists, and flexordigitorium tendons over the volar surface of the wrist and forearm, accompanied by pitting oedema and, sometimes, redness and warmth of the dorsum of the hands and feet and, in some instances, pretibial areas. The condition is accompanied by marked morning stiffness, lasting up to 6 h. Carpal tunnel syndrome may be present. Constitutional symptoms, such as fever and fatigue are infrequent. Radiographs reveal no evidence of joint destruction, either initially or over a follow-up of up to 5 years. While synovitis may be present, the involvement focuses primarily in tendon sheaths. Rheumatoid factor, by latex fixation test, is absent. Low titres of antinuclear antibodies may be present. Erythrocyte sedimentation rate is often elevated, sometimes as high as 93 mm/1 h. HLA typing reveals a disproportionate number of patients with HLA-B7.

By 1994, 31 cases of this syndrome had been described (Russell *et al*. 1990; Olivo *et al*. 1994). Many patients become quite incapacitated by the symptoms, sometimes requiring hospitalization. Various treatment regimens have been utilized, including non-steroidal anti-inflammatory drugs, hydroxychloroquine, gold, and prednisone. Prednisone, in doses comparable to those employs in polymyalgia rheumatica, yielded prompt resolution of the symptoms in several cases, and low-dose prednisone therapy appears to be the optimal form of treatment. Regardless of therapy, all patients entered a substantial remission within a year, with complete subsidence of the inflammatory manifestations but, in some, a small reduction in range of motion in the hands and wrists. While many rheumatologists regard this syndrome as a specific entity, Healey has postulated that this entity, seronegative rheumatoid arthritis, and polymyalgia rheumatica may represent different phases or manifestations of a common disorder (Healey 1990).

Systemic lupus erythematosus

Systemic lupus erythematosus occurs primarily in young adults, with progressive declines occurring throughout late adult life and a frequency close to zero among the very old. However, the disease does occur in the latter age group and provides a particular diagnostic challenge for two reasons. First, the rarity of the entity, in contrast to the increasing frequency of other conditions with somewhat similar manifestations (such as rheumatoid arthritis, Sjögren's syndrome, and carcinomatosis) places it low in the index of suspicion of physicians caring for persons in this age group. Second, the clinical manifestations of lupus, among persons at late midlife, appear to be significantly different from the 'textbook description' of this disease, which has been based primarily on studies of patients at a younger age.

While there is general agreement that these differences do exist, the published studies on this point do not yet achieve total agreement concerning the details. Review of data published by Dimant *et al*. (216 younger patients/16 older), Maddison (93 younger/19 older), Cervera (1910 younger/90 older), and a meta-analysis of nine studies conducted by Ward and Polisson illustrate this point (Dimant *et al*. 1979; Maddison 1987; Cervera 1993; Ward and Polisson 1989). All authors agree that patients with onset of the disease at late midlife have a increased frequency of pulmonary manifestations. The three articles which comment on Raynaud's phenomena (Dimant *et al*. 1979; Maddison 1987; Cervera 1993) state that the frequency is reduced among persons at late midlife but Ward and Pollison found no difference. The same three articles contained comments on the frequency of Sjögren's-like manifestations, and found them to be increased among those with onset at late midlife. Madison and Dimant found the frequency of photosensitivity to be increased, but Cervera found it to be decreased, and Ward and Polisson found no difference. The two studies which commented on neurological manifestations (Dimant *et al*. 1979; Ward and Polisson 1989) both found them to be decreased in frequency in late midlife.

With regard to serological manifestations of later-onset systemic lupus erythematosus, Maddisons' findings will serve as an example (Table 7). However, in Ward and Polisson's meta analysis, anti-Ro antibodies were encountered in only 16 per cent of later onset patients; anti-La in 6 per cent. Anti-nRNP and anti-Sm were present in 5 per cent each. There is general agreement that further studies are needed to document these clinical and serological differences, and these should be based on defined populations rather than referred cases and include more data on patients age 70 years and older. To date, most authors agree that the differences between early and late-onset systemic lupus erythematosus are more likely to represent progressive age-related changes rather than two distinct syndromes.

Serological feature	Patients (%)	
	Late onset (*n*=19)	Younger onset (*n*=93)
Antinuclear antibody	95	95
Anti-DNA	53	65
Anti-Ro (SSA)	84	29 $p<0.0001$
Anti-La (SSB)	63	9 $p<0.0001$
Anti-nRNP	0	37 $p<0.001$
Anti-Sm	0	6
Rheumatoid factor	63	40
Hypocomplementaemia	53	57

Reproduced (with slight modification) from Maddison (1987), with permission.

Table 7 Serological features of systemic lupus erythematosus with onset in youth and midlife as compared with elder-onset disease (61–89 years)

From the clinical point of view, the occasional presence of systemic lupus erythematosus in patients age 70 years and older assumes importance for two reasons. Firstly, the condition does occur and deserves to be correctly diagnosed and appropriately treated. Secondly, for every old patient one sees who actually has systemic lupus erythematosus, there will be many who are referred by primary care physicians for the possibility of this disorder. The explanation lies in the frequent occurrence of rash, alopecia, chronic renal disease, polyarthritis, epilepsy, and neuropsychiatric disorders suggestive of a clinical diagnosis of systemic lupus erythematosus but due, instead, to a combination of four or five independent chronic diseases. The problem is confounded by the fact that a considerable number of older persons, without any known immunological disorder, will exhibit a positive antinuclear antibody test (Hallgren *et al*. 1973). Obviously, to present to a person with an over-supply of chronic diseases of this sort the added burden of corticosteroid or immunosuppressive therapy, in the mistaken impression that he or she is suffering from systemic lupus erythematosus, is a serious abrogation of the Hippocratic oath to do no harm.

Little objective information has as yet been obtained concerning treatment of persons with older-onset systemic lupus erythematosus. Initial treatment with high doses of prednisone is clearly indicated, with tapering in accordance with clinical manifestations. Recent information on the effectiveness of the bisphosphonates in inhibiting the osteopenic effect of long-term prednisone therapy provides an important new arena of preventive care in these patients. Although one prefers not to use cytotoxic drugs in this age group, the adverse prognosis of many patients with older-onset systemic lupus erythematosus must be kept in mind (Reveille *et al*. 1990). In this study, there was no relationship between the dosage of prednisone at last hospitalization or the 'frequency of recent immunosuppressive therapy' and death due to infection.

Information for patients and the families of patients suffering from lupus erythematosus is provided in *Lupus news*, published by the Lupus Foundation of America, Inc., 4 Research Place, Suite 180, Rockville, MD 20850–3226, telephone (301) 670–9292.

Drug-induced lupus

In contrast to systemic lupus erythematosus, this syndrome occurs with increased frequency in patients in the older age group due, at least in part, to the large number of drugs many of these patients consume (Solenger 1988). Procainamide or hydralazine therapy result in the development of antinuclear antibodies in 50 to 70 per cent of cases, but only about 30 per cent of Caucasians who exhibit these antibodies develop symptoms. The syndrome is very rare among blacks. The time of appearance of the symptoms after commencing procainamide therapy depends, at least to some degree, on the genetically controlled activity of the *N*-acetotransferase system in the liver (Woodley *et al*. 1978). Patients with reduced activity of this enzyme (slow acetylators) have a higher frequency of drug induced lupus than rapid acetylators, and develop the clinical manifestations after a shorter period of drug therapy (an average of 12 months as compared to 48 months). Clinical characteristics of drug-induced lupus include symmetrical polyarticular arthritis, often accompanied by striking morning stiffness, pleuritis, pericarditis, and, in some, parenchymal involvement of the lung. Thus, the manifestations resemble those of older-onset systemic lupus erythematosus. Rash, alopecia, and renal involvement are rarely seen. Although patients may exhibit haemolytic anaemia, thrombocytopenia and leucopenia are rarely encountered. Most patients with procainamide induced lupus are males; the majority of those with hydralazine induced lupus are females. Essentially all patients with this syndrome will exhibit positive antinuclear antibody reactions with titres of 1:640 or higher. Antibodies to n-DNA, RNP, Sm, Ro, and La are rarely seen. If the clinical manifestations do not subside within 2 months of discontinuing the offending drug, one must consider the possibility that the drug has proved to be an inciting agent for the development of systemic lupus erythematosus.

Sjögren's syndrome

Sicca symptoms occur in approximately 40 per cent of patients age 65 years and older, with increased frequency as the patient moves towards the older years (Strickland *et al*. 1987). In most cases this is due to age-related atrophy of the salivary glands or as a result of medications that have anticholinergic properties. Many of these patients will have a positive Schirmer's test. Sjögren's syndrome differs from sicca syndrome in the aged in that the dryness of eyes and mouth is accompanied by any of a wide variety of systemic manifestations, such as hoarseness, difficulty in swallowing, pneumonitis, interstitial lung disease, achlorhydria, nephritis, peripheral neuropathy, and a variety of psychiatric disorders—see Chapter 5.10. In view of the propensity of older people to suffer from several chronic diseases, it is easy for a physician to overlook the possibility that these manifestations might be due to a single syndrome. Thus, the disease undoubtedly occurs more frequently than is recognized. The presence of the disorder can be substantiated by a lip biopsy and demonstration of focal lymphocytic infiltration in the minor salivary glands. A positive test for anti-Ro(SSA) antibodies, present in 57 per cent of cases, provides added confirmation.

Although patients with this disorder have an increased likelihood for the development of lymphoma, and also renal involvement, most patients show good survival rates but face highly troublesome symptoms. In the United States, the Sjögren's Syndrome Foundation provides extremely effective support services, including a monthly publication, *The moisture seekers*, circulation of information materials through the internet, national and regional symposia, and a support network for patients and families. This is a disorder in which a positive attitude and attention to detail on the part of the patient can make a big difference to the patient's overall effectiveness, happiness, and independence. The foundation can be reached at 333 North Broadway, Hericho, New York, telephone (516) 933–6365, fax (516) 933–6368.

Systemic sclerosis

Systemic sclerosis (scleroderma) is a relatively uncommon rheumatic disease with onset occurring primarily at midlife. Of 63 patients with either diffuse or limited disease, described by Maddison *et al*., 55 had their onset between ages 20 and 60 years; only one developed the disease after age 60 (Maddison *et al*. 1993). However, since the patients usually live for a number of years, with the mean duration of disease for the CREST syndrome in one series (Aeschlimann *et al*. 1989) of 26 years, one should expect to see a number of patients with this disorder in a rheumatological practice with older patients.

When systemic sclerosis occurs in old persons, the close resemblance of its manifestations, especially changes in facial expression, to those of normal ageing is such that the diagnosis is easily overlooked (Holti and Schuster 1981). Obtaining an antinuclear antibody test in persons suspected of having this disorder will almost always lead to the diagnosis, since this test is positive in essentially all patients. The antitopoisomerase antibody (anti-Scl-70), present in between 20 and 40 per cent of the patients, will provide added confirmation, if present. The diagnosis is confirmed by skin biopsy. For further details concerning scleroderma and its treatment, the reader is referred to Chapter 5.8.1 of this book.

Soft tissue rheumatism

Articular structures themselves represent only one component of the musculoskeletal system. In older patients, disorders of the periarticular tissues (capsule, tendinous insertions, and bursas) and other tissues remote from the joints, such as muscle and fascial sheaths, probably account for a larger share of musculoskeletal symptoms than the classic articular diseases. Age-related decreases in muscle function and atrophy of tendons and muscle contribute, substantially, to the frequency of these disorders. The range of disorders includes acute and chronic tendinitis, bursitis (at numerous sites), enthesitis (inflammation of the tendinous insertions into the bony periosteum), muscle tears and strains, fasciitis, and involvement of paraspinal tissues secondary to chronic strain from poor posture and/or spondylolisthesis. Even intervertebral disc disease might be included in this list since the intervertebral disc, in life, is not a solid or semisolid structure but is a soft

sack, filled with a liquid gel, within which floats a firmer structure or nucleus.

While these periarticular disorders are frequently accompanied by decreased function of the adjacent joint, and are referred to by patient as 'arthritis,' they can be distinguished from involvement of the joint itself by careful history and physical examination, and, in most instances, will respond well to appropriate treatment.

Characteristically, the pain from periarticular involvement does not occur at rest but is exacerbated by motion of the adjacent joint, especially if it is resisted. Pain due to involvement of periarticular tissues of the shoulder is often exacerbated when the patient lies on the affected shoulder, thus interfering with sleep. In many instances, the pain due to these soft tissue lesions is perceived not in the specific area of involvement but in a more diffuse area, distal to the joint. This so-called referred pain is due to shared innervation of many connective tissues with specific areas of the skin.

The physical examination is important. For example for involvement of the shoulder region, one first seeks to identify, by careful palpation, diffuse swelling and tenderness of the synovial tissues. The presence of articular involvement is further confirmed by demonstration of decreased range of motion. This is best elicited by placing one hand firmly on the clavicle, trapezius, and scapula and, with the other hand, assessing the extent of abduction and internal and external rotation of the shoulder joint. In a normal individual, each of these motions should be approximately 80 to 90 per cent.

In patients who exhibit a full range of motion and the absence of diffuse synovial thickening one can be virtually certain that the symptoms arise from the periarticular tissues. Careful palpation of each area, seeking localized tenderness, will usually permit identification of the specific problem. Confirmation of bicipital tendinitis can be confirmed by eliciting pain over the tendon while the patient attempts to externally rotate the arm against resistance.

Treatment consists of rest, local application of heat or ice (whichever proves more effective), careful use of non-steroidal anti-inflammatory drugs and, if necessary, local injection of the bursa or tendon sheaths. It is our practice to infuse 20 mg of methylprednisolone acetate (Depo-Medrol) plus 2 ml of 1 per cent lidocaine, through a 21 gauge needle. Guidance for techniques which will help ensure that the material is injection within the bursa or tendon sheaths, rather than within the tendon itself, periosteum, or non-specifically in surrounding connective tissues, is provided in the references (Botstein 1990; Dorman and Ravin 1991; Neustadt 1991; Doherty *et al*. 1992).

In the management of patients with involvement of the periarticular structures surrounding the shoulder, attention should also be given to instructing the patient in pendulum exercises with, perhaps, a 1 kg weight held in the hand, for 5 to 10 min each day, in order to avoid the superimposed problem of a frozen shoulder. Guidance in the management of periarticular tissues in the elbow, wrist, hip, knee, neck, and back and additional information relevant to the shoulder is provided in the references cited above.

The topic of fibromyalgia, also covered in Chapter 5.14, is of special interest and importance. Although many rheumatologists remain unconvinced of the importance or even existence of this syndrome, others encounter patients meeting the criteria for this disease in a growing proportion of their practice. Many aspects of this syndrome overlap with another frequent and puzzling disorder, chronic fatigue syndrome (Buchwald and Garrity 1994). A new and promising approach to the treatment of latter disorder (Boh-Holaigah *et al*. 1995) may provide a new approach to the issue of fibromyalgia as well. Information for patients with fibromyalgia is provided in the *Fibromyalgia network newsletter*, obtainable form the Fibromyalgia Network, PO Box 31750, Tucson, AZ 85751, telephone (602) 290–5508.

Summary

Musculoskeletal symptoms provide the most common cause of morbidity among patients age 65 years and older (National Center for Health Statistics 1986). This fact, plus the increasing size of this population, renders an understanding of the biology of ageing and the unique characteristics of care for older persons of increasing relevance to the practice of rheumatology. This chapter has attempted to outline the major elements of the 'geriatric perspective', and discussed the application of these principles to several rheumatic diseases of special importance among older patients.

1.1.4 Principles of examination

Elisabeth Paice

General principles

The examination of the musculoskeletal system can be considered under two headings: (i) the systematic screening of virtually all the accessible joints of the body to identify abnormalities and establish their distribution; (ii) the more detailed analysis of an abnormal joint or group of joints. The screening is intended to be brief but comprehensive and efficient. It can be accomplished in a few minutes and should be part of the routine examination taught to all medical students.

The patient is best examined lying comfortably on a couch or bed for most of the examination, but sitting up for the shoulders and neck, and standing for the final stages of examining the feet and the movements of the back. Walking should be observed, either at the start in the outpatient clinic or at the end of the examination if the patient is already undressed and in bed. In a very young child, much of the examination can be carried out while he or she sits on the parent's lap.

The examination starts most logically with the hands, the calling cards of many of the rheumatic diseases, then moves up the arms to the joints of the shoulder girdle and the jaw, down the spine from the neck to the coccyx and on to the legs, finishing with the toes.

The same basic pattern governs the examination of the most of the joints: inspection, palpation, and establishing the range of movement. This pattern is altered for some parts, for example the back, in the interests of efficiency.

Inspection (Table 1)

Colour
Skin or other local changes
Muscle wasting
Swelling
Deformity

Table 1 Inspection of joints

Where a joint is paired, both should be exposed to allow comparison of the two sides. Redness overlying a joint is an important indicator of acute inflammation, as in gout or septic arthritis. Any skin rash, subcutaneous nodules, cysts, scars, or evidence of local infection are noted. Muscle wasting is often associated with joint disease, but may be masked by joint swelling. Swelling or deformity should be sought. Discrepancies in limb or digit length may indicate growth problems secondary to inflammation, as in juvenile chronic arthritis.

Palpation (Table 2)

Temperature
Tenderness
Swelling:
Bone
Soft tissue
Fluid
Crepitus

Table 2 Palpation of joints

Temperature change is assessed relative to the same joint on the other side, or to surrounding normal skin. The back of the hand is rapidly moved between the areas to be compared. Errors may occur if one side has been kept warmer by a bandage, glove, or splint.

Tenderness is elicited with firm pressure along the joint margins, and over tendons and ligaments. This should be carried out with the examiner's eyes on those of the patient, rather than on the joint, so as to pick up the first signs of discomfort.

Swelling noted on inspection is palpated, to answer the question: 'Is this swelling bone, soft tissue, or fluid?' Bony swelling is especially a feature of osteoarthritis. Other causes are new bone formation with psoriatic arthritis, Charcot's joints, and callus formation after a fracture. Soft tissue swelling about a joint is most often synovial. The consistency of synovial swelling is more doughy than bouncy, like foam rubber. Where synovial fluid and synovial swelling coexist, the fluid can be pushed away or aspirated, allowing the synovium to be palpated. Fluid is recognizable for its incompressibility. Palpating a lax effusion is easy, because the fluid can be milked from one part of the joint to another. A tense effusion can be recognized by its 'bouncy' quality, like a firm rubber ball.

Joint noises are frequently better felt than heard. Loud cracks and snaps, particularly on pulling the fingers or rotating the ankles, may be quite normal. Pulling the fingers creates a vacuum and the popping sound represents the sudden development of a gas cavity in the joint fluid. The snap on rotating an ankle is related to the slipping of one tendon over another. Similar harmless snapping and crunching noises occur when the head is extended and rotated from side to side, or the shoulders are braced back and rotated.

Velvet crepitations are too soft to be audible, but may be felt. They occur when the joint contains small particles of proteinaceous material, most typically in rheumatoid arthritis. Crepitus in the joint of a patient with osteoarthritis feels like a dull, coarse crunching, and is caused by irregularities in the cartilage.

Eburnation crepitus is both heard and felt, occurring when the cartilage has been destroyed and the two bony surfaces are in contact. The name means 'turning to ivory' and the sound is thought to be similar to that of ivory grinding on ivory. Most often it emanates from the hip or the knee, and then care is needed to work out which is the affected joint as the vibrations are well transmitted up or down the femur. To demonstrate eburnation crepitus the examiner lays a hand on the joint and asks the patient to move it. Passive movement may fail to elicit the sign because the joint surfaces are not so closely opposed when the muscles are relaxed.

Range of movement

The patient is usually first asked to move the joint actively. If a full range of active movement can be carried out without discomfort, there is rarely any need to proceed to passive movement. If the patient is unable to carry out the full range of active movement, then the passive movements will be most informative. In general, where active and passive restriction are the same, limitation of movement will reflect one of the following: inflammation of a joint; contracture of the tendons or ligaments surrounding the joint; destruction of bone or cartilage in the joint. Restriction of active but not passive movement indicates rupture or inflammation of a tendon, muscle weakness, or failure of the nerve supply to the muscle.

The 'normal' range of movement must be interpreted with caution. There is much variation in joint mobility with age and race, and from individual to individual. The figures commonly given are those considered to be at the lower end of the usual range. An excessive range of movement in otherwise normal joints is referred to as the hypermobility syndrome. An excessive range in diseased joints reflects damage to the articular surfaces or the capsule and ligaments, leading to instability.

Recording measurements

In order to keep accurate records of a patient's progress, especially in the context of a clinical trial, reproducible measurements are needed. The following have proved reliable for serial observations by the same examiner, although significant interobserver variation occurs.

Ritchie index

This is a method of recording activity in rheumatoid arthritis by means of grading the tenderness to firm pressure or pain on movement in a standard selection of joints.

Ring size

This is useful for recording the degree of swelling in the proximal interphalangeal joints. The smallest size that will slip easily over the joint is recorded.

Goniometer

For accurate measurement of angles of movement or degrees of deformity a goniometer is necessary. It is useful to have a long-limbed one for large joints and a smaller one for joints of hands and feet. The limbs of the goniometer should be lined up along the long axis of the joint, the hinge on the joint line, and the maximum angles of flexion and extension recorded. The position of the joint in the extended anatomical position is taken as zero, and further extension is recorded as a minus value. A spirit-level inclinometer is also available for measuring angles of spinal movement.

Grip strength

A special sphygmomanometer with its own manometer is most convenient, though a small cuff attached to a standard mercury manometer is also satisfactory. The cuff is inflated to 30 mmHg and the patient squeezes it with one hand. The maximum reading achieved in three attempts is recorded.

The systematic survey

The whole patient (Table 3)

Dress: unkempt or neat

Shoes: high fashion or slippers

Getting out of chair: use of arms, help

Walking aids: stick, frame

First steps: gelling phenomenon

Gait: antalgic, waddling

Posture: erect, kyphotic, hangdog

Undressing: trouble with buttons, jacket

Table 3 Observing the whole patient

Rheumatic diseases are often multisystem in their effects, and many systemic diseases will present with rheumatic complaints. The discussion of the examination of the other systems in the body is outside the scope of this chapter, but it should be remembered that the examination of the musculoskeletal system is only one aspect of the careful and comprehensive history-taking and general physical examination that makes up the assessment of the patient with rheumatic symptoms.

Posture and gait

It is instructive to observe how the patient gets off a chair and starts moving after a period of inactivity. Gelling, or stiffness after inactivity, is a common feature of many arthritic conditions. Posture may give a clue to disorders of the back, and gait to problems in the lower limbs. Watching the patient undress is a valuable opportunity for observing whether there are difficulties. In a paediatric setting, quiet observation of the child at play can be extremely valuable in discovering whether a limb is being protected.

The hands

Screening

Inspect the hands, back and front. Palpate each of the finger joints in turn, one hand at a time, moving from the distal row proximally, including the thumbs, checking for tenderness or swelling. Ask the patient to make the hands into fists and straighten them out again. Offer the patient two fingers to grip each side and assess grip strength.

Table 4 Inspecting the hands

Nails

The nails may show the pitting or lifting from the nail bed (onycholysis) typical of psoriasis, nail-fold infarcts typical of vasculitis, or the shaggy cuticles and periungual erythema of dermatomyositis. Dilated capillary loops in the nail fold can be seen with the naked eye, though more easily with a magnifying glass, and tend to accompany certain rheumatic diseases, for example systemic sclerosis and dermatomyositis.

Skin

A rash on the backs of the hands may be due to psoriasis or to dermatomyositis, best distinguished from each other by the distribution. Dermatomyositis tends to affect the extensor surfaces of the joints in a neat and symmetrical fashion while psoriasis is more likely to be distributed at random across the hand. Palmar erythema is common in patients with connective tissue diseases, and is frequently different in nature from the palmar erythema of pregnancy or liver disease, looking more mottled and indeed more like palmar livedo reticularis than erythema. This appearance seems to be associated with systemic vasculitis.

Muscle wasting

This is common whenever joints are inflamed, but attention should be paid to any significant patterns of muscle wasting, such as the wasting of the thenar eminence in carpal tunnel syndrome, which spares only the adductor pollicis, visible as a band parallel to the wrist. Wasting of opponens pollicis commonly accompanies osteoarthritis of the first carpometacarpal joint.

Tendon involvement

Tenosynovitis of the flexor tendons may be seen as a fullness in the palm. It may be differentiated from Dupuytren's contracture by the absence of skin tethering over the surface, and the presence of crepitus on flexing the fingers. To detect crepitus of the flexor tendon the examiner places the index and middle fingers over the course of the tendon, with the thumb on the back of the hand exerting firm pressure. The patient is then asked to make a fist, and crepitus or nodularity may be felt as the tendon moves within its sheath. The procedure is repeated for each of the flexor tendons in turn.

Trigger finger occurs when the finger locks in flexion, but can be passively (albeit painfully) straightened. This is caused by a nodule on the tendon passing through a stricture in the tendon sheath. The weaker extensor muscles are unable to pull the nodule back through the same obstruction. The nodule is usually to be found in the palm just proximal to the metacarpal head, but will only be detected during active movement of the affected digit. Tendon involvement may also be recognized in the fingers by pinching the thickened soft tissues at the palmar surface of the base of each finger.

Swelling

The hands may look generally puffy with no localization of this over joints. This is especially common in mixed connective tissue disease or early systemic sclerosis, where the hands may resemble a bunch of sausages, and also occurs with systemic lupus erythematosus, dermatomyositis, polymyalgia rheumatica, reflex sympathetic dystrophy, and with early rheumatoid arthritis.

Where only one or two fingers have a diffuse, cylindrical swelling, not centred on a joint, we speak of a 'sausage' digit. These may represent swelling of the flexor tendon, as in the seronegative spondylarthropathies, diffuse soft tissue inflammation as in gout, or infection as in leprosy or tuberculosis.

Synovial swelling in the proximal interphalangeal joints is sometimes called spindling because of the fusiform appearance. Osteoarthritis causes a swelling of these joints that is bony and irregular, occasionally with effusions.

Distribution

The distribution of joint swelling gives an immediate clue to the diagnosis. Swelling predominantly of the terminal (distal) interphalangeal joints indicates osteoarthritis, psoriatic arthritis, or occasionally gout. Osteoarthritis also predominantly affects the first carpometacarpal joint, an articulation spared by most other arthropathies. The joint looks to be squared, because of osteophyte formation, wasting of the surrounding muscles, and adduction of the thumb. Rheumatoid arthritis has a predilection for the second and third metacarpophalangeal joints, as well as the proximal interphalangeal joints.

Deformities

Note deformities such as swan neck, boutonnière, ulnar drift, and Z thumbs. Palmar subluxation of the metacarpophalangeal joints is often mistaken for synovial swelling, but the exposed metacarpal heads are rounded and bony on palpation. Palmar subluxation is easily confirmed by running a finger along the back of the patient's hand and fingers to assess whether the phalanges are on the same plane as the metacarpals. Wherever deformities are found, assess whether they are

reversible, either actively or passively.

Range of movement

The patient should be able to make a fist, burying the fingertips in the palm, a movement that requires 90° of flexion in each of the three phalangeal joints. Hypermobility is indicated by more than 90° extension in the metacarpophalangeal joints and ability to approximate thumb to forearm, passively.

The wrist

Screening

Inspect both wrists, front and back, and palpate the joint line for tenderness or swelling. Ask the patient to press both palms together and bring the elbows out at right angles in the 'prayer position'. Then reverse the position with the backs of the hands together to demonstrate palmar flexion (Fig. 1, Fig. 2). If the hands, wrists, or elbows are deformed, this test cannot be carried out. In this case, assess the range of active and passive movement at each wrist in turn.

Fig. 1 The 'prayer position', demonstrating wrist dorsiflexion. (photography inthis andoither Figures in this chapter by courtesy of Eric Leung, The Photography and Illustration Centre, University College London.)

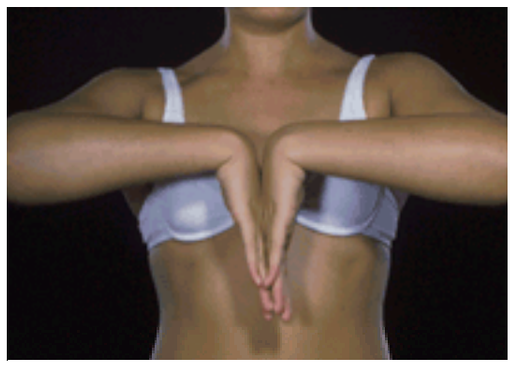

Fig. 2 The reversed 'prayer position', demonstrating wrist palmar flexion

Swelling

In rheumatoid arthritis, exuberant soft tissue swelling may be seen, originating either from the wrist joint itself or from the synovial tendon sheaths, and spreading both sides of the extensor pollucis retinaculum. An undulating swelling of the ulnar border of the wrist is a particular feature of rheumatoid arthritis. The undulations are the result of synovial swelling pushing its way through the fibres of the extensor retinaculum. This appearance is sometimes called the caput ulnae, and is associated with an increased risk of rupture of the fourth and fifth extensor pollucis tendons. Synovial proliferation is less often visible on the palmar aspect of the joint, although sometimes a visible fullness extends under the flexor retinaculum and into the palm.

Swelling of the wrist joint is associated with compression of the median nerve in the carpal tunnel. Particular attention should be paid to looking for evidence of this complication.

Inflammation of the abductor pollicis longus tendon at the wrist (de Quervain's tenosynovitis) is best diagnosed by inspecting the wrists from the radial side, with the palms together and any watches or bracelets removed. Unilateral swelling may then easily be seen, extending from the first carpometacarpal joint proximally. The diagnosis can be confirmed using Finkelstein's test. In this the patient is asked to bring the thumb across the palm and clasp the fingers around it. The examiner holds the clenched fist and tweaks it sharply in an ulnar direction, putting a sudden but not excessive pull on the inflamed tendon. This elicits a sharp pain, and should be done with care, watching the patient's face for signs of discomfort.

Repetitive strain injuries often affect the muscles of the wrist, giving a diffuse swelling of the muscles of the forearm, with crepitus on moving the fingers.

Deformity

Deformity of the wrist joint usually takes the form of palmar subluxation, owing to the stronger pull of the flexor than the extensor muscles of the forearm. Prominence of the lower end of the ulna is also common, because synovial proliferation at the inferior radioulnar joint weakens the ligaments and allows the bone to ride up in a deformity that may be either fixed or mobile. When the bone is mobile it is often painful, giving rise to the 'piano-key' sign, whereby pressure on the bone leads to the production of an audible protest from the patient.

Range of movement

The 'prayer position' normally allows 90° of passive palmar and dorsiflexion. The active range is 20° less in each direction.

The elbow

Screening

Ask the patient to fold the arms across the chest. Compare the elbow joints in this position. Inspect the extensor surface of each. Ask the patient to extend and flex the elbows, then with the elbows flexed and held against the sides, to show in turn the palms and the backs of the hands.

Inspection

Inspecting the elbows is a fruitful source of clues to the diagnosis in many rheumatic diseases. Rheumatoid nodules, gouty tophi, tendon xanthomata, olecranon bursitis, and the rash of psoriasis or of dermatomyositis may all be detected by a glance at the extensor surface of the elbow, just distal to the olecranon. The joints

are most easily compared with the elbows flexed and the arms folded.

Palpation

Palpation for synovial proliferation or joint effusion is best done in the groove between the lateral epicondyle and the olecranon process. The radioulnar joints are frequently involved in rheumatoid arthritis, leading to loss of pronation and supination. The examiner places one thumb on the radial head and the other on the inferior radioulnar joint at the wrist, then passively pronates and supinates the patient's forearm, feeling for crepitus in one or both joints.

Tenderness of the lateral or medial epicondyles and the muscles inserting into them is found in 'tennis' or 'golfer's elbow', respectively. To confirm, the patient is asked to clench the fist and to extend or flex the wrist against resistance. These manoeuvres should cause pain at the affected muscle insertion.

Range of movement

Flexion is usually limited by the interposition of soft tissues, and should be about 150°. Extension beyond –10° implies hypermobility. Pronation and supination take place at the superior and inferior radioulnar joints and must be done with the elbows flexed to exclude movement at the shoulder joint. The hands can normally be fully supinated and pronated.

The shoulder girdle

The three shoulder-girdle joints are best considered together, as all three work together in movements of the shoulder, and pain from all three is felt around the shoulder and upper arm. Acromioclavicular pain is usually felt at the tip of the shoulder. Pain in the sternoclavicular and glenohumeral joints is most often felt over the deltoid muscle and midhumerus. The manubriosternal joint is often swollen and sometimes painful in rheumatoid arthritis and in seronegative spondylarthritis.

Screening

Inspect the shoulder girdles both from the front and the back. Palpate the sternoclavicular and acromioclavicular joints for tenderness or swelling, then the glenohumeral joints starting from the anterior joint line, across the subacromial bursa, and on to the posterior joint line. Ask the patient to raise the arms sideways above the head, clasp the hands behind the neck with elbows well back, then clasp them behind the back as far up as possible (Fig. 3, Fig. 4).

Fig. 3 Clasping the hands behind the neck to demonstrate external rotation.

Fig. 4 Raising the hands as high as possible behind the back. The opposite scapula can just be reached.

A common source of error lies in what seems to be the attraction of symmetry. The patient with one stiff shoulder will often respond to a request to raise both arms by lifting both to the limit of the range of the abnormal shoulder, thereby giving the impression that both are stiff. It is worth encouraging the patient to make sure that the maximum range of each joint is being demonstrated.

The sternoclavicular joint

The sternoclavicular joint is often neglected, despite the fact that it is frequently affected in a variety of arthropathies, including polymyalgia rheumatica, rheumatoid arthritis, the seronegative spondylarthropathies, and septic arthritis. Pain is rarely localized to the joint, even when there is obvious swelling and redness, but is referred to the upper arm. Palpation should include the inner end of the clavicle and the articular surface of the manubrium, directly below it. Pain can best be elicited by asking the patient to brace the shoulders forward and back, or to shrug the shoulders up and down, movements which do not involve the glenohumeral joint. If these movements are painful but external rotation of the shoulder is not, there is strong evidence of sternoclavicular disease.

The acromioclavicular joint

The acromioclavicular joint is near the surface and can easily be seen and palpated if swollen. Passive adduction of the arm across the chest will often cause pain if the joint is inflamed. There may be a painful arc on abduction above 90°.

The shoulder (glenohumeral) joint

Inspection

Wasting of muscles should be noted both from the front and the back.

Swelling of the shoulder joint is not always obvious. A shoulder effusion in a patient with rheumatoid arthritis may give that shoulder a more normal-looking contour. Rupture of the shoulder capsule may lead to fluid tracking down to the upper arm.

A dislocated shoulder may appear square and dropped, while in rheumatoid arthritis the shoulders appear both square and raised, owing to upward subluxation of the

humeral heads as a result of dysfunction of the rotator cuff and muscle contracture.

Palpation

A shoulder effusion is best felt by placing the thumb in front and the fingers behind the joint and fluctuating the fluid back and forth across the shoulder. Tenderness may be elicited over the whole line of the joint in capsulitis or inflammatory arthritis, or may be localized where there is an isolated lesion of the tendon. Inflammation of the long head of biceps gives tenderness in the bicipital groove anteriorly, while supraspinatus tendinitis causes tenderness in the subacromial bursa.

Rupture of the long head of biceps is best appreciated by asking the patient to contract the muscle against resistance. The affected muscle will form a ball (the 'Popeye sign').

Movements of the shoulder girdle

Although individual arcs of movement may be attributed to each of the three joints of the shoulder girdle, in practice they work smoothly together when the arm is raised. The sternoclavicular joint is the single point of bony connection between the arm and the trunk, and allows considerable movement of the clavicle, which in turn acts as a strut to add freedom of movement to the arm. The acromioclavicular joint has less movement, but allows for rotation of the scapula on the thorax.

Pure glenohumeral movement can be isolated from movement of the scapula across the thorax by fixing the inferior angle of the scapula with one hand and passively abducting the arm with the other (Fig. 5). Normally the scapula starts to move at 30° of abduction, but if it is fixed at least 90° of glenohumeral movement is possible. Passive external rotation is another reliable measure of pure glenohumeral movement. The last few degrees of abduction may be lost in patients with a painful neck lesion.

Fig. 5 Fixing the inferior angle of the scapula, while passively abducting the arm, to demonstrate true glenohumeral movement.

Passive movements should always be checked if the active range is incomplete. Loss of active and passive range in equal measure suggests intracapsular disease such as arthritis or adhesive capsulitis ('frozen shoulder'). Loss of active more than passive movement, accompanied by pain, suggests a lesion of tendon or rotator cuff. Limitation or weakness of active movement with a full and pain-free passive range suggests muscular or neurological disease.

The painful arc

During abduction of the arm, pain may be experienced in an arc, above or below which movement is pain free. The most common cause is supra spinatus tendinitis. In this condition pain occurs somewhere in the arc from 60 to 100° as the greater tuberosity impinges on the acromion, pinching the supraspinatus tendon. The pain may be severe enough to prevent abduction. The patient is often able to elevate the arm fully by forward flexion, but if asked to take it down sideways, will complain of pain as the upper limit of the painful arc is reached. A painful arc above 90° occurs in acromioclavicular disease.

Resisted movements

Specific tendon lesions can be identified by using resisted movements to elicit pain. Pain on resisted abduction suggests a supraspinatus lesion. Pain on resisted external rotation suggests an infraspinatus lesion. Pain on resisted internal rotation suggests a subscapularis lesion (Fig. 6).

Fig. 6 Testing resisted internal rotation of the shoulder.

Range of movement

Movement at the shoulder comprises forward flexion to 180°, abduction to 180°, extension to 45°, and rotation to 70° internally and externally. Movement at the sternoclavicular joint includes protraction and retraction of the clavicle in an arc of 60°, and elevation of the clavicle to 60°.

The temporomandibular joint

Screening

Palpate the joints for tenderness or swelling and ask the patient to open the mouth wide.

These joints are most frequently involved in rheumatoid arthritis but other inflammatory arthropathies may also affect them. The complaint is of pain on chewing or yawning and sometimes of pain in the ear. The joints rarely look abnormal, but there is local tenderness and pain on opening the jaws. Normally it is possible for the fully open jaws to accommodate the middle three digits of the patient's hand, held vertically between the teeth. Restricted mouth opening from disease of the temporomandibular joints, may be differentiated from that caused by scleroderma by inspecting the lips, which will be drawn tight in scleroderma.

Micrognathia occurs as a result of temporomandibular joint inflammation in childhood, as in juvenile chronic arthritis (juvenile rheumatoid arthritis). Premature closure

of the epiphysis leads to failure of normal development of the mandible.

The cervical spine

Screening

Inspect posture: palpate the spinous processes for tenderness and alteration of the normal curve; ask the patient to flex, extend, rotate, and laterally flex the neck to left and right. It is important to remember that the detailed examination of the neck should not be considered complete until a neurological assessment has also been made.

Inspection

Neck posture may indicate underlying disease. A poking chin with dorsal kyphosis often accompanies cervical spondylosis. Acute torticollis can be recognized as the patient enters the room, one sternocleidomastoid muscle in spasm and the head tilted to the side and slightly rotated. The patient with rheumatoid arthritis will often have lost neck height and there may be a lateral asymmetry if there has been softening and erosion of bone.

Palpation

Palpation of the neck should include the occipital ridge, the spinous processes, and the paravertebral muscles overlying the facet joints. The occipital ridge is frequently tender in cervical spondylosis, especially over the greater occipital nerve. The spinous processes normally form a lordotic arc, with C2 and C7 being prominent at either end of the curve. Loss of lordosis or even a reversed curve can be appreciated by palpation. Palpation of the paravertebral muscles may reveal spasm in any case of neck pain, but especially after a whiplash injury or in cases of headache and neck pain related to stress. Through the paravertebral muscles, the facet joints can be felt, and tenderness or swelling elicited. Each pair of facet joints should be palpated in turn.

Range of movement

The patient should be able to touch the chin to the chest, tip the head back until the forehead and nose are parallel to the ceiling, and rotate in each direction to 70°. Lateral flexion is normally 45° each side, and this movement is lost early in ankylosing spondylitis. Passive neck movements are not a part of the routine examination, as neck instability is a feature of the rheumatic diseases.

Lhermitte's sign is more correctly a symptom. The patient complains of paraesthesia down the body on flexing the neck. It is sometimes present in cases of compression of the cervical cord, especially in rheumatoid arthritis. The examiner should not attempt to elicit this sign by forcible neck flexion.

The thoracic spine

Screening

Inspect the thoracic spine for swellings or deformities; palpate the spinous processes in turn; assess chest expansion. It is important to remember that the detailed examination of the thoracic spine should not be considered complete until a neurological assessment, including all four limbs, has also been made.

Inspection

This will reveal postural abnormality such as kyphosis or scoliosis. Destruction or collapse of vertebrae may lead to a sharply angled kyphosis, or angular gibbus, most often seen in tuberculosis. Kyphosis in adolescents suggests Scheuermann's disease. Scoliosis may be developmental, in which case there is usually some rotation of the ribs, which can be exaggerated by asking the patient to bend forward so that the rotation is more easily appreciated. Scoliosis resulting from muscle spasm becomes less obvious on forward flexion.

Palpation

The spinous processes and paravertebral muscles are next palpated, especially for tenderness. Recent collapse of a vertebra, malignant deposits, or vertebral osteomyelitis all produce local or 'point' tenderness. If direct pressure over the spinous process is insufficient to elicit this, it is worth trying percussion, laying two fingers over each process in turn and striking these with the fist, gently at first, then more firmly if no discomfort is elicited. Tenderness of the upper thoracic vertebrae and the paravertebral muscles is a common feature of thoracic spondylosis.

Range of movement

Rotation is best assessed with the patient seated to fix the pelvis and is usually 45°. Flexion is most easily measured with a tape measure. Distraction on flexion between marks made at C7 and T12 is normally at least 2.5 cm. Costovertebral movement is measured by chest expansion at the level of the nipples, usually more than 7 cm.

The lumbar spine

Screening

Inspect the standing patient from behind; palpate for tenderness or muscle spasm; ask them to touch the toes, lean back, and bend from side to side. With four fingers along the lumbar spine, assess whether movement is taking place at the lumbar spine rather than the hips. It is important to remember that the detailed examination of the lumbar spine should not be considered complete until a neurological assessment of the lower limbs has been made. This may conveniently be done as an intrinsic part of the examination of the back, which takes place in three positions as indicated in Table 5 and below.

Table 5 Examination of the lumbar spine

Examination

The patient standing

The examiner inspects the back for abnormality of posture or deformity, such as scoliosis or kyphosis, then palpates the paravertebral muscles for evidence of spasm. Palpation for tenderness is best left until the patient is lying down.

The patient is then asked to carry out the movements outlined in Table 5. Forward flexion and extension are relatively more restricted in the patient with a mechanical back pain, while lateral flexion is the first to be lost in ankylosing spondylitis. Scheber's test is a useful method of measuring lumbar flexion, especially in ankylosing spondylitis. Using a tape measure, the examiner makes two marks, one 5 cm below the level of the sacroiliac dimples and one 10 cm above. The patient bends forward and the examiner measures the distance between the marks. Distraction of at least 5 cm is normal.

Asking the patient to take a few steps on the heels and toes is a crude but useful test of power in the legs and feet, and at the same time the buttocks can be inspected for any evidence of a Trendelenburg sign (dipping down of the pelvis when the ipsilateral foot is raised from the ground) suggesting muscle weakness.

The patient lying face up

Straight-leg raise (Lasègue's sign)
The patient lies supine while the examiner grasps one of the ankles and raises it from the couch, keeping the knee straight with a hand on the knee, and watching the patient's face for any sign of discomfort (Fig. 7). Normally 80 to 90° can be attained without discomfort, depending on the tightness of the hamstrings. Irritation of the dural sleeve of any of the nerve roots contributing to the sciatic nerve will result in pain when the sciatic nerve is put on the stretch, and a much reduced straight-leg raise on the affected side. The usual cause of this is a prolapsed lumbar disc protruding posterolaterally. Bilateral reduction in straight-leg raising implies a central disc prolapse. To distinguish between sciatic irritation and hip disease, the leg is raised with the knee flexed. This will now be painless in sciatic irritation, but just as uncomfortable in hip disease.

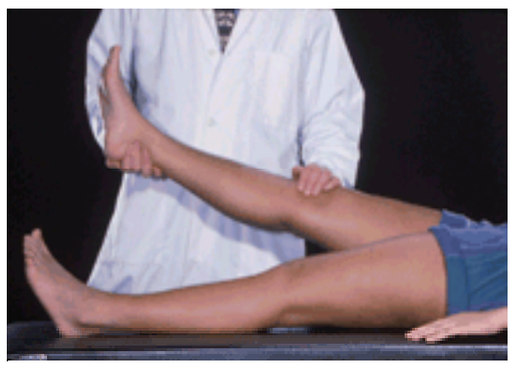

Fig. 7 The straight leg raise.

The sciatic stretch test may be useful in distinguishing sciatic irritation from tight hamstrings if the straight-leg raise is reduced. Once the limit of straight-leg raising is established, the leg is lowered a fraction until the pain is relieved. Now the examiner dorsiflexes the foot. If the pain was due to sciatic irritation, it returns.

After the straight-leg raise, the examiner tests the knee, ankle, and plantar reflexes. Testing power in each of the major muscle groups of the legs, especially the hip muscles, may cause difficulties if the patient is in pain. It may be necessary to reassess the patient after adequate control of the pain. Sensation to light touch and pinprick is next elicited, following a dermatomal pattern over the anterior aspects of both legs and the soles of the feet.

The patient lying face down

It is important to have the couch flat, with pillows removed to avoid painful hyperextension. A pillow under the patient's abdomen will usually increase comfort and render the examination easier. The examiner palpates each spinous process in turn, gently at first, then increasing the pressure by using one hand laid on the other. Then the examiner palpates for tenderness in the paravertebral muscles, the posterior iliac crests, and over the sacrum and coccyx. Coccygeal tenderness may also be felt by a rectal examination. Point tenderness is a feature of local infection or malignancy. More diffuse tenderness is common in patients with mechanical back pain.

The femoral stretch test is the parallel of the straight leg-raising test, putting the femoral nerve roots on the stretch. The examiner takes the prone patient's ankle in one hand, flexing the knee to 90°, and raising the bent leg to extend the hip (Fig. 8). Pain during this manoeuvre may indicate a lesion of a high lumbar disc or hip disease.

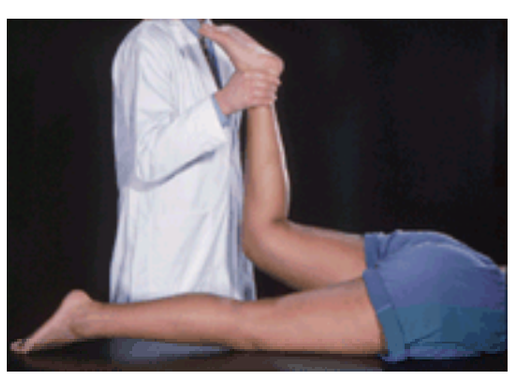

Fig. 8 The femoral stretch test.

Loss of sensation around the saddle area is an important clue to the presence of cauda equina lesions and should always be tested for. Buttock tone is assessed by asking the patient to pinch the cheeks of the buttocks together as hard as possible, and palpating the two sides. A rectal examination is helpful where there is any hint of a lesion of the cauda equina, to assess sphincter tone and sensation, in addition to its importance as part of the general assessment of the patient.

The sacroiliac joints

Screening

Inspect and palpate the joints from behind (Fig. 9), and stress them by pressure on the sacrum; roll the patient on one side and press again over the uppermost iliac crest.

Fig. 9 Palpating over the sacroiliac joint.

Inspection and palpation

Inspecting the joints from behind may reveal evidence of swelling or deformity, especially in tuberculous infection. Palpation is best done with the four fingers of the hand along the length of the joint. Nodules of tender fibrofatty tissue often overlie the joints, and are of no significance except that they are often found in patients with chronic back pain. Bony fusion of the joints in ankylosing spondylitis obliterates the joint line. The synovial portion of the joint lies too deep to be felt under normal circumstances.

Range of movement

Moving the sacroiliac joints is not easy, as there is only a small amount of rotational glide, but they may be stressed by a variety of manoeuvres. The simplest method is to press firmly on the sacrum while the patient lies on the front, then on the pelvic brim as he or she lies on the back and on the side (Fig. 10, Fig. 11). If the sacroiliac joints are inflamed, these manoeuvres may elicit pain. Instability of the sacroiliac joints, especially postpartum, may cause pain, which is aggravated when the patient is asked to stand on one leg. Sometimes the excessive movement can be appreciated by placing one finger on each side of the joint as the patient makes the manoeuvre.

Fig. 10 Stressing the sacroiliac joints from the back.

Fig. 11 Stressing the sacroiliac joints from the side.

The hip

Screening

Inspect leg length and position. Grasp the leg at knee and ankle, with the knee flexed; now flex the hip as far as it will go. Return the hip to 90° of flexion and test internal and external rotation using the foot as a pointer and the knee as a pivot (Fig. 12). Straighten the leg, grasp the opposite iliac crest and test abduction and adduction with the pelvis thus flexed (Fig. 13).

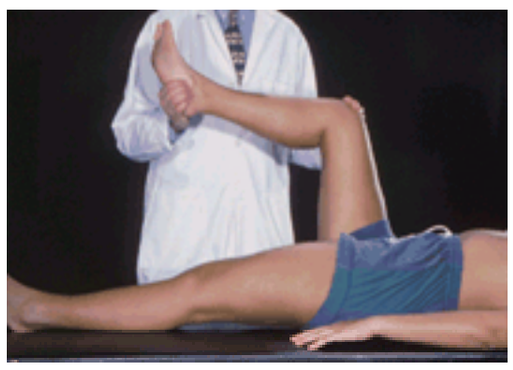

Fig. 12 Testing hip rotation using the foot as a pointer.

Fig. 13 Abducting the hip, with the pelvis fixed.

Inspection

The gait is particularly important in the assessment of the lower limb joints. The patient with a fixed flexion deformity of the hips throws the spine into an exaggerated lordosis to compensate. The patient with weak hip muscles walks with a waddle, and the one with a painful hip walks in such a way as to spend the least time possible on the painful leg, leaning to the opposite side, often with a walking-stick. This is called the antalgic gait.

Inspection of the hips should always include comparison of leg lengths and attention to the position of the leg. The leg that is short and externally rotated suggests a fractured neck of femur, or a legacy of juvenile chronic arthritis. Failure to observe the back of the hips may mean that the evidence of previous surgery is missed.

Palpation

Palpation of the hip is difficult because the joint is so deep, although occasionally an effusion can be detected by fluctuation just beneath the inguinal ligament. A psoas abscess may cause a very painful, stiff hip with spasm that cannot be overcome without anaesthesia. The psoas abscess will eventually point as a mass below the inguinal ligament. The greater trochanteric bursa lies over the greater trochanter and if it is inflamed, tenderness can easily be elicited with the patient lying on the unaffected side.

Range of movement

Flexion, 110°; extension, –30°; abduction, 50°; adduction, 30°; internal and external rotation, each 45°.

A fixed flexion deformity can be demonstrated with Thomas's test. The patient lies supine and one knee and hip are flexed until any lumbar lordosis has been obliterated. Flexion of the other hip during this manoeuvre indicates a fixed flexion deformity of that hip.

A catch for the inexperienced is the patient with a painful knee that is held in flexion. Attempts to straighten the knee in the bed are unsuccessful because of pain, and yet no other abnormality is seen in the knee. This patient probably has disease of the hip, with a fixed flexion deformity and pain referred to the knee. If the examiner were to straighten the knee while maintaining a flexed hip, a full range of movement would be found in most cases.

Rotation may also be tested in extension, by rolling the leg. Where both hips have a limited range of abduction, it is useful to record the maximum distance between the two medial malleoli. Extension of the hip is best measured with the patient lying on the side or prone.

The knee

Screening

Inspect for swelling, abnormal alignment, or quadriceps wasting. Palpate for tenderness, effusion, popliteal cyst. Flex and extend. Test ligament stability.

Inspection

Knee swellings can be recognized by fullness of the suprapatellar pouch and obliteration of the hollows either side of the patella. Quadriceps wasting may be masked by swelling of the knee and measurement of quadriceps bulk should be made above the upper limit of the supra patellar bursa. Deformities may be varus or valgus, forward or backward slip.

Palpation

P>Tenderness of the medial collateral ligaments occurs early in osteoarthritis, followed by the development of a tender bony ridge as osteophytes develop.

A knee effusion can be demonstrated in one of three ways, depending on the quantity of fluid present, as follows.

1. A small effusion can be milked from one side of the patella to the other in the 'bulge sign'. Any fluid in the medial side of the joint is swept firmly upward and laterally into the suprapatellar pouch. Then the back of the hand presses firmly and sharply on the lateral side of the joint. When a small effusion is present, a bulge will appear on the medial side of the joint as the fluid returns.
2. A moderate effusion is best detected by eliciting the 'patellar tap' (Fig. 14). One hand is placed on the suprapatellar pouch, the finger and thumb exerting side-to-side pressure, squeezing any fluid in the pouch to the retropatellar space. The patella is then sharply depressed with the fingers of the other hand, so that it floats through the fluid to strike the lower end of the femur. This sharp tap will not be felt if the undersurface of the patella is covered with synovial pannus, which acts as a blanket to muffle the impact. A tap may be felt in the absence of fluid if intra-articular fat is squeezed behind the patella.

Fig. 14 Eliciting a patellar tap.

3. A large, tense effusion can be confirmed by fluctuation across the joint, from one side of the patella to the other.

A cyst of the calf or popliteal fossa is often easier to feel than see, and has the consistency of a firm rubber ball.

The patellar compression test

The patient lies supine with the quadriceps relaxed. The examiner presses the patella firmly distally between finger and thumb. The patient is then asked to push the knee hard into the bed. If this causes pain or crepitus it suggests retropatellar disease, such as chondromalacia patellae in the young or osteoarthritis in the elderly.

Testing stability

To test the cruciate ligaments the examiner grasps the leg just below the knee, with both hands, and exerts pressure first anteriorly, then posteriorly. To test the medial and lateral collaterals the examiner raises the patient's leg, supported with the fingers of one hand under the knee, holding it slightly flexed, and the other under the ankle (Fig. 15). Then pressure is exerted with the heel of each hand, producing a stress across the knee joint, centred on the ligament to be tested.

Fig. 15 Testing for lateral collateral ligament stability at the knee.

McMurray's sign

This is a test for cartilage tears. The patient lies supine and the examiner grasps the knee in one hand and the ankle in the other. The examiner then flexes the knee fully, internally rotates the lower leg as far as it will go, and slowly straightens the knee. Then the test is repeated with external rotation. If the hand over the knee detects a clunk on straightening, accompanied by wincing or other expression of pain from the patient, the test is positive.

Range of movement

Extension, 0°; flexion, 135°. Hyperextension can be tested by holding the knee firmly on the bed and lifting the ankle. Extension beyond –10° is abnormal.

The ankle joint

Screening

Inspect for swelling or deformity. Palpate the anterior joint line for tenderness, swelling. Assess dorsiflexion and plantar flexion.

Swelling can be detected anteriorly, between the malleoli, where it has the appearance and feeling of a 'spare tyre', quite unlike the diffuse swelling of ankle oedema. Swelling behind the lateral malleolus suggests peroneal tendinitis. Synovitis of the extensor tendons results in swelling both above and below the extensor retinaculum.

Range of movement

Dorsiflexion, –20°; plantar flexion, 70°.

The subtalar (talocalcaneal) joint

Screening

Inspect for varus or valgus deformity of the hindfoot. Grasp the heel and assess inversion and eversion (Fig. 16).

Fig. 16 Testing subtalar movement.

Swelling is seen below the malleoli. This joint is prone to symptomless involvement, especially in rheumatoid arthritis and juvenile chronic arthritis. Talipes valgus deformity usually results, and is best appreciated from behind, with the patient standing.

Range of movement

Inversion, 25°; eversion, 15°.

The heel and foot

Screening

Inspect both the dorsal and plantar aspects of the foot, and the back of the heel. Palpate the Achilles tendon insertion, the plantar fascia insertion (Fig. 17), and the metatarsophalangeal joints. Apply torsion to the midfoot to test movement in the midtarsal joints.

Fig. 17 Eliciting tenderness over the plantar fascia insertion.

Painful feet may be caused by vascular or neurological lesions. The peripheral pulses and sensation should always be assessed, and search made for ulcers, sinuses, or skin infarcts. Occasionally a prolapsed lumbar disc will present with foot pain without back pain or sciatica.

The Achilles tendon

This is inspected from behind, either with the patient standing or lying prone. Thickening, tenderness, and rupture can be detected. With rupture, the patient may have difficulty in standing on tiptoe at first, though fibrosis later occurs, rendering the movement possible. The Achilles tendon is a common site for traumatic bursas related to pressure from shoes, rheumatoid nodules, gouty tophi, and tendon xanthomata.

Heel

Heel pain is commonly due to plantar fasciitis. The heel can be inspected from below with the patient lying down. It is unusual to see swelling or discoloration, though the affected side often feels firmer. Tenderness is elicited by pressure directly upwards from the centre of the heel and by pressure from side to side at the level of the anterior margin of the calcaneum.

Midfoot

The naviculocuneiform joint is subject to osteoarthritis and is often found to show bony enlargement.

The sole

Callosities under the metatarsal heads develop when the metatarsophalangeal joints are subluxated. The rash of psoriasis or keratoderma blennorrhagica may be detected on the soles. Perforating foot ulcers may be a sign of systemic disease.

The arches

Flattening of the transverse or longitudinal arches is best seen with the patient standing. Pes cavus should also be assessed while standing.

The toes

Inspect the toes for deformities such as hallux valgus, clawing, overlapping toes, undersized toes. In rheumatoid arthritis, fibular drift of the toes is common. Clawed toes press on the uppers of shoes and callosities form over the proximal interphalangeal joints. 'Sausage toes' suggest Reiter's disease, gout, or psoriatic arthropathy. A bursa between the joints will spread the toes. Diffuse swelling over the metatarsophalangeal joints may be easier to feel than see; tenderness may be elicited by palpating each joint individually. Beware of squeezing the forefoot, as this can cause severe pain if the joints are inflamed.

1.1.5 Outcomes assessment in rheumatology

Oliver Sangha, Gerold Stucki and Matthew H. Liang

Introduction

Rheumatic disorders vary in their clinical expression, yet each has a major effect on function and health status. The major goal in the management of rheumatic disorders is to control or cure the disease and to preserve and control function and health status. This requires standardized assessment of organ morphology and function, as well as health status. Health-care professionals are accustomed to the measurement of organ pathology but if effective treatment is to improve, the assessment of health status is critical. There are several possible approaches to assess health status in a more standardized way: (i) the judgement of a health professional, (ii) performing standardized activities by the patient, and (iii) self-report of patients to standardized questionnaires.

In 1949, the American Rheumatism Association (now the American College of Rheumatology) Functional Classes were developed (Steinbrocker *et al*. 1949). Since then, hundreds of *ad hoc*, non-standardized, assessments of activities of daily living using one of the three approaches have been used. Beginning in the early 1980s, sophisticated, validated, and reproducible questionnaires to measure health status became available.

The literature on the psychometrics and properties of these instruments and their application to clinical trials is now commonplace, whereas their use in clinical practice is not established and the reasons why under study (Deyo 1982; Deyo and Carter 1992; Golden 1992).

This chapter reviews the patient-outcomes measurement of function, health status, and quality of life in the rheumatic and musculoskeletal diseases, conceptual limitations to their use, and guidelines for the selection of measures for specific applications.

Definitions and conceptual framework

The terms used in this chapter which describe the impact of rheumatic conditions on the individual are defined:

'Impairment' is defined as any loss or abnormality of psychological, physiological, or anatomical structure or function. It refers to the level of an individual organ or an organ system. Altered organ morphology or 'damage' may cause organ dysfunction. Impairment is concerned with abnormalities of body structure and appearance, and with organ or system function resulting from any cause. For instance, patients with synovitis usually demonstrate a limited range of motion. It is important to distinguish morphological changes and organ function from functional disability. A patient with a limited range of motion in joints may or may not be limited in activities of daily living (Ferraz *et al*. 1990).

'Disability' is the physical and psychological functional limitation caused by an impairment which is described by an individual when there is a discrepancy between one's capacity and an actual or perceived need for a specific function. A patient's expectations, motivation, the social support system, and the actual demands imposed by the physical limitations are critical determinants of this perception. Function changes over the course of people's development as to their capacity to do and what they wish or need to do.

In children and adolescents, rapid change and maturation of physical, cognitive, behavioural, emotional, and psychological function are the rule, whereas in adult life, those capacities are stable but life circumstances are changing and physical abilities may be declining gradually.

Physical function is dependent on physical integrity of the joints and neuromotor system to perform tasks needed for daily living, to care for oneself, to do recreational activities, to work, etc. When these activities of the daily living concept are extended beyond activities in the home and community, the term 'instrumental activities of daily living' is used. These include using a telephone, shopping for groceries, etc. Disability in instrumental activities of daily living suggests a need for special services.

'Health status' or 'quality of life', an ephemeral concept, embodies the dimensions of physical, social, and emotional function. If these concepts are attributed to health, the term health-related quality of life is used. Although there seems to be a general agreement on the dimensions which are included, there is considerable variation in the terminology and interpretation of this concept. Most correspond to the World Health Organization definition of health as a state of 'complete physical, mental and social well-being' (WHO 1958). Health status instruments usually include the dimensions of physical function, social function, emotional function, pain, and perception of well being.

Characteristics of a health status measure

The attributes of any quantitative measure are validity, reliability, responsiveness, and practical usefulness (Liang and Jette 1981).

'Validity' refers to whether an instrument measures what it is supposed to measure. Ideally, one would compare a measure with a gold standard, for example, comparing a suspicious nodule on a chest radiograph with a biopsy showing cancer (criterion validity).

For health status no reference or gold standard exists to judge the validity of a particular instrument. Instead one assesses the extent to which a measure is consistent with a theoretical concept (construct) concerning the phenomenon of interest (construct validity). Face validity (it 'looks like' it measures what it intends to measure) or content validity (it represents the domain of interest) are other techniques to strengthen the validity of a construct.

'Reliability' is the extent to which a measurement yields the same result on repeated administration of the questionnaire under the same circumstances (reproducibility). If scores of a health status instrument have little random error, they are considered reliable.

Validity and reliability are minimal criteria when one wants to differentiate individuals at one point in time. However, when used to evaluate changes over time, an instrument needs to be able to capture clinically meaningful changes. 'Sensitivity' denotes the capacity of a measure to show any change whether it is meaningful or not. This can be done by statistical techniques such as the standardized response mean (Liang *et al*. 1985), the effect size (Kazis *et al*. 1989), or Guyatt's responsiveness statistic (Guyatt *et al*. 1987). 'Responsiveness', on the other hand, is the capacity to show a change that is clinically meaningful to the patient and/or the physician. Responsiveness of a measure, is the criterion which ultimately determines the usefulness of any outcome measure in the evaluation of chronic conditions but is the measurement criterion least established for health status instruments. Finally, one needs to assess 'the practical utility' of a health status instrument for a given setting. In practice and research applications, the time needed to complete a questionnaire should be no more than 10 to 15 minutes to ensure compliance. In general, self-administered questionnaires are more practical than instruments requiring a trained interviewer. However, in multicultural populations or

where literacy levels are variable, a standardized interview might be the only way to obtain reliable information.

In the following we describe commonly used instruments which have been evaluated for their metric properties.

Health status and quality of life measurement

The instruments for measuring health status or quality of life cover a variety of dimensions of health, including physical, social, and emotional functioning. Some instruments are general health status measures which have been applied to rheumatic disorders. Others are measures developed for rheumatoid arthritis, osteoarthritis, the spondylarthropathies, and low back. Two rheumatoid arthritis instruments assess patient satisfaction with their function (Pincus *et al*. 1983; Meenan *et al*. 1992) and only one is an individualized measure of health status in rheumatoid arthritis (Tugwell *et al*. 1987) (Table 1).

General
Sickness Impact Profile (SIP) (Bergner *et al*. 1976)
Quality of Well-Being Index (QWB) (Balaban *et al*.)
Nottingham Health Profile (NHP) (McDowell *et al*. 1978)
Medical Outcome Study Short Form 36 (SF-36) (Ware and Sherbourne 1992)
Arthritis specific
Health Assessment Questionnaire (HAQ) (Fries *et al*. 1980)
Arthritis Impact Measurement Scales (AIMS) (Meenan *et al*. 1980)
McMaster Toronto Arthritis Patient Preference Disability Questionnaire (MACTAR) (Tugwell *et al*. 1987)
Lee Functional Status Index (Lee *et al*. 1973)
Toronto Functional Capacity Questionnaire (TFCQ) (Helewa *et al*. 1982)

Table 1 Selected health status measures in systemic rheumatic disease

General health status instruments measure multiple aspects of health, including physical function, social function, and pain and are suitable for the comparison of health status across multiple diseases or the value of competing clinical programmes. Generic health status instruments are useful in the evaluation of subjects with multiple chronic conditions, since they can detect changes arising from different organ systems. This is of particular interest when interventions can have effects or adverse effects on several organ systems.

Disease-specific instruments are useful for measuring clinically important changes in response to treatments (Patrick and Deyo 1989). Since these instruments include the elements most relevant to a particular disease, they are usually more sensitive to subtle improvements in health status. Disease-specific instruments are reliable as traditional measures of improvement in clinical status, such as anthropometric approaches (25-metre walk time) or laboratory tests (erythrocyte sedimentation rate). Health status instruments are interchangeable in their ability to measure major clinically significant improvement, but have varying ability to demonstrate changes in subdimensions such as social and global function (Liang *et al*. 1985; Bombardier *et al*. 1986). Measures of function or health status predict mortality and utilization of health services (McNevitt *et al*. 1986; Mitchell *et al*. 1986). A functional questionnaire is an economical and efficient technique for finding subjects with rheumatic and musculoskeletal diseases and has been applied in developing countries for evaluating community burden (Liang *et al*. 1981).

Generic health status measures

The Sickness Impact Profile (**SIP**) (Bergner *et al*. 1976) is a widely used general health status instrument containing 136 items that have true or false answers. Scores use predetermined weights based on rater panel estimates of relative severity of the dysfunction. The categories of ambulation, body care, and mobility are aggregated into a physical dimension, and four categories (emotional behaviour, social interaction, alertness behaviour, and communication) into a psychosocial dimension (Table 2).

Instrument	Dimensions covered	Mode of administration	Time to complete
Sickness Impact Profile (SIP) (Bergner *et al*. 1976)	Physical function, psychosocial, work, sleep and rest, eating, home management, recreation and pastimes	Self-administered or interview	~30 min
Quality of Well-Being (QWB) (Balaban *et al*. 1986)	Mobility, physical activity, social activity	Interview	~20 min
McMaster Health Index Questionnaire (MHIQ) (Chambers *et al*. 1982)	Physical function, social function, emotional function	Self-administered	~15–20 min

Table 2 Generic health status measures

The remaining categories are work, sleep and rest, eating, home management, and recreation and pastimes. The Sickness Impact Profile is available as a self-administered questionnaire or interview. It takes up to 30 min to complete as an interview. The SIP has been used in a number of studies on arthritis. The instrument demonstrates change in groups of arthritis patients, but is relatively insensitive to changes in individual patients (Deyo and Inui 1984; Liang *et al*. 1985; Stucki *et al*. 1995).

The Quality of Well-Being Index (**QWB**) and an earlier version, the Index of Well-Being, (Kaplan *et al*. 1976) assess mobility, physical activity, and social activity. An interviewer asks whether the patient was limited performing certain tasks during the last 6 days because of illness. Scoring for particular functions is based on preference weights derived from the normal population. These have been validated in patients with rheumatoid arthritis (Balaban *et al*. 1986). The interview requires a trained assessor and takes about 20 min. The instrument has been validated, but was not as sensitive to change as other measures in a clinical trial in rheumatoid arthritis (Bombardier *et al*. 1986). Major limitations are the complexity of the instrument and the requirement of a specially trained interviewer.

The McMaster Health Index Questionnaire (**MHIQ**) (Chambers *et al*. 1982) evaluates the quality of life in patients with rheumatoid diseases but has had limited application. A physical function index covers physical activities, self-care activities, mobility, communication, and global physical activity. A social index combines general well being, work performance, material welfare, support, participation with friends and family, and global social function. The emotional index measures feelings about personal relationships, self-esteem, the future, critical life events, and global emotional function. The MHIQ has 59 self-administered questions and takes 15 to 20 min to complete.

Short forms

One disadvantage of the instruments described above is that most require at least 15 to 20 min to complete. This becomes burdensome if general health status is measured along with disease-specific measures in a study, and may be a problem in daily practice. When studied, shorter measures appear to retain the psychometric properties of the longer instruments (Table 3).

Instrument	Dimensions covered	Mode of administration	Time to complete
Medical Outcome Study Short Form 36 (SF-36) (Ware and Sherbourne 1992)	Physical health, mental health, social functioning, role functioning, general health, vitality	Self-administered or interview or telephone interview	~10 min
Nottingham Health Profile (NHP) (McDowell et al. 1978)	Physical mobility, pain, emotional reaction, energy level, sleep, social interaction	Self-administered	~10 min

Table 3 Generic health status (short questionnaires)

The Medical Outcome Study Short Form 36 (**SF-36**) (Ware and Sherbourne 1992) comes from a larger battery of questions administered in the Medical Outcomes Study. The SF-36 includes eight multi-item scales containing 2 to 10 items each and a single item to assess health transition. The scales cover the dimensions of physical health, mental health, social functioning, role functioning, general health, and vitality. Forms cover a week or a month. The use of subscales is encouraged and the questionnaire can be self-administered or interviewer administered. The SF-36 is the most widely used general health status instrument and has been translated into many languages. The instrument is suitable for subjects aged 14 years and older and takes approximately 10 min to complete. Studies show excellent psychometric properties and there seems to be good sensitivity to change in patients with rheumatic conditions compared with longer instruments (Katz *et al*. 1990b).

The SF-36 allows scoring of the eight subscales and the construction of two summary scales, the physical component summary (**PCS**) and the mental component summary (**MCS**) scales. Futher evaluation of these summary scales provided the foundation for the construction of an instrument that is much shorter than the SF-36 (Ware *et al*. 1996). This new short form, the SF-12, uses 12 items from the SF-36, and demonstrates satisfactory reproducibility of the PCS and MCS with correlation coefficients of 0.93 to 0.97 on cross validation with the whole instrument. The new short form is likely to perform well enough for monitoring general populations; however, it does not allow scoring of individual SF-36 subscales such as bodily pain or social functioning.

While the SF-36 and SF-12 are commonplace in clinical and health services research, a previous version, the SF-20, is losing importance. The SF-20 was also developed and tested as part of the Medical Outcomes Survey (Stewart *et al*. 1988). Six health concepts are represented (physical, role, and social functioning, mental health, health perceptions, and pain) with between one and six items for each dimension. The instrument was developed in response to the problem that larger instruments taking up to 45 min to complete were impractical in clinical settings, and the poorer precision and reliability of single-item measures. The SF-20 is potentially less sensitive than the SF-36.

The Nottingham Health Profile (**NHP**) (McDowell *et al*. 1978) and its predecessor the Nottingham Health Index (**NHI**) (Hunt *et al*. 1985) assess perceived physical, social, and emotional health with 38 items answered yes or no. It uses weighted scores from panels' judgement about the severity of individual items. The NHP covers physical mobility, pain, emotional reaction, energy level, sleep, and social isolation and can provide dimension-specific scores.

The NHP is designed to represent rather severe problems, giving individuals with minor difficulties little room to improve. The NHP's reliability and validity have been assessed in rheumatoid arthritis, osteoarthritis, and in patients undergoing hip replacement. The instrument is self-administered and takes approximately 10 min to complete.

Short health status forms offer the promise of decreasing respondent burden in clinical research and integrating health status measurement into clinical practice. However, these measures have few items relevant to upper extremity function and therefore should be supplemented with disease-specific questions for use in rheumatoid arthritis. While shorter instruments are desirable, sensitivity is probably greater for the longer instruments.

Condition-specific measures

Rheumatoid arthritis

Disability as seen in rheumatoid arthritis is characterized by multiple joint involvement, chronicity, variable symptoms of disability, and occasional constitutional symptoms such as fatigue, fever, and weight loss. Rheumatoid disability is affected by the person's age and social role. In middle age, polyarthritis may affect career development, raising a family, family relationships, or return to work when children are grown up. Polyarthritis in older persons accentuates the ageing process and accelerates physical dependency.

Functional disability is the major consequence of disease in patients with rheumatoid arthritis. Relevant outcomes in rheumatoid arthritis include the evaluation of physical function, pain, treatment side-effects, quality of life, and cost-effectiveness (Table 4).

Instrument	Dimensions covered	Mode of administration	Time to complete
Arthritis Impact Measurement Scales (AIMS) (Meenan *et al*. 1980)	Mobility, physical activity, dexterity, social role functioning, social activity, activities of daily living, depression, anxiety, pain	Self-administered	~20 min
Health Assessment Questionnaire (HAQ) (Fries *et al*. 1980)	Physical disability (dressing and grooming, arising, eating, walking, hygiene, grip, activities), pain	Self-administered	~10 min
McMaster Toronto Arthritis Patient Preference Disability Questionnaire (MACTAR) (Tugwell *et al*. 1987)	Open-ended self-identified functional priorities, closed-ended physical activities	Interview	~10 min
Functional Status Index (FSI) (Jette 1980)	Activities of daily living (basic activities, gross mobility, personal care, home chores, interpersonal activities)	Interview	20–30 min
Toronto Functional Capacity Questionnaire (TFCQ) (Reisine *et al*. 1982)	Function in personal care, activities of upper extremities, mobility, leisure activities	Interview	~20 min
Kaleé Index (Kaleé *et al*. 1971)	Mobility, ambulation, self-care tasks	Clinician observation	~15 min
Lee Functional Status Index (Lee *et al*. 1973)	Physical function	Self-administered or interview	~10 min
Convery Polyarticular Disability Index (Convery *et al*. 1967)	Mobility, activities of daily living	Self-administered	~15 min

Table 4 Arthritis-specific measures—rheumatoid arthritis

The Arthritis Impact Measurement Scales (**AIMS**), a health status or quality of life instrument developed for rheumatoid arthritis, has 48 multiple-choice questions with nine subscales measuring mobility, physical activity, dexterity, social role functioning, social activity, activities of daily living, depression, anxiety, and pain (Meenan *et al*. 1980). The possible range of scores on each subscale is 0 to 10; subscale results are averaged to obtain a global score. The questionnaire is self-administered and takes 15 to 20 min to complete. AIMS 2 (Meenan *et al*. 1992) is an improved and expanded version which has additional scales measuring arm function, work, and support from family and friends, and a problem attribution section with yes/no questions. The scales also include three new questions to assess satisfaction with current level of functioning, specific impact of arthritis on an individual's health status, and prioritization of three areas where patients would most likely achieve improvement. Reliability and internal validity of the AIMS 2 have been demonstrated. Although the sensitivity to change has not been tested for AIMS 2, it is likely to be the same as or more sensitive than the original version.

Wallston *et al*. (Wallston *et al*. 1989) have shortened the original AIMS from 48 to 18 items by selecting two questions for each of the nine subscales. The abbreviated AIMS is slightly less reliable but has comparable validity to the whole instrument.

The Health Assessment Questionnaire (**HAQ**) (Fries *et al*. 1980) asks questions about physical and psychological disability, pain, global severity, employment, income, cost of medical care, and drug-related side-effects. The portion about disability and pain is composed of 24 questions on activities of daily living and mobility

including a single pain scale. The HAQ takes approximately 5 min to complete. The short form yields a summated index between 0 and 3 on a continuous scale.

The HAQ is probably the most widely used health status instrument in rheumatoid arthritis and has been tested extensively for validity and reliability and captures clinically meaningful changes over time but may be insensitive to early or advanced disability. It is included in the United States National Health and Nutrition Examination Survey (**NHANES**).

The Modified Health Assessment Questionnaire (**M-HAQ**) (Pincus *et al*. 1983) reduces the HAQ disability subscales to 8 questions and is reliable, valid, and sensitive to clinically meaningful change and is a useful alternative to the parent instrument.

The McMaster Toronto Arthritis Patient Preference Disability Questionnaire (**MACTAR**) (Tugwell *et al*. 1987) asks patients in a semi-structured interview to specify their own key functional activities. The five activities that rank highest are evaluated. On reassessment, patients are asked if their previously indicated limitations have improved, worsened, or remained the same. The MACTAR takes about 10 min to complete.

The Functional Status Index (**FSI**) (Jette 1980) measures pain, limitations, and dependence in performing 18 activities of daily living grouped as hand activities, gross mobility, personal care, home chores, and interpersonal activities. Each activity is rated between 0 and 4 on each dimension. Studies on patients with rheumatoid arthritis show validity and a high degree of interobserver reliability. However, the FSI has had little usage as judged by publications.

The Toronto Functional Capacity Questionnaire (**TFCQ**) (Helewa *et al*. 1982) assesses function in personal care, activities using the upper extremities, mobility, and leisure activities. The TFCQ takes approximately 20 min to complete and requires an interviewer. Scoring includes weighting based on panels of occupational and physical therapists and rheumatologists. The instrument is valid and responsive in clinical trials (Bombardier *et al*. 1986).

The Convery Polyarticular Disability Index (Convery *et al*. 1977) uses 16 items to rate functional impairment in polyarticular arthritis. The index is based on 9 mobility items and 7 activities of daily living. The questionnaire requires approximately 15 min to complete and is reliable and valid. There are no studies on its responsiveness.

The American College of Rheumatology (**ACR**) Revised Criteria for Classification of Global Functional Status in Rheumatoid Arthritis (Hochberg *et al*. 1992) rates patients from complete independence to limited abilities in performing usual self-care, vocational, and avocational activities. The criteria expand the original Rheumatoid Arthritis Classification of Functional Capacity (Steinbrocker *et al*. 1949). As an ordinal scale it is useful for stratifying or describing patients but less useful for showing change.

Unlike the questionnaires above, the Keitel Index (Keitel *et al*. 1971) consists of 24 standardized tasks which are rated by a trained examiner. The index tests motions of axial and peripheral joints focusing on mobility, ambulation, and self-care tasks. The complete test takes approximately 15 min to complete. Validity and reliability of the instrument, and the responsiveness in a clinical trial have been demonstrated.

The Lee Functional Status Index (Lee *et al*. 1973) includes 17 activities to assess the functional ability of the upper and lower extremities and the axial joints. The instrument has good psychometric properties and can be self-administered or interviewer based and takes less than 10 min to complete.

Childhood arthritis

In children, polyarthritis affects musculoskeletal, psychological, and social growth and development. It may interfere with the attainment of educational goals. In adolescence and young adulthood it may interfere with the acquisition of job skills, with emancipation from parents, achieving economic independence, interacting with peers, self-esteem, body image, and finding a partner.

The evaluation of physical function and health status in young patients requires measures different than those used to assess health status of adults with rheumatic diseases. Health status in children is conceptualized as achieving normal development and participating fully in developmentally appropriate physical, psychological, and social activities. Pain reporting is different in children than adults with a tendency to report less pain. Self-report is not considered reliable in children whose developmental or chronological age is below 4 years and necessitates a proxy or performance testing.

In children with juvenile rheumatoid arthritis, research has focused on the assessment of gross and fine motor skills and the evaluation of disability and pain. (Table 5)

Instrument	Dimensions covered	Age	Mode of administration	Time to complete
Development				
Hoskins and Squires Test for Gross Motor and Reflex Development (Hoskins and Squires 1973)	Gross motor, reflexes	0–5 years	Clinician observation	30–60 min
Denver Development and Screening Test (DDST) (Frankenburg *et al*. 1970; 1971)	Personal-social, fine motor adaptive and gross motor skills, language	1 month–6 years	Clinician observation	15–30 min
Newington Children's Hospital Juvenile Rheumatoid Arthritis Evaluation (Rhodes *et al*. 1988)	Motor tasks	1–6 years	Clinician observation	30–60 min
Function				
Adapted Arthritis Impact Measurement Scales for Children (AIMS) (Coulton *et al*. 1987)	Physical disability (dressing and grooming, arising, eating, walking, hygiene, grip activities), pain	All ages	Self-administered (parent or child)	~ 10 min
Juvenile Arthritis Functional Assessment Scale (JAFAS) (Lovell *et al*. 1988)	Physical activities	1–18 years	Clinician observation	~ 10 min
Juvenile Arthritis Functional Assessment Report for Children (JAFAR-C) and parents (JAFAR-P) (Howe *et al*. 1991)	Physical activities	1–18 years	Self-administered (child or parent)	~ 10 min
World Health Organization Study Scale (WHO) (Ellertsen *et al*. 1979)	Mobility, physical activity, role functioning, self-care	0–13 years	Interview and parent report	

Table 5 Arthritis-specific measures—childhood arthritis

Measures of developmental status

The Hoskins and Squires Test for Gross Motor and Reflex Development (Hoskins and Squires 1973) asks an infant to perform 60 voluntary physical tasks that are rated by a clinician on a scale from 1 to 4. The 'motor age' is calculated by finding the highest level where the subject can perform at least 50 per cent of the required voluntary skills. The assessment covers children from birth to 5 years with normal values derived from the literature. The instrument has been tested for interrater reliability and validity.

The Denver Development and Screening Test (**DDST**) (Frankenburg *et al*. 1970; Frankenburg *et al*. 1971) consists of a questionnaire to parents and a simple observational screening test for children. The test covers personal–social, fine motor-adaptive, language, and gross motor skills and is applicable to children aged between 1 month and 6 years. Test scores are used to assess whether a child has achieved age standardized milestones.

The Newington Children's Hospital Juvenile Rheumatoid Arthritis Evaluation (Rhodes *et al*. 1988) measures quality of motor performance against chronological age at which the task is typically mastered on a scale of 0 to 4. The index assumes that central nervous system development is normal and that tasks are sequentially learned. Fifty-eight motor tasks are evaluated and weighted equally. The instrument is designed to assess children aged from 1 to 6 years. Measures that evaluate developmental status measure impairment rather than functional disability and are restricted to children under 6 years of age.

Health status measures

The Adapted Arthritis Impact Measurement Scales for Children (Coulton *et al*. 1987) apply components of the AIMS to children with juvenile arthritis. The instrument includes scales covering physical disability and pain. Each scale contains four or five items with response options scored on a 0 to 10 scale. The pain scale is most reliable in children with active and inactive arthritis, and the physical activity and dexterity scales have reasonable reliability. The AIMS for children is administered by a health professional to the parents of an affected child.

The Childhood Health Assessment Questionnaire (**CHAQ**) (Singh *et al*. 1994) is based on the adult HAQ (Fries *et al*. 1980). The questionnaire is either parent or self-administered and can be used for all age groups. The CHAQ covers two domains, pain and disability. The latter assesses function in dressing and grooming, arising, eating, walking, hygiene, grip, and activities. Each item is rated on a four-point scale with the highest scoring question determining the score for the functional area. The CHAQ has been tested for validity and reliability and can be completed in less than 10 min.

The Juvenile Arthritis Functional Assessment Scale (**JAFAS**) (Lovell *et al*. 1989) is a series of timed tests using items from the AIMS, HAQ, and MHIQ and a consensus process among paediatric occupational and physical therapists experienced with patients with juvenile rheumatoid arthritis. The instrument has 10 items that differentiate children with juvenile rheumatoid arthritis and age-matched controls. The test is administered by a health professional, takes approximately 10 min to complete, and requires special equipment.

The Juvenile Arthritis Functional Assessment Report (**JAFAR**) is a self-reported version of the JAFAS (Howe *et al*. 1991). There are two questionnaires. The JAFAR-C is administered to children, the JAFAR-P to their parents. Patient and parent reports correlate highly with each other and with objective assessment by a physical/occupational therapist. Questionnaire scores were independent of the child's age.

JAFAS and JAFAR appear to be a convenient method to assess disability in patients with juvenile rheumatoid arthritis. Both instruments are reliable and valid, but there is no published data on their sensitivity. JAFAS and JAFAR cannot be administered to children under 6 years of age.

The Rand Health Insurance Study Scale (**HIS**) (Eisen *et al*. 1979; Eisen *et al*. 1980) assesses health status in children. The domains covered are mobility, physical activity, role functioning, and self-care. The Rand scale is administered by an interviewer who asks the parents questions. The items on social relations and parental concerns are relevant only to children aged 5 to 13 years. However, the remaining questions pertain to children from birth to 13 years. The instrument has good psychometric properties and was used in a study of the impact of childhood rheumatic diseases on the family (McCormick *et al*. 1986).

Osteoarthritis

Osteoarthritis disability, with its involvement of the small joints of the hand, the weight-bearing joints, and/or the axial joints is characterized by onset in middle or old age, lack of systemic symptoms, and mono- or pauci-articular involvement. Osteoarthritis disability unfolds slowly, paralleling the ageing process. Its impact on function occurs at a time when expectations and physical demands are less. Several studies have show that the radiographic appearance of osteoarthritis does not correspond with symptoms (Lawrence *et al*. 1966).

Patient-centred measures of osteoarthritis have concentrated on a careful assessment of pain and functional status. These include measures for evaluating specific interventions such as surgery, osteoarthritis-specific measures, and measures of generic health status.

Generic health status instruments (see Table 1 and Table 2) covering dimensions of social function, emotional function, role function, pain, and physical function are relevant to patients with chronic osteoarthritis (Table 6).

Instrument	Dimensions covered	Mode of administration	Time to complete
Western Ontario McMaster University (WOMAC) Osteoarthritis Index (Bellamy *et al*. 1988)	Physical disability, pain, stiffness	Self-administered	~10 min
Lequesne Index (Lequesne *et al*. 1987)	Pain, discomfort, activities of daily living, walking distance (separate scale for hip and knee joint)	Interview	~10 min
Hip Rating Questionnaire (Johanson *et al*. 1992)	Pain, function, walking	Self-administered	~10 min
Hip Arthroplasty Outcome Evaluation Questionnaire (Katz *et al*. 1995)	Pain, function	Self-administered	~10 min

Table 6 Arthritis-specific measures—osteoarthritis

Measures to evaluate osteoarthritis-specific interventions

Since the advent of total joint arthroplasty surgery, rating schemes have been used to evaluate the success of surgery (Larson 1963; Harris 1969) but until recently were unstandardized, untested for validity and reliability, and based solely on the surgeons assessment or anthropometric criteria, disregarding the patient's judgement.

It is not surprising, therefore, that whether a surgical intervention is judged as a success is dependent on the rating scale employed (Andersson 1972). In recognition of these limitations orthopaedic societies have led the way in developing psychometrically sound, standardized instruments in shifting over to groups of related joints and to the evaluation of all interventions rather than only joint arthroplasty (Liang *et al*. 1991; Johanson *et al*. 1992; Katz *et al*. 1995; Daltroy *et al*. 1996).

The Hip Rating Questionnaire (Johanson *et al*. 1992) is a standardized instrument to assess the outcome of total hip replacement. The questionnaire is one of the very few rating scales in orthopaedic surgery that has been tested for validity, reliability, and sensitivity to change. The domains of global impact of arthritic pain, walking, and function are represented in the self-administered questionnaire that can be completed in about 10 min.

Osteoarthritis-specific measures

Standardized health status measures have been validated for the use in patients with osteoarthritis of the joints of the lower extremities and all assess pain and physical function. The Arthritis Impact Measurement Scales (**AIMS**) (Meenan *et al*. 1980) and the Stanford Health Assessment Questionnaire (**HAQ**) (Fries *et al*. 1980) have been applied as outcome measures in pharmacological, surgical, and rehabilitative interventions in osteoarthritis.

The Lequesne Index (Lequesne *et al*. 1987) and the Western Ontario and McMaster Universities Osteoarthritis Index (**WOMAC**) (Bellamy *et al*. 1988) were exclusively developed for patients with osteoarthritis. The Lequesne Index contains two scales, one for the hip and one for the knee. Each scale covers pain and discomfort, activities of daily living, and maximum walking distance. The hip scale includes a question on sexual unction.

The Lequesne Index has been widely used in clinical and epidemiological studies of osteoarthritis and is tested for validity and reliability. A time period covered by the items is not defined and may affect its sensitivity. The hip or the knee scale can be completed in less than 10 min.

The WOMAC is a 24-item questionnaire focusing on the domains of pain, stiffness, and physical disability. The items were selected from the AIMS and HAQ and supplemented by questions felt to be important by 100 patients with hip and knee osteoarthritis. The WOMAC is tested for validity, reliability, and sensitivity to change, and has been used as the principal outcome measure in studies of surgical, physiotherapy, and pharmacological interventions. The instrument is self-administered and takes approximately 10 min to complete. Two versions of the WOMAC are available, a version utilizing five-point Likert response categories and a version scoring responses on a 10 cm visual analogue scale. Both scales produce comparable results.

Multiple studies that have used either instrument as key outcome measure in osteoarthritis research, and both scales have been recommended as suitable measures for testing slow acting drugs in osteoarthritis (Lequesne *et al*. 1994).

Spondylarthropathies

Disability in spondylarthropathy is characterized by stiffness or restrictive movement of the spine, with occasional involvement of the peripheral joints, most commonly the shoulder, hip, or knee. The disability is characterized by male predominance, onset in young and middle-aged adults, and by the episodic nature of the peripheral arthritis. Disability in spondylarthropathies is generally compatible with good function except when it involves weight-bearing joints in which case mobility may be affected. Spondylitis in young adult males may affect self-esteem, body image, and leisure.

Measurements used to evaluate the efficacy of treatments in ankylosing spondylitis include spinal and chest movement, duration and severity of morning stiffness, and quality of sleep. Health status indices such as the HAQ or AIMS are not readily applicable to ankylosing spondylitis since the items which might be affected by spinal mobility and symptoms are sparse (Table 7)

Instrument	Dimensions covered	Mode of administration	Time to complete
Health Assessment Questionnaire for the Spondylarthropathies (S-HAQ) (Daltroy *et al*. 1988)	Physical disability (dressing and grooming, arising, eating, walking, hygiene, grip activities), pain	Self-administered	~10 min
Dougados Functional Index (Dougados *et al*. 1988)	Physical function	Self-administered	~10 min
Leeds Disability Questionnaire (Abbott *et al*. 1994)	Pain, mobility, bending, reaching, neck movement, posture	Self-administered	~10 min
Bath Ankylosing Spondylitis Functional Index (Calin *et al*. 1995)	Physical function, activities of daily living	Self-administered	<10 min

Table 7 Arthritis-specific measures—spondylarthropathies

Daltroy *et al*. (1988) developed a functional status measure (**S-HAQ**) for patients with spondylitis by adding five items to the HAQ, to cover the activities identified to be most problematic in a survey of 300 British patients with ankylosing spondylitis. The instrument is valid and reliable.

Dougados *et al*. (1988) developed a 20-item functional index for the assessment of ankylosing spondylitis (Dougados Index). An item inventory was derived from a consensus of three rheumatologists and this was reduced by statistical procedures. The Dougados Index is valid and reliable and shows sufficient responsiveness (Dougados *et al*. 1990).

HAQ, AIMS, S-HAQ, and the Dougados Index have been compared to test their ability to capture physical limitations in patients with spondylarthropathies, demonstrating that the S-HAQ had the highest correlations with physical measures, particularly in patients with long-standing disease (Kuzis and Ward 1994).

The Leeds Disability Questionnaire (Abbott *et al*. 1994) assesses disability in ankylosing spondylitis, inquiring about four areas of function: mobility, bending down, reaching up and neck movements, and postures. The 16-item self-administered questionnaire is valid, reliable, and sensitive to change.

The Bath Ankylosing Spondylitis Functional Index (**BASFI**) (Calin *et al*. 1995) is a 10-item self-administered questionnaire to assess function and activities of daily living in patients with ankylosing spondylitis. The questionnaire takes less then 10 min to complete and has been tested for validity, reliability, and sensitivity to change.

Low back pain and other miscellaneous measures

A number of questionnaires have been specifically designed for people with back pain of mechanical or structural origin. Probably, the most widely used are the Oswestry Low Back Pain Disability Questionnaire (Fairbank *et al*. 1980), the Roland Disability Questionnaire derived from the Sickness Impact Profile (Roland and Morris 1983), and the Million Visual Analogue Scale (Million *et al*. 1982). Other measures have been reported (Mooney *et al*. 1976; Lankhorst *et al*. 1982; Lehmann *et al*. 1983; Evans and Kagan 1986; Lawlis *et al*. 1989; Greenough and Fraser 1992; Coste *et al*. 1993; Kopec *et al*. 1995; Daltroy *et al*. 1996).

The dimensions measured in all these measures include pain, functional, and pain-limiting activities. The instruments whose indicators of reliability and validity have been reported include the Roland Disability Questionnaire (Roland and Morris 1983), Oswestry Low Back Pain Disability Questionnaire (Fairbank *et al*. 1980), Million Visual Analogue Scale (Million *et al*. 1982), Dallas Pain Questionnaire (Lawlis *et al*. 1989), North American Spine Society (**NASS**) Lumbar Spine Outcome Assessment Instrument (Daltroy *et al*. 1996), Quebec Back Pain Disability Scale (Kopec *et al*. 1995), and EIFEL Questionnaire (Coste *et al*. 1993). The responsiveness of the Roland Disability Questionnaire was at least as good as that of the full SIP (Deyo 1986). Responsiveness has not been examined for the remaining scales, apart from demonstrating changes in the total score over time (the Oswestry and Million instruments).

Other outcome questionnaires have been developed for carpal tunnel syndrome (Levine *et al*. 1993; Katz *et al*. 1994a), fatigue in systemic lupus erythematosus (Krupp *et al*. 1989), shoulder pain (Roach *et al*. 1991), and fibromyalgia (Burckhardt *et al*. 1991).

Limitations of outcomes measures

Multidimensional instruments or subscales of these instruments have floors or ceilings in their capacity to detect change and this relates to the subject's baseline score and the number of items or gradations of change that address one end or the other of the continuum of the function observed (Stucki *et al*. 1996).

Function is multideterminate. Psychometrically sound instruments assume that function can be measured in all patients with the same instrument. However, patients' function is relative to their age, sex, motivation, social supports, priorities, and goals, and to their needs. Function is relative and, therefore, a small change in an individual's function may make a lot of difference.

The small change may be totally adequate for the person's needs, yet may not be statistically significant or captured by a questionnaire. Individualized quality of life and functional measures have been developed to capture patient priorities better, but whether the greater resources required to administer these measures results in sufficiently improved validity or responsiveness remains largely unexplored.

The measurement of specific functions in questionnaires is too coarse for monitoring patients closely. For example, function of hand and fingers may be assessed by a question on difficulty with fastening buttons or doing zippers. More subtle change would be assessed more appropriately by impairment measures such as grip and pinch strength and standardized dexterity measures. Self-reported symptoms and function do not necessarily correlate with objective impairments (Spiegel *et al*. 1985; Katz *et al*. 1990a; Liang *et al*. 1991; Davis *et al*. 1992) underscoring the fact that self-reported information complements measures of impairment and vice versa.

From a clinical perspective, not all activities of daily living are equal for a given patient, and the technology of eliciting preference weights is far from perfect (Thompson *et al*. 1982; Thompson *et al*. 1984; Katz *et al*. 1994b). Preferences of the sick and anxious do not remain constant during the vicissitudes of rheumatic illnesses, which are characterized by chronicity and an unpredictable waxing and waning course. Values change with time, and experiences of illness or personal circumstances change because people learn, adjust, or accommodate over the course of illness.

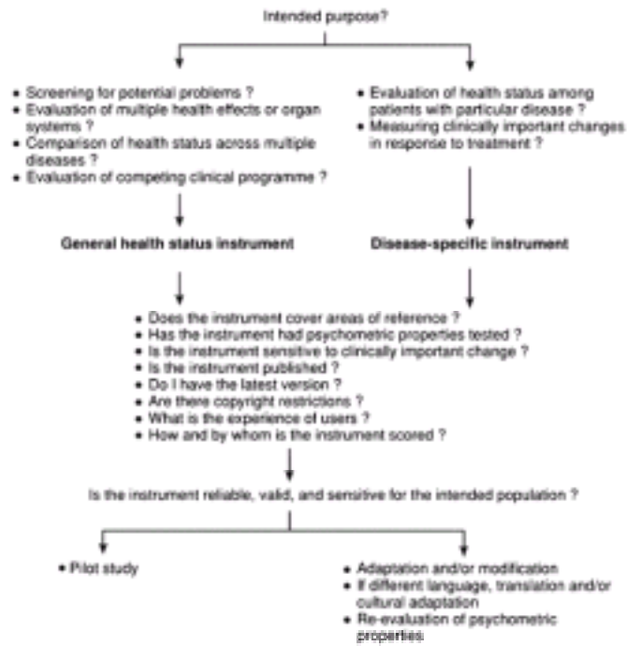
Selection of appropriate measures

For research applications, one should only use instruments with demonstrated psychometric properties which have been published. See Box 1 for the selection of

appropriate measures.

Published instruments are frequently revised and improved, and it is important to get the latest version and permission if protected by copyright. Strictly speaking, the validity and reliability of an instrument are characteristic of the instrument for a specific population and should be re-evaluated in a new population. This may not always be possible but, at a minimum, individual items should be inspected carefully to assess face validity and to make sure that all relevant outcomes and potential adverse consequences are included. The scale should cover the range of severity and the magnitude of the changes expected. A small pilot on individuals that are representative of the ones to be studied can be extremely informative. When a functional or health status measure is used in circumstances where language or cultural setting of the original instrument is different, a comprehensive procedure must be used to ensure its reliability and validity. Guidelines have been proposed (Guillemin *et al*. 1993).

Box 1 Selection of appropriate health status measures



The goal of medical care is to do no harm, to relieve pain and suffering, and to improve and maintain the patient's function, and in some instances, to prevent disability or improve self-image. Thus, any evaluation of an intervention, whether it is medication, surgery, or a programme with elements of these, should examine if these goals are achieved and to what extent.

In selecting measures for clinical trials in rheumatic conditions one needs an understanding of the range of benefits and adverse effects that might be expected and to get the best measure for each of the positive and negative consequences. Traditional anthropometric measures should be supplemented by self-reported measures of physical function and health status. The battery should include a general health status measure if the results are to be used in health policy. If available, a disease-specific health status measure such as the Arthritis Impact Measurement Scale or the Health Assessment Questionnaire should also be used.

Some interventions relieve symptoms and improve function promptly, whereas others may take time or require that a patient be rehabilitated from some stable level of function. Similarly, known and unknown adverse consequences can occur immediately or after a period of time. For a medical intervention designed to treat a root cause or primary mechanism of joint destruction, such as synovitis, one should see evidence that inflammation has been controlled. To the degree that psychosocial dysfunction results from the rheumatic condition, one would expect improvement of these parameters. However, prolonged psychological symptoms or innate traits are not likely to be helped by attention to synovitis alone. In fact, a discrepancy between one's perceived function and objective signs of disease is often a clue that there is something else going on which needs attention.

General health status measures are needed in studies used in health policy in which decision makers must allocate resources to different conditions. The use of such scales in a clinical trial can help the investigator relate the findings to other diseases and the policy maker to understand the trade-offs in resource allocation. The use of a general health status measure may not capture the specific outcomes seen in a disorder.

Arthritis-specific scales usually provide better coverage of dimensions of health thought to be important for that condition. The advantage of using an arthritis-specific scale is that clinicians may have a better feeling for what a change on the scale means.

The evaluation should include a measure of whether or not a change has occurred and if the change was important to the patient, and whether the treatment was worthwhile considering all the positive effects on disease and negative effects. Studies show that the importance of change can be judged differently by the patient and the physician (Redelmeier *et al*. 1993). We would recommend two simple questions: 'Have you experienced a change in your condition?' (and, if so) 'Has this been an important change?'

The Sickness Impact Profile, Index of Well-Being, Functional Status Index, Arthritis Impact Measurement Scale, and Modified Health Assessment Questionnaire have been compared using joint replacement surgery as an assay system to study their relative measurement sensitivity (Liang *et al*. 1985). The instruments correlate highly with one another and showed change. Of the five instruments, the Arthritis Impact Measurement Scale, Functional Status Index, and Sickness Impact Profile were equally efficient in detecting improvement in mobility, but the Health Assessment Questionnaire and Index of Well-Being were about one-half as efficient as the other three instruments. For pain evaluation, the Arthritis Impact Measurement Scale was more sensitive than the Health Assessment Questionnaire. The Index of Well-Being and Sickness Impact Profile do not have a pain subscale. With regard to social function, the Sickness Impact Profile, Index of Well-Being, and Health Assessment Questionnaire were more sensitive than the Arthritis Impact Measurement Scale. For overall or global function, the Sickness Impact Profile, Arthritis Impact Measurement Scale, and Index of Well-Being were the most sensitive.

In practice, the Index of Well-Being is a difficult questionnaire to administer, somewhat artificial for patients, and requires trained interviewers. However, it has the advantage of being a ratio scale with a true zero point which, though not often relevant in rheumatic disease, allows for the calculation of quality-adjusted life–years in cost–benefit studies. In a controlled drug trial in rheumatoid arthritis, it displayed the smallest change (Bombardier *et al*. 1986). The omission of pain as a dimension makes it less desirable as a single instrument in rheumatic disorders since pain is a central concern for patients. The Sickness Impact Profile is much easier to understand by patients, is self-administered, and has been used successfully in several rheumatic disorders. It results in one number. Its dichotomous response categories are less responsive than multi-item responses. It contains questions on continence and communication which are not relevant to rheumatic disorders.

Ultimately, if patient care and outcome are to be improved, attention to function must be incorporated into practice. Improved outcome will probably come from improved understanding of basic pathophysiology of the disease, improved treatment and understanding of the natural course of functional decline, and the critical points in which intervention might make a difference. To know a functional problem exists is only the start, and one needs to have improved understanding of when and what can be done to improve function.

For routine patient care the most desirable features of function or health status are severity, their utility in systematic problem identification (screening), and in following a patient and deciding whether that patient is better or worse (sensitivity and responsiveness). The instruments that have the widest usage in clinical settings are the HAQ and AIMS or the SF-36. To these we would add a transition question alluded to above.

Increasingly, policy makers are looking to outcome measurement as a way to assess the quality of care delivered by individual physicians, institutions, or systems of care, and to reduce ineffective practice variation. Randomized trials evaluating whether the collection of functional status information aids decision-making or improves outcomes have been disappointingly negative (McVey *et al*. 1989; Rubenstein *et al*. 1989; Kazis *et al*. 1990; Calkins *et al*. 1994), and indicate that much work remains to be done before the technology of functional status assessment is successfully transferred to improved patient care.

The reason for lack of improvement in functional status in these studies may have been the insensitivity of the functional measures, inadequate training of the

physicians to deal with functional problems, the timing of the information fed to the physician, or the intractability and multifactorial nature of disability.

Summary

The evaluation of clinical status in rheumatic and musculoskeletal diseases is not complete without an assessment of its impact in the patient's terms. Measures evolving over the last 20 years have made the measurement of these so-called 'soft' outcomes harder and more practical and should make research and patient care more relevant to patient's concerns.

1.1.6 Psychological aspects of rheumatic disease

S. P. Newman

Introduction

The search for cures for many rheumatic conditions continues but progress has been limited. Treatment tends to revolve around attempting to manage and control the symptoms, and reduce the disabling consequences of the illness. The main thrust of treatment has been pharmacological or surgical (e.g. joint replacement), but also includes a range of non-medical interventions such as physiotherapy, pain control, weight-loss regimens, and self-management courses.

The shift from cure for individuals with a rheumatological condition mirrors the general shift in industrial societies from acute care to the management and treatment of chronic illness. This has posed a considerable challenge to health-care professionals and has led to an increasing focus on the psychological and social aspects surrounding chronic illnesses. Most chronic rheumatological conditions require major psychological adaptation when individuals face a lifetime of painful and increasingly disabling illness without prospect of a cure. They have to take regular medication and face the possibility of major surgery some time in their lives. Not only do individuals have to come to terms with the symptoms and treatment; they also have to adapt to altered life plans, reduced employment prospects, and uncertainty about the future course of the disease and its impact on their lives.

When individuals with rheumatoid arthritis are assessed about their concerns, they are most troubled about the symptoms of pain and fatigue but also have specific worries about current and future problems of mobility and disability (Burckhardt *et al*. 1993). Those with systemic lupus erythematosus have similar complaints about the symptoms of fatigue and pain, and are also concerned about uncertainty, lack of control, and appearance (Shortall *et al*. 1995).

Impact of rheumatological disorders on the individual

Introduction

Terminology continues to cast a cloud over the understanding of this domain of research. Various different and often overlapping terms are commonly used to refer to the more general consequences of rheumatological diseases on the individual. These terms include health status, functional status, impairment, disability, handicap, quality of life, activities of daily living. The term quality of life has been used to accommodate all of these dimensions but has also on occasions been used to refer to a more limited domain such as mood state and psychiatric disturbance. In this chapter 'quality of life' will be used to refer to composite measures of functional ability, mood and psychiatric state, and lifestyle. In those studies where composite measures of the quality of life have been used, significant associations have been found with levels of disability (see, for example, Bendtsen and Hornquist 1993).

The majority of studies of chronic disease in general and rheumatological disorders in particular have, however, tended to examine specific aspects of quality of life: physical function, symptoms, social and psychological well-being (Fitzpatrick *et al*. 1992). The focus on different areas of functioning enables the specific impact of the illness on different areas of life to be examined. The divisions of quality of life into symptoms, physical functioning, social functioning, and psychological well-being will be used in this chapter, although it must be recognized that this does impose arbitrary boundaries in relation to the realities of chronic illness for the individual (Newman *et al*. 1996).

Symptoms

Pain

Pain is customarily ranked as the most important symptom for adults with rheumatoid arthritis (Gibson and Clark 1985) and concerns about being free of pain are patients' primary concerns (Deyo 1988). The extent of pain is found to be related to general measures of physical disability. Using the functional classes (Steinbrocker *et al*. 1949), Parker *et al*. (1988a) found that patients classified as functional class III ('functional capacity quite limited') reported more pain on a visual analogue scale of pain intensity and that a greater area of their body was painful, in contrast to those from classes I and II. Clinical measures of disease activity or damage have, in general, not been found to predict the extent of pain reported by individuals with rheumatological conditions. In the study by Parker *et al*. (1988a), clinical variables such as erythrocyte sedimentation rate, Ritchie articular index, grip strength, walking speed, and morning stiffness were only able to account for 3 per cent of the variance in pain scores. In contrast, sociodemographic factors such as age and income were reasonable predictors of pain. Other studies, discussed further below, emphasize the importance of psychological variables such as 'self-efficacy' (Buescher *et al*. 1991) and coping (Newman *et al*. 1990) as mediators of reports of the extent of pain.

Merely describing the extent of pain does not enable the differing qualities of pain experience to be understood. The McGill pain questionnaire tests 78 qualities of pain and is widely used as an assessment of the quality of pain. Melzack (1975) reported that the majority of patients with arthritis used words like aching, exhausting, and rhythmic to describe their pain and more than a third mentioned gnawing, annoying, and constant. Other research has suggested that such patients use terms such as throbbing and burning, but do not use terms such as scalding, drilling, or *cutting* (Wagstaff *et al*. 1985). Pain quality also appears to be dependent on the nature of the activity that individuals are engaged in. In rheumatological illness, pain at rest and pain while moving appear to be qualitatively different. Pain at rest tends to be described as throbbing or aching, whereas shooting and spreading better describe pain on movement (Papageorgiou and Badley 1989).

Stiffness

In contrast to pain, stiffness has not been subjected to much research. Little is known about whether it is a symptom that can be clearly distinguished from pain by most individuals with rheumatological conditions. The subjective qualities of stiffness are also less well understood than those of pain. In one study of 100 patients, spontaneous descriptions of joints included the term stiffness, which they described as limitations in their movement (Rhind *et al*. 1980).

One characteristic of stiffness in rheumatoid arthritis is its temporal nature. Those individuals who are able to adjust their timetable to accommodate early-morning stiffness may be more able to accommodate to the problems of stiffness in arthritis. The ability to be flexible in work has been shown to be important and for many who

have early-morning stiffness rescheduling their day would be one way of dealing with this aspect of stiffness.

Fatigue

Fatigue is a primary symptom of rheumatoid arthritis and in some studies was considered by sufferers as their most severe symptom (Fitzpatrick *et al*. 1992). It tends to fluctuate with the characteristics of the disease as well as increase in times of emotional distress (Tack 1990). As with pain, when patients with rheumatoid arthritis are asked in detail they claim they can identify different types of fatigue (Papageorgiou 1994). Fatigue is also a major symptom of systemic lupus erythematosus and in some studies was the most problematical aspect of the illness (Shortall *et al*. 1995).

In both rheumatoid arthritis and systemic lupus erythematosus, fatigue is associated with sleep difficulties, and in both it also appears to be associated with mood problems and in particular depression (Basia 1995; McKinley *et al*. 1995; Shortall *et al*. 1995). In addition, fatigue in rheumatoid arthritis was also associated with functional disability, pain, and depression as well as with a lower haematocrit (Basia 1995). Determining the causal direction of these influences is difficult, but McKinley *et al*. (1995) have provided data to suggest that the experience of fatigue in systemic lupus erythematosus is best understood by the impact of the disease mediated through sleep and emotional difficulties.

Physical functioning—disability and handicap

Prevalence of disability

Population surveys of disability arising from musculoskeletal disorders produce estimates ranging from 5 per cent up to 8 per cent of individuals experiencing substantial disability (Badley 1992), with arthritis identified as the most common cause of disability (Martin *et al*. 1988). Most surveys show an age-related increase in disability (e.g. Badley and Tennant 1993).

In population studies that have specifically examined rheumatic conditions, differences in the numbers and level of disability in different types of rheumatic disease have been found. Badley and Tennant (1993) found that osteoarthritis and back disorders were the most common cause of disability in rheumatic disease, but that those reporting rheumatoid arthritis had the most current symptoms, made use of medical services the most, and had the highest level of disability.

Reporting disability

Many techniques for assessing disability rely on self-reports of individual capability without obtaining an independent observed assessment. Self-reports may be coloured by an individual's psychological state. For example, individuals who are depressed may underestimate their abilities. Studies have shown that self-reports of functional performance are related to other factors such as mental health and also health perceptions (Spiegel *et al*. 1988). Self-perceptions of health appear in turn to be related to demographic factors such as education as well as physical activity and depression (Guccione *et al*. 1995).

Among young children who have juvenile rheumatoid arthritis a problem exists as to whether their information correlates with that obtained from a parent. In essence this is a problem in all areas of information where more than one informant is used. It is emphasized within juvenile rheumatoid arthritis because of the need to obtain an accurate history and concerns that children may not be accurate. Doherty *et al*. (1993), using a formal questionnaire (the Child Health Assessment Questionnaire), found a relatively good concordance between assessments of their disability and pain made by young individuals with rheumatoid arthritis and those made by their parents.

Predicting disability

What factors influence or determine disability in rheumatic diseases is an important question, as the answers may guide clinicians to potentially useful areas of intervention. There are large individual differences in the health status of people with rheumatic disease. In particular, individuals with rheumatological illnesses that appear to be similar by clinical criteria often exhibit different levels of health status. This has led to the argument that one needs to incorporate both biological and psychosocial factors when looking at predictors of disability. Studies that have used both clinical and psychosocial variables have been able to achieve much greater levels of prediction of health status than those using disease measures alone. One study (Lorish *et al*. 1991) examined and followed 155 patients with rheumatoid arthritis and examined the association of clinical and psychosocial with physical disability. Cross-sectional step-wise regression analysis showed that the two sets of variables combined accounted for 54 per cent of the variance at baseline and 35 per cent at 12-month follow-up. The psychological measure of helplessness in this study added significantly to the ability to predict disability independent of disease severity.

A number of follow-up studies that have investigated predictors of disability have used the Health assessment questionnaire as the outcome measure. Leigh and Fries (1992) made an 8-year follow-up study and Eberhardt and Fex (1995) a 5-year follow-up study on individuals with early rheumatoid arthritis. Both these studies found the level of disability at outset of the study to be the most important predictor of future disability, as had been reported previously (Wolfe and Cathey 1991). The sex of the patient was also a significant predictor of disability, in that women were found to be more disabled (see also Thompson and Pegley 1991). What factors are included in the assessment of disability appears to influence the likelihood of finding sex differences in disability in rheumatic disease. While studies have demonstrated a gender difference on the Health assessment questionnaire, the Groningen activity restriction scale appears to show smaller sex differences (Doeglas *et al*. 1995a).

Other sociodemographic factors are important predictors of disability. Leigh and Fries (1992) found that older patients and those who were single at the time of the first assessment (never married, divorced or widowed) showed increasing disability over time. The latter finding has been related to the role and importance of social supports as buffers against the stresses of rheumatic disease and is discussed further below.

Level of pain, global health status, and number of working hours assessed at the outset were also predictive of disability 8 years later (Leigh and Fries 1992). The investigators offer two explanations to account for this last finding. First, and most obvious, is that individuals with lower levels of disability would be more likely to be in work. The second explanation is more psychological and interprets the increase in disability through the effects of unemployment on self-esteem and depression and the health-protective effects of employment. Further longitudinal study is required to see which of these explanations is the more accurate.

Higher levels of education were associated with lower levels of disability in the study by Eberhardt and Fex (1995), a well-documented finding on disability in rheumatoid arthritis also (Pincus and Callahan 1985). One interpretation of this finding is that higher levels of education are associated with more 'white collar' work and higher incomes, and as a result better work and social conditions. Improved economic resources and social conditions may lead to reduced disablement. Education may therefore be a marker of the importance of social factors on the course of disability in rheumatoid arthritis.

Social well-being

Employment and work

Rheumatoid arthritis has a dramatic impact on employment, with over half of individuals with rheumatoid arthritis who worked before the onset of the disease stopping work within 10 years of diagnosis (Yelin *et al*. 1980). Workforce participation of individuals with arthritis and limitations of movement is 20 to 33 per cent lower than that of individuals without arthritis. Participation in the workforce appears to be declining for arthritic men in the United States, in particular for those between the ages of 55 and 64 years, where from the 1970s to 1980s participation declined from 54 per cent to 38 per cent (Yelin 1992). In contrast, younger women with arthritis and limitation have increased their participation in the workforce. While both these trends are also apparent in the general population, the decline in men's participation is accentuated for those with arthritis and limitations.

Work performance and occupational status are affected by rheumatoid arthritis even soon after it has been diagnosed. Doeglas *et al*. (1995b) examined a group of patients in Holland who had a mean time since diagnosis of 2 years; they found that 90 per cent had either given up work or had made changes in their work because of their rheumatoid arthritis.

The decline in workforce participation of individuals with arthritis has a considerable impact on their income. In one study in the United States, men with rheumatoid arthritis had 48 per cent and women 27 per cent of the income of those without the disease (Mitchell *et al*. 1988). The nature of work appears to be an important

predictor of the likelihood of retaining employment. Those in professional or managerial occupations are more likely to stay in employment after the onset of rheumatoid arthritis (Callahan *et al*. 1992). The absence of paid employment for individuals with rheumatoid arthritis appears to have an independent effect on symptoms and mood. Fifield *et al*. (1991) assessed 723 patients attending clinics for rheumatoid arthritis and found that those without paid employment reported higher levels of pain and depression, even when confounding factors such as disease severity were controlled.

Whether individuals with rheumatoid arthritis will continue to work appears to be best predicted by the social characteristics of work. Yelin *et al*. (1980) found that the four best variables measuring the social characteristics of work, which included being able to control the pace of work and being self-employed, had greater explanatory power than the four best medical items (1.8 times greater) in predicting continuing work. The most important issue appears to be the flexibility of, and control over, work enabling individuals with rheumatoid arthritis to control the pace and timing of their activities at work. Doeglas *et al*. (1995b) found an association between educational level and remaining in employment despite rheumatoid arthritis. They attribute this to the nature of work performed by the more highly educated. In their study 32 per cent on the non-manual workers as opposed to 80 per cent of the manual workers with rheumatoid arthritis had left their jobs.

The problem of employment for individuals who have juvenile rheumatoid arthritis revolves around making the transition between the relatively sheltered world of education to the world of work. Programmes have been devised to assist this transition. One report of a programme in Cincinnati indicates a high level of training and education as well as high levels of employment for individuals with juvenile rheumatoid arthritis (White and Shear 1992). In the sample of 242, the majority of whom had juvenile rheumatoid arthritis, 27 per cent had completed 4 years of college education, which was well above that achieved by the general population (9 per cent), and only 6 per cent were unemployed.

The fulfilling of domestic roles and activities is particularly pertinent in considering a disease such as rheumatoid arthritis with its preponderance in women. It is not surprising that the many women with rheumatoid arthritis experienced limitations in cleaning the house (73 per cent), in laundry work (65 per cent), and shopping (61 per cent) (Reisine *et al*. 1987). More importantly, rheumatoid arthritis appears to affect the ability to perform the nurturing roles such as giving attention and support to other household members and maintaining family ties with others outside the household such as relatives and friends. (Allaire *et al*. 1991) examined the impact of rheumatoid arthritis and family and personal factors on work disability in a study that included a comparison group. Women with mild rheumatoid arthritis spent as much time on household work than the control group, but they appeared to accomplish less in that time. In contrast, women with more severe rheumatoid arthritis (Health assessment questionnaire score of over 1) did less housework and spent less time on housework than those in the mild and non-rheumatoid arthritis groups, but this reduction was compensated for by their families, who spent on average 7 h more time per week on household chores.

Family relationships

Rheumatoid arthritis

Studies on the frequency of divorce in arthritis are inconclusive (Anderson *et al*. 1985; Fitzpatrick 1993). Early studies suggested an increased frequency of divorce in rheumatoid arthritis but later studies have tended to find similar rates of divorce to those of the general population (Hull 1988; Hawley *et al*. 1991).

It is clear, however, that difficulties in relationships do arise when one partner has arthritis. In some cases these appear to result from a decreased interest in sexual relations (Reisine *et al*. 1987). Other issues that appear to create some difficulties in relationships include problems of dependency, shared problems of isolation, and reduced income (Locker 1983; Williams 1987). Specific symptoms may also lead indirectly to problems within relationships. Individuals with pain have increased levels of irritability and bad temper. These may in turn put increased pressure on their relationship.

There is, however, little apparent loss of the quality of close relationships when assessed from the perspective of the person with rheumatoid arthritis. Fitzpatrick *et al*. (1988) found little or no difference in how individuals with rheumatoid arthritis rate the quality of their close relationship. They also found no reduction in the quality of the relationship in those who had more severe disease.

Social relationships

Social relationships appear to be more at risk than close relationships in arthritis. Individuals with rheumatoid arthritis reduce their social contacts with others (Deyo *et al*. 1982). Over time as disability increases, individuals with arthritis have fewer opportunities for contact with friends and acquaintances and also derive less satisfaction with these relationships (Fitzpatrick *et al*. 1988). With further progression of the disease and reduced mobility, social contacts become even more difficult and social withdrawal may arise in some individuals. The social withdrawal may not, however, simply be attributable to increasing disability. Some individuals may withdraw socially in order to avoid the stigma and embarrassment associated with rheumatoid arthritis (Williams and Wood 1988 ; Locker 1989).

Psychological well-being

Prevalence of depression

The reported prevalence of clinical depression in rheumatoid arthritis ranges between 8 and 22 per cent in different studies (Creed 1990). While these proportions are higher than those found in the general population, similar rates were found among individuals with other chronic illnesses (Frank *et al*. 1988; Murphy *et al*. 1988; DeVellis 1993). Thus the increased levels of depression that occur in rheumatoid arthritis are not specific to that disease but appear to reflect the general effects of a chronic illness.

Hawley and Wolfe (1993) compared the incidence of depression and depressed mood in a large group of individuals with a variety of rheumatic conditions. They found no evidence to support the notion that patients with rheumatoid arthritis, in comparison to individuals with other rheumatological conditions, have a particular propensity to develop depression (Hawley and Wolfe 1993).

Factors associated with depression and low mood

A number of studies have attempted to identify the factors that lead to depression. While a simple interpretation might be that those with more severe disease are more likely to be depressed or have low mood, no direct relation between markers of the severity of arthritis and clinical depression or depressed mood has been found (McFarlane and Brooks 1988; Newman *et al*. 1989; Creed 1990; Blalock and DeVellis 1992). The most important predictor of depression and depressed mood in adults with rheumatoid arthritis and in juvenile arthritis appears to be disability (Newman *et al*. 1989; David *et al*. 1994). The research therefore suggests that two of the consequences of arthritis, depression and disability, are associated with each other but that neither is linked with clinical markers of the severity or activity of the disease. These associations serve to emphasize that how individuals respond to and experience their arthritis may be very different from what would be expected by trying to interpret the personal consequences from clinical measures of the disease.

In studies of individuals with arthritis, pain is commonly associated with depression and/or distress (e.g. Hawley and Wolfe 1988; Smedstad *et al*. 1995). It is commonly thought that the direction of this association is of pain causing the mental distress, although it could well be the opposite, with individuals who are distressed reporting higher levels of pain. Smedstad *et al*. (1995) attempted to distinguish between these two alternatives and concluded that mental distress is secondary to pain.

The impact of rheumatoid arthritis and its symptoms is apparently mediated through a number of psychological and social factors. Notable amongst these are coping responses and social supports, which are discussed below, but other important factors include social isolation and economic resources (Newman *et al*. 1989).

An important consideration is how low mood or depression may affect other aspects of the quality of life. Depressed mood is generally associated with dramatically reduced perceptions of quality of life (Sensky and Catalan 1992) and individuals with high levels of depression may restrict their social activities and become isolated. High levels of depression may also affect the individual's perceptions of their functioning and thus their self-reports of their functional status may be worse (Spiegel *et al*. 1988; Brooks *et al*. 1990; Guccione *et al*. 1995). These interactions between mood and other measures underlie the importance of studies that are conducted longitudinally and can examine causal direction between variables.

Impact of psychological variables on health status and well-being

A simple model of arthritic disease and its consequences would suggest a linear relation leading from disease to disablement and psychological well-being. The research findings suggest that this simple model is untenable and that the consequences of arthritis are dependent upon how individuals interpret their illness, how others respond to their needs, and aspects of their environment. A number of psychological concepts have been used in attempting to account for the mediation between disease and its consequences, and it is to these that we now turn. In order to place the psychological concepts into context a schematic model is presented in Fig. 1. This model illustrates the mediating position occupied by psychological and social factors in our understanding of the consequences of arthritis. The research relating to some of these central concepts is discussed below.

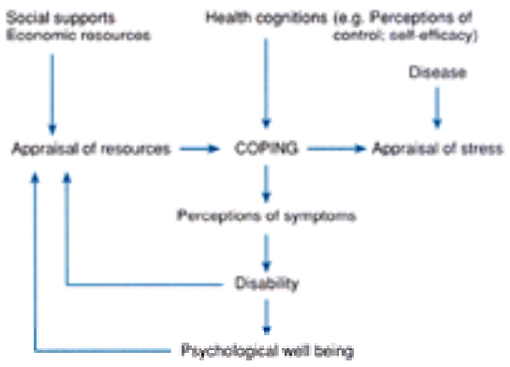

Fig. 1 How psychological and social variables influence outcome in rheumatic disease.

Coping

The term coping is used to refer to what individuals attempt to do to limit the impact of a stressor such as arthritis. Research on the way in which individuals cope with rheumatoid arthritis has been growing in recent years (see Newman and Revenson 1993). This body of work may be divided into studies that have examined coping with rheumatoid arthritis in general and those that have focused on coping with specific symptoms of rheumatoid arthritis, such as pain.

In studies that have looked at coping with arthritis in general, the most popular inventory used to assess coping in rheumatoid arthritis is the Ways of Coping Scale (Folkman and Lazarus 1980) and the Ways of Coping Scale—revised (Folkman and Lazarus 1988), although the questionnaire is frequently revised for the purposes of assessing arthritis. The questionnaire has eight subscales divided between two broad classifications of coping: problem-focused coping (e.g. 'Come up with a couple of solutions to the problem') and emotion-focused coping (e.g. 'I am changing or growing as a person in a good way'). Three studies have used variants of the Ways of Coping Scale and found that patients with rheumatoid arthritis who use the coping strategy of cognitive restructuring (broadly defined as 'attempts to seek new meaning in their situation') had better psychological well-being (Felton *et al*. 1984; Parker *et al*. 1988b; Manne and Zautra 1989). In addition, in one study, seeking information about the illness was also associated with improved psychological well-being (Manne and Zautra 1989). The importance of information seeking should be viewed against the background of the increasing popularization of medical knowledge coupled with the easy access to information about medical issues. Many individuals with arthritis have some knowledge of arthritis before they are diagnosed and/or become knowledgeable early in their illness. The value of information seeking by someone who is knowledgeable may therefore be reduced for some individuals with arthritis.

In these studies (Felton *et al*. 1984; Parker *et al*. 1988b; Manne and Zautra 1989) those who used the coping strategy of wishful thinking (e.g. 'Wish that the situation would go away or somehow be over with') tended to have lower psychological well-being. These studies all addressed arthritis in general. Long and Sangster (1993), rather than asking patients how they coped with arthritis in general, asked them how they coped with the most stressful event they had faced over the past month. Thus, the stressor was defined by the patient, and was not necessarily related to the arthritis. As in the studies mentioned above, wishful thinking was associated with poorer adaptation.

Using a questionnaire designed specifically to assess coping with rheumatoid arthritis (the London coping with rheumatoid arthritis questionnaire), Newman *et al*. (1990) used a cluster analysis to divide 158 patients into distinct groups according to how they attempted to cope with their disease. The groups defined in this way did not differ on clinical measures of disease. One group, which tended to be the most open and active in the manner in which they attempted to deal with the stresses of arthritis, had significantly lower scores on measures of pain, stiffness, and disability, as well as higher levels of psychological well-being. The findings suggest that how individuals attempt to deal with their arthritis, in terms of actions and thoughts, has an impact on psychological well-being, symptom reporting, and disability (see Fig. 1).

Some studies have examined the ways in which individuals with arthritis cope with the dominant symptom of the disease, pain. A number of measures of coping with pain have been developed and those used in arthritis include the Coping Strategies Questionnaire (Rosenstiel and Keefe 1983) and the Vanderbilt pain management inventory (Brown and Nicassio 1987), and the Vanderbilt multidimensional pain coping inventory (Smith and Wallston 1993).

Specific coping strategies appear to influence the impact of pain on psychological well-being. Perceptions of control over the pain lead to higher levels of psychological well-being and lower levels of disability (Beckham *et al*. 1991). Keefe *et al*. (1989) found that high scores on the 'catastrophising scale' of the Coping Strategies Questionnaire were associated with poorer outcome on measures of disability and psychological well-being 6 months later. The Vanderbilt pain management inventory has its origins in research on chronic pain and was designed to assess both thoughts and behavioural strategies for coping with pain. Longitudinal research with this instrument has demonstrated that active coping strategies lead to more favourable outcomes and passive strategies unfavourable outcomes; passive coping during periods of high pain may be particularly detrimental to psychological well-being (Brown and Nicassio 1987; Brown *et al*. 1989).

Taken together these studies suggest that the psychological responses to arthritis and its symptoms are important determinants of resulting health status. Both the disease and the psychological processes of trying to deal with arthritis are not static. This implies an approach to understanding the consequences of arthritis which accepts that both the disease and the individual's attempts to cope with the stresses of the disease change over time. The research in this area also opens up the possibility that psychological interventions to alter coping behaviour may be able to reduce the impact of arthritis.

Social comparison

Individuals' attempts to cope with the stresses of their arthritis take place in a social context. Part of the processes associated with coping involves making comparisons with others in order to provide a reference point to evaluate one's relative position. Social comparison constitutes a part of the coping mechanism used by some individuals. It is particularly important when the means to change the situation are not available (Wills 1987). In the context of arthritis, individuals compare themselves with others who have arthritis. This may involve a comparison with others in a worse state and in this manner they are able to judge their state as being 'relatively' good; the net effect of this comparison is to preserve their psychological well-being. The making of social comparisons has been studied in arthritis. The findings suggest that individuals with rheumatoid arthritis do predominantly tend to make comparisons with those in a worse state and that this type of comparison is associated with better psychological well-being (Affleck *et al*. 1988; DeVellis *et al*. 1990).

Social support

The process of dealing with the stresses caused by arthritis involves others in the social world not only as points of comparison but also as potential providers of both practical help and emotional support. The term 'social support' refers to the process by which interpersonal relationships promote well-being and protect people from a decline in health. In healthy individuals, social support reduces morbidity and mortality (Berkman 1985), particularly at times when they are facing stressful life circumstances (Cohen 1988), and improves mental health (Kessler and McLeod 1985).

Eliciting social support is one coping strategy that many individuals use. This is dependent upon having people in the environment from whom support may be elicited. In most societies there are natural groups and individuals who provide social support. These include family, friends, health-care professionals, and patients' groups. These individuals and groups may provide emotional support by offering a receptive ear when individuals are upset as well as practical support such as assistance

and advice about how to deal with a problem.

A large number of studies show the importance of social support for the psychological well-being of individuals with arthritis. At the simplest level, married people with rheumatoid arthritis show slower progression in their disability than those without partners (Ward and Leigh 1993). An interpretation of these findings is that a partner who provides emotional and practical support to those with rheumatoid arthritis acts to protect them against resulting disability.

Other studies have shown that individuals with rheumatoid arthritis who have more social contacts have lower levels of depression (Newman *et al*. 1989). Most studies of social support, however, suggest that the number of individuals with whom one has contact is less important than the belief that one has adequate support available. These studies have demonstrated that those individuals with rheumatoid arthritis who perceive greater social support exhibit greater self-esteem (Fitzpatrick *et al*. 1988) and life satisfaction (Smith *et al*. 1991), are better adjusted (Affleck *et al*. 1988), show less depression (Fitzpatrick *et al*. 1991; Doeglas *et al*. 1994), and cope better with their arthritis (Manne and Zautra 1990). The important role of the individuals' judgement of their social support parallel findings in both epidemiological studies and studies in other illnesses. It further emphasizes the mediating role of psychological factors in determining the impact of processes in the world on an individual.

It is important to recognize that the provision of support implies shared understandings of need, what is required, when it is required, and an ability to negotiate the provision of support at a time when the provider is ready to offer it (Newman *et al*. 1996). This process takes place within a reciprocal relationship in which the individual with rheumatoid arthritis is also a support provider. Given these factors it is not surprising that some social support may have negative effects (Revenson *et al*. 1991). In some cases the negative effects may be intended. The relation between negative social support and coping efficacy was well demonstrated in a study by Manne and Zautra (1989), who examined the impact of husbands' criticism on their wives' coping and found a direct relation between spouses' critical comments and wives' coping and adaptation to their rheumatoid arthritis. Patients with critical spouses tended to engage in more wishful thinking, which led to poorer psychological outcomes. The authors argue that spouses' criticism 'may encourage ineffective and even harmful coping strategies'. Patients who perceived their spouses as supportive engaged more in cognitive restructuring and information seeking, strategies that proved to be more adaptive in dealing with the stresses of arthritis. (Kraaimaat *et al*. 1995) report similar findings but found that spousal criticism led to anxiety in men and both anxiety and depression in women.

Some researchers have looked at the impact of different types of social support and found that not all elements of support lead to improved health status or psychological well-being in individuals with arthritis. Taal *et al*. (1993) found that while emotional support was not positively related to health status, practical support was. Doeglas *et al*. (1994) found that receiving greater amounts of emotional support around problems had a negative relation to some aspects of psychological well-being. These findings suggest that to understand fully the impact of social support in arthritis further research needs to examine the nature of the support provided and who provides it. In addition it is likely that the timing of the support is important as well as whether it is requested.

Control, self-efficacy, and perceived competence

Aside from specific attempts to deal with the stresses of arthritis and the important role that others in the environment can play through social support, individuals hold more general beliefs about their health and what they are able to do about the course of their arthritis (see Fig. 1). Some of these more general beliefs are discussed next.

Beliefs about whether and who may influence the course of health and illness in the future have been widely studied. This concept, known as health locus of control, has three dimensions. The internal health locus of control (**IHLC**) is the belief that the individual has an influence over future health and illness; the chance health locus of control (CHLC) is the belief that fate and chance will determine future health and illness, and 'powerful other' health locus of control (POHLC) is the belief that others such as health-care professionals will wield an important influence on future health and illness (Wallston *et al*. 1978). This concept usefully identifies that individuals with arthritis who join self-help groups have higher IHLC scores (Volle *et al*. 1990). While this is not a surprising finding it raises the important methodological issue that studies of self-help groups will not necessarily be representative of all individuals with arthritis.

Early cross-sectional research suggested that beliefs that one had control over future illness and health (IHLC) had positive effects on psychological well-being in rheumatoid and osteoarthritis (Wallston 1993). Later studies have shown the issue about control to be more complex. A study that distinguished between control over treatment and control over symptoms found that personal control over treatment was associated with higher psychological well-being while perceptions of greater control over symptoms by health-care providers were associated with lower psychological well-being (Affleck *et al*. 1987). A later study by the same group (Tennen *et al*. 1992) showed that patients who believed they had control over their pain (IHLC) at the beginning of an intensive daily study reported less pain. More interestingly, it appeared that when individuals believed they could control their pain but were thwarted by higher levels of pain than expected, they become distressed. These studies clearly demonstrate that perceptions of personal control over arthritis do not necessarily lead to improved outcomes.

Perceived competence and self-efficacy are terms used to describe individuals' beliefs that they have the skills to be able to deal effectively with issues in the environment. It has been argued that these beliefs act as a mediator between measures of disease and adaptation. One study (Smith *et al*. 1991) found that, in cross-sectional and longitudinal analyses, levels of competence did act as a mediator between levels of disease, perceptions of control and social support on the one hand, and life satisfaction and depression on the other.

Intervention studies

Studies on psychological factors have demonstrated how they mediate between the disease on the one hand and outcome on the other. These investigations have led to the development of intervention studies, which attempt to modify individuals' understanding, beliefs, coping styles, and social supports in order to influence psychological well-being and health status. These studies customarily involve a range of factors, which are discussed next.

Information

Information about arthritis is a small but significant component that appears integral to most intervention studies. Lorig *et al*. (1987) reviewed the literature in 1987 and reported on 34 educational studies, of which 32 (94 per cent) found increases in knowledge among the participants. The difficulty has been to observe a translation of knowledge into behaviour. There is little evidence to support the view that the provision of general information alone has any benefits on individuals with arthritis (DeVellis and Blalock 1993).

Patient education

Most patient education programmes have a number of different components. Most include skills taught by other health-care professionals such as physiotherapists and nurses, with the aim of developing self-management skills. Most well-known amongst this form of intervention in arthritis is the arthritis self-management programme (**ASMP**) developed by Lorig and colleagues (Lorig 1986). The ASMP uses 'lay leaders' in groups of patients with arthritis to deliver a programme in which education and skills training are core components. Although the effects of this intervention have not always been consistent, early research suggested that the programme is effective in reducing levels of pain and depression and increasing physical activity (DeVellis and Blalock 1993; Lorig *et al*. 1993). These benefits were apparent 4 years after the intervention. Most striking was the research which suggested that these changes were not the result of specific self-management activity but rather individuals' beliefs (self-efficacy) that they could cope with the consequences of arthritis.

Of importance are the potential economic benefits of such a programme. The ASMP reduced the number of visits to the physician, and Lorig *et al*. (1993) estimated the 4-year savings of the programme to be US$701.68 per patient with rheumatoid arthritis and US$189.24 per patient with osteoarthritis. These savings, if projected to the entire population of patients with these arthritides in the United States, would result in savings of over US$13 billion for rheumatoid arthritis and over US$19 billion for osteoarthritis.

Another investigation of patient education has also produced some positive results. Lindroth *et al*. (1995) made a 5-year follow-up study on a control group and an intervention group of patients with rheumatoid and osteoarthritis. The intervention group had received six sessions of 2.5 h of education that focused on medical and treatment aspects, pain management, stress management, self-awareness and communication skills, and exercise and work. Knowledge was higher in the intervention group and, in contrast to that group, the control group reported significant increased disability and pain. As with the ASMP, there were no differences in behaviour (exercise and joint protection) between the two groups at 5 years.

Social support interventions

Many of the psychological and educational interventions have ignored the social context and have been directed solely at the individual with rheumatoid arthritis. Despite this focus, by bringing individuals with arthritis into contact with others, social support may have been an influence on the outcome of the intervention (DeVellis and Blalock 1993). Other studies have used a social support intervention and directed their attention to the individual with rheumatoid or osteoarthritis (Shearn and Fireman 1985).

At the minimal level of intervention, Weinberger *et al*. (1986) and Weinberger *et al*. (1989) used a telephone contact with patients with osteoarthritis and found improved levels of functional status along with increased levels of social support. In a randomized control study they found that sustained telephone contact with a non-professional was more effective than interventions by physicians at outpatient appointments. In a more detailed analysis to determine what factors could account for the improved functional status, the investigators used telephone calls to discuss symptoms, provide advice, impart information, reduce non-compliance, and improve morale. They found no effects of the telephone contacts on social support, satisfaction with care, morale or compliance (Weinberger *et al*. 1991). They suggest that this may be due to the telephone calls having a large advice component, which may have led to them being perceived as an extension of medical treatment.

Conclusion

Research on the psychological factors associated with arthritis is still in its infancy. The work has shown that attempts to predict disability and psychological well-being in individuals with arthritis need to incorporate how individuals perceive their arthritis, how they try to deal with the stresses it creates, as well as factors in their social environments. This area of research and its resulting interventions are likely to lead to important findings in the future.

1.1.7 Growth and skeletal maturation

Daniel J. Lovell and Patricia Woo

Introduction

Growth, like beauty, is a multifaceted concept varying greatly from person to person. For some, 'growth' is a continuum that involves changes in body size and form, physiological function, and biological maturation. Some of the changes in this continuum include embryogenesis, compensatory growth, and wound healing. For others, 'growth' is the process of increasing intellectual and emotional sophistication which for many is a lifelong pursuit but for all extends much beyond the traditional paediatric age. Growth, historically, has been an area of intense interest to paediatricians but only fairly recently have individuals involved in paediatrics and child health come to realize that growth is a basic science peculiar to their art (Falkner and Tanner 1986). This is a science that incorporates, among others, the disciplines of anatomy, physiology, biochemistry, and biology, and is no longer only observational. Molecular biology has provided the ability to synthesize a variety of proteins (e.g. growth hormone, insulin-like growth factors, releasing hormones) which can profoundly change human growth processes. These growth-modifying agents have stimulated an already intense interest in the physiology, psychology, ethics, and economics of poor growth.

In this chapter, an overview of concepts of early growth, growth and maturation measurement, analysis of growth data, growth rates in various developmental stages, and factors influencing growth (especially the role of chronic inflammation in growth) will be developed. More detailed information can be found in Falkner and Tanner (Falkner and Tanner 1986).

Prenatal concepts

The variation of mature body weights in different species of mammals is enormous. It is therefore remarkable that all species start life as a single cell of approximately the same size (1000 μm^3) and that at the time of implantation in the uterus the majority of the cells are directed towards supporting nutrient flow from the mother to the fetus and only a small number of cells are precursors for organogenesis (Reeds and Fiorotto 1990).

Two important, but related, concepts are necessary to understand the process of development—critical periods and canalization. The phenomenon of critical periods in development was first described by Stockard (Stockard 1921). Critical periods occur at times of rapid and important change in a system. A system may be an embryological cell, an organ system, or an entire animal. But most importantly, during this time of rapid change, a decision is made that cannot be repeated or reversed at a later time. The most striking examples come from embryology. There is only a brief period during development in which an individual can be influenced to develop more than the normal number of digits. No later interference can alter the number produced except by amputation. Moreover, many critical periods occur during development and as they proceed, the process places the organism in a deeper and deeper canal whose boundaries limit further choices—'canalization' (Waddington 1962).

A more detailed description of prenatal development is beyond the scope of this chapter but the reader is referred to Chapter 2.3, Chapter 2.4, and Chapter 2.6 for detailed discussions of the development of bone, cartilage, and muscle.

Measurement of growth

When seen from a distance with uninitiated eyes, the problem of measurement of physical growth seems relatively simple. When reviewing the literature of 'auxological anthropometry', that is the systemized art of measuring and taking observations of somatic growth in humans, one begins to develop the feeling that this discipline is plagued by the human equivalent of the Heisenberg Uncertainty Principle! In this chapter, a clinical approach will be presented that will alert the reader to commonly encountered problems in the measurement of growth in children. It is certainly true that the measurement of somatic growth involves a close, fine dance between the subject, instrument, and observer in an interactive situation that the observer is constantly attempting to standardize so as to measure the only important change—that of the subject. At this time, sufficiently sophisticated instruments are available to make the hardware part of the dance quite a reliable partner. To complicate the situation in paediatrics further, the subject is in a constant mode of change from measurement to measurement; in addition, in many clinical situations the identity of the observer may change. Efforts should be made to minimize variation in the observer especially if growth parameters are to be utilized as part of a research study. The record for longevity of observer stability to which all subsequent researchers have aspired is that of the Harpenden Growth Study initiated in 1949 by Professor J.M. Tanner and continued for 25 years. One of the results of this dogged dedication to anthropometric measurements was the realization of measurement instruments that are both ergonomically designed and accurate. These anthropometric instruments are widely accepted for their accuracy, consistency, and ease of use.

A long list of standardized measures have been developed by auxological anthropometrists but only the basic measurements that might be used in standard clinical or growth research studies reported in the rheumatological literature will be included in this chapter. Figure 1 outlines a small subset of the bodily landmarks and standardized surface measurements that are utilized by anthropometrists.

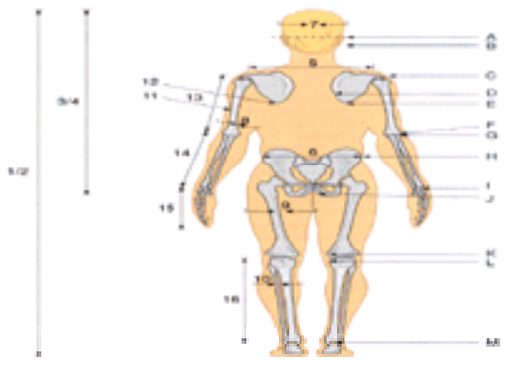

Fig. 1 Body landmarks and standard surface markers utilized in anthropometric measurements in humans (Tanner 1978). *Measurements*: 1/2 stature-recumbent length; 3/4 sitting height (crown–rump length); 5, biacrominal diameter; 6, biiliac diameter; 7, head circumference; 8, extended upper-arm circumference; 9,

upper-thigh circumference; 10, maximum calf circumference; 11, triceps skinfold; 12, subscapular skinfold; 13, upper-arm length; 14, forearm length; 15, hand length; 16, tibial length. *Landmarks:* A, Frankfurt plane; B, mastoid process; C, lateral border of the acromium; D, medial border of the scapula; E, inferior angle of the scapula; F, head of the radius; G, medial and lateral humeral epicondyles; H, iliac crest; I, distal end of the radius; J, gluteal fold; K, medial and lateral femoral epicondyles; L, medial aspect of the femorotibial joint space; M, medial malleolus.

Height

Assessment of height is the anthropometric measurement to which most attention has been paid in terms of development of instrumentation and accuracy. In children able to stand independently, the Harpenden stadiometer is the best readily available instrument. This stadiometer combines two critically important advances in measurement technique. It has a rigid horizontal wooden headboard which moves up and down a rigid backboard on miniature rollers and has a display counter from which the observer can read the height directly. The cost of this instrument should not preclude its use in paediatric settings. However, if alternative equipment must be used, a rigid horizontal wooden headboard must be incorporated. The greatest inaccuracies in height measurement occur when using an instrument based on a flexible horizontal headboard at an approximate angle of 90° to the wall. The use of a flexible horizontal headpiece can introduce up to 2 cm of inaccuracy in height measurements (Tanner 1978). Figure 2 shows the Harpenden stadiometer in use. The technique for measuring height is also of critical importance. The subject's shoes and socks must be removed, not only because they will affect the height of the subject but also they may conceal slight raising of the heels. The subject should stand straight so that his or her heels, buttocks, and shoulders are in contact with the backboard of the stadiometer or wall. In younger children, it may be necessary to assist by pressing down the feet so that the undersides of the heels are in contact with the ground. The legs should be positioned so that the knees or the medial mallei are touching, depending on whether the patient has knock-knee or has straight legs. The shoulders should be relaxed and sloping slightly forward in the natural position. The head is held erect in the Frankfort plane (Fig. 1) and the rigid horizontal headboard is moved downwards until the backboard touches the subject's head with slight weight or pressure on the headboard to minimize the effect of hair thickness. While the subject is in this position, he is instructed to take a deep breath and stand tall while keeping his heels flat on the ground. In younger children, stretching of the spine is assisted by gentle upward pressure applied beneath the mastoid processes by the measurer. This technique also minimizes diurnal variation. Without the use of pressure applied to the mastoid processes, diurnal variation in measured height may be as much as 20 mm (Strickland and Shearin 1972) but with pressure it is normally less than 5 mm (Whitehouse *et al*. 1974). If a subject has leg length asymmetry, the overall skeletal height can be accurately measured by having the child stand on the longer leg with the shorter leg supported by a wedge or block. The sensitivity of the Harpenden stadiometer is sufficient for an accurate assessment of the actual leg inequality to be obtained by taking two measurements of height. The two measurements are based on the child standing on each leg independently with the alternate leg supported by a block. Measurement of height utilizing the shorter leg will require that the patient place the longer leg slightly flexed on the block.

Fig. 2 Demonstration of use of Harpenden stadiometer to measure standing height.

Sitting height

In those subjects in whom muscle weakness, hip contracture, and/or knee contracture prevent an accurate measurement of standing height, sitting height is an excellent alternative. Sitting height may be measured using the same equipment that is used for standing height but requires the use of a sitting platform (Fig. 3). The technique used for positioning the patient against the backboard and stretching his or her spine with gentle pressure on the mastoid processes is similar to that used for standing height. The only precaution is to ensure that the sitting platform is properly horizontal and has sufficient depth to be stable. To obtain the actual sitting height, the height of the sitting platform is subtracted from the total height of the subject sitting upon it. The technique of having the child sit on the floor with legs outstretched as an alternative for the sitting height box is not recommended because of the inaccuracies introduced by hip flexion contractures or hamstring tightness and the compensatory lumbar lordosis.

Fig. 3 Demonstration of measurement of sitting height using adaptation of standard Harpenden stadiometer and sitting platform.

Weight

Instruments accurate to 0.1 kg should be used for patients of the age range generally seen in a rheumatology clinic. Platform–balance beam instruments remain the most widely used and accepted. Digital read-out instruments which are highly accurate are available. The subject should be weighed wearing a minimum of clothing. When weighing frightened or unco-operative subjects such as young children, more accurate results are achieved by weighing the parent and the child together, then the parent alone.

Skinfold measurements

These measurements are useful to distinguish lean body mass from subcutaneous fat in growth assessment. Lange and Harpenden skinfold callipers are the preferred instruments, although many other types are available. Lange callipers are more commonly used in paediatric populations. The technique for skinfold measurement is uniform across all skinfold sites. The tissue to be measured is obtained by parting the observer's index or middle finger and thumb some 6 to 8 cm and sweeping them together over the surface of the skin to collect the subcutaneous tissue pulled away from the underlying fascia (Fig. 4). This technique is not easily mastered and is subject to error even with very skilled operators. The absolute error is approximately 5 per cent for skinfold thicknesses of 10 mm or less but 5 to 10 per cent for skinfold thicknesses greater than 10 mm (Cameron 1986).

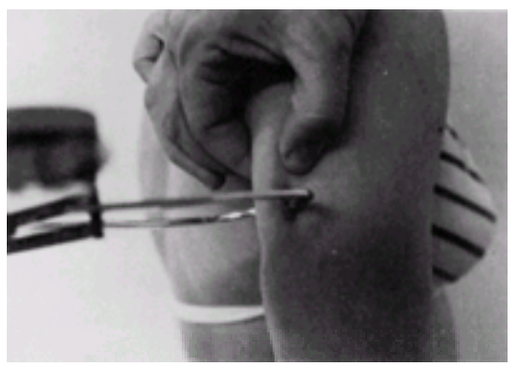

Fig. 4 Demonstration of technique for measuring skinfold thickness with callipers.

Standards for physical measurements

Growth charts have been developed to demonstrate the progressive changes in a number of growth parameters with age and sex. The range of variability is expressed either in percentiles or standard deviations from the mean. For children demonstrating normal growth patterns, percentile-based charts are entirely adequate. However, those children displaying growth patterns significantly above or below the mean are often poorly served by percentile-based growth charts. For example children with significant growth retardation are generally more than 3.5 standard deviations (SD) below the mean height for age. However, children between -2.5 and -3.5 SD have growth retardation of borderline significance. All of these children will be depicted as below the first percentile mark on a percentile-based growth chart and relative changes in growth would be difficult to determine. For this reason, growth charts giving the mean and SD for various ages are more helpful.

Currently accepted growth charts in the United States are based on an extensive cross-sectional study by the United States Public Health Service of 7000 normal children. This study measured each child on one occasion; minimal differences were seen between children residing in six different geographic areas of the United States and the heights of black and white children were closely equivalent. Growth charts for children of other ethnic backgrounds are not available at this time. Growth charts derived in the United States and United Kingdom for well-nurtured children of similar socioeconomic background show no major discrepancies, particularly in height (Kaplan 1937). Generally accepted growth charts in the United Kingdom are those derived by Tanner and Whitehouse. They are based on longitudinal growth data from British children and have the advantage of being able to discern differences in growth based on differences in timing of the adolescent growth spurt (Tanner 1978). Tables of normative values for length, weight, and head circumference by age and sex to 18 years of age are available. Figure 5 and Figure 6 show revised graphs prepared in 1995 in the United Kingdom of percentiles for stature and weight in males and females aged 2 to 19 years. In addition, the pubertal stages are included for the first time.

Fig. 5 Percentiles for stature and weight for age, boys, 2 to 19 years.

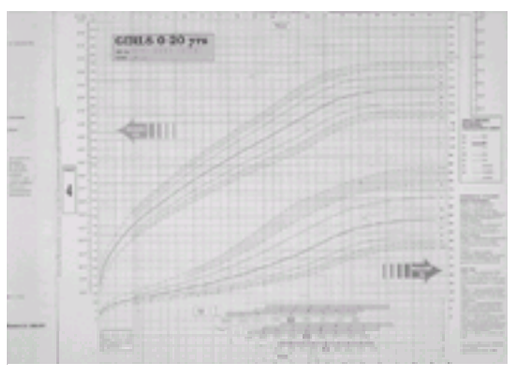

Fig. 6 Percentiles for stature and weight for age, girls, 2 to 19 years.

In those children who have contractures of the lower extremity or have weakness preventing them from standing erect, sitting height represents a reproducible and reliable alternative. Age and sex adjusted standards for sitting heights have been developed (Johnson *et al*. 1981). Standards for sitting heights for males and females are shown in Table 1 and Table 2.

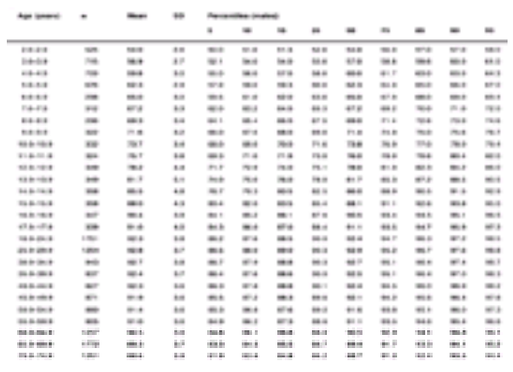

Table 1 Means, standard deviations, and percentiles of standards of sitting height (cm) by age for males (Frisancho 1990)

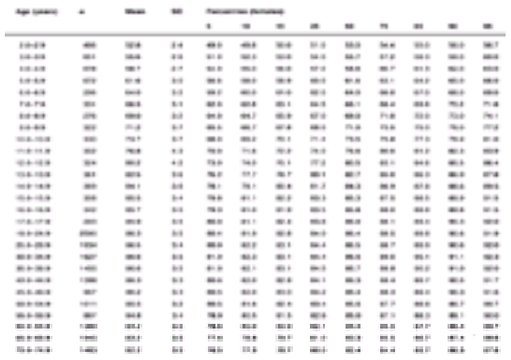

Table 2 Means, standard deviations, and percentiles of standards of sitting height (cm) by age for females (Frisancho 1990)

Standards for skinfold thicknesses have been developed. Norms vary by sex and age. Figure 7 demonstrates variation in subscapular and triceps skinfolds from birth to 19 years of age. Percentile values for triceps and subscapular skinfolds are available arranged by age and sex (Lohman *et al*. 1988; Frisancho 1990).

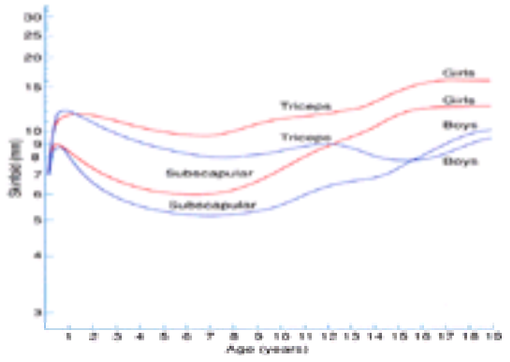

Fig. 7 Skinfold thickness by age and sex as measured by Harpenden callipers. The lines shown are the average for British children (Tanner 1978).

Approach to measurement of skeletal maturation

Several methods for quantifying skeletal maturation have been developed. These are based on the recognition of the orderly and reproducible sequences of changes in the appearance of the skeleton during childhood. Determination of the age of skeletal maturation is important in the diagnosis of a variety of endocrinopathies, assessment of the correlation between chronological age and skeletal maturation, and prediction of adult height. Skeletal maturity assessment can also be used in planning orthopaedic procedures in which the timing and the outcome of the procedure is influenced by subsequent growth, such as surgical management of leg length discrepancy or joint replacement.

Detailed discussion of the influence and overall characteristics of the process of skeletal maturations is the topic of Chapter 2.4. This section will focus only on radiographic methods used to assess skeletal maturation.

Radiographic assessment of skeletal maturity in the child is usually based on the appearance of the hand and wrist but methods are available which assess the entire hemiskeleton, knee, and ankle/foot (Hoerr *et al*. 1962; Pyle and Hoerr 1969). Results from all these methods compare well. Utilization of hand/wrist methods results in a very small radiation dose to the child, is an easily obtained and reproducible radiographic technique, and both left and right hands or wrists can be easily obtained in a single film allowing assessment of significant anharmonic skeletal growth. However, hand/wrist radiographs are unreliable during the first year of life since carpal bones are generally unossified at this stage resulting in very slight alterations in radiographic appearances. In children under 2 years of age, radiographs of the knee and/or ankle are generally used to assess skeletal maturation.

Many methods have been used to determine skeletal maturation: these include timing the onset of ossification of growth centres (Garn method) (Garn *et al*. 1967), comparison of radiographs with illustrations in a standard atlas (Greulich–Pyle method) (Greulich and Pyle 1959), or calculated maturation scores using a standardized methodology (Tanner–Whitehouse) (Tanner *et al*. 1975). There are other important influences on skeletal maturation that must be taken into account when selecting a particular methodology for clinical use. The rate of skeletal maturation is quite strikingly different between boys and girls and there are moderate differences in the rate of skeletal maturation between the black and white races. There are also regional dissimilarities between the populations used to develop standards. The importance of this becomes obvious when it is remembered that the Tanner–Whitehouse system was developed using British children as norms and the Greulich–Pyle atlas was developed using growth of American children.

The Garn method uses published tables showing the timing of onset of ossification of the growth centres throughout the body in normal children (Table 3). Skeletal age is assessed by determining which growth centres in the child under study have begun to ossify compared with published standards. With this method, assessment of radiographs is simplified, as a growth centre is either ossified or not, resulting in a relatively low interobserver variability. Separate standards have been developed for white and black children and for males and females. However, the Garn method is dependent upon the development of new growth centres which occurs only intermittently in the development process. For example, the hand and wrist centres change relatively little during the first 1 to 2 years of life and some of the growth centres in the hand have very limited predictive value because normal children will ossify a particular centre over a very wide range of ages. As a result, in younger children and in studies requiring a high degree of precision, large portions of the skeleton must be routinely surveyed, incurring greater radiation dose and cost.

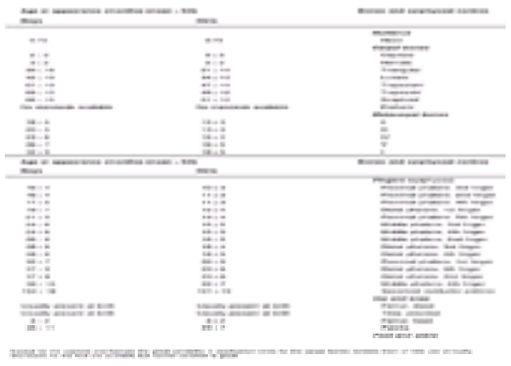

Table 3 Timing of calcification of centres of ossification in infancy and childhood to the nearest month

The most commonly used method in the United States is comparison of hand/wrist radiographs with standard illustrations in the Greulich–Pyle atlas (Greulich and Pyle 1959). The study population for which this atlas was developed was 1000 healthy, United-States-born, Caucasian children of above average socioeconomic and educational backgrounds. These children were studied radiologically longitudinally at 3-month intervals during the first year of life, at 6-month intervals until the 12th

year, and annually until maturity. The atlas consists of a series of standard radiographs representing skeletal ages ordered in increasing maturity with the intervals approximating those at which the population was studied during development of the standards. Once the closest match has been determined between the patient's radiographs and the atlas standards, the normal range for the skeletal age can be determined by using charts contained in the atlas. These provide separate values for standard deviation for boys and girls. The observed differences on the standard radiographs is usually obvious until between the ages of 10 and 14 years. At this point there are only slight changes in the appearance of the radiographic standards resulting in greater inaccuracy and interobserver variability in this age range. In general, greater weight is given to the appearance of the metacarpals, phalanges, and distal radius and ulna than to the carpal bones because of the much greater influence of systemic illness on maturation of the carpal bones.

In the United Kingdom, the Tanner–Whitehouse method is generally used. This method determines skeletal maturation based on the extent of ossification and the morphology of each of 20 bones in the hands and wrists. Each bone is evaluated individually and is assigned a particular development stage based on drawings and reproductions of radiographs. Appropriate written text is provided for each of the 20 skeletal areas (Tanner *et al*. 1975). Two separate summary scores are calculated:

1. a RUS score represents the evaluation of the distal radius and ulna and the phalanges and metacarpals of the first, third, and fifth fingers;
2. a carpal score is based on the evaluation of the carpal bones excluding the pisiform.

The RUS score and the carpal score are averaged resulting in an overall Tanner–Whitehouse score (range 0–100). Finally, skeletal age is determined by plotting the Tanner–Whitehouse score on a graph which provides the mean and a range of 3rd to 97th percentile values. Separate standards are provided for males and females. The Tanner–Whitehouse method requires much more training and experience to be used reproducibly and accurately than the Greulich–Pyle atlas method, although, when mastered, it has relatively less interobserver variability. Comparisons of the skeletal ages derived from each of the methods shows that the Tanner–Whitehouse method is generally between 2 and 12 months ahead of that assigned using the Greulich–Pyle atlas. Perhaps the most important consideration is the fact that the standards for each method are geographically distinct. The observer would be well advised to use the method that most closely coincides with the location of his or her clinic.

In those cases in which significant arthritis of the hand and wrist may make either of the methods unreliable or unworkable, a system based on assessment of anterior–posterior radiographs of the knee is available—the Roche–Wainer–Thissen method (Roche *et al*. 1975). Overall, this method has shown acceptable correlation with Greulich–Pyle standards and could be used in a child in which arthritis of the knee is either absent or unilateral.

Prediction of adult height based on radiographic assessments of skeletal maturation is possible. Garn has developed a method for predicting adult height based on published charts of skeletal maturation. Adult height is calculated by multiplying the child's height at the time of the examination by a 'multiplicity factor' for the estimated skeletal age at that point in time (Posnanzki *et al*. 1976). Bayley and Pinneau have developed an alternative method using the Greulich–Pyle atlas. Tables have been devised showing the percentage of predicted mature height at each skeletal age for children of delayed, average, and advanced skeletal maturity, with separate standards for boys and girls (Bayley and Pinneau 1952). Tanner and Whitehouse have also developed a method of predicting adult height based on a regression equation that includes current height, current chronological age, and RUS bone age plus a constant. In addition, separate tables have been developed for boys and girls which give age-specific coefficients for the factors in the regression equation (Tanner *et al*. 1975). Methods are available for both the Tanner–Whitehouse method and the Greulich–Pyle atlas method incorporating midparental heights into the equation to predict adult height. Comparison of the various methods for predicting adult height showed that the most important determinant was the radiological method used to assess skeletal maturity rather than the mathematical method used to calculate the height (Harris *et al*. 1980). The methodology used should thus be based on the geographic location of the population being studied. Whatever the method used, the accuracy of the prediction is better the closer the child is to maturity (Fig. 8) and the closer the match between skeletal age and height age. Moreover, none of these methods take into account acceleration or retardation of growth which may occur after the prediction has been made because of future illnesses or therapies.

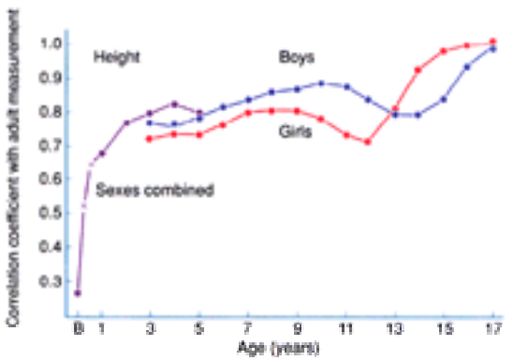

Fig. 8 Correlation between adult height and height of the same individuals in childhood (Tanner *et al*. 1975).

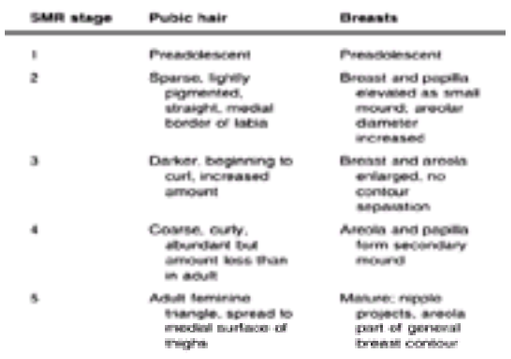
Assessment of pubertal development

Assessment of pubertal development has been made systematic by Tanner in such a thorough and practical fashion that it has become the standard for assessment worldwide. Assessment of the stage of pubertal development is enormously important, not only for the recognition of large changes in the size and functional structure of the reproductive organs themselves but also the major changes in hormonal and growth potential associated with the various sexual stages. Defects in hormones associated with growth at this period can be detected early if the stages of pubertal development are defined. Pubertal development is divided into five stages for both males and females—sexual maturity ratings (**SMR**). Stage I represents prepubertal status, SMR1. Early adolescence coincides with SMR2 and maturation at this stage is initiated by increased secretion of pituitary gonadotropins and growth hormone. Middle adolescence refers to the period corresponding to SMR3 and 4. It is the period of the most dramatic growth and change in body habitus. Late adolescence is associated with secondary sexual characteristics described in SMR5 which approximate adult size and appearance. Little additional linear growth is achieved during late adolescence. Table 4 and Table 5 describe the classification of the sexual maturity stages for girls and boys, respectively.



SMR stage	Pubic hair	Breasts
1	Preadolescent	Preadolescent
2	Sparse, lightly pigmented, straight, medial border of labia	Breast and papilla elevated as small mound, areolar diameter increased
3	Darker, beginning to curl, increased amount	Breast and areola enlarged, no contour separation
4	Coarse, curly, abundant but amount less than in adult	Areola and papilla form secondary mound
5	Adult feminine triangle, spread to medial surface of thighs	Mature: nipple projects, areola part of general breast contour

Table 4 Classification of physical, sexual maturity stages in girls (Tanner 1962)

SMR stage	Pubic hair	Penis	Testes
1	None	Preadolescent	Preadolescent
2	Scanty, long, slightly pigmented	Slight enlargement	Enlarged scrotum, pink texture altered
3	Darker, starts to curl, small amount	Longer	Larger
4	Resembles adult type, but less in quantity, coarse, curly	Larger, glans and breadth increase in size	Larger, scrotum dark
5	Adult distribution, spread to medial surface of thighs	Adult size	Adult size

Table 5 Classification of physical, sexual maturity stages in boys (Tanner 1962)

Despite the tremendous variety and complexity of changes in the body taking place during sexual maturation, the simplicity and accuracy of the Tanner staging method have led to its universal adoption. Numerous studies have shown that although there are secular and geographic variations in the chronological age at which these pubertal changes are attained, the overall sequence of changes is remarkably similar despite wide variations in nutritional status, genetic backgrounds, psychosocial status, and geographical location (Tanner 1978).

Analysis of growth data

The approach to the analysis of cross-sectional growth data generally used is a 'distance standard' which is a set of smooth curves giving the percentile values for a range of ages. This is the form of the standardized growth chart used by almost all paediatricians (Fig. 5 and Fig. 6), and allows determination of the actual percentile of the measured height or weight for a child of particular age and sex compared with a very large population of similar age and sex-matched normal subjects.

An alternative method is to assess growth velocity. The essential statistical point about a growth velocity measurement standard is the pair of measurements summarized by a single quantity (their difference), which is readily interpretable and for which a standard can be constructed (Fig. 9). It is of paramount importance to cross refer the observed growth velocity to some other maturational measurement. This provides much more accurate information about a child's growth than consecutive values from a single child plotted on a distance standard. A child who moves from one percentile curve to another percentile curve on distance standard may be entirely normal when the changes in dimension are compared with a velocity standard. This is especially so during a growth spurt. The interpretation of a series of measurements of height or weight will be much clearer when the velocity standard is used.

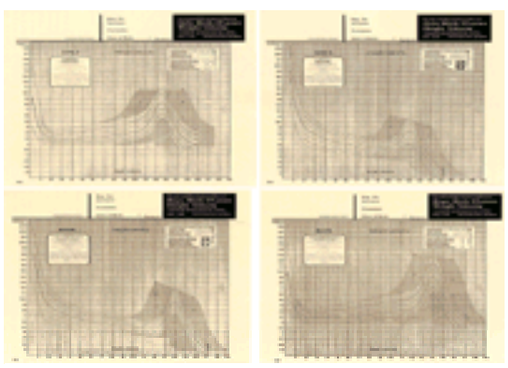


Fig. 9 (a) and (b) Examples of height and weight velocity tables used in the United Kingdom. (Reproduced with permission from Castlemead Publications.)

There are two circumstances in which growth standards are extraordinarily helpful. They are a powerful device for investigation in groups of not overtly ill children to see whether particular individuals might benefit from special medical, educational, or social care and nutritional intervention. Also growth standards, and especially those for velocity, are helpful in assessing the effects of disease and the response to treatment in children known to be ill, for example in growth hormone deficiency, adrenal hyperplasia, asthma, kidney disease, and arthritis. However, growth standards are not appropriate when growth data are to be used as an index of the health and nutrition of a population or subpopulation thought to be at risk, for example ethnic minorities. Comparison of data from the subpopulation under study with data collected from other subpopulations is not appropriate.

The effect of inflammation on growth in juvenile chronic arthritis

Disturbance of growth is a well-recognized problem for children suffering from juvenile chronic arthritis. Sir George Frederic Still referred to the general arrest of development that occurs when the disease begins before the second dentition in his first description of juvenile chronic arthritis in 1897 (Still 1941). Later Kuhns and Swain described three types of growth disorders in juvenile chronic arthritis: generalized retardation of body growth, persistence of infantile proportions, and asymmetry of growth (Kuhns and Swain 1932). Recognition of growth impairment is important because juvenile chronic arthritis is a disease which often remits by late adolescence and growth impairment may be one of the important, permanent sequelae.

Local disturbance in growth

Local disturbance in growth is seen at sites of inflammation. This can be in the form of overgrowth or undergrowth. The mechanism of epiphyseal overgrowth is not clear, but may relate to hyperaemia and growth factor release. The joints most commonly affected are the knees, followed by the ankles and subtalar joints and the wrists. There is a tendency to accelerated epiphyseal maturation, and with knee disease there is usually overgrowth, especially of the medial epicondyle of the femur, resulting in valgus deformity and unilateral increase in leg length (Fig. 10(a)). Compensatory scoliosis of the spine can result from untreated leg length discrepancy. In the wrists and ankles, increased maturation of epiphyses occurs early in the disease, leading to overcrowding and fusion of the joint (Fig. 10(b)). In addition, arthritis of the wrist often leads to growth failure of the ulnar head, causing a shortened ulna with ulnar deviation of the wrist. Because of wrist or ankle involvement, the hand or foot distally is often less well developed compared with the involved side (Fig. 10(b)). This may be due to local inflammatory factors as well as relative sparing of the affected limb in daily activities. Other joints that are underdeveloped as a result of disease are the temporomandibular and the hip joints. In both cases the fossa that articulates with the long bones are underdeveloped, probably due to lack of normal use.

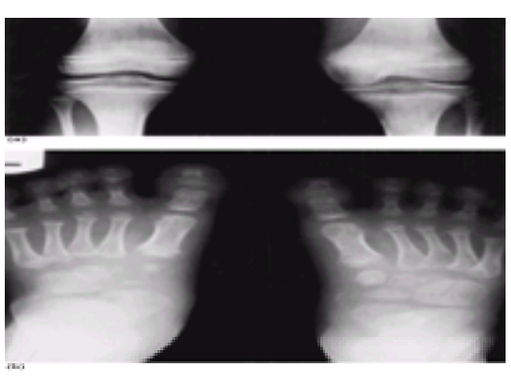

Fig. 10 (a) Radiograph of knees to show overgrowth of the medial epicondyle of the femur due to persistent arthritis of that knee. (b) Radiography of feet to show

asymmetric growth. There is acceleration of ossification in the tarsus on the affected side, and undergrowth of distal phalanges.

The spine is often involved in juvenile chronic arthritis. Common abnormalities of the cervical spine include apophyseal joint-space narrowing and eventual fusion, particularly C2–C3. As a result, undergrowth of the vertebral bodies occurs and the patient eventually has a short neck, increase in cervical lordosis, and dorsal kyphosis. Similar changes can also occur rarely in the dorsolumbar spine in severe systemic juvenile chronic arthritis. Vertebral collapse is often seen, more commonly in patients receiving corticosteroids.

Generalized disturbance in growth

In 1956, Ansell and Bywaters reported a survey of growth and bone development in 119 children aged under 14 with juvenile chronic arthritis of more than 1 year's duration. For this study the period of observation for each subject was 5 years (Ansell and Bywaters 1956). Their findings suggested that disease activity retards general growth, and indicated that corticosteroid therapy aggravated this problem (Fig. 11). Twenty of 120 height measurements from children with active disease were more than 10 per cent below the mean, whereas this was the case in only two of 70 measurements from children with inactive disease ($p < 0.01$). Provided that premature fusion of the epiphyses had not occurred, many of the younger children showed 'catch-up' or accelerated growth in remission, but not those with long-standing and severe disease. In addition, long-term treatment with cortisone was usually associated with failure to grow in height despite good disease control.

Fig. 11 (a) The shorter twin had juvenile chronic arthritis but has not been treated with corticosteroid. (b) The shorter twin had juvenile chronic arthritis and has been treated with corticosteroid.

In a more recent study in the United States by Lovell and White, subgroups of juvenile chronic arthritis were shown to affect growth differently (Lovell and White 1991). Fifty-six children with juvenile chronic arthritis of at least 1 year's duration and aged between 4 and 18, randomly chosen from a rheumatic disease clinic, were measured for height and weight. The mean heights for the systemic and polyarticular-onset groups were on the 31st and 35th centile respectively. The long-term morbidity of generalized growth delay was also reviewed from the records of 156 patients with juvenile chronic arthritis followed beyond 18 years of age. There were significantly more patients with systemic-onset and fewer with pauciarticular-onset disease in the growth failure group. There was no difference in sex, current age, or age at onset. The systemic-onset juvenile chronic arthritis subgroup was also found to have the highest growth failure rate by Bernstein *et al*. (Bernstein *et al*. 1977). In order to assess the relative effect of corticosteroids and disease activity, the authors compared the growth rate of 11 systemic juvenile chronic arthritis patients with that of 13 systemic lupus erythematosus children on equivalent doses of corticosteroid. The former had significantly more growth delay.

Corticosteroids and growth

In systemic juvenile chronic arthritis, corticosteroids are very effective in suppressing disease activity. However, it is well known that glucocorticoids inhibit growth and delay skeletal maturation, particularly when given in large doses for prolonged periods (Blodgett *et al*. 1956; and above). The form, dose, and frequency of administration of steroid are important variables. Doses of 45 mg/m^2 per day of cortisone will suppress growth in children without demonstrable endocrine abnormality, with the effect more marked in younger children (Blodgett *et al*. 1956). Ansell and Bywaters found that, in children under 5 years, the critical daily dose of cortisone above which growth was impaired was 37.5 mg, whereas in older children a daily dose of less than 50 mg of cortisone allowed normal growth (Ansell and Bywaters 1956). The synthetic glucocorticoid, prednisolone, is thought to have a more potent effect on growth; in children with asthma, growth retardation has been reported with a daily dose of 4 to 6 mg/m^2 (Falliers *et al*. 1963; Kerrebijn and Kroon 1968).

The mode of steroid administration can also effect growth differently. Following observations that the therapeutic effect of a single dose of steroid may last longer than its adrenal suppressive effect (Reichling and Kligman 1961), an alternate day corticosteroid regimen was advocated as a means of maintaining equivalent disease control with less growth retardation by Ansell and Bywaters (Ansell and Bywaters 1974). They reported continuation of growth in 28 children with juvenile chronic arthritis receiving treatment with alternate-day prednisolone in doses between 10 and 30 mg/m^2 every 48 h. However, the growth rates were less than normal. A further 21 patients were converted with some difficulty from a daily divided dose to a single morning dose alternate-day regimen to maximize night time growth hormone secretion. In most of these patients there was resumption of growth and loss of cushingoid appearance after 6 to 12 months. In a study by Loftus *et al*., an oxazolone derivative of prednisolone, deflazacort, was shown to have less effect on bone mineral depletion than prednisolone (Loftus *et al*. 1991).

Osteoporosis

Osteoporosis invariably accompanies the lack of growth in height in children with acute disease (reviewed in Woo 1994). This can be severe if the disease is uncontrolled and the relative lack of activity in children with juvenile chronic arthritis is only part of the answer. Measurement of serum calcium, vitamin D, and parathyroid hormone levels, as well as urinary excretion of calcium and phosphate, from different patient cohorts are conflicting. Measurements of bone density and bone mineral content have shown values below the 3rd centile of normal controls (Lovell *et al*. 1986; Hopp *et al*. 1991).

In a recent study in the United Kingdom, measurements of alkaline phosphatase, serum calcium, and phosphate were within normal limits compared to age and sex matched controls. Assessment of bone turnover by measuring urinary hydroxyproline and calcium/creatinine ratios have been within normal limits. However, in a very recent study, bone mineral density was seen at a number of sites in juvenile chronic arthritis patients, associated with low serum concentrations of osteocalcin and bone-specific alkaline phosphatase, suggesting reduced bone formation. Low urinary markers of bone turnover also suggested decreased resorption. Lower bone mineral density was seen with patients with active articular disease and those with a larger number of involved joints (Pepmueller 1996). Thus, these findings fulfil the biochemical and radiological definitions of osteoporosis.

Possible mechanisms of generalized growth retardation and osteoporosis

Nutrition

Several factors have been shown to be responsible for the impairment of linear growth in juvenile chronic arthritis. One important factor is the effect of prolonged periods of systemic illness with fever, leading to diminished appetite and hence poor nutrition.

The first report of nutritional deficiencies in children with arthritis was from a cohort of children in the United States (Bacon *et al*. 1988). Serum vitamin A, zinc, and vitamin D were below normal ranges for that age group. More detailed studies of nutritional requirements by several groups have also shown low protein–energy malnutrition in children with juvenile chronic arthritis (Henderson and Lovell 1989; Mortensen *et al*. 1990). Furthermore, the requirement for children with chronic inflammation may be higher than normal. Nasogastric tube feeding at night in a pilot study has shown improvement in linear growth (Lovell, unpublished

observations).

Growth hormone studies in juvenile chronic arthritis

There are several possible endocrine mechanisms for growth failure. Growth hormone may be suppressed in active chronic juvenile arthritis, or the target tissues may be somehow rendered 'less sensitive' to growth hormone by the disease with or without steroids.

Sturge *et al*. studied linear growth and the secretion of growth hormone and cortisol in 20 patients suffering from systemic juvenile chronic arthritis on four types of treatment regimen to assess the effect of corticosteroid on growth (Sturge *et al*. 1970). The height of children on prolonged daily corticosteroid therapy were below the 3rd centile, whereas children who had only received corticosteroid by an alternate-day regimen had normal growth rates.

Insulin tolerance tests were performed to assess growth hormone and cortisol secretion 10 h after corticosteroid administration. Although there was considerable variation in growth hormone response, there was no significant difference in mean levels between the four groups. In contrast, five of the six children on daily corticosteroid had subnormal mean basal plasma cortisol levels and failed to show a satisfactory rise on insulin tolerance test. Cortisol levels and response were normal in the other groups. Later, Byron *et al*. from the same unit showed the pattern of basal cortisol levels tended to parallel that for height velocity, confirming the impact of adrenal suppression on growth (Byron *et al*. 1983). More detailed studies of growth hormone secretion have been reported using insulin tolerance tests on 22 juvenile chronic arthritis patients and 20 healthy patients with a history of familial dwarfism (Butenandt *et al*. 1976). In this study, defective growth hormone secretion was demonstrated in juvenile chronic arthritis. Allen *et al*. showed increased pulse frequency of growth hormone secretion (Allen *et al*. 1991). More recently, study of 24-h growth hormone secretion in 16 United Kingdom children with juvenile chronic arthritis and severe growth retardation revealed normal pulsatile patterns of growth hormone secretion, and the mean and median levels were comparable to that of healthy children with short stature (Davies *et al*. 1994). Thus, there is unlikely to be significant growth hormone deficiency.

Insulin-like growth factor I (IGF-I) in juvenile chronic arthritis

Insulin-like growth factors (**IGF**) I and II are stimulated by growth hormone to act on target tissues and stimulate cell growth, that is they are important mediators of growth hormone action. The amino acid homology between IGF-I and -II is 62 per cent. There are two regions of homology to the proinsulin a and b chains respectively, thus conferring some cross reactivity with insulin receptors, although IGFs have their own receptors. The site of IGF-I production is mainly the liver, but it is also synthesized by many other tissues. IGF-II is more important in fetal life. These proteins are bound to carrier proteins in the circulation (the main ones being IGFBP-1 and -3). Previous reports have shown that corticosteroid therapy in childhood causes reduction in somatomedin (now known as IGF-I) activity (Philips *et al*. 1974; Elders *et al*. 1975), and subsequently there have been several studies on IGF-I in juvenile chronic arthritis.

Levels of IGF-I have been described to be reduced or normal in juvenile chronic arthritis (Takami *et al*. 1982; Bennett *et al*. 1988; Aitman *et al*. 1989; Allen *et al*. 1991). In a study of 15 systemic juvenile chronic arthritis patients and 79 normal children, Bennett *et al*. showed that serum IGF-I levels were lower than the mean normal values for age, irrespective of steroid therapy (Bennett *et al*. 1988). Furthermore, IGF-I showed a significant negative correlation with erythrocyte sedimentation rate as a measure of disease activity but no correlation with growth rate. In contrast, in the study by Aitman *et al*. of 32 children with juvenile chronic arthritis with a spectrum of growth from normal to severe retardation, serum IGF levels showed significant correlation with height ($p<0.01$) and to a lesser extent with height velocity ($p<0.05$). In this study there was no correlation between IGF-I and diet history or steroid dosage (Aitman *et al*..

More recently, low IGF-I concentrations in children with juvenile chronic arthritis have been reported (Allen *et al*. 1991). These workers also confirmed earlier reports that the disease itself is a major factor in growth retardation, independent of steroid therapy. It has also been shown that the low serum IGF-1 levels are not due to high carrier protein levels, that is IGFBP-1 is normal and IGFBP-3 is low correlating with IGF-1. Thus, there is deficient synthesis of IGF-1 in these children in spite of normal levels of growth hormone (Davies *et al*. 1997). This is in contrast to the growth failure in chronic renal failure where growth hormone 'resistance' in these patients is at least partly due to higher concentrations of IGFBP-3, reducing the amount of 'free' IGF-1 available to stimulate growth (Tonshoff *et al*. 1990).

IGF-1 synthesis is not only stimulated by growth hormone but is also affected by the nutritional state. Further, parathyroid hormone also stimulates IGF-1 and it may be low in juvenile chronic arthritis. Since IGF-1 stimulates obsteoblasts to produce osteocalcin, measurements of serum osteocalcin have shown that they are correspondingly low. However, osteoblasts are also affected by a number of other hormones, for example growth hormone and parathyroid hormone, as well as vitamin D and inflammatory cytokines. Therefore, the observed osteocalcin levels are a net effect of all these factors.

Treatment with growth hormone

There are a number of studies where growth hormone is used as a pharmacological 'anabolic' agent in growth-retarded children with juvenile chronic arthritis (Svantesson 1991; Davies *et al*. 1994; Hopp *et al*. 1995). They all show some improvement. In a comparative study with the largest cohort of patients described so far, Davies *et al*. showed significant linear growth of 3 to 5 cm during 1 year's treatment with 24 iu/m^2 per week. Further, the same group showed increase in bone density, in parallel with body surface area (Rooney *et al*., in press). The improvement, however, was abolished during flares of disease activity. The improved linear growth was maintained at 5-year follow-up (Rooney, unpublished observation).

Further prospective studies are needed to investigate the possibility of early intervention and the duration of treatment to achieve optimal final height.

1.2.1.1 Spinal problems in adults

Andrew O. Frank

Summary

Back pain has now reached epidemic proportions in Western societies. Few with back pain have serious medical (non-spinal) conditions, significant spinal pathology, or direct involvement of nerve roots such as to require surgery. Although the causes of back pain remain unclear, the effects at work or leisure of physical stress and its consequences on discs, facet joints, and supporting soft-tissue structures are mostly implicated.

Modern management emphasizes the role of self-care, which should begin in general practice at presentation of the first episode and be reinforced by all health professionals. In the absence of root compression, bed rest should not usually be longer than 48 h. A positive approach is encouraged, acknowledging that returning to a normal life may require working through pain. More emphasis is laid on actively encouraging a return to physical fitness and other activities, including employment. Medication plays a part in facilitating these objectives. The role of tricyclic antidepressants to break pain cycles and treat the depression that may be present in long-standing pain syndromes is increasingly thought to be valuable.

Studies have shown our ability to lessen the duration and severity of individual episodes of back pain, and reduce recurrences and their cost in terms of suffering and lost work. No one should remain in pain longer than 6 weeks without being referred to a specialist service. This should include provision of information, access to manual therapists with postgraduate training (or other appropriately trained manipulators if physiotherapists are not available), education on back-strain prevention and physical fitness, pain services through clinical psychology, and consultant rheumatological or orthopaedic support. Comprehensive (and inpatient) pain and rehabilitation services should be accessible to all populations (e.g. through a regional service).

The main challenges for the future lie in detecting those individuals who are unlikely to respond well to physical and educational measures so that a major emphasis on developing coping strategies, reducing the inhibitory effects of fear, and managing social issues may reduce the number of people who will require costly, intensive, and probably inpatient rehabilitation.

Never again should it be said that 'there is nothing to be done for backache'.

Introduction

In Great Britain, between 3 to 7 million people consult their general practitioner each year for back pain and over 1 million visit hospital annually (Fig. 1). Many are likely to be out of work (Table 1), taking medication, and probably making demands on primary and secondary health care as well as the private sector (both orthodox and heterodox practitioners) (Clinical Standards Advisory Group 1994a).

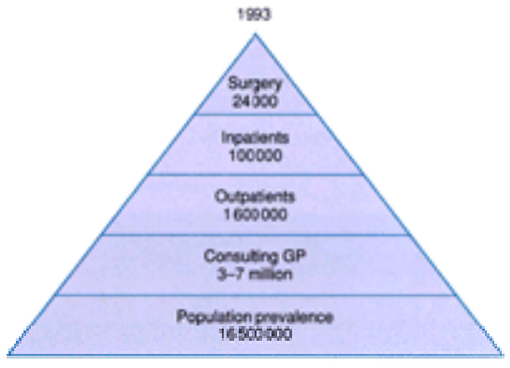

Fig. 1 Estimated annual healthcare for back pain in 1993 —from Report of a Clinical Standards Advisory Group Committee 1994 (United Kingdom)

Estimated total work incapacity:
150 million working days, 1993
Lost output:
Estimated loss (1993) £3800 million
General practitioner consultations:
Estimated 3–7 million annually
Hospital outpatient consultations:
Estimated 1.6 million annually
Hospital inpatient episodes:
Estimated 100 000

From Clinical Standards Advisory Group (1994a).

Table 1 Estimated consequences of the back-pain epidemic 1993 (United Kingdom) From Clinical Standards Advisory Group (1994a).

Definition of low back pain is difficult (Spitzer 1987). In this chapter the term 'low back pain' will imply the symptom complex where pain is localized to the lumbar spine or refers into the leg or foot, and where other specific conditions causing such pain have been excluded (hereafter referred to as low back pain). As pain from non-disc structures such as facet joints causes pain that may refer to the distal leg and foot (Mooney and Robertson 1976), the term sciatica is not used and 'leg pain' is used instead.

The Clinical Standards Advisory Group (1994 *a*) has recommended the term 'simple backache' for this group of patients. I have not adopted this term because I believe that many patients in severe distress will have difficulty accepting their doctor's advice if this term is used. Other terminology used in this chapter is shown in Table 2: it has been modified from the Quebec Task Force (Spitzer 1987), who used the period of 7 weeks to define the transition from subacute to chronic pain—assuming that healing would have taken place by 7 weeks and thus pain should have disappeared. Whether it is realistic to assume this time scale for the healing of tissues that are being continuously stressed mechanically is questionable. It must be emphasized that the precise timings suggested in this chapter are less important than the idea that the pattern of underlying spinal (dys)function will change over time. Health workers must adopt strategies that allow for this.

Acute pain: from 0–7 days duration (pain-free at onset)
Acute on chronic pain: significant exacerbation of pre-existing pain
Subacute pain: from 7 days to 3 months' duration
Chronic pain: duration over 3 months
Chronic pain syndrome: psychological and social consequences of chronic pain influencing behaviour
Intractable pain: failed conservative treatment of chronic pain
Back school: outpatient programme of treatment emphasizing educational management
Intensive rehabilitation: multiprofessional combination of skills and therapeutic modalities to minimize pain and disability
Lumbar segment: two adjacent vertebrae and their intervening soft tissues (Waddell 1982)

From Frank (1993a).

Table 2 Terminology

Most of us assume a biomechanical basis for spinal pain, although we seldom understand why some patients suffer badly and others do not. Explanations will probably be found in factors such as the elasticity of the soft-tissue, spinal-support structures, the biochemistry of the disc, and the shape and size of the spinal canal. The roles of the dorsal horn of the spinal cord and areas of the brain are discussed by Jayson (1994).

Doctors trained to intervene in well-understood disease processes may have difficulty in coping with spinal pain (Roland 1994), where there are few objective physical signs and no laboratory investigations to confirm the precise cause and severity of the complaint (Waddell 1982). The availability of MRI and CT scanning is gradually expanding our understanding of back pain (Butler *et al*. 1990), but the majority of people with minor symptoms will not have the advantage of these investigations, which may not be helpful. Consequently, many doctors have difficulty in inspiring confidence in their patient, who may therefore seek help from heterodox practitioners (Moore *et al*. 1985; Aldridge 1989).

Back pain is an extraordinarily complicated subject. Our seeming inability to help many people suffering from it is reflected in the large number of therapies available to the average district general hospital (Table 3). It is possible that medical training hinders a satisfactory approach by concentrating on the exclusion of pathology, when what patients want is understanding of their problems (Armstrong 1991), alleviation of their symptoms, and positive encouragement that activity will not harm them but be therapeutic.

Table 3 Therapeutic options

An individual's attitudes, personal strengths, and weaknesses may also play a part: e.g. in their positive or negative responses, the reactions of family and colleagues, and their ability to 'fight' to prevent recurrences. Thus a positive attitude is required from 'professional advisors' from the initial acute attack onwards. Some would argue that the two questions in back-pain management are: (i) when to take control of the pain from the patient; and (ii) when (and how) to return control to them. Thus 'person management' is a prerequisite to back-pain management, and to translating rehabilitation philosophy into back-pain practice.

Most attacks are short and self-limiting. Those remaining episodes may require additional therapy that may sometimes need to be organized through hospital. A combination of the measures outlined (Table 3) may be needed, but these more difficult problems are mostly resolved or greatly alleviated within a year. A few patients, however, do badly. They should be considered as 'failed conservative treatment' and require different strategies of management (see Intractable back pain below).

The specific management of lumbar disc disease is discussed in Chapter 5.18.1 and of the cervical spine in Chapter 5.18.2. Spinal problems in children are reviewed in Chapter 1.2.1.2.

The spine

The spine is extremely complex, constituting 139 joints, 24 discs, numerous bursas, and a vast number of ligaments and muscles comprising support structures.

The five lumbar vertebrae are linked by intervertebral discs anteriorly, two synovial facet joints posteriorly, and many supporting structures including ligaments and muscles. A segment is defined as two adjacent vertebrae and their intervening soft tissues (Waddell 1982). Pain, a subjective symptom, may arise from any of these structures, which are all innervated, and is the cardinal feature of spinal disorders.

Compartmentalization of the spine into cervical, thoracic, and lumbar regions makes sense on anatomical grounds but may hinder realistic approaches to treatment. The cervical spine has a low weight-bearing capacity. The atlantoaxial and facet joints are designed to facilitate mobility. The thoracic spine is splinted by the costovertebral joints, possibly explaining the decreased frequency of symptoms arising from the thoracic spine (Waddell 1982; see also Table 4). The lumbar spine is designed to take the weight of the upper part of the body, with less facility for movement.

Table 4 Conditions presenting to a rheumatology clinic with an interest in spinal conditions

Non-specific low back pain, that is pain to which no specific pathological (as opposed to degenerative) process can be attributed, may occur through all age groups for differing reasons. Under the age of 25, congenital factors are likely to be involved (Table 5): for example, the size and shape of the spinal canal may be a key factor in determining who will suffer symptoms from degenerative spinal disease (Porter *et al*. 1978). Disc lesions are more likely in early middle life. In later years the aftermath of previous disc disease may be seen in the form of osteoarthrosis of the facet joints. In old age, osteoarthrosis may be compounded (particularly in women) by osteoporosis. Exceptions abound: for example, adolescent discitis. Injuries caused by overuse of poorly prepared structures during sport and leisure occur at any age. Facetal osteoarthrosis rarely precedes disc disease (Butler *et al*. 1990).

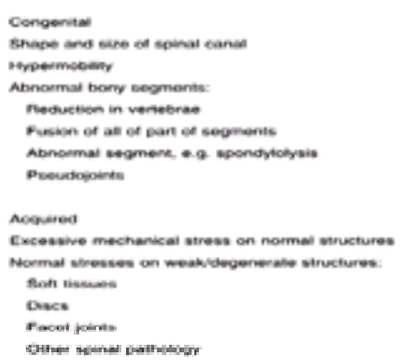

Table 5 Potential factors predisposing to spinal pain

Mechanical stress is taken predominately through the lower cervical and lower lumbar segments. It is not surprising that lesions at these two sites often coexist. It is thus important to consider the spine as a whole to ensure that advice given for one area does not aggravate another. Thus, advice to a patient with acute back pain to rest prone may be counterproductive as this sleeping posture often aggravates pain arising from the neck.

This chapter will, for brevity, concentrate on management of pain arising from the lower spine, as this problem seems to have a greater effect on the economy through sickness absence from work.

Difficulties with the evaluation of therapies for low back pain

The clinical course of low back pain creates difficulties for the investigator. Up to 85 per cent of patients with low back pain cannot be given a definitive diagnosis (Deyo 1991) because of the poor associations between symptoms, signs, imaging results, and pathological findings. In chronic back pain, the intercurrent effects of exacerbations on the underlying pain make assessment difficult, as it is hard to distinguish this from a new attack of pain. The assessment of pain is outside the scope of this review, but the pain/disability scores used in the best studies may not discriminate between the physical and psychological components of low back-pain disability (Main *et al*. 1992).

Many studies have not differentiated between acute, acute on chronic, chronic, and intractable pain. Whilst arguably failing to differentiate between nociceptive pain and pain where other factors may be of importance (e.g. pain/sickness behaviour), in practice it has been shown that some people respond to physical measures in spite of pain lasting longer than 1 month (Meade 1990) or many months (Koes *et al*. 1992). In particular, studies of chronic pain have not differentiated between previously untreated chronic pain and pain that has not responded to standard conservative therapy. For this group the term 'intractable back pain' has been suggested (Frank 1993a).

The scope and techniques involved in the many types of manipulation vary (Spitzer *et al*. 1987) and are beyond the scope of this review. In all studies, readers should take account of the method(s) of manipulation used. The study by Carette *et al*. (1991) demonstrated the importance of a placebo group in studies of low back pain. This common response may reflect not only the non-specific effects of attention and caring (Deyo 1991) but also the transfer of responsibility of care from 'self' to a trained individual (Fordyce *et al*. 1986). In addition there is the constant variation of intensity and duration of symptoms—particularly of rapid improvement for most with acute low back pain. The difficulties of assessing studies on therapy in low back pain are reviewed elsewhere (Deyo 1983; Spitzer *et al*. 1987; Koes *et al*. 1991), but, for some patients, benefit has been demonstrated in randomized controlled trials and I have concentrated (not exclusively) on reviewing such studies.

Epidemiology

Scale of the problem

The scale of the back pain epidemic (Editorial 1989a) is frightening and of enormous economic proportions (Table 1). The Clinical Standards Advisory Group (1994a) has estimated that costs to the National Health Service in the United Kingdom in 1993 were £481 million. Indirect costs were estimated to exceed £5 billion for lost work (Fig. 2) and social security benefits alone. In the United States, medical costs exceed $24 billion (Lahad *et al*. 1994) and indirect costs may exceed $30 billion (Frymoyer 1993).

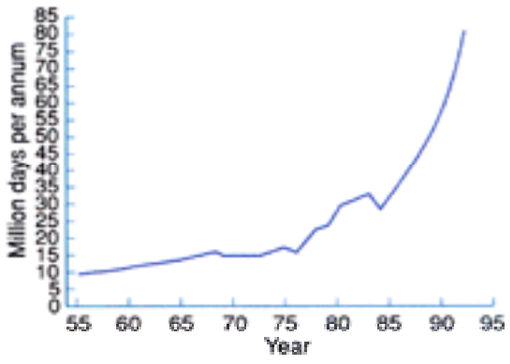

Fig. 2 Total British Sickness and Invalidity benefit for back incapacitation — from a Report of the Clinical Standards Advisory Group Committee (1994)

There are no recent data on the frequency of cervical pain: a relatively recent report did not distinguish between upper or lower back pain (Leigh and Sheetz 1989), and low back pain has been studied in more detail. The limitations of epidemiological techniques in studying this problem are discussed elsewhere (Wood and Badley 1980). In the United Kingdom it is estimated that there are 12 million general practitioner consultations annually for low back pain, resulting in 2.4 million outpatient visits (Clinical Standards Advisory Group 1994a). In 1993, approximately 100 000 people were admitted to hospital for spinal pain in England, Scotland, and Wales (Clinical Standards Advisory Group 1994a) (see Fig. 1), of which about 3 per cent may be cervical (Wells 1985).

Approximately 12000 operations are performed on lumbar discs annually in the United Kingdom (Clinical Standards Advisory Group 1994b), with less than 2000 fusions. In contrast, in the United States, approx. 200 000 surgical procedures involving lumbar disc excision are performed each year. Of these, as many as 30 000 are unsuccessful, joining the 'high-cost, high-demand, and highly emotional subset of the low back disabled' (Hanley 1992). The chances of any individual coming to back surgery are six times greater in North America than in Europe, with documented variations of nearly twofold in rates of disc excision in different parts of the United States (Keller 1992). Rates for cervical and lumbar spine surgery in hospital are increasing rapidly for both sexes in the United States (Davis 1994; Taylor *et al*. 1994). There are wide variations in rates for spinal surgery, being greatest in the United States, where there was more than five times the rate of the least, England and Scotland (Cherkin *et al*. 1994).

Conversely, low back pain is a relatively small cause of permanent, severe disability. Figures vary from 34 to 52 per 1000 people with significant morbidity from low back pain, of which only 0.2 to 4 per 1000 are severely disabled (Wood and Badley 1980). Nonetheless, consequences for employment and provision of health care are enormous. Back pain is one of the most common causes of inability to work through illness in the United Kingdom, with a total work incapacity estimated at 150 million days lost in Britain in 1993 at a cost of £5.2 billion. Such calculations of lost output and social security costs ignore the effects on individuals, their families, and of litigation.

Prevalence

Back pain is predominantly a feature of Western society. Chronic disability from the 'back pain epidemic' did not exist until legislated social support became available at the end of the nineteenth century (Allan and Waddell 1989). In the United Kingdom, the point prevalence of back pain is 14 per cent, period prevalence is 39 per cent in 1 month and 36 to 37 per cent in 1 year, and lifetime prevalence is 58 per cent (Clinical Standards Advisory Group 1994b).

The cumulative lifetime prevalence of episodes lasting two or more weeks in the United States is approx. 14 per cent, with a point prevalence of 7 per cent at any moment in time (Deyo and Tsui-Wu 1987). Of those reporting an episode of 2 weeks or more, about one-third had pain of less than 1 month's duration, about one-third had pain lasting 1 to 5 months, and the remaining one-third pain lasting 6 months or more (Deyo and Tsui-Wu 1987). The cumulative lifetime prevalence was greatest in the white population, and varied with the region of the United States and with the degree of education (greater prevalence with lesser education). The usual average age of presentation to back-pain clinics is around 40, with greatest prevalence between 45 and 64 years (Deyo and Tsui-Wu 1987; Leigh and Sheetz 1989; Clinical Standards Advisory Group 1994b).

The lifetime prevalence rate in 14-year-old Finnish schoolchildren is 30 per cent (Salminen *et al*. 1992). This suggests that lifetime prevalence data, which rely on patients' remembering symptoms from the past, may underestimate the problem.

Sex

There may be differences in spinal structure between males and females (Cooper *et al*. 1992). Back pain is equally prevalent in both sexes (Walsh *et al*. 1992a), although its clinical course may be different. Thus those requiring surgery are more frequently men (Davis 1994), possibly because disc disease is more prevalent in men (Kelsey *et al*. 1984), whilst women are more likely to attend a pain clinic (Davies *et al*. 1992). Fordyce *et al*. (1986) has noted that males may be more likely than females to incur back pain that brings them to the health-care system for help, but females may be more likely than males to have back pain that lingers into chronicity. It is unclear whether these differences relate to physical, psychological, or social factors. In men, the only socioeconomic link with back pain seems to be a manual occupation (Croft and Rigby 1994). Women with no formal educational qualification, or who lived in households in the lowest income category, are more likely to have back pain, but the reasons for this are not known (Croft and Rigby 1994).

Nearly half of all pregnant women suffer from back or posterior pelvic pain during pregnancy, often losing time from work (Ostgaard *et al*. 1994). The relation between low back pain and pregnancy, menstruation, and the menopause has been extensively investigated and reviewed. Pregnancy is a factor contributing to the problem of low back pain, with the number of abortions and a higher number of live births being associated. Hormonal changes are also important, particularly as they influence the development of osteoporosis (Svenson *et al*. 1990). Thirty-five per cent of women aged 16 to 34 years thought their back pain started in relation to pregnancy or childbirth (Mason 1994). There is currently considerable debate as to the relation between epidural analgesia and postpuerpural back pain (MacArthur *et al*. 1993). Back pain appears to occur more frequently after epidural analgesia, but the cause is thought to be postural, and the pain is not severe (Russell *et al*. 1993).

Occupation

The relation between low back pain and occupation has been recognized since at least 1705 (Allan and Waddell 1989). The 'railway spine' became recognized as being more common than backache in mariners, miners, and labourers (Allan and Waddell 1989). Jobs requiring physically heavy work, static work postures, frequent

bending and twisting, lifting and forceful movements, and repetitive work and vibrations (including those from driving vehicles; Frymoyer *et al*. 1983; Kelsey *et al*. 1984; Behrens *et al*. 1994) predispose to low back pain (Andersson 1981).

Psychological factors, such as monotony and dissatisfaction at work are implicated (Andersson 1981; Bergenudd and Nilsson 1994). Individuals who stated that they 'hardly ever' enjoyed their job tasks were 2.5 times more likely to report a back injury than those who 'almost always' enjoyed them (Bigos *et al*. 1991). Many blue-collar workers believe that work contributes to their back pain, although correlations with observed physical-work demands are not always present (Lindstrom *et al*. 1994).

There have been several studies on the frequency of back pain in hospital workers (Kaplan and Deyo 1987). Nurses are at high risk of back injury, being greatest for those doing the most physical work (aides and auxiliaries) and least for registered nurses. Indeed, nursing auxiliaries have a greater annual incidence of back pain than construction workers, garbage collectors, and truck drivers (Kaplan and Deyo 1987).

Risk of recurrent attacks/return to work

Factors influencing a return to work are sex, duration of sick leave, reported need for analgesics, pain in the dorsal and cervical regions of the spine (in addition to lumbar pain), patients' negative attitudes to their own capabilities, and after-work fatigue (Sandstrom 1986).

The recurrence rate of occupational back pain from any part of the spine in Canada was 20 per cent at 1 year and 33 per cent at 3 years. Men had a higher chance of recurrence. There was a lower risk of recurrence for thoracic symptoms than for cervical and lumbar symptoms, which had an equal risk. Drivers had the highest recurrence rate and nurses the highest average number of recurrences (Abenhaim *et al*. 1988).

In England, Troup *et al*. (1981) examined all patients returning to full-time work after sickness absence following an episode of low back pain or an accident at work. Residual pain in the leg and positive clinical signs on return to work, longer sickness absence, and two or more previous attacks were associated with recurrences. Falls were associated with a longer period of absence after the current attack and a higher rate of recurrence. Caldwell and Glanville (1980) followed a cohort of 373 patients under the age of 40 years presenting to general practitioners or hospital consultants in 1963. Only 11 per cent of patients had had a single attack, though the majority of attacks lasted fewer than 2 weeks. Only 33 per cent had had no time off work due to back pain over the 10 years, 3.3 per cent of men gave up work or took early retirement, 21 per cent changed job, 10 per cent took a reduction in working hours, and 19 per cent of men and 10 per cent of women had loss of income or potential income from their pain.

In Sweden, the pioneering work of Bergquist-Ullman (1977) showed that, in a population of workers at the Volvo plant, episodes of pain lasted less than 1 month in 35 per cent, less than 3 months in 87 per cent, and 4 per cent had pain at 1 year. The mean duration of pain was 35 days. Just over 60 per cent of this group had recurrences during the first year (mean 1.3 per patient).

A history of previous low back pain remains the single most useful predictor of future episodes of pain (Harber *et al*. 1994).

Other social factors

A high incidence of social factors has been found in back patients. Their social and economic situation is on average less good, a greater proportion suffer from drug and alcohol abuse, divorces and family problems are more frequent, and their educational level is often found to be lower (Andersson 1981; Croft and Rigby 1994). It is difficult to assess whether such factors are primary or secondary, and the interrelations with smoking and occupation are unclear.

Risk factors

Smoking is a risk factor for prolapsed lumbar intervertebral disc (Kelsey *et al*. 1984; Battie *et al*. 1991), as well as for the first attack (Biering-Sorensen *et al*. 1989) and the severity of low back pain (Frymoyer *et al*. 1983). A dose–effect relation was found between the severity of back pain and both the number of cigarettes smoked and the duration of smoking (Frymoyer *et al*. 1983). Possible explanations include impaired blood supply to the involved spinal segment (Frymoyer *et al*. 1983; Battie *et al*. 1991), carbonmonoxidaemia (Dimberg *et al*. 1989), coughing (Biering-Sorensen *et al*. 1989), and ergonomic factors related to smoking, which may be associated with people's attitudes, life-styles, and behaviour patterns (Frymoyer *et al*. 1983; Dimberg *et al*. 1989; Battie *et al*. 1991).

Vibrations around 5 Hz are the most troublesome in relation to back pain, which may explain the prevalence of back pain in those spending prolonged periods in motor vehicles (Editorial 1989b). A mismatch between physical stress and strength predisposes to back problems (Editorial 1989b).

Walsh *et al*. (1992b) have shown that a person under the age of 60 who is admitted to hospital for a traffic accident or a fall has a 7 per cent chance of developing low back pain as a result of the injury. The link between the injury and subsequent symptoms is often not obvious to the patient.

Health associations

Previous hospital admissions/operations are more frequent in those with a first episode of low back pain (Biering-Sorensen *et al*. 1989). People with back pain appear to have a propensity to use health services. Porter and Oakshot (1994) has shown that cardiovascular and gastrointestinal symptoms are more common in those with narrow spinal canals. Those with wider canals had more post-school qualifications than those with smaller canals. He postulates that the association between a smaller canal and impairment of health and certain intellectual abilities may result from an adverse environment that affects growing systems early in life (Porter and Oakshot 1994).

The associations with smoking (see above) may be linked with atherosclerosis of the abdominal aorta. Kauppila *et al*. (1994) examined 86 males at autopsy, comparing radiological evidence of disc degeneration with the presence of atherosclerosis of the abdominal aorta. They postulated that stenosis of the ostia of the segmental arteries may play a part in lumbar disc degeneration. These findings may explain the increased risk of dying from ischaemic heart disease in a cohort of Finnish farmers aged 30 to 49 years who reported low back pain or sciatica in a postal survey (Penttinen 1994).

The nature of low back pain

Waddell (1982) has helpfully classified low back pain into that caused by mechanical back pain (arising from the lumbar segment without direct nerve-root involvement); direct nerve-root involvement from structures within the lumbar segment; and spinal pathology, which includes inflammatory disorders such as ankylosing spondylitis, tumour, infection, bone disease (e.g. Paget's), and primary neurological disease (Table 6).

Table 6 Some causes of low back pain

Over 90 per cent of all episodes of low back pain may be considered idiopathic when non-spinal conditions (e.g. arthritis of the hip, proximal myopathy) and spinal pathology have been excluded. The important questions relate to whether the pain that arises from the lumbar segment does or does not involve the nerve root.

Many treatments for low back pain are based on the assumption (Frank and Hills 1988) that it is usually associated with excessive mechanical stress at work or leisure on normal structures, normal stresses on degenerate discs/facet joints, or the poorly resolved aftermath of an acute episode (e.g. a lifting injury). The physical nature of the problem has been identified in the epidemiological section above. Thus doctors and therapists have concentrated on physical measures to alleviate the problem. More recently, attention has been paid to psychological approaches to management. Whilst this has been predominately aimed at helping those with prolonged and chronic low-back pain, an intriguing use of the behavioural approach to back-pain management in acute situations is described by Fordyce *et al*. (1986).

Bremner and Simpson (1959) commented that “the patient's ability to 'live with his back' seems to be more important than the form of treatment”. It is likely that the longer an episode continues, the more important it is effectively to manage individuals and their problems. Most programmes for chronic back-pain sufferers and 'back schools' have a major emphasis on psychological management.

Few studies have followed patients over many years. In contrast to the pessimistic outcome described by Caldwell and Glanville (1980), Wilson and Wilson (1964), who studied 117 employees 10 years after an episode of back pain, found that 52 per cent had remained at work over 10 years without time off (including 50 per cent of the heavy manual workers), although over 80 per cent of those at greatest risk had recurrences. Only 13 patients were referred to hospital after failed therapy at work; only two changed job. They concluded that patients should be treated optimistically and not given bed rest or referred to hospital if this could possibly be avoided. This sentiment is now being repeated nearly 30 years later by Waddell (1987), to whom the 'back pain epidemic' is partly contributed to by doctors prescribing rest and partly by social concepts of disability, and who contrasts the traditional medical model of illness with a biopsychosocial model (Fig. 3).

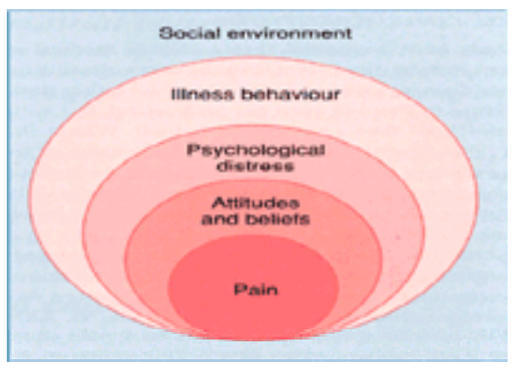

Fig. 3 A biopsychosocial model of low back pain disability — from Report of a CSAG Committee 1994.

Most attacks of acute low back pain are self-limiting and of short duration (Coste *et al*. 1994), although this picture has recently been challenged by Von Korff *et al*. (1993), who followed a cohort of patients in primary care for 1 year. They showed that 69 per cent of patients with pain of recent onset had had pain in the previous month, compared with 82 per cent of those with pain of greater than 6 months' duration. The important fact is that once an individual has had a major episode of back pain, the risk of a recurrent attack is always present (see Occupation above). Management must emphasize the importance of adopting strategies in the patient's life that minimize the risks of such attacks (see Table 7 and Table 8). At this stage a positive attitude is essential, minimizing rest and medication (Von Korff *et al*. 1994).

Things to avoid
Prolonged leaning forward, e.g. by use of long-handled garden tools; bath/change nappy/dress baby on high table with everything handy
Non-stop driving (longer than 30 min)
Soft or unyielding mattress
Low easy chairs
Lifting with a bent spine or with outstretched arms
Jerking or twisting the spine
Overstretching, e.g. reaching into high cupboards
Uneven loading of spine, e.g. shopping should be carried in two evenly weighted bags

Things to consider
Frequent changes in posture during routine activities
Seating modifications at work/hobbies
Use small lumbar supports in seats
Use castors on heavy furniture, e.g. fridges
Use webbings to assist lifting awkward furniture, e.g. wardrobe
Regular exercise, e.g. swimming
Sweep and brush with a sideways action from upright posture
Daily relaxation regime
Use of orthotic heelpads or wearing trainers (sneakers in North America) if standing or walking continuously

Source from Frank and Hills (1988).

Table 7 Some suggestions for those with spinal pain

Task	Method
Washing up	Raise bowl within sink or use high stool to sit on
Ironing	Use adjustable height ironing board and high stool
Loading washing machine/ dishwasher	Kneel to load, use front loaders; for top-loading washing machines use longs
Making beds	Perform kneeling — consider duvets
Cleaning bath	Clean from inside; kneel outside; use short-handled mops and rinse with shower attachment
Brushing teeth	Do sitting*
Washing hair	Stand upright using shower attachment
Picking up	From kneeling or squatting position, use 'helping hand' for light objects if unable to kneel, e.g. for osteoarthritic knees
For older people	
Getting up	High chairs
	High toilet seats
	Appropriate height of bed

Table 8 Hints to avoid bending and stooping

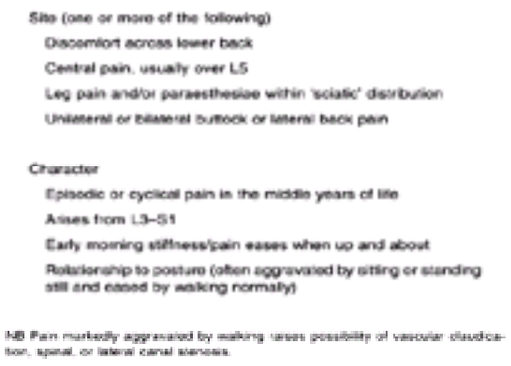
Differential diagnosis

General considerations

It has already been suggested that a strictly medical approach to management may be disadvantageous by concentrating on the exclusion of other diseases presenting as spinal pain rather than dedicating sufficient time to helping patients understand the nature of their problem and how they can best be helped. Whilst the measures outlined (Table 3) will help, much of the control of the situation needs to be grasped by the patient. Ultimately the patients' attitudes to avoiding aggravating factors, to exercise (Philips *et al*. 1991), and to a positive approach may be more important than physical management (Frank and Hills 1988).

It is important to balance safeguarding the requirement not to miss treatable organic pathology with the need to avoid unnecessary and costly investigations. This is best achieved by pattern recognition of common presentations of low back pain (Table 9). Although often diagnosed by exclusion, non-specific low back pain should be diagnosed on positive grounds (Table 9). Sometimes one side predominates, or more rarely the pain is entirely localized to a buttock or leg. Not infrequently the pain may be localized to the midline. Leg pain is not an uncommon presentation, usually felt within the sciatic distribution on the lateral border of the calf, or rarely the

foot. A careful history often gives a pattern of occasionally radiating up to the buttock or back. Sometimes paraesthesias give a clue as to the nature of the underlying pain in the presence of atypical leg pain. There are three important groups of patients to consider: those with non-specific low back pain ('backache'), nerve-root compression, and back pain caused by other conditions (Clinical Standards Advisory Group 1994a). More complex algorithms can be consulted (Waddell 1982; Gavin and Wiesal 1991), and a fuller review of the differential diagnosis is available (Jayson 1992).



Site (one or more of the following)
Discomfort across lower back
Central pain, usually over L5
Leg pain and/or paraesthesiae within 'sciatic' distribution
Unilateral or bilateral buttock or lateral back pain

Character
Episodic or cyclical pain in the middle years of life
Arises from L3–S1
Early morning stiffness/pain eases when up and about
Relationship to posture (often aggravated by sitting or standing still and eased by walking normally)

NB Pain markedly aggravated by walking raises possibility of vascular claudication, spinal, or lateral canal stenosis.

Table 9 Features of non-specific mechanical low back pain

Other factors suggestive of the symptom complex of mechanical low back pain are episodic or cyclical pain in the middle years of life arising from the L3–S1 area, associated with morning stiffness/aggravation of pain that lasts until the individual is up and about (Waddell 1982). A marked relation to body posture is common: the pain is often aggravated by sitting or standing still and eased by walking at a normal pace. Pain markedly aggravated by walking raises the possibility of vascular claudication, or stenosis of the spinal or lateral canals.

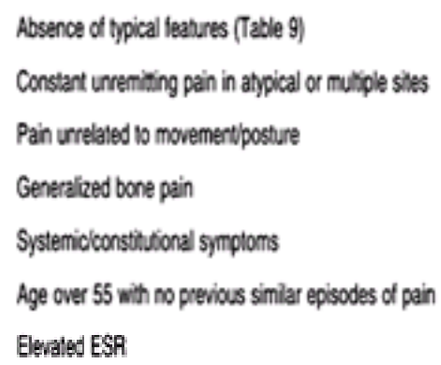
Thoracic pain is much less common than either lumbar or cervical pain (Table 4) and always requires investigation. Often, in older patients, vertebral collapse will be due to osteoporosis, but a high index of suspicion is required to exclude myeloma or secondary malignancy. Tuberculosis classically effects the lower thoracic or upper lumbar vertebrae (see Infections below).

Investigations—exclusion of other pathology

Age is important. Before the age of 25, radiographs are indicated to exclude congenital disorders such as spondylolisthesis (Waddell 1982). Inclusion of the sacroiliac joints will help exclude ankylosing spondylitis. The sudden onset of low back pain after the age of 55 warrants investigation. In a series of 900 patients presenting to an orthopaedic back clinic, 46 per cent of those over 55 had a definite abnormality, including 11 per cent with malignant disease (Waddell 1982). Patients over 55 presenting with episodes of pain similar to those suffered earlier in life do not usually require investigation.

Different clinics will have variable referral patterns. The relative rarity of infections and malignant disease is seen in Table 4: 825 consecutive referrals to a rheumatologist with an interest in back pain are reviewed with 1336 diagnoses; only nine tumours were found, just under 1.1 per cent of the 825 patients, not all of whom had spinal pain. It should be noted how even such a crude diagnostic index demonstrates the frequency of multiple rheumatic diagnoses. Ankylosing spondylitis and metabolic bone disease were the most common diagnoses other than non-specific or degenerative back pain.

Thus most patients with back pain will not require investigation to exclude pathology. In this situation, radiographs will only be needed for reassurance that serious pathology is not present, to explain possible mechanical factors to the patient, or to assist physiotherapists in their management. Usually blood tests are not helpful, but when in doubt an erythrocyte sedimentation rate is the most helpful screening test (Waddell 1982). Table 10 outlines factors that should alert physicians to the possibility that the cause of back pain may be sinister.



Absence of typical features (Table 9)

Constant unremitting pain in atypical or multiple sites

Pain unrelated to movement/posture

Generalized bone pain

Systemic/constitutional symptoms

Age over 55 with no previous similar episodes of pain

Elevated ESR

Table 10 Features suggestive of malignancy

The same principles hold true for those with a previous history of cancer, as they will frequently suffer from mechanical low back pain. As radiographs may not show deposits till late in the disease, a higher threshold for radiological investigation is needed (Table 11). In this situation a bone scan is often the most helpful investigation unless the level of the lesion is clearly established on clinical grounds.

Table 11 Guidelines for radiological investigation

Leg pain

There is a widely held belief that pain in the leg invariably reflects nerve-root pain and usually is caused by disc disease. That this is not necessarily so was demonstrated by Mooney and Robertson (1976) with their pioneering work on the facet joint. They demonstrated that injection into the facet joints caused intense local pain that subsequently radiated posteriorly down the leg and sometimes into the foot. Hamstring spasm subsequent to this was abolished by local anaesthetic. In

some patients, previously reduced tendon reflexes returned to normal. Thus leg pain (even below the knee) can arise from the facet joint (Mooney 1992) and probably most structures within a segment.

Leg pain caused by root irritation is generally more clearly defined, sharper, and often has an element of paraesthesia (Waddell 1982).

Extraspinal causes of pain

Three per cent of apparent back troubles presenting to an orthopaedic clinic are due to extraspinal causes such as retroperitoneal or pelvic pathology, hip disease, peripheral vascular disease, or primary neurological disease (Waddell 1982), and need appropriate investigation.

Pelvic pathology is not easy to exclude on history as many women notice that their pain is more severe in the last few days of their menstrual cycle, easing off on the first or second day of their period. This may also be noted in women with neck pain or headaches and is non-specific. Where there is doubt, abdominal and pelvic examinations are required.

Spinal causes

Children and adolescents often require investigation. Acute pain may be caused by spondylolisthesis or by a developing scoliosis and warrants referral to a specialist orthopaedic clinic. In the absence of spinal disorders, adolescent discitis may cause severe pain and only be diagnosed retrospectively. Physiotherapy is important in this condition.

Spondylolisthesis is not uncommon and is usually unrelated to low back pain. At the L5/S1 level it is usually stable and does not require follow-up. At the L4/L5 level, however, instability may develop (diagnosed by lateral lumbar spine views in flexion and extension) and on occasions requires fusion, particularly if root involvement is present.

Lumbar disc disease

This is considered separately in Chapter 5.18.1, but it is the most frequent major pathology seen in back pain clinics and requires some consideration here. Firstly, physicians must know when to investigate to ensure that they are not missing surgically correctable pathology. It is the presence of nerve-root compression that usually benefits from surgery by decompression. Here, leg pain usually dominates over back pain. The presence of symptoms correlating with objective physical signs (usually of loss of sensation, power and/or reflexes), confirmed by myelography or an equivalent scanning technique, suggests that surgery should be 95 per cent successful (Bell *et al*. 1984). Secondly, it is important to recognize that a central disc prolapse may give bilateral leg pain in the absence of demonstrable signs and with a normal straight-leg raise test. Sphincter disturbances may reflect spinal-cord compression and often require emergency treatment.

Spinal stenosis

Spinal stenosis is a symptom complex of root pain and sensory or motor symptoms that come on during walking and that pass off after a few minutes of sitting down or flexing the spine. Symptoms may be aggravated by extension (Waddell 1982). Although occasionally symptoms are associated with a congenitally narrow spinal canal, more often additional pathology develops in later life. This may reflect disc disease or osteoarthrosis of the facet joints separately or together combining with hypertrophy of the soft tissues (particularly the ligamentum flavum) to compress the cauda equina. If such compression is predominately lateral, usually due to bony outgrowths from an osteoarthritic facet joint, the term 'lateral canal stenosis' is sometimes used. There may be narrowing of the exit foramen, compressing the root, and resulting, when bilateral, in a trifoliate shape to the canal (Porter 1992; see Fig. 4).

Fig. 4 Spinal stenosis secondary to a combination of degenerate disc protruding posteriorly and laterally (a) and hypertrophy of the ligamenta flava (b) in an individual with osteoarthritis in the facet joints intruding into the lateral recesses (c) to produce symptoms of spinal stenosis. The anterior margin of the disc is degenerate (d).

Infections

Brucellosis is a disease of those working in abattoirs, or with animals, such as vets. Back pain may be very generalized and often associated with evidence of systemic disease. In contrast, most infections of the spine are clearly localized and give rise to constant pain, often in an unusual or atypical site.

Tuberculosis classically affects the lower thoracic or upper lumbar vertebrae and must always be considered for people at risk for this disease, for example, in the United Kingdom, those arrived as immigrants from the Indian subcontinent within the last decade, the frail elderly, or those immunocompromised from therapy or for other reasons. This is in distinction to degenerative lumbar disease that usually affects the L5/S1 or L4/L5 levels (Kelsey *et al*. 1984) or less commonly L3/4. Other organisms may be found, such as staphylococci. Where suspicion exists without localizing changes on plain radiographs and no certain spinal level found, a bone scan may be helpful, although not all tuberculous lesions produce a hot spot. If a level is suspected, CT or MRI will confirm abnormalities. Biopsy under radiological guidance or occasionally an open biopsy will usually provide microbiological and histological evidence of the causal organism. Confirmation of tuberculosis is not always obtained and occasionally a trial of antituberculous chemotherapy is needed.

Tumours

Primary tumours of the spine are rare and outside the scope of this chapter. Benign tumours may be found in the upper lumbar spine and are easily missed if too much reliance is placed on CT scanning as the reliability of CT depends on the correct levels being scanned. Myelography or MRI may be required to exclude such tumours (Bell *et al*. 1984).

Secondary tumours from myeloma, lymphoma or carcinoma present to all back clinics. Suspicion is raised (Table 10) by constant unremitting pain in unusual or multiple sites in an individual with systemic symptoms. Routine haematological and biochemical investigations will usually confirm the presence of disseminated disease. Spinal investigations will follow the pattern outlined above for infection (Table 11).

Ankylosing spondylitis

This is the most common specific condition to present in a back-pain clinic: it is more frequent in men than women and usually presents at a younger age than mechanical or discogenic back pain. Stiffness, particularly in the morning, is usually a cardinal symptom; it is usually relieved by movement and/or exercise. It is important to diagnose ankylosing spondylitis as early as possible as its treatment differs from that of non-specific low back pain and because of its family and other associations. A vigorous exercise programme maintains spinal movement (thus preventing spinal contracture) and may inhibit the process of calcification at the enthesis. There is usually a good response to non-steroidal anti-inflammatory drugs, particularly if a long-acting preparation is taken after food last thing at night as it

inhibits the early-morning pain and stiffness. This facilitates performance of the recommended early-morning exercise programme. In the early stages, plain radiographs of the spine and sacroiliac joints are normal, and CT or MRI scanning of the sacroiliac joints may show early erosive change. Less specific changes may be found by bone scans of these joints. Less commonly the disease presents with localized calcified segments of the spine, even in the neck.

The genetic predisposition to the disease is associated with the presence of the *HLA-B27* genotype. This is not diagnostic of the disease but its detection may be helpful in those patients with a very suspicious clinical picture and negative investigations. Its presence is always compatible with, but never diagnostic of, ankylosing spondylitis. Its absence does not exclude the diagnosis.

Bone disease

Metabolic diseases of bone may be found in the back-pain clinic. Osteoporosis must be considered in women who had an early menopause or have other risk factors. In older patients, as mentioned above, vertebral collapse will be due usually to osteoporosis but myeloma or secondary malignancy may need to be excluded (Table 10). If plain films of the lumbothoracic spine are normal, bone densitometry will determine the bone mass. In rheumatological practice, osteoporosis secondary to steroid use is not infrequent, particularly in older women with polymyalgia rheumatica or arteritis.

Osteomalacia is rarely seen in the United Kingdom, except among female immigrants from the Indian subcontinent who may spend much of their time indoors. An elevated alkaline phophatase in the presence of normal liver function tests confirms the diagnosis. The generalized nature of the pains of osteoporosis and osteomalacia generally makes the diagnosis relatively simple.

Paget's disease is occasionally destructive and then complicates the diagnosis as infection and tumour lie within the differential. Biopsy is sometimes required. More frequently it is found on radiographs, when its significance is uncertain. Activity may be demonstrated on bone scan and by an elevated alkaline phosphatase.

Sickle-cell disease must also be considered in populations at specific risk (Ozoh *et al*. 1990).

Referred pain to head, thorax, and abdomen

This chapter will not detail the clinical features and management of cervical and thoracic pain, but it is important to note the range of presentations of spinal pain. Cervical pain may refer to the scalp, particularly the bifrontal areas, to present as headaches. Facial pain may arise from involvement of the upper cervical segments, or from the extensions of the Vth nerve nuclei into the cervical cord. Dizziness is not infrequent and may not always be due to vertebrobasilar insufficiency. Pain frequently radiates to the shoulders, where it may contribute to symptom complexes associated with capsulitis or painful arc syndromes (perhaps by involvement of the sympathetic nerves), and is more frequent in those with narrow-diameter cervical canals. Similarly, epicondylitis and carpal tunnel syndromes are associated with narrow cervical canals. Less appreciated is the referral of pain, which may be very severe, to the anterior chest wall (Hockaday and Whitty 1967) where it is often superficial, unilateral, and associated with tenderness over the pectoral muscles, ribs or costochondral junctions—a cause of many visits to accident and emergency departments for fear of ischaemic heart disease (Taylor and Dawes 1990).

Acute abdominal pain referred from the spine is usually a diagnosis of exclusion, although a careful history of pain radiating from or to the spine may be obtained. Sometimes the pain can be reproduced by rotation of the spine, or by spinal palpation/mobilization by trained manipulators. Often patients have had unnecessary investigations for gastrointestinal or renal disease.

Acute low back pain

Although acute low-back pain develops insidiously in some, or is noted on waking in others, many episodes have a clearly defined cause that must be noted and explained to the patient. Trauma or inappropriate spinal movements may not give rise to severe pain until the next morning. Where an incident or injury has taken place more than 48 h before the onset of symptoms, experience suggests there is unlikely to be a causal relation, whilst acute leg pain may develop after a period of up to 2 weeks. Provision of educational literature at this stage may prevent referral to hospital, referral for physiotherapy, admission to hospital, and need for laminectomy (Roland and Dixon 1989).

Patient compliance may also be increased if the possibility of progression of pain with occasional need for surgery is discussed at the initial consultation (Hickson 1983).

Patients without leg pain fare better than those with leg pain, which may develop after the onset of pain (Chavennes *et al*. 1986).

The crucial therapeutic interventions in general family practice are to take the patient seriously, and to take a positive view (Roland 1994). In the absence of root signs, or suggestions of a serious problem, advice that activity is helpful, clicks are not harmful, and that pain is not necessarily bad are all important.

Bed rest and getting going

Bed rest

Minimal bed rest only is encouraged, particularly in the absence of nerve-root irritation. A random sample of patients with back pain (mostly acute) from the United States resting for 2 days did as well as those resting for 7 days (Deyo *et al*. 1986). A comparison of bed rest with physiotherapy and education from family practices in Canada showed no difference between the two groups, suggesting bed rest was not advantageous (Morrison *et al*. 1988). Bed rest is usually best in the position of maximum comfort. Often flexing both hips and knees tilts the pelvis, flattening the lordosis with immediate reduction of pain intensity (see Fig. 5). Supporting the hip and knee of the affected leg with cushions or pillows, or even sleeping in a chair, may be appropriate in the presence of femoral root irritation.

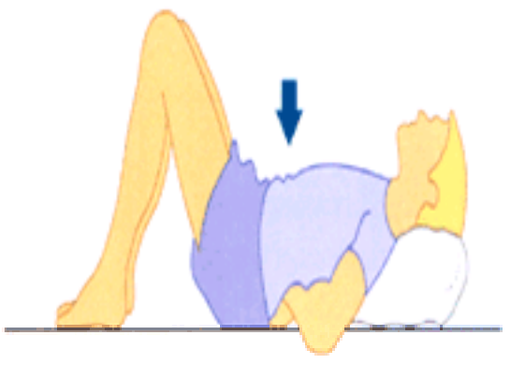


Fig. 5 Flattening of the lumbar lordosis is often helpful in easing the pain following an acute attack; some exercises encourage adoption of this position (reproduced by kind permission of the Northwick Park Hospital Department of Physiotherapy).

For those with very severe attacks of pain, or the elderly, attention must be paid to good-quality rest and adequate support during mobilization. The mattress should not sag, the height of the bed should be appropriate, and domiciliary physiotherapists should help take the mechanical stress off the spine with walking sticks or elbow crutches. The positions of rest are important, sitting often aggravates acute pain.

Mobilization after bed rest

Provision of a corset may greatly facilitate initial mobilization. Social services' or rehabilitation staff may be able to provide blocks to raise chair or bed, a more

appropriate chair, and a toilet raise to facilitate mobility at home. Prolonged bed rest is particularly contraindicated for the very old; joints stiffen up and osteoporosis is enhanced. For this group of back sufferers, domiciliary physiotherapy greatly improves confidence and self-image. A commode by the bed is often essential to prevent long walks to the (often cold) toilet. As with other forms of arthritis, the stairs may become a major barrier to health if the only toilet is upstairs. Elderly people often have coincidental urinary problems (often related to diuretics) and repeated visits upstairs put unnecessary strains on the spine and legs, which may be reduced by banisters (stair rails), having a bed downstairs, and the use of a commode (Frank and Hills 1988; Turner-Stokes and Frank 1992).

When the patient starts to improve, referral for physiotherapy is usually helpful (see below). A contraindication is that of exacerbation of symptoms related to sitting whilst travelling to hospital, particularly if there is involvement of an L5 or S1 root, when domiciliary therapy may still be advised.

Drugs

Analgesia

Ensuring compliance and getting people back to work cannot be done if they are in severe pain. Important judgements are needed as to when, how much, and for how long medication should be prescribed to obtain the best balance of benefit versus risk in taking medication.

The danger is that people will take unnecessary rest to control pain that could be helped by analgesics and that would enhance the ability to regain normal activity patterns quickly. As an inflammatory component is highly likely in an acute episode, a non-steroidal anti-inflammatory drug is often helpful (Deyo 1983), particularly to obtain a reasonable duration of analgesia for a good night's rest. A recent example of a good study is that of Szpalski and Hayez (1994). Non-steroidals are often the only non-opiate derivatives available giving analgesia that lasts through the night. The risks of short courses may be no more than the risks of prescribing the stronger opiate derivatives (see below), which may be the only alternative. Care must be taken in smokers, those with a history of ulcer disease, severe dyspepsia, or elderly people.

Many people suffer side-effects arising from the gastrointestinal tract when taking non-steroidal anti-inflammatory drugs. Whilst omitting drugs giving side-effects is always the best policy, sometimes this is not in the patient's best interests. Here, men or older women may be helped by taking misoprostol separately, or combined with a non-steroidal anti-inflammatory drug such as diclofenac or naproxen. 'Pro-preparations' may have fewer side-effects. Alternatively, side-effects may be minimized by prescribing acid-suppression tablets. Where gastric pathology has been confirmed, for example erosions, omeprazole is the drug of choice. If duodenal pathology is present, ranitidine may be preferred.

Non-steroidal anti-inflammatory drugs can be augmented by analgesia that occasionally may require opiate derivatives (e.g. nefopam, meptazinol or buprenorphine) if the compound paracetamol containing preparations are insufficient. Many require only mild analgesics (e.g. compound paracetamol preparations). Antiemetics are helpful in those inclined to vomit after drugs, as vomiting will almost certainly inhibit healing and aggravate pain. Opiates should rarely if ever be prescribed in the home for acute or chronic back pain. Failure to control pain with these measures requires admission to hospital.

Other drugs

Antispasm medications may be used in the first few days (Deyo 1983), although non-steroidal anti-inflammatory drugs seem more appropriate. Benzodiazepine drugs may be of value for a maximum of 1 week for those having difficulty resting. They may facilitate a good night's sleep, essential to enable individuals to cope with the next day's pain. Those with a history of mood disorders, insomnia or dependency are treated more safely with a tricyclic compound with sedative properties, for example amitriptyline.

Injections

Most interest has been in the effect of local injections of lignocaine and/or corticosteroid around the area of maximal tenderness (Garvey *et al*. 1989; Collée *et al*. 1991), or into the disc (Simmons *et al*. 1992) or facet joint (Lillius *et al*. 1989; Carette *et al*. 1991). There is no good evidence that they offer widespread benefit. The local effect of a mechanical stimulus may be more important than the drug injected (Garvey *et al*. 1989), and injections given by specialists in clinic may be more efficacious than those given in a general practice setting (Collée *et al*. 1991). Injections have been combined with manipulation with good effect (Blomberg *et al*. 1992).

Injections by the epidural route are discussed in the section on intractable pain.

Physical management

Considerable evidence supports the role of physical therapy in acute back pain. Increased compliance with better results from physiotherapy can be obtained by simultaneous use of complementary literature and by planned review of patients after a course of treatment. Benefits of therapy may be lost in those who do not persist with recommended treatment (Manniche *et al*. 1991). Few studies have compared physical with non-physical methods of treating acute low-back pain. In part this probably reflects the difficulties of comparing two differing modes of therapy when the type of therapy cannot be 'blind'. Overman *et al*. (1988) randomly assigned 107 patients in a 'walk-in low back pain clinic' to internists or to physical therapists. The latter referred more patients to physical therapy than did internists and recommended less bed rest and medication. Those managed by the physical therapists expressed greater satisfaction with care and had significantly greater functional improvement.

Meade *et al*. (1990), in a sample of 741 patients for whom manipulation was not contraindicated (derived from hospital or chiropractic clinics), compared hospital outpatient management with that of chiropractors. In the group with symptoms of less than 1 months' duration (acute and subacute back pain), no difference was noted until 2 years, when those treated by chiropractors appeared less disabled. A preliminary study of osteopathic manipulation in acute/subacute low-back pain has suggested benefit (MacDonald and Bell 1990). Reviews of manipulative treatment show that manipulation may speed recovery of a few with acute backache (Koes *et al*. 1991; Shekelle *et al*. 1992; Frank 1993a), views supported by more recent studies (Blomberg *et al*. 1992; Koes *et al*. 1992).

A prospective, randomized study of manipulation, transcutaneous muscle stimulation, massage, and corset showed minimum drop-out in the manipulation group and maximum drop-out in the muscle-stimulation and corset groups (Pope *et al*. 1994). This supports the criteria for use of a corset suggested by Frank and Hills (1988), that corsets should be reserved for those with failed manipulation.

A novel approach by Fordyce *et al*. (1986) compared traditional and behavioural methods of treating acute back pain of 10 days' duration or less and showed no difference at 6 weeks. But at 9 to 12 months those given more supervision and planned withdrawal of treatment (behavioural group) were 'less sick' and claimed 'less impairment' than the group able to control their own schedules of medication, activity, exercise, and follow up (traditional group). This shows the benefits of taking control from the patient and giving it to the therapist.

McKenzie techniques of passive extension and postural correction have been compared with a one-session 'mini back school'. This school consisted of a 45-min session only and perhaps was an unfair comparison to a technique involving considerable therapeutic input. McKenzie techniques were shown to be superior in relieving pain, promoting return to work, reducing sick leave during the initial attack, controlling recurrences during the follow-up year, and promoting movement (Stankovic and Johnell 1990).

A graded-activity programme with a behavioural therapy approach for those with subacute back pain improved mobility, strength, and fitness, resulting in an earlier return to work than in a control group (Lindstrom *et al*. 1992). Mitchell and Carmen (1990) and Mitchell and Carmen (1994) also included elements of 'behavioural support' in their sports injury approach, 'functional restoration', basically hard exercise. This approach reduced absence from work, compensation costs, and disability award costs.

Many studies have not differentiated between acute and chronic back pain. Whilst this can be argued as failing to differentiate between totally nociceptive pain and pain where other factors may be of importance (e.g. pain/sickness behaviour), in practice it has been shown that many people respond to standard conservative physical measures in spite of pain of long duration (Meade *et al*. 1990; Koes *et al*. 1992). Unfortunately, many studies do not define the duration of the current

episode of low back pain or the time of onset of the first episode of pain.

As cervical symptoms often coexist with low-back symptoms, advice about physical and ergonomic measures must be appropriate for all parts of the spine. Thus, as mentioned earlier, lying prone may help some people with low back pain, but aggravate neck problems that have may been mild or asymptomatic.

Exercises may be used in acute pain (see below).

The elderly

Back pain in elderly people is a strangely neglected topic. Its management did not feature in a 330-page review of 'arthritis in the elderly' (Kean 1986). The deleterious effect of musculoskeletal disorders is important (Williams 1985; Hodkinson 1988; Turner-Stokes and Frank 1992).

A recent review of 187 patients referred to my back clinic revealed that 21 per cent were over the age of 65. Some had major degenerative problems (spinal stenosis and root compression). Many also had additional medical problems that complicated their management, for example cardiac and gastrointestinal diseases, peripheral arthritis, and cervical degenerative changes. The differential diagnosis can be difficult in old age when acute pain may be due to osteoporotic collapse or to aggravations of disc or facetal degenerative disease. The two diseases may coexist.

Prolonged rest is usually contraindicated as joints stiffen and osteoporosis is encouraged. For this group, domiciliary physiotherapy greatly improves confidence, mobility, and self-image. If rest is required, attention must be paid to resting posture (usually avoiding sitting), taking pressure off protruding bony points, and adequate support during mobilization. The domiciliary physiotherapy service may assess the patient for their ideal resting posture. Resting sitting is preferable if the femoral roots are involved. A checklist is given in Table 12 to ensure that the everyday stresses on the spine are minimized, advice being given by the domiciliary physiotherapy service, social services department or the hospital occupational therapy service, separately or in combination (depending on local circumstances).

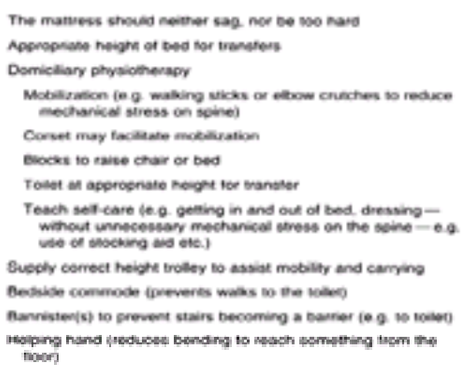

Table 12 Checklist for supporting the elderly person with back pain

Particularly for the old person with acute or chronic back pain, a visit to the home by a physician or a member of the primary-care or community team is an ideal method of teaching self-care. Self-care is not likely to be absorbed in an environment away from the home. A simple check that the tasks of everyday living can be performed without placing unnecessary mechanical stress on the spine (e.g. getting in and out of bed, putting on trousers, shoes or slippers) may encourage a speedier resolution of pain and minimize risks of recurrence if the advice is understood and maintained by the patient and their partner, friend or care assistant.

Elderly patients should be encouraged to acquire a 'helping hand' device (Frank and Hills 1988), which reduces their need to bend the spine to reach something from the floor.

Care needs to be taken with medication. Trials with the simplest analgesics initially may give adequate relief. The risk:benefit ratio in elderly patients shifts towards greater side-effects, requiring increased vigilance on the part of the physician (Hodinka 1991; Girgis and Brooks 1994). Ibuprofen is invariably found safer than any it is compared with in terms of its gastrointestinal toxicity (Bateman 1994; Committee on Safety of Medicines 1994). Ketoprofen has been variously reviewed (Committee on Safety of Medicines 1994) but has been found not to influence control of hypertension (Weiss *et al*. 1991) and to be well tolerated by an elderly population, mean age 72 (Schattenkirchner 1991).

Prevention (Table 13)

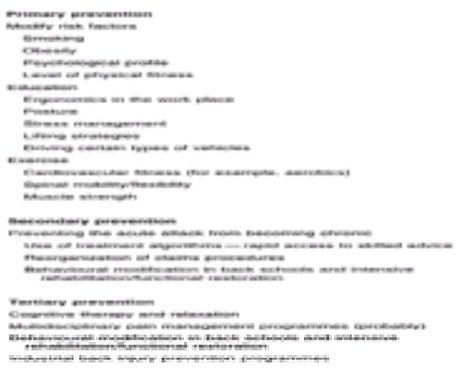

Table 13 Strategies for preventing back pain

Primary prevention

There have been no studies to show the effectiveness of psychological methods of preventing low back pain, although corporate stress-management programmes at three high-risk work sites have reduced the number of accidents and related costs (Weiser and Cedraschi 1992). There have been no studies on the benefits of stopping smoking on low back pain.

A review of ergonomic changes in the United States railroad industry (where the physically demanding nature of the job results in numerous musculoskeletal injuries) showed low back injuries to be the most common. They are also most costly in terms of compensation and productivity. Corrective measures have included storing tools and materials off the ground at between knee and shoulder height, with the heaviest items at knuckle height; devising winches to lift and handle heavy equipment; and designing work-tables, dollies, and carts to handle more easily railroad-car parts and tools. Management took a participatory approach and encouraged workers to design their own tools and material-handling devices to make their tasks easier and safer. This approach resulted in low back injuries and lost work days falling to zero and absenteeism falling from 4 to 1 per cent (Brown *et al*. 1991).

Teaching and social support, by themselves, may not be enough to alter behaviour (Daltroy *et al*. 1993). In a hospital environment, teaching plus ward instruction on lifting techniques may change behaviour of nurses in the short term (Feldstein *et al*. 1993).

Secondary prevention

This topic is addressed in the sections on back schools and intensive rehabilitation, and has been reviewed by Weiser and Cedraschi (1992). It is the combination of intensive physical training, behavioural principles, and attention to the working environment that appears to be effective. Back schools may be more effective in the work environment (Weiser and Cedraschi 1992).

Tertiary prevention

Weiser and Cedraschi (1992) have argued that studies reporting follow-up data of 6 months' duration may be considered preventive. Thus Turner and Jenson (1993) showed at 6 and 12 months that patients given cognitive therapy, relaxation, and cognitive therapy with relaxation all improved significantly compared to a waiting-list control group. There are few suggestions of the efficacy of multidisciplinary pain-control clinics (Weiser and Cedraschi 1992). In the United States, but not necessarily elsewhere, intensive rehabilitation in the form of 'functional restoration programmes' appears effective (Mayer *et al*. 1987).

Once back pain has become chronic or intractable, psychosocial and behavioural interventions are necessary for successful rehabilitation, probably combined with intensive physical programmes that are designed to get people back into employment. Back education from specially trained physiotherapists during pregnancy reduced the amount of back pain and sick leave during pregnancy, and back pain post partum (Ostgaard *et al*. 1994). In California, a 1-year back-injury prevention programme consisting of a combination of education, training, physical fitness activities, and ergonomic improvement showed a net benefit for introducing the programme of $161 108, with a return on investment of 179 per cent (Shi 1993).

Chronic low back pain

Exercises

Exercise regimens may aim to increase range of movement, strengthen muscles, stretch tightened structures, or toughen up physically and mentally (Frank and Hills 1988; Jenkins and Borenstein 1994). Allowing for difficulties in methodology and interpretation, there is evidence that back extension (Manniche *et al*. 1988; Manniche *et al*. 1991; Hansen *et al*. 1993; Manniche *et al*. 1993; Risch *et al* 1993), calisthenics (Donchin *et al*. 1990), and a mixed exercise regimen help people with low back pain (Deyo *et al*. 1990). Isometric flexion exercises (Hume Kendall and Jenkins 1968; Zylbergold and Piper 1981), mobilizing exercises (Hume Kendall and Jenkins 1968), and calisthenics (Donchin *et al*. 1990) are beneficial. Deyo *et al*. (1990) advised a wide variety of exercises, including relaxation, in a pattern similar to some back schools. The McKenzie programme aims to centralize pain through an individualized exercise programme and is twice as effective as traction and back schools alone (DiMaggio and Mooney 1987).

There is little evidence to support the idea that particular theoretical rationales have been justified as patients usually have not been selected to meet criteria to justify particular exercises. However, Manniche *et al*. (1993) has shown that active back-extension exercises appear most effective in women with sedentary jobs, who might be expected to have less physical strength.

Exercises combined with behavioural methods are more effective than exercises alone, both being more effective than inaction (Turner *et al*. 1990). Behavioural principles have also been shown to reduce sickness behaviour (Alaranta *et al*. 1994) and get people back to work quicker (Lindstrom *et al*. 1992).

Both active-flexion and active-extension exercises may increase the range of movement of the spine, but not necessarily reduce the pain and disability (Elnaggar *et al*. 1991).

Aerobic exercise is increasingly recommended and has been shown to augment the benefits of an English back school (Frost *et al*. 1995). Benefits of exercise may not only be physical. There is a suggestion that specific muscle strengthening or aerobic fitness training may improve nurses' job satisfaction as well as decreasing the duration of back-pain episodes (Kaplan and Deyo 1987).

Intensive outpatient physical retraining consisting of pain relief and mobilization, increasing movement and muscle strengthening, and work conditioning has been shown to reduce work absence. The increased costs to health care were more than offset by savings in 'wages loss cost' (Mitchell and Carmen 1990; Mitchell and Carmen 1994). Work conditioning has not been separately evaluated but its use in intensive rehabilitation settings is believed to be of value (Frank *et al*. 1987).

Manual therapy and manipulation

Manipulation (Fig. 6) has been defined as 'abrupt passive movement of a vertebra beyond its physiological range but within its anatomic range' (Spitzer 1987), although some would include movements that are active with the patient moving in one direction whilst the manipulator applies force in another. In all reports, readers should note the methodology as all will use slightly different definitions and varieties of manipulation.

Fig. 6 Mobilization or manipulation of the lumbar spine is helpful in reducing morbidity and duration of symptoms in acute and chronic, but not intractable low back pain (reproduced by kind permission of the Northwick Park Hospital Department of Physiotherapy).

Shekelle *et al*. (1992) and Shekelle (1994) reviewed the studies on manipulation in acute low-back pain. Meade *et al*. (1990), Koes *et al*. (1992), and Blomberg (1992) give support to the view that manual therapy including manipulation is effective in reducing pain of longer duration. Mathews *et al*. (1987) included patients with acute and chronic pain in their study, which demonstrated early benefits from manipulation.

The effect of manipulation in acute pain has been referred to above. Hadler *et al*. (1987) have suggested that manipulation may be more effective in pain of longer duration, and this view is supported by Meade *et al*. (1990) in their comparison of hospital outpatient management with that of chiropractors. That study showed major long-term benefit in a group of people subjected to chiropractic manipulation compared to a group treated by a combination of outpatient hospital techniques, which included hydrotherapy and traction in addition to manipulation/mobilization by Maitland or Cyriax techniques. The benefits were mostly with those having chronic or severe pain. Although it has been argued that their results could be explained by increased numbers of treatment sessions, greater level of skill (more experienced manipulators) or greater communication or interpersonal skills, in my view the type of manipulation was likely to play a part as it is compatible with the theory that loosening stiffened spinal segments may ease current, and reduce subsequent, symptoms by redistributing forces that act on the spine more evenly.

Individually, these studies do not prove that these forms of manual therapy are effective. All are capable of many interpretations. Together, however, they lead me to conclude that these forms of therapy are effective. The beneficial effects on the economy of 'a few days' saved for work by more effective means of treatment are potentially enormous.

Similar arguments might have been used in a controlled comparison of short-wave diathermy with osteopathy (Gibson 1985); here, however, no significant differences were found. Mathews *et al*. (1987) compared manipulation and placebo infrared for those with back pain with or without impaired straight-leg raising and showed the beneficial effects of manipulation between the second and eighth days of therapy.

Other physical treatments

Corsets are frequently prescribed for chronic low back pain, although criteria for their use are not clear. Our criteria (Frank and Hills 1988) assume that they should be reserved for those patients in whom attempts to mobilize the spine have failed. They definitely help some patients in this category (Million *et al*. 1982). Other logical categories include those with pain on physical activities (particularly if it facilitates remaining at work) and those with scoliosis or unstable spondylolisthesis for whom symptoms persist and surgery is not indicated. More recently, Kaplan and Sinaki (1993) have piloted the use of posture training supports, which may be more acceptable than ordinary corsets and help those with a kyphosis. They may be useful adjuncts to other forms of physical management. Corsets are likely to be less effective than active therapy for unselected patients (Hsieh *et al*. 1992).

Traction may also be helpful in a few patients, though demonstration of its benefits in controlled studies is lacking. Patients in hospital may find bed rest in traction upsetting and avoiding this has been recommended (Clinical Standards Advisory Group 1994*a*).

Heterodox management

Whilst most experienced back-pain practitioners agree on pattern recognition of symptoms, many disagree about likely cause and rationale of treatment; this has been summarized elsewhere (Frank 1990). It is crucial that those claiming to help people with low back pain are prepared to allow their treatments to be evaluated. It is likely that osteopathy will be shown to be effective (MacDonald and Bell 1990). A number of studies on chiropractic have now been performed (Assendelft *et al*. 1992); the best on methodological grounds was that of Meade *et al*. (1990), which has shown that orthodox practitioners cannot afford to be complacent. Conversely, the public clearly needs safeguards against those using unproven techniques that may be harmful or unhelpful. Doctors are best advised not to recommend heterodox treatment unless the practitioner is a member of a recognized professional association (Frank 1990).

Medication

The role of non-steroidal anti-inflammatory drugs was covered in the section on acute pain. The risks of serious side-effects from these drugs are probably less than 2 per cent, but as the risks become more clearly understood, so one becomes more cautious. It is worth attempting to wean patients off non-steroidals, giving them the opportunity to have 5- to 10-day courses when necessary for exacerbations of pain (e.g. after lifting or bending inappropriately). The use of non-steroidal anti-inflammatory drugs in the elderly was discussed above.

Similarly, longer-term analgesia may encourage sedation or adverse effects on the gastrointestinal tract and many patients discontinue their use. Having a bottle of tablets that are known to be effective 'on hand' is prudent, and the knowledge that they are available helps counter the fear of aggravation with activity and may inhibit the risks of depression (Frank and Hills 1988).

One of the major advances in the management of chronic pain has been the use of tricyclic antidepressant compounds (Pheasant *et al*. 1983; Ward 1986). Their mode of action is unclear; a suggestion is that they increase serotonergic uptake in the central nervous system (Ward 1986). Benefits are shown for those who are or are not depressed and for those known to have a physical basis for their pain. The effects appear to be independent of any sedative properties of the drugs. However, the sedative side-effects can be used advantageously in those having disturbed sleep and patients often find they facilitate relaxation. Appropriate warnings about sedation and a dry mouth must be given. Patients will need reassurance that tricyclic antidepressants are not addictive and that they are not being prescribed for psychiatric purposes.

Intractable low back pain

A few patients have persistent, disabling pain despite therapy (usually including non-steroidal anti-inflammatory drugs, analgesics, physiotherapy and often advice from heterodox practitioners). Investigations (often including MRI or radiculography) are usually negative. Having excluded spinal and non-spinal pathology and direct nerve-root involvement, patients should be considered as having 'failed conservative treatment'. The term 'intractable' low back pain is used to differentiate failed conservative management from chronic pain, which may never have been treated before, or 'chronic pain syndrome', when changes in behaviour are apparent (Frank 1993a). Of those with failed medical management, up to 10 per cent may have a major underlying medical problem (Wiesel *et al*. 1988).

At this stage, it has to be determined whether physical or psychological factors are most likely to be influencing current symptoms (Frank and Hills 1988; Philips and Grant 1991). Often both will coexist, but on occasions it will be clear that either the physical or the psychological are predominating. Thus, although for the sake of clarity they are described separately, the two aspects of management must go hand in hand as is the situation in most back schools and rehabilitation programmes.

Physical management

Clues that physical aspects are important lie in the pattern of pain. When episodic and related to movement or posture, physical issues are likely to predominate (Table 14). Often faulty posture at work or leisure places abnormal stress on normal tissue or causes recurrent stress on degenerate structures within the lumbar segment. Management consists of education (Fordyce *et al*. 1986; Lehmann *et al*. 1986) into the mechanical and ergonomic factors that are relevant (see 'Education and self-care').

Repetitive lifting
Inappropriate bed or mattress
Sleeping unsupported or in an inappropriate position
Getting in/out of bed incorrectly
Sitting for longer than 30 min (particularly when driving)
Recurrent bending (e.g. when brushing teeth)
Stopping exercise regime when 'better'
Defaulting medication or corset
Lack of physical fitness

Table 14 Physical barriers to successful outcome

Sleep patterns are important. After checking that bedding and mattress are satisfactory (Frank and Hills 1988), it must be established whether sleep loss is due to insomnia, pain, or depression. Constant pain day and night suggests that depression may be present. If pain disturbs sleep a long-acting non-steroidal anti-inflammatory drug may be helpful. On occasions, questioning 'what is thought about when lying awake' gives a clue to social factors that may reflect the causes or consequences of the spinal condition.

Physical measures

Transcutaneous electrical nerve stimulation (**TENS**) is now widely used to try and control pain for which conservative measures were unsuccessful and surgery is not contemplated (Gersh and Wolf 1985; Wynn Parry and Girgis 1988). Proof of efficacy to date is lacking (Lehmann *et al*. 1986; Deyo *et al*. 1990; Herman *et al*. 1994). If successful, TENS is continued at home for months or years with patients having their own machine. These machines cost around £90 each and patients may be

admitted to hospital for a few days' assessment during which the optimum site for placement of electrodes and the duration of treatment is decided. Some centres assess people as outpatients, and some loan stimulators from the pain clinic or the physiotherapy department. In other districts, patients are requested to purchase their own equipment (Anonymous 1989).

Acupuncture is now frequently offered by pain clinics (Coan *et al*. 1980; Lehmann *et al*. 1986) and some physiotherapy departments. Currently it is not possible to predict who will do well with either TENS or acupuncture (Lewith 1984; Anonymous 1989). Both TENS and acupuncture are being increasing used in therapy earlier in the course of a patient's back pain.

Medication; local and epidural injections

Tricyclic antidepressant compounds, as detailed above, are apparently effective for some who may or may not be depressed and for those known to have a physical basis for their pain (Pheasant *et al*. 1983; Ward 1986). Warnings about sedation and dry mouth, and reassurance that tricyclics are not addictive and not being prescribed for psychiatric purposes, are appropriate.

The role of local injections was discussed above in the section on acute pain. For decades, enthusiasts have injected a 'sclerosant' mixture of phenol, dextrose, glycerine, and water into the supraspinous, iliolumbar, and sacroiliac ligaments (Mathews *et al*. 1987; Ongley *et al*. 1987; Klein *et al*. 1993). It seems likely that this is an effective form of treatment, although follow-up beyond 12 months has not been reported.

Epidural injections

Opiates, steroids, and local anaesthetics have all been administered by this route. The use of morphine for the treatment of postoperative pain has not been shown to be helpful, and is hazardous. Epidural steroids are helpful in reducing postoperative pain following laminectomy (Ang *et al*. 1988).

The use of epidural local anaesthetic with or without steroids has been reviewed by Benzon (1986) for the management of acute, chronic, or intractable low back pain. Drugs may be introduced into the epidural space via sacral, lumbar, thoracic or cervical routes, at the level of the presumed lesion, or randomly, with varying doses of steroid or local anaesthetic. These factors complicate any serious evaluation of epidural injections for low back pain.

Controlled trials have given contradictory results in the management of acute back pain with radiculopathy and their use remains controversial (Bush and Hillier 1991; Power *et al*. 1992). I know of no decisive controlled studies demonstrating unequivocal cost-effectiveness in the management of chronic or intractable back pain (Occupational Medicine Forum Committee 1994).

As has been noted with some other means of treatment for low back pain (e.g. traction), epidural injections are widely used by surgeons, physicians and in pain clinics, and has major benefits for patients even though specific indications remain unclear.

Psychological and social management

A significant group of patients presents with pain that is continuous and does not alter over the 24-h period. Often they claim to have suffered non-stop pain for many years. They are best considered as suffering from the 'pain or illness behaviour syndrome' (Chapman and Brena 1982; Waddell 1987), sometimes considered as 'learned helplessness', which is discussed elsewhere (Fordyce 1988). Examination may not reveal signs compatible with the disability described. The pattern of pain may be non-anatomical (Ransford *et al*. 1976) and examination is often accompanied by exaggerated gestures of pain, particularly during the straight-leg raise test (Waddell *et al*. 1980). Insomnia is frequent (see above).

Patients may admit to problems consequent to loss of earnings or to changing marital/sexual relationships. Often unrealistic fears exist (Table 15): that long-standing pain cannot be due to common musculoskeletal causes and must be caused by horrific disorders, for example cancer or multiple sclerosis. The fear of aggravating pain may act as an excessive inhibition, keeping patients inactive and away from work unnecessarily (Waddell *et al*. 1993). The effect on the spouse may be critical. The importance of meeting the spouse or 'significant other' cannot be overstressed (Fordyce 1988), particularly if overprotection or excessive sympathy has encouraged adoption of a 'sick/patient role'.

1. Fear
   - Of Medication — drug dependency, side-effects, effectiveness will mask pain, creating further damage
   - Of physical activity — will increase pain particularly during recovery
   - Of the cause — e.g. cancer, multiple sclerosis
   - Of the consequences — loss of job (status and poverty), disability (e.g. in a wheelchair)
   - Of clicking in the back — frightened of damage to spine
2. Effects on the family — particularly on the partner (potential to develop learned helplessness or pain behaviour)
3. Psychiatric consequences
   - Depression
   - Phobic disorders
   - Substance abuse, e.g. alcohol
   - Post-traumatic stress disorder
4. Previous psychiatric history
5. Other — job dissatisfaction, litigation/compensation

Table 15 Psychological barriers to successful outcome

Other strains may be placed on marital and family relationships (Frank and Hills 1988). Thus a heavy manual worker unable to continue work may find the dependence on the spouse an unbearable strain. Where the marital relationship has been difficult before the onset of back pain, the pain may be used as an excuse to withdraw from the sexual side of the relationship, putting further strain upon it. Not all patients will be able to continue a normal sexual relationship when in severe pain, but many people can be helped by the intelligent use of positioning (Fahrni 1978).

Both hypnosis and relaxation have been evaluated in a small study (McCauley *et al*. 1983), both groups having less pain and depression than control patients.

Sensory deprivation (Shea *et al*. 1991) has been shown to be helpful in chronic (and probably intractable) low back pain. This suggests continued avenues for management of those with failed conservative management. Other psychological factors that may inhibit resolution of symptoms are listed in Table 15. Many are amenable to psychological/psychiatric intervention.

It may take a long time to unravel the many psychological and social problems that have become associated with an individual's 'pain'. Not every problem is soluble. Often the time taken to come to grips with these problems is worthwhile, and back-pain sufferers and their families can learn to cope with life again. Self-help may be facilitated by literature such as 'Living with your pain' (Broome and Jellicoe 1987). Sometimes specialist counselling is required from a social worker or a psychologist.

Psychologists also have an increasingly important role in helping patients to cope with their pain. This may be done singly or in group work. Groups are particularly helpful in boosting patient's confidence through sharing experiences and realizing they are not alone in their suffering. Skinner *et al*. (1990) have shown significant improvements in mood, coping skills, physical disability, and analgesic consumption in a British study of a cognitive behavioural treatment programme, but without any controls.

Psychologists are also helpful in advising the rehabilitation team on possible behavioural approaches to management. Recognition by the patient that psychosocial problems predominate may not occur for some time. Usually both physical and behavioural approaches are combined simultaneously (Fordyce *et al*. 1986; Turner *et al*. 1990; Lindstrom *et al*. 1992), the physiotherapist often being essential to 'allow' the individual to get better even if the programme does not have a major physical component. Incorporation of behavioural models (Fordyce *et al*. 1986) into early physical therapy may offer the best hope of reducing the morbidity of pain behaviour.

Pre-existing psychopathology is frequent in those requiring intensive rehabilitation (Polatin *et al*. 1993) and does not militate against a successful outcome if the treatment programme is structured to manage psychopathology appropriately (Gatchel *et al*. 1994). The results of physically demanding programmes vary between individuals with different psychological profiles (Harkapaa *et al*. 1991, Talo *et al*. 1992).

Depression is a well-accepted consequence of chronic pain. However, other variables such as irritability and increased somatization may be important (Pelz and Merskey 1982; Main *et al*. 1992).

Trauma and litigation

Trauma remains a complicated issue when 'distress' is commonly seen (Waddell *et al*. 1980) and symptoms fail to resolve as expected. The reasons are unclear and do not always revolve around litigation. Negative attitudes may play a part, such as bitterness and an inability to understand 'why me?'. Depression may go undetected (as is often the case with chronic pain and long-standing disability) and phobias may develop (McCarthy *et al*. 1990).

Litigation may be another complicating problem. The adverse effects on prognosis of trauma at work have already been referred to (Troup *et al*. 1981). Teasell and White (1994) argue that many reasons exist to militate against resolution of disability when litigation is involved. They include the need to persuade doctors that their injuries are serious: medical disbelief hardens attitudes; compensation vindicates patients who blame third parties; fears that a return to work would compromise their safety; use of disability to avoid difficult situations; and financial anxieties. There is abundant evidence, however, that settlement of litigation does not relieve symptoms (Editorial 1991).

Once medical reports have been obtained from both parties, patients can be assured that the basis for a settlement is highly likely and that they must now concentrate on positive matters, such as return to work, the development of new interests, or looking after the family whilst the spouse works. Although symptoms do not disappear from such people when litigation is settled, the uncertainty surrounding it is not helpful.

Insight into the possible nature of the causes of unexplained pain after road traffic accidents has been shown by Twomey and Taylor (1993), who performed autopsies after road traffic accidents and showed haemorrhage into the outer annulus of the disc and haemarthroses, and capsular or synovial tears to the facet joints, in addition to traumatic herniation of the disc. The concept of the 'hidden disc' (Simon and Goldstein 1992) is important, emphasizing that trauma may result in a syndrome of '(a) intractable back pain with aggravation of the pain and loss of spinal motion with any physical exercise, (b) leg pain, (c) loss of energy, (d) marked weight loss, (e) profound depression'. This concept is particularly important when expert witnesses for plaintiff and defendants will not always be from musculoskeletal specialties. The psychological consequences of road traffic accidents have been largely ignored in the past. Mayou *et al*. (1993) have shown that 1 in 10 patients had mood disturbances 1 year after a road traffic accident. At 1 year, severe horrific intrusive memories of the accident were present in 6 to 11 per cent of the patients, with travel anxiety being present in 12 to 18 per cent. In a small series of patients involved in litigation, irritability, tearfulness, sleep disturbance, and travel anxiety each occurred in over half of the sample (Frank 1993b). The profound ignorance among orthopaedic surgeons of the assessment, diagnosis, and treatment of emotional problems following trauma creates real difficulties for patients whether they are involved in litigation or not.

Back schools

The term 'back school' may mean any programme with an educational content (Fig. 7) varying from a 1-session programme (Stankovic and Johnell 1990), variable sessions as an outpatient (Berquist-Ullman and Larsson 1977; Klaber-Moffett *et al* 1986; Morrison *et al*. 1988), or an inpatient programme (Harkapaa *et al*. 1990). In this review it will refer only to outpatient education with or without concurrent therapy. Three to four sessions (Berquist-Ullman and Larsson 1977; Klaber-Moffett *et al*. 1986) and 15 sessions (Harkapaa *et al*. 1990) have been shown to decrease back pain and disability.

Fig. 7 Patien education has been shown to reduce back pain (reproduced by kind permission of the Northwick Park Hospital Department of Physiotherapy).

This subject has been reviewed by Koes *et al*. (1994). The best studies suggested that back schools are effective, particularly in occupational settings in acute, recurrent, or chronic conditions. The best-rated study (Harkapaa *et al*. 1990) has been discussed in the section on 'Intensive rehabilitation', indicating the wide variety of settings and programmes on to which a back school may be grafted. Results, however, are short term. It appears that attempts to change human behaviour over the long term (greater than 1 year) continue to escape us, with non-compliance and relapse remaining as major problems (Turk and Rudy 1991).

Intensive rehabilitation

Most rehabilitation programmes involve elements of intensity and multiprofessional input covering physical, psychosocial, educational, and vocational components. It also implies a failure of conservative or surgical management. Intensive rehabilitation includes those components of Table 3 under long-term measures. Whilst factors listed in Table 3, Table 7, and Table 8 should be part of any back-pain programme, the main features consist of learning to function in spite of pain, sharing experiences in groups with a skilled leader, and physically 'toughening up'—developing physical tolerance in both fitness (Frost *et al*. 1995) and vocational programmes, for example the Helsinki (Harkapaa *et al*. 1990; Mellin *et al*. 1990; Harkapaa *et al*. 1991), Texas (Mayer *et al*. 1987) and Turku (Alaranta *et al*. 1994) programmes.

It can be postulated that one of the reasons that complex rehabilitation programmes are successful is that opportunities present to sort out some of the social and psychological problems that follow low back pain. A model programme was evaluated in Helsinki by Harkapaa *et al*. (1990), where 459 patients were randomly allocated into control, inpatient, or outpatient management groups. Each group contained, in addition to physical therapies, education and the role of self-care in the prevention and early rehabilitation of low back disability, ergonomics, relaxation techniques, and group work. It is not clear whether the extra expense of the apparently superior inpatient treatment is really cost-effective; in the inpatient group there was some suggestion that inpatient was superior to outpatient rehabilitation at reducing pain, disability, and in enhancing compliance. Intensive rehabilitation would appear to be one of the few indications for admitting patients to hospital (Table 16).

1. Diagnosis and management of atypical pain or severe root compression
2. Pain management
3. Surgery
4. Assessment of intractable pain/pain behaviour
5. Initiation of rehabilitation of intractable pain

Table 16 Indications for hospitalization

The evidence suggests that intensive, multiprofessional programmes that encourage individuals to ignore pain, toughen up, and take away control of pain before giving it back to them are cost-effective. Long-term benefits have yet to be demonstrated, suggesting that the art of changing human behaviour is as yet far from understood (Turk and Rudy 1991).

Education and self-care

The first presentation of back pain is an opportunity to illustrate, for the purposes of patient education, the common predisposing factors. The history is often that of a trivial bending episode, possibly related to twisting, for example, putting a bottle of milk in a low refrigerator or bending over the wash basin to brush one's teeth. A demonstration of correct lifting techniques is important (Fig. 8). Few patients presenting to my back-pain clinic understand the importance of technique in approaching the floor (to pick up an object) or to lift. Whilst squatting is usually recommended (to avoid bending the trunk with straight legs), this is often awkward and inappropriate for older people.

Fig. 8 (a) Incorrect lifting technique: the lumbar lordosis is lost with maximal strain being placed on the spine; (b) correct lifting technique: use of the kneeling position minimizes strain on the back and is more stable than lifting from squatting or bending; painful knees from osteoarthritis or other causes prevent this and increase patients' disability (reproduced by kind permission of the Northwick Park Hospital Department of Physiotherapy).

Approaching the floor from the kneeling position can often overcome this, and older people (who are not using 'helping hands') may find help by using their arms to assist rising. The combination of arthritis of the large joints of the legs and back pain is particularly disabling. 'Helping hands' may help avoid bending.

An educational booklet has been developed and evaluated by general practitioners and given to a random sample of all patients presenting with back pain in five group practices. In the period from 2 weeks to 1 year following receipt of the booklets, there were significantly fewer reconsultations with back pain. Referrals to hospital consultants, for physiotherapy, admissions to hospital, and laminectomies were all less common in the booklet group. It was concluded that the booklets had some effect in altering both the knowledge and the behaviour of patients with back pain (Roland and Dixon 1989).

Bergquist-Ullman (1977) illustrated the potential importance of education into vocational and ergonomic aspects of self-care following episodes of back pain.

The model of the 'back school' has been followed throughout the world, being introduced into programmes at many different stages of the back patient's career. It has now developed into standard practice in many United Kingdom departments of physiotherapy (Frank and Hills 1988). A simple 3-session back school has been shown to improve functional disability and pain levels (Klaber Moffett *et al*. 1986). A similar 6-session outpatient programme has been reported from a community hospital in Canada (Morrison *et al*. 1988). The concept of back schools is discussed in more depth above.

Simple advice for back pain sufferers such as may be provided in simple educational form is given below (living with back pain).

Self-help may be facilitated by literature (Roland and Dixon 1989) or self-help groups (Webb 1982), but group education interventions in patients with low back pain are not conclusively successful (Cohen *et al*. 1994). Sometimes specialist counselling is required from a social worker or a psychologist, who may help overcome some of the problems (Table 15).

Whereas in acute stages patients often prefer professionals to take responsibility for their back care, which is therapeutic (Fordyce *et al*. 1986), this responsibility has to be transferred back to patients as pain becomes chronic and intractable. Thus responsibility to keep fit, maintain their individual exercise programme, remain relaxed so as to avoid physically (and ergonomically) stressing the spine is that of the individual, not of the professionals.

Living with low back pain

In hospital practice it is not infrequent for patients to have persisting low back pain in spite of many forms of therapy. Some patients come to the conclusion that they can live with their pain. Others can be helped to that conclusion, particularly if they are convinced they have received good treatment and that diseases have been excluded.

Such individuals can be helped to minimize mechanical stress on the spine by simple advice, some of which is listed in Table 7 and Table 8. The incorporation of such advice into everyday life can be rewarding and may remove triggering factors that perpetuate the current episode and may precipitate a further recurrence.

Some details of bedding, mattresses, chairs, and cars have been outlined elsewhere (Frank and Hills 1988). The importance of avoiding prolonged sitting must be stressed, particularly for those who recognize that their pain is aggravated by sitting. Approaches to sitting are reviewed elsewhere (Frank and Hills 1988). Continuous passive motion in sitting may be useful when fully developed (Reinecke *et al*. 1994).

Psychological factors may be equally important and are not well understood. Avoiding rushing about, being relaxed, and having time to plan one's activities clearly reduce the risk of doing everyday tasks in an unplanned way, thus decreasing the chance of doing them at a mechanical disadvantage. Simple advice has been produced by the British Psychological Society (Broome and Jellicoe 1987). The development of coping strategies (Rosenthiel and Keefe 1983) is important. Those who may benefit from professional psychological advice include those whose pain was the result of trauma (particularly at work).

Some individuals find sharing their experiences with fellow sufferers helpful and this may be in a group setting with a professional group counsellor (Webb 1982). Others may join branches of the Back Pain Society. The National Ankylosing Spondylitis Society has developed some groups that have a very physically orientated approach to their group meetings. At the request of the members of the group (some of whom are not being treated at the hospital) a physiotherapist helps organize and supervise the physical activities, which sometimes take place in the hydrotherapy pool.

Many appreciate further information about their condition. The Arthritis and Rheumatism Council produces a number of leaflets about rheumatic conditions; those on neck pain, backache, and seating are well worth recommending to patients with spinal pain if their local department does not produce information.

Return to work

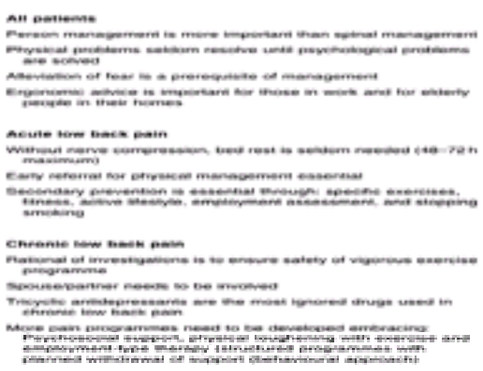
A minority of patients with low back pain may be 'off sick' for prolonged periods and have difficulty returning to work. Problems arise from the fear that work will aggravate the pain or cause it to recur; the prolonged adoption of the 'patient role', which may discourage a positive approach to work; the loss of self-discipline, which may result in poor time-keeping; and the lack of stamina and strength due to prolonged inactivity, which may have been consequent to bed rest. Such people can be helped by a general toughening up in the physiotherapy department and/or supervision of an increasing range of activities by therapists.

A return to normal working may require working through the pain and fears discussed above to develop stamina and the ability to cope with sitting, standing, and lifting. Sessions of therapy (physiotherapy or occupational therapy) should be increased to mimic a full day at work to reassure both patient and staff that a return to work will be viable. Ideally such programmes should include the teaching of coping strategies (Rosenthiel and Keefe 1983) so patients learn how to continue with life in spite of pain. Regrettably the shortage of clinical psychologists in the United Kingdom has inhibited the adequate development of programmes to include such strategies, sometimes with unfortunate results (Leak *et al*. 1989). This type of rehabilitation programme should be available at any large district general hospital and is suitable for outpatients, although, as detailed above, comparisons of inpatient versus outpatient rehabilitation regimens have favoured the more costly inpatient programmes (Harkapaa *et al*. 1990). When rehabilitation fails, or if it is not available locally, patients should be offered a residential assessment in the rehabilitation ward of the district general hospital or at a medical rehabilitation unit. Here, a thorough medical, nursing, psychological, remedial therapeutic, and social assessment can take place as the patient is under observation for the whole of the 24-h period. Such programmes have not been evaluated in the United Kingdom. In the United States, Mayer *et al*. (1987), in an uncontrolled evaluation of a 3-week, outpatient, 'functional restoration programme', combined a physical programme with work simulation/hardening, resulting in an 85 per cent return to work by 1 year. Pre-existing psychopathology does not militate against a successful outcome if the treatment programme is structured to manage psychopathology appropriately (Gatchel *et al*. 1994).

A recent meta-analysis of 37 studies that gave detailed definitions of patients' status, delineated patients' work status before treatment and at follow-up, and documented the proportion of patients employed at follow-up showed that non-surgical treatment for chronic pain does return patients to work, increased rates of return to work are due to treatment, and that benefits of treatment are not temporary (Cutler *et al*. 1994).

Those aged 50 or more are less likely to return to work (Frederickson *et al*. 1988). When a rehabilitation programme clarifies that people will not be able to return to their previous work, referral to the Disability Employment Adviser (United Kingdom) may be helpful. The adviser can discuss with employers alternative work that should be within the individual's capabilities. Where none is available, advice is given about retirement on the grounds of ill health, or other job options. Younger people (under 40–45) may be referred to an Employment Rehabilitation Centre where they are assessed for their retraining potential. The Disability Employment Adviser can register people 'disabled' and can help them to find work in a variety of ways. Although their titles vary, most industrialized nations have schemes that facilitate employment for those disadvantaged through illness or disability.

Service implications (Table 17)



All patients

Person management is more important than spinal management

Physical problems seldom resolve until psychological problems are solved

Alleviation of fear is a prerequisite of management

Ergonomic advice is important for those in work and for elderly people in their homes

Acute low back pain

Without nerve compression, bed rest is seldom needed (48–72 h maximum)

Early referral for physical management essential

Secondary prevention is essential through: specific exercises, fitness, active lifestyle, employment assessment, and stopping smoking

Chronic low back pain

Rational of investigations is to ensure safety of vigorous exercise programme

Spouse/partner needs to be involved

Tricyclic antidepressants are the most ignored drugs used in chronic low back pain

More pain programmes need to be developed embracing: Psychosocial support, physical toughening with exercise and employment-type (family involved programmes with planned withdrawal of support (behavioural approach)

Table 17 Summary of important points to remember

Until recently it was assumed that no particular therapy had demonstrable efficacy. Bed rest, symptomatic relief, and exclusion of other pathology were the prongs of therapy, with surgery for those requiring it. The evidence now shows that back pain and disability can be ameliorated, and often further episodes minimized, by professional intervention at the initiation of the first attack, shortening absence from work via physiotherapeutic and chiropractic (and probably osteopathic) manipulation, physical training, a variety of exercise programmes, and multiprofessional rehabilitation. Minimal rest and a planned withdrawal of support are important developments with demonstrable benefit.

Delays in referral for specialist advice, delays in being seen in hospital, and delays in the provision of therapy are all likely to contribute to non-resolution of acute/subacute back pain, increasing the pool of patients with chronic pain and the risk of pain becoming intractable, with the consequent suffering shared by the patient with the family. These people may progress to pain and illness behaviour, becoming more costly for employers and the state. Research now suggests that early (within 3 months), multiprofessional, integrated programmes can abort this negative process (Lindstrom *et al*. 1992).

The development of proper diagnostic and treatment protocols can decrease accidents and lost work days and be cost-effective (Wiesel *et al*. 1988) if costs to all sections of national life (state and industry) are considered. Services have not developed in line with the research evidence of efficacy, exposing both industry and public sectors to unnecessary disadvantage through avoidable sickness absence.

1.2.1.2 Spinal problems in children

Charles S. B. Galasko

Children with spinal disorders present with deformity, pain, neurological disturbances, or a combination. Deformity, either scoliosis or kyphosis, is probably the commonest presenting symptom. Frequently the deformity is not noted by the patient, but was detected by a relative, at school, or by a dressmaker.

The incidence of back pain in children is low, as seen by the number of referrals to the orthopaedic clinic (Winter and Lipscomb 1978; Hoffman 1980; Bunnell 1982), but school-based studies suggest that the incidence of backache may be high (Grantham 1977; Fairbank *et al*. 1984; Balague *et al*. 1988; Chan and Ryan 1992), though the vast majority of children did not seek specialist medical advice. Analysis of the referrals to the Royal Manchester Children's Hospital indicated that back pain counted for just under 2 per cent of non-trauma referrals to the orthopaedic clinic (Turner *et al*. 1989), whereas it has been estimated that 80 per cent of adults will visit a medical practitioner at some time because of back pain.

Turner *et al*. (1989) found that the patients fell into two distinct groups. In just over half the patients, a definite underlying pathological cause was found. No specific pathological cause was detected in 29 of the 61 patients. The study has now been extended to 233 patients, 75 of whom had no specific pathological cause (Table 1). There was no significant difference between the two groups in terms of age, sex, or site of the pain and none of the patients in the non-specific group was subsequently found to have developed a specific cause of back pain. In contrast, a survey of 100 children with back pain at the University of Michigan in 1980, revealed that all but 15 per cent had a definite identifiable cause for their complaint (Hensinger 1989). Eighteen per cent had either a tumour or infection, and approximately 33 per cent were found to have a post-traumatic cause such as an occult fracture or spondylolysis/spondylolisthesis.

Table 1 Causes of back pain in childhood in 233 patients

History and examination

A careful history and clinical examination must be made for all children. The history may be very non-specific and, if the child is very young, may be nothing more than a recent refusal to walk, or the development of a postural change. Even older children are often not able to localize their symptoms.

There frequently is a history of trauma, but this does not imply that the pain is traumatic in origin. If the pain occurs during sport spondylosis, spondylolisthesis, or possible injury should be excluded. The presence of night pain is suggestive of a tumour; morning stiffness is suggestive of an inflammatory spondylarthropathy.

The history should not just concentrate on the features of the presenting complaint, but should seek to establish the general health of the patient, the presence or absence of symptoms affecting other parts of the locomotor system, and the psychological background of the patient. Persistent pain that is unrelieved by rest or immobilization, increasing pain, and symptoms of systemic illness suggest infection or tumour. These patients may also present with abdominal pain and guarding.

A neurological history must also be taken, although neurological symptoms are uncommon in children. The presence of radicular pain, paraesthesia, or weakness suggests significant compression of the cord or nerve roots. Change in sphincteric control in a previously continent child requires immediate investigation. A foot deformity may be secondary to a neurological abnormality including spinal dysraphism.

Scoliosis is usually pain free. The combination of pain and scoliosis usually indicates significant underlying pathology, such as tumour, infection, or a prolapsed intervertebral disc.

A family history should be taken and the presence of any other diseases established. Scoliosis, for example, frequently complicates neuromuscular disease (Fig. 1), mesenchymal disorders such as Marfan's syndrome and Ehlers–Danlos syndrome, neurofibromatosis, the osteochondrodystrophies, rheumatoid disease, tumours of the spinal column or spinal cord, and metabolic disorders (Table 2). Scoliosis may also follow irradiation, for example of a Wilms tumour, or a thoracotomy. Kyphosis may also be secondary to an underlying disorder (Table 3; Fig. 2).

Fig. 1 Scoliosis in a patient with Duchenne muscular dystrophy. The patient has a typical collapsing 'C'-shaped scoliosis which involves the entire spine. In neuromuscular scoliosis, progression of the curve is usually associated with increase in pelvic obliquity, which makes sitting uncomfortable and affects seating balance.

Structural	Idiopathic Infantile (0–3 years) (1) Resolving (2) Progressive Juvenile (3–10 years) Adolescent (> 10 years) Neuromuscular Congenital Neurofibromatosis Mesenchymal disorders (e.g. Marfan's; Ehlers–Danlos syndrome) Rheumatoid disease Trauma Fracture Surgical (laminectomy; post thoracoplasty) Irradiation Fibrous/scar contractures (posterior/burns; post burns) Skeletal dysplasias Infection Metabolic disorders Related to lumbosacral joint (spondylolysis and spondylolisthesis; congenital anomalies) Tumours
Non-structural	Postural Hysterical Nerve root irritation (e.g. prolapsed disc; tumour) Inflammatory (e.g. appendicitis) Related to long-length discrepancy Related to contractures about the hip

Table 3 Causes of kyphosis

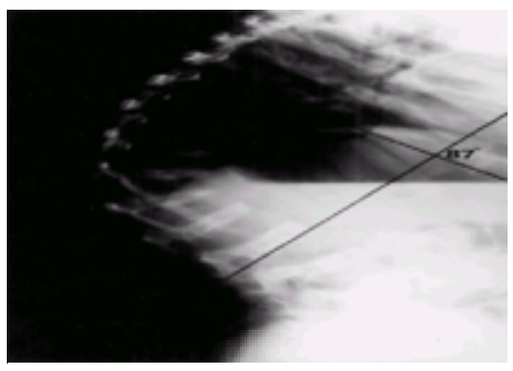

Fig. 2 Kyphosis secondary to an osteochondrodystrophy.

Refusal to walk in a very young child may be the first manifestation of a spinal disorder, such as discitis. A limp may be the presenting symptom. Irritation of the psoas muscle, secondary to a spinal disorder may result in flexion of the hip, a limp, and reduced movements of the hip on clinical examination. Other presenting features of a spinal disorder include postural change and morning stiffness.

The physical examination must include a general examination of the patient, an examination of the spine, and a detailed neurological examination. The spine should be examined standing, sitting, and prone. The presence of any deformity should be noted. If pain is present and if the patient is old enough, the patient should be asked to indicate the site and distribution of the pain. Any tenderness should be elicited and the movements of the spine determined. The immature spine is normally very flexible. Hamstring tightness may result in severe restriction of spinal flexion. Any deformity of the lower limbs should be noted and the child's gait should be observed, as well as the ability of the child to hop. In addition to assessing carefully sensation (including perineal sensation), if a child is old enough, power, reflexes, and any bladder or bowel involvement must be assessed.

The investigations should be based on the clinical findings. A standard 'work-up' is not indicated. The patients whose symptoms are severe enough to warrant referral to an orthopaedic clinic should have plain radiographs taken of their spine. If scoliosis or kyphosis is present, erect radiographs should be taken.

In the series of Turner *et al*. (1989), the plain radiographs provided the diagnosis in 58 per cent of their patients. If infection is considered, a white cell count and erythrocyte sedimentation rate should be carried out. This proved positive in 14 per cent of their patients. A painful scoliosis in a child usually implies a significant lesion producing the deformity, such as a prolapsed disc, tumour, or infection and magnetic resonance imaging (**MRI**) is indicated. Restriction of spinal movement and/or limited straight leg raising might indicate compression of the spinal cord or nerve roots and MRI is indicated. Turner *et al*. (1989) found that radiculography, combined with computed tomography (**CT**), demonstrated compression of the cord or nerve root in 30 per cent of their patients, but this investigation has largely been replaced by MRI where the facilities are available.

Without such investigations the diagnosis may be delayed. Turner *et al*. (1989) recorded a delay of 6 months or more in 16 per cent of patients with serious spinal pathology, all being tertiary referrals, the delay occurring prior to referral to their clinic. These included: two patients originally diagnosed as having Scheuermann's disease, but who were found to have cord tumours; an adolescent girl with spastic diplegia and severe hip flexion contractures, who had undergone soft tissue release of her hip flexors, but in whom a diagnosis of isthmic spondylolysis was made 4 years after the onset of increasing back pain; and a 14-year-old boy whose

prolapsed disc was diagnosed by combined radiculography and CT scanning 3 years after the onset of back pain. Galasko (1990) reported the case of an adolescent male who presented with a 3-year history of severe back pain. Previous investigations, carried out prior to his referral to the orthopaedic clinic, had included radiculography and plain radiographs, which were normal. His pain had not responded to treatment and, before labelling him as 'psychogenic', an orthopaedic opinion was sought. On examination he had a mild scoliosis and movements of his spine were limited. The plain radiographs were normal. Skeletal scintigraphy showed increased uptake in the right L5 pedicle (Fig. 3). Prior to surgery he was given 370 MBq of technetium-99m methyl diphosphonate (MDP) and a sterilizable probe was used to detect the areas of greatest activity. These were excised and histological examination revealed the presence of two osteoid osteomas.

Fig. 3 Patient with osteoid osteoma who had complained of back pain for 3 years prior to referral to the orthopaedic clinic. A technetium-99m MDP scintigram showed increased uptake in the pedicle of L5. At surgery, two areas of increased uptake were found. Both proved to be osteoid osteomas. Following excision of the lesions, his pain settled completely.

Skeletal scintigraphy is a useful investigation in many patients and demonstrated the lesion in 10 per cent of the patients of Turner *et al*. It is useful in the diagnosis of discitis, particularly in a young child who is unable to localize the pain. Disorders of the genitourinary tract may be identified on the scintigram. Sacroiliac joint infection can cause back pain and is best diagnosed by skeletal scintigraphy. These patients complain of back, hip, and buttock pain. The Faber test is usually positive. In this test, the hip is flexed, abducted, and externally rotated, stressing the sacroiliac joint, whilst the pelvis is stabilized on the contralateral side.

Wenger (1993) described four levels of work-up. In level 1, the history usually includes a recent minor injury. Clinical examination is negative and there is no hamstring tightness, local muscle spasm, limitation of straight leg raising or neurological sign. The child requires a careful examination but usually no investigations. Treatment is symptomatic and the patient is seen 1 to 2 weeks later if the symptoms persist. If the symptoms have not resolved, level 2 work-up may be required.

A level 2 assessment is carried out when the history is less clear. Usually, there is no specific injury. The child has often had pain for several weeks. Physical examination is inconclusive without specific neurological signs, but the child may have tight hamstrings or minor spinal asymmetry. There are no systemic signs. The investigations include anteroposterior and lateral radiographs of the part of the spine that seems to be the source of pain. If the lumbosacral area is involved, oblique views are considered to evaluate a possible spondylolysis. If the radiographs are normal, the patient is treated symptomatically and is seen for review after several weeks. If the symptoms have not resolved a level 3 work-up may be required.

A level 3 assessment is required in children who have had significant pain for some weeks, with normal plain radiographs and in whom a diagnosis has not been established. The clinical examination is usually non-specific. There is no neurological deficit, but hamstring tightness, limited straight leg raising, and/or back muscle spasm are commonly present and may be severe. The child may be pyrexial. Investigations include plain radiographs as indicated above. If radiographs have already been taken and they are of poor quality, they should be repeated, since poor quality radiographs are a common reason for initially missing the diagnosis in a child with back pain. The child should have a complete blood count and an erythrocyte sedimentation rate carried out. In most cases, Wenger advised a skeletal scintigram with pinhole collimator views of suspected levels of involvement. Treatment is symptomatic with watchful waiting if the plain radiographs, blood count, erythrocyte sedimentation rate, and skeletal scintigram are normal. If the investigations reveal a specific diagnosis, such as spondylolysis, tumour, or discitis, specific treatment is required.

A level 4 assessment is required in patients who are experiencing severe symptoms. Often these symptoms have been present for weeks or months and may include pyrexia and/or complaints suggesting a neurological deficit. There may be extreme focal back pain and muscle spasm, positive straight leg raising, or neurological deficit on clinical examination. The investigations include a complete blood count, erthrocyte sedimentation rate, and in most cases an urgent CT scan and/or MRI. Often a skeletal scintigram is also included. The underlying spinal condition requires appropriate treatment.

Prevention

Back pain may occur in patients who develop a progressive collapsing scoliosis, secondary to neuromuscular disease such as Duchenne muscular dystrophy. Untreated, well over 90 per cent of patients with Duchenne muscular dystrophy develop a progressive scoliosis, once they are no longer able to walk and stand. The curve is progressive and is associated with increasing pelvic obliquity. The optimum treatment for such curves is spinal stabilization, once the patient has lost his independent ambulation, has developed a progressive scoliosis, or has a scoliosis greater than 20 degrees, and is still fit for surgery in terms of his respiratory and cardiac function (Galasko *et al*. 1992). The use of spinal orthoses may slow the progression of such a curve, but does not stop a curve from progressing once it has reached 30 to 40 degrees (Hsu 1983; Colbert and Craig 1987). Unfortunately, the more effective the orthosis, the more it affects the already limited lung function in these patients. Without treatment the curve continues to progress and is associated with pelvic obliquity which leads to loss of sitting balance, sitting discomfort, and eventually may make sitting impossible because of the associated pain. This pain can be prevented by timely spinal stabilization, which not only stops the progression of scoliosis and maintains sitting balance but also slows down the deterioration in lung function (Galasko *et al*. 1992). Spinal stabilization is also associated with maintenance of sitting balance and comfort in many other neuromuscular conditions including spinal muscle atrophy and Friedreich's ataxia.

Non-specific causes of back pain

The term 'non-specific' is a useful term, but does not adequately describe the lesion. In these patients the symptoms usually settle within a few months, with no specific treatment or physiotherapy. However, this group does include a number of patients with psychogenic elements to their pain. This occurs more commonly in girls. In patients whose pain persisted for more than 1 year, there was a high incidence of other complaints, such as headache or abdominal pain, and frequently there was also a strong family history of back pain (Turner *et al*. 1989). True hysterical pain is rare in childhood or adolescence, but does occur.

In the absence of any neurological symptoms or signs, with a mobile spine and normal straight leg raising, and without the development of a deformity, a 'wait and see' policy is justified, the symptoms being treated by analgesics, physiotherapy, and very occasionally, a simple spinal orthosis. The vast majority of patients with non-specific back pain will settle on this regimen but, if the pain persists, further investigation, such as MRI, CT scanning, or skeletal scintigraphy may be indicated.

Salminen *et al*. (1992) compared spinal mobility and trunk muscle strength in 38 15-year-old children suffering from low back pain with 38 asymptomatic controls. The boys with back pain were over 4 cm taller than those in the control group and in both sexes lumbar extension and straight leg raising were decreased and lumbar flexion was increased. Endurance strength was decreased in the abdominal and back muscles in the children with back pain.

The patients who suffered from sciatica in addition to recurrent low back pain had decreased lumbar flexion and side bending compared with those who suffered from recurrent low back pain without sciatica.

Specific causes of back pain in children and adolescents

Tumours

Tumours may arise from the vertebral column or from within the spinal canal (Galasko 1990). Bone tumours are uncommon and tumours arising from the spine even less common. They may be confused with non-neoplastic disease, and a high index of suspicion is required if an early diagnosis is to be made. An accurate diagnosis is essential for early and appropriate treatment. They may present as accidental findings or with pain, deformity, stiffness, or neurological symptoms.

The commonest presenting symptom is pain, which usually is persistent and is not significantly alleviated by rest. Occasionally, the patient may present with neurological symptoms or the sequelae of neural involvement such as pes cavus, equinus, or a foot droop. The combination of back pain and bilateral sciatica may be due to an intradural tumour. Examination may reveal local tenderness, muscle spasm, scoliosis, and limited movement. Occasionally, a lump may be palpable.

Children with leukaemia occasionally present with back pain, but this can usually be excluded by the blood count. Other serological investigations will depend on the age of the patient and the likely diagnosis. If metastatic neuroblastoma is considered, a urinary vanillyl mandelic acid may be required.

Radiological investigations may include plain radiographs, CT scanning, MRI, and/or angiography. A spinal lytic lesion may be due to infection, tumour-like conditions such as fibrous dysplasia, a benign tumour such as an aneurysmal bone cyst, or a malignant tumour such as a small round cell tumour.

A tissue diagnosis by biopsy is important, the type of biopsy depending on the site of the lesion. The choices include a needle (aspiration), trocar, open, or excision biopsy. Aspiration and trocar biopsy should be carried out under radiological control.

Spinal tumours may be classified as to whether they are primary benign, primary malignant, metastatic, intraspinal, or paraspinal, which includes tumours arising in the paraspinal musculature.

Osteochondroma

This is a benign cartilage-capped exostosis and can arise from any bone that develops from cartilage. It is the commonest primary tumour of bone and about 3 per cent occur in the spine (Novick *et al*. 1982). They usually present as a solitary lesion but may be multiple (diaphyseal aclasis) and rarely cause symptoms. When they do, they present as a painless lump and rarely with pain or neurological dysfunction. There is a definite, albeit small, predisposition to malignant degeneration, particularly in diaphyseal aclasis. This should be suspected in any osteochondroma that becomes painful or increases in size. Treatment of the osteochondroma is by excision, if the symptoms warrant it.

Osteoid osteoma

This lesion accounts for approximately 1 per cent of all tumours. Jackson *et al*. (1977) reviewed 860 osteoid osteomata, of which 85 occurred in the spine. It is commoner in males and usually presents between the ages of 10 and 25 years. Painless lesions have been reported (Pettine and Klassen 1986), although this is rare. The patients classically present with pain which is usually well localized, may be worse at night, may interfere with sleep, and may appear to be exacerbated by rest and activity. The pain is not necessarily relieved by aspirin. It gradually increases in severity and becomes more constant. There may be local tenderness and, frequently, there is an associated scoliosis (Fig. 4). Muscle spasm, limitation of spinal movement, and a limp may be present. Plain radiographs are frequently normal. Skeletal scintigraphy is indicated whenever the lesion is suspected, and has greatly reduced the delay in diagnosis. CT scanning of the area of increased uptake is required to pinpoint the lesion. CT scanning is preferable for localizing bony lesions, whereas MRI gives more information about the soft tissues and bone marrow.

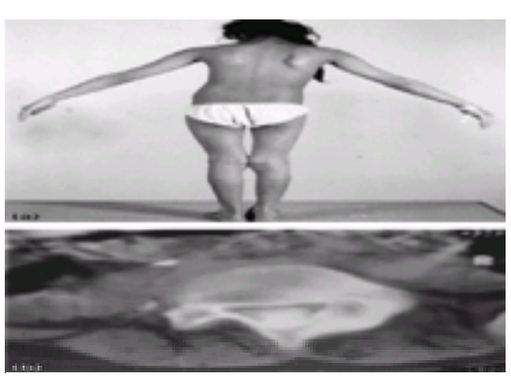

Fig. 4 Osteoid osteoma. This adolescent female presented with a painful scoliosis (a). Her skeletal scintigram showed an area of increased uptake in the right pedicle of L5. Computed tomography confirmed the lesion (b). Following resection of the osteoid osteoma, which was confirmed by histological examination, both her pain and scoliosis disappeared.

It sometimes may be difficult to localize the lesion at surgery, and the increased avidity of these lesions for bone-seeking radionuclides can be used to help pinpoint the lesion and minimize the amount of bone resected. Prior to surgery, the patient is given a bisphosphonate labelled with technetium-99m and is a sterilized probe used to detect the area of greatest activity, which is then excised. If a further area of increased activity is noted, it must also be excised. Failure to relieve pain might indicate that a second lesion was left or the wrong piece of bone resected. If the pain is not relieved, postoperative skeletal scintigraphy, CT scanning, or MRI is indicated to exclude a persistent osteoid osteoma.

An important differential diagnosis is the sclerotic phase of spondylosis. These patients present with a unilateral defect in one pars interarticularis and an area of sclerosis in the contralateral pedicle (Sherman *et al*. 1977). This area of sclerosis is associated with increased uptake of the bone-seeking radionuclide. Single-photon emission computed tomographic (**SPECT**) skeletal scintigraphy is more sensitive than planar skeletal scintigraphy in demonstrating this lesion (Bellah *et al*. 1991). CT scanning of the area of increased radionuclide uptake is required to differentiate osteoid osteoma from this lesion. If it is excised, the result is a bilateral interarticularis defect with resultant instability.

Osteoid osteoma has been reported as the commonest cause of a painful scoliosis (Mehta and Murray 1977). If the scoliosis has been present for less than 12 to 18 months, it usually disappears following excision of the tumour. However, it may persist and become structural. This depends on the age of the patient and the duration of the symptoms (Mehta and Murray 1977). It is my practice to carry out skeletal scintigraphy and/or MRI in all children and adolescents whose back pain has not settled within 2 to 3 months and whose plain radiographs are normal.

Osteoblastoma

This tumour has a predilection for the spine (approximately 40 per cent), particularly the posterior elements (Fig. 5) (Byers 1968; De Souza and Frost 1973; Jackson *et al*. 1977; Akbarnia and Rooholamini 1981). The patients are usually under the age of 30 years, the lesions tend to be larger than osteoid osteomas, and neurological deficit occurs more commonly. As with osteoid osteoma, the patient may complain of pain for 2 or 3 years before the diagnosis is made. The lesion appears lytic and expansile on plain radiographs, with varying degrees of central ossification and a thin rim of periosteal new bone. This tumour is most often benign, but it may recur and even metastasize. Treatment is by excision.

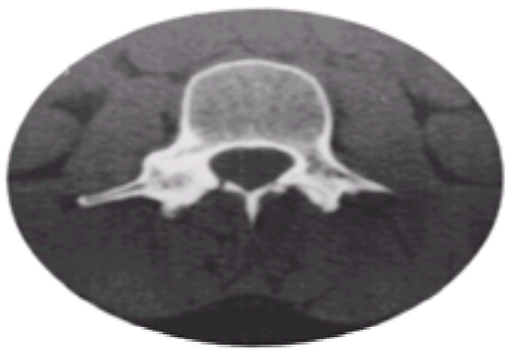

Fig. 5 Osteoblastoma affecting the left pedicle and extending into the transverse process.

Aneurysmal bone cyst

These tumours are rare and account for only 1 per cent of primary bone tumours, but 11 to 22 per cent of the lesions are located in the spine (Hay *et al*. 1978; Capanna *et al*. 1985). The tumours usually occur in the second decade of life and most commonly in the lumbar spine. In 20 to 40 per cent of patients there is involvement of more than one vertebra. The lesions usually present with pain, but may also present with loss of movement and/or scoliosis. Local tenderness may be present and, if a lesion is large, swelling may be observed. Capanna *et al*. (1985) recorded a neurological deficit in 12 of their 22 patients.

The lesions are ill defined and may be missed on the initial radiograph. As the tumour grows a thin cortex is noticed around an expansile lesion with some periosteal new bone. The cavity may contain fine trabeculae seen on tomography or computed tomography. Destruction of the entire vertebral body may cause collapse with vertebra plana. The lesion may extend to the adjacent rib or vertebra and there may be a soft tissue component. Radiculography may show a complete block or an irregular extradural defect. MRI is helpful to delineate the soft tissue spread and cord or nerve root compression. There is usually increased uptake on skeletal scintigraphy, and angiography shows arteriovenous shunting.

Needle biopsy may be associated with profound bleeding. Treatment is by surgical excision, radiotherapy, or their combination. The lesion is usually curetted out, but Hay *et al*. (1978) reported a 25 per cent recurrence rate following incomplete excision. If feasible, selective embolization, prior to resection of the tumour, is advisable to minimize the extent of intraoperative bleeding; cryosurgery has been employed for a similar reason. Capanna *et al*. (1985) reported poor results with radiotherapy. Furthermore, the latter may result in growth disturbance or radiation myelopathy. Sarcomatous change has been reported following irradiation of a spinal aneurysmal bone cyst (Tillman *et al*. 1968).

Langerhans cell histiocytosis (eosinophilic granuloma)

This may occur as a solitary lesion, may be polyostotic, or may be associated with systemic involvement. Lichtenstein (1953) coined the phrase histiocytosis X (now called Langerhans cell histiocytosis) to include all forms of eosinophilic granuloma. Letterer–Siwe disease and Hand–Schüller–Christian disease represent the acute and chronic form, respectively, of the systemic illness. The disease may affect infants, children, or young adults. The condition is probably not a true neoplasm and accounts for less than 1 per cent of all tumour and tumour-like conditions of bones.

It most frequently presents in an adolescent with back pain of some weeks' duration. Neurological deficit is rare. It is characterized radiographically by areas of well-circumscribed osteolysis and is the most common cause of vertebra plana in the skeletally immature spine. Considerable collapse of the vertebral body may occur without neurological compromise (Fig. 6), but spinal cord involvement may occur from acute collapse or occasionally from extradural spread of the lesion. In the spine, the lesion occurs most commonly in the thoracic region. Occasionally, several adjacent vertebral bodies are involved; this occurs more commonly in the systemic form. The diagnosis can often be made from the radiographs, but biopsy may be required.

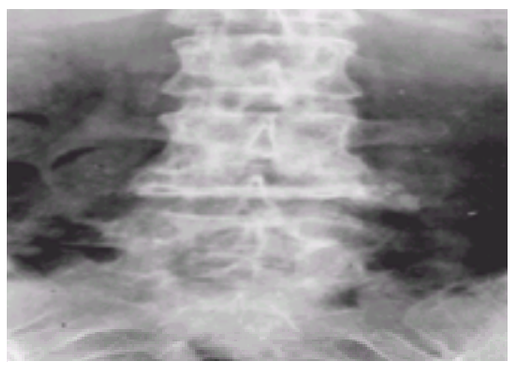

Fig. 6 Vertebra plana secondary to eosinophilic granuloma. There are many causes of severe collapse of a vertebral body, but in an adolescent the commonest cause is eosinophilic granuloma.

Treatment of eosinophilic granuloma depends upon the presence or absence of neurological compromise and the degree of vertebral collapse.

The solitary form of eosinophilic granuloma is self-limiting and restoration is variable, but the younger the patient the more likely a vertebra plana will reconstitute to an almost normal configuration. Treatment usually consists of an hyperextension orthosis, which maintains alignment of the spine whilst reconstitution is occurring. Following complete collapse of the vertebral body, immobilization of the spine is probably all that is required.

Neurological deficit, secondary to soft-tissue tumour extension, is treated with radiotherapy; but, if it is secondary to bony impingement, decompression and fusion are required. Chemotherapy is required for the systemic forms of the condition. Radiation is no longer considered appropriate or necessary for a single lesion unless there is cord compression.

Other benign tumours

Other benign tumours may affect the spine but are extremely rare in childhood. Haemangiomas usually occur after the age of 40 years. Giant-cell tumours rarely occur in the spine and, when they do, they usually involve the sacrum.

Malignant tumours

These are rare. The commonest primary malignant tumour of bone is a myeloma, which usually occurs after the age of 50 years.

It may be difficult to make the diagnosis of a malignant tumour from plain radiographs. The tumours may cause neural compression. Total excision may be impossible. Biopsy is essential. Many of these tumours are radioinsensitive. Irradiation is also limited by the dose to the spinal cord.

Ewing's sarcoma usually occurs in the 5 to 20 years age group. It rarely arises in the spine but when it does, usually presents with localized pain. Tumour growth may result in compression of the neural elements. The tumour may metastasize to the spine from a primary Ewing's sarcoma in the pelvis or long bone. It occasionally is

accompanied by a low-grade fever, elevated erythrocyte sedimentation rate, and leucocytosis. The latter findings are frequently associated with a fulminating course. The radiographic appearance is usually one of moth-eaten destruction and may be difficult to differentiate from infection. There usually is a large soft tissue component. Accurate tissue diagnosis is essential. The prognosis is particularly poor, but radiotherapy may result in marked amelioration of symptoms and good local control in many patients. The addition of chemotherapy has improved the survival. Surgical decompression and spinal stabilization is occasionally indicated.

Malignant lymphoma (reticulum cell sarcoma) of bone is a rare condition. It occurs most commonly in the young adult and may eventually metastasize. The radiographic appearance is of a sclerotic response, and an 'ivory' vertebra may be seen. Treatment is by radiation therapy.

Osteosarcoma is the second commonest primary malignant tumour of bone, but primary involvement of the spine is rare, and spinal involvement is usually due to metastases from osteosarcoma at other sites. The tumour occurs most commonly in the second decade of life. Radiographs show a combination of lytic bone destruction with bone formation. A tissue diagnosis is essential.

Treatment is by resection and spinal reconstruction (whenever possible), chemotherapy, and local irradiation. Unfortunately, radical excision of a primary malignant tumour of the spine is often impossible without compromising the integrity of the spinal cord. Spinal cord or cauda equina compression is treated by debulking the tumour, decompressing the neural elements, and stabilizing the spine.

Other malignant tumours, such as chondrosarcoma, fibrosarcoma, and chordoma usually occur in the adult.

The commonest malignant tumour of bone is metastatic cancer, but this usually affects the adult. In the child, the malignancies most likely to metastasize to the spine are neuroblastoma and leukaemia. These patients usually present with pain which may be localized or may be neuritic in nature. In the majority of patients, the symptoms are controlled by localized radiotherapy and/or chemotherapy. Surgical decompression and stabilization may be required for spinal cord or cauda equina compression, and surgical stabilization for instability secondary to metastatic bone destruction.

Intra- and extramedullary spinal tumours

Primary intramedullary spinal cord tumours may be present for months, or even years, before the diagnosis is made (Reimer and Onofrio 1985). Fearnside and Adams (1978) reported a median delay of 2 years before the diagnosis of a cauda equina tumour was made. The symptoms and physical signs in 57 patients with intradural tumours are shown in Table 4 and Table 5. The mean delay in diagnosis was 4.2 years (Pena *et al*. 1992) and the initial diagnosis was incorrect in 62 per cent.

Symptom	No.	%
Low back pain	28	49.12
Lower limb weakness	14	24.56
Sciatic pain	12	21.05
Thoracic back pain	7	12.28
Altered sensation in legs	4	7.02
Urinary incontinence	4	7.02
Night pain	3	5.26
Upper limb weakness	2	3.51
Thigh pain	1	1.75
Neck pain	1	1.75

(After Pena *et al*. 1992).

Table 4 Presenting symptoms in 57 patients with intradural spinal tumours

Physical sign	No.	%
Muscle weakness	40	70.18
Spastic paraparesis	22	38.60
Spastic paraplegia	2	3.51
Extensor plantar reflexes	25	43.86
Clonus	19	33.33
Absent/reduced reflexes	26	45.61
Sensory level	19	33.33
Localized sensory loss	18	31.58
Absent/impaired vibration/position sense	20	35.09
Positive Romberg test	3	5.26
Urinary retention	8	14.04
Scoliosis	4	7.02
Pes cavus	4	7.02
Claw toes	1	1.75
Drop foot	1	1.75
Tight Achilles tendon	3	5.26
Visual disturbance	2	3.51
Café-au-lait spots	2	3.51

(After Pena *et al*. 1992).

Table 5 Abnormal physical sign at the time of diagnosis in 57 patients with intradural spinal tumours

Woltman *et al*. (1951) found the mean delay in diagnosis of intramedullary tumours was 4.8 years and for extramedullary tumours 2.9 years. Some run a fluctuant neurological course and, in others, symptoms can be precipitated by trivial spinal injury.

Between 40 and 50 per cent of patients complain of a dull aching back pain at the level of the tumour, whereas 20 per cent complain of radicular pain. The presence of nocturnal back pain should raise the suspicion of a spinal tumour (Stern 1978). The tumour may present with spinal rigidity, muscle spasm, scoliosis, or disturbance of gait. On examination there may be neurological signs including weakness, absent or reduced reflexes, an extensor plantar response, spastic paraparesis, abnormalities of sensation, and urinary retention. Foot deformities may be present such as claw toes, pes cavus, or tight Achilles tendon. Up to 50 per cent of patients have abnormal plain radiographs, with increasing width of the spinal canal, medial erosion of the pedicles and scalloping of the vertebral body. Radiculography, CT scanning, and/or MRI show widening of the spinal cord and there may be a block. MRI is the investigation of choice. Treatment is by neurosurgical removal of the tumour. If an extensive laminectomy is required, the spine should be stabilized at the time of surgery.

Approximately two-thirds of intraspinal tumours are extramedullary. The clinical presentation partly depends on the pathological type, but progressive loss of cord function predominates. Pain occurs more frequently than with intramedullary tumours. The extramedullary lesions occur more commonly in adults.

Tachdjian and Matson (1965) reported that the initial diagnosis was incorrect in 70 per cent of 115 children with spinal tumours of all types.

Infection

Spinal osteomyelitis

This occurs much less commonly than osteomyelitis affecting the appendicular skeleton. It occurs most commonly in the adult but in young children there is often more of a systemic reaction. Frequently, the child is ill with a high pyrexia and radiographically significant bone destruction is noted. The organism most commonly responsible for the infection is *Staphylococcus aureus*. It may be difficult to differentiate pyogenic infection from tuberculosis (Fig. 7) and a needle biopsy may be required to isolate the organism before instituting treatment. Treatment normally consists of appropriate antibiotics and immobilization of the spine with an orthosis. Surgery is occasionally required.

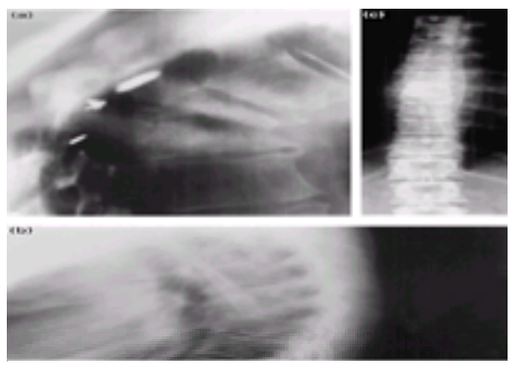

Fig. 7 Spinal infection. It may be difficult to differentiate a pyogenic infection (a) from tuberculosis (b). Needle biopsy may occasionally be required. *Staphylococcus aureus* was cultured from the needle biopsy taken from the patient shown in (a). Tuberculosis is usually associated with a paravertebral abscess (c), which usually does not occur with pyogenic spondylitis.

Tuberculosis

Tuberculosis may affect any bone or joint, but is most commonly found in the spine. Typically, a disc and adjacent vertebrae are involved (Fig. 7(b and c)), although several adjacent vertebrae may be affected. Collapse of the disc with damage to adjacent vertebrae is the characteristic radiographic appearance and produces a localized kyphosis, which may be very severe depending on the amount of destruction (Fig. 8). The tuberculous pus spreads along the soft tissue planes and may extend posteriorly to involve the spinal canal. Usually a paravertebral abscess is evident on the plain radiographs (Fig. 7(c)).

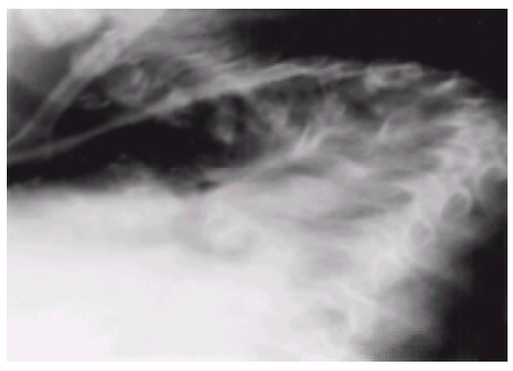

Fig. 8 Tuberculosis of the spine associated with significant destruction and a severe kyphosis.

The patient presents with pain frequently associated with a localized kyphosis. There may be a cold abscess, depending upon the spread of pus. Neurological symptoms may arise from pressure on the cord or cauda equina secondary to deformation of the spine, or compression of the neural tissues by fragmented bone and/or pus.

The erythrocyte sedimentation rate is raised and the Mantoux (tuberculin) test is positive. The typical radiographic appearance is of localized destruction of a disc and the adjacent two vertebrae, although the destruction may be more extensive. Usually a soft tissue abscess is seen in the paravertebral tissues.

The diagnosis can only be proved by identifying the organism or demonstrating the typical histological features, but this is not always required. In most cases, infection can be treated by antituberculous chemotherapy and immobilization of the spine in a plaster jacket or orthosis, although the latter may not be essential (Medical Research Council 1985). Large abscesses should be drained after chemotherapy has been instituted and, if there is any suggestion of spinal cord or cauda equina compression, the neural tissues must be decompressed and the spine stabilized, usually with an anterior bone graft.

Plain radiographs provide most of the information necessary for diagnosis and treatment. The main value of CT and MRI is in the preoperative evaluation of the small proportion of patients who require surgical treatment (Hoffman *et al*. 1993). Skeletal scintigraphy or MRI may be useful in diagnosing a recurrent infection (Fig. 9).

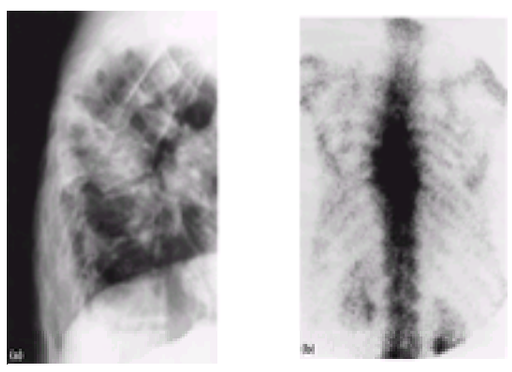

Fig. 9 (a) Recurrent tuberculosis. This patient had previously been treated for tuberculosis but returned some years later complaining of recurrent back pain. From the radiographs it was impossible to determine whether there was any active infection. (b) The skeletal scintigram showed increased uptake at the site of the previous infection. This appearance, together with the symptoms, suggested that she had reactivated tuberculosis and required a further course of therapy.

Discitis

This implies an infection of the discs. There are two varieties (Galasko 1989): postoperative discitis, which is a rare complication of discectomy and occurs in adults; and discitis of childhood.

Discitis of childhood

This most frequently occurs in children between the ages of 2 and 6 years, who present with irritability and a painful, tender, and stiff back (Fig. 10). The degree of stiffness is usually striking. Often the child cannot bend down and pick up an object from the floor without squatting. Sometimes the child limps. The tenderness may be localized, but in a younger child it may be diffuse across the back. There is no neurological involvement. The erythrocyte sedimentation rate may be elevated but the white cell count is frequently normal. There may be a history of recent febrile illness, such as a sore throat or earache (Wenger *et al*. 1978). Widespread paravertebral muscle spasm and limited back movement are characteristic signs. Pain may radiate to the abdomen, anterior thigh, or lower limbs. The presentation may be similar to that of an irritable hip or other hip disorders because of a limp in an older child, refusal to walk in a child under the age of 3 years, and radiation of the pain to the anterior thigh.

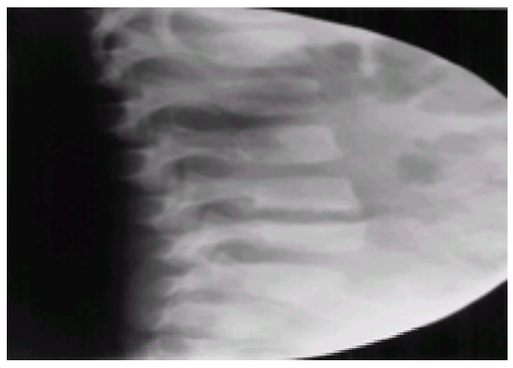

Fig. 10 Discitis. There is narrowing of the affected disc with involvement of the adjacent vertebrae.

In the early case, the radiographs may be normal, but subsequent radiographs show narrowing of the intervertebral disc (Fig. 10) followed by erosion of the adjacent vertebrae. A kyphosis may develop. Occasionally, fusion of the adjacent vertebrae may occur after the infection has settled. Increased uptake of radionuclide may be seen in skeletal, and particularly gallium-67, scintigrams (Norris *et al*. 1978; Bruschwein *et al*. 1980) prior to the development of radiographic signs. MRI is more sensitive but may have to be carried out under a general anaesthetic. Organisms are found in only half of the patients (Wenger *et al*. 1978) and, in many centres, no attempt is made to find the organism. The patient is usually treated with antibiotics. Where an organism has been found, the commonest is *Staphylococcus aureus* and the antibiotics most frequently used are flucloxacillin or a cephalosporin. Blood cultures should be taken prior to starting antibiotic therapy, which may be given intravenously for the first 3 to 4 days. The spine is also immobilized in a plaster jacket for approximately 6 weeks. If the patient does not respond to empiric antibiotic treatment, needle aspiration or biopsy may be required. A CT-guided needle biopsy is usually carried out by a radiologist.

Not all patients make a full recovery. Jansen *et al*. (1993) followed up 35 children for 12 to 35 years, with an average follow-up of 17 years. Fifteen patients still complained of backache. Flexion of the spine was normal in 32 patients whereas extension was restricted in 30. Twenty-six patients had a blocked vertebra and 28 patients had narrowing of the vertebral canal.

Wenger (1993) suggested that discitis and vertebral osteomyelitis were variations of a similar disorder, the infection beginning as a microabscess in the vertebral body adjacent to the vertebral endplate. This is a rapidly growing portion of the vertebral body, anatomically similar to the metaphysis of a long bone where osteomyelitis usually begins. The disc is involved early by the infection because of the vascular channels. Wenger suggested that vertebral osteomyelitis occurred when the infection progressed to the point of causing destructive changes in the vertebral body with collapse.

Discitis occurs much more frequently than vertebral osteomyelitis. However, patients with vertebral osteomyelitis usually have a very short history, whereas some patients with discitis may have been symptomatic for a number of weeks before the diagnosis is made. Wenger concluded that both conditions are due to infection. In both disorders, the commonest organism is *Staphylococcus aureus* and Wenger suggested that the difference may be due to the response of the host to the infection.

In contrast, Ryöppy *et al*. (1993) carried out an operative biopsy in 16 of 18 patients who were treated for non-specific discitis. The mean age at admission was 3 years and 3 months. The characteristic clinical findings were restriction of spinal mobility and an elevated erythrocyte sedimentation rate. Radiographic narrowing of the affected disc space was seen 4 to 5 weeks after the initial symptoms. A histological diagnosis of chronic or subacute non-specific inflammation was made in 10 patients. There were non-specific changes in 2 and normal tissue was found in 5. The patients were either treated with bed rest and antibiotics or bed rest alone. They found that all patients made a full clinical recovery, their follow-up ranging from 5 months to 9 years. Bacterial staining and cultures were negative in all the patients. Ryöppy and colleagues queried whether discitis was infective and suggested that antibiotics should only be given to patients with systemic signs, with positive bacterial cultures from other foci, or to patients who did not respond to adequate immobilization.

Intramedullary spinal cord abscess

This is a rare condition (Bartels *et al*. 1995). The presentation can be confusing, mimicking thoracic or abdominal disease. It is associated with neurological signs. MRI is the investigation of choice. An early diagnosis and emergency decompression of the intramedullary abscess is required to offer the patient the best opportunity of regaining neural function. Appropriate antibiotics are given. Dexamethasone is required to reduce the oedema. A high initial dose is given and the dose is gradually reduced.

Prolapsed intervertebral disc

There are three types of underlying pathology:

1. a bulging unripe disc;
2. a sequestrated disc;
3. occasionally, a slipped vertebral epiphysis.

Although it is not as common as in the adult, disc herniation can occur in children and adolescents. The symptoms are frequently less severe in children and there is less commonly a precipitating event. De Orio and Bianco (1982) suggested that disc herniation in children was more likely to be due to cumulative trauma than to a single event, i.e. the result of a fatigue failure of the annular fibres. MRI has shown that several of the discs are abnormal in an adolescent with a prolapsed intervertebral disc, although only a single disc prolapses. The commonest levels are at L4/5 and L5/S1.

Back pain is the commonest presenting symptom. Typically, the pain is aggravated by activity and relieved by rest. It may be increased by coughing and sneezing. Local tenderness may be present. There usually is significant spinal spasm and the patient frequently has a shuffling gait. The straight leg raising is usually restricted and other sciatic nerve tension signs are usually positive, but objective neurological findings are uncommon. The plain radiographs are usually normal and the diagnosis is usually based on CT scanning, radiculography, or MRI.

Unlike the adult, the adolescent disc prolapse does not frequently respond to conservative treatment and surgical excision is required more often. In the majority of patients, excision relieves the lower back pain, stiffness, and hamstring spasm (Silvers *et al*. 1994) but it may take months, following removal of the disc, for the stiffness to settle. De Luca *et al*. (1994) found that patients treated by discectomy did better than patients treated conservatively.

Slipping of the vertebral epiphysis occurs only in adolescence, is more common in males, and is usually associated with heavy lifting. The posterior, inferior epiphysis of L4 is most frequently affected. The slipped epiphysis with its adjacent disc is displaced into the vertebral canal (Lowrey 1973; Keller 1974; Lippitt 1976; Handel *et al*. 1979: Banerian *et al*. 1990). It is analogous to a slipped upper femoral epiphysis and occurs in the same age group. The symptoms and signs are similar to those of a prolapsed disc and there are often signs of neurological impairment. A small bony fragment (the edge of the vertebral endplate) may be seen within the spinal canal on plain radiographs. The rim of the epiphysis is usually seen within the canal on CT scans and MRI. The radiculographic appearance is of a large anterior defect or a complete block. Surgical excision of both the extruding disc and the bony ridge is required for relief of symptoms.

Tertti *et al*. (1991) compared 39 15-year-old children with low back pain with 39 asymptomatic control children. When examined by MRI, disc degeneration was found in 15 (38 per cent) of the patients with pain and 10 (26 per cent) of the controls. The difference was not significant. There were no differences between the two groups in Scheuermann-type changes in the lumbar spine, transitional vertebrae, or disc space narrowing. Only disc protrusion was more common in patients in the low back pain group (8 as opposed to 1 in the control group, $p < 0.05$). The authors concluded that disc degeneration was frequently found in this age group and is often asymptomatic.

Scheuermann's osteochondritis

Scheuermann's osteochondritis is a common cause of a thoracic kyphosis in the adolescent and can be painful, although the patient usually presents with a painless kyphosis. The diagnosis is made on plain lateral radiographs of the spine.

Scheuermann's osteochondritis has been classified into two types. Type 1 affects the thoracic spine. It is the commonest form (Fig. 11) and is associated with wedging of the thoracic vertebrae. The typical radiographic appearance (Sorensen 1964) is of wedging of more than 5 degrees of three or more adjacent vertebrae with endplate irregularity. It is usually associated with excessive lumbar and cervical lordosis, tight hamstrings, tight pectoralis muscles, tight hip flexors and anterior pelvic tilt. Progressive curves of more than 45 to 50 degrees are often treated by bracing (Fig. 12) until growth stops (Bradford *et al*. 1974; Sachs *et al*. 1987), but orthotic treatment is only likely to be successful in co-operative, skeletally immature patients. Surgery is sometimes indicated in curves greater than 70 degrees. The majority of patients require physiotherapy, which should include postural awareness, hamstring and pectoral stretching, and trunk extensor strengthening.

Fig. 11 Patient with painful thoracic Scheuermann's osteochondritis. Note the involvement of the anterior ring epiphyses, with slight wedging of the affected vertebrae.

Fig. 12 Scheuermann's osteochondritis. The kyphosis may be associated with a secondary lumbar lordosis.

Type 2 Scheuermann's osteochondritis affects the thoracolumbar and lumbar spine. It is less severe in magnitude but is more commonly painful (Greene *et al*. 1985). It is treated with extension exercises and bracing may sometimes be required.

There is a relationship between lumbar Scheuermann's osteochondritis and hard physical labour in immature teenagers (Greene *et al*. 1985) and it occurs more commonly in young athletes (Micheli 1979), suggesting that it might be due to trauma to the vertebral growth plates. When present, the pain is usually aggravated by activity and responds to simple rest and, if necessary, immobilization in an orthosis.

Other forms of kyphosis (Table 3)

There are two types of congenital kyphosis. Failure of formation is associated with a posterior hemivertebra and can cause paraplegia. Ideally, a posterior fusion *in situ* is required under the age of 2 years. The fusion may have to be re-explored and augmented 6 months after the original operation. If the diagnosis is made later, anterior and posterior fusion are required with anterior resection of the short ligaments, discs, and all the cartilage remnants. A patient with a paraparesis usually requires anterior cord decompression, and anterior and posterior fusion.

Failure of segmentation is associated with an anterior bar. The kyphosis progresses more slowly and the risk of paraplegia is much less.

Neurosurgeons often have to carry out a laminectomy to remove a tumour from a spinal cord or canal. In growing children this will nearly always result in a progressive kyphosis. The longer the laminectomy, the worse the deformity, particularly if the facet joints have had to be removed. Sometimes the laminectomy is combined with posterior fusion. If the child develops a progressive kyphosis, anterior and posterior fusion is required. Bracing can be used as a temporizing measure, but the only definitive treatment for a progressive post-laminectomy kyphosis is fusion.

Spinal deformity is the commonest skeletal problem in patients with neurofibromatosis. It can take the form of a scoliosis or a kyphosis. A scoliosis with significant rotation may present as a kyphoscoliosis. The treatment of a neurofibromatous kyphosis is by anterior and posterior fusion.

Progressive kyphosis secondary to skeletal dysplasia (Fig. 2) may also cause progressive paraparesis and may require anterior and posterior fusion.

In patients with a progressive kyphosis, an early fusion *in situ* is preferable to a fusion with correction of deformity once the latter has progressed to an advanced stage. Surgery for kyphosis carries a definite, albeit small, risk of paraplegia, usually consequent upon vascular damage to the spinal cord, particularly in the thoracic region. In general terms, fusion *in situ* is less likely to be associated with this complication than a fusion combined with correction of the deformity but, nevertheless, neurological sequelae can still occur. Severe kyphosis may continue to worsen after growth has ceased.

Postural kyphosis is by definition a flexible deformity. It is often associated with rounded shoulders and an increased lumbar lordosis. It is treated with postural awareness and an exercise programme. Occasionally, bracing is required.

Spondylolysis and spondylolisthesis

Spondylolysis probably represents a stress or fatigue fracture of the pars interarticularis (Wiltse *et al*. 1975). Although the condition probably occurs in childhood, the symptoms may not occur for many years, and are frequently precipitated by minor trauma. Many individuals remain asymptomatic. Fredrickson *et al*. (1984) found an incidence of spondylolysis with or without spondylolisthesis in 4.4 per cent of schoolchildren at the age of 6 years, increasing to 6 per cent by adolescence. Very few had symptoms. Symptoms commonly occur during the adolescent growth spurt, but may occur in older patients. Jackson *et al*. (1976) found that the incidence was four times higher than expected in female gymnasts, some of whom initially had normal radiographs, and Wiltse *et al*. (1975) reported acute spondylolysis in soldiers who carried heavy back packs and performed exercises to which they were unaccustomed.

The pain is generally localized to the low back and there may be some tenderness and muscle spasm. The origin of the pain is not certain but it has recently been shown that there are nerve endings within the pars defect tissue (Schneiderman *et al*. 1995). Hamstring tightness is commonly found in the symptomatic patient. A

careful neurological examination is essential, but there is rarely any neurological impairment in children with a spondylolysis or grade I spondylolisthesis.

If large, the defect in the pars interarticularis may be seen on routine anteroposterior and lateral radiographs of the spine but, if the defect is unilateral, is small, or is not associated with a spondylolisthesis, it may only be seen on oblique radiographs of the lumbar spine (Fig. 13).

Fig. 13 Spondylolysis. The defect in the pars interarticularis (arrowed) may only be noted on the oblique view. This patient has been treated by a spinal fusion (open arrows).

Occasionally the lesion is due to an acute fracture of the pars interarticularis, when the radiographic appearance is of a narrow gap with irregular edges, whereas in the chronic lesion the edges are smooth. A stress fracture may be detected on a skeletal scintigram, CT scan, or MRI before it becomes evident on radiographs. There may be reactive sclerosis and hypertrophy of one pedicle with a contralateral spondylolysis in the same vertebra (see above). This probably is due to repeated trauma in the presence of an unstable neural arch. Radiographically, and scintigraphically, the lesion can be confused with an osteoid osteoma, but CT scanning will indicate whether a nidus is present (see above).

Asymptomatic spondylolysis does not require treatment. The spondylolytic defect may heal with immobilization in a cast or orthosis in children or adolescents with an acute onset of symptoms and a clearly documented injury (Micheli 1979).

If the spondylolysis has been present for a long time, restriction of vigorous activities and isometric spinal and abdominal muscle strengthening exercises are frequently successful in controlling the pain. If the symptoms are more severe or more persistent, immobilization in a plaster cast or orthosis may be required. The majority of adolescents respond to simple measures. Persistence of hamstring tightness usually indicates that treatment is not successful. If the symptoms do not settle, or if the patient is not prepared to curtail his/her activities, surgical fusion may be required.

Spondylolysis is frequently asymptomatic and the presence of a spondylolytic defect on the radiographs does not necessarily mean that the patient's symptoms are due to the lesion. Other causes of back pain must be excluded.

The vast majority of spondylolistheses (forward slipping of one vertebra upon another) in childhood and adolescence are secondary to spondylolysis (isthmic spondylolisthesis). Clinically, a step may be palpable in the spine and a transverse crease may be noted across the back (Fig. 14). There is a lumbosacral kyphosis.

Fig. 14 Spondylolisthesis. Occasionally an abnormal crease may be seen across the back in a patient with a significant spondylolisthesis. Frequently a step is palpable in the spine at the level of the slip.

Occasionally dysplastic spondylolisthesis is noted. Here, the posterior structures are poorly developed, with elongation and attenuation of the pars interarticularis. There is usually marked limitation of forward flexion and significant hamstring tightness. If required, treatment is by fusion.

Degenerative spondylolisthesis does not occur in children and pathological spondylolisthesis is rare. It either results from a generalized skeletal dysplasia, such as osteopetrosis or a mucopolysaccharidosis, or from localized bone destruction, for example following infection or a tumour.

Isthmic spondylolisthesis may progress, particularly during the rapid adolescent growth spurt. Progression seldom occurs after the age of 25 years. In general terms, the spondylolisthesis is more likely to progress if the slip on the initial radiographs is greater than 30 per cent. Severe slip occurs more frequently in females and patients with dysplasia at the lumbosacral junction, including spina bifida. However, these two variables have no statistical value for predicting progression.

The more severe a spondylolisthesis, the less likely are the symptoms to respond to conservative measures. Immobilization in a lightweight plaster cast or orthosis is a useful adjunct in the preoperative assessment. In general, if the symptoms are related to activity and are greatly improved by bed rest or immobilization in a plaster cast or orthosis, a localized fusion is all that is required (Fig. 15). If the symptoms are not relieved by bed rest and/or immobilization, or if there is significant neurological impairment, MRI is indicated and, if necessary, spinal fusion should be combined with decompression. There may be an associated prolapsed disc which requires discectomy at the time of fusion.

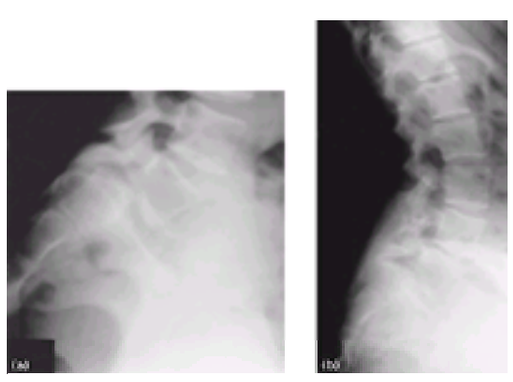

Fig. 15 (a) Patient with spondylolisthesis of long standing and without neurological signs. L5 has slipped forward by about 50 per cent. Note the bone that has developed on the anterior surface of the first sacral segment as a response to the chronic slip. A lumbar kyphosis is clinically evident. (b)This was treated by a

posterior fusion with total relief of her symptoms.

The indications for surgery are slip progression, persistent deformity and abnormal gait, refractory pain, neurological symptoms, and a high slip angle of more than 50 per cent, in a skeletally immature individual. Decompression alone has no place in the management of spondylolisthesis. It leads to increased instability, slip progression, and increased lumbosacral kyphosis.

The rare individual with severe deformity may benefit from reduction of the slippage along with fusion. These are patients with a severe lumbosacral kyphosis for whom *in situ* fusion may be inadequate for postural improvement and symptom relief. However, Poussa *et al*. (1993) compared the results of *in situ* fusion in 11 patients with slips of more than 50 per cent with reduction, internal fixation, and fusion in a similar group of 11 patients and found that the results were better for *in situ* fusion because there were fewer complications and fewer reoperations. The clinical results were the same in both groups. McGuire and Amundson (1993) found no difference in the fusion rate between in situ fusion compared with internal fixation without reduction in a prospective randomized study.

Pedicle sclerosis

Back pain in young athletes may be due to stress-related microfractures in the pars. Radiographs may show a defect or sclerosis. However, the plain radiographs, including oblique views, may appear normal. Under these circumstances, skeletal scintigraphy including SPECT scintigraphy is indicated. This may show an area of increased activity in the pars. The treatment is immobilization in a spinal orthosis for 3 to 6 months. Failure to detect and treat the lesion in the sclerotic phase may lead to a stress fracture and spondylolysis. Biopsy is contraindicated (see above).

Spinal dysraphism

The condition is associated with some evidence of nerve tissue anomaly plus a bony anomaly. The bony anomaly is usually a spina bifida occulta. The neural anomaly is cord tethering which is due to or associated with a variety of disorders including a thickened filum terminale, lipomyelomeningocele, fibrous bands, diastematomyelia, meningocele, neuroenteric cysts, and dermoid cysts. It may be associated with cutaneous manifestations such as a hairy patch, dimple, haemangioma, lipoma, or an area of thin atrophic skin. It may present with back pain; neurological symptoms including leg weakness, fatigue, and urinary incontinence; deformity such as limb length inequality, foot deformity including clawed toes, pes cavus, and foot size inequality; trophic ulceration; and/or sciatica. Scoliosis may be the first manifestation and patients with a congenital scoliosis should undergo MRI to exclude the presence of spinal cord tethering prior to corrective surgery.

The onset may be insidious or may occur acutely after minor trauma. It is thought that the neurological symptoms are due to tethering of the spinal cord with stretching of the cord or nerve roots. However, deterioration may occur at any time during childhood or even in adult life and does not just occur during the growth spurts.

MRI is the investigation of choice. If this is not available, myelography should be carried out with computed tomography. Surgery is not without its hazards and should be carried out by an experienced neurosurgeon. There is some debate as to the indications. In general terms, most neurosurgeons agree that surgery is indicated in newborn children with a lumbosacral lipoma and tethered cord but no neurological abnormalities, patients with neurological symptoms including bladder involvement, and patients with an associated scoliosis who will be undergoing corrective surgery. There is some debate as to whether surgical release is indicated in the asymptomatic adolescent or adult.

Foot size inequality (Fig. 16) or limb length inequality may be secondary to spinal dysraphism and examination of the spine should be undertaken in a child who presents with either of these conditions. Widening of the interpedicular distance may be seen on plain radiographs of the spine and is an indication for MRI.

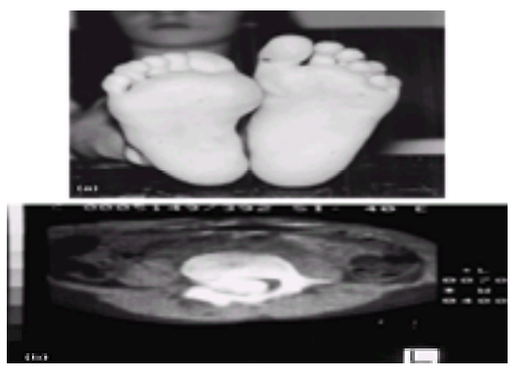

Fig. 16 (a) Patient who presented with inequality of foot size. (b) This was found to be secondary to a thickened and adherent filum terminale.

Spina bifida occulta occurs commonly and in the majority of patients is benign, is not associated with any symptoms, and there is no associated cord tethering.

Diastematomyelia may be seen on plain radiographs but radiculography, CT scanning (Fig. 17), or MRI may be required to make the diagnosis.

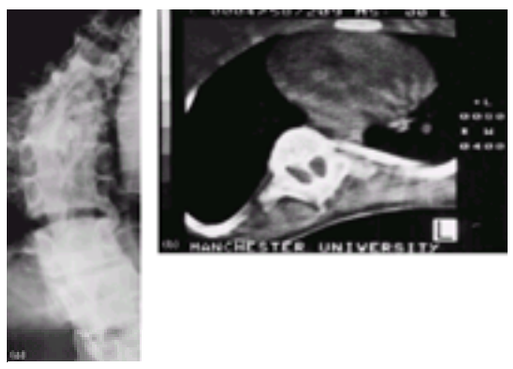

Fig. 17 (a) Patient with congenital scoliosis. A bony spur can just be made out in the centre of the scoliotic segment. (b) CT scan showing the diastematomyelia. This patient had a complete bony spur dividing the spinal canal into two. The diastematomyelia may produce neurological symptoms. Traction on the spinal cord during elective surgery for scoliosis can produce paraplegia and, if a patient has a diastematomyelia, the spur must be resected prior to embarking upon scoliotic corrective surgery.

Congenital deformities of the spine may be associated with congenital deformities elsewhere, particularly in the urinary tract.

Inflammatory disorders

Juvenile ankylosing spondylitis usually occurs in young adults, but can occur in a younger age group. In about 8 to 9 per cent of patients with seronegative

spondylarthropathy, the symptoms start between the ages of 10 and 15 years (Hart 1955; Schaller 1977). However, there is usually a considerable delay before the diagnosis is established. In addition to back pain, these patients may develop a transient arthropathy of the larger peripheral joints. The condition occurs most commonly in males and examination usually reveals diminished chest expansion and restriction of spinal movement. The vast majority of patients have the HLA B27 antigen. Radiographs are usually normal early on in the course of the disease, but there is increased sacroiliac uptake of radionuclide, best revealed by measuring the sacroiliac uptake ratio. Treatment is by non-steroidal anti-inflammatory agents and mobilizing exercises.

Seronegative spondylarthropathies in childhood are often misdiagnosed as juvenile rheumatoid arthritis (Kredich and Patrone 1990). Reiter's syndrome, psoriatic arthritis, and the arthritis associated with inflammatory bowel disease may occur in young adults, but may also be present in children. Extra-articular manifestations include inflammation of the eyes, skin, gastrointestinal tract, and genitourinary tract, and enthesopathies should be sought. The treatment is different to that required for juvenile chronic arthritis (juvenile rheumatoid arthritis) (see Chapter 5.5.2).

Juvenile osteoporosis

Juvenile osteoporosis is a rare disease, particularly when compared with postmenopausal or senile osteoporosis. It may lead to vertebral collapse (Fig. 18) and kyphosis. In general terms, osteoporosis in children may be primary or secondary. The latter complicates disorders such as Cushing's syndrome, the use of steroids, inflammatory spondylarthropathies, juvenile chronic arthritis, and has been described in association with diabetes. Soejima and Landing (1986) showed that osteoporosis was a regular feature of juvenile-onset diabetes mellitus and suggested that the degree of bone matrix and mineral deficiency in such patients was greater than usual. Osteoporosis also occurs with disuse. For example, severe disuse osteoporosis may be seen in patients with severe neuromuscular disorders who are confined to wheelchairs and have very little residual function. Other known causes are coeliac disease, Turner's syndrome, and homocystinuria. Serious disorders such as leukaemia must also be considered in the differential diagnosis.

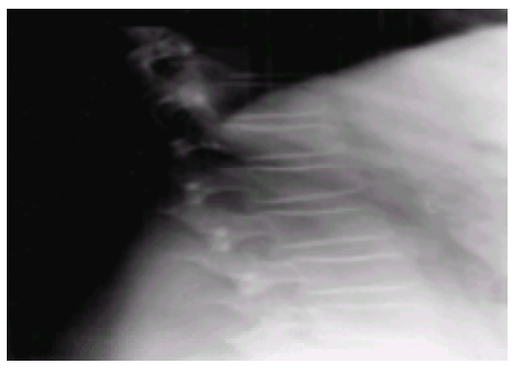

Fig. 18 Osteoporosis. This patient was treated with high doses of steroids for focal multinodular myositis. Within 3 months he developed significant collapse of several vertebrae.

Juvenile idiopathic osteoporosis is a rare condition. The onset is usually between 6 and 13 years of age. It is commoner in males. The patient usually presents with pain, resultant upon a compression fracture of the vertebral body. Height loss of the vertebrae is common. Radiographs show osteopenia.

The patients may also present with a fracture of the lower extremities following a minor fall. Juvenile osteoporosis should be suspected in any child between 6 and 18 years of age who sustains a fracture without a reasonable cause, and these patients should have a spinal radiograph taken. The main differential diagnosis is osteogenesis imperfecta.

The cause of idiopathic juvenile osteoporosis is unknown, although some have postulated a deficiency of 1,25-dihydroxy vitamin D (Marder *et al*. 1982; Saggese *et al*. 1991), and treatment with 1,25-dihydroxycholecalciferol has been suggested.

Routine biochemical measurements are usually within the normal range when due account is taken of the normal increase in alkaline phosphatase and urinary hydroxyproline in the preadolescent growth phase, but Dent and Friedman (1965) and Jowsey and Johnson (1972) reported a tendency for high values of urine calcium in some patients. Dent and Friedman (1965) also reported malabsorption of calcium in some patients. In his experience of 21 patients, Smith (1995) found that routine biochemical measurements were within the normal range as were vitamin D metabolites. In his series the main presenting symptoms were long bone fracture (7), back pain (7), difficulty in walking (5), progressive kyphosis (1), and failure to thrive (1). Some patients had more than one of these symptoms simultaneously. Although pain in the back was not a constant first symptom, the vertebrae were always radiologically abnormal. In the absence of overt fracture, the most striking sign was pain and difficulty in walking. Apart from bone fragility, no patient had features of osteogenesis imperfecta.

Patients with juvenile osteoporosis are likely to develop crush fractures of their vertebral bodies, irrespective of the cause of their osteoporosis. The vertebral trabecular bone density is abnormally low (Fredericks *et al*. 1990), the lowest values being found in the spine and hip soon after the onset of symptoms (Smith 1995). Bone biopsy shows either the features of osteoporosis alone or of an excess of osteocytes sometimes associated with woven bone or changes similar to those found in type IV osteogenesis imperfecta (Smith 1995). Smith (1995) suggested that the primary defect was a failure of osteoblastic activity, whereas Hoekman *et al*. (1985) suggested that it was uncontrolled activity of the metaphyseal osteoclasts and that treatment with bisphosphonates may be beneficial. Collagen studies are usually normal although minor abnormalities were found in occasional patients (Smith 1995).

Radiographs show metaphyseal compression fracture in the long bone and progressive loss of height in the vertebrae. When the condition improves, improvement is first noted in the vertebral bodies. Unlike osteogenesis imperfecta, patients with idiopathic juvenile osteoporosis do not have Wormian bones or the other features of osteogenesis imperfecta. Radiographs of the vertebral column show vertebral collapse, biconcave vertebrae, wedged vertebrae, and loss of vertebral height.

In most patients, significant improvement occurs after the adolescent growth spurt is complete, although mild kyphosis and probably a low normal bone density may persist (Smith 1995). Because improvement may occur spontaneously, it is difficult to assess the effectiveness of the many treatments that have been given. These include appropriate sex hormones (Wright *et al*. 1995), additional calcium, physiological amounts of vitamin D, bisphosphonates (Hoekman *et al*. 1985; Levis *et al*. 1993), and calcitonin (Jackson *et al*. 1988), given separately or together. However, improvement does not always occur. Smith (1995) found that 11 of 14 patients, who had been followed up until growth had ceased, improved substantially or completely, but the remaining 3 were disabled and were eventually confined to a wheelchair.

If osteoporosis is suspected, it is essential to exclude possible causes. For example, patients with leukaemia may present with back pain. The pain may be associated with osteoporosis and vertebral compression fractures. Chemotherapy often includes steroids such as prednisolone or dexamethazone, which may cause osteoporosis. This is reversible and settles after treatment is discontinued. Once these causes of osteoporosis have been excluded, a skin biopsy for fibroblast culture and collagen studies is indicated to exclude the possibility of osteogenesis imperfecta. If there is a reduction in 1,25-dihydrovitamin D, treatment with 1,25-dihydroxycholecalciferol may be worthwhile. Bone biopsy may be helpful in excluding haematological disorders. If the diagnosis of idiopathic juvenile osteoporosis is established and if the investigations are normal, there is probably no indication for the use of sex hormones or bisphosphonates but symptomatic treatment is indicated.

Trauma

Trauma of the spine probably occurs quite often in children and adolescents. Sardelic and Ryan (1989) surveyed 2489 students, aged 11 to 18 years. Only 4.5 per cent (111) had had disabling low back pain and 0.4 per cent (11) had been admitted to hospital. However, 53.1 per cent had complained of pain, the commonest age of onset being 13 years. Of those who experienced pain, 58.4 per cent could recall a preceding back injury. Grantham (1977) found that 11.5 per cent of the male adolescent population of the school he studied complained of back pain, and Fairbank *et al*. (1984) found that 26 per cent of the students they studied, who ranged in age from 14 to 17 years, suffered from back pain. It is likely that trauma is responsible for most cases of non-specific back pain, the pain usually resolving rapidly

without treatment. Trauma may precipitate pain from underlying conditions, such as spondylolysis.

In children, trauma is very rarely associated with a significant injury, but fractures of the spine do occur in childhood (Fig. 19). If stable (e.g. minor compression fractures), the treatment is symptomatic but, if unstable, the fracture must be treated on its merits.

Fig. 19 Compression fractures of L1, L2, and L3 following a fall from a height. The patient was treated with bed rest until the acute pain had settled. He was then mobilized with a spinal orthosis, which he wore for some weeks, and physiotherapy.

Deformity

Spinal deformity in children is usually pain free. If it is associated with pain, it usually implies a significant underlying pathological process which requires investigation and treatment (see above). However, some patients with idiopathic scoliosis complain of mild back pain that responds to physiotherapy.

Scoliosis

Non-structural scoliosis

There is usually a list to one side without associated rotation. It is frequently secondary to an underlying disorder and provided the underlying disorder is corrected, the list will disappear. However, if the underlying disorder is allowed to persist, the scoliosis may become structural.

The commonest causes for a non-structural scoliosis include postural scoliosis, nerve root irritation (for example caused by a prolapsed intervertebral disc or tumour), inflammation (for example appendicitis), lower limb length discrepancy, or contractures around the hip with pelvic obliquity. It may rarely be psychogenic.

Structural scoliosis

This occurs most commonly in adolescents. School screening studies suggest that approximately 3 per cent of adolescent girls have a curve greater than 10 degrees, but in only a tenth of such patients is treatment indicated. The causes of scoliosis are shown in Table 2.

The aetiology of idiopathic scoliosis is not known. However, it occurs most commonly in adolescent girls and there is a genetic predisposition. It has been suggested that it is a balance disorder involving central vestibular centres. There are many other suggestions, none of which have been confirmed. The deformity consists of a lateral curvature of the spine which has also rotated so that the ribs on the convex side become more prominent and, in the lumbar spine, the paravertebral muscles are more prominent on the convex side. This rotation forms the basis of the bending test for the early diagnosis. The child bends forward and the examiner looks for a rotatory prominence of the ribs/paravertebral region. The degree of rotation can be measured.

The severity of the curve is measured on a posteroanterior view of the spine. This minimizes breast irradiation compared with an anteroposterior film. Patients with congenital scoliosis have a high incidence of associated congenital renal abnormalities and renal ultrasound may be necessary. Left-sided curves, particularly in boys, may be associated with intraspinal anomalies.

Modern methods of instrumentation may help to derotate the spine at the time of surgery (if indicated) but, in patients with a severe rib prominence, a costoplasty is often carried out at the time of posterior fusion and instrumentation. Division of the most prominent ribs, usually near the costovertebral joint, allows the rib cage to be remoulded and reduces the severe rib prominence.

Treatment depends on the severity of the curve, the age of the patient, and the underlying cause. In general terms, idiopathic and congenital scoliosis tend to affect one part of the spine, whereas neuromuscular scoliosis tends to affect the thoracic and lumbar spine, the patient developing an extensive 'C'-shaped collapsing spine. This usually involves the sacrum and pelvis, and progression of the curve is usually associated with progressive pelvic obliquity.

Idiopathic or congenital scoliosis may be associated with respiratory involvement if the curve is very severe and develops in the first few years of life; whereas some forms of neuromuscular scoliosis are always associated with respiratory changes. For example, the vital capacity is reduced by 4 per cent for every 10-degree increase in curve in patients with Duchenne muscular dystrophy (Kurz *et al*. 1983).

Unless severe, idiopathic or congenital scoliosis tend not to progress once growth has ceased, but neuromuscular scoliosis maintains its tendency to progress throughout life.

The treatment of each type of scoliosis is beyond the scope of this chapter. In general terms, adolescent idiopathic scoliosis is treated by regular observation until skeletal maturity if the curve is less than 25 to 30 degrees. Moderate curves of 30 to 45 degrees are frequently treated by bracing until skeletal maturity, whereas curves greater than 40 to 45 degrees in a growing adolescent are often treated by surgical correction and spinal fusion. Progressive congenital scoliosis is usually treated by spinal fusion. Progressive neuromuscular scoliosis is usually treated by spinal stabilization and fusion. In some disorders, such as Duchenne muscular dystrophy, spinal stabilization and fusion is indicated in much smaller curves whilst the patient is still fit for surgery (Galasko *et al*. 1992). In neuromuscular scoliosis, spinal stabilization and fusion may be associated with improved maintenance of lung function. The type of fusion depends on the site and severity of the curve.

Box 1 Important points to remember

1. Children with spinal disorders may present with deformity, pain, neurological disturbance, or a combination.

2. A young child may present with refusal to walk. An older child may present with a limp.

3. Symptoms and signs may be minor despite the child having a serious and even possibly a life-threatening disorder.

4. All patients require a careful history and clinical examination.

5. The history may be non-specific.

6. The examination must include a general examination of the patient, the spine, and the lower limbs and a detailed neurological examination.

7. The investigations should be based on the history and clinical findings. A standard 'work up' is not indicated.

8. A painful scoliosis usually implies a significant lesion producing the deformity.

9. Spinal tumours are rare. They may present as accidental findings or with pain, deformity, stiffness, or neurological symptoms. Because the initial symptoms and signs may be 'minor', the diagnosis may be significantly delayed particularly with intraspinal tumours.

10. Spinal infection occurs rarely in children. Discitis of childhood usually occurs between the ages of 2 and 5. The degree of stiffness is usually striking.

11. Disc herniation can occur in childhood and adolescence. The symptoms are usually less severe than in the adult and significant spasm is usually present.

12. There are several causes for kyphosis. Those associated with a posterior hemivertebra may cause paraplegia. Ideally, a posterior fusion *in situ* is required under the age of 2 years. Post-laminectomy kyphosis may require anterior and posterior fusion.

13. Asymptomatic spondylolysis does not require treatment. The presence of a spondylolytic defect on a radiograph does not necessarily mean that the patient's symptoms are due to the lesion. Other causes of back pain must be excluded.

14. Foot deformities such as pes cavus, clawed toes, foot size inequality and limb length inequality may be due to spinal dysraphism. Cutaneous manifestations in the low back may also be present. Cord tethering may lead to significant neurological loss. The onset may be insidious.

15. The spine may be involved in inflammatory disorders.

16. Juvenile osteoporosis is rare. It may be primary or secondary.

17. Trauma of the spine probably occurs commonly but rarely causes disabling symptoms or significant problems.

18. Spinal deformity in children and adolescents is usually pain free. If it is painful it frequently is secondary to a significant underlying pathological process.

19. Back pain may be referred from other sites, e.g. renal disease.

20. Back pain in children often indicates severe underlying pathology. In the absence of any neurological symptoms or signs and in the absence of a secondary deformity, conservative measures are indicated in patients with a mobile spine and normal straight leg raising. If symptoms persist for more than 2 months, further investigation is required.

21. In the majority of children and adolescents spinal deformity requires no active treatment. Underlying neuromuscular and other conditions must be excluded. Severe or progressive deformities, particularly if they are likely to be associated with progressive impairment of pulmonary or neurological function, require correction and surgical stabilization.

Kyphosis (see above)

Lordosis

This is usually postural, but may be secondary to congenital deformities, dorsal kyphosis (Fig. 12), neuromuscular disease associated with an hyperextension spinal contracture, or fixed flexion contractures of the hips.

Referred pain

Back pain may be the presenting feature of renal disease, gastrointestinal disorders, or gynaecological disorders even in premenarchal adolescents (Letts and Haasbeek 1990), including haematocolpus and haematometra. A child with pneumonia may present with back pain.

Conclusions

Back pain that requires referral to an orthopaedic surgeon occurs infrequently in children and adolescents, but it often indicates serious underlying pathology. A careful history and clinical examination is essential (see Box 1). If there is any associated neurological impairment, immediate investigation is required. However, in the absence of any neurological symptoms or signs and in the absence of a secondary deformity, conservative measures are indicated in patients with a mobile spine and a normal straight leg raising but, if the symptoms persist for more than 2 months, further investigation is required.

Spinal deformity is also relatively uncommon and in the vast majority of patients requires no active treatment. Underlying neuromuscular and other conditions must be excluded. Severe or progressive deformities, particularly if they are likely to be associated with progressive impairment of pulmonary or neurological function, require correction and surgical stabilization.

1.2.2.1 The upper limbs in adults

Adel G. Fam

Applied anatomy

Shoulder

Shoulder movements are a synthesis of motion at four articulations: glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic (Lucas 1973; Rothman *et al*. 1975; Poppen and Walker 1976; Bateman 1978; Polley and Hunder 1978; Bechtol 1980; Sarrafian 1983; Williams *et al*. 1989).

The sternoclavicular joint is a spheroidal joint between the medial end of the clavicle and the manubrium sterni and first costal cartilage. An intra-articular fibrocartilaginous disc divides the joint into two cavities. The joint capsule is reinforced by the anterior and posterior sternoclavicular ligaments.

The acromioclavicular joint is a spheroidal joint between the lateral end of the clavicle and the acromion. An intra-articular fibrocartilaginous disc divides the joint into two compartments. The joint capsule is strengthened by the superior and inferior acromioclavicular ligaments. The coracoclavicular ligament (conoid and trapezoid parts) extends between the distal clavicle and the coracoid process of the scapula. It stabilizes both the clavicle and scapula, and maintains a close relation between the two bones during shoulder movements, thus limiting scapular rotation around the acromioclavicular joint. A subcutaneous, often non-communicating, bursa may be present over the joint.

Movements at the sternoclavicular and acromioclavicular joints enable slight rotation of the clavicle along its long axis, and allow elevation or depression (as in shoulder shrugging), and flexion or extension (as in forward or backward thrusting) of the shoulder girdle.

The glenohumeral joint is a ball-and-socket articulation between the glenoid fossa of the scapula and the humeral head (Fig. 1). The lax articular capsule, and the small area of contact between the shallow glenoid cavity and the spheroidal humeral head, permit a wide range of movements. The stability of the joint depends upon a number of static and dynamic stabilizers. Static stabilizers include the capsule, glenoid labrum, and ligaments (glenohumeral and coracohumeral). The capsule has two apertures: one for the long biceps tendon and the second for the subscapularis bursa. Dynamic stabilizers play a greater part in the stability of the shoulder, and include two musculotendinous layers: an inner stratum, made of the rotator cuff muscles (supraspinatus, infraspinatus, teres minor and subscapularis), and the tendon of the long head of the biceps, and an outer stratum made of the deltoid, teres major, pectoralis major, latissimus dorsi, and trapezius muscles.

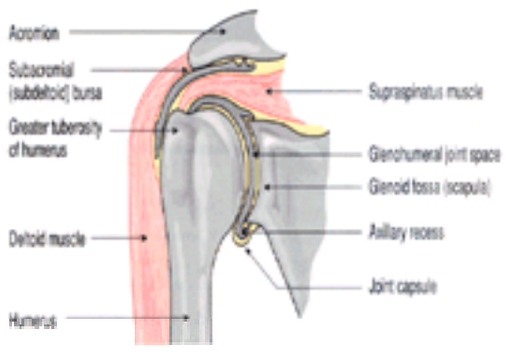

Fig. 1 The shoulder.

The muscles of the inner stratum stabilize and retain the humeral head in the glenoid cavity during shoulder movements, while simultaneously providing abduction (through the supraspinatus, which inserts into the superior part of the greater tuberosity), external rotation (through the infraspinatus and teres minor, which insert into the posterior aspect of the greater tuberosity), and internal rotation (through the subscapularis, which inserts into the lesser tuberosity). At the initiation of shoulder abduction, the rotator cuff muscles and the long biceps tendon depress and fix the humeral head against the glenoid cavity to counteract the upward pull of the more powerful deltoid muscle. The mechanism whereby these two groups of muscles combine to produce abduction, the one elevating (deltoid muscle) and the other stabilizing the humeral head (rotator cuff and biceps tendons), is termed 'force-couple' (Lucas 1973; Rothman *et al*. 1975; Bechtol 1980).

The muscles of the outer stratum are the prime movers of the shoulder, although the trapezius acts through movements of the scapula and clavicle. These muscles provide abduction, flexion, extension, adduction and some degree of rotation, and together with the rotator cuff muscles (which provide more rotation of the humeral head) permit a wide range of movement at the shoulder.

The coracoacromial arch (coracoid, coracoacromial ligament, and acromion) acts as a secondary socket for the humeral head under which the rotator cuff tendons and long head of the biceps tendon glide, with the subacromial bursa lying in between. The arch protects the humeral head and the rotator cuff from direct trauma. The subacromial bursa facilitates movements of the greater tuberosity beneath the rigid coracoacromial arch during shoulder abduction, and acts as a cushion minimizing the impingement of the acromion on the supraspinatus, infraspinatus, teres minor, and long biceps tendons during abduction (Fig. 1) (Lucas 1973). The bursa, which extends beneath the deltoid (subdeltoid part), communicates with the cavity of the glenohumeral joint in about one-third of adults. The synovium of the shoulder has two extracapsular outpouchings: the synovial tendon sheath of the long biceps tendon, and the subscapularis bursa lying beneath the subscapularis tendon (Fig. 2). The subcoracoid bursa lies between the shoulder capsule and coracoid process, but it rarely communicates with the subacromial bursa (Lucas 1973; Rothman *et al*. 1975; Poppen and Walker 1976; Bateman 1978; Polley and Hunder 1978; Bechtol 1980; Sarrafian 1983; Williams *et al*. 1989).

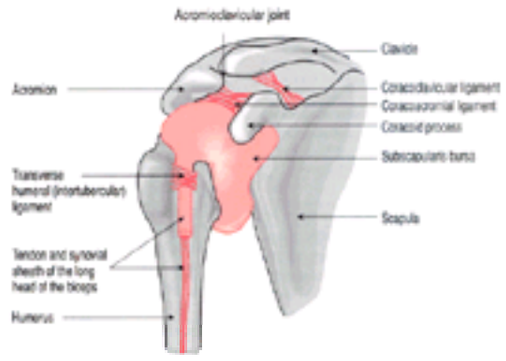

Fig. 2 The shoulder (synovial membrane and its outpouchings).

Scapulothoracic articulation

The scapula is connected to the posterior aspect of the chest wall by the axioappendicular muscles. The scapula provides the origin for the rotator cuff muscles and deltoid, and the trapezius inserts into its superior aspect. Scapulothoracic movements, including rotation, elevation, depression, protrusion, retraction and circumduction, are important for the normal functioning of the shoulder (Lucas 1973; Rothman *et al*. 1975; Poppen and Walker 1976 ; Bateman 1978; Polley and Hunder 1978; Bechtol 1980; Sarrafian 1983; Williams *et al*. 1989).

Shoulder abduction involves synchronous movements of the glenohumeral, sternoclavicular, and acromioclavicular joints and rotation of the scapula on the chest wall. The initial 30° of abduction, achieved by contraction of the supraspinatus, takes place at the glenohumeral joint with little movement of the scapula. Beyond 30°, an approximate 2:1 ratio exists between movements at the glenohumeral joint and the scapula. The combined movement is referred to as the 'scapulohumeral rhythm' (Lucas 1973). Abduction of the shoulder (normal range, 180°) is associated with external rotation of the humerus. The prime movers are the supraspinatus and deltoid muscles. The flexors of the shoulders (normal range, 180°) are the deltoid and coracobrachialis muscles. The normal range of shoulder adduction across the front of the chest is about 50°. The pectoralis major muscle is the main adductor. The normal range of extension (posterior flexion) is about 50°. The latissimus dorsi, teres major, and deltoid muscles are the principal extensors. With the shoulder abducted to 90° and the elbow flexed at a right angle, the normal range of internal and external rotation is 90° each. The normal range of external rotation with the elbow placed by the side at the waist is about 45°, and internal rotation is to 55° (before its motion is stopped by the body), or to 120° if the patient can reach behind the back to touch the inferior angle of the opposite scapula. The prime movers of internal rotation are subscapularis, and pectoralis major. The infraspinatus and teres minor are the main external rotators.

Elbow

The elbow is a relatively stable hinge joint formed by the humeroulnar (trochleo-ulnar), humeroradial (capitelloradial) and proximal radio-ulnar articulations (Fig. 3), with the trochleo-ulnar being the principal joint (Polley and Hunder 1978; Williams *et al*. 1989). The stability of the joint depends on its congruity, anterior capsule, and ulnar and radial collateral ligaments (Morrey and An 1983). The common flexor tendon (pronator teres, flexor carpi radialis, palmaris longus, flexor carpi ulnaris, and flexor digitorum superficialis) takes origin from the medial epicondyle of the humerus. The common extensor tendon (brachioradialis, extensor carpi radialis longus and brevis, extensor digitorum communis and anconeus) originates from the lateral epicondyle. The annular ligament is a strong, cup-shaped band that encircles the radial head at the proximal radio-ulnar joint. The paraolecranon grooves are the depressions between the ulnar olecranon process and the medial and lateral epicondyles. The ulnar nerve runs in a groove (cubital tunnel) behind the medial epicondyle.

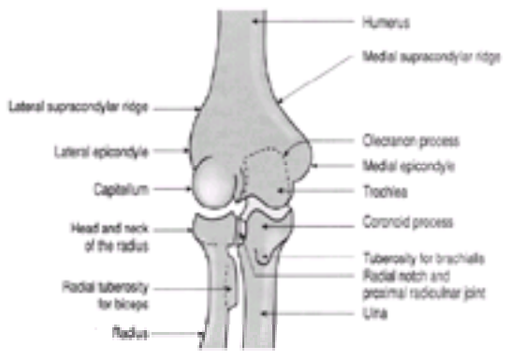

Fig. 3 The elbow.

The trochleo-ulnar, capitelloradial, and proximal radio-ulnar joints share a common synovial cavity. The subcutaneous olecranon bursa overlies the olecranon process but does not communicate with the joint (Polley and Hunder 1978; Williams *et al*. 1989).

The neutral position or position of complete extension of the elbow is designated 0°. Some normal individuals (particularly muscular athletes) lack 5° to 10° of full extension, while others (particularly women) may demonstrate 5° to 10° of hyperextension. The normal range of flexion at the cubital (humeroulnar and humeroradial) joint is 150° to 160°. The brachialis, biceps, and brachioradialis muscles are the main elbow flexors. Extensors of the elbow include the triceps and anconeus muscles.

Due to the oblique shape of the trochlea, extension of the elbow is associated with slight lateral (valgus) angulation of 5° to 15°. This is known as the 'carrying angle' of the elbow. The normal angle is about 5° in men and 10 to 15° in women. During flexion of the elbow, the ulna becomes more parallel with the humerus.

Pronation of forearm and hand (palm of the hand turned backward) to 90°, and supination (palm turned forward) to 90° occur at the proximal and distal radio-ulnar joints. During these movements the radial head pivots on the capitellum while the distal radius rotates around the ulna. The biceps and supinator muscles are the primary supinators of the radio-ulnar joints, and the pronator teres and pronator quadratus are the principal pronators.

Wrist (radiocarpal) joint

This is an ellipsoid joint between the distal radius and articular disc proximally and the scaphoid, lunate, and triquetrum distally (Fig. 4) (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a). The articular capsule is strengthened by the radiocarpal (dorsal and palmar), and collateral (radial and ulnar) ligaments. The articular disc, or triangular fibrocartilage of the wrist, joins the radius to the ulna. Its base is attached to the ulnar border of the distal radius and its apex to the base of the ulnar styloid process. The synovial cavity of the distal radio-ulnar joint is L-shaped and extends distally beneath the triangular fibrocartilage but is usually separated from the radiocarpal joint (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

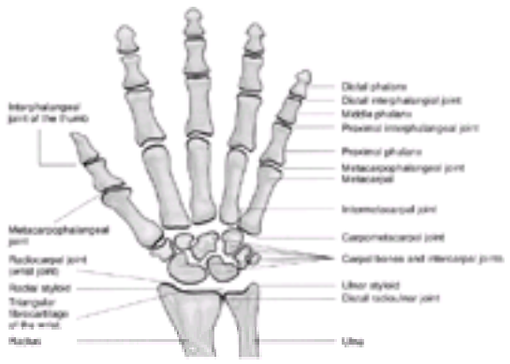

Fig. 4 Bones and joints of the wrist and hand.

The radiocarpal, intercarpal, midcarpal (located between the proximal and distal rows of the carpal bones), carpometacarpal, and intermetacarpal joints often intercommunicate through a common synovial cavity (Fig. 4).

The carpal bones form a volar concave arch or carpal tunnel: pisiform and hook of the hamate on the ulnar side, and scaphoid tubercle and crest of the trapezium on the radial side. The four bony prominences are joined by the flexor retinaculum (transverse carpal ligament), which forms the roof of the carpal tunnel. The palmaris longus (absent in 10 to 15 per cent of the population) partly inserts into the flexor retinaculum and partly fans out into the palm forming the palmar aponeurosis (fascia). The aponeurosis divides distally into four digital slips that attach to the finger flexor tendon sheaths, metacarpophalangeal joint capsules, and proximal phalanges (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

Tendons crossing the wrist are enclosed for part of their course in tenosynovial sheaths. The common flexor tendon sheath encloses the long flexor tendons of the fingers (flexor digitorum superficialis and flexor digitorum profundus) and extends from approx. 2.5 cm proximal to the wrist crease to the mid-palm. It runs with the flexor pollicis longus tendon sheath and the median nerve through the carpal tunnel (Fig. 5). The tendon sheath of the little finger is usually continuous with the common flexor sheath. The flexor pollicis longus tendon to the thumb runs through a separate tenosynovial sheath, but may join the common flexor sheath. The flexor carpi radialis is invested in a short tendon sheath as it crosses the volar aspect of the wrist between the split radial attachment of the flexor retinaculum. The flexor retinaculum straps down the flexor tendons as they cross at the wrist. The ulnar nerve, artery, and vein cross over the retinaculum but are sometimes covered by a fibrous band—the superficial part of the transverse carpal ligament—to form the ulnar tunnel or Guyon's canal (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

Fig. 5 Flexor tendon sheaths of the wrist and hand.

On the dorsum of the wrist, the extensor tendons pass through six tenosynovial, fibro-osseous tunnels beneath the extensor retinaculum (dorsal carpal ligament): abductor pollicis longus and extensor pollicis brevis, usually in a single sheath (first extensor compartment, most radial); extensor carpi radialis longus and brevis; extensor pollicis longus; extensor digitorum communis and extensor indicis proprius; extensor digiti minimi; and extensor carpi ulnaris (sixth extensor compartment, most ulnar) (Fig. 6). Each tenosynovial sheath extends about 2.5 cm proximally and distally from the retinaculum. The extensor retinaculum, by its deep attachments to the distal radius and ulnar, binds down and prevents bowstringing of the extensor tendons as they cross the wrist.

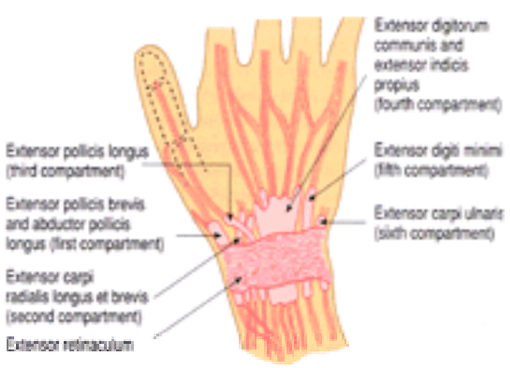

Fig. 6 Extensor tendon sheaths of the wrist.

Movements of the wrist include palmar flexion (flexion), dorsiflexion (extension), ulnar deviation, radial deviation, and circumduction. The intercarpal joints contribute to wrist movements, particularly palmar flexion. Prime wrist palmar flexors are flexor carpi radialis, flexor carpi ulnaris, and palmaris longus. The prime dorsiflexors are the extensor carpi radialis longus and brevis, and the extensor carpi ulnaris (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

The first carpometacarpal joint is a saddle-shaped, very mobile joint between the trapezium and the base of the first metacarpal. It allows 40 to 50° of thumb flexion–extension (parallel to the plane of the palm) and 40 to 70° of adduction–abduction (perpendicular to the plane of the palm). These movements are important in bringing the thumb into opposition with the fingers.

The metacarpophalangeal joints are modified hinge joints that lie about 1 cm distal to the knuckles (metacarpal heads) (Fig. 4). Their capsule is strengthened by the radial and ulnar collateral ligaments on the sides and by the palmar (volar) plate on the volar surface. The collateral ligaments are loose in the neutral position, allowing radial and ulnar deviations, but become tight in the fully flexed position preventing side-to-side motion (referred to as 'sagittal cam effect'). The deep transverse metacarpal ligament joins the volar plates of the second to fifth metacarpophalangeal joints. The metacarpophalangeal joint of the thumb is large and has two sesamoid bones overlying its volar surface (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

Where the long extensor tendon of the digit reaches the metacarpal head it is joined by the tendons of the interossei and lumbricales, and it expands over the dorsum of the metacarpophalangeal joint and digit to form the extensor hood or expansion (Fig. 7). The expansion divides over the dorsum of the proximal phalanx into an

intermediate slip, which is inserted principally into the base of the middle phalanx, and two collateral slips, which are inserted into the base of the distal phalanx.

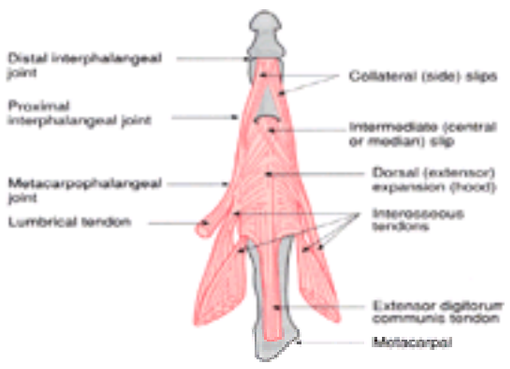

Fig. 7 Extensor expansion of the finger.

The first metacarpophalangeal joint permits 50 to 70° palmar flexion and 10 to 30° dorsiflexion. Radial and ulnar deviations are limited to less than 10 to 20°. The other metacarpophalangeal joints allow 90° palmar flexion, 30° dorsiflexion, and 35° of radial and ulnar movements. The extensor pollicis brevis, extensor indicis proprius, extensor digitorum communis, and extensor digiti minimi dorsiflex the metacarpophalangeal joints. The palmar flexors are the flexor pollicis brevis, lumbricales, interossei, and flexor digiti minimi brevis assisted by the long flexors. Radial and ulnar movements of the second to fifth metacarpophalangeal joints are a function of the intrinsic muscles (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

The interphalangeal joints

The proximal and distal interphalangeal joints of the fingers and the interphalangeal joints of the thumbs are hinge joints (Fig. 4). Their capsules are strengthened by the collateral ligaments on the sides and by the volar plate on the palmar surface. The volar plates serve to limit hyperextension, particularly at the proximal interphalangeal joints. Unlike the metacarpophalangeal joints, the radial and ulnar collateral ligaments remain taut in all positions, providing side-to-side stability throughout the range of movement.

The flexor tendon sheaths for the fingers enclose the flexor digitorum superficialis and profundus tendons to their insertions on the middle and distal phalanges, respectively. The sheaths extend from just proximal to the metacarpophalangeal joints to the bases of the distal phalanges (Fig. 5). The flexor pollicis longus tendon sheath of the thumb extends proximally to the carpal tunnel. The flexor sheath of the little finger is often continuous with the common flexor tendon sheath of the wrist. Segmental condensations, or annular pulleys, in the digital flexor sheaths prevent bowstringing of the tendons, and are mechanically critical for full digital flexion (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

The proximal interphalangeal joints do not normally hyperextend. They allow 100 to 120° palmar flexion. The distal interphalangeal joints permit 50 to 80° palmar flexion and 5 to 10° dorsiflexion. The interphalangeal joint of the thumb allows 80 to 90° palmar flexion and 20 to 35° dorsiflexion. The flexor digitorum superficialis flexes the proximal interphalangeal joints, and the flexor digitorum profundus flexes the distal interphalangeal joints of the fingers. The prime dorsiflexors are the interossei and lumbrical muscles. The flexor pollicis longus flexes the interphalangeal joint of the thumb and the extensor pollicis longus dorsiflexes the joint (Polley and Hunder 1978; Markison and Kilgore 1987; Williams *et al*. 1989; Fam 1994a).

General considerations and differential diagnosis of regional rheumatic pain syndromes of the upper extremities in adults (also see Chapter 5.14)

General considerations

Upper extremity regional pain syndromes are a common presentation in general, rheumatological, and orthopaedic practices. Table 1 provides a classification of painful disorders of the shoulder, elbows, wrists, and hand based upon the site of origin and the predominant location of pain.

Table 1 Classification of painful upper-limb disorders

Precise diagnosis of regional rheumatic pain syndromes in the upper limb depends upon greater awareness of these disorders, knowledge of basic regional anatomy, a detailed history, a thorough physical examination of the joints, periarticular structures, cervical spine nerve and blood supplies to the upper limb, and a few carefully selected diagnostic studies.

The onset of many musculoskeletal pain syndromes in the upper limb is often insidious. An antecedent history of repetitive, excessive, or unaccustomed physical activity is common. Less frequently, the pain results from a specific activity or injury. With ageing, tendons become less flexible and less elastic, making them more susceptible to injury. A shortened musculotendinous unit, from lack of regular stretching exercises, is also more prone to injury.

In addition to plain radiographs and arthrography, the newer methods of imaging, such as ultrasonography, computed tomography (**CT**), and magnetic resonance imaging (**MRI**), have improved diagnostic accuracy in shoulder disorders. Arthroscopy of the shoulder is particularly useful in the diagnosis and treatment of subacromial and intra-articular conditions.

The following is a brief summary of the most common causes of shoulder, elbow, wrist, and hand pain (excluding arthritis). Not included in this chapter are nerve entrapment syndromes, pain arising from sternoclavicular joints, pain originating from the cervical spine, spinal cord and spinal nerves, pain referred from the thoracic outlet, intrathoracic and intra-abdominal structures, and pain due to reflex sympathetic dystrophy syndrome, fibromyalgia, and vascular disorders.

Disorders of the shoulder region

Shoulder pain is a common musculoskeletal symptom of diverse causes (Table 1). The pain may have its origin in the glenohumeral joint, acromioclavicular joint or periarticular structures, or be referred from the cervical spine (felt at the supraspinatus region), thoracic outlet, subdiaphragmatic conditions (felt at the tip of the

shoulder), or brachial plexus (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Chard and Hazleman 1987; Vecchio *et al*. 1995).

Periarticular disorders are by far the most common cause of shoulder pain in adults (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Chard and Hazleman 1987; Vecchio *et al*. 1995). The anatomical configuration of the shoulder joint is such that during abduction the rotator cuff and long biceps tendon are subjected to impingement between the greater tuberosity and coracoacromial arch (Neer 1983; Miniaci and Fowler 1993; Frieman *et al*. 1994). This leads to tendinitis and tears of the rotator cuff, which compromises its function as a stabilizer and depressor of the humeral head, resulting in chronic glenohumeral instability, superior migration of the humeral head (due to unopposed upward pull of the deltoid), and further impingement on both the rotator cuff and long biceps tendons. Osteophytes on the inferior surface of the acromioclavicular joint can also aggravate this impingement. Thus, the spectrum of chronic impingement syndrome ranges from mild tendinitis of the rotator cuff, with or without inflammation of the adjacent subacromial bursa, to bicipital tendinitis, tears of the rotator cuff and chronic glenohumeral instability with superior migration of the humeral head, and secondary glenohumeral osteoarthritis ('cuff tear arthropathy'). The causes of shoulder impingement include repetitive low-grade trauma or unaccustomed activities, excessive overhead use in sport or work, lack of conditioning, ageing factors, and structural abnormalities (e.g. acromial spur) that compromise the cuff space. It is likely that both chronic impingement and degenerative tendinopathy (presumably the result of ischaemia) contribute to the development of rotator cuff disease. Vascular compromise of the rotator cuff tendons in diabetic patients is an important predisposing factor (Frieman *et al*. 1994).

The pathology of shoulder impingement syndrome can be divided into three overlapping stages (Neer 1983; Miniaci and Fowler 1993; Frieman *et al*. 1994). Stage I consists of oedema, swelling, and haemorrhage of the rotator cuff and subacromial bursa. Stage II is characterized by tendon tears, inflammation, fibrosis, and thickening of the rotator cuff, bicipital tendon, and subacromial bursa. Stage III is marked by fraying or rupture of the rotator cuff and/or long biceps tendon, instability, and secondary glenohumeral osteoarthritis. Stage I often begins in young individuals under 25 years of age. Stage II usually occurs in patients aged 25 to 40 years and stage III in those over 40 years of age. The term 'impingement syndrome' replaces the old expression 'painful arc syndrome' (Kessel and Wastson 1977), and includes such disorders as rotator cuff tendinitis, subacromial bursitis, and bicipital tendinitis.

Rotator cuff tendinitis

Rotator cuff tendinitis is the most common cause of shoulder pain. The disorder may be acute or chronic (Bland *et al*. 1977; Kapandji 1982; Neer 1983; Neviaser 1983; Chard and Hazleman 1987; Birrer *et al*. 1989; Miniaci and Fowler 1993; Snyder 1993; Frieman *et al*. 1994; Vecchio *et al*. 1995). In young persons an acute sport injury due to use of the arms in an overhead position (e.g. baseball, racquet ball, tennis, swimming) is common (Miniaci and Fowler 1993). In middle-aged and elderly individuals the onset is more gradual, and an antecedent history of repetitive movements above the shoulder level or of strenuous or unaccustomed arm activity is common. Symptoms include aching pain in the shoulder, pain with movements, particularly abduction and internal rotation, night pain when rolling on to the affected side, restriction of shoulder movements, and, sometimes, weakness due to a traumatic or degenerative tear of the rotator cuff. The patient typically experiences pain on active abduction, especially between 60 and 120°, and sometimes when lowering the arm. Patients complain of difficulty with overhead work or lifting and with reaching behind their back when dressing. The pain is often felt over the lateral aspect of upper arm and deltoid insertion rather than in the point of the shoulder. Less commonly, it radiates to the scapula, root of the neck or elbow. Clinical findings include a painful arc between 60 to 120° of abduction, limitation of active movement by pain, and tenderness localized to the rotator cuff and greater tuberosity (Kessel and Wastson 1977; Neer 1983; Birrer *et al*. 1989; Miniaci and Fowler 1993; Snyder 1993; Frieman *et al*. 1994). There is often pain on resisted movement of the affected tendon. The 'supraspinatus' or 'empty can' sign (pain on resisted elevation of the arm to 90° midway between abduction and forward flexion with the thumb pointing downwards in internal rotation) is often positive (Birrer *et al*. 1989). Neer's 'impingement sign' (one hand of the examiner forward flexing the patient's arm while the other hand restricting scapular rotation) is positive: the patient develops pain in the overhead position near the end of full flexion (Neer 1983). In Hawkin's 'impingement sign', the humerus is both forward flexed to 90° and internally rotated while on the other hand restricting scapular movements, causing impingement of the greater tuberosity against the anterior acromion with reproduction of patient's symptoms (Miniaci and Fowler 1993; Frieman *et al*. 1994). The 'impingement test' is also positive: pain relief and greater range of abduction following injection of 2 to 5 ml of 2 per cent of lidocaine into the subacromial bursa (Neer 1983; Miniaci and Fowler 1993).

Calcification of the cuff tendons may be asymptomatic, but can present either as an acute condition in the younger patient, or as a chronic calcific tendinitis associated with aching pain and symptoms of impingement (Re and Karzel 1993). In the acute phase (acute calcific rotator cuff tendinitis) the onset is often explosive, with severe pain, exquisite local tenderness, muscle spasm, and marked painful restriction of all shoulder movements. An acute calcific subacromial bursitis may also be present when calcific material ruptures into the adjacent bursa.

Shoulder radiographs in acute cuff tendinitis may appear either normal, or show oval or round calcific deposits in the region of the rotator cuff tendons, particularly that of the supraspinatus (Fig. 8). These deposits often disappear following resolution of an attack of acute calcific tendinitis. In chronic tendinitis the presence of sclerosis, cystic changes, and osteophytes of the greater tuberosity is suggestive of chronic impingement and insertional damage (Snyder 1993) (Fig. 9). Tendinitis, rotator cuff tears, and thickening or fluid distension of the subacromial bursa may be demonstrated by MRI and by grey-scale, dynamic or power Doppler sonography (Ryu *et al*. 1993; Snyder 1993).

Fig. 8 Acute calcific tendinitis of left shoulder.

Fig. 9 Sclerosis and cystic changes of the greater tuberosity in a patient with chronic shoulder impingement.

Initial management of rotator cuff tendinitis consists of rest, non-steroidal anti-inflammatory drugs, and physical treatments including heat application, and range of movement exercises (Miniaci and Fowler 1993; Snyder 1993; Dalton 1994; Frieman *et al*. 1994). Early mobilization of the shoulder is important in minimizing disability, and reducing the risk of adhesive capsulitis or reflex sympathetic dystrophy. If symptoms persist for more than 2 to 4 weeks, injection of a depot corticosteroid into the nearby subacromial bursa (posterior subacromial approach) is often beneficial. Once the pain is controlled, strengthening exercises are important to restore the function of the rotator cuff muscles and reduce the likelihood of further injury. Diagnostic imaging with MRI, ultrasound, or arthrography to determine the presence and size of a possible cuff tear is indicated in those not responding to 6 to 12 weeks of non-operative treatment. Surgical (or arthroscopic) subacromial decompression (anterior acromioplasty with reshaping the anterior acromion and section of the coracoacromial ligament) is reserved for patients with

chronic symptoms refractory to medical treatment (Miniaci and Fowler 1993; Snyder 1993; Dalton 1994; Frieman *et al*. 1994).

Treatment of acute calcific rotator cuff tendinitis consists of cold application and non-steroidal anti-inflammatory drugs (Re and Karzel 1993). If symptoms persist, a local injection into the subacromial bursa of lidocaine followed by a depot corticosteroid is helpful. Surgical or arthroscopic excision of the calcific deposits is rarely necessary in chronic cases (Re and Karzel 1993).

Rotator cuff tears

Rotator cuff tears can be partial or complete, acute or chronic. They are further classified as small (£1 cm), medium (1–3 cm), large (3–5 cm) and massive (³5 cm) (Snyder 1993; Post *et al*. 1983). In young adults acute tears can result from direct trauma, unexpected falls or a sport injury. In older patients, minor less severe trauma, superimposed on an already degenerated cuff tendon from chronic impingement and age-related attritional changes, can lead to partial tears (Snyder 1993; Post *et al*. 1983).

Clinical features include shoulder pain on abduction, night pain, varying degrees of weakness of abduction and external rotation, local tenderness, and loss of range of movement. The supraspinatus and impingement signs are usually positive. In complete tears, the 'drop-arm' sign is positive: inability to actively maintain 90° of passive shoulder abduction. Subacromial crepitus and rupture of the long biceps tendon may be present (Snyder 1993; Post *et al*. 1983).

Radiographic findings include sclerosis and cystic degeneration of the greater tuberosity, superior migration of the humeral head with narrowing of the subacromial (acromiohumeral) space (less than 6 mm indicates a tear), and secondary glenohumeral osteoarthritis (Snyder 1993; Post *et al*. 1983). The diagnosis of a complete tear can be confirmed by single- or double-contrast arthrography showing a communication between the glenohumeral joint and subacromial bursa (Fig. 10) (Snyder 1993; Post *et al*. 1983). In partial tears there is no communication but the arthrogram may show a crater-like defect in the rotator cuff. Ultrasonography (Newman *et al*. 1994) and MRI (Recht and Resnick 1993) are non-invasive methods that are useful in identifying rotator cuff tears. Arthroscopy is particularly valuable in assessing the size of the tear, and the status of the labrum, long biceps tendon, and glenohumeral joint (Snyder 1993).

Fig. 10 Right shoulder arthrogram in a patient with a rotator cuff tear showing a communication between glenohumeral joint and subacromial bursa. Note abnormal communication with the acromioclavicular joint.

Partial tears are treated conservatively with rest, physical therapy, and non-steroidal anti-inflammatory drugs (Snyder 1993; Dalton 1994). The role of local corticosteroid injections has not been established, but they are not recommended within 4 to 6 weeks of an acute cuff tear. In patients with persistent symptoms a subacromial injection of a depot corticosteroid is usually beneficial.

Early surgical repair is recommended for acute, complete ruptures of the cuff in the young active patient (Snyder 1993). In contrast, chronic complete tears are treated non-operatively in the first instance. Functional disability and failure to achieve pain relief are the main indications for surgical (Snyder 1993; Frieman *et al*. 1994) or arthroscopic (Burkhart 1993) treatment; acromioplasty, and debridement to relieve impingement, and whenever possible, repair of tears of the rotator cuff and long biceps tendon. However, complete pain relief or return to full function are uncommon after surgery.

Bicipital tendinitis

Bicipital tendinitis is often related to chronic impingement of the bicipital tendon by the acromion. The long biceps tendon becomes fibrotic, frayed, and may rupture. Bicipital tendinitis usually occurs in association with rotator cuff tendinitis and glenohumeral instability (Bland *et al*. 1977; Neviaser 1980; Kapandji 1982; Neer 1983; Neviaser 1983; Chard and Hazleman 1987; Miniaci and Fowler 1993; Frieman *et al*. 1994; Vecchio *et al*. 1995). Primary, isolated, bicipital tendinitis is rare, and develops as an overuse injury due to repetitive stresses applied to the tendon in certain sports such as weight lifting and ball throwing.

The pain is felt over the anterior aspect of the shoulder, but may radiate into the biceps muscle. It is increased by overhead activities, shoulder extension, and elbow flexion. Localized tenderness is present over the tendon in the bicipital groove. Signs of chronic impingement and glenohumeral instability are often present. Bicipital tendon pain can be reproduced by resisted supination of the pronated forearm with the elbow 90° flexed (Yergason's sign), shoulder flexion against resistance (Speed's test), passive extension of the shoulder, or by resisted flexion of the elbow (Bland *et al*. 1977; Neviaser 1980; Kapandji 1982; Neer 1983; Neviaser 1983; Chard and Hazleman 1987). Rupture of the long biceps tendon typically occurs at the superior edge of the bicipital groove. It produces a characteristic bunching up of the lateral half of the muscle belly, best seen with resisted elbow flexion and supination ('Popeye sign').

Subluxation of the bicipital tendon is also related to chronic impingement. It results from traumatic rupture of the intertubercular ligament, which normally straps the tendon in the bicipital groove. Pain in the anterior aspect of the shoulder, and a clicking sensation of the shoulder 'going out and popping back in', are the principal symptoms (Neviaser 1980). Patients are usually able to reduce the tendon themselves. Tenderness in the bicipital groove and a snap over the tendon when the arm is passively abducted to 90° then moved through internal and external rotation, are usually present (Neviaser 1980).

Treatment of bicipital tendinitis consists of physiotherapy and non-steroidal anti-inflammatory drugs. Corticosteroid injections into the bicipital sheath, with care being taken not to inject the tendon itself, are often beneficial (Bland *et al*. 1977; Neviaser 1980; Kapandji 1982; Neer 1983; Neviaser 1983; Chard and Hazleman 1987). Surgical subacromial decompression is required in patients with chronic impingement. Repair of subluxation and/or rupture of the bicipital tendon is indicated in the younger, more active patient.

Subacromial bursitis

Chronic subacromial bursitis, with thickening and fibrosis of the bursal wall, often occurs in association with rotator cuff tendinitis and chronic impingement. Primary subacromial bursitis due to trauma, infection, rheumatoid arthritis, or other arthritic disorders is rare. Abduction is painful, and there is local tenderness and sometimes fluid distension of the bursa, which is visible just anterior to the acromion with the shoulder extended (Bland *et al*. 1977; Kapandji 1982; Neer 1983; Neviaser 1983; Chard and Hazleman 1987).

Treatment of acute traumatic subacromial bursitis is symptomatic, with ice packs, rest, non-steroidal anti-inflammatory drugs, range-of-movement exercises, and if indicated, a subacromial corticosteroid injection. Surgical excision and debridement of the bursa may be indicated in those requiring operative treatment for chronic impingement.

Adhesive capsulitis

Adhesive capsulitis, also known as frozen shoulder, pericapsulitis and obliterative bursitis, is characterized by progressive, global restriction of shoulder movements associated with pain and functional disability (Bland *et al*. 1977; Kapandji 1982; Neer 1983; Neviaser 1983; Bulgen *et al*. 1984; Chard and Hazleman 1987; Birrer *et al*. 1989; Hulstyn and Weiss 1993). The condition is rare before the age of 40 years, and is bilateral in about 15 per cent of patients. A period of immobility of the

shoulder is the most commonly identified predisposing factor. The onset is insidious, and the capsulitis is often secondary to rotator cuff tendinitis, rotator cuff tears, bicipital tendinitis, or glenohumeral arthritis. The condition may also coexist with diabetes mellitus, hypothyroidism, lung carcinoma, myocardial infarction, cardiac surgery, cerebrovascular events, and shoulder trauma. Primary or idiopathic shoulder capsulitis is rare. No autoimmune disturbance or association with histocompatibility antigen has been demonstrated in this disorder.

Limited histological studies demonstrate an initial phase with increased vascularity, sparse chronic inflammatory cellular infiltrate, and fibroblastic proliferation. This is followed by fibrous thickening and contraction of the capsular folds, recesses, and surrounding ligamentous structures. The capsule often adheres to the humeral neck, and the axillary pouch becomes obliterated causing restricted movements (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Chard and Hazleman 1987; Hulstyn and Weiss 1993; Vecchio *et al*. 1995).

Clinical features

The natural history of adhesive capsulitis can be divided into three overlapping phases, each lasting a few months: a painful ('freezing') phase, an adhesive ('frozen') phase, and a resolution ('thawing') phase (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Chard and Hazleman 1987; Hulstyn and Weiss 1993; Vecchio *et al*. 1995). The painful or 'freezing' phase is characterized by the insidious onset of shoulder pain, diffuse tenderness, night pain, and progressive restriction of shoulder movements. The classic finding is limitation of external rotation in the absence of glenohumeral arthritis. During the adhesive or 'frozen' phase, pain and local tenderness decrease but shoulder movements become globally more restricted. Disuse atrophy of the deltoid and scapular muscles is common. In the resolution or 'thawing phase', pain becomes less evident and there is slow increase in the range of shoulder movements. Although adhesive capsulitis is often a self-limiting disorder, the extent and rate of recovery are variable. About 90 per cent of patients recover use of the extremity within 12 to 18 months, but about 10 per cent develop more prolonged pain and functional disability.

The diagnosis of adhesive capsulitis depends primarily on the clinical findings. The erythrocyte sedimentation rate and acute-phase reactants are usually normal. Radiographs may show changes of chronic rotator-cuff tendinitis with or without calcification. Double-contrast arthrography is diagnostic, showing a marked decrease in the joint volume to under 10 ml (normal values: 20–35 ml), loss of the normal axillary recess, and reduced filling of the bicipital tendon sheath (Hulstyn and Weiss 1993). Dynamic sonography, demonstrating limitation of sliding movements of the supraspinatus tendon during abduction of the arm, is a reliable, non-invasive, rapid technique for the diagnosis of this disorder (Ryu *et al*. 1993). Arthroscopy allows evaluation of any underlying shoulder pathology. Increased uptake on bone scanning is a non-specific finding and does not predict outcome or response to therapy (Hulstyn and Weiss 1993).

Treatment of adhesive capsulitis consists of non-steroidal anti-inflammatory drugs, physical therapy and corticosteroid injections into both the glenohumeral joint and subacromial bursa (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Bulgen *et al*. 1984; Chard and Hazleman 1987; Petri *et al*. 1987; Hulstyn and Weiss 1993; Vecchio *et al*. 1995). Physiotherapy to relieve pain and improve the range of movement is important. Gentle range-of-movement exercises, beginning with pendulum exercises and wall climbing with the fingers, and finally active strengthening exercises, are required to restore joint mobility. Other physical methods have been advocated but proof of their efficacy is lacking. Included among these are transcutaneous electrical nerve stimulation, ultrasound, laser, magnetotherapy, and gentle manipulation.

Oral corticosteroids (beginning with 30 mg prednisone per day with gradual tapering off within 1–2 months), by virtue of their anti-inflammatory effects, appear to have a beneficial effect in the early rehabilitation and pain relief of shoulder capsulitis (Petri *et al*. 1987; Baslund *et al*. 1990; Hulstyn and Weiss 1993).

In the chronic adhesive phase, three treatments have been used with inconsistent results: infiltration brisement, manipulation, and open surgical release. Brisement, or hydraulic saline distension of the shoulder joint under local anaesthesia, by releasing and dissecting the capsule from the underlying glenoid and humerus, has been shown to reduce pain and increase shoulder mobility in some patients (Hulstyn and Weiss 1993). Favourable results have also been obtained with arthrographic distension and rupture of the capsule through injection under pressure, of a 30-ml mixture containing 8 ml of 1 per cent lidocaine, 80 mg methylprednisolone, and 20 ml of water-soluble contrast material (Rizk *et al*. 1994). Manipulation of the shoulder under anaesthesia, to rupture the inferior capsule, is a controversial form of therapy. Restoration of shoulder movements following the procedure is variable. The treatment can cause soft tissue damage and shoulder dislocation, and long-term studies suggest that manipulation does not significantly alter the rate of recovery (Hulstyn and Weiss 1993). Operative capsulotomy, with surgical release of the coracohumeral ligament and of subacromial adhesions, is occasionally beneficial in patients with chronic symptoms refractory to conservative treatment (including injections, physiotherapy, oral corticosteroids, and manipulations) (Hulstyn and Weiss 1993).

Glenohumeral instability

Subtle, traumatic tears of the rotator cuff and capsule leading to chronic, multidirectional, glenohumeral instability are a frequent cause of shoulder pain, particularly in the young, active athlete (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Chard and Hazleman 1987; Vecchio *et al*. 1995). Although the findings may resemble those of rotator cuff tendinitis (with which it often coexists), laxity of the glenohumeral joint can be demonstrated by a number of tests. These include anterior and posterior 'drawer' signs (the humeral head and proximal humerus are moved forward and backward in the glenoid fossa), the 'sulcus' sign (applying distal traction on the upper arm while palpating the gap between the humeral head and the acromion), and the 'containment' sign (with the patient lying supine and the shoulder abducted 90°, the examiner slowly extends and externally rotates the arm). A patient with anterior glenohumeral instability experiences pain that is relieved when downward pressure is applied to the subluxed humeral head (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Bulgen *et al*. 1984; Chard and Hazleman 1987; Petri *et al*. 1987; Hulstyn and Weiss 1993; Vecchio *et al*. 1995).

Treatment of glenohumeral instability occurring in association with rotator cuff tendinitis consists of non-steroidal anti-inflammatory drugs, and an exercise programme to strengthen the dynamic stabilizers: rotator cuff and biceps muscle. A stabilizing operative procedure is indicated in resistant cases.

Traumatic lesions of the acromioclavicular joint

Acute and chronic trauma to the acromioclavicular joint can lead to disruption of the joint capsule, dislocation, or damage to the fibrocartilaginous disc. Late sequelae include chronic acromioclavicular instability, acromioclavicular separation, osteolysis of the lateral end of the clavicle, and secondary osteoarthritis (Bland *et al*. 1977; Kapandji 1982; Neviaser 1983; Bulgen *et al*. 1984; Chard and Hazleman 1987; Petri *et al*. 1987; Hulstyn and Weiss 1993; Vecchio *et al*. 1995).

Local pain, tenderness, and sometimes swelling of the acromioclavicular joint are the main clinical findings. Pain at the acromioclavicular joint can be localized by performing various 'stress' tests: the 'adduction stress' test (passive adduction of the extended shoulder behind the back), and the 'cross-arm acromioclavicular loading' test (shoulder abducted 90° and then adducted across the chest at shoulder height). A painful arc from 90° of abduction upwards is characteristic.

Treatment consists of physiotherapy, non-steroidal anti-inflammatory drugs, and sometimes, an intra-articular injection of corticosteroid. A surgical stabilizing procedure is indicated in chronic cases.

Disorders of the elbow region

Lateral epicondylitis, medial epicondylitis, and olecranon bursitis are the three most common soft-tissue lesions at the elbow.

Lateral epicondylitis (tennis elbow)

This is one of the most common painful lesions of the upper extremity. It affects 1 to 3 per cent of the adult population, mostly those between 40 and 60 years of age (Leach and Miller 1987; Birrer *et al*. 1989; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994). The dominant arm is most frequently involved. Although about 40 per cent of tennis players suffer with lateral epicondylitis, less than 10 per cent of patients in clinical practice acquire the disorder through playing tennis. It occurs most often in non-athletes who overuse their arms in recreational or occupational activities (Leach and Miller 1987; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994).

The exact mechanism of lateral epicondylitis is not entirely clear. It is generally regarded as a cumulative trauma overuse disorder due to repetitive mechanical overloading of the origin of the common forearm extensor muscles (Leach and Miller 1987; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994). An abnormality of local microvascular control, presumably due to sympathetic dysfunction, has also been postulated (Smith *et al*. 1994a). Limited pathological studies have demonstrated small tears, granulation tissue, sparse round-cell infiltration, and fibrous degeneration of the attachment of the common extensor tendon into the

lateral epicondyle, particularly that portion derived from the extensor carpi radialis brevis (Leach and Miller 1987; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994). Fibrocartilaginous and bony transformation, and an increase in glycosaminoglycan content within the tendon close to its insertion, have also been observed (Chard *et al*. 1994).

The typical patient with tennis elbow is a middle-aged or elderly individual who is active in gardening, hobbies, or sports. With ageing, muscles and tendons become less flexible and less elastic, making them more susceptible to overuse or work-related injuries, particularly near their bony attachments. The onset is often insidious, and bilateral occurrence is not uncommon. A rapid onset following a direct blow to the lateral epicondyle or a sports-related injury is more frequent in the younger, more active patient (Leach and Miller 1987; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994). Pain is localized to the lateral epicondyle but may extend both distally and proximally. It may occur during handshakes, turning doorknobs, carrying a briefcase, lifting or gripping, resulting in restricted hand activities. Localized tenderness just distal and slightly anterior to the lateral epicondyle is the hallmark of tennis elbow (Leach and Miller 1987; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994). The elbow pain can be increased by a number of manoeuvres: resisting dorsiflexion of the wrist with the elbow in extension, extending the elbow with the wrist flexed and pronated, and by resisted forearm pronation. The 'chair-lift' test, in which the patient lifts a chair or any similarly heavy object with the forearm pronated, will cause sharp pain at the lateral epicondyle. The range of movement of the elbow joint is normal, but in chronic cases a slight flexion deformity may be present. The grip strength, measured by a dynamometer, is usually diminished.

Elbow radiographs are often normal, but periarticular calcification or exostosis may be present in those with chronic symptoms. Infrared thermography may show localized increased heat in the region of the lateral epicondyle. MRI may show an extensor tendon tear in young athletes with acute onset of symptoms (Warhold *et al*. 1993). MRI in patients with chronic lateral epicondylitis has demonstrated unexplained increased signal intensity of the anconeus, a muscle not known to be involved in this disorder (Coel *et al*. 1993).

Treatment of lateral epicondylitis consists of an initial period of rest from the workplace or sporting activity, the identification and modification of activities that aggravate symptoms, applications of ice packs or heat, and non-steroidal anti-inflammatory drugs (Leach and Miller 1987; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994). A forearm brace, a wrist cock-up splint to provide 20° extension, or strapping of forearm muscles 4 to 5 cm distal to the elbow may be of benefit in some patients. Tennis-elbow bands worn during activity change the direction of muscle pull and short-circuit the force of contraction by reducing the effective length of the muscle. There are two types of band, static and counterforce. The static band wraps around the proximal forearm and applies equal pressure to all areas of the forearm. The counterforce band applies most of the pressure directly over the extensor muscle mechanism constraining full muscle contraction, thereby reducing injury-producing tension on the attachment of the extensor tendon. A local corticosteroid injection (methylprednisolone acetate 10 mg or triamcinolone hexacetonide 4 mg) into the site of maximal tenderness at the anterior part of the lateral epicondyle near the origin of extensor carpi radialis brevis produces relief in about 90 per cent of patients. Complications are rare: they include postinjection flare and infection. Repeated corticosteroid injections can cause loss of subcutaneous fat, depigmentation, and calcification at the site of injection. Steroid injections may be repeated after 4 to 8 weeks in the event of either failure to respond or relapse, but should not be repeated more than three to four times as they are unlikely then to improve the outcome. After the pain has subsided, graded exercises to stretch and strengthen the extensor forearm muscles are important for the prevention of recurrences and long-term rehabilitation. A number of other treatments have been used but their efficacy remains unproven. Included among these are pulsed therapeutic ultrasound, use of a whirlpool, medical laser-light therapy, acupuncture (Molsberger and Hille 1994), and manipulation. Ultrasound, by virtue of its ability to cross myofascial planes and concentrate near bone, has theoretical but unproven advantages.

Lateral epicondylitis is a self-limiting disorder; most patients improve within a year, but some may continue to have chronic symptoms. Surgical treatment is indicated in those with refractory symptoms for more than 6 to 12 months (about 10 per cent of patients) (Leach and Miller 1987; Gellman 1992; Foley 1993; Warhold *et al*. 1993; Geoffroy *et al*. 1994). Release of the origin of the common extensor tendon is the surgical treatment of choice (Verhaar *et al*. 1993). Other operative procedures include excision of granulation tissue and repair of extensor tendon tears, distal tenotomy to lengthen the common extensor tendon, division of the tendinous origin of extensor carpi radialis brevis, and combined release of the common extensor tendon and resection of the proximal third of the annular ligament (Verhaar *et al*. 1993).

Medial epicondylitis (golfer's elbow)

Medial epicondylitis affects the common flexor tendon at the medial epicondyle and is considerably less common and less disabling than lateral epicondylitis (Leach and Miller 1987; Birrer *et al*. 1989; Glazebrook *et al*. 1994). It commonly occurs in individuals who overuse their arms, and its pathology is essentially similar to that of tennis elbow. Cumulative repetitive strains, and increased activity of the common flexor muscles of the forearm in golfing, baseball pitching or work-related activities, can lead to disruption and tears of the common flexor muscle–tendon unit (particularly that portion derived from the pronator teres), near its origin from the medial epicondyle. Electromyographic activity recorded from forearm flexor muscles is significantly greater in golfers with medial epicondylitis than in those without (Glazebrook *et al*. 1994).

The onset is often insidious, with pain localized to the medial epicondyle. The pain may spread widely down the forearm, and may occur during lifting, grasping, and other activities involving the hands. There is tenderness at and just distal to the medial epicondyle. Resisted palmar flexion of the wrist with the elbow extended exacerbates the pain. Flexion of the fingers rather than of the wrists may sometimes elicit pain at the medial epicondyle.

Modification of forearm activities, ice packs or heat, non-steroidal anti-inflammatory drugs, and occasionally a local corticosteroid injection are sufficient therapy for most patients with medial epicondylitis. Enlarged golf-club handles and medial forearm counterforce braces (Glazebrook *et al*. 1994) may provide subjective relief in some patients. Exercises to strengthen the wrist flexors and forearm pronators are important. Surgical release of the common extensor tendon is indicated in those with chronic symptoms (Leach and Miller 1987; Birrer *et al*. 1989).

Olecranon bursitis

The subcutaneous olecranon bursa is a frequent site for traumatic, inflammatory, and septic bursitis (Fam 1992; Zimmermann *et al*. 1995).

Non-septic olecranon bursitis can result from either a discrete injury, for example an acute blow (traumatic olecranon bursitis), or from repetitive, minor, or occult trauma to the elbow, for example excessive leaning (idiopathic olecranon bursitis). 'Dialysis elbow' refers to olecranon bursitis that may occur in patients on haemodialysis due to sustained pressure on the resting elbow with the venous access during dialysis. 'Miner's elbow' and 'student's elbow' also refer to traumatic olecranon bursitis due to excessive friction on the elbow (Fam 1992).

Pain is usually minimal except when pressure is exerted on the swollen bursa. Bursal fluid distension and local tenderness are present but elbow joint movements are usually unimpaired and painless. Bursal fluid is either clear or blood-tinged, with reduced viscosity and a low, predominantly mononuclear, leucocyte count (£2000×10^6/l). Immunophenotypic characterization of bursal fluid mononuclear cells in idiopathic olecranon bursitis showed a preponderance of activated T-cell subpopulations and monocyte/macrophages; this suggested an immunological role for these cells in the development and perpetuation of non-septic bursitis (Smith *et al*. 1994b).

Treatment of traumatic and idiopathic olecranon bursitis consists of aspiration, a compressive elastic bandage, protection of the elbow from further friction, non-steroidal anti-inflammatory drugs, and one or more intrabursal injections of corticosteroid as required (Fam 1992; Zimmermann *et al*. 1995). Surgical bursectomy is rarely indicated in those with recurrent bursitis.

Inflammatory olecranon bursitis may be due to rheumatoid arthritis, psoriatic arthritis, or gout. It is associated with local tenderness, bursal distension, and an inflammatory synovial effusion with a high, predominantly polymorphonuclear, leucocyte count (> 2000 × 10^6/l). Treatment includes aspiration, non-steroidal anti-inflammatory drugs, one or more intrabursal injections of steroid, and therapy for the underlying disorder. Local sclerotherapy with intrabursal tetracycline has recently been shown to be effective in the recurrent treatment of rheumatoid bursitis resistant to intrabursal steroid injections (Hassell *et al*. 1994).

Septic olecranon bursitis usually results from the direct introduction of bacteria through a skin abrasion (Fam 1992; Fam 1994b; Zimmermann *et al*. 1995). It typically occurs in otherwise healthy adult men engaged in physical work involving frequent trauma to the elbows (e.g. plumbers, miners, gardeners, construction workers, etc.). *Staphylococcus aureus* is the most frequent pathogen.

Clinical findings include local pain, swelling, tender bursal effusion, warmth, erythema, peribursal cellulitis, and diffuse oedema. Bursal fluid is opaque, yellow, with a high, predominantly polymorphonuclear, leucocyte count (>10 000–50 000 × 10^6/l). The diagnosis is confirmed by culture of the causative organism from the bursal

fluid and, rarely, from blood.

Treatment of septic olecranon bursitis consists of appropriate antibiotic therapy and repeated bursal needle aspirations (Fam 1994b; Zimmermann *et al*. 1995). Surgical bursotomy is indicated in patients with resistant or loculated septic bursitis.

Other less common elbow tendinitis

Tendinitis of the musculotendinous insertion of the biceps tendon is an uncommon cause of antecubital pain. The pain is increased by resisted flexion and supination of the forearm. It is associated with local tenderness at the distal insertion of the biceps tendon into the radial tuberosity, restriction of full elbow extension, and sometimes a local swelling (Sheon *et al*. 1982). The condition is traumatic in origin. Heat, non-steroidal anti-inflammatory drugs, rest, modification of activity, and occasionally a local corticosteroid injection are often beneficial.

Triceps tendinitis is a less common traumatic lesion, characterized by posterior elbow pain, tenderness, and sometimes swelling of the triceps tendon insertion into the olecranon process. Treatment consists of modification of precipitating activities, non-steroidal anti-inflammatory drugs, and physiotherapy (Sheon *et al*. 1982).

Disorders of the wrist and hand

Pain in the wrist and hand is of diverse causes (Table 1). Only three relatively common painful disorders will be discussed in this section: de Quervain's tenosynovitis, trigger finger or thumb, and Dupuytren's contracture.

De Quervain's tenosynovitis

De Quervain's stenosing tenosynovitis of the abductor pollicis longus and extensor pollicis brevis is commonly due to occupational or vocational repetitive activity, involving pinching with the thumb while moving the wrist in radial and ulnar directions (Thompson and Phelps 1990; Thorson and Szabo 1992). This results in frictional inflammation, thickening, and stenosis of the fibrous tendon sheath as it passes over the distal radius beneath the extensor retinaculum. It may also occur in association with rheumatoid arthritis, psoriatic arthritis, direct trauma, and pregnancy, and during the postpartum period (Nygaard *et al*. 1989).

Most patients report several weeks or months of pain on the radial aspect of the wrist and at thumb base during pinch grip, grasping, and other hand activities. The affected tendon sheath is tender and often swollen. Finkelstein's test is positive (passive ulnar deviation of the wrist with the fingers flexed over the thumb placed in the palm stretches the tendons and reproduces the pain over the radial side), and a tendon crepitus may be palpable (Nygaard *et al*. 1989; Thompson and Phelps 1990; Thorson and Szabo 1992).

Treatment consists of heat application, non-steroidal anti-inflammatory drugs, and splinting (Nygaard *et al*. 1989; Thompson and Phelps 1990; Witt *et al*. 1991; Thorson and Szabo 1992; Sampson *et al*. 1994; Weiss *et al*. 1994). A radial-gutter light support splint immobilizes the wrist in slight extension and radial deviation and the first metacarpophalangeal joint in slight extension. The interphalangeal joint of the thumb is left unrestricted. Modification of hand activities with avoidance of tasks that require repetitive thumb movements or pinch grasping is helpful. In those with persistent pain, one or more corticosteroid injections into the affected tenosynovial sheath are often beneficial (Witt *et al*. 1991). Surgical decompression, with or without tenosynovectomy, is indicated in those with persistent or recurrent symptoms for more than 6 months (Witt *et al*. 1991; Sampson *et al*. 1994; Weiss *et al*. 1994).

Trigger finger or thumb (stenosing digital tenosynovitis)

Trigger finger or thumb, also known as stenosing digital tenosynovitis, or snapping finger or thumb, is the most common repetitive strain injury of the hand (Thompson and Phelps 1990; Thorson and Szabo 1992). The pathological lesion is a tenosynovitis of the flexor tendons of the finger or thumb, resulting in fibrosis and constriction localized to the first annular pulley that overlies the metacarpophalangeal joint (Freiberg *et al*. 1989; Canoso 1990; Thompson and Phelps 1990; Thorson and Szabo 1992). A nodular thickening of the tendon often develops at the site of stenosis; this interferes mechanically with the normal gliding of the tendon, resulting in pain over the area of the pulley and 'snapping', 'triggering', or 'catching' movement of the finger or thumb. Pain over the sheath with resisted flexion, and pain on stretching the tendon passively in extension, are common. Intermittent locking of the digit in flexion may also develop, particularly upon arising in the morning. Passive extension of the proximal interphalangeal joint of the finger or interphalangeal joint of the thumb may produce a crepitus and a popping sensation as the digit is straightened. Examination reveals tenderness over the area of the proximal pulley, linear tenderness and swelling of the flexor tendon sheath, tendon crepitus, and, often, limitation of digital flexion and extension. A nodular swelling of the tendon can usually be palpated in the palm just proximal to the metacarpophalangeal joint as it moves during finger or thumb flexion and extension (Freiberg *et al*. 1989; Canoso 1990; Thompson and Phelps 1990; Thorson and Szabo 1992). The most common cause of trigger finger or thumb is overuse trauma of the hands from repetitive gripping activities, with increased pull and friction on the flexor tendons. One digit is often affected, usually the thumb, middle, or ring fingers in that order. Other causes of flexor digital tenosynovitis include rheumatoid arthritis, psoriatic arthritis, diabetes mellitus, and infections, including tuberculosis, *Mycobacterium marinum*, and sporotrichosis (Canoso 1990).

Management consists of modification of hand activity, local heat application, gentle exercises and non-steroidal anti-inflammatory drugs as required (Freiberg *et al*. 1989; Canoso 1990; Thompson and Phelps 1990; Thorson and Szabo 1992; Sampson *et al*. 1994). Extension splinting of the affected digit at night prevents painful flexion during sleep. Although trigger thumb may resolve spontaneously (Schofield and Citron 1993), one or more injections of corticosteroid into the affected flexor tendon sheath are effective in the majority of patients (Canoso 1990; Thompson and Phelps 1990; Anderson and Kaye 1991; Thorson and Szabo 1992; Schofield and Citron 1993; Sampson *et al*. 1994). Surgical release with transection of the fibrous annular pulley of the finger or thumb flexor sheath is required for those with chronic symptoms not responding to medical treatment (Freiberg *et al*. 1989; Canoso 1990; Thompson and Phelps 1990; Thorson and Szabo 1992; Sampson *et al*. 1994).

Dupuytren's contracture

This is a relatively common condition characterized by nodular thickening and contraction of the palmar fascia, often leading to disabling flexion contractures of the fingers (Wooldridge 1988; McFarlane 1990). In most patients, Dupuytren's contracture affects the ulnar side of both hands. The fourth finger is usually affected earliest, followed by the fifth, third, and second fingers in decreasing order of frequency. Fibrous nodules, composed of whorls of proliferating fibroblasts and myofibroblasts in the superficial layers of the palmar fascia, are the earliest abnormality. The dermis is invaded by fibroblastic cells, resulting in puckering, dimpling, and tethering of the overlying skin. There is usually little pain initially. However, after a variable period of months or years, the aponeurotic thickening may extend distally to involve the digits. The fingers become flexed at the metacarpophalangeal joints by taut fibrous bands radiating from the palmar fascia (Fig. 11), and the hand cannot be placed flat on a table (positive 'table top' test). Although there is no direct involvement of the joints or tendons, progressive flexion deformity of the fingers can lead to severe functional impairment.

Fig. 11 Dupuytren's contracture.

The aetiology of Dupuytren's contracture is poorly understood (Wooldridge 1988; McFarlane 1990). The disorder is rare in non-Caucasian individuals. Its incidence

rises with increasing age and the sex ratio is predominantly male (5:1). Familial predisposition is frequent, suggesting an autosomal-dominant pattern with variable penetrance. A pathogenetic role for local repetitive injury and occupational trauma remains unproven. An association with cigarette smoking, producing microvascular occlusion, has been suggested (An *et al*. 1988). Dupuytren's contracture has been observed in association with idiopathic epilepsy, alcohol abuse, diabetes mellitus, chronic pulmonary disease, and reflex sympathetic dystrophy syndrome. The association of Dupuytren's disease with other localized fibroses, such as nodular plantar fibromatosis, nodular fasciitis of the popliteal fascia, Peyronie's disease, and dorsal knuckle pads, has led to the concept of a 'Dupuytren's diathesis' (Wheeler and Meals 1981; Wooldridge 1988; McFarlane 1990). The cause of these fibrosing diseases is unknown but seems to be determined by a dominant gene with high penetrance in males, usually middle-aged white men of Celtic ancestry (Wooldridge 1988; McFarlane 1990).

The pathological lesion in Dupuytren's disease is characterized by marked fibroblastic proliferation and vascular hyperplasia. This is followed by dense, disorderly, collagen deposition with thickening of the palmar fascia, and nodule formation (Gelberman *et al*. 1980; Wooldridge 1988; McFarlane 1990). The abnormal fascia contains elevated total amounts of collagen with increased content of reducible cross-links and hydroxylysine; about 25 per cent of the collagen is type III, which is not normally present in the palmar fascia (Gelberman *et al*. 1980; McFarlane 1990). Ultrastructurally, contractile, smooth muscle-like fibroblasts or myofibroblasts, surrounded by bundles of disarrayed collagenous fibrils and completely or partially occluded capillaries, are present in the fibrotic nodules and cords (Gelberman *et al*. 1980; McFarlane 1990; McCann *et al*. 1993). Although myofibroblasts are not specific to Dupuytren's contracture, they are believed to be responsible for contraction of the palmar fascia and finger deformities (Gelberman *et al*. 1980; McCann *et al*. 1993). The finding of isolated foci of smooth-muscle -actin (an antibody marker for myofibroblasts) -positive fibroblasts dispersed in the dermis remote from the main Dupuytren's tissue may explain the high recurrence rate of Dupuytren's disease after fasciectomy (McCann *et al*. 1993). The vasoactive prostaglandins E_2 and F_{2a} are present in increased concentrations in Dupuytren's nodules, and are thought to influence myofibroblast contractility and contribute to the formation of the contracture (Badalamente *et al*. 1988). Increased expression of growth factors, including platelet-derived growth factor-b, transforming growth factor-b, and basic fibroblast growth factor in Dupuytren's fascial lesions, suggests that these mediators may play a part in fibroblastic proliferation in this disorder (Baird *et al*. 1993; Terek *et al*. 1995). Production of oxygen-derived free radicals may also be an important feature of the pathogenesis of Dupuytren's and other fibrotic conditions (Duthie and Francis 1988). Excessive formation of superoxide, hydrogen peroxide, and hydroxyl radicals resulting from microvascular occlusion and relative ischaemia of the palmar fascia can lead to tissue damage and enhanced fibroblastic proliferation (Duthie and Francis 1988). Flow cytometry of inflammatory cells from Dupuytren's lesions has demonstrated a predominance of CD3+ T lymphocytes and increased expression of major histocompatibility complex class II proteins (Baird *et al*. 1993a; Baird *et al*. 1993b). An association between Dupuytren's contracture, HLA-DR3, and autoantibodies to collagen types I to IV has also be demonstrated (Neumuller *et al*. 1994). Factor XIIIa-positive dermal dendrocytes of macrophage lineage are present in and around Dupuytren's nodules; these cells may be an important local source of fibrogenic cytokines (Sugden *et al*. 1993). These observations suggest that Dupuytren's disease may represent a T-cell-mediated autoimmune disorder (Baird *et al*. 1993; Sugden *et al*. 1993; Neumuller *et al*. 1994).

Dupuytren's contracture runs a variable course: some patients show little change or incapacity over a period of many years, while in others fascial contraction progresses rapidly with severe deformity and impairment of hand function within a short period of time (McFarlane 1990).

The treatment depends on the rate of progression and severity of the lesions. Recent observations suggest that MRI may be useful in assessing the extent and degree of cellularity, and hence 'activity' of the lesion (Yacoe *et al*. 1993). Local heat, stretching exercises, and the use of protective padded gloves during heavy manual grasping tasks are often helpful in patients with mild contracture (Wooldridge 1988; McFarlane 1990). Many patients learn the benign nature of the condition and adapt to it. In more severe lesions, with pain and inability to straighten the fingers, intralesional injections of corticosteroid may be beneficial (Wooldridge 1988; McFarlane 1990). Repeated intralesional infiltrations of interferon-g, a cytokine produced by T-helper lymphocytes that inhibits fibroblastic proliferation and collagen formation, is a promising but untested new treatment (Pittet *et al*. 1994). A limited or total palmar fasciectomy, with or without skin-graft replacement, is indicated in those with advanced disease with progressive digital contracture of more than 30°, a positive table-top test, and functional impairment (Ketchum and Hixson 1987; Wooldridge 1988; McFarlane 1990). The risk of recurrence is increased in young patients with active bilateral disease and cellular nodules, and in those with a strong family history and/or other ectopic fibrotic lesions (Ketchum and Hixson 1987; Wooldridge 1988; Yacoe *et al*. 1993).

1.2.2.2 The lower limbs in adults

Robert W. Simms

Applied anatomy

Applied anatomy of the hip

The hip joint is a diarthrodial ball-and-socket joint and comprises the head of the femur and the acetabulum of the pelvis (Fig. 1). The acetabular cavity comprises the bones of ilium, ischium, and pubis, which present a horse-shoe shaped cavity to accommodate the head of the femur. This arrangement facilitates one of the strongest ball-and-socket-type joints in the human body. The glenoid labrum or lip, a circular fibrocatilagenous rim, forms an additional reinforcement to the hip joint. At the centre and lower portion of the acetabular cavity is a fat pad lined by synovium. The transverse ligament bridges the lower portion of a gap in the labrum and gives rise to the ligamentum teres, an intracapsular ligament which attaches to a small depression in the head of the femur and carries blood vessels to the femur. These vessels provide nutrients to a small area of the head of the femur adjacent to the ligament attachment. The head of the femur itself is lined with hyaline cartilage which varies somewhat in thickness over its surface; it is thickest over the superior and posterior aspects (3 mm) and thinnest at the lateral margins (2–2.5 mm). The capsule of the hip is a dense, fibrous structure which attaches to the acetabulum, labrum, and the transverse ligament. The capsule is reinforced by three ligaments—anteriorly by the iliofemoral ligament, inferiorly by the pubofemoral ligament, and posteriorly by the ischiofemoral ligament. The capsule is lined by synovial membrane on its inner surface.

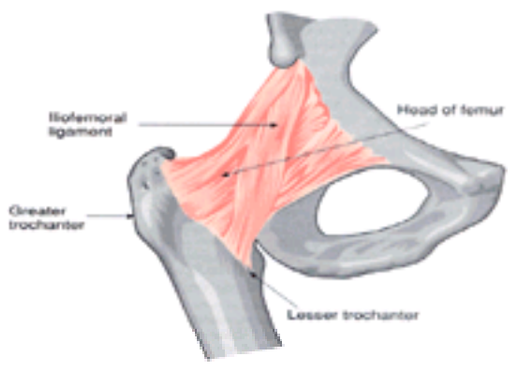

Fig. 1 The anterior view of the hip joint.

A number of bursae have been identified on or about the hip joint (Fig. 2 and Fig. 3). The most important clinically are the trochanteric bursae, the iliopectineal or iliopsoas bursae, and the ischiogluteal bursae (Larsson and Baum 1986). The trochanteric bursae actually comprises three bursae—the gluteus maximus bursa at the site of the insertion of the gluteus maximus muscle and the gluteus medius and gluteus minimus bursae at the sites of the respective muscle attachments (Fig. 2). Clinically the most important bursa is the gluteus maximus bursa. The iliopectineal or iliopsoas bursa lies anteriorly between the psoas muscle and the joint capsule. The ischiogluteal bursa lies over the ischeal tuberosity and facilitates gliding of the gluteus maximus over the tuberosity.

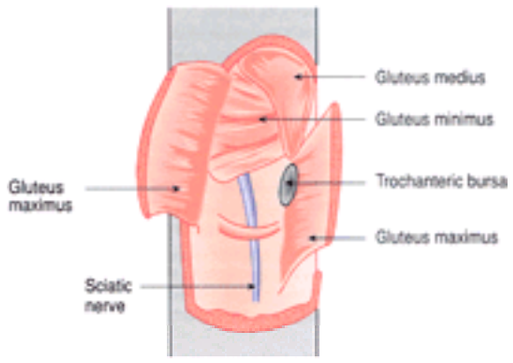

Fig. 2 The posterior view of the hip joint.

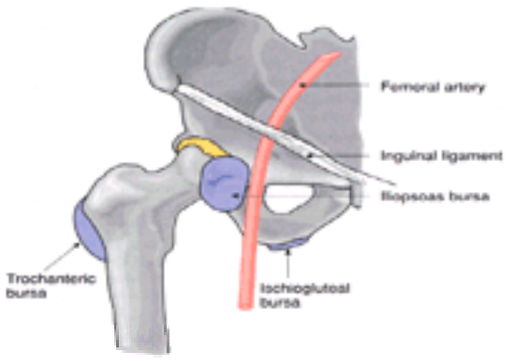

Fig. 3 The bursae of the hip joint.

Hip joint movement is facilitated by several powerful muscle groups. Flexion is accomplished chiefly by the iliopsoas with accessory function of the rectus femoris, pectineus, sartorius, and adductor longus. Extension is accomplished principally by the gluteus maximus and the hamstrings with accessory function by the ischial head of the adductor magnus. Abduction is primarily accomplished by the gluteus medius with accessory function by the gluteus minimus. Adduction is accomplished primarily by the adductor magnus with accessory function by the adductor longus, adductor brevis, pectineus, and gracilis. External rotation is accomplished by the gluteus maximus, quadratus femoris, and piriformis with accessory function by the sartorius and gracilis. Internal rotation is accomplished by the gluteus minimus with accessory function by the gluteus maximus, gluteus medius, adductor longus, adductor brevis, adductor magnus, pectineus, iliacus, and psoas. Normal hip range of motion varies with the manner in which it is examined. With the knee in flexion the hip can be flexed to 120°. With the knee extended, the hip can be flexed to only approximately 90°, being limited by the pull of the hamstrings. Internal rotation is normally to 40° with external rotation to 45°. Abduction is normally to 45° and adduction to 20 to 30°.

The normal gait cycle involves two basic phases—the stance phase and the swing phase (Fig. 4) (Morris *et al*. 1994). The stance phase begins with heal contact. Full weight bearing begins with forefoot contact and ends with heel lift. The stance phase then ends with lift off and starts the swing phase. The swing phase then continues until heel contact and the cycle repeats. Under normal conditions the stance phase comprises approximately 65 per cent of the gait cycle whereas the swing phase comprises approximately 35 per cent (Fig. 4). Hip disorders may cause the patient to walk with a shortened stance phase or with an antalgic gait since he will try to minimize the time spent on full weight bearing. Chronic hip disorders frequently produce weakness of the gluteus medius or a Trendelenberg gait. Here, hip abduction is impaired and the pelvis on the opposite side drops during the stance phase. The body leans toward the diseased side when weight bearing is on the diseased hip.

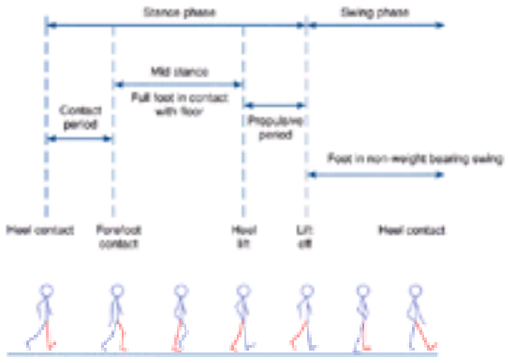

Fig. 4 The gait cycle.

Applied anatomy of the knee

The knee is the most complex and the largest joint in the human body (Fig. 5). It is a modified hinge joint with three compartments; the medial and lateral tibiofemoral compartments and the patellofemoral compartment. The knee is not a simple hinge joint since it is capable of flexion, extension, and rotation. The latter movement occurs as the knee approaches full extension and is due to the shape of the joint surfaces and ligament tension, which causes internal rotation of the femur—the so-called 'screwed-home position'. Stability is provided by the cruciate ligaments and menisci and the capsule with its associated capsular ligaments.

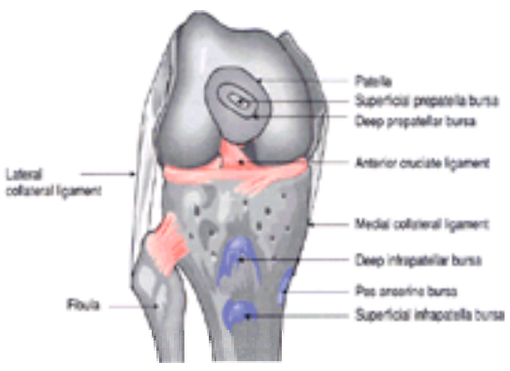

Fig. 5 The anterior view of the knee joint with associated bursae.

The menisci or semilunar cartilages are crescent-shaped structures consisting of fibrocartilage, which transmit up to 70 per cent of the force through the tibiotalar joint and also have a lubricating role (Fig. 6). They are predominately avascular, although the peripheral 10 to 30 per cent and the anterior and posterior horns receive blood supply from the geniculate vessels and therefore they have the capability for repair. The remainder of the menisci receive nutrients passively from the synovial fluid and have little capacity for repair.

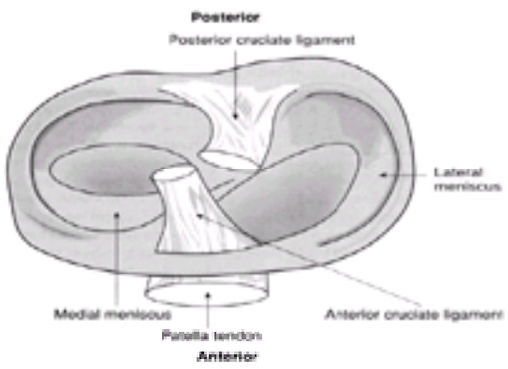

Fig. 6 The meniscii of the knee.

The anterior and posterior cruciate ligaments together with the medial and lateral collateral ligaments are accessory ligaments of the capsule of the knee (Fig. 6). The anterior and posterior cruciate ligaments cross each other within the joint and are formed by twisting rope-like fibres of collagen of different lengths. The cruciate ligaments are the principal knee stabilizers in the anteroposterior plane with the anterior cruciate preventing anterior slippage of the femur relative to the tibia, and the posterior cruciate preventing posterior slippage. The cruciates also provide rotational stability. The collateral ligaments provide medial and lateral stability. The iliotibial band is a fascial band connecting the ilium with the lateral tibia and contributes to the lateral stability of the knee (Fig. 7).

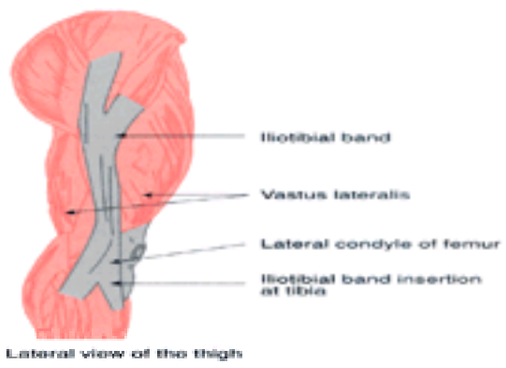

Fig. 7 The iliotibial band.

The patella is the largest sesamoid bone in the human body and its undersurface possesses the thickest articular cartilage. The primary function of the patella is to increase the lever arm of the quadriceps. The stability of the patella is provided statically by the bony interface between the trochlea of the femur and the undersurface of the patella. Dynamic stability is provided predominately by the extensor mechanism. There is considerable variation in the articular anatomy of the patella. The most common shape is a relatively larger lateral facet when compared to the medial facet. The shape of the femoral trochlea also varies considerably—it may be shallow and broad or deeply V-shaped or in between these extremes. The quadriceps mechanism and its attachment to the knee is complex. Most anterior is the rectus femoris which inserts anteriorly and most superficially to the patella. Medially the vastus medialis inserts obliquely at an angle of 60° to 70° and provides dynamic medial stability for the patella. This counteracts the lateral dynamic force on the patella imposed by the majority of the quadriceps mechanism which is a consequence of the normal slight varus angulation of the lower leg in relation to the femur. Patellar tracking is influenced by the direction of pull of the quadriceps and the position of attachment of the patellar tendon into the tibial tubercle (Tria *et al*. 1992). This relationship is expressed by the patella Q angle, which is the angle formed by a line between the centre of the patella extending proximally to the anterosuperior iliac spine and extending distally to the centre of the tibal tubercle (Fig. 8). The normal Q angle is 10° in men and 15° in women. Femoral neck anteversion and external tibial torsion increases the Q angle, whereas femoral neck retroversion and internal tibial torsion decreases the Q angle (Tria *et al*. 1992). An excessive Q angle may predispose to patella subluxation or dislocation, since as the Q angle increases the patella tends to track more laterally.

Fig. 8 The patella Q angle.

There are a number of bursae surrounding the knee joint (Fig. 5). Anteriorly is the subcutaneous, prepatellar bursa which lies over the lower pole of the patella. Inferiorly are the infrapatellar bursae; the superficial infrapatellar bursa which lies between the patella tendon and the tibial tubercle and the deep infrapatellar bursa which lie between the patellar tendon and the proximal tibia. Medial and inferior to the joint is the pes anserine bursa which lies between the medial collateral ligament and the insertion of the adductor muscles of the thigh; the sartorius, gracilis, and semitendinosus. Posteriorly is the gastrocnemius–semimembranous bursa which is a complex structure and comprises three components; a base which is located under the capsular insertion of the gastrocnemius muscle, the medial extent between the heads of the gastrocnemius and the semimembranous muscle, and a small subfascial extension. In over 50 per cent of individuals over the age of 50 years there is communication between the gastrocnemius–semimembranous bursa and the knee joint (Canoso 1981). When a communication exists synovial fluid from any aetiology may enter the bursa. If a large volume of synovial fluid expands into the gastrocnemius–semimembranous bursa suddenly it may bulge into the popliteal fossa or it may rupture into the calf producing the so-called ruptured Baker's cyst or pseudothrombophlebitis (Rauschning 1980).

Applied anatomy of the foot and ankle

The foot comprises 26 bones and 38 muscles along with a variable number of sesamoids which are held together by 125 interconnecting ligaments and must absorb up to six times the body weight with each step (Fig. 9). The foot is usually divided into three sections; the forefoot, the midfoot, and the hindfoot. The forefoot consists of the five metatarsals and is separated from the midfoot by the tarsometatarsal joint of Lisfranc. The midfoot contains the three cuneiforms, the navicular, and the cuboid and is separated from the hindfoot by the transverse midtarsal joint. The hindfoot consists of the calcaneus and the talus.

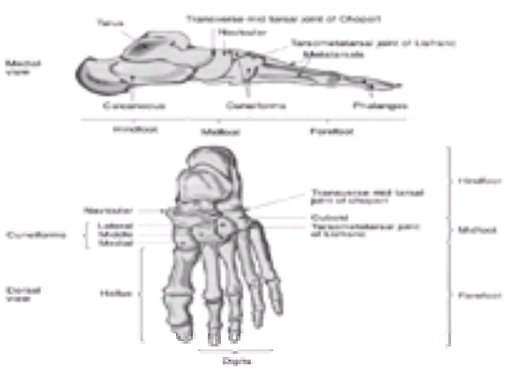

Fig. 9 The bones of the foot.

The ankle joint comprises three articulations; the tibiotalar joint, the subtalar joint, and the talonavicular joint. The tibiotalar joint or 'true' ankle joint is the result of the articulation of the dome of the talus, the roof or plafond of the distal tibia, and the distal tibiofibular joint. The joint is stabilized medially by the medial bony protrusion of the distal tibia, the medial malleolus, and the distal lateral fibula forming the lateral malleolus. Motion at the tibiotalar joint consists of 20° of dorsiflexion and 50° of plantar flexion. A complex set of ligaments additionally stabilizes the ankle. The deltoid ligament (comprising four ligaments; the posterior tibiotalar ligament, the tibiocalcaneal ligament, the tibionavicular ligament, and the anterior tibiotalar ligament) provides medial stability. The lateral collateral ligament (comprising the posterior talofibular ligament, the calcaneofibular ligament, and the anterior talofibular ligament) provides lateral stability.

The subtalar joint is composed of the articulation of the calcaneous and the talus, is surrounded by its own distinct capsule, and does not articulate with other joints. Normal range of motion of the subtalar joint is 5° of inversion and 5° of eversion. The subtalar joint provides inversion and eversion of the heel and facilitates walking on uneven terrain. The transverse midtarsal joint of Chopart is composed of the talonavicular joint and the calcaneocuboid joint and permits multiaxial motion—inversion and eversion of the midfoot and forefoot and, to a lesser degree, dorsiflexion and plantar flexion and abduction and adduction. It is stabilized by the bifurcate ligament which has two components; the calcaneonavicular segment and the calcaneocuboid component. The tarsometatarsal joint of Lisfranc comprises the interconnected second to fifth tarsometatarsal joints. A complex set of ligaments on their dorsal and plantar aspects provide stability and consists of two principal components; the dorsal tarsometatarsal ligaments and the plantar tarsometatarsal ligaments.

The metatarsophalangeal joints are analogous to the metacarpophalangeal joints of the hands and are stabilized by the deep transverse metatarsal ligament and the plantar ligaments. The first metatarsophalangeal joint plays a critical role in normal gait. Under most conditions, 65° to 75° of dorsiflexion of the hallux on the first metatarsal is required for normal gait and for the hallux to function in propulsion (Mahan 1994). Disorders such as hallux valgus and hallux rigidus affect gait adversely by limiting dorsiflexion of the first metatarsophalangeal joint.

The interphalangeal joints of the toes are analogous to those of the hand and consist of hinge joints stabilized by collateral ligaments and a plantar capsular ligament with a fibrous plate. The plantar aponeurosis or plantar fascias runs from the plantar aspect of the calcaneous to the region of the metatarsal heads. It comprises two distinct layers; the superficial and deep. The superficial layer blends with subcutaneous tissue, whereas the deep layer joins the deep transverse metatarsal ligament and the flexor tendons.

Attached to the foot and ankle are the tendons of the extrinsic muscles which form three compartments in the lower leg; the anterior compartment containing the dorsiflexors or extensors of the foot and ankle, the lateral compartment containing the peroneal muscles which act as plantar flexors and abductors, and the posterior compartment which contains the plantar flexors (Fig. 10). Posterior to the ankle is the Achilles tendon, formed by the conjoined tendons of the gastrocnemius and the soleus muscles which functions to plantar flex the foot. Medially at the ankle is the tibialis posterior tendon complex, comprising the tendons of the flexor digitorum longus, the tibialis posterior, and the flexor hallucis longus which pass underneath the flexor retinaculum posterior to the medial malleolus. Between the sheaths of the flexor digitorum longus and the flexor hallucis longus tendons lies the posterior tibial artery and nerve within the tarsal tunnel. Tenosynovitis of either the tibialis posterior, flexor hallucis longus, or flexor digitiorum longus tendons may produce functional compression of the posterior tibial nerve producing tarsal tunnel syndrome (Grumbine *et al*. 1990). The tibialis posterior is the principal inverter of the foot and maintains the longitudinal arch by its insertion to the navicular and medial and intermediate cuneiforms and bases of the second, third, and forth metatarsals (Sarrafian *et al*. 1983). Laterally at the ankle, passing under the superior and inferior peroneal retinacula, is the common sheath of the peroneus longus and brevis tendons, which are the principal everters and abductors of the foot. Anteriorly, the extrinsic extensor tendons of the foot (the extensor digitorum longus, the peroneus tertius, and the extensor hallucis longus tendons) within their tendon sheaths pass under the fibrous superior and inferior extensor retinacula.

Fig. 10 The ankle: lateral and medial views.

There are several pertinent bursae of the foot and ankle (Fig. 10 and Fig. 11). The retrocalcaneal bursa lies between the calcaneus anteriorly and the Achilles tendon posteriorly (Fig. 11). This bursa has a synovial lining which abuts the Achilles fat pad. Anteriorly, the bursal wall is composed of fibrocartilage and posteriorly is contiguous with the Achilles tendon (Frey *et al*. 1992; Canoso *et al*. 1984). The bursa itself is horseshoe shaped with the average length of the legs measuring 22 mm and the width 4 mm, with the width of the body measuring 8 mm (Frey *et al*. 1992). Between the skin and the Achilles tendon posteriorly is the subcutaneous calcaneal bursa. At the plantar aspect of the midcalcaneous is the subcalcaneal bursa.

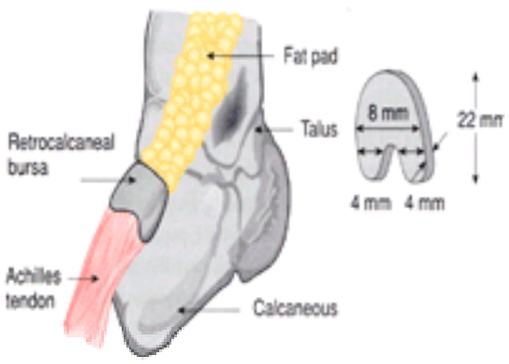

Fig. 11 The retrocalcaneal bursa.

General approach to regional disorders of the lower extremities

Lower extremity regional pain syndromes are common in rheumatology and orthopaedic practices although precise population-based incidence data are not available. A detailed survey and examination of soft tissue abnormalities in 123 unselected medical students revealed that approximately 10 per cent had either bursitis, tendinitis, or chondromalacia patellae (Raskin and Lawless 1982). Lower extremity regional pain conditions often present a challenge to the clinician because of their complexity, frequent confusion with other conditions, and lack of precise diagnostic tests. However, careful history and physical examination combined with knowledge of the relevant anatomy will generally permit identification of these conditions. Table 1 provides a classification of the regional disorders of the lower extremity based on location.

Table 1 Classification of painful lower limb disorders

Many of the conditions producing lower extremity regional pain are bursal disorders. It is worthwhile to review some general concepts relevant to bursae. Bursae are synovial-lined sacs which are located to facilitate tissue gliding. Bursae can be generally divided into deep and subcutaneous varieties. Subcutaneous bursae generally overlie bony prominences and permit skin movement without undue stretching and tearing and they develop after birth (Canoso 1981; Canoso and Yood 1979). Deep bursae are located between divergently pulling tendons or between tendons and bone and generally form in early fetal development. Normal bursal fluid has characteristics similar to synovial fluid—a high content of hyaluronic acid, low leucocyte count (300/mm ^{3}) with a predominance of mononuclear cells (Canoso 1981; Canoso *et al*. 1983). A variety of disorders can affect bursae, particularly the subcutaneous variety. This includes trauma, infection, and systemic or metabolic conditions such as rheumatoid arthritis or gout. Septic subcutaneous bursitis is particularly important to exclude. In the lower extremity, subcutaneous bursae around the knee are the most common sites of infection. Prepatellar bursitis is the second most common form of septic bursitis behind olecranon bursitis, accounting for 27 per cent of 49 cases of septic bursitis in one series (Raddatz *et al*. 1987). Identifiable risk factors for septic bursitis include skin breakdown, trauma, immunosuppression (diabetes, concurrent immunosuppressive medication), and occupations involving frequent or sustained pressure on bursae, such as roofing or carpentry (Raddatz *et al*. 1987). By far the most common organism responsible for septic bursitis is *Staphylococcus aureus*, accounting for approximately 80 per cent of all cases (Raddatz *et al*. 1987; Ho *et al*. 1978; Ho and Ticer 1979). Less frequently other organisms may be cultured (Meys *et al*. 1992; McDermott *et al*. 1994). Aspiration of symptomatic subcutaneous bursae is generally required to exclude infection. In the case of the prepatellar bursa, aspiration should be performed on the lateral site of the bursa to prevent a chronic draining sinus which can occur if aspiration is performed over the apex of the bursa. Bursal fluid leucocyte counts which exceed 5000/mm^{3} should be suspected of being septic and empirical antibiotic coverage directed against *S. aureus* should be considered in this setting. Optimal treatment consists of frequent aspiration until no fluid reaccumulates and either oral or intravenous antibiotics (Ho and Su 1981). The length of time required to achieve culture sterility with antibiotic therapy of septic bursitis (mean of 4 days) was correlated with the duration of symptoms prior to diagnosis in one series (Ho and Su 1981). In patients treated within 2 weeks from the onset of symptoms, culture sterility occurred within 1 week of therapy, while longer duration of symptoms was associated with delayed response (Ho and Su 1981).

Hip region pain

Trochanteric bursitis

There are three bursae in the greater trochanteric region of the hip. The most important clinically, and the largest, is the gluteus maximus bursa which separates the fibres of the gluteus maximus from the greater trochanter (Larsson and Baum 1986). The two other bursae lie between the gluteus medius and greater trochanter and gluteus minimus and greater trochanter respectively. Patients with trochanteric bursitis present with a deep, aching pain over the lateral upper thigh which is often intensified by walking but it may be worse at night, especially when the patient is lying on the affected side. The course is variable with an acute phase lasting several days followed by gradual improvement and resolution over a period of days or weeks. In some cases the course may be quite protracted with symptoms which persist for months. The diagnosis is confirmed with palpation of the posterior aspect of the greater trochanter which elicits local tenderness in this area. Resisted abduction of hip on the affected side may also be painful.

The aetiology of trochanteric bursitis is unknown; however, potential risk factors include local trauma, overuse activities such as jogging, and leg length discrepancies (primarily on the side with the longer leg). These factors are thought to lead to increased tension of the gluteus maximus on the iliotibial band and produce bursal inflammation. The differential diagnosis of trochanteric bursitis includes lumbar radiculopathy (particularly the L1 and L2 nerve roots), meralgia paraesthetica (entrapment of the lateral cutaneous nerve of the thigh as it passes under the inguinal ligament), true hip joint disease, and intra-abdominal pathology. These potentially confounding conditions can generally be excluded by careful history and physical examination.

Treatment of trochanteric bursitis is best accomplished by avoiding aggravating activity and local injection of a long-acting corticosteroid preparation. Referral to physical therapy in resistant cases may be helpful, particularly for exercises to stretch the iliotibial band.

Ischiogluteal bursitis

The ischiogluteal bursa lies over the ischeal tuberosity and facilitates gliding of the gluteus maximus muscle over the tuberosity (Fig. 3). In the sitting position, the gluteus maximus slides superiorly exposing the ischeal tuberosity to potential friction.

Prolonged sitting on hard surfaces or repeated leg flexion and extension in the sitting position may predispose to repeated friction on the ischiogluteal bursa and lead to bursitis, also known as 'weaver's bottom.' Rarely the ischiogluteal bursa may become infected (Lambie *et al*. 1989). The diagnosis is made by the characteristic history and by eliciting tenderness on palpation of the ischeal tuberosity with the patient lying supine and with the hip and knee flexed. Treatment consists of using a cushioning 'doughnut' seat and performing trunk and knee-to-chest stretching exercises while lying on the cushion. A local injection of corticosteroid is useful in refractory cases, although care should be taken to avoid the sciatic nerve which lies just lateral to the ischiogluteal bursa.

Iliopsoas bursitis

The iliopsoas bursa (also called the iliopectineal bursa) lies over the anterior surface of the hip joint under the iliopsoas muscle and between the hip joint capsule (Fig. 3). In most cases of reported iliopsoas bursitis, communication between the hip joint and the bursa occurs, either due to pre-existing communication (which occurs in approximately 15–20 per cent of normal cases) and associated excessive synovial fluid accumulation or due to rupture of the hip joint capsule (Canoso 1981). The condition has been described in association with a number of hip disorders including osteoarthritis, rheumatoid arthritis, synovial chrondromatosis, pigmented villonodular synovitis, osteonecrosis, and septic arthritis (Broadhurst 1995; Flanagan *et al*. 1995; Generini *et al*. 1993; Letourneau *et al*. 1991; Manueddu *et al*. 1991). Typically, patients present with an inguinal mass which may be painful and may be associated with secondary femoral vein obstruction or femoral nerve compression (Savarese *et al*. 1991; Lavyne *et al*. 1982). Computed tomography is considered the optimal modality to diagnose iliopsoas bursitis. Treatment of the underlying hip disorder is generally sufficient, although surgical excision is sometimes required.

Knee pain

Knee pain is among the most common articular complaints. Non-arthritic conditions are a large proportion of knee complaints, particularly in younger age groups.

Knee pain in adolescence (see also Chapter 1.2.2.3)

A variety of knee pain syndromes occur in the adolescent (age 10–18 years) which are unique to this age group. Osgood–Schlatter disease is one such condition and generally presents with activity-related pain around the tibial tubercle. This condition is thought to result from submaximal, repetitive tensile stresses acting on the immature junction of the patellar ligament, tibial tubercle, and tibia, causing mild avulsion injury followed by attempts at osseous repair with proliferation of cartilage and bone (Ogden *et al*. 1976; Kujala *et al*. 1985). Pain is generally intermittent and increased with activities, especially those which require kneeling, squatting, or repeated jumping. Athletically active boys were found to have a fivefold risk of Osgood–Schlatter disease compared to inactive controls in one study (Kujala *et al*. 1985). An increased Q angle has also been associated with Osgood–Schlatter disease (Kujala *et al*. 1985). Physical examination is notable for swelling and

prominence of the tibial tubercle with local tenderness. In approximately 50 per cent of cases a discrete ossicle is noted at the tibial tubercle. Radiographs of the knee may be useful to exclude tumours and infection. Treatment with ice, anti-inflammatory agents, an appropriately contoured knee pad, and maintaining hamstring and quadriceps flexibility are usually sufficient to control symptoms which may take up to 12 months to resolve. Progressive or disabling symptoms may require a course of immobilization for 7 to 10 days.

Sinding–Larsen–Johansson disease is another cause of anterior knee pain in the adolescent and is similar to Osgood–Schlatter disease, except that tenderness is localized to the inferior pole of the patella, or occasionally at the junction of the quadriceps tendon and the patella (Medlar and Lyne 1978). This condition is thought to be the result of persistent traction at the cartilagenous junction of the patella and the patella ligament. Radiographs may show ossification at the junction of the patella and the ligament. The treatment programme outlined for Osgood–Schlatter disease is generally successful in the management of Sinding–Larsen–Johansson disease.

Prepatellar bursitis

Prepatellar bursitis presents as a painful, red, swelling anterior to the kneecap and is seen most often in people who spend a lot of time kneeling, for example roofers or carpet fitters (Raddatz *et al*. 1987). Active knee extension is usually quite painful although passive knee flexion is usually only minimally limited. Infection and gout should be excluded by aspirating any bursal fluid. In most cases rest and avoiding sustained kneeling results in resolution. Septic bursitis is usually due to *S. aureus* and requires antibiotic therapy as well as repeated drainage if fluid reaccumulates (Raddatz *et al*. 1987; Ho *et al*. 1978; Ho and Su 1981; Kerr 1993). Rarely, recurrent episodes of inflammation require surgical excision of the bursa (Kerr 1993).

Infrapatellar bursitis

The deep infrapatellar bursa lies between the upper portion of the tibial tuberosity and patellar ligament and it is separated from the knee joint synovium by a fat pad (Fig. 5). Infrapatellar bursitis presents in a similar fashion to prepatellar bursitis, although the location of swelling and tenderness is in the soft tissues on either side of the patellar ligament just proximal to its insertion on the tibial tubercle. As a result, inflammation in this bursa may be more difficult to detect than in a subcutaneous bursa (Taylor 1989). The risk factors for the development of infrapatellar bursitis are the same as for prepatellar bursitis (Meys *et al*. 1992; Taylor 1989).

Anserine bursitis

The anserine bursa lies under and about the pes anserinus—the insertion of the thigh adductor complex consisting of the sartorius, gracilis, and semitendinosus muscles (Fig. 5). It is located about 5 cm below the medial aspect of the joint space. Rarely, fluid distension of the bursa has been reported. Another bursa, the subtendinea musculi sartorii bursa, lies in this region which is located approximately 0.5 to 1 cm cranial to the anserine bursa. Anserine bursitis is a term loosely applied to pain and associated local tenderness in this region, although 'medial ligament' syndrome and pes anserinus tendinitis may be impossible to separate. Nocturnal pain, often leading to the use of a pillow between the knees, is characteristic. Rarely, a palpable mass may be detected (Zeiss *et al*. 1993; Voorneveld *et al*. 1989). Women seem more likely to develop anserine bursitis, perhaps because of a broader pelvic area and greater angulation of the adductors at the knee joint producing more tension on these attachments (Larsson and Baum 1985). Obesity and osteoarthritis of the knees appear to be additional predisposing factors (Larsson and Baum 1985). Optimal treatment includes the use of local corticosteroid injection mixed with local anaesthetic.

Gastrocnemius–semimembranous bursitis (Baker's cyst)

Any cause of synovitis in the knee can lead to leakage into the popliteal space when a communication exists between the gastrocnemius–semimembranous bursa. A communication between the gastrocnemius–semimembranous bursa and the anterior knee joint occurs in 40 per cent of normal adults and increases in frequency with age (Morris *et al*. 1994). Symptoms consist of fullness and tightness in the popliteal space which increases with walking. A Baker's cyst can be detected clinically by palpation of fullness in the medial third of the popliteal fossa, although there is wide variation in the size of Baker's cysts, ranging from politeal cysts to large calf cysts (Smith *et al*. 1988). Baker's cysts become softer with semiflexion and harder with extension of the knee (Foucher's sign) (Wigley 1982). Knee effusions are generally present although they may be small and are often overlooked. Baker's cysts may dissect into the muscles of the calf, simulating thrombophlebitis (Hench *et al*. 1966). The presence of crescent bruising beneath the medial malleolus, the 'haemorrhagic crescent sign', is felt to be a useful clinical clue to the presence of popliteal cyst rupture or calf haematoma (Kraag *et al*. 1976). Rupture of a Baker's cyst should be confirmed by Doppler ultrasound which can also exclude thrombophlebitis of the popliteal vein (Fam *et al*. 1982). To confirm a ruptured Baker's cyst the ultrasonographer's attention must be directed to the soft tissue plains of the calf where dissecting fluid is generally seen. Rarely, rupture of a Baker's cyst causes associated thrombophlebitis or compressive neuropathy due to extensive venous or neural compression (Nakano 1978).

Treatment of an intact or ruptured Baker's cyst requires treating the cause of the excess or abnormal synovial fluid production in the knee. Optimal management includes aspiration of the knee joint with synovial fluid analysis and culture. Direct posterior aspiration of the Baker's cyst should not be performed due to the close proximity of neurovascular structures. In non-infectious synovitis of the knee, intra-articular instillation of corticosteroid is an effective treatment.

Iliotibial band syndrome (Runner's knee)

The iliotibial band is a fascial band connecting the ilium with the lateral tibia, connecting to the tensor fasciae latae and the gluteus maximus (Fig. 7). Repetitive flexion and extension, particularly with high intensity running, can lead to inflammation of the iliotibial band or at its associated bursa overlying the lateral femoral condyle (Sutker 1981; Martens *et al*. 1989). Excessive foot pronation resulting in tightening of the iliotibial band and increased friction across the femoral epicondyle has also been proposed as a cause of iliotibial band syndrome (Bouche *et al*. 1994). Examination reveals tenderness localized to the lateral femoral condyle approximately 2 cm above the joint line, pain with weight bearing on the knee flexed 30° to 40°, and a positive Ober test (the patient lies on his or her side with the lower leg flexed to eliminate lordosis of the lumbar spine, the knee of the upper leg is flexed to 90°, and the thigh is abducted and extended—a positive test occurs when the hip remains abducted when the examiner's supporting hand is removed). Treatment consists of rest, locally applied heat, and orthotics when excessive foot pronation is present. Occasionally, a local injection of corticosteroid into the painful area is required. Partial resection of the iliotibial band over the lateral femoral condyle is reserved for the most resistant cases (Martens *et al*. 1989).

Pelligrini–Stieda disease

This condition results from calcification of a haematoma at the femoral insertion of the medial collateral ligament following injury. Examination reveals local tenderness and pain with application of valgus stress to the knee. Radiographs show characteristic calcification of the insertion of the medial collateral ligament. The condition is usually self limited. Treatment consists of rest, non-steroidal anti-inflammatory agents, and, occasionally, local corticosteroid injection.

Plica syndrome

Synovial plica are normal folds of the synovium that are remnants of the embryonic development of the synovial sac and are found in approximately 50 per cent of cadaveric knees (Galloway and Jokl 1990). With the advent of arthroscopy and direct visualization of these structures, they have been implicated in previously undiagnosed knee symptoms (Patel 1978). Pathological plica appear to result from two mechanisms:

1. direct trauma with resultant haemorrhage, oedema, and progressive fibrosis;
2. overuse often associated with minor irregularities in knee mechanics causing progressive inflammation with recurrent synovitis, oedema, and fibrosis with resultant thickening of the plica which then irritates surrounding tissue (O'Dwyer and Peace 1988; Tindel and Nisonson 1992).

Patients with symptomatic plica in the knee complain of snapping or popping of the knee at particular degrees of flexion. Medial plica are most often implicated as a cause of knee symptoms, presumably occurring when the plica rubs across the femoral condyle (Galloway and Jokl 1990). Examination often reveals tenderness at the joint line and the palpation of the plica, especially with the knee in 20 of flexion. Most patients respond to a combination of quadriceps strengthening and flexibility exercises and anti-inflammatory medication. Surgical resection is sometimes advocated but remains a controversial therapy (Tindel and Nisonson 1992).

Internal derangements

Internal derangements of the knee refers to disruption of the normal functioning of the ligaments and menisci. Disruption of the ligaments is most often the result of

significant, often athletic, trauma. Acute meniscal injury in young adults is usually the result of a twisting force applied to the weight-bearing knee and results in a longitudinal tear which, if it is large enough, may cause the knee to lock (a 'bucket-handle' tear). Degenerative tears are more frequent in older adults and typically consist of radial tears. Chronic tears of this nature may occur without obvious trauma but are generally accompanied by symptoms of knee locking or giving way. Examination generally reveals pain with forced extension and generally normal or only mildly reduced flexion. McMurray's test (flexing and extending the knee while the tibia is internally and then externally rotated with a positive test indicated by pain and an associated click) may he helpful if positive but is relatively insensitive (Simonsen *et al*. 1984; Gillies and Seligson 1979). In the United States, magnetic resonance imaging (**MRI**) is widely used to diagnose suspected meniscal tears and to help plan the therapeutic approach. Early studies with MRI suggested a relatively high rate of false-positive findings, although currently, with improved technology and experience, this appears to be less of a problem but there still may be substantial variation in accuracy among centres (Watt 1991; Fischer *et al*. 1991; Reicher *et al*. 1986). Symptomatic peripheral tears (i.e. the outer one-third) of the meniscus in the young adult are generally repaired since there is potential for healing. Partial menisectomy is recommended if tears involve the avascular inner two-thirds of the meniscus. Non-operative treatment can be considered in the older patient with a degenerative meniscal tear, although arthroscopic resection may be required for persistent symptoms. Total menisectomy is generally avoided since long-term follow-up studies have demonstrated high rates of osteoarthritis following this procedure (Cooper 1995).

Patellofemoral pain syndrome

Chondromalacia patellae is a term which has been used synonymously with patellofemoral pain. Most authorities now urge that the term be abandoned in this setting given the almost universal presence of asymptomatic cartilage changes on the medial facet of the patella and the observation via arthroscopy that most, if not many, individuals with anterior knee symptoms have normal articular surfaces (Tria *et al*. 1992; Griffiths and Pinder 1981; Kelly and Insall 1992). Chrondromalacia patellae is now recommended to connote gross pathological observation made operatively or at autopsy (Tria *et al*. 1992). Patellofemoral pain is now the recommended term applied to ill-defined, anterior knee pain.

Patellofemoral pain syndrome is most commonly use to describe poorly localized, anterior knee pain, frequently accompanied by the 'grab' sign (patients cover the entire front of the knee with the hand when asked to identify the location of the discomfort). Pain frequently occurs after prolonged sitting with flexed knees, the so-called 'theatre' sign. Physical examination may reveal tenderness of the medial or lateral facets of the patella, pain with compression of the patella on the femoral condyle, or a patellar 'shrug' sign (pain when pressure is applied to the patella while the patient contracts the quadriceps). An abnormally increased Q angle (greater than 15° in males and greater than 20° in females) appears to predispose to patellofemoral pain (Tria *et al*. 1992). The Q angle is easily measured by determining the angle formed between a line drawn from the anterior superior iliac spine to the midpoint of the patella and a line drawn from the tibial tubercle to the same point on the patella (Fig. 8). Patellofemoral pain syndrome is thought to result from either anatomical abnormalities (such as anatomical misalignment of the patella tracking mechanism, quadriceps dysplasia, or patellofemoral ligament imbalance) or from repetitive microtrauma to the patella surface (Tria *et al*. 1992). Standard radiographs are usually not helpful in the evaluation of anterior knee pain—particularly for patellar tracking since most tracking abnormalities occur during dynamic use. Non-operative treatment of idiopathic anterior knee pain is successful in 75 to 90 per cent of patients (Tria *et al*. 1992). Treatment modalities include avoidance of overuse, exercises, orthoses, and anti-inflammatory medications.

Foot pain

Heel pain

The most common causes of heel pain are Achilles tendinitis, retrocalcaneal bursitis, and plantar fasciitis. Achilles tendinitis is generally caused by repetitive trauma and microscopic tears of the tendon at its insertion on the calcaneous (Puddu *et al*. 1976). Occasionally Achilles tendinitis may be seen in patients with seronegative spondylarthropathies without a history of overuse. The usual presentation is a gradual onset of pain with foot push off. Physical examination reveals tenderness and occasionally thickening of the tendon. Rest, anti-inflammatory medication, heel lift gentle stretching exercises, and local heat application are effective treatment measures. The Achilles tendon is vulnerable to rupture in the elderly.

The retrocalcaneal bursa resides between the Achilles tendon and a fat pad posterior to the talus (Fig. 11). Retrocalcaneal bursitis is associated with posterior heel pain which is made worse with passive dorsiflexion of the ankle and may be associated with tender swelling on both sides of the insertion of the tendon (Canoso *et al*. 1984; Frey *et al*. 1992). Causes include repetitive trauma due to athletic activity, rheumatoid arthritis, and all of the seronegative spondylarthropathies (Goldenstein-Schainberg *et al*. 1992; Hernandez *et al*. 1991). Treatment is the same as for Achilles tendinitis, although cautious use of local corticosteroid injection may be necessary in resistant cases.

Plantar fasciitis is attributed to repetitive microtrauma to the attachment of the plantar fascia at the calcaneous producing periostitis and degenerative changes in the origin of the plantar fascia (Karr 1994; Kwong *et al*. 1988). Localized pain with weight bearing on the undersurface of the heel is the typical presentation. Examination shows local tenderness over the anteromedial portion of the plantar surface of the calcaneous, with the symptom worsening on passive dorsiflexion of the toes. Radiographs may show a plantar calcaneal spur. Associated conditions include enthesopathy due to any of the seronegative spondylarthropathies (Gerster 1980). Subcalcaneal or infracalcaneal bursitis may be difficult to distinguish from plantar fasciitis, although passive dorsiflexion of the toes dose not increase symptoms. Treatment consists of a heel pad or cushion, rest, application of local heat, and anti-inflammatory agents. Local injection of corticosteroid at the insertion of the plantar fascia may be useful. The vast majority of patients respond to these conservative measures. Surgical approaches, such as fasciotomy and spur excision, are infrequently required in resistant cases (Karr 1994).

Metatarsalgia

Metatarsalgia is the symptom of pain across the plantar surface of one or more metatarsophalangeal joints and may be due to diverse causes including muscle imbalance, fat pad atrophy, Morton's neuroma, hallux valgus or rigidus, callosities, flat (pes planus) or cavus foot, arthritis of the metatarsophalangeal joints, intermetatarsophalangeal bursitis, tarsal tunnel syndrome, and arterial insufficiency. Symptomatic treatment (for patients with muscle imbalance and fat pad atrophy) includes the use of a metatarsal pad and flexion exercises. Arch supports are recommended for patients with flat or pronated feet.

Hallux valgus and rigidus are common deformities of the great toe which produce pain in the first metatarsophalangeal joint. Hallux valgus may result from excessively narrow foot wear or high heels or from osteoarthritis of the first metatarsophalangeal joint (Caughlin 1984). It is often associated with bursitis over the medial aspect of the metatarsophalangeal joint and, as a result of altered weight-bearing, may result in secondary callosities under the second metatarsophalangeal joint and a hammer toe deformity of the second toe (Schoenhaus and Cohen 1992). Treatment consists of the use of accommodating footwear and a bunion pad. Surgical correction may be required for resistant cases or marked deformities.

Hallux rigidus produces progressive pain and loss of motion in the first metatarsophalangeal joint. The causes are potentially multiple and include osteoarthritis of the first metatarsophalangeal and congenital deformities of the hallux (Mahan 1994). Conservative treatment is designed to reduce the need for first metatarsophalangeal dorsiflexion and consists of wide, stiff soled shoes. Surgical procedures such as the bunionectomy, implant arthroplasties, and first metatarsophalangeal fusion are advocated for severely affected patients (Mahan 1994).

Morton's neuroma is a relatively common cause of foot pain and is caused by neurofibroma or perineural fibrosis of the large superficial branch of the external plantar nerve between the metatarsal heads (Miller 1987). The most common cause is probably repetitive microtrauma of the common digital nerve. Women seem to be affected more often than men, probably because of increased use of tight-fitting footwear. The typical presentation is paraesthesias or dysaesthesias in interdigital web spaces, particularly between the third and fourth interspaces. Pain is increased by weight bearing or with the use of tight-fitting footwear. Examination reveals interspace tenderness with palpation. The diagnosis may be confirmed with an injection of 1 per cent lidocaine into the interspace, which results in almost immediate relief in symptoms. Treatment consists of using low heel and wider width footwear. Local injection of corticosteroids or surgical resection may be required in resistant cases (Miller 1987).

Tarsal tunnel syndrome most often refers to compression of the posterior tibial nerve as it courses around the medial malleolus with the posterior tibial artery and the tibialis posterior, flexor digitorum longus, and flexor hallucis tendons under the flexor retinaculum (Fig. 10). Tarsal tunnel syndrome has diverse potential aetiologies including mechanical factors, such as excessive subtalar joint pronation, tenosynovitis of the tendons accompanying the posterior tibial nerve, synovitis of the ankle joint, and trauma (Grumbine *et al*. 1990; Grabois *et al*. 1981). The typical presentation is with dysaesthesias involving the plantar aspect of the foot that is often more prominent at night. Examination reveals a Tinel's sign with percussion of the flexor retinaculum. Reduced vibratory sensation and decreased two point discrimination may be present on the plantar aspect of the foot and toes. The diagnosis of tarsal tunnel syndrome may be confirmed by nerve conduction studies documenting delay in conduction of the posterior tibial nerve across the ankle (Goodgold *et al*. 1965). MRI may also be useful in the evaluation of the relevant anatomical structures

(Erickson *et al*. 1990). Conservative treatment consists of local corticosteroid injection, use of non-steroidal anti-inflammatory drugs, and orthotic devices. Surgical decompression of the posterior tibial nerve is reserved for resistant cases.

1.2.2.3 The arm and leg in children

Patience H. White

Musculoskeletal problems are frequent in childhood but incidence and prevalence data are incomplete. For example musculoskeletal complaints are the second most common complaint after headaches recorded in a questionnaire survey of school-aged children (Oster and Nielson 1972). In the National Center for Health Statistics questionnaire, the prevalence of arthritis and rheumatic complaints was second only to epilepsy at 2.2/1000 children under the age of 16 years (National Center for Health Statistics 1976). Also, in a Finnish prospective study of the incidence of arthralgias and arthritis documented by paediatric rheumatologists, the overall incidence of musculoskeletal conditions was 109/100 000, with transient synovitis of the hip being the most common at 51.9/100 000 children less than 16 years of age (Kunnamo *et al*. 1986).

In considering a child with a musculoskeletal complaint, the examiner must clarify first if the problem is local or part of a systemic process and, if local, whether it involves the periarticular structures (tendons, ligaments, bursas), intra-articular structures, or is due to referred pain from another source (Table 1). This chapter will focus on the diagnosis of regional problems and touch on only a few of the entities which cause generalized aches and pains that can present as a localized process seen in the paediatric age group. More generalized processes, such as infections of bones and joints, connective tissue diseases (e.g. juvenile arthritis), postinfectious processes (e.g. rheumatic fever), and tumours, are covered in detail in other chapters but must always be considered in the differential diagnosis of regional pain syndromes (Table 2).

Local versus systemic aetiology
Location of pain

Generalized aching conditions

Table 2 Major causes of regional pain syndromes peculiar to children

There are multiple causes of regional musculoskeletal pain which include both serious conditions, such as infections and malignancy, as well as self-limited problems such as bursitis and tendonitis. Thus, in any one area of the body, the differential diagnosis of a pain syndrome can be extensive. To guide the examiner to the most likely possibility, it is important to clarify the following considerations; the age of the child at the onset of the problem, history of trauma, constitutional symptoms, the severity, location and quality of pain, and if there is any family history of similar problems.

The age of the child at the time the painful condition started will help focus on the possible causes. For instance, certain conditions are seen most commonly in particular age groups; for example hip pain presenting in a 5 to 10 year old is likely to be Legg–Calve–Perthes' disease, whereas similar pain in an adolescent is most likely to be due to a slipped capital femoral epiphysis. A common cause of regional musculoskeletal pain is trauma. Other physical signs of injury such as bruising and swelling often direct the assessment towards a search for a fracture, tendon injury, or tear. Constitutional complaints and signs, such as fever, anorexia, malaise, and weight loss, in association with a regional pain syndrome draw attention towards the possibility of infection, malignancy, or other systemic disease. Recurrent, predictable symptoms following a specific activity suggest local ligamentous or bursal inflammation or internal derangement of the joint, and may be seen more often in active children with hypermobile joints. Equally important is the intensity, timing, and location of the pain because this information may help define its cause. Severe, constant pain with constitutional symptoms brings infection and malignancy to the top of the differential diagnostic list. Milder pain or no pain associated with upper or lower extremity disease (e.g. limp) is often seen in chronic arthritis due to juvenile arthritis or aseptic necrosis. Morning pain associated with morning stiffness is highly suggestive of a chronic inflammatory condition such as juvenile arthritis, whereas pain occurring at night without constitutional symptoms may be due to an osteoid osteoma or growing pains. As mentioned earlier, the physician should attempt to discern the anatomical location of the pain syndrome. The examiner often needs to know the local anatomy to determine if the painful process is periarticular, intra-articular, or referred from another area. Periarticular pain is often worse at the end of the day and occasionally keeps the child awake at night. Last, but not least, inquiry into family history should be made. Known inherited diseases in families very often give a clue to the child's current, local musculoskeletal problem, such as sickle-cell disease or haemophilia.

An accurate physical examination to localize the problem is a key to finding the cause of the pain. Examine the areas for local tenderness, swelling, range of motion, and muscle size and symmetry. Also look for growth abnormalities that can occur in chronic conditions. On physical examination, periarticular disorders or referred pain syndromes, in contrast to intra-articular disorders, will often result in localized tenderness and the active range of motion of the joint will be less than the passive range of motion (Klaiman and Gerber 1996).

The arm (Table 3)

Shoulder
Subdeltoid bursitis

Wrist and hand
Trigger thumbs
De Quervain's tenosynovitis
Carpal tunnel syndrome
Diabetic cheiroarthropathy
Reflex sympathetic dystrophy (algodystrophy)

Table 3 Arm regional pain syndromes seen in children

Shoulder complaints can resemble those seen in adults. In particular, subdeltoid bursitis and bicipital tendinitis are also seen in children. Anatomically the subdeltoid bursa lies next to the supraspinatus tendon making it difficult clinically to separate out which structure is inflamed. Both result in pain in the lateral aspect of the shoulder worsened by raising the child's hand above his or her head or resisting adduction of the shoulder. Bicipital tendonitis causes pain in the anterior aspect of the shoulder on resisted forward flexion of the shoulder. Pain can also be brought on by having the child supinate the flexed forearm against the examiner's resisting hand. This manoeuvre is called Yergason's sign.

In the elbow children present with particular problems not seen in adults. A common injury in the preschool-aged child is the nursemaid's elbow, or pulled elbow, a result of a strong pull on the forearm or wrist which tears the annular ligament surrounding the radial neck. The child presents with a painful flexed and pronated elbow and the radiographic examination is normal. 'Little-league' elbow is most commonly seen in baseball pitchers between 9 and 13 years of age and is most likely due to an overuse syndrome. Pain and swelling may be localized to the medial, lateral, or posterior aspect of the elbow region. The most common site is in the medial epicondyle; fragmentation and/or calcification in the soft tissues is sometimes visible on the plain radiograph. Tennis elbow can also occur in middle to late childhood.

Avascular necrosis can occur in childhood in multiple locations. Panner's disease is avascular necrosis of the capitellum of the humerus; it occurs most often in middle or late childhood. The child may complain of pain and have swelling around the elbow with slight loss of motion, but the diagnosis is made by the sclerosis and irregularity of the capitellum on radiography. Comparison views of the opposite elbow are helpful in diagnosing mild instances (Woodward and Bianco 1975). Olecranon bursitis is rarer than prepatellar bursitis of the knee because the olecranon bursas develops between the ages of 7 and 10 years and the prepatella bursa develops at a younger age. Pain and swelling of the olecranon bursa can be secondary to infection or idiopathic inflammation found in students or sports enthusiasts such as gymnasts, weight lifters, or wrestlers (Zimmerman *et al*. 1995).

Regional pain disorders of the wrist and hand are often secondary to fractures in childhood. Fractures of the distal forearm are very common in children and fractures of the carpal bones are rare. The most common carpal fracture is a fracture of the navicular and it is seen in adolescents. The trigger thumb seen in children mimics trigger finger in the adult in its presenting signs and symptoms as do de Quervain's stenosing tenosynovitis and carpal tunnel syndrome. It should be remembered that tendonitis of the wrist in an adolescent may be the first sign of disseminated gonoccocaemia. Diabetic cheiroarthropathy, though rare in diabetic adults, is commonly seen in adolescents with onset of diabetes in early childhood. The adolescent presents with painless thickening and tightening of the soft tissues around the fingers resulting in progressive stiffness and flexion contractures, first of the distal interphalangeal joints and the proximal interphalangeal joints (Sergic *et al*. 1976). Another disorder, reflex sympathetic dystrophy (algodystrophy), can occur in the upper or lower extremity. It is discussed below as it may occur more commonly in the lower extremity in children.

Accessory navicular
Talus dysplasia
Avascular necrosis
Tarsal coalition

Table 4 Leg regional pain syndromes

Generalized leg pains are very frequent in childhood and the most common causes are growing pains, shin splints, and stress fractures. Growing pain occurs in approximately 10 to 20 per cent of school-aged children and young adolescents. It has an aching or sometimes crampy quality and is usually localized to both lower extremities, most often in the thigh, shin, or calf. The pain is never associated with a limp and often occurs in the evening and can interrupt sleep. The child is completely normal by the morning and all laboratory and radiographic investigations are normal. The term 'growing pains' is a misnomer; the aetiology of this disorder is unknown and it occurs after the time of most rapid growth (Peterson 1986).

Shin splints result in pain after activity that is relieved by rest. The pain occurs along the medial or lateral tibial shaft and is thought to be due to microtears of muscle, tendons, and ligaments, muscle inflammation, periostitis, and muscle compartment syndromes. A similar pain syndrome is found with stress fractures. These occur anywhere in the weight-bearing skeleton but are most common in the diaphysial region of the tibia. They present with localized pain that worsens with activity. Plain radiographs will often be negative until new bone formation occurs, which may take at least 2 weeks. A technetium bone scan can be positive much earlier and will differentiate this condition from shin splints which should have negative radiographic studies (Devas 1963).

Unequal leg length can be an important sign of a regional musculoskeletal disorder. Leg length inequality is defined as greater than 2-cm difference between the length of the legs and can result in a limp, scoliosis, and leg or back pain. The leg length discrepancy can be due to overgrowth early in childhood or early epiphyseal closure in adolescence. Some causes are hemihypertrophy, fractures, infections, tumours, intra-articular abnormalities in the hip, knee, or feet (such as juvenile arthritis or avascular necrosis), and neurological disorders such as poliomyelitis (Siffert 1987; Rothenberg 1988). Accurate measurements of the true or apparent discrepancy in the leg length can be difficult and often the best determination is done by plain radiographs of the pelvis centred at the level of the femoral heads when the child is standing.

Regional pain syndromes are much more common in the lower than in the upper extremities. The most common presentation is that of a limp (see Chapter 1.1.2). Abnormalities in the pelvis or back such as discitis or spinal cord lesions can refer pain to the lower extremities. Similarly, hip inflammation may refer pain to the knee. If, on examining the painful area, no focal abnormalities are found, a referral source for the pain should be suspected (Rose and Doughty 1991).

Hip pain

Pain from the hip region is usually localized to the anterior groin, around the greater trochanter, and down the anterolateral thigh to the knee. The differential diagnosis of hip pain includes tumours of the pelvis, spine, or proximal femur, infections of the hip joint, discitis, congenital dislocation, Legg–Calvé–Perthes' disease,

slipped capital femoral epiphysis, and toxic or transient synovitis of the hip.

The most common disorder causing hip pain in children is transient synovitis of the hip. It occurs between the ages of 2 and 12 years, is a self-limited, unilateral condition, and is frequently preceded by a mild upper respiratory infection. Children can have mild hip or knee pain or can present with a painless limp. The hip motion is painful and is limited in internal rotation and abduction. The circumference of the thigh in the affected limb may be decreased. Occasionally a fever is present. The complete blood count and sedimentation rate are usually normal but occasionally the latter can be elevated. A technetium bone scan shows a mild diffuse uptake over the affected hip joint (Wingstrand 1986). The mainstay of treatment is restriction of activities which ranges from axillary crutches to bed rest with traction if the pain is severe. The majority of children with toxic synovitis are better in 2 to 3 weeks. Toxic synovitis is a diagnosis of exclusion and other more serious diagnoses, such as aseptic necrosis, Lyme disease, or poststreptococcal arthritis, must be ruled out.

Legg-Calve-Perthes' disease is avascular necrosis of the femoral head and is seen in children between 3 and 12 years of age with the ratio of boys to girls between 4 and 5:1. The incidence is 1:20 000 and 20 per cent of cases are familial. Both hips are affected in 10 to 18 per cent of children. Almost 90 per cent of children have retarded bone age and hip pain with a loss of hip motion, especially in rotation and abduction. Radiographic findings depend on the stage of the subchondral fracture (Fig. 1). Before the appearance of bony changes on plain radiography, a bone scan will be positive with increased uptake in the femoral head (McCarthy 1988). There is considerable debate, not only about what is the best method of treatment, but also what is the best classification system to identify the stages and severity of the disease. In general, if the child is less than 5 years old at onset and had minimal involvement of the femoral head by any classification system, they are more likely to have a good outcome. Treatment aims at improving the range of motion of the affected hip and containing the hip within the acetabulum by either non-operative or operative means (Wenger *et al*. 1991).

Fig. 1 Legg–Calvé–Perthes' disease—8-year-old child with flattened dense right femoral head characteristic of femoral capital collapse from ischemic necrosis or Legg–Calvé–Perthes' disease.

Slipped capital femoral epiphysis is the gradual or abrupt slippage of the femoral neck anteriorly and superiorly from the femoral head through the growth plate. The most common age of onset is between 8 and 16 years and boys are more likely to develop it than girls in a ratio of 2.2:1. Most cases are unilateral but up to one-third will be bilateral. Approximately 50 to 80 per cent of the affected individuals are obese. Most children have painful weight bearing and have limited range of motion. A pathognomonic sign for this condition is seen when flexing of the involved hip will produce a concomitant external rotation of the hip. Slipped capital femoral epiphysis is associated with endocrine disorders. The diagnosis can be missed unless both anteroposterior and lateral radiographic views are taken as a mild slip can be missed on an anteroposterior view (Busch and Morrisey 1987; Crawford 1988) (Fig. 2). Treatment of a slipped capital femoral epiphysis in the early stages is aimed at preventing further slip and correction of the deformity while minimizing the risk of avascular necrosis and chondrolysis. If the slip of the femoral head is minimal (less than 1 cm in the lateral projection), surgical stabilization is the best treatment. It is more difficult to find agreement in the literature as to the best surgical approach if the slip is chronic and greater than 1 cm.

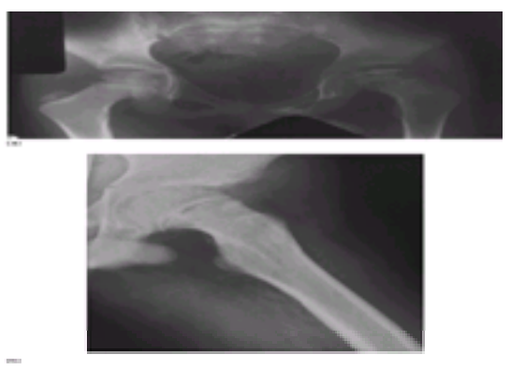

Fig. 2 Slipped capital femoral epiphysis—12-year-old, overweight boy. In the anteroposterior view (a) note the widening of the growth plate and blurring of the metaphyseal side of the growth plate of the left femoral head. The abduction/externally rotated view (b) or frog leg view shows that the femoral capital epiphysis appears to have slipped medially and posteriorly.

Congenital dislocation and subluxation of the hip are quite common with a prevalence of 1.5 per 1000 live births. Girls are affected eight times more commonly than boys and the dislocation is bilateral in 50 per cent. It is important to make the diagnosis early in the new-born period so as to lessen the long-term sequelae, which often result in a total hip replacement. Barlow's manoeuvre of flexion, adduction, and axial pressure in a posterior direction can demonstrate dislocation occurring in the hip. Another physical sign which is significant at any age is shortening of the affected femur. This can be detected when both hips are flexed to 90° with the child lying down on his or her back; the knee on the side of the affected hip is lower than its normal counterpart. If children are not diagnosed until a later age, they present with painful weight bearing and limited range of motion in the affected hip. Radiographic studies may not be diagnostic and the examiner must rely on the physical examination to make the diagnosis (Hensinger 1979).

As in adults, trochanteric bursitis or inflammation of the fascia lata overlying the greater trochanter occurs in children. The pain is localized over the greater trochanter and is worse with walking or lying on the affected side. The pain can be reproduced if pressure is applied to the lateral aspect of the greater trochanter or the fascia lata is put on stretch.

Knee disorders

Patellofemoral disorders of the knee are most commonly seen in adolescence to young adulthood. The disorder is thought to result from malalignment and/or instability of the patellofemoral joint. Symptoms include dull or aching knee pain most commonly with activity such as climbing stairs or squatting and, when the symptoms are severe, there may be intermittent giving way or buckling of the knee due to quadriceps weakness. Locking of the knee is more consistent with an internal derangement or meniscal disorder of the knee. Pain can be precipitated if the patella is compressed or restrained when the quadriceps is contracting. Atrophy of the vastus medialis, patella alta, increased genua valgus, femoral anteversion, and hypermobility are also seen (Lonner and Harwin 1996). Laboratory tests are normal. Radiographs are normal unless there is significant malalignment. Arthroscopic examination of the knee reveals fissuring, fibrillation, and fragmentation of the retropatellar anterior cartilage (Radin 1984; Fulkerson and Shea 1990). Mild patellofemoral pain can be improved by a programme of isometric exercises, designed both to stretch the tight iliotibial band and to strengthen the hamstrings and quadriceps muscle. If exercises fail, surgery must be considered.

A plica is an abnormal synovial band that originates in the suprapatellar area and extends down to the medial side of the knee. It can become trapped between the

tibia and femur resulting in pain, giving way, and locking of the knee. The condition is often diagnosed at arthrography (Reid *et al*. 1980).

The fat-pad syndrome or Hoffa's disease is characterized by intermittent pain and swelling in the anterior knee joint underneath the patellar tendon. Singling–Larsen–Johanssen syndrome occurs in adolescence; it results in pain at the insertion of the patellar tendon where it attaches to the patella and is worsened by activity. Radiographs show calcification at the insertion of the patellar tendon.

Internal derangement of the knee can be secondary to a meniscal tear, torn cruciate ligament, or loose body within the knee joint such as synovial chondromatosis. A child with a meniscal tear presents with a significant past history of trauma. No matter what the aetiology, locking, giving way, pain, and intermittent swelling are found in association with the presence of foreign bodies within the joint space (Renshaw 1986).

Osteochondritis of the knee in children occurs most commonly in the medial femoral condyle. Its prevalence peaks in late childhood and adolescence and it is more common in boys. In about 10 per cent of cases the disease is bilateral. Early in the condition, when the articular cartilage is intact, symptoms consist of vague aching after activity and occasional 'giving-out' of the knee. Localized tenderness of the condyle palpated when the knee is flexed can be the only physical finding. At late stages (Fig. 3), when the fragment can partially separate from the condyle, symptoms such as limping, swelling, and locking occur. Radiographs demonstrate that the subchondral bone of the fragment is separated from the condyle by a thin radiolucent line or the fragment may be displaced (Renshaw 1986). If the articular cartilage is intact, the treatment consists of restricting activity to the child's tolerance level. Healing can take up to several months. If it is possible that the fragment is loose, arthroscopy to remove small pieces or surgery to replace significant bony components should be undertaken. Genu varum (bowed legs) is normal in children under age 2 years. The most common pathological condition that can cause genu varum is Blount's disease. Blount's disease is a disorder of the posterior or the medial tibial physis and those most commonly affected are black males. Radiographs show diminished height of the medial tibial plateau (Fig. 4).

Fig. 3 Osteochondritis dissecans—12-year-old adolescent with a dense ovoid subchondral body on the medial femoral chondyle next to the interchondylar notch.

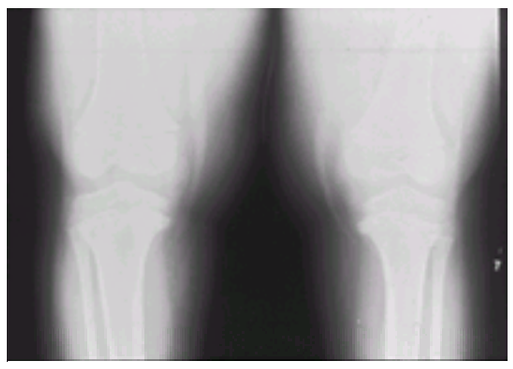

Fig. 4 Blount's disease—4-year-old child with a varus configuration of the right knee. The height of the medial tibial plateau appears to be diminished with sclerosis of the medial tibial metaphysis.

Osgood–Schlatter disease, osteochondritis of the tibial tubercle, is thought to be an overuse syndrome involving the attachment of the patellar tendon to the tibial tubercle and is often caused by recurrent microtrauma. This condition is seen in preadolescence and adolescence and is more common in males. There is pain and swelling around the tibial tubercle which is worsened by strenuous physical activity. Radiographs may be normal in the early stages but can show slight avulsion or fragmentation of the tubercle or both (Renshaw 1986, p. 110). This condition is usually mild and often asymptomatic. If the pain is significant or recurrent, restriction of activity or immobilization of the knee may be necessary.

Another regional condition is a Baker's or popliteal cyst. This is a cystic mass filled with synovial fluid or gelatinous fluid resembling that in ganglion cysts of the wrist. This cystic mass can arise from the joint itself or from the semimembranosus bursas. A cyst in a child is usually a self-limited condition, resolving spontaneously over several months. In contrast to Baker's cysts seen in adults, Baker's cysts in children are not usually associated with intra-articular pathology, and thus investigation of the knee of an asymptomatic child with a Baker's cyst is often unhelpful (Renshaw 1986, p. 111).

There are two benign tumours that must be considered in the differential of regional musculoskeletal pain of the knee; pigmented villonodular synovitis and synovial chrondromatosis. Both occur in teenagers and affect the knee most commonly. Pigmented villonodular synovitis results in a bloody arthrocentesis and has a characteristic histopathology including a cellular infiltrate of the synovium with haemosiderin-laden stromal cells. Synovial chrondromatosis is a condition in which intrasynovial cartilaginous nodules develop and may project into the joint space, resulting in symptoms of pain and locking. Unless the nodules calcify, this diagnosis must be made by arthroscopy.

Prepatellar bursitis is a common problem of the periarticular region of the knee in adults. It can occur in children, but is much less common than in adults. Because of its superficial location, it is often inflamed secondary to a bacterial infection from a nearby cellulitis.

Ankle and foot problems

Foot pain in young children is rare; it becomes more common as the child grows older. Foot discomfort in children can be divided into the following categories; hypermobile flat feet, trauma, infections, apophysitis, neurological disorders, tumours, and boney abnormalities such as avascular necrosis and tarsal or subtalar coalition.

Flat feet are usual in infants and common in children. It can be described as a loss of the longitudinal arch of the weight-bearing foot joint. Pain is unusual and, if it occurs, it is located in the arch, on the medial side of the ankle, or at the insertion of the plantar fascia at the metatarsal heads or calcaneus. If pain is present it is important to distinguish between a flexible planovalgus (flat) foot and a peroneal spastic flat foot. A flexible flat foot is supple with full ankle and subtalar joint motion and the arch is restored when one stands on the toes. In the peroneal spastic flat foot, ankle motion is normal but there is limited inversion and eversion of the foot and/or subtalar joint. Also the arch is not restored when not weight bearing. Peroneal spastic flat foot may be caused by a tarsal coalition or by inflammatory arthritis (Craig and Goldberg 1993). Tarsal coalition is the leading cause of peroneal spastic flat foot. Calcaneonavicular coalition is most common and the next most common is the talocalcaneal coalition which is seen most often between the ages of 12 and 16 years and is best demonstrated by computed tomography (**CT**) scan (Fig. 5).

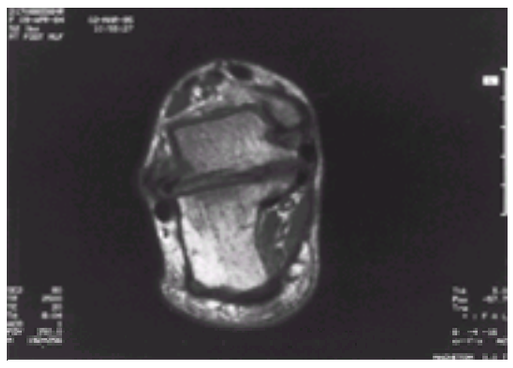

Fig. 5 Subtalar fusion or coalition—a CT scan of the hindfoot of a 12-year-old child demonstrating the lack of definition of the cortex of the subtalar joint on the medial side of the heel.

Flexible flat foot or hypermobile pes planus is a normal part of the development of the foot. At the age of 1 year when the child starts to walk the midfoot is flat to the floor due to normal ligamentous laxity. The foot usually develops the normal longitudinal arch by 5 years. Children with flexible flat feet due to ligamentous laxity form a good arch when standing on tiptoe. No treatment with corrective shoes is thought necessary for the asymptomatic flat foot. Occasionally the hypermobile flat foot may result in pain at the medial side of the arch on weight bearing. Mild genovalgus, slight flexion of the knees and hips, as well as lordosis can occur due to this pes planus and result in lower extremity pain. Often mild symptoms can be improved with a moulded insert.

Another cause of painful flat feet is the hypermobile foot with a short Achille's tendon. The diagnosis is made when dorsiflexion of the ankle with an inverted foot does not reach 90°. Heel-cord stretching exercises are usually helpful. Rarely, an accessory navicular will result in foot pain necessitating its excision. An accessory navicular is found in 50 per cent of all feet; most are asymptomatic.

The most common non-neuromuscular cause of the rigid flat foot in the 8- to 16-year-old age group is tarsal coalition which occurs when two or more of the tarsal bones are joined, either by a bony bar or a fibrocartilaginous bridge. Clinically the adolescent has a rigid flat foot associated occasionally with peroneal spasm. The coalitions are diagnosed by radiography but special views are often needed to demonstrate the coalition, for example an oblique view of the hindfoot is necessary to demonstrate a calcaneonavicular bar.

In adolescents a common cause of foot pain is stress fractures of the second and third metatarsal shafts. Like other stress fractures, they may be difficult to see early in the radiographs. They can either be documented by a technetium bone scan or callus formation on a plain radiograph can be awaited. This takes approximately 3 weeks to form.

There are three tendon–bone junctions in the foot that present problems in preadolescents. Calcaneal apophysitis (Sever's disease) occurs in both girls and boys between the ages of 8 and 10 years, usually in those who are just beginning to play competitive sports. The pain localizes to the insertion of the Achille's tendon where it inserts on to the calcaneus, and adolescents with this condition often have difficulty walking on their heels. Radiographs are normal, often showing a dense fragmented calcaneal apophysis, which is a normal finding at this age. A second condition seen in children aged 10 to 12 years is swelling and pain at the insertion of the peroneus brevis into the apophysis of the base of the fifth metatarsal. There can be a secondary ossification centre in the apophysis and this can cause pain, particularly if narrow shoes are worn. Finally, an accessory navicular bone can result in foot pain. In 75 per cent of cases an accessory navicular will fuse with the main navicular bone. Pain can occur over the accessory navicular and is usually relieved with rest (Wilkings 1988).

Reflex sympathetic dystrophy can occur in the hand but is much more common in the foot. This condition is often initiated by trauma and presents with a diffusely swollen, painful foot. The pain is worse at night and is not relieved by rest. Often the symptoms appear out of proportion to the physical findings. As the condition progresses, the foot can become hypersensitive and demonstrate vascular changes such as being cool, sweaty, and swollen; finally, muscle wasting and contractures can develop if no treatment with physiotherapy is begun. Radiographs can show osteopenia and diffuse increased uptake is found in a technetium bone scan (Forster 1985).

Two painful conditions of the foot are due to avascular necrosis; Kohler's disease and Freiberg's infraction. Kohler's disease occurs in girls and boys between the ages of 4 and 6 years. Pain with exercise slowly develops over the tarsal navicula and radiographs demonstrate a 'pancake' condition of the navicula. Freiberg's infarction is aseptic necrosis of the metatarsal head and most commonly affects the head of the second metatarsal. Very active adolescent girls are most affected and pain is localized to the metatarsal head involved.

There are many tendinous attachments and bursas around the foot and inflammation, such as plantar fasciitis, 'pump bumps' underneath the bursa near the insertion of the Achille's tendon on the calcaneus, and Achille's tendinitis due to type IIa or IV hyperproteinaemia, are often seen in many of these structures. Similarly, bunions or hallux valgus are most common in adolescence but occur in all age groups. Many of these conditions are described elsewhere as they are more common in adults (Wilkings 1988).

Generalized conditions that can present as regional musculoskeletal pain syndromesTable 5)

Hypermobility
Hypomobility
Genetic disorders
Fibromyalgia
Hyperostosis

Table 5 Generalized conditions often presenting as regional pain in children

There are several systemic conditions that can present to the rheumatologist with regional musculoskeletal complaints. It is only after a careful, general examination that the systemic condition may be revealed. One example is hypermobility which occurs in 12 to 19.5 per cent of the population. Joint laxity predisposes periarticular structures to injury resulting in musculoskeletal pain around one or several joints. This painful syndrome is more common in girls with a family history of hypermobility (Biro *et al.* 1983). Pain due to joint laxity is also a feature of other inherited disorders of joint laxity, such as Marfan's syndrome, Ehlers–Danlos syndrome, and Larsen's syndrome.

Disorders that result in acquired hypomobility result in joint contractures and little signs of inflammation are found. The mucopolysaccharidoses and mucolipidoses can present with limited motion of the fingers and, occasionally, other joints. Fabry's disease requires the attention of a rheumatologist because patients with this disease develop degenerative changes and flexion contractures of the fingers. Severe, burning pain in the fingers and toes occurs in 80 per cent of children or young adults with Fabry's disease (Sheth and Bernhard 1979). Gaucher's disease also has hip and knee pain as a component of the syndrome. The Stickler syndrome is the most common connective disease dysplasia in the American midwest. Ankle, knee, and wrists become enlarged in childhood and cause intermittent arthralgias (Liberfarb *et al*. 1981). The epiphyseal dysplasia syndromes can result in pain around or in a joint and a plain radiograph assists in the diagnosis. Another genetic

syndrome that often presents with regional musculoskeletal pain is sickle-cell disease. Synovial, capsular, and tendon infarction can occur in sickle-cell disease resulting in joint pain (Diggs 1967).

Fibromyalgia occurs in the paediatric age group. This condition usually presents as diffuse musculoskeletal aching in a 9 to 15 year old complaining of fatigue. There is a preponderance of girls. The diagnosis is one of exclusion and is based on the demonstration of tender points often found in periarticular locations associated with bursas, epicondyles, and insertion of tendons. Occasionally the child complains of pain in only one or two of these periarticular areas and the cause of the regional pain syndrome is revealed only after looking for multiple tender points (Yanus and Masi 1985; Sherry *et al*. 1991). Myopathies can also present as leg aching or tenderness and should be considered in the differential diagnosis of regional pain syndromes.

Conditions associated with hyperostosis often result in regional pain syndromes. Primary hypertrophic osteoarthropathy is an autosomal dominant disorder seen in adolescent boys with 'spade-like' enlargement of the hands and feet and pain in the distal long bones (Calabro *et al*. 1966). Secondary hypertrophic osteoarthropathy is associated most commonly with malignancy but can occur in pulmonary disease (cystic fibrosis, infections, fibrosis), cardiovascular disease (subacute bacterial endocarditis, cyanotic congenital heart disease), gastrointestinal disease (inflammatory bowel disease, bacterial or parasitic colitis, subphrenic abscess, cirrhosis), and endocrine (thyroid) conditions. Most children present with clubbing of the fingers, periostitis and pain in the long bones, and arthritis of the large joints (Petty *et al*. 1976). Infantile cortical hyperostosis of Caffey's disease is an uncommon disease with hyperostosis in which a child has a symmetrical painful enlargement of the mandible or shoulder girdles or long bones. It is self-limiting and usually occurs before 6 months of age (Prieur 1990).

In conclusion, focal pain syndromes in children and adolescents are common and the physician must decide if the problem is due to a local condition or one that is part of a systemic illness.

1.2.3 Extra-articular features of rheumatic diseases

Ian D. Griffiths

Introduction

The so-called rheumatic or musculoskeletal disorders encompass a wide variety of disorders, of which many are multisystemic. In some of these disorders the articular features are frequently mild and often inconsequential, for example in primary Sjögren's syndrome or the antiphospholipid syndrome.

This chapter does not attempt to catalogue all the extra-articular features encountered in the rheumatic diseases but addresses the problem of underlying rheumatic diseases that may present in a non-rheumatological fashion. In practice this may occur before the rheumatic features have manifested themselves, when the non-articular features clinically dwarf the rheumatic symptoms, or when the underlying rheumatic disease produces only mild symptoms or subtle clinical joint manifestations.

The most critical factor in establishing the diagnosis at presentation is the competence of the attending doctor in obtaining a history and performing an examination which will elicit features of the underlying musculoskeletal disorder (Doherty *et al*. 1990). Failure to identify a musculoskeletal disorder, or to recognize its relevance in the context of the overall clinical picture, is more than an 'academic' nicety. Most clinicians have experience of patients who have been invasively (and expensively) investigated for symptoms, signs, or laboratory abnormalities which could have been readily accounted for if the underlying diagnosis had been recognized. More alarming are the patients who have been inappropriately treated (e.g. lymph node biopsies which have been misclassified and subsequently treated as lymphoma by the pathologist who was not made aware of the coexisting diagnosis of rheumatoid arthritis).

The development of medical specialization means that undifferentiated diseases may be directed to a wide variety of disciplines depending upon the predominant symptoms at the time. There remains a tendency in standard medical textbooks to under recognize the frequency with which non-specific systemic features, such as fever or weight loss, may be the presenting feature of a rheumatic disorder.

This chapter considers 'extra-articular' presentation of musculoskeletal disorders under three broad headings: general systemic features, specific systems, and clinical patterns.

General systemic features

These are very common in inflammatory joint and connective tissue disorders (Table 1). It is often the combination of features which suggests an underlying cause, for example swinging fever and rash in adult onset Still's disease. Similarly, in the non-inflammatory disorders, the coexistence of problems may point towards a diagnosis, for example lethargy and poor sleep patterns in fibromyalgia. This section considers some of the more common systemic problems.

Table 1 Generalized systemic features which may be the presenting complaint of an underlying rheumatological disorder

Weight loss

Musculoskeletal disorders are hampered by the lack of objective, numerical clinical measurements for management. Weight is a simple measure and a history of weight loss at the onset or during the early stages of several diseases is not uncommon (Fig. 1).

Fig. 1 Profound weight loss in a man with inflammatory polyarthritis, subcutaneous nodules, and low grade persistent pyrexia. The final diagnosis, on histology, was multicentric reticulohistiocytosis.

There is no agreed definition of significant weight loss. In practice, working definitions have included weight loss of 2 kg or more, or a decrease of 10 per cent in body weight. It is rare to have weight loss greater than 10 kg due to arthritis. The weight loss tends to plateau after a few months, unlike that associated with malignancy or endocrine disease. Calculation of Body Mass Index (weight (kg)/ height (m) ^{2}) may offer some standardization but is not routinely undertaken.

In clinical practice, weight loss is most commonly encountered as an early feature of rheumatoid arthritis. It occurs particularly in elderly onset rheumatoid arthritis, being present in 50 per cent of subjects in one series (Terkeltaub *et al*. 1983). Often the articular features are mild and atypical. The weight loss is often associated with other systemic features, such as lymphadenopathy and low grade pyrexia, so suggesting a wide range of diagnostic possibilities, particularly lymphoma. There is the suggestion that reduction of Lean Body Mass in rheumatoid arthritis may be related to tumour necrosis factor-a levels (Roubenoff *et al*. 1992).

However, as may be expected, weight loss is not confined to rheumatoid arthritis and can occur in association with any inflammatory joint or connective tissue disorder. It is particularly in the elderly (if associated with rather non-specific symptoms such as in polymyalgia rheumatica, polyarteritis nodosa, or a related inflammatory vasculitis) that the major diagnostic dilemmas emerge, especially in relationship to underlying neoplasms. The evaluation depends upon detailed clinical, radiological, and laboratory assessment, which should include routine urine testing, full blood count, erythrocyte sedimentation rate (or other measure of acute phase response), biochemical profile (including thyroid function and protein electrophoresis), autoantibodies (including antineutrophil antiplasmic antibodies), and a chest radiograph. Neoplasms which in their turn may mimic musculoskeletal disorders include carcinoma of the bronchus, renal carcinoma, lymphomas, and primary and secondary neoplasms of bone.

Other disorders of the gastrointestinal tract that may present with musculoskeletal features and weight loss include inflammatory bowel disease, Whipple's disease, and adult coeliac disease. It is often the presence of an unusual feature, for example the failure of an iron deficiency anaemia to respond to oral iron, that suggests the diagnosis.

True weight loss in children due to juvenile chronic arthritis or related disorders is extremely uncommon, but a downward shift to lower percentile lines on both weight and height growth curves is frequent in active disease.

Fever

Pyrexia is a common feature of many rheumatic disorders that have an inflammatory component (Fig. 2 and Fig. 3), including septic arthritis, crystal induced arthritis, chronic inflammatory joint disease, and connective tissue disorders (Pinals 1994). In most of these cases the associated rheumatic disorder will be apparent; the major exception is septic arthritis in a young child, where the presentation may be as non-specific as the 'irritable, febrile child'.

Fig. 2 Man who presented with fever, marked raised erythrocyte sedimentation rate (greater than 100) and right upper arm pain due to a septic arthritis of the right shoulder tracking down the long head of the biceps to present as swelling in the right upper arm.

Fig. 3 A 60-year-old woman who presented with left hip pain, weight loss, and low grade pyrexia. Radiographs show erosion in the left greater trochanter and calcified pyometrium. Aspiration and culture of the left greater trochanter bursa revealed *Mycobacterium tuberculosis*.

Fever as an early or presenting feature of a rheumatic disease is more difficult to evaluate. Fever patterns can be considered as:

1. intermittent, when the temperature is swinging but returns to normal between episodes;
2. remittent, when the temperature varies but does not return to normal;
3. sustained, when no variation is occurring.

If no cause for the fever is found after 1 week of investigation, it is usually labelled as fever of unknown origin. A review of patients presenting with persistent fever of unknown origin in the 1980s showed that rheumatological disorders in the wide sense equalled infections as the most common underlying cause, accounting for a third of the cases where a cause was found (Knockaert *et al*. 1992). The most frequent rheumatological disorder was temporal arteritis. A similar finding emerged

when patients with intermittent fever of unknown origin were studied but in that group an underlying disorder was found less frequently (Knockaert *et al*. 1993).

If sepsis has been excluded with reasonable confidence, the intermittent fever pattern with a diurnal variation, with temperatures of 39°C or above occurring in the later afternoon to evening and returning to normal by morning (quotidian), is very suggestive of systemic onset juvenile chronic arthritis in the child or adult Still's disease. The finding of the typical evanescent macular rash at the height of the fever would further support the diagnosis. The fever may precede the arthritis in both juvenile and adult forms of the disease, sometimes by many months, causing diagnostic problems (Martin *et al*. 1994). Approximately 10 per cent of fevers of unknown origin in children are eventually found to be associated with juvenile chronic arthritis.

In adults, there is often a considerable delay before the diagnosis of adult onset Still's is established (Pouchot *et al*. 1991; Wouter and Van de Putte 1986). Several reasons exist for this; the patient often presents as a fever of unknown origin to the general medical department, other 'non-articular' features may dominate the clinical picture, for example deranged liver function tests, or pleuropericardial disease. While no diagnostic tests exist, the absence of a marked leucocytosis, normal acute phase reactants, and the absence of marked elevation of the serum ferritin (>1000 mg/l) all weigh heavily against the diagnosis.

Continuous or remittent fever is an integral feature of some forms of chronic infectious disorders associated with arthritis, for example brucellosis and Lyme disease (O'Connell 1995), and certain forms of vasculitis, for example Kawasaki's syndrome. The more complex situation arises in the patient with a low grade pyrexia, often with a raised erythrocyte sedimentation rate, and in whom infection and neoplasia has been excluded. Rheumatological disorders that can be easily overlooked include Reiter's syndrome, particularly in the younger adult as there tends to be a lack of recognition of the sometimes severe systemic nature of Reiter's. Also, Reiter's syndrome increasingly presents as an 'incomplete' form in which the precipitating event may be overlooked, particularly if it was a transient gastrointestinal disturbance. The clinical finding of an enthesitis, sacroiliitis, or asymptomatic oral ulcers would support the diagnosis.

In the middle-aged to elderly population temporal arteritis, primary Sjögren's syndrome and polymyalgia rheumatica, may present as low grade pyrexia with elevated erythrocyte sedimentation rate, with little evidence of the underlying disorder. Specific enquiry about dry eyes and mouth coupled with a simple bedside screening test (e.g. Schirmer's test) may help and the striking diurnal symptoms of polymyalgia may suggest the diagnosis.

Malaise, lethargy, and fatigue

These symptoms give rise to difficulties in medical definition but are frequent clinical complaints. While these are common and well recognized accompaniments of chronic inflammatory joint and connective tissue disorders, they may be the presenting or sole clinical feature of some disorders which fall within the rheumatological spectrum. Arbitrarily they have been divided on the basis of a normal erythrocyte sedimentation rate and raised erythrocyte sedimentation rate.

Normal erythrocyte sedimentation rate

Fibromyalgia is probably the most common associated problem. The subject is typically a middle-aged woman with a non-restorative sleep pattern and diffuse pains in a girdle distribution with multiple symmetrical tender points. Clinically, overlap seems to exist with other syndromes, where profound tiredness and lethargy may exist in the absence of clear physical or laboratory abnormalities, for example post viral fatigue syndromes, myalgic encephalomyelitis and chronic fatigue syndromes (Goldenberg 1993). Metabolic and endocrine disorders such as periodic hypokalaemic paralysis, Addison's disease, and hypothyroidism need be excluded.

Raised erythrocyte sedimentation rate

Primary Sjögren's syndrome frequently presents under this guise, and lethargy is well recognized as one of the most distressing features of primary Sjögren's. There are no specific features in the history to point to the diagnosis and the patient just complains of intense fatigue. Sleep disturbance may be found but trigger points are not present; otherwise the sex and age distribution is very similar to fibromyalgia. As well as the raised erythrocyte sedimentation rate, polyclonal hypergammaglobulinaemia and serological abnormalities such as positive rheumatoid factor, antinuclear factor, and anti-Ro/La antibodies are often present.

Although less common disorders, profound lethargy with a raised erythrocyte sedimentation rate may be the presenting features of bacterial endocarditis, polyarteritis (and the other vasculitides), cryoglobulinaemia, Waldenström's macroglobulinaemia, polymyalgia, and a wide variety of malignancies of which lymphoma, bronchogenic neoplasm, and renal cell carcinoma are probably the most commonly encountered as presenting under a rheumatological guise.

Lymphadenopathy

This alarming clinical feature may occur as a presenting one in both children and adults.

In children, generalized lymphadenopathy is usual in systemic juvenile chronic arthritis and Kawasaki's disease (Bissenden and Hall 1990). It has to be remembered, however, that leukaemia in children may also present as polyarthralgia or a true polyarthritis.

In the adult, lymphadenopathy is common in rheumatoid arthritis and the connective tissue disorder, and may occur early in the disease. One study reviewing patients who had undergone lymph node biopsies for unexplained lymphadenopathy and in which the histology had shown reactive hyperplasia, found that one-third of them developed a connective tissue disorder within a year of biopsy. A more common clinical problem arises when marked lymphadenopathy develops in a patient with connective tissue disease or rheumatoid arthritis. If, on clinical grounds, it is felt desirable to have a lymph node biopsy to exclude neoplastic disease, then it is important that the histopathologist is informed about the associated connective tissue disorder, as the histological differential diagnosis of marked reactive hyperplasia and giant follicular cell lymphoma may be difficult without immunohistological analysis (Kelly *et al*. 1987).

Persistent lymphadenopathy above the clavicles usually causes greatest clinical concern. A review of 13 patients with a variety of rheumatological disorders, who had lymph node biopsies of either supraclavicular or cervical lymph nodes because of persisting lymphadenopathy, failed to detect changes other than 'reactive' hyperplasia in any of the biopsies (Kelly *et al*. 1987).

Specific systems

This section considers some individual systems and their disorders that may be the presenting feature of an underlying rheumatological disorder. It cannot be completely comprehensive as anecdotal reports exist about virtually all known medical disorders being associated with some rheumatological conditions (e.g. systemic lupus erythematosus). It attempts to identify those non-articular 'rheumatological' disorders which are commonly seen either prior to or in a very early stage of the rheumatic disease process (Table 2).

Table 2 Specific system involvement that may be the presenting feature of an underlying rheumatological disorder

Mucocutaneous systems

Ocular system

In practice, the commonest disorder is acute anterior uveitis occurring in association with spondylarthropathies or reactive arthritis. Other eye problems which should prompt a clinical/serological evaluation for a rheumatological disorder include chronic anterior uveitis (pauciarticular juvenile chronic arthritis), uveitis (Behçet's syndrome), episcleritis (relapsing polychondritis), keratoconjunctivitis (primary Sjögren's syndrome), visual loss (temporal arteritis), and cortical blindness (systemic lupus erythematosus).

Oropharyngeal system

Presenting disorders include xerostomia (primary Sjögren's syndrome), painful oral ulceration (Behçet's syndrome and systemic lupus erythematosus), painless oral ulceration (reactive arthritis), and apparent 'toothache' (temporomandibular joint involvement). Occasionally, apparently unrelated events may suggest a rheumatological disorder (e.g. severe dental caries and primary Sjögren's syndrome).

Cutaneous system

The vast range of cutaneous features associated with rheumatological disorders is dealt with elsewhere. Table 2 lists some cutaneous disorders that may be the presenting feature of rheumatological disorders. In clinical practice Raynaud's, psoriasis, various rashes, and vasculitis are the most commonly encountered.

Cardiovascular system

Table 2 lists cardiovascular problems which may be the presenting features. Again, in clinical practice, the most commonly seen are pericarditis (with rheumatoid arthritis, systemic lupus erythematosus, and systemic juvenile chronic arthritis) (Kelly *et al*. 1990), valvular heart disease (with systemic lupus erythematosus and spondylarthropathies), peripheral ischaemia (with polyarthritis and other forms of medium/large vasculitis), congenital complete heart block (with maternal anti-Ro-positive systemic lupus erythematosus /Sjögren's syndrome) (McCredie *et al*. 1990).

Cardiomyopathies (e.g. with amyloid, polymyositis, and scleroderma) tend to occur later in the natural history of the underlying disease.

Respiratory system

Lung and respiratory tract involvement is common to many rheumatological disorders. Breathlessness is a common presenting feature of many rheumatological disorders. In clinical practice the most frequently encountered are pleural disease (rheumatoid arthritis and systemic lupus erythematosus), pulmonary fibrosis (rheumatoid arthritis and connective tissue disorders), asthma (Churg-Strauss vasculitis), pulmonary opacities on routine chest radiography (rheumatoid arthritis, Wegener's granulomatosis), and bronchial 'irritability' (Sjögren's syndrome). Sinus disorders with Wegener's granulomatosis are common.

Gastrointestinal system

Although the associations of rheumatic diseases and gastrointestinal disorders, particularly infectious and chronic inflammatory diseases, is well established, it is more common to see these problems causing diagnostic confusion because of their rheumatological presentation—for example Crohn's disease, where the gastrointestinal features may be less apparent in the early stages.

Areas of overlap encountered in clinical practice tend to relate to abdominal pain arising from spinal disease, mesenteric vasculitis, or polyserositis (e.g. familial Mediterranean fever), abnormal biochemical tests (particularly liver function tests) detected on 'routine' tests and secondary to an underlying chronic inflammatory rheumatological disease, and apparent bowel disturbance in the irritable bowel/fibromyalgia overlapping group of patients (Wolfe 1989).

Dysphagia in systemic sclerosis is very rarely a presenting complaint.

Urogenital and renal systems

Renal system

Kidney involvement is frequently the presenting feature of the connective tissue disorders (e.g. systemic lupus erythematosus, polyarteritis). Renal tubular acidosis (detected either clinically as secondary osteomalacia or biochemically) may be the presenting feature of primary Sjögren's syndrome (Maher 1989). Renal calculi may develop prior to clinical gout. Acute hypertensive renal failure can be the presenting feature of systemic sclerosis.

Male urogenital tract

Urethritis is the rule with both gonococcal and non-gonococcal sexually acquired arthritis. It may also occur in reactive arthritis secondary to gastrointestinal infections. Balanitis occurs and may reoccur in Reiter's syndrome without fresh exposure to infectious agents (Fisk 1982).

Impotence is a rare presenting feature of large vessel vasculitis (mimicking the Le Riche syndrome) and is not uncommon in systemic sclerosis. Peyronies' disease associates with other disorders of collagen deposition (e.g. Dupuytren's contracture, knuckle pads, and systemic sclerosis).

Female urogenital tract

Probably the most common presenting disorders are dyspareunia (with primary Sjögren's syndrome), recurrent spontaneous abortion (with the antiphospholipid syndrome) (Hughes 1983; Hughes *et al*. 1989), vaginal ulceration (Behçet's), and vaginal prolapse (hypermobility syndrome and its variants) (Al Rawi and Al Rawi 1982).

Neurological system

Disorders affecting this system are frequently the presenting complaint in rheumatological disease.

The wide diversity of neurological features occurring in systemic lupus erythematosus is well recognized. Entrapment neuropathies, most commonly carpal tunnel, is a frequent presenting complaint in inflammatory joint disease (e.g. rheumatoid arthritis). Mononeuritis is common in polyarteritis. Headaches are a feature of temporal arteritis and cervical spondylosis. Migraine occurs more commonly in systemic lupus erythematosus and Sjögren's syndrome (Pal *et al*. 1989). Spastic quadriplegia may be the presenting feature of cervical spondylosis and ossification of the posterior longitudinal ligament (Griffiths and Fitzjohn 1987).

Clinical patterns

The enormously varied nature of clinical medicine means that every physician will have anecdotes about bizarre presentations of relatively common disorders (e.g. the patient who complained 'she waddled when she ran' due to a proximal myopathy, due to osteomalacia, due to renal tubular acidosis, due to primary Sjögren's syndrome; or the patient with gout who snored, both of which resolved when his hypothyroidism was treated). While diagnosis in these patients may provide an intellectual challenge, the successes tend to be matched by the failure to recognize, for example, the patient with polymyalgia who had a hypernephroma.

Certain patterns of disease occur sufficiently frequently, however, that the systemic confirmation or exclusion of an underlying 'rheumatological' disorder is essential.

The commonest problems encountered in the United Kingdom are described below.

Children

The ill, febrile child with a rash suggests the need to exclude systemic juvenile chronic arthritis. Recognition of significant articular pathology is not easy in a small, unhappy, and irritable child.

Young women

Multisystem disease in young women should always raise the possibility of systemic lupus erythematosus. It is in this group that serological tests are most likely to be helpful.

Young men

Reactive arthritis, either sexually or gastrointestinally acquired, frequently causes a systemic illness of greater severity than is usually recognized by the medical profession. In an ill, febrile young man with weight loss and a subacute history, a careful search for clues (e.g. mild back pain and stiffness, a single swollen metatarsal phalangeal joint or toe, or tenderness under the calcanum may provide clinical pointers).

Middle-aged women

Three main diagnostic groups may present in a 'non-rheumatological guise'.

Rheumatoid arthritis not infrequently may present in a non-articular fashion. Pulmonary or pleuropericardial involvement tends to be the most frequent manifestation.

Two disorders may present as malaise or lethargy often associated with other non-specific symptoms. The symptom complex of 'fibromyalgia' is suggested by the finding of multiple tender points and normal screening laboratory investigations. Primary Sjögren's syndrome often also presents in this non-specific fashion. Specific questions about ocular and oral dryness suggest the diagnosis and laboratory investigations (particularly erythrocyte sedimentation rate and serology) are often surprisingly abnormal against a relatively normal physical examination.

Middle-aged men

Rheumatoid arthritis presenting either pleuropericardial disease or pulmonary involvement is the commonest clinical situation. Polyarteritis nodosum may also cause diagnostic confusion in this group with its variety of clinical features ranging from malaise through to mononeuritis multiplex.

Elderly women

Two disorders commonly cause diagnostic confusion—polymyalgia rheumatica and temporal arteritis, as both the non-musculoskeletal features (malaise, weight loss, fever of unknown origin) are often attributed to other conditions and the more specific features (e.g. proximal myalgias and headaches) may be misinterpreted unless a low diagnostic threshold for this treatable disorder is maintained.

Tophaceous gout in the elderly female taking diuretics is increasingly common. The lesions on the distal interphalangeal joints are often diagnosed as Heberden's nodes and ulcerating lesions adjacent to the first metatarsal phalangeal joint attributed to either vascular insufficiency or trophic changes.

Elderly men

Extra-articular presentation of rheumatic disorders is less common in this age group. More commonly one encounters the reverse situation of non-rheumatological disorders (particularly neoplastic) presenting under a rheumatological guise of either joint or bone pain of a paraneoplastic syndrome.

Conclusions

The recognition of an underlying rheumatological diagnosis as the cause of non-articular disease is not merely an academic exercise. To overlook certain diagnoses (e.g. systemic lupus erythematosus or temporal arteritis) may have severe consequences in terms of morbidity and mortality. Furthermore, to pursue increasingly invasive investigations in a patient with fibromyalgia exposes them to all the risks of iatrogenesis.

Ultimately, the establishment of the underlying cause usually depends upon clinical acumen, often helped by maintaining an 'open mind' when diagnostic uncertainty exists, and the passage of time.

1.3.1.1 Pregnancy

W. Watson Buchanan and Walter F. Kean

Three events made 1948 the *annus mirabilis* of rheumatology. First, the description of agglutination of sensitized sheep erythrocytes by sera of patients with rheumatoid arthritis (Rose *et al*. 1948) (although this phenomenon had previously been described by Waaler 1940). Second, there was the discovery by Hargraves *et al*. (1948) at the Mayo Clinic of the 'LE' cell. Third, at the same institution, Hench and his co-workers (Hench *et al*. 1949a; Hench *et al*. 1949b) described the effects of the adrenal cortical hormone, 17-hydroxy-11-dehydrocorticosterone (compound E), and pituitary adrenocorticotrophic hormone in rheumatoid arthritis and rheumatic fever. The discovery of cortisone by Hench, which was to earn him a Nobel Prize in Medicine in 1950, had been prompted by his earlier observation of the ameliorative effects of pregnancy in rheumatoid arthritis, which he reasoned was due to a substance released from the adrenal glands (Hench 1938).

This chapter deals with the effect of pregnancy in rheumatic disease, and the effects of rheumatic disease on pregnancy and the fetus.

Rheumatoid arthritis

There have been several reviews on the effects of pregnancy on rheumatoid arthritis (Klipple and Cecere 1989; Kean and Buchanan 1990; Bellamy *et al*. 1991; Spector and Da Silva 1992). Despite the fact that many studies include only a relatively small number of patients and provide only global assessments of improvement, there seems to be overwhelming evidence that pregnancy has a beneficial effect on rheumatoid arthritis. Overall it has been estimated that 75 per cent of patients improve during pregnancy, especially during the last trimester. Improvement frequently begins in the first trimester, and, with few exceptions, is maintained throughout pregnancy. Improvement may be dramatic with complete remission of symptoms, and in some patients even a reduction in the number and size of subcutaneous nodules, so allowing complete discontinuation of all antirheumatic medication. Fluctuation in disease activity is, however, common, even in patients whose arthritis improves or goes into remission. Improvement in one pregnancy usually predicts the same in future pregnancies; likewise, failure to improve or deterioration postpartum is equally predictive. Currently there is no method of predicting the clinical outcome of rheumatoid arthritis during pregnancy, although a role for fetal paternally-inherited class II HLA antigens in amelioration of symptoms has been suggested (Nelson *et al*. 1992a; Nelson *et al*. 1992b; Nelson *et al*. 1993). When symptoms do not improve, progressive erosive changes may be evident on joint radiographs.

Arthritic symptoms usually recur within 1 to 2 months of delivery. Although the degree of joint inflammation may become more severe postpartum, disease activity usually returns to that prior to conception. Lactation has no effect on either timing or severity of postpartum relapse.

Patients with rheumatoid arthritis develop no more side-effects of pregnancy, such as pre-eclampsia, than do healthy subjects. Problems with delivery, likewise, are no greater, although hip involvement may make vaginal delivery more difficult and painful. Rheumatoid arthritis is, therefore, generally not considered a reason for therapeutic abortion (Felbo and Snorrason 1961). Some studies, but not all, have suggested that spontaneous abortion may be more common in patients with rheumatoid arthritis. Still birth rates may also be slightly increased (Spector and Silman 1990). Rheumatoid arthritis otherwise appears to carry no risk for the fetus, and does not affect lactation or resumption of menses. No difference has been observed in pregnancy before the onset of rheumatoid arthritis (Nelson *et al*. 1992).

The reason why so many patients with rheumatoid arthritis improve during pregnancy remains elusive. (Rook *et al*. 1991; Da Silva and Spector 1992). Klipple and Cecere (1989) have summarized the circulating factors with anti-inflammatory and immunoregulatory activity (Table 1), and the potential factors which might operate in lessening of disease activity during pregnancy (Table 2). Although both the total and free plasma cortisol concentrations rise during pregnancy, this is not of sufficient degree to explain remission in rheumatoid arthritis (Persellin 1981). Thus, one of the great quantum leaps in rheumatology was based on a false hypothesis! The placenta may play a significant role as an immune-modifying organ (Klipple and Cecere 1989), but none of the many immunological changes (Pope 1990; Klipple and Cecere 1989), including pregnancy-associated a-glycoprotein (Ostensen *et al*. 1983; Unger 1983), provide an adequate explanation. Sany *et al*. (1986) have reported improvement in patients with rheumatoid arthritis treated with IgG eluted from placental tissue. This was an open study, and will require confirmation by a double-blind, placebo-controlled trial.

Fetal factors
α-Fetoprotein
Other factors in maternal sera
Trophoblast hormones
Oestrogens
Progesterone
Human chorionic gonadotrophin
Human placental lactogen
Maternal factors
Corticosteroids
Blocking antibodies including antitrophoblastic antibodies
Trophoblastic-decidual placental proteins
Pregnancy-associated plasma protein A
Pregnancy-associated α2 globulin
Placental protein 14
Pregnancy-specific β$_1$-glycoprotein
Other pregnancy serum proteins

Reproduced by kind permission of Klipple and Cecere (1989).

Table 1 Circulating factors with immunoregulatory or anti-inflammatory activity in pregnancy sera

Humoral factors
Immunomodulation by circulating trophoblast-antitrophoblast immune complexes
Removal of circulating aggregated immunoglobulins by the placental 'sponge'
Alteration in the carbohydrate side-chain composition of immunoglobulins leading to decreased 'stickiness'
Decreased IgG levels (mild)
Fetal suppression of the maternal immune system
Soluble factors including α-fetoprotein
Fetal suppressor cells in maternal circulation
Depression of cell-mediated immunity
Depression of delayed hypersensitivity by skin testing
Delayed rejection of skin allografts
Increased virulence of recurrence of intracellular pathogens
Decreased lymphocyte counts
Decreased helper T cells with decreased helper/suppressor ratio
Depressed in vitro lymphocyte responses
Decreased natural killer activity
Circulating suppressors of cell-mediated immunity including blocking antibodies
Suppression of inflammatory reactions
Impaired chemotaxis, adherence, phagocytosis, normal breast tissue reduction
Decreased cathepsin B activity
Suppressive serum factor(s)

Table 2 Potential factors in the amelioration of rheumatoid arthritis during pregnancy

Pregnancy has been shown to have the same beneficial effects on experimental arthritis as in humans (Hirahara *et al*. 1986). In mice with collagen-induced arthritis, improvement did not correlate with serum anticollagen antibodies (Williams and Whyte 1989), but a delay in antibody production was observed when the mice were immunized during pregnancy (Whyte *et al*. 1988). Oestrogens when administered to non-pregnant animals so as to maintain pregnancy serum concentrations of oestrogen have been shown to suppress experimental arthritis (Mattson *et al*. 1991). However, progesterone alone had no such effect, but enhanced the effect of oestrogen (Jansson and Holmdahl 1989). Bromocriptine has been shown to suppress postpartum exacerbation of collagen-induced arthritis, probably due to suppression of prolactin release that normally occurs postpartum (Whyte and Williams 1988). Female sex hormones, especially oestradiol, affect the immune status (Ahmed and Talal 1990; Lahita 1990), and the dramatic hormonal changes which occur during pregnancy might be expected to account for improvement in rheumatoid arthritis. It is therefore disappointing that controlled clinical trials of ethinyloestradiol in non-pregnant female patients with rheumatoid arthritis have shown no benefit (Bijlsma *et al*. 1987; Bijlsma and Van den Brink 1992; Da Silva and Hall 1992). Whether oral contraceptives have a protective effect on the development and course of rheumatoid arthritis remains controversial (Hazes *et al*. 1990). Likewise, whether women who develop rheumatoid arthritis are subfertile before the onset of their disease (Yoshino and Uchida 1981; Spector and Silman 1990) or whether multiparity is associated with an increased risk of developing rheumatoid arthritis (Klipple and Cecere 1989) also remain controversial. Although the onset of rheumatoid arthritis is lower than expected during pregnancy while increased after delivery (Silman *et al*. 1992; Lansink *et al*. 1993), female sex hormones probably do not predispose females to development of rheumatoid arthritis (Pritchard 1992). No evidence has been found in twin studies of a strong interaction between genetic and environmental factors (Brennan and Silman 1994). James (1993) has suggested a low androgen level may predispose to the development of rheumatoid arthritis, and it is of interest that males with rheumatoid arthritis tend to have a reduction in testosterone and dihydroepiandrosterone (Catula *et al*. 1984).

Rheumatoid arthritis frequently adversely affects female sexuality with a loss of libido and reduction in frequency of sexual intercourse (Yoshino and Uchida 1981). Nothing has been reported to the authors' knowledge on sexual disturbances in the male patient with rheumatoid arthritis.

Systemic lupus erythematosus

There are a number of difficulties in interpreting the literature on the effects of pregnancy on systemic lupus erythematosus. There is an absence of a generally agreed definition of disease activity, and difficulty in differentiating between systemic lupus erythematosus and pregnancy complications, such as pre-eclampsia. Most studies do not include control data, and differences in hospital referral patterns lead to differences in severity of disease between different groups. In addition, the racial make-up between studies differs: for instance the study reported by Wong *et al*. (1991) from Hong Kong consisted entirely of Chinese patients, whereas in the study of Pistiner *et al*. (1991) from California, 75 per cent of the patients were white, 11 per cent black, 8 per cent Hispanic, and only 6 per cent Asian. Flares in disease activity during pregnancy may be the result of discontinuing drug therapy, as in the study reported by Lockshin *et al*. (1984), in which two patients had exacerbation of cutaneous lupus following withdrawal of hydroxychloroquine therapy. Despite all of these problems, it is possible to conclude from the large number of studies that exacerbation of systemic lupus erythematosus is more likely in pregnancy when the disease is inactive at conception (Lockshin *et al*. 1984; Hayslett 1991; Petri *et al*. 1991; Hayslett 1992; Urowitz *et al*. 1993). Previous pregnancy outcome (Ramsay-Goldman *et al*. 1992; Ramsay-Goldman *et al*. 1993b), low socio-economic status (McAlindon *et al*. 1993), and pre-existing renal disease (Nicklin 1991; Rubbert *et al*. 1992) are also important determinants. Transient impairment in renal function is usually the result of superimposed pre-eclampsia in patients whose systemic lupus erythematosus is otherwise quiescent (Burkett 1989). Pregnancy does not appear to worsen the long-term prognosis of systemic lupus erythematosus (Burkett 1989), and flares in disease activity do not necessarily influence the outcome of pregnancy (Petri *et al*. 1991).

Fertility does not appear to be impaired in women with systemic lupus erythematosus (Tozman *et al*. 1980). However, fertility is probably reduced when the disease activity is severe (Cecere and Persillin 1981; Pistiner *et al*. 1991) since amenorrhoea is common (Martinez-Cordero *et al*. 1982), and sexual intercourse less frequent, if at all (Bellamy *et al*. 1991). The role of drug therapy, such as corticosteroids, on fertility is unknown.

A major pregnancy-associated complication for the mother is pre-eclampsia. This may be difficult to distinguish from an exacerbation of systemic lupus erythematosus (Bellamy *et al*. 1991). The presence of haematuria and red cell casts suggests lupus nephritis, whereas a rapid increase in proteinuria is more suggestive of pre-eclampsia (Bellamy *et al*. 1991). Both the classical and alternate complement pathways are activated during flares in activity of systemic lupus erythematosus during pregnancy (Buyon *et al*. 1992; Hopkinson and Powell 1992). Activation of both pathways with depression of C3 and C4 levels also occurs in pre-eclampsia, but the total CH5O remains normal and may help in the differential diagnosis (Abramson and Buyon 1992). Delivery by caesarean section is common in patients with systemic lupus erythematosus as a result of concern for both mother and child (Urowitz and Gladman 1982). Avascular necrosis of the hips may give rise to mechanical difficulties during vaginal delivery. A case of breast vasculitis and gigantism controlled with high doses of corticosteroids has been described (Propper *et al*. 1991).

Fetal mortality is increased in women with systemic lupus erythematosus (Bellamy *et al*. 1991; Ferro *et al*. 1992; Kutteh *et al*. 1993; Petri 1994). Although earlier literature suggested that early abortions were more common in patients with this disease, recent reports have indicated a rate not significantly different from the expected rate of spontaneous abortion in the normal population (Cecere and Persellin 1981; Mintz and Rodriguez-Alvarez 1989). In contrast, fetal death is markedly increased in the later stages of pregnancy with a still birth rate of approximately 10 per cent (Cecere and Persellin 1981; Mintz and Rodriguez-Alvarez 1989), and especially in those patients with hypocomplementaemia (Shibata *et al*. 1992). Although Jara-Quezada *et al*. (1991) have suggested that this increased late fetal loss might be due to gonadal hormone and prolactin increase, it is much more likely to be the result of antiphospholipid antibodies (Lockshin *et al*. 1987; Harris 1990; Birdsall *et al*. 1992; Ferro *et al*. 1992; Ginsberg *et al*. 1992; Kerslake *et al*. 1992; Out *et al*. 1992; Vianna *et al*. 1992). Delivery of a term infant in a patient with systemic lupus erythematosus and antiphospholipid antibodies is extremely uncommon (Khamashta and Wallington 1991). Lockshin *et al*. (1987) has suggested that antiphospholipid antibodies are the most sensitive marker of pregnancy loss, with a sensitivity of 0.85, and specificity of 0.92. Antiphospholipid antibodies are either IgG, IgA, or IgM, or all three, with a wide spectrum of antibody specificities (Triplett 1989; Chamley *et al*. 1991; Reyes *et al*. 1994). No single test is sufficient because of this heterogeneity and a panel of screening procedures, inhibitor identification, and confirmatory procedures has recently been recommended (Barna and Triplett 1991). IgA antiphospholipid antibodies (Lopez *et al*. 1992) and the lupus anticoagulant (Julkunen *et al*. 1993) appear most likely to result in fetal death. However, although the finding of antiphospholipid antibodies is a major risk factor in pregnancy, several normal pregnancies have been reported (McHugh and Laurent 1989; McHugh *et al*. 1989). Antiphospholipid antibodies have a low incidence in certain races, especially Malays, Chinese, and Indians (Jones *et al*. 1991). They have also been reported to have an increased prevalence among first-degree relatives of patients (Molta *et al*. 1993). Tests for antiphospholipid antibodies need only be performed if the patient has systemic lupus erythematosus or other suggestive clinical features (Harris and Spinato 1991; Out *et al*. 1991a). Fetal death is essentially the result of thromboses causing placental infarction (Out *et al*. 1991b). Chamley *et al*. (1993) have demonstrated that thrombosis may be due to inhibition of heparin-dependent antithrombin III activation by anticardiolipin antibodies. Antiphospholipid antibodies have also been shown to trigger thromboxane production, which can be eliminated by small doses of aspirin (Kaaja *et al*. 1993a). Inflammatory vascular changes also occur in the vascular bed and may lead to thrombosis, which explains the beneficial effects of corticosteroids (Erlendsson *et al*. 1993). Antiphospholipid antibodies do not interfere with the natural inhibitors of blood coagulation and fibrinolysis (Kordich *et al*. 1992). Acute audiovestibular failure has been attributed to antiphospholipid antibodies (Vyse *et al*. 1994). Regular assessment of intrauterine growth to predict fetuses at risk is recommended, and in the later stages of pregnancy this can be supplemented with Doppler flow studies of uteroplacental and umbilical artery circulation (Trudinger *et al*. 1988; Benifla *et al*. 1992; Guzman *et al*. 1992; Walkinshaw *et al*. 1994).

There is still no agreement regarding the medication that patients with antiphospholipid antibodies should be prescribed, and whether this should be given only when there is an indication of danger to the fetus (Derksen 1991; Buchanan *et al*. 1992; Many *et al*. 1992; Tambyraja 1993). High doses of prednisone have been recommended but their beneficial effects have been questioned (Lockshin *et al*. 1989). Low-dose aspirin, used to inhibit thromboxane A_2 synthesis and thrombosis (Branch *et al*. 1985; Kaaja *et al*. 1993a), is currently undergoing clinical trial (Barton and Sibai 1991). Subcutaneous heparin does not cross the placenta and may prove useful in preventing abortion, although maternal bone loss may prove a problem. Other therapies include cytotoxic drugs, dipyridamole, and warfarin, plasma exchange, and high-dose immunoglobulins (Khamashta and Wallington 1991; Ramsay-Goldman *et al*. 1993a). Human IgG has been shown to neutralize lupus anticoagulant activity in vitro, (Said *et al*. 1992), and an intravenous dose of 1 g/kg body weight has been suggested as a prophylactic measure (Kaaja *et al*. 1993b). Immunoadsorbent plasmapheresis has been reported to decrease significantly antiphospholipid antibody titres, but only in a single patient (Kobayashi *et al*. 1992). Further research on antiphospholipid antibodies may lead to more targeted approaches to treatment (Gonzalez-Buritica *et al*. 1988). Antiphospholipid antibodies are not only found in systemic lupus erythematosus but also in several connective tissue diseases, where they are associated with high fetal loss (Buchanan *et al*. 1989; Imai *et al*. 1991). Patients who are discovered to have antiphosopholipid antibodies but have no symptoms should be followed carefully as many will later develop systemic lupus erythematosus (Bagger *et al*. 1993).

The neonatal lupus syndrome is discussed in Chapter 5.7.2 and further discussion of antiphospholipid antibodies in Chapter 5.7.3.

Systemic sclerosis

There is no reliable prospective statistical information on the outcome of pregnancy in progressive systemic sclerosis for either mother or fetus (Black 1990). However, case–control studies have been recently published. An increased rate of infertility in patients destined to develop systemic sclerosis was observed (Silman and Black 1988; Englert *et al*. 1992; Silman 1992). Patients with the disease had three times the rate of fertility problems compared with controls. The study by Giordano *et al*. (1985) showed no evidence of infertility in patients with progressive systemic sclerosis. Steen *et al*. (1989) did not address this problem. Prematurity and low birth weights have been reported (Steen *et al*. 1989; Silman 1992), and a possible increased rate of spontaneous abortions (Silman and Black 1988; Steen *et al*. 1989; Silman 1992).

Scleroderma involving the uterine cervix and perineal skin may cause difficulty in delivery, but is rare (Bellamy *et al*. 1991). Renal crisis is the most serious complication to develop during pregnancy, and appears to occur especially in patients with rapidly progressive diffuse skin involvement (Steen *et al*. 1989). At present there are no absolute prognosticators regarding the outcome of either mother or fetus (Avrech *et al*. 1992; Englert *et al*. 1992). However, patients should be tested for antiphospholipid, anti-Ro (anti-SSA), and anti-La (anti-SSB) antibodies.

Juvenile chronic (rheumatoid) arthritis

Ostensen (Ostensen 1991; Ostensen 1992) has recently reviewed the outcome of juvenile rheumatoid arthritis during pregnancy. Some 60 per cent of patients experienced improvement or total remission of their arthritis, especially during the second half of gestation. No improvement in uveitis was noted. Functional impairment was the main limiting factor in having children, and delivery by caesarean section is frequently required. Postpartum flare occurred in approximately 50 per cent of patients. Attempts to control such flares with infusions of autologous plasma have been unsuccessful (Wallace *et al*. 1987). Adult-onset Still's disease has been reported both during and after pregnancies (Stein *et al*. 1980; de Miguel *et al*. 1992; Le Loet *et al*. 1993). Vasculitis resulting in coronary thrombosis has also been described postpartum (Parry *et al*. 1992). Ostensen (1992) noted that fetal outcome was not affected.

Ankylosing spondylitis

Ankylosing spondylitis in women is milder and often atypical when compared with men (Marks *et al*. 1983). There is no evidence that patients with the disease are less fertile or have an increased frequency of spontaneous abortion, premature labour, or still birth (Husby *et al*. 1988). Ostensen (1992) reported that 80 per cent of disease activity remained unaltered or was aggravated during pregnancy. Gran and Husby (1992) considered ibuprofen to be the preferred drug for control of pain during pregnancy. Postpartum flares unrelated to lactation or return of the menses have been observed (Ostensen 1992). Whether pregnancy causes worsening of the radiological changes, as has been reported, awaits further study. Amyloid-related serum protein concentration has been found to be a useful indicator to monitor disease activity during pregnancy (Ostensen *et al*. 1985). No laboratory test has been found useful in predicting gestational activity of disease (Ostensen 1984). There is a risk that children born to an HLA B27-positive mother with ankylosing spondylitis will develop the disease in later life: this has been estimated at 10 per cent if the child is HLA-B27 positive and virtually zero if the child is HLA-B27 negative (Van der Linden and Khan 1984).

Psoriatic arthritis

There have been few reports of the effects of pregnancy on psoriatic arthritis. In general, less amelioration of arthritis symptoms has been reported in patients with psoriatic arthritis compared with rheumatoid arthritis (Ostensen 1988). However, McNeill (1988) has reported multiple pregnancy-induced remissions in a patient with psoriatic arthritis, and a recent study by Ostensen (1992) suggests that improvement or remission may occur in as many as 80 per cent of patients. No change has been reported in the skin lesions during pregnancy. McHugh and Laurent (1989) noted that 18 per cent of 33 patients had the onset of their arthritis within three months postpartum. The recent studies of Ostensen (1992) put the figure of postpartum flares as high as 70 per cent. No such relation was noted with psoriasis. Further studies with larger numbers of patients require to be performed to confirm the assertion of McHugh and Laurent (1989) that pregnancy may be a risk factor for psoriatic arthritis. Fetal outcome does not appear to be affected (Ostensen 1992).

Gonococcal arthritis

Pregnancy predisposes to disseminated gonococcal infection, especially during the third trimester (Taylor *et al*. 1966; Einstein and Masi 1981). Destructive arthropathy may result if antibiotic therapy is not promptly instituted (Einstein and Masi 1981). No unfavourable effects on either mother or child will occur with proper care.

Gout

Hyperuricaemia and gouty arthritis are rare in premenopausal women. Serum urate concentrations fall to exceeding low levels early in pregnancy, and the finding of hypouricaemia in a young woman should alert the physician to the possibility of pregnancy (Boyle *et al*. 1966). The serum urate concentration gradually rises to within the normal range towards the third trimester. Hyperuricaemia occurs with pre-eclampsia. Lee and Loeffler (1962) reported five spontaneous abortions in 22 pregnancies in patients with gout, and Talbott (1957) suggested that gouty patients might be subfertile. Colchicine is absolutely contraindicated in pregnancy (Levy *et al*. 1991).

Relapsing polychondritis, Wegener's granulomatosis, Sjögren's syndrome, dermatomyositis, and polyarteritis nodosa

Bellamy and Dewar (1990) have reported a favourable maternal and fetal outcome in a patient with relapsing polychondritis: this appears to be the only reference to pregnancy in this condition in the literature.

Patients with Wegener's granulomatosis have been described who had healthy full-term babies (Biesenbach *et al*. 1991) despite treatment with cyclophosphamide (Fields *et al*. 1991).

Sjögren's syndrome predominantly affects middle-aged and elderly women but also occasionally women in the child-bearing years and even children. Patients with primary Sjögren's syndrome have normal pregnancies and healthy babies (Takaya *et al*. 1991; Manthorpe and Manthorpe 1992). However, patients with anti-Ro (anti-SSA) and anti-La (anti-SSB) have the risk of having infants with congenital heart block (Imai *et al*. 1991).

Favourable maternal and fetal outcomes have been reported in dermatomyositis (Ishii *et al*. 1991; Ohno *et al*. 1992), but no series of patients has been published to our knowledge.

An infant born of a mother with polyarteritis nodosa has been described with cutaneous lesions of the disease (Stone *et al*. 1993).

The successful outcome of a pregnancy has been reported in a mother with multicentric reticulohistiocytosis (Conaghan *et al*. 1993).

Miscellaneous musculoskeletal complaints

During the later stages of pregnancy there is an increase in lumbar lordosis, angulation of the lumbosacral junction, and obliquity of the pelvic bones, due to softening of ligaments as a result of hormonal changes. In addition, sliding movement occurs in the sacroiliac joints and radiographs frequently demonstrate gas present as a result of movement. Likewise, hypermobility of the symphysis pubis results in the development of osteitis pubis. It is therefore not surprising that almost 50 per cent of women complain of lumbar backache during the later stages of their pregnancy (Mantle *et al*. 1977). The pain radiates into the buttocks and occasionally down the legs, and may be sufficiently severe to interfere with sleep. The pain is increased during labour, but usually disappears soon after delivery. Patients who experience low-back pain during pregnancy are said to suffer later from lumbar disc disease, but this has not been the subject of a properly controlled study. Acute lumbar disc prolapse has been reported during pregnancy, but whether the incidence of this complication is any higher than in non-pregnant age-matched females has not been studied.

Patients with hypermobility of the sacroiliac joints may go on to develop osteitis condensans ilii, which is usually asymptomatic or associated with only mild symptoms. Patients who develop osteitis condensans ilii are HLA-B27 negative, and the radiological changes usually disappear with time. Wilbur *et al*. (1988) have reported the

use of magnetic resonance imaging to diagnose sacroiliac joint infection during pregnancy. Pain and tenderness over the symphysis pubis may cause difficulty in walking.

Another rarer complication which may give rise to hip pain and difficulty with walking is transient osteoporosis (Longstreth *et al*. 1973). This is usually unilateral and full recovery occurs 3 months to 1 year after delivery. The cause of this complication is unknown (Resnick 1988). Ischaemic necrosis of bone, especially affecting the femoral heads, has been reported in a few patients during pregnancy (Resnick 1988). Generalized osteopenia associated with pregnancy and lactation has been reported (Nordin and Roper 1955). Another extremely rare complication of pregnancy is osteitis condensans of the medial end of the clavicle. Bone sclerosis is apparent on radiography, and the lesion is 'hot' on an isotope bone scan (Resnick 1988). The lesion is quite distinct from sternoclavicular hyperostosis associated with pustulosis palmaris et plantaris.

Carpal tunnel syndrome occurs in approximately one-third of patients during pregnancy, especially in the third trimester. Patients who develop pre-eclampsia are particularly likely to develop this complication. Compression of both median and ulnar nerves is common, with classical median nerve compression alone less common, and ulnar nerve compression alone relatively rare (McLennan *et al*. 1987). Carpal tunnel symptoms spontaneously resolve after delivery, and surgical treatment is only rarely required (Melvin *et al*. 1969).

We dedicate this chapter to the late Nobelist Dr Philip S. Hench (1896–1965) whose discovery of cortisone did so much to promote the development of the medical subspeciality of rheumatology.

1.3.1.2 Antirheumatic drugs in pregnancy and lactation

W. Watson Buchanan and Walter F. Kean

The placenta was considered until the middle of this century as a protective barrier for the fetus against harmful environmental toxins. It became only too evident that this was not the case with the reports that maternal rubella infection (Gregg 1941) and thalidomide (McBride 1961) could seriously damage the developing fetus. Unfortunately the results of all experimental findings in animals cannot be extrapolated to humans (thalidomide had produced problems in animals). The fetus is at greatest risk during the first 3 months of gestation, and most drugs have the ability to cross the placenta into the fetal blood stream. There is also concern regarding the delayed effects of drugs following intrauterine exposure: the classic example being the increased risk of adenocarcinoma of the vagina in female fetuses exposed to diethylstilboestrol (Herbst 1981). Thus both short-term and long-term effects of maternal use of drugs is a matter of considerable concern. Unfortunately clinical data are woefully lacking with most drugs. Pregnancy has effects on the pharmacokinetics of antirheumatic drugs (Witter 1993), but, on the whole, these are not of clinical significance. Several excellent reviews of antirheumatic and antigout drugs in pregnancy are available (Berkowitz *et al*. 1986; Brooks and Needs 1989; Brooks and Needs 1990; Kean and Buchanan 1990; Bellamy *et al*. 1991; Buchanan *et al*. 1992; Briggs *et al*. 1994) and we acknowledge and refer to the works of these authors throughout this text.

Pharmacokinetics

The disposition of antirheumatic drugs can be influenced by the physiological changes of pregnancy. Gastric pH, alterations in mucus production, and delay in gastric emptying will affect absorption rates. The concomitant use of antacids and so-called gastric protective agents have the potential to influence the absorption of non-steroidal anti-inflammatory drugs (**NSAIDs**) and other analgesics (Kean and Buchanan 1987). Supplementary mineral compounds and iron preparations may influence the absorption of a NSAID (Day *et al*. 1984) or D-penicillamine (Osman *et al*. 1983). However, the evidence in the literature does not suggest that these influences on absorption are clinically significant (Harkness and Blake 1982; Kean and Buchanan 1987). The increased blood volume of pregnancy results in an apparent increase in the volume of distribution. There is a resultant lower serum albumin level which theoretically produces an increased free fraction of active drug. However, since both type I and type II hepatic biotransformation pathways and renal excretory pathways are intact, these physiological changes are unlikely to have a significant clinical influence on the pregnant patient (Buchanan and Kean 1987). Increased protein binding of salicylates has been recorded in neonatal plasma (84.4 per cent) compared with maternal plasma (77.9 per cent) (Levy 1975). Increase in hepatic biotransformation will influence drugs which are essentially metabolized by the liver. Serum cholinesterase activity is reduced during pregnancy, and this could influence the metabolism of aspirin and methylprednisolone. Drugs such as indomethacin, piroxicam, sulindac, and sulphasalazine, which undergo significant enterohepatic circulation, could have altered kinetic activity related to the relative cholestasis of pregnancy. Renal blood flow and creatinine clearance increase during early pregnancy, therefore drugs such as azapropazone which are primarily excreted by the kidneys could be cleared more rapidly in pregnant patients. However, although this is a theoretical issue, there is no evidence that this occurs in practice. (Krauer and Krauer 1983)

The pharmacokinetic changes in absorption, distribution, metabolism, and excretion by the mother have the potential to influence drug transfer to the fetus. The integrity of the maternal circulation and the rate of transfer across the placenta have the potential to influence the fetus. Levy (1975) has stated that the pharmacodynamics and pharmacokinetics, especially drug elimination by the fetus, have to be considered as important issues when investigating the effects of drugs on the pregnant patient and the fetus.

Analgesics

Notwithstanding the extensive media warnings with respect to the potential side-effects of drugs on the fetus, simple analgesics are frequently prescribed or purchased over the counter during pregnancy. (Barrow and Souder 1971; Levy *et al*. 1975a; Heinonen *et al*. 1977; Golden and Perman 1980; Mangurten and Benawra 1980; Golden *et al*. 1982; Aselton *et al*. 1985) Codeine and acetaminophen do not cross the placenta; it has not been confirmed if they cause fetal malformation (Tyson 1974; Mangurten and Benawra 1980; Golden *et al*. 1982).

Acetaminophen appears safe in short-term use, but long-term high doses have been reported as a possible cause of fatal kidney disease in the newborn (Char *et al*. 1975). The drug is probably not teratogenic, but a possible association with congenital dislocation of the hip and club foot has been described (Heinonen *et al*. 1977). Although acetaminophen has been used extensively by pregnant mothers, there is no evidence that this compound or its metabolites cause congenital abnormalities or fetal morbidity (Collins 1981; Golden *et al*. 1982; Lee 1985). Acetaminophen, unlike aspirin and NSAIDs poses no problem with increase in haemorrhage.

Dextropropoxyphene may cause congenital abnormalities. Dextropropoxyphene and codeine have been implicated in the cause of a neonatal drug withdrawal syndrome (Tyson 1974).

Aspirin

Chronic aspirin use during pregnancy increases the risk of anaemia, intra- and post-partum haemorrhage, and prolongs gestation and labour (Slone *et al*. 1976; Collins 1981; Lee 1985; Benigni *et al*. 1989). Anaemia during pregnancy is significantly increased in mothers receiving aspirin compared with controls (Bleyer and Breckenridge 1970). Low-dose aspirin has been employed to prevent pregnancy-induced hypertension and pre-eclampsia (Romero *et al*. 1988; Schiff *et al*. 1989) although recent studies have failed to prove its efficacy (Italian Study of Aspirin in Pregnancy 1993 ; Sibai *et al*. 1993; CLASP [Collaborative Low-dose Aspirin Study in Pregnancy] Group 1994). No toxic effects in the fetus have been observed with this therapy (Benigni *et al*. 1989; Sibai *et al*. 1989), or with the occasional use of aspirin (Collins 1981 ; Barton and Sibai 1991), although more studies are required to be absolutely certain on this point (Romero *et al*. 1988). Low-dose aspirin is also currently used to prevent fetal loss due to antiphospholipid antibodies in patients with systemic lupus erythematosus (Branch *et al*. 1985; Elder *et al*. 1988), perhaps by preventing antiphospholipid antibodies triggering the production of thromboxane over prostacyclin (Kaaja *et al*. 1993).

There is concern that high doses of aspirin may lead to intrauterine growth retardation, congenital salicylate intoxication, depressed albumin-binding capacity (but no increase in jaundice), an increase in still birth associated with antepartum haemorrhage, and an increase in perinatal mortality (Earle 1961; Arcilla *et al*. 1969; Turner and Collins 1975; Lynd *et al*. 1976; Shapiro *et al*. 1976; Aterman *et al*. 1980). Newborn infants have been described with diminished clotting ability, haemorrhages and a purpuric rash, and increased bleeding at circumcision (Haslam 1975; Rumack *et al*. 1981; Soller and Stander 1981; Stuart *et al*. 1982; Stuart 1983). Maternal aspirin ingestion 1 week prior to delivery has been associated with an increased incidence of intracranial haemorrhage in premature infants (Rumack *et al*. 1981). Aspirin readily crosses the placenta and at term has a higher concentration in the neonate than in the mother (Levy *et al*. 1975b). Non-acetylated salicylates are equally as effective as aspirin in rheumatoid arthritis (Preston *et al*. 1989) and are not associated with bleeding, and should be used routinely to control pain and inflammation in inflammatory joint disease (Bleyer 1974).

Laboratory animal research, with acetylsalicylic acid concentrations in excess of therapeutic doses used in humans, has resulted in fetal abnormalities, including learning difficulties, in the offspring (Butcher *et al*. 1972).

Whether aspirin causes congenital defects in humans remains controversial (Briggs *et al*. 1994). The fact that the Collaborative Perinatal Project which monitored 50 282 mother–child pairs, 14 864 who used aspirin during the first trimester, found no evidence of an increase in congenital defects (Slone *et al*. 1976) does not exclude the possibility that high doses may be teratogenic. Streissguth *et al*. (1987) reported lower intelligence quotients in children born of mothers who had been prescribed aspirin during their pregnancies, but this has not been confirmed by other workers (Klebanoff and Berendes 1988).

Failure of intrauterine devices to prevent conception has been attributed to the anti-inflammatory action of aspirin (Buhler and Papiernik 1983).

Indomethacin and sulindac

No ill effects on the fetus have been reported with the use of sulindac (Carlan *et al*. 1992).

Indomethacin rapidly crosses the placental barrier with resultant similar metabolite concentrations in the plasma of the mother and child. Serious fetal effects have been recorded with the use of indomethacin in the treatment of premature labour, especially primary pulmonary hypertension (Demandt *et al*. 1990; Besinger *et al*. 1991), patent ductus arteriosus constriction and tricuspid regurgitation (Moise *et al*. 1988; Eronen *et al*. 1991; Evans *et al*. 1992), and intracranial haemorrhage and necrotizing enterocolitis (Norton *et al*. 1993). Zuckerman *et al*. (1974) reported on 5 of 12 infants, whose mother had received indomethacin for premature labour, who died within 48 h of birth from respiratory distress. Wiquest *et al*. (1975) did not identify an increase in fetal mortality when indomethacin was used to treat premature labour. It has been suggested that the respiratory failure in the newborn might be a reflection of the prematurity and not necessarily the indomethacin-induced pulmonary hypertension from duct closure. Nevertheless, histological studies have identified increased amounts of smooth muscle in the pulmonary arterial wall of some of the children with pulmonary hypertension whose mothers received indomethacin (Manchester *et al*. 1976). Treatment of polyhydramnios has been reported to cause premature ductal closure (Kirshon *et al*. 1990a; Kirshon *et al*. 1990b; Buderus *et al*. 1993), and also renal failure (Moise 1991). A variety of serious complications has been recorded in fetuses of mothers treated with high doses of indomethacin, including hydrops, oliguric renal failure, gastrointestinal and intraventricular bleeding, and perforation of the terminal ilium (van Haesebrouck *et al*. 1988). However, other workers have reported no congenital fetal abnormalities in mothers who have been treated with indomethacin (Niebyl and Witter 1986), and patent ductus arteriosus has been described in infants born of mothers treated with indomethacin (Atad *et al*. 1987). Indomethacin, like aspirin, can both delay and prolong labour (Morales and Madhav 1993) and increase the risk of post-partum haemorrhage (Reiss *et al*. 1976). Indomethacin can also inhibit the effects of b-blocking drugs and induce maternal hypertension (Schoenfeld *et al*. 1989).

Diflunisal

Fetal abnormalities have not been reported with diflunisal use in humans but the drug has similar effects on parturition and closure of the ductus arteriosus as other NSAIDs. When used in higher doses than those recommended in humans, the drug has been shown to be teratogenic in laboratory animals (van Winzum and Verhaest 1979).

Phenylbutazone

Use of phenylbutazone in clinical practice is now restricted to management of patients with refractory seronegative spondylarthropathies who have failed to respond to other available NSAIDs. Phenylbutazone is not recommended in pregnancy because of its potent prostaglandin inhibitory properties and the potential for serious haematological adverse effects (Buchanan and Kean 1994).

Although congenital fetal abnormalities have been reported with maternal use of phenylbutazone, there is doubt that the relationship is causal (Kullander and Kallen 1976) and the evidence is currently in favour of both phenylbutazone and its metabolite, oxyphenbutazone, being non-teratogenic (Ostensen and Husby 1985).

Diclofenac

Brooks and Needs (1989) have stated that there are no reported fetal abnormalities in humans related to diclofenac; however minor fetal abnormalities in rats and in mice treated with high-dose diclofenac have been reported (Medoricawa *et al*. 1972).

Proprionic acid drugs

No ill effects on the fetus have been reported with the use of ibuprofen (Barry *et al*. 1984). There is no evidence that naproxen, fenoprofen, or ketoprofen are teratogenic in animals or in man but as with all NSAIDs there is the potential for inhibition of labour, prolongation of pregnancy, increase in pre- and post-partum haemorrhage, and premature closure of the ductus arteriosus with resultant pulmonary hypertension (Wilkinson 1980). Wilkinson *et al*. (1979) reported on a case of triplets delivered at 30 weeks who suffered from severe hypoxaemia. The mother had been taking naproxen to suppress labour. The ductus arteriosus was closed in the infants. High concentrations of naproxen (60 µg/ml) were found in the neonatal plasma. Fluid retention and hyponatraemia have been reported in an neonate whose mother took 5 g of naproxen 8 h prior to delivery. The child recovered completely with no observable sequelae (Alun-Jones *et al*. 1986).

Oxicam

Oxicams have been shown to delay parturition in laboratory animals (Wiseman 1985) but piroxicam and tenoxicam have not been shown to have any teratogenic effects in animals and there are no reports of fetal abnormalities in man.

Corticosteroids

No ill effects have been recorded in children born of mothers who received betamethasone during their pregnancies, at least in terms of cognitive and psychological development, motor development and school achievement, and socio-emotional function (MacArthur *et al*. 1981; MacArthur *et al*. 1982; Schmand *et al*. 1990;

Smolders-de Haas *et al*. 1990), although more infections were noted during the first few years of life (Smolders-de Haas *et al*. 1990). High maternal doses of prednisone have been reported to cause immunosuppression in newborn infants (Cote *et al*. 1974), although most had no ill effects (Cederqvist *et al*. 1977). Long-term studies of children whose mothers were treated with dexamethasone showed no ill effects (Wong *et al*. 1982; Collaborative Group on Antenatal Steroid Therapy 1984). A reduction in the incidence of premature closure of the ductus arteriosus has been claimed with the administration of betamethasone to mothers with premature babies (Waffarn *et al*. 1983; Morales *et al*. 1989), but no such effect has been observed in normal weight infants (Wasserstrum *et al*. 1989). An increase in still births has been reported with prednisone treatment of the mother by Warrell and Taylor (1968) , but has not been confirmed by other investigators. An increased risk of fetal death has been reported in mothers treated with betamethasone to prevent respiratory distress syndrome (Liggins and Howie 1972), but refuted by others (Nochimson and Petrie 1979). Low levels of cortisol have been observed in premature infants of mothers prescribed betamethasone within 48 h of delivery, although this corrected within 2 h of birth (Dorr *et al*. 1986). An increased incidence of hypoglycaemia has been noted in newborn infants whose mothers received betamethasone (Papageorgiou *et al*. 1979), and congenital cataracts have been attributed to maternal prednisone therapy (Kraus 1975). Leukaemoid reactions in newborn infants may occur with maternal betamethasone (Bielawski *et al*. 1978) and dexamethasone therapy (Otero *et al*. 1981; Anday and Harris 1982). Large doses of corticosteroid administered to the mother during the first trimester have been associated with cleft palate in the offspring (Bongiovani and McPadden 1960). Popert (1962) in a study of 10 patients treated with corticosteroids for rheumatic disease during pregnancy, found that there were no maternal or fetal abnormalities in 20 pregnancies. Grigor *et al*. (1977) reported that fetal immaturity occurred in the offspring of pregnant women with systemic lupus treated with corticosteroids.

Although there have been case reports linking congenital malformations with cortisone therapy in the mother, there are no such reports with prednisone, dexamethasone, and betamethasone. Prednisone therapy does not affect either the number or morphology of chromosomes (Jensen 1967) but high doses may cause damage to spermatogenesis, which, however, is reversible (Mancini *et al*. 1966). Betamethasone has been reported as a potentiating factor in a ritodrine-induced crisis in a mother (Gonen *et al*. 1982). There is scant information on the use of small doses of prednisone (10 mg daily or equivalent) in pregnancy, and although probably safe, should be avoided if at all possible. Corticosteroids should only be administered in pregnancy when it is considered absolutely necessary for the treatment of the mother.

Gold complexes

Gold complexes have been extensively used in pregnant mothers. There are reports of fetal abnormalities in infants born of mothers who received gold sodium thiomalate during pregnancy (Miyamoto *et al*. 1974; Rogers *et al*. 1980; Fuchs and Lippert 1986). Other authors (Cohen *et al*. 1981; Tarp and Graudal 1985) did not find that gold complexes were associated with fetal abnormalities. Gold concentrations have been found in infants at delivery that are similar to gold concentrations found in the mothers (Rocker and Henderson 1976; Richards 1977; Cohen *et al*. 1981), but no obvious adverse effects were identified in the infants. A small number of pregnant mothers who received the oral gold complex, auranofin, have been followed. No adverse effects were identified either in the mother or in the child, but in view of the potential immunosuppressant effects of the triethylphosphine ligand of the auranofin, it is our opinion that this compound should be avoided during pregnancy. Ostensen and Husby (1985) have suggested that intramuscular gold may be given with caution during pregnancy; but how does one monitor the effects on the fetus?

Sulphasalazine

Sulphasalazine is a conjugate of 5-aminosalicylic acid, a salicylate analogue, linked by an azo bond to sulphapyridine. Sulphasalazine results in a reduced sperm count in males but does not appear to affect female fertility. Sulphasalazine and its metabolites, including sulphapyridine, cross the placenta, and case reports of children born with congenital malformation whose mothers received the drug during pregnancy have been recorded (Jarnerot *et al*. 1981; Newman and Correy 1983). There does not appear to be an increased incidence of fetal abnormality when mothers have received sulphasalazine for the treatment of inflammatory bowel disease (Mogadam 1981; Vender and Spirol 1982; Newman and Correy 1983).

Although several reports have suggested that there might be a fetal risk with the use of sulphasalazine in pregnancy (Craxi and Pagliarello 1980; Newman and Correy 1983; Hoo *et al*. 1988) on the whole this does not appear to be clinically significant (Brooks and Needs 1989; Briggs *et al*. 1994). It should be noted that all available data are for inflammatory bowel disease not rheumatoid arthritis.

Aminoquinolines

Chloroquine phosphate and hydroxychloroqine sulphate are 4-amino-7-chloroquinoline compounds that were first synthesized in the earlier part of the twentieth century and used during the Second World War as a treatment for malaria. Chloroquine differs from hydroxychloroqine in that the n-ethyl portion of the chloroquine is b-hydroxylated, otherwise the structure is equivalent to the parent molecule. Antimalarial compounds cross the placenta and can accumulate in the fetus, although the concentrations are much lower than in maternal tissue (Ullberg *et al*. 1970). Chromosomal damage has been reported *in vitro* with antimalarial drugs (Neill *et al*. 1973) and fetal sensory neural hearing loss has been reported after exposure to chloroquine phosphate prescribed during the first trimester (Hart and Naunton 1964). Dr Anne Parke (1993) has reported that fetal loss in systemic lupus is not due to the antimalarial drug therapy, but to the disease process.

Some workers have reported no significant risk to the fetus (Ross and Garatsos 1974; Suhonen 1983) or increase in congenital abnormalities (Roubenoff *et al*. 1988), but the potential for accumulation of the drugs in the uveal tract (Ullberg *et al*. 1970) and to cause chromosomal damage (Neill *et al*. 1973) have led to almost uniform avoidance of their use in pregnancy (Roubenoff *et al*. 1988).

D-Penicillamine

D-Penicillamine can cross the placenta and is therefore potentially teratogenic (Lyle 1978; Rosa 1986). The reaction of penicillamine with an aldehyde or ketone results in water elimination and formation of a five-membered thiazolidine ring with the carbon atom of the carbonyl group and the attached organic group incorporated into the ring, bonding to the sulphur and nitrogen atoms. During collagen synthesis, penicillamine can inhibit or impair tropocollagen cross-linking between the allysine and hydroxyl lysine residues by thiazolidine formation between the aldehyde group of allysine and the amino and sulphur functions of D-penicillamine; the result is the formation of a thiazolidine ring.

Endres (1981) reported on 87 cases of patients who have used D-penicillamine during pregnancy. Two of the children had severe connective tissue defects. In one case, the mother had rheumatoid disease and received D-penicillamine at a dosage of 900 mg per day for 5 months during the pregnancy (Soloman *et al*. 1977), and in the other case, a patient with cystinuria received 2000 mg per day of D-penicillamine for 9 months of pregnancy (Mjolnerod *et al*. 1971). Toxicity appears to be dose related, i.e. less than 500 mg per day is unlikely to be associated with fetal abnormalities (Endres 1981). In general D-penicillamine taken in pregnancy has proven safe (Roubenoff *et al*. 1988) but there are case reports of cutis laxa and other connective tissue impairment in infants whose mothers received the drug during pregnancy (Mjolnerod *et al*. 1971; Soloman *et al*. 1977; Lyle 1978; Endres 1981; Harpey *et al*. 1983).

It is not possible from the above reports to establish a relative risk; however, the potential for teratogenicities is sufficiently serious to suggest that in a non-fatal disease such as rheumatoid arthritis, D-penicillamine should be withheld during pregnancy, especially since the majority of patients will improve during the gestation period. D-Penicillamine should also be withheld in cystinuric patients but high fluid volume and increased urinary pH should be maintained. In patients with Wilson's disease, the dosage of D-penicillamine should not be reduced during pregnancy as the disease process increases the risk of spontaneous abortion. In 1976, Lakatos and colleagues reported that D-penicillamine was of benefit in the treatment of hyperbilinrubinaemia due to haemolytic disease of the newborn (Lakatos *et al*. 1976). The author stated that the bilirubin was destroyed by a copper–penicillamine complex. This finding was not supported by biochemical evidence in the report and to our knowledge this study has neither been confirmed nor refuted.

The controversy whether D-penicillamine should be continued during pregnancy is ongoing, but probably should be avoided (Ostensen and Husby 1985; Miehle 1988).

Methotrexate

There is a considerable body of evidence that treatment with methotrexate in pregnancy may cause congenital abnormalities (Milunsky *et al*. 1968; Powell and Ekert 1971; Warkany 1981) and myelosuppression in the fetus (Okun *et al*. 1979; Pizzuto *et al*. 1980). The drug can cause chromosomal abnormalities (Schleuning and Clemm 1987), but whether these predict abnormalities in the fetus has not been determined. Methotrexate can reduce ovarian and testicular function, but is reversible, and subsequent successful pregnancies have been reported (Barnes and Link 1983) with no higher than expected frequency of congenital abnormalities in the fetus (Rustin *et al*. 1984). A patient treated for Reiter's syndrome over 5 years, subsequently fathered a normal infant (Perry 1983). Methotrexate should, if

possible, be avoided in pregnancy (Ostensen and Husby 1985).

Azathioprine

Immunosuppression of the newborn has been reported with doses prescribed for rheumatoid arthritis (Cote *et al*. 1974; De Witte *et al*. 1984), although reduction in dosage at 32 weeks of pregnancy reduces the risk (Davison *et al*. 1985). Infants that are small for their gestational age have been reported in mothers receiving azathioprine, but this was probably due to underlying disease. Chromosomal abnormalities have been described with the use of azathioprine but the clinical significance has not been determined (Registration Committee of the European Dialysis and Transplant Association 1980). Azathioprine appears to interfere with the effectiveness of intrauterine contraceptives (Zerner *et al*. 1981; Davison and Lindheimer 1982). Surprisingly most workers have found azathioprine to be relatively safe in pregnancy, even in large doses, with no ill effects on the fetus (Kirk 1991). Ostensen and Husby (1985) recommended that azathioprine might be given in pregnancy, but advised caution.

Cyclophosphamide

Although malformed newborns have been described as a result of the use of cyclophosphamide, healthy infants have also been born (Coates 1970; Sweet and Kinzie 1976; Kirshon *et al*. 1988). Many of the mothers who had malformed newborns also had received other antineoplastic drugs and radiation. Less damage to the fetus appears to occur when treatment is confined to the second and third trimester (Nicholson 1968; Dobbing 1977). Congenital abnormalities have also been reported with paternal use of cyclophosphamide (Russell *et al*. 1976; Evenson *et al*. 1984). Permanent amenorrhoea may result from the use of cyclophosphamide (Uldall *et al*. 1972), but normal pregnancies have been reported in patients who had had high doses of cyclophosphamide for the treatment of neoplasms (Lee *et al*. 1989). Azoospermia can occur in the male (Hinkes and Plotkin 1973), but is reversible (Watson *et al*. 1985). Congenital abnormalities have been reported in infants fathered by patients who had had azoospermia as a result of cyclophosphamide, but had recovered (Russell *et al*. 1976; Evenson *et al*. 1984). Chromosomal abnormalities have been described with the use of cyclophosphamide, but the clinical significance is not known (Tolchin *et al*. 1974). Nurses should not handle cyclophosphamide when pregnant. The consensus of opinion is that cyclophosphamide should be avoided in pregnancy (Ostensen and Husby 1985).

Cyclosporin

Abortions and fetal abnormalities (Pujals *et al*. 1989) and growth retardation (Lau and Scott 1985) have been described with the use of cyclosporin in pregnancy. However, successful pregnancies have also been reported (Doria *et al*. 1992). Although cyclosporin does not appear to pose a major risk to the fetus or to be a human teratogen (Briggs *et al*. 1994), the numbers of reports to date are few. Cyclosporin should therefore probably be avoided in pregnancy until more data are available.

Allopurinol

No adverse fetal effects have been attributable to allopurinol (Briggs *et al*. 1994). However, gout is uncommon in women of child-bearing age, and the drug, if it has to be used, should be prescribed in as low a dose as possible.

Probenecid

No congenital defects have been reported with the use of probenecid in pregnancy (Lee and Loeffler 1962). The comments above regarding allopurinol pertain also to probenecid.

Colchicine

Colchicine is used in gout, chondrocalcinosis, and familial Mediterranean fever. In a small number of human fetuses exposed to colchicine, no congenital abnormalities were reported (Sokal and Lessmann 1960; Zemer *et al*. 1976; Cohen *et al*. 1977; Levy and Yaffe 1978). Colchicine may produce azoospermia (Merlin 1972), but not in all men (Bremer and Paulsen 1976). There has been concern of the mutagenic effects on sperm causing a higher risk of trisomic offspring (Cestari *et al*. 1965; Ferreira and Buoniconti 1968). Levy *et al*. (1991a) in a recent state-of-the-art review conclude that colchicine should be avoided in pregnancy because of its cytogenic effects and reported association with Down's syndrome.

Lactation

It has been estimated that approximately 50 per cent of babies discharged from hospitals in the United States are breast fed, and this number appears to be increasing (Briggs *et al*. 1994). Despite the fact that the potential for harm to the suckling infant from maternal ingestion of drugs has long been recognized (Soranus of Ephesus in the second century AD warned nursing mothers to refrain from taking medicines and alcohol), there is at present a relative paucity of knowledge on the safety of maternally-ingested medicaments on the nursing infant. A nursing mother produces on average 600 ml of milk per day. The milk has a pH greater than 7.1, and consists of a suspension of proteins, mostly casein and lactalbumin, and fat, in a carbohydrate—mineral solution. Drugs excreted in milk may be bound either to the proteins or adsorbed or sequestered in the milk fat globules. Drugs pass through the ductal cells primarily by passive diffusion, the concentration achieved being dependent on the concentration gradient, lipid solubility, and degree of ionization of the drug, and on its binding to protein and milk fat globules. Despite the large number of antirheumatic drugs and their extensive use, few data are available concerning drug concentrations in human milk or the effects of these drugs on the suckling infant. Drugs for which no clinical or biochemical data are available include: cortisone, betamethasone, and dexamethasone; diflunisal, meclofenamate, and sulindac; penicillamine; and probenecid (Briggs *et al*. 1994). The use of antirheumatic drugs during lactation has been the subject of several reviews (Ostensen and Husby 1985; Roubenoff *et al*. 1988; Brooks and Needs 1989; Kean and Buchanan 1990; Bellamy *et al*. 1991; Briggs *et al*. 1994). The following is a brief summary of the various antirheumatic and antigout drugs in lactation.

Analgesics

Acetaminophen is excreted in breast milk in very small concentrations but has been considered a safe analgesic for use in nursing mothers (Bitzen *et al*. 1981). A single case of rash in a breast-feeding infant has been described (Matheson *et al*. 1985). Codeine is lipid soluble and could be present in breast milk, however like acetaminophen, it is considered by the Committee on Drugs of the American Academy of Pediatrics (1994) as compatible with breast feeding.

Aspirin and NSAIDs

Aspirin has a short half-life of 10 to 15 min and is readily converted to salicylate after ingestion. The latter is excreted into breast milk in low concentrations. Kinetic studies have shown that after administration of 450 to 650 mg of aspirin to the mother, 21 per cent of the maternal dose appears in the breast milk over a 24-h period (Berlin *et al*. 1980; Findlay *et al*. 1981). Infants have the ability to cleave salicyl phenolic glucuronide and absorb the free salicylic acid. Maximum salicylate concentrations are found in breast milk 2 h after the maternal maximal concentrations (Findlay *et al*. 1981). Since the elimination of salicylates does not follow first-order kinetics, but is dose dependent, the plasma half-life increases as the dose increases. Thus, with small oral doses the plasma half-life may be only 1 to 2 h, whereas with doses exceeding 3 g per day the half-life may be as long as 18 h. With low dosage of aspirin or other salicylates, i.e. less than 3 g per day, there is probably little risk to the suckling infant (Ostensen and Husby 1985; Committee on Drugs of the American Academy of Pediatrics 1994); but with doses in excess of 3 g per day, salicylate intoxication is a distinct possibility. There is, however, only one report of an infant developing salicylate toxicity (Clark and Wilson 1981). Kwan *et al*. (1978) have recommended that because of the long half-life of sulindac and its active metabolites, this medication should not be given to nursing mothers because of the risk of transfer of this drug to the fetal circulation. Similarly, drugs such as diflunisal that have a long half-life are not appropriate for pregnant mothers during lactation.

As previously mentioned no clinical or biochemical data exist on a number of NSAIDs. However, ibuprofen, naproxen, phenylbutazone and oxyphenbutazone, piroxicam, and tolmetin have all been considered compatible with breast feeding by the Committee on Drugs of the American Academy of Pediatrics (1994). Brooks and Needs (1990) have stated that diclofenac sodium has not been detected in human milk after single doses of 50 mg or after 1 week of treatment at 100 mg per day. The authors have stated that since only a small amount of diclofenac is present in breast milk and since the drug has a short half-life of 2 h, that it is suitable for use in lactating mothers. They also state that some of the metabolites have longer half-lives and may be present in the breast milk, but in small quantities. Ibuprofen was not detected in the breast milk of 12 pregnant patients receiving 1600 mg of ibuprofen over 24 h (Townsend *et al*. 1984). Small amounts of naproxen were recovered in breast milk after administration of 250 mg of naproxen to a pregnant mother, but less than 0.26 per cent of the maternal dose was identified in the infant

(Jamali and Stevens 1983). Minimal concentrations of fenoprofen and ketoprofen have been identified in breast milk (Rubin *et al*. 1984). Piroxicam use during lactation results in 1 to 3 per cent of the maternal plasma concentration being present in the breast milk (Ostensen 1983; Ostensen *et al*. 1988). Ostensen and Husby (1985) have also considered diclofenac, flufenamic acid, ketoprofen, and mefenamic acid to pose no risk. Seizures in a breast-fed infant whose mother was receiving indomethacin have been described (Eeg-Olofsson *et al*. 1978), although whether these could be attributed to the drug has been questioned (Fairhead 1978). Nevertheless, indomethacin has been considered compatible with breast feeding (Committee on Drugs of the American Academy of Pediatrics 1994).

Corticosteroids

Systemic corticosteroids, e.g. prednisone, enter breast milk in small quantities. Administration of 5 mg of prednisolone to the mother results in less than 0.23 per cent of the dose being present in the breast milk (McKenzie *et al*. 1975). Surprisingly there is no data on the effect of these drugs on the suckling infant. However, in the standard doses used to treat rheumatoid arthritis, i.e. 10 mg/day or less of prednisone or equivalent, there seems little chance of an infant receiving significant amounts (Brooks and Needs 1989; Committee on Drugs of the American Academy of Pediatrics 1994). There also seems little chance of an infant being breast fed by a mother ill with serious systemic lupus erythematosus or vasculitis who requires large doses of corticosteroids.

Gold complexes

Ostensen *et al*. (1986) estimated that suckling infants might receive 20 per cent of the maternal dose of gold complexes. Trace amounts of aurothioglucose have been identified in breast milk (Blau 1973; Ostensen *et al*. 1986). Rashes, hepatitis, nephritis, and blood disorders have been reported in infants (Blau 1973) and Ostensen *et al*. (1986) concluded that probably nursing is best avoided. However, the Committee on Drugs of the American Academy of Pediatrics (1994) concluded that breast feeding was compatible with treatment with gold sodium thiomalate.

Sulphasalazine

Unmetabolized sulphasalazine and 5-aminosalicylic acid are either present in milk in minute amounts or are undetectable, but sulphapyridine is present in 30 to 60 per cent of maternal serum concentrations (Janerot and Into-Malmberg 1979). One infant has been described who developed bloody diarrhoea while the mother, a slow acetylator, was receiving sulphasalazine (Branski *et al*. 1986). The acetylator status of the infant was not determined. Sulphasalazine should therefore be given to nursing mothers with caution (Committee on Drugs of the American Academy of Pediatrics 1994).

Hydroxychloroquine and chloroquine

Nation *et al*. (1984) estimated that a suckling infant would receive approximately one-third of the mother's daily dose of these antimalarial drugs, but other workers found very small amounts in milk (Ostensen *et al*. 1985). In a study of 27 pregnancies in which the mothers received antimalarial drugs during the first trimester, there was no evidence that the infants were in any way affected (Levy *et al*. 1991b). Despite these findings, it is best to avoid the use of antimalarial drugs during breast feeding if at all possible (Anderson 1991; Levy *et al*. 1991b; Parke 1993; Committee on Drugs of the American Academy of Pediatrics 1994).

Penicillamine

No data is available on the effects of maternal ingestion of penicillamine on the suckling infant. Since congenital abnormalities have been reported in infants of mothers receiving penicillamine (Lyle 1978), the drug is best avoided during breast feeding (Ostensen and Husby 1985).

Methotrexate

Only small amounts of methotrexate are excreted in milk (Johns *et al*. 1972). However, in view of the potential for immunosuppression, neutropenia, effects on growth, and carcinogenesis in the suckling infant, it would seem prudent to avoid prescribing the drug to nursing mothers (Committee on Drugs of the American Academy of Pediatrics 1994).

Azathioprine

Little information is available on the use azathioprine during breast feeding. Only small amounts of azathioprine are present in milk (Anderson 1977) and, as a consequence, the drug has been considered safe but should be given with caution (Bellamy *et al*. 1991).

Cyclophosphamide

Cyclophosphamide is only prescribed in rheumatic practice for two conditions: lupus glomerulonephritis and vasculitis. It is excreted in large quantities in breast milk (Wiernik and Duncan 1971). It is absolutely contraindicated during breast feeding (Committee on Drugs of the American Academy of Pediatrics 1994).

Cyclosporin

There are no reports on the use of cyclosporin during breast feeding, but it is not recommended (Committee on Drugs of the American Academy of Pediatrics 1994).

Allopurinol

Gout is relatively rare in premenopausal women, and no clinical data are available. Allopurinol is present only in very small amounts in milk, and only slightly higher concentrations of the metabolite, oxypurinol, are found. The drug is considered safe during breast feeding (Committee on Drugs of the American Academy of Pediatrics 1994).

Probenecid

No data is available on the use of probenecid during breast feeding.

Colchicine

Colchicine is present in very small amounts in breast milk (Milunsky and Milunsky 1991). The Committee on Drugs of the American Academy of Pediatrics (1994) considers colchicine compatible with breast feeding.

Box 1 Drugs and pregnancy

DO'S	DON'TS
Do not take any drug or medicinal agent when pregnant or if pregnancy is suspected, unless that medication has been recommended by a physician In general the only medications which can be permitted are those which are considered to be essential, e.g., insulin and other products for diabetes, thyroid replacement hormone, antiseizure medication, etc. Under appropriate circumstances drugs which are essential to cardiovascular function, e.g., digoxin, and to respiratory function, e.g., inhalers for asthma, may be permitted when considered necessary by a physician Antirheumatic drugs should not be taken (see don'ts) except under exceptional circumstances when musculoskeletal pain is severe and cannot be controlled by the use of local physical measures, such as hot packs, ice packs, and physical therapy	Antirheumatic medications should not be taken during pregnancy or if pregnancy is suspected It is the opinion of the authors that there is an inadequate evidence base on which to recommend the use of anti-inflammatory drugs, except in exceptional circumstances

Box 2 Antirheumatic drug use by lactating mothers

It is the opinion of the authors that there is insufficient evidence upon which to recommend the use of antirheumatic drugs during lactation. While the case reports and studies referrred to in this chapter suggest that the effects on the child would be minimal, it is the opinion of the authors that there is insufficient quantity of data to support unrestricted use of antirheumatic drugs for the lactating mother

By convention, most rheumatologists will prescribe NSAIDs to lactating mothers, if the clinical situation warrants the use of these drugs

Conclusion

It can be appreciated that we are woefully lacking in data on the effects of antirheumatic drugs on the fetus and the suckling infant. Many of the new drugs have no data either in pregnancy or during lactation. In general most reports are anecdotal or at best on small series of patients.

The decision to use these various antirheumatic and antigout drugs depends on the severity of the patient's illness and the availability of therapeutic alternatives. It is useful to remember that although alcohol has been considered dangerous to the breast-fed infant since antiquity, it was considered to be no more than a superstition in this century until two decades ago (Shaywitz 1978). In general it is wise to avoid all drugs or medicaments during lactation. None of the drugs recommended as compatible with breast feeding have adequate clinical data on adverse effects on breast-fed infants, and rely entirely on comparison of the concentrations of the drugs found in milk samples in relation to maternal serum.

A helpful simple guide is the 'rule of three' (Sackett *et al*. 1986), which is useful when no events of a particular kind are observed. The 'rule of three' states that if no events of a particular kind are observed in a study of *x* individuals, one can be 95 per cent certain that the event occurs no more than 3 divided by *x*. Thus, if 3000 patients are studied then one can be certain that any event that does not occur in any of these patients occurs less often than 3 times in 3000 exposed subjects, or that it has an incidence rate of less than 0.001. In most studies of antirheumatic drugs in pregnancy and lactation the number of patients studied is less than 100. Needless to say it has proved extremely difficult to estimate risk, especially as patients may have more than one disease and be taking other medication (Roubenoff *et al*. 1988). If there is a place for pharmacoepidemiological studies then it is in this area of clinical therapeutics. Large population registers and population databases are necessary to provide accurate numerator/denominator ratios. The answer can only come with a database of drugs used in pregnancy and lactation (Bellamy *et al*. 1991). Meanwhile it seems prudent to use the lowest possible dose of a drug during pregnancy and lactation to control symptoms, and to avoid completely those drugs which are not recommended. Important points to remember when prescribing drugs during pregnancy and lactation are summarized in Box 1 and Box 2.

1.3.2 The skin

C. R. Lovell and P. J. Maddison

Introduction

Why is it important to examine the skin in a patient with arthritis? The skin is the most accessible organ for clinical examination and investigation. Pattern recognition of skin lesions is valuable in the diagnosis and prognosis of underlying joint disease. Often, the skin bears the brunt of toxicity from antirheumatic drugs.

Joint abnormalities may be mirrored by similar changes in the skin. For example, joint hypermobility and skin hyperextensibility coexist in heritable disorders of connective tissue, such as the Ehlers–Danlos syndrome. Cutaneous erythema and hyperpigmentation may overlie an inflamed joint. Furthermore, many patterns of cutaneous involvement are highly specific to certain arthropathies, such as the characteristic erythematous eruption of erythema marginatum in rheumatic fever (Fig. 1), the 'butterfly' facial erythema of acute lupus erythematosus and erythema chronicum migrans following infection with *Borrelia burgdorferi*, which can result in Lyme disease.

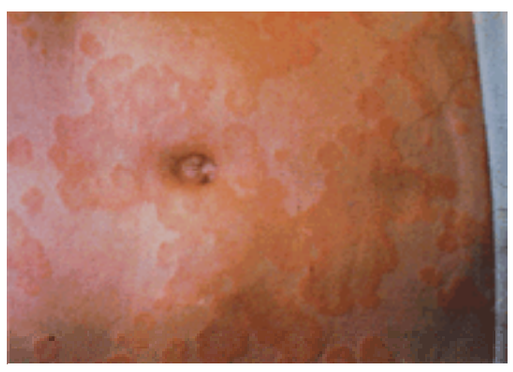

Fig. 1 Erythema marginatum in rheumatic fever: reddish annular lesions may expand rapidly to form large figurate patches; the eruption is typically evanescent, lasting 2 to 3 days at most (photograph by courtesy of Dr E. Pascual).

The degree and extent of skin lesions can be of prognostic importance, for example the cutaneous vasculitis and nodules in rheumatoid disease.

Finally, several antirheumatic drugs produce highly specific, and potentially serious, cutaneous reactions that require accurate diagnosis and prompt management.

This chapter comprises:

1. A brief outline of the major descriptive terms used in dermatology and the simple investigations required to make a firm dermatological diagnosis.
2. The differential diagnoses of important cutaneous abnormalities.
3. Aspects of treatment of the skin in rheumatic disorders.
4. Cutaneous side-effects of commonly used antirheumatic drugs.

The approach to the patient with skin lesions

History

A careful history should include the following features.

1. duration of the eruption;
2. duration of individual lesions (e.g. weals in simple urticaria individually last less than 24 h, whereas they persist for two or more days in urticarial vasculitis);
3. timing of lesions (e.g. the eruption of Still's disease is typically worse in the early afternoon, and evening);
4. seasonal variation of lesions (e.g. 'summer' vasculitis);
5. the relation of skin lesions to joint disease (e.g. scattered gonococcal pustules occurring with flitting arthritis in the bacteraemic phase);
6. whether the skin lesions occur singly or in crops, as in Henoch–Schönlein purpura;
7. where the lesions occur;
8. do lesions blister or crust? (Remember that many infiltrated or hyperkeratotic lesions may be described as 'blisters' by the patient. True blisters are seen in some drug reactions, notably fixed drug eruption and erythema multiforme. Superficial blisters rupture early, leaving eroded areas, as in penicillamine-induced pemphigus.);
9. whether lesions itch;
10. whether lesions are tender;
11. are lesions caused or aggravated by light? (Several drugs cause photosensitivity and cutaneous lupus typically occurs on areas of sun exposure.);
12. whether there is cold sensitivity—enquire about features of Raynaud's phenomenon;
13. whether there is orogenital ulceration of recent onset;
14. a careful history of present and recent drug therapy.

Examination

The skin should be examined in a good, preferably natural, light. A torch and pocket magnifying glass are invaluable. Since some skin lesions are transient, repeated examination of the skin may be necessary.

Note the distribution and morphology of individual lesions. Knowledge of a few technical terms is essential (Table 1).

Term	Definition	Examples
Macule	A flat, impalpable area of altered skin colour	A cafe-au-lait spot
Papule	A lump smaller than 0.5–1 cm diameter	A viral wart
Nodule	A lump greater than 0.5–1 cm diameter	An epidermoid ('sebaceous') cyst
Plaque	A slightly raised, circumscribed area, often disc shaped	Plaque psoriasis
Vesicle	A small blister (fluid-filled lesion), less than 0.5 cm diameter	Herpes simplex
Bulla	A blister greater than 0.5 cm diameter	A friction blister
Pustule	An accumulation of pus in the skin	Folliculitis
Erosion	A loss of epidermis that heals without scarring	An abrasion
Ulcer	A defect or loss of dermis and epidermis produced by sloughing of necrotic tissue	Pyoderma gangrenosum
Telangiectasia	Visibly dilated, small vascular lesions that blanch on pressure	'Spider naevi'
Purpura	Extravasation of blood, forming coalescent areas of discoloration, which does not blanch on pressure; small lesions are termed petechiae (1–2 mm diameter)	
	Larger areas of extravasation of blood are termed ecchymoses	Traumatic bruising
Erythema	Redness	
Violaceous	Purplish hue	Lichen planus
Weal	A transient area of dermal oedema which produces a white or skin-coloured papule or nodule surrounded by a 'flare' of erythema	Urticaria
Atrophy	Skin thinning with reduction of recognizable structures and perhaps translucency	
Poikilodermia	Atrophy with telangiectasia	Radiotherapy scars, dermatomyositis
Alopecia	Loss of hair. It may be localized (e.g. alopecia areata) or diffuse (e.g. systemic lupus erythematosus or iron deficiency). Scarring alopecia, with destruction of hair follicles, is a feature of discoid lupus affecting the scalp	
Onycholysis	Increased free edge of the nail	Psoriasis, thyroid's phenomenon

Table 1 Important descriptive terms in dermatology

The regional distribution of lesions

Scalp

Look for alopecia. Is it diffuse or localized? Is it non-scarring (the scalp itself looks normal) or scarring (Fig. 2) (when there are inflammatory changes around hair follicles and evidence of cutaneous atrophy or sclerosis). Look for the well-demarcated areas of scaling typical of psoriasis.

Fig. 2 Scarring alopecia of the scalp in discoid lupus erythematosus.

Face

1. Look for evidence of photosensitivity (which classically spares the 'shaded' areas such as the nasolabial folds, eyelids, chin, and Wilkinson's triangle (behind the ears)).
2. Is there periorbital oedema or the 'heliotrope' violaceous erythema characteristic of dermatomyositis?
3. Examine the nose for infiltration (e.g. lupus pernio in sarcoidosis). Inability to evert the lower eyelid is an early feature of systemic sclerosis.
4. Look inside the mouth for ulcers and the lace-like white streaks of oral lichen planus (Fig. 3 and Fig. 4).

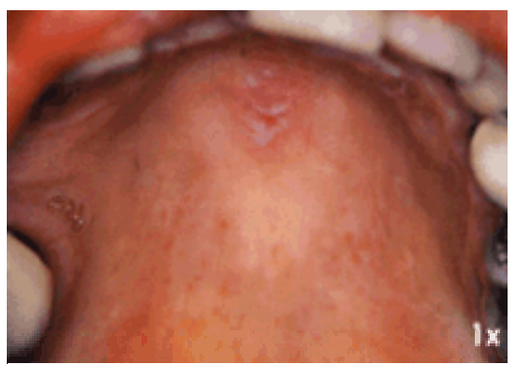

Fig. 3 Involvement of hard palate in subacute lupus erythematosus.

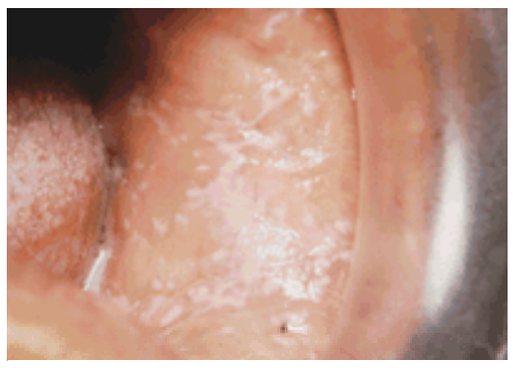

Fig. 4 Oral lichen planus—white streaks on buccal mucosa.

Ears

These are an important site for discoid lupus erythematosus (Fig. 5), gouty tophi, and, occasionally, rheumatoid nodules.

Fig. 5 Discoid lupus erythematosus affecting the external ear.

Hands and feet

1. A photosensitive eruption spares the finger webs and palms. The distribution of erythema on the backs of the fingers helps to distinguish systemic lupus erythematosus from dermatomyositis (Fig. 6).

Fig. 6 Plaques of discoid lupus erythematosus on the fingers.

2. In a patient with Raynaud's phenomenon, evidence of ulceration of fingertips, atrophy of finger pulps, induration, and tethering of skin indicates systemic sclerosis. Later features include telangiectasia and calcinosis.
3. Look for palmar erythema, especially seen in rheumatoid disease.
4. Examine the soles for keratoderma blennorrhagica or localized pustular psoriasis.

Nails

1. Look for onycholysis, pitting, salmon patches, and subungual hyperkeratosis (typical of psoriasis) (Fig. 7, Fig. 8 and Fig. 9).

Fig. 7 Psoriasis: nail pits with early onycholysis.

Fig. 8 Psoriasis: onycholysis with 'salmon patch'.

Fig. 9 Psoriasis: onycholysis, gross pitting, and nail deformity.

2. Examine the nailfolds for periungual erythema, digital vasculitis, periungual papules (e.g. in multicentric reticulohistiocytosis), and paronychia (Fig. 10).

Fig. 10 Dermatomyositis: nailfold vasculopathy (photograph by courtesy of Dr R. S-H. Tan).

3. It is helpful to assess the nailfold capillaries with an ophthalmoscope set at 40 dioptres (10), applying a drop of oil to the cuticle. Capillaroscopy (see below under Investigations) is a useful investigation.
4. Examine the whole body, including the natal cleft and umbilicus (common sites for psoriasis). Look for penile or vulval ulceration, which, like oral ulceration, may be asymptomatic.

For further reading, see Ashton (1995), Burton (1985), and Lovell *et al*. (1990).

Investigation

Routine histological examination of a formalin-fixed skin biopsy may provide considerable useful information (Harrison 1980). The histological features of many lesions are diagnostic, e.g. the palisading granulomas seen in rheumatoid nodules and 'liquefaction degeneration' in cutaneous lupus. Where possible, take an elliptical biopsy across the edge of an early lesion, following skin folds. The biopsy should be at least 10 × 5 mm, unless this is undesirable cosmetically. Include subcutaneous fat in the biopsy. (This is especially important if a panniculitis is suspected, and allows easier closure of the wound.) Use a skin hook or the tip of a needle to lift the end of the biopsy, avoiding forceps trauma. Close the wound with 4/0 or 5/0 silk or prolene. A 5-mm punch biopsy may be adequate for small lesions. Mount the biopsy on filter paper to ensure correct orientation for sectioning. Special stains may be indicated, for example a mucin stain for dermatomyositis. An elastin stain may show the depletion of normal connective tissue structures in localized scleroderma or systemic sclerosis.

Direct skin immunofluorescence is of particular value in lupus erythematosus and in the investigation of blistering disorders. The lupus band test (granular deposition of immunoglobulins at the dermoepidermal junction) is positive in lesional skin in discoid lupus erythematosus and negative in normal skin. It may be negative in early subacute cutaneous lupus erythematosus. In systemic lupus erythematosus, the lupus band test is positive in clinically non-involved skin in 70 per cent of cases, particularly if the biopsy is taken from a sun-exposed site such as the extensor forearm. A punch biopsy is usually adequate for direct immunofluorescence and should be snap-frozen immediately in liquid nitrogen or despatched to the laboratory in appropriate transport medium.

A Kveim test may help in the diagnosis of sarcoidosis, although it is now used less frequently because of the variable reliability of the antigen source. The technique is to inject the antigen intradermally at an identifiable site such as near a mole, or an area tattooed with permanent ink. The site should be biopsied after 4 weeks, whether or not a papule has developed.

Several non-invasive techniques can be used to measure tissue perfusion in the skin, including laser-Doppler flowmetry, transcutaneous oxygen-pressure measurement, thermography, and capillary microscopy. Thermography, using an infrared radiometer or liquid crystal contact, is a useful non-invasive technique in the assessment of Raynaud's phenomenon. Digital blood flow can be measured in a resting state or following a mild thermal stress. Thermography can be used to measure the degree of severity of Raynaud's phenomenon and its response to therapy; it may help to distinguish primary Raynaud's phenomenon from that secondary to connective tissue disease (Love 1980; Ring and Phillips 1984 ; Will *et al*. 1992).

In connective tissue diseases, local vascular changes can be studied by capillary microscopy of the nailfold. This area is easily accessible for examination and the arrangement of the capillaries in the nailfold allows the visualization of the complete capillary loop. In addition, vascular abnormalities appear earlier in the course of the disease than at other sites of the skin of the finger. The morphology of skin capillaries can be studied directly with an ordinary light microscope. Recently, capillaroscopy has been coupled with a videophotometric system and used with computer software to analyse the number and morphology of capillary loops as well as blood-cell velocity under various physiological conditions including local cold exposure (Mahler *et al*. 1987; Fagrell *et al*. 1988).

Morphological changes in capillaries seen in primary Raynaud's approximate those seen in normal individual but the blood-cell velocity is decreased markedly after exposure to cold (Jacohs *et al*. 1987). Characteristic structural abnormalities are found to a much greater extent in connective tissue diseases such as systemic sclerosis, overlap syndromes (including 'mixed connective tissue disease'), and dermatomyositis. They include enlargement of capillary loops (a non-specific finding in idiopathic Raynaud's phenomenon) and, particularly in systemic sclerosis, deformed capillary loops, segmental (or rarely diffuse) loss of capillaries, new capillary formation leading to excessive branching (arborization), and haemorrhage into the nailfold. Their presence in patients presenting with Raynaud's has prognostic significance (Houtman *et al*. 1986).

These changes are dynamic, especially in dermatomyositis. Rapid evolution of structural changes, especially loss of capillaries, is linked with a poor prognosis in systemic sclerosis (Maricq 1988).

Differential diagnosis of common physical signs

Erythema

The red face

Photosensitivity, for example drug-induced
Subacute and acute cutaneous lupus erythematosus may cause diffuse facial erythema. An important cause of photosensitivity is polymorphic light eruption (Fig. 11), which affects 10 per cent of Caucasian females but typically spares the face and hands (Ros and Wennersten 1986).

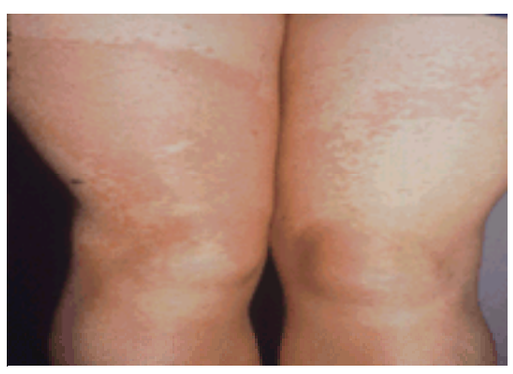

Fig. 11 Polymorphic light eruption: itchy maculopapular lesions occur within hours of sun exposure to sites habitually covered (in this patient the eruption extends to

the line of her Bermuda shorts).

Papules
Telangiectatic papules are found in rosacea and papular lupus erythematosus. These may need to be distinguished by skin biopsy. Papules occur around the alae nasi and lips in sarcoid (Fig. 12), particularly in the Afro-Caribbean patient, and in multicentric reticulohistiocytosis.

Fig. 12 Cutaneous sarcoid in an Afro-Caribbean patient: yellowish papules around the eyelids.

'Heliotrope'
Violaceous erythema and oedema affect both eyelids in dermatomyositis. Episodic oedema of eyelids, and swollen tongue and lips are characteristic of angioedema, which may be a presenting feature of systemic lupus erythematosus.

'Slapped cheek' erythema
This is characteristic of erythema infectiosum (due to parvovirus infection) (Anderson *et al*. 1983).

Strawberry erythema of the tongue and lips
This occurs in streptococcal infections and in Kawasaki disease, where it is associated with red palms and soles, followed a few days later by a generalized eruption.

Exanthem

1. Maculopapular eruptions are typical of viral infections. The circumscribed pink macules of rubella tend to start on the face, and later become confluent and spread to the limbs. In erythema infectiosum, the 'slapped cheek' erythema is followed by a reticulate eruption starting on the buttocks and spreading distally.
2. The 'raindrop' erythematous lesions of guttate psoriasis occur on the trunk and limbs and may follow a streptococcal sore throat. Scaling may be minimal.
3. Widespread erythema may be a feature of a connective tissue disease, particularly dermatomyositis, in which dusky erythema occurs on light exposed areas and extensor surfaces, later developing telangiectasia and atrophy (poikiloderma).
4. An evanescent, non-pruritic, pinkish maculopapular eruption occurs on the trunk and limbs in Still's disease. Often it is most marked in the late afternoon, and evening at the height of fever.
5. In rheumatic fever, annular erythematous lesions enlarge to form large figurate patches within hours.
6. Erythema chronicum migrans, the characteristic skin lesion of Lyme disease, is a solitary, annular lesion gradually expanding around the site of a tick bite (Fig. 13) (Steere 1989).

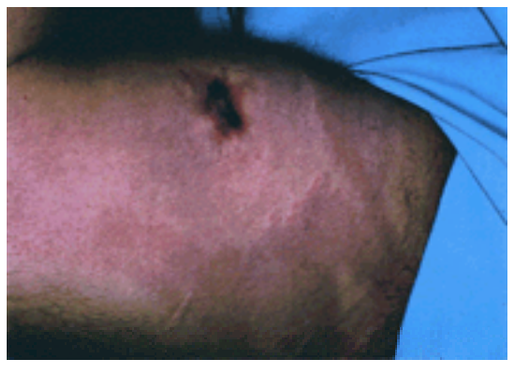

Fig. 13 Erythema chronicum migrans: annular erythema is developing around the site of the tick bite on the thigh (photograph by courtesy of Dr E. Pascual).

7. Many drugs cause a generalized maculopapular eruption (see below).

Localized erythema

Periarticular erythema may be seen around inflamed joints in rheumatoid disease and is a feature of gout and septic arthritis. Erythema may occur over early Heberden's nodes.

Erythroderma

Generalized erythema may be a presenting feature of psoriasis, particularly in the elderly male (Fig. 14). It may also be caused by drugs.

Fig. 14 Erythrodermic psoriasis involving the hands in an elderly man with psoriatic arthritis.

Scaling skin

Scaling is caused by easily detachable keratin, and is due to disordered regulation of epidermal turnover. Any acute inflammation may cause scaling related to the intensity of inflammation, e.g. after gout and drug-induced exanthems. Scaling is characteristic of the different forms of psoriasis and is seen also in lupus erythematosus, particularly discoid forms (Fig. 15 and Fig. 16). In the 'psoriasiform' subset of subacute lupus erythematosus, there is a rim of scale at the periphery of the lesion.

Fig. 15 Scaling plaque of discoid lupus erythematosus on a light-exposed area of forehead.

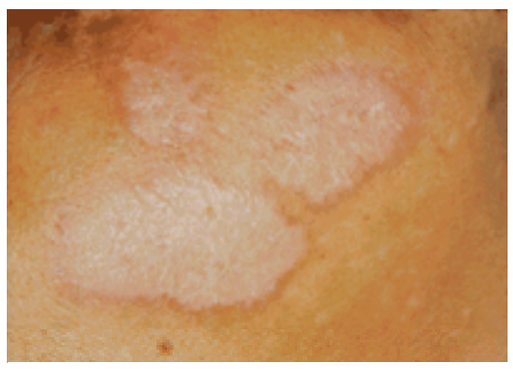

Fig. 16 Discoid lupus erythematosus on the trunk.

Blisters and pustules

Blisters are a feature of pemphigus and pemphigoid, which may be drug-induced. Bullous lesions occur rarely in morphoea, lichen sclerosus et atrophicus, and lupus erythematosus. Epidermolysis bullosa acquisita, characterized by skin fragility, blisters, and milia, may presage the development of systemic lupus erythematosus (Boh *et al*. 1990). Similar lesions are seen in porphyria cutanea tarda and 'pseudoporphyrias' associated with non-steroidal anti-inflammatory drugs (Fig. 17). Widespread bullae are seen in drug-induced erythema multiforme; typical 'target lesions' are seen, particularly on the hands and feet (Fig. 18). Drug-induced toxic epidermal necrolysis is characterized by widespread shedding of skin. Fixed drug eruptions may be bullous; they tend to recur at the same site after repeated exposure to the drug.

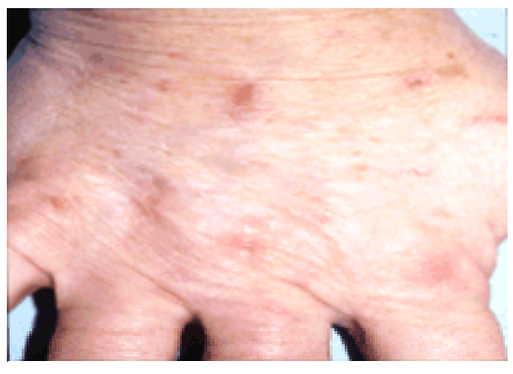

Fig. 17 'Pseudoporphyria' due to naproxen: blisters, milia and scars.

Fig. 18 Erythema multiforme: characteristic 'target lesions' on the palms.

Pustules may be localized to the hands and feet, as in Reiter's syndrome. Localized forms of pustular psoriasis can be indistinguishable. Generalized pustulation may be seen in pustular vasculitis, Behçet's syndrome, intestinal bypass syndromes, and gonococcal bacteraemia, where they may be scanty. Severe pustular acne and hidradenitis suppurativa, a chronic pustular eruption of the flexures, may be associated with inflammatory arthritis. Early lesions of pyoderma gangrenosum may be pustular. A characteristic neutrophilic eruption has been reported as typical of rheumatoid disease (Scherbenske *et al*. 1989), as has subcorneal pustular dermatosis (Sneddon–Wilkinson disease) (Butt and Burge 1995).

Plaques

Plaques on extensor surfaces and the scalp are characteristic of chronic psoriasis. The infiltrated plaques of sarcoidosis occur typically at the anterior scalp margin. Xanthelasmata are a feature of multicentric reticulohistiocytosis and hyperlipidaemias. Plaques of discoid lupus erythematosus are characterized by hyperkeratosis and scarring with 'tintack' scales. Plum-coloured plaques (Fig. 19) occur, especially around the neck and upper trunk, in Sweet's syndrome (acute neutrophilic dermatitis) (van den Driesch 1994). Indurated, tender areas are a feature of panniculitis and erythema nodosum. Localized plaques of morphoea are initially typically violaceous and later become ivory-white and sclerotic. Lesions resembling linear scleroderma are seen in melorheostosis (Fig. 20) (Wagers *et al*. 1972). Urticarial plaques may be a feature of vasculitis and familial Mediterranean fever.

Fig. 19 Sweet's syndrome: plum-coloured plaques on forearm and hand.

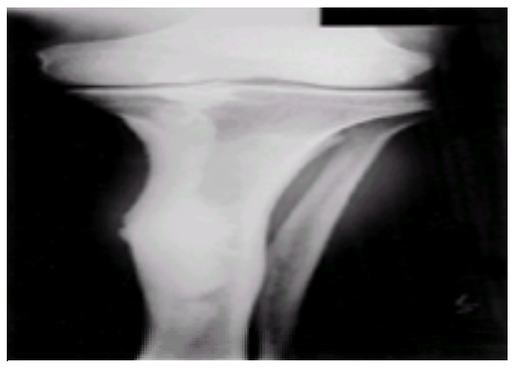

Fig. 20 Melorheostosis: the linear sclerotic streaks resemble dripping candle wax (photograph by courtesy of Dr G. Evison).

Connective tissue naevi present in childhood as firm, skin-coloured or yellowish nodules or plaques distributed asymmetrically on the trunk and proximal limbs. In the Buschke–Ollendorf syndrome they are associated with radiological features of osteopoikilosis (Fig. 21) (Verbov and Graham 1972).

Fig. 21 Osteopoikilosis: note stippling of bone, especially adjacent to joint (photograph by courtesy of Dr G. Evison).

Papules and nodules

Important causes are summarized in Table 2.

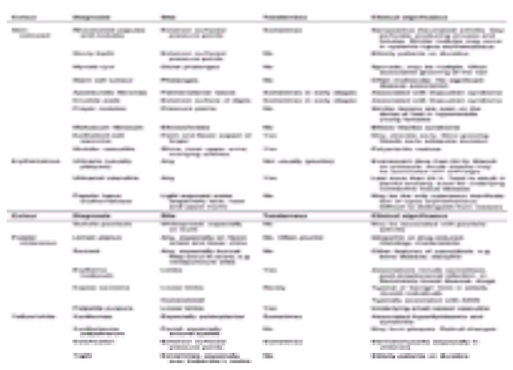

Table 2 Papules and nodules

Purpura and telangiectasia

Impalpable purpuric lesions may be due to diminished numbers of platelets or their dysfunction, for example idiopathic thrombocytopenic purpura or drug-induced marrow aplasia. Trauma, including battering and sports injuries, causes ecchymoses. The 'talon noir', a black area of subcutaneous haemorrhage, occurs on the heel typically in tennis and squash players and may be misdiagnosed as a malignant melanoma. Similarly, splinter haemorrhages and ecchymoses under nails may be due to trauma. The 'crescent sign' occurs typically over the medial or lateral malleoli after a ruptured Baker's cyst. Purpura and ecchymoses are also a feature of corticosteroid toxicity, Ehlers–Danlos syndrome, and haemophilia. Perifollicular haemorrhages occur in scurvy.

Palpable purpura reflects vasculitis, including drug-induced vasculitis and the hypergammaglobulinaemic purpura associated with Sjögren's syndrome. The matt

telangiectasia of hereditary haemorrhagic telangiectasia is indistinguishable from those seen in systemic sclerosis. Telangiectasia and atrophy (poikiloderma) are characteristic of dermatomyositis.

Ulcers

Cutaneous ulceration may have more than one cause in connective tissue diseases. Thus, in rheumatoid arthritis, punched-out ulcers due to vasculitis are common, particularly on the lower limbs. Venous hypertension may play a part in the immobile patient and ulceration may occur over nodules on pressure points. Rheumatoid arthritis is an important cause of pyoderma gangrenosum, which presents as an indurated, expanding, plum-coloured plaque or an acne-like pustule; this ulcerates early and the resulting crater has irregular, 'undermined', thickened, bluish margins. The ulcers may be multiple and heal with considerable scarring. Pyoderma gangrenosum can occur in association with other inflammatory disorders such as Behçet's syndrome.

Neurotropic ulceration occurs rarely in rheumatoid disease, in association with mononeuritis multiplex and severe vasculitis. Foot ulceration may occur with Charcot joints in the patient with syphilis. Similar changes occur in the upper limb in syringomyelia. Cranial arteritis may cause ulceration on the scalp and tongue.

Superficial erosions may be due to pemphigus or more commonly to scratching; in the absence of an obvious dermatosis, pruritus may be due to metabolic causes such as low serum iron or bile-salt retention.

Fingertip ulceration occurs in systemic sclerosis, leaving brownish scars. Severe widespread ulceration may develop rapidly in a child with active dermatomyositis, and reflects the underlying vasculopathy.

Orogenital ulceration

It is important to remember that aphthous ulcers are common in the general population.

In Behçet's syndrome, oral and genital ulcers tend to be more severe and persistent, each lesion often lasting several weeks. They tend to heal with scarring. The ulceration in Reiter's syndrome is typically superficial and painless. Oral lesions of discoid lupus erythematosus occur on the vermilion border and oral mucosa. They are dull red and may have radiating white streaks similar to lichen planus. Oral and palatal ulceration is common in systemic lupus erythematosus and reflects disease activity. Bullous disorders, particularly erythema multiforme, are associated with orogenital involvement. Oral ulceration is common in patients on methotrexate and also occurs following therapy with non-steroidal anti-inflammatory drugs. Gold therapy causes a punctate stomatitis.

Ulceration of part of the tongue may occur in cranial arteritis. A 'geographical' tongue is generally a normal variant, but can occur in psoriasis and Reiter's syndrome.

Pigmentary changes

Relevant causes of hyper- and hypopigmentation are listed in Table 3. Yellow–brown infiltrated lesions include xanthomas and xanthelasmas. Granulomas, such as sarcoid nodules, are dull yellowish on pressure. Rippled yellow streaks occur around the neck and inner arms in pseudoxanthoma elasticum.

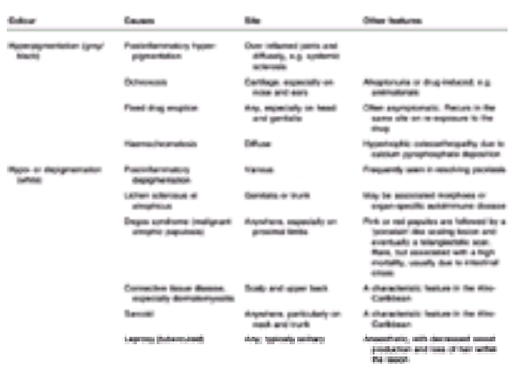

Table 3 Cutaneous hyper- and hypopigmentation

Induration or thickening of skin or subcutis (Jablonska 1975; Jayson and Black 1988)

Diffuse cutaneous sclerosis is the hallmark of systemic sclerosis, where it typically affects the extremities and face, spreading proximally. In generalized morphoea the sclerosis tends to be truncal, with sparing of the areolae; sometimes a typical violaceous margin is seen.

Scleroderma-like changes occur in several metabolic disorders, including phenylketonuria, scurvy, and porphyria cutanea tarda, where cutaneous sclerosis occurs in light-exposed areas. Several industrial chemicals trigger scleroderma-like syndromes (Table 4).

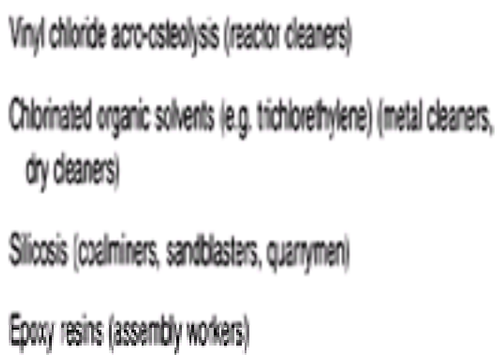

Table 4 Scleroderma-like syndromes due to industrial chemicals

Solid oedema and sclerosis of the limbs occur in the eosinophilia–myalgia syndrome associated with l-tryptophan ingestion (Connolly *et al*. 1990). Stiff swollen fingers, resembling acrosclerosis, occur in rheumatoid arthritis and in overlap connective tissue syndromes. Stiff skin and joint contractures occur rarely in diabetes mellitus. Scleroedema of Buschke affects the upper trunk and neck; the skin can be 'wrinkled' over the indurated subcutis. Fibrotic induration of the lower legs occurs in lipodermatosclerosis ('champagne-bottle legs'), associated with chronic venous stasis. Malignant infiltration of the skin, overlying lung or breast carcinoma, causes extensive erythema and induration (carcinoma erysipelatoides). Gross skin thickening, forming deep folds, is associated with thickened digits in pachydermoperiostosis (Fam *et al*. 1983).

Hair abnormalities

Increased hair growth (hypertrichosis) occurs over sites of hyperaemia such as arteriovenous fistulas and chronically inflamed joints. Drugs, such as corticosteroids,

penicillamine and cyclosporin, and metabolic disorders, such as porphyria cutanea tarda, cause hypertrichosis.

Treatment of cutaneous manifestations of rheumatic diseases

The skin has the advantage of being accessible to topical therapy; high concentrations of otherwise toxic agents can be achieved in the epidermis and superficial dermis. Percutaneous absorption of drugs is affected by many factors, including inflammation of the skin and site variation in the density of dermal connective tissue and epidermal thickness. The most important topical agents in this context are corticosteroids, which are available in bewildering variety. They can be classified in four main groups: mild, moderately potent, potent, and very potent (Table 5).

Potency	Pharmacological name	Trade name
Mild	Hydrocortisone 0.1–2.5%	Various
	Fluocinolone acetonide 0.0025%	Synalar 1:10
Moderate	Clobetasone butyrate 0.05%	Eumovate
	Desoximethasone 0.05%	Stiedex LP
	Flurandrenolone 0.0125%	Haelan
Potent	Betamethasone valerate 0.025%	Betnovate RD
	Betamethasone valerate 0.05%	Betnovate
	Desoximethasone 0.25%	Stiedex
	Fluocinonide 0.05%	Metosyn
	Hydrocortisone 17-butyrate 0.1%	Locoid
	Mometasone furoate 0.1%	Elocon*
	Fluticasone propionate 0.05%	Cutivate*
	Betamethasone dipropionate 0.05%	Diprosalic*
	Fludrocortisone acetonide 0.025%	Topilar
	Beclomethasone dipropionate 0.025%	Propaderm
	Budesonide 0.025%	Pulmicort
Very potent	Clobetasol propionate 0.05%	Dermovate
	Mometasone furoate 0.1%	Elocon
	Flurandrenolone-impregnated tape	Haelan tape — for hospital use only

*Licensed for one whole daily treatment.
†Licensed for nocturnal dressing of hyperkeratinous eczematous skin.
‡Addition of salicylic acid to formulation makes it useful in hyperkeratosis lesions, e.g. corticosteroid tape, psoriasis tape, pharmaceuticals.
Common immunotherapeutic preparations are available for infected lesions and combined preparations for use in infected or suspected psoriasis.

Table 5 Relative potencies of some commonly used topical corticosteroids

Topical sunscreens are also important, particularly in individuals with connective tissue disease. Several are freely available and a few may be had on prescription. The sun protection factor is the ratio of the dose of a particular wavelength of ultraviolet (**UV**)B irradiation that causes minimum erythema with sunscreen over that without sunscreen. Most sunscreens protect the skin adequately from short wavelengths of UV (UVC and UVB) but are inadequate against long-wavelength UV (UVA) and visible light. There is no internationally agreed standard for measuring the degree of protection against UVA or visible light. In recent years, sunscreens are becoming available that contain micromized particles of titanium dioxide or zinc oxide. These preparations block a wider spectrum of light than those that rely on chemical absorption at a specific wavelength. However, individual preference is important; it is essential that the patient is willing to use the preparation regularly.

Systemic agents, such as b-carotene, are somewhat photoprotective.

Cosmetic camouflage is particularly effective for vascular lesions, such as matt telangiectasia in systemic sclerosis.

Treatment of cutaneous ulceration requires careful assessment of the causes and correction of contributory factors such as severe anaemia.

Large, punched-out ulcers reflect necrotizing vasculitis and justify aggressive immunosuppressive therapy. Most vasculitic ulcers are clean and require minimal local interference. Excessive slough can be removed by surgical debridement or the application of a preparation such as Varidase (streptokinase/streptodornase powder for preparing topical solutions). Clean indolent ulcers should respond to hydrocolloid dressings. Sometimes admission to hospital is necessary, often for long periods. Grafting has been found to be necessary on occasion. There are reports of the beneficial use of methotrexate in intractable rheumatoid ulcers.

Rapidly expanding ulcers with a bluish 'undermined' edge should raise the possibility of pyoderma gangrenosum. This requires specific therapy; usually prednisolone (40–60 mg/day) results in rapid healing. Stubborn lesions may require intralesional triamcinolone. Milder forms of pyoderma gangrenosum sometimes respond to minocycline (100 mg twice daily). Other therapeutic agents include clofazimine, dapsone, cyclosporin, and topical disodium cromoglycate.

Digital ulceration occurs with Raynaud's phenomenon, particularly in systemic sclerosis. Patients should avoid excessive manicuring of the cuticles. Digital ulcers can be treated with a topical antimicrobial. Hydrocolloids or occlusive dressings can be helpful.

Management of specific disorders

Cutaneous lupus

A moderate to very potent steroid ointment is generally necessary for chronic discoid lesions, even on the face. Stubborn lesions may even require polythene occlusion. For small lesions, flurandrenolone tape can be cut to size. Prolonged use of topical corticosteroids produces telangiectasia and cutaneous atrophy. Rarely, intralesional triamcinolone (10 mg/ml) is necessary, particularly for lesions on the ears and nose. Injections should be directed as superficially as possible, but even so there is still a risk of atrophic scarring. Disfiguring lesions may respond well to excision and grafting or even dermabrasion. CO_2 laser therapy is an alternative destructive technique (Henderson and Odom 1986)

Sunscreens should be used regularly and, in some cases of subacute cutaneous lupus (Fig. 22), may be the only therapy required.

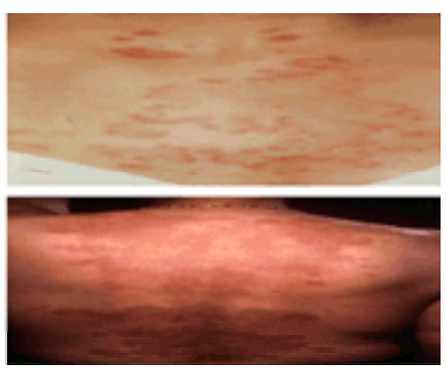

Fig. 22 Subacute cutaneous lupus erythematosus affecting (a) the neck and upper chest, (b) the back. This condition flared after sun exposure and lesions cleared totally with the use of a sunscreen.

In many patients, systemic therapy is necessary. Antimalarials are the drugs of choice, either hydroxychloroquine (400 mg daily) or chloroquine (200 mg daily). Mepacrine may be preferred, although it causes yellow discoloration of the skin and sclerae in therapeutic doses (Fig. 23). (This may enhance the photoprotective effect of the drug.) A combination of two antimalarials may have a synergistic effect without necessarily increased toxicity, although this observation has not yet been confirmed in a controlled study. Although the retinal risk is minimal, patients on antimalarials continuously should have annual ophthalmological assessments. Other drugs used in cutaneous lupus include clofazimine (100 mg daily), dapsone (50–100 mg daily), azathioprine (Askinoff *et al*. 1988), and oral gold (6 mg daily). Aromatic retinoids such as acetretin (50–75 mg daily) (Ruzicka *et al*. 1988) decrease hyperkeratosis and can be used together with antimalarials. Some patients with chilblain lupus or lupus profundus respond dramatically to thalidomide (Knop *et al*. 1983). It is unusual for systemic steroids to be necessary for cutaneous lesions alone.

Fig. 23 Yellow pigmentation of the skin and sclerae due to mepacrine.

Dermatomyositis

Extensive skin lesions can be treated with a moderately potent topical steroid. Sunscreens are important. Systemic treatment is usually required. Mild cases respond well to antimalarials but most require corticosteroids, initially in moderately high doses (1 mg/kg body wt) with an immunosuppressive agent, such as methotrexate, as a steroid-sparing agent.

Scleroderma

Localized forms of scleroderma (e.g. morphoea) are often self-limiting, although a topical corticosteroid or occasionally intralesional triamcinolone may help. Extensive lesions may require systemic therapy. Penicillamine (300–600 mg daily) appears to 'soften' skin lesions and may reduce contractures (Fig. 24). Sulphasalazine has been used in generalized morphoea. Severe hemifacial atrophy and ossifying lesions may respond well to plastic surgical reconstruction, sometimes with tissue expansion (Handfield-Jones *et al*. 1988).

Fig. 24 Linear morphoea: this patient observed increased joint mobility and softening of the skin following penicillamine therapy.

Treatment of the skin lesions in systemic sclerosis is generally supportive, and includes emollients, and treatment of digital ulcers.

Itch is often a major symptom in patients with systemic sclerosis. Its cause is unclear. Symptomatic treatments include the use of emollients such as aqueous cream or emulsifying ointment, applied directly to the skin or as soap substitutes; these also counteract dryness of the skin. Sedative antihistamines may help, as may topical preparations such as 1 to 2 per cent menthol in aqueous cream, or even topical corticosteroids.

Digital ulcers may respond to topical nitroglycerine or stable prostaglandins. In severe digital ulceration, or incipient gangrene of a digit, intravenous infusions of vasodilators such as prostaglandin E_1 or prostacyclin may be helpful.

Psoriasis

Superficial lesions (e.g. guttate psoriasis) respond to topical tar preparations, the topical vitamin D analogue, calcipotriol, or dilute corticosteroids. Potent steroids should not be used. Dithranol is used for thicker plaques. Its use should be supervised carefully as it is irritant and stains skin and clothing. Several different concentrations and bases are available. Initially a weak preparation (e.g. 0.1 per cent) can be used as short-contact therapy and washed off after 30 to 120 min. The strength and duration of therapy can be increased gradually. Dithranol must not be used on the flexures or face. Often admission or day-centre therapy is necessary. Other treatments include tar baths and ultraviolet light.

A minority of patients with extensive or unstable disease (e.g. generalized pustular psoriasis) will require second-line therapy. This includes drugs such as etretinate and acetretin, aromatic retinoids related to vitamin A. They are teratogenic and may cause hypercholesterolaemia and hypertriglyceridaemia. Methotrexate, in low weekly dosage (5–15 mg) is especially useful in erythrodermic or generalized pustular psoriasis, particularly in elderly people. Since the drug appears to be more hepatotoxic in patients with psoriasis than those with rheumatoid disease, most dermatologists would carry out routine liver biopsies in psoriatic patients under 65 years on long-term methotrexate therapy. Hydroxyurea (0.5–1.5 g) is sometimes of value in a proportion of patients; although it may cause short-term marrow toxicity, fatalities are rare (Layton *et al*. 1989). There are encouraging results from cyclosporin, initially 3 to 5 mg/kg per day, in patients with severe disease (Ellis *et al*. 1991), although the long-term renal toxicity of the drug is uncertain. Regular monitoring should include measurement of blood pressure, serum creatinine and measurement of glomerular filtration rate.

PUVA (psoralen + UVA) is valuable in recalcitrant psoriasis of hands and feet or in some individuals with widespread disease. It is particularly effective in combination with low-dose retinoids (Saurat *et al*. 1988). PUVA is potentially carcinogenic to the skin, particularly in patients who have previously received other carcinogens such as methotrexate.

Antimalarials should not be used in psoriatic arthritis, as they may exacerbate cutaneous psoriasis.

Cutaneous side-effects of antirheumatic therapy

Skin lesions are common in patients receiving antirheumatic therapy. They are often non-specific and trivial, although sometimes they may be severe enough to warrant stopping the drug. In the following we list important cutaneous adverse effects of the different forms of antirheumatic therapy (Breathnach and Hintner 1992; Lovell and Maddison 1992).

Non-steroidal anti-inflammatory drugs

1. Non-specific exanthems/morbilliform eruptions are common.
2. Generalized exfoliative dermatitis is rare (has been caused by phenylbutazone, oxyphenbutazone, and indomethacin).
3. Photoallergic reactions (e.g. caused by fenbufen, piroxicam).
4. Photo-onycholysis, skin fragility in light exposed sites, and features resembling porphyria cutanea tarda appear to be a direct phototoxic effect of drugs. These

effects were seen typically with benoxaprofen, but can occur with other non-steroidal anti-inflammatory drugs.
5. Acneiform lesions (e.g. caused by naproxen).
6. Stomatitis has been reported with indomethacin.
7. Urticaria may be immunologically mediated (e.g. caused by diclofenac, mefanamic acid) or may be a pharmacological effect of the drug (typically aspirin in patients with nasal polyposis).
8. Erythema multiforme and toxic epidermal necrolysis (Fig. 25) (Korstanje 1995) (e.g. caused by fenbufen, benoxaprofen, piroxicam, sulindac, and especially phenylbutazone, oxyphenbutazone, and diclofenac, where it has been fatal).

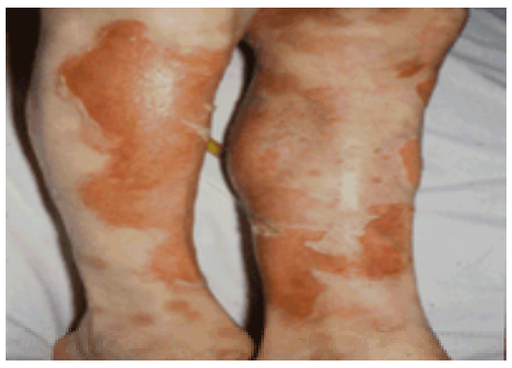

Fig. 25 Toxic epidermal necrolysis.

9. Fixed drug eruptions (Fig. 26). One or more well-demarcated erythematous lesions, sometimes with blistering, resolve, leaving persistent, dusky grey-black pigmented areas. The eruption occurs at the same site, with or without further lesions, on re-exposure to the drug. Systemic symptoms are few, if any, and re-exposure to the drug is justifiable if diagnostically necessary. Oxyphenbutazone is a classical cause, although a non-pigmenting fixed drug eruption has been reported due to piroxicam.

Fig. 26 Fixed drug eruption. A well-demarcated, often ovoid, dusky area of erythema, later followed by slatey hyperpigmentation.

10. Several topically applied non-steroidals (e.g. ketoprofen) cause allergic contact dermatitis and photoallergic contact dermatitis.
11. Purpura may be due to thrombocytopenia (e.g. caused by fenoprofen, phenylbutazone) or allergic vasculitis (e.g. caused by phenylbutazone, naproxen).

Gold

Cutaneous reactions occur at any stage of treatment in 25 per cent more of patients on intramuscular gold salts; they may require cessation of therapy. A high incidence of mucocutaneous side-effects appears to be linked with therapeutic efficacy. Gold-salt dermatitis appears to be related to HLA class I B35 antigen. Oral gold (auranofin) causes similar, although less severe, toxic reactions to intramuscular gold. Important side-effects include the following.

1. Pruritus.
2. Non-specific maculopapular/morbilliform eruptions—these may progress to fatal erythroderma if the drug is continued.
3. An eczematous or pityriasis rosea-like eruption. Even in relatively banal eruptions, histology may reveal striking features resembling lichen planus. Typical lichen planus (Fig. 27) may develop, with hyperkeratotic changes, especially in the scalp, sometimes causing scarring alopecia.

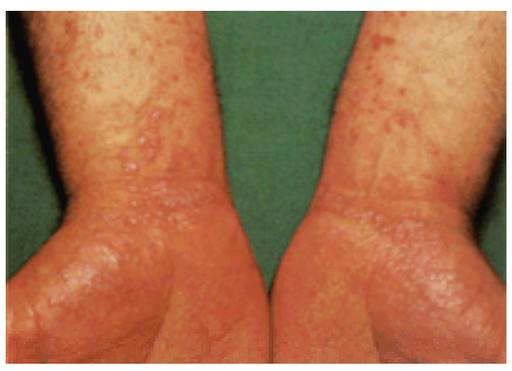

Fig. 27 Lichen planus: typical violaceous papules. Drug-induced lichen planus may be indistinguishable from the idiopathic form or may also exhibit eczematous features.

4. Intramuscular gold therapy may reactivate pre-existing nickel sensitivity (e.g. to jewellery).
5. Punctuate or aphthous stomatitis (common, may be the only adverse effect).
6. Purpura due to thrombocytopenia or (rarely) vasculitis.
7. Erythema multiforme and toxic epidermal necrolysis (rare).
8. Prolonged gold therapy may cause slate-grey pigmentation (chrysiasis), especially in light-exposed sites.

D-Penicillamine

Many adverse effects from this drug are similar to those seen in gold therapy. An urticarial or morbilliform eruption is common early in therapy, although usually it can be avoided by a 'go low, go slow' dose regimen.

Immunologically mediated skin reactions may mimic inflammatory dermatoses such as lichen planus. The eruptions may persist for several years after the drug is discontinued. Typical cicatricial pemphigoid may occur, with the development of fibrous conjunctival bands (synechiae). Pemphigus foliaceus is the most common pattern induced by penicillamine; it may be mild and the crusted erythematous truncal lesions may mimic eczema (Fig. 28). However, direct immunofluorescence of uninvolved skin reveals the characteristic intercellular deposition of IgG. More rarely, the drug may induce pemphigus vulgaris, in which flaccid bullae rupture to form extensive eroded areas of skin. Oral lesions and vulvovaginitis may occur. Penicillamine may precipitate lesions closely resembling morphoea, systemic sclerosis, dermatomyositis, and both discoid and systemic lupus erythematosus. Antibodies to native DNA are found, unlike in other forms of drug-induced lupus. Other

inflammatory adverse effects include thrombocytopenic purpura, stomatitis, glossitis, and alopecia.

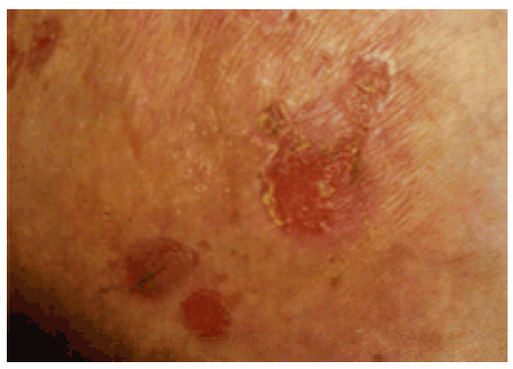

Fig. 28 Pemphigus foliaceus of the trunk, induced by D-penicillamine. The superficial, eroded eruption can be confused with eczema.

Penicillamine has a profound effect on connective tissue proteins: it inhibits collagen synthesis and cleaves newly formed intermolecular cross-links; it also stimulates elastin synthesis. Although effects on connective tissue are generally associated with the high doses used in metabolic disorders such as Wilson's disease, elastosis perforans serpiginosa has been reported in one child receiving penicillamine for rheumatoid arthritis. Typical features include serpiginous and annular crusted plaques on the limbs. Histological changes include transepidermal elimination of elastin. Pseudoxanthoma elasticum-like changes and elastosis may occur in relatively low doses (e.g. 750 mg/day).

Sulphasalazine

Eruptions caused by the sulphapyridine moiety are typical of those induced by sulphonamides in general. They include:

1. leucocytoclastic vasculitis;
2. photosensitivity;
3. a pruritic, scaly, maculopapular eruption (common)—desensitization may be possible;
4. a lupus-like syndrome;
5. erythema multiforme/toxic epidermal necrolysis (rare).

Antimalarials

Reactions include:

1. diffuse grey itchy pigmentation, especially in light-exposed areas;
2. blackish pigmentation (especially nose and ears) due to acquired ochronosis—nails may also be affected;
3. bright yellow pigmentation (mepacrine);
4. bleaching of red or blonde hair;
5. photosensitivity or exacerbation of porphyria cutanea tarda;
6. exacerbation of psoriasis;
7. toxic epidermal necrolysis (rare);
8. lichenoid eruptions (rare);
9. a generalized pustular eruption (hydroxychloroquine).

Corticosteroids

Reactions include:

1. atrophy, telangiectasia, and easy bruising;
2. increased risk of cutaneous sepsis;
3. dermal atrophy, causing dimpled scars (Fig. 29)—this may follow injudicious local infiltration with corticosteroids.

Fig. 29 Dermal atrophy from corticosteroid injection.

Immunosuppressive drugs

Reactions include:

1. Opportunistic infections (e.g. multiple warts and molluscum contagiosum lesions) may follow chronic immunosuppressive therapy (e.g. with azathioprine and methotrexate).
2. Cytotoxic agents cause alopecia.
3. Pigmentation of skin and nails occurs with cyclophosphamide.
4. Hypersensitivity reactions to azathioprine may present as an exanthem or generalized urticarial eruption.
5. Orogenital ulcers occur typically with methotrexate.

Some key points for skin manifestations of rheumatic diseases (Table 6)

1. Examination of the skin in good light may clarify a rheumatological diagnosis. Examine skin thoroughly, including nailfolds, genitalia, and feet. Examine oral mucosa.
2. Describe and record skin lesions accurately
3. Skin biopsy for conventional histology or immunofluorescence is often helpful. Try to biopsy an early lesion and orientate correctly.
4. Cutaneous manifestations of rheumatic diseases require specific, often topical, therapy. Don't be afraid to use potent topical corticosteroids in cutaneous lupus—but keep under review. Don't overtreat cutaneous lupus with systemic therapy.
5. Antirheumatic drugs produce a wide range of skin side-effects; even after several months of therapy, cutaneous intolerance may develop. In any rash that doesn't fit a precise pattern—consider a drug cause.
6. Stress the importance of photoprotection.

1.3.3 Neurological complications

I. T. Ferguson and Peter Hollingworth

Introduction

When acute, as in cervical cord compression, neurological complications are among the few rheumatological emergencies. When they cause a gradual functional decline, they may be misconstrued as deterioration of the arthritis. Either way, the addition of weakness or sensory symptoms to an already painful, stiff limb may result in severe disability. Drugs used in the treatment of rheumatic diseases (Blain and Stewart-Wynne 1986 ; Mastaglia 1989) can themselves cause neurological side-effects (Table 1). Coincidental neurological diseases must be considered in the differential diagnosis and some neurological disorders have musculoskeletal manifestations (Table 2). Such is the interplay between rheumatological and neurological disorders that the rheumatologist must be alert to the diagnostic pitfalls they present (Table 3).

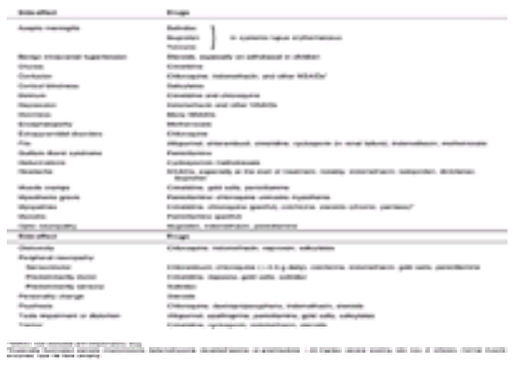

Table 1 Neurological side-effects of drugs used for rheumatic disorders

Neurological disorders	Rheumatic symptoms and signs
Parkinson's disease	Partial, stiff shoulder, arm or hand; less frequently lower limb
Multiple sclerosis	Stiff (spastic) legs may be confused with or coincide with cervical spondylitic myelopathy
Spinal cord tumour	Radicular pain with aching, stiff legs; legs feel swollen with dorsal column involvement
Dorsal root entry-zone lesion e.g. multiple sclerosis, tumour, neuropathies	Lightning limb pains
Motor neurone disease	Wasted hand, confused with T1 root lesion from cervical spondylosis
Syringomyelia, tabes dorsalis, primary sensory neuropathy, diabetes	Neuropathic joints; swollen fingers (*main en casserole*) with syringomyelia
Hereditary sensorimotor neuropathy (Charcot-Marie-Tooth)	Pes cavus
Myotonias	Stiff hands, often worse in cold
Myasthenia	Weak, sometimes aching muscles, may be confused with polymyositis

Table 2 Neurological disorders presenting with rheumatic symptoms (see also Table 3)

Table 3 Some important points to remember

Accurate assessment of power, tone, reflexes, or the plantar response may be impossible in a limb already weak, stiff, or deformed from arthritis, so recognition of

these complications demands a high index of suspicion and help from sophisticated investigations.

The recognition of patterns of symptoms and signs is necessary in forming a diagnosis (Box 1).

Box 1 Important points for the rheumatologist to remember

1. Joint damage often prevents a meaningful clinical assessment of neurological symptoms, so special investigations are usually necessary.
2. Beware of attributing deteriorating function to progression of joint disease in rheumatoid arthritis: consider superimposed neurological complications.
3. Be alert to hysteria, mimicking neurological disease, coexisting with rheumatological or organic neurological diseases.
4. The differential diagnosis of cerebral lupus includes complications of lupus uraemia, sepsis and hypertensive encephalopathy, and side-effects of drugs in its treatment.
5. Cervical myelopathy and rheumatoid arthritis is suggested by deteriorating function, 'electric shocks' in the arms; recent worsening of neck pain.
6. Mononeuritis multiplex may progress rapidly and is a rheumatological emergency.
7. Entrapment neuropathies are the commonest neurological complication of rheumatic diseases.

Weakness patterns

The distribution of weakness is important. Symmetrical, proximal weakness suggests muscle disease but other causes should be considered (Table 4). Difficulty getting out of a chair, climbing stairs, lifting objects from a high shelf, or brushing hair are common.

Table 4 Causes of proximal weakness in adults

In upper motor neurone disease, shoulder abductors and arm extensors are affected more than the flexors, whereas in the legs the flexors are affected more than the extensors. Hyper-reflexia, hypertonia, and an extensor plantar response are usually present.

Myasthenia gravis is characterized by fluctuating weakness with fatiguability. The weakness tends to be proximal and associated with diplopia and dysarthria towards the end of the day. Symptomatic myasthenia responding to intravenous edrophonium can occur in polymyositis, where a reduced number of acetylcholine receptors has been demonstrated. Penicillamine may produce myasthenia responsive to the edrophonium test. Antibodies to acetylcholine receptors are present and recovery usually follows withdrawal of the drug. The Eaton–Lambert syndrome, with painful, proximal muscle weakness, is not associated with antibodies to acetylcholine receptors. Three-quarters of males and 30 per cent of females will have an underlying carcinoma. Electromyography is diagnostic.

Distal weakness usually results from disease of peripheral nerves, either of their roots or a polyneuropathy. Involvement of specific muscle groups may allow precise anatomical localization (Guarantors of Brain 1988). Weakness of one limb is usually neurogenic, except for tendon rupture. The differential diagnosis includes motor neurone disease, neuralgic amyotrophy, and early fascioscapulohumeral dystrophy. Hysterical or non-organic weakness (Table 5) is commonly superimposed on organic disease (Marsden 1986).

Great display of effort to little effect
Intermittent or jerky weakness
Simultaneous contraction of agonist and antagonist muscles
Failure of stabilizing or synergistic muscles to contract when testing limb power
Inconsistencies in performance: for example the patient may have weak quadriceps when lying on the couch yet be able to walk, squat, or jump normally

Table 5 Features of hysterical weakness

Muscle pain

When at rest, this is rarely from primary muscle disease. Exertion pain is commonly non-organic, once peripheral vascular disease has been excluded. However, McArdle's disease (mild myophosphorylase deficiency) and phosphofructokinase deficiency should be considered if the pain is in the calves, increases with further exertion, and leads to myoglobulinuria. The ischaemic lactate test, electromyography, and muscle biopsy are necessary for diagnosis.

Muscle twitching

Fasciculation is painless, visible, muscle contractions of small groups of muscle fibres, often felt by the patient. It is benign in the absence of weakness or wasting which, if present, suggests anterior horn cell disease or motor neuropathy. Fibrillation is contraction of single fibres seen in the tongue or exposed muscle, and may be recorded by electromyography. Myokymia is a slower or coarse contraction of bands of muscle fibres, most often seen in healthy individuals. Facial myokymia can occur in brain-stem multiple sclerosis and Whipple's disease.

Contractures

These occur in both neurogenic and myopathic muscle disease; Duchenne muscular dystrophy, spinal muscular atrophy, and Friedreich's ataxia are common causes. They may develop rapidly in acute polymyositis.

Reflex patterns

Deep tendon reflexes may be absent at joints stiffened by arthritis. The plantar response may be difficult to assess in hallux valgus or after Keller's operation. Absent ankle jerks after the age of 60 is often normal. Exaggerated reflexes, especially with clonus, point to an upper motor-neurone lesion. Absent or depressed reflexes occur in peripheral neuropathies. A combination of an absent segmental reflex and hyper-reflexia below that level, as in the inverted supinator sign (absent biceps and supinator jerk but present triceps jerk, indicating a C5/6 cord lesion), is of considerable localizing value. In polymyositis, the reflexes may be increased, possibly

because of muscle spindle hyperexcitability secondary to inflammation.

Sensory patterns

Sensory loss may be the most important clue to involvement of the nervous system in patients with arthritis. The distribution and type of sensory deficit usually permits anatomical localization (Guarantors of Brain 1988); for example anaesthesia of the little finger and ulnar half of the ring finger and palm, extending no further than the wrist crease, indicates an ulnar nerve lesion rather than a C8 radiculopathy.

Knowledge of key dermatomes (Fig. 3) and the area supplied by peripheral nerves is essential. Loss of pain and temperature with sparing of joint position sense points to a cord or brain-stem lesion. Cervical cord compression from atalantoaxial subluxation may be confused with a peripheral neuropathy, as the sensory loss can be in a glove-and-stocking distribution, perhaps from cord ischaemia. As sensory examination is subjective, electrophysiological testing may be the only way to determine the site of nerve damage.

Fig. 3 Variation and overlap occurs between dermatomes. Also applies to fingers, but thumb is usually supplied by C6 and little finger C8. (Adapted from Guarantors of Brain 1988.)

Central nervous system involvement in rheumatic diseases

Fortunately, central nervous system complications are a common manifestation of only the rarer rheumatic diseases. Most are mild and self limiting, but some have devastating consequences. Difficulties abound in understanding these complications as there is a dearth of agreed diagnostic criteria, specific signs, laboratory tests, or imaging techniques. When a patient with a rheumatic disease disorder develops central nervous system disease, one should ask whether it is:

1. a direct complication and, if so, is it residual or progressive;
2. secondary to another complication, such as uraemia, infection, or hypertension;
3. a side-effect of therapy, such as steroid psychosis or drug-induced systemic lupus erythematosus;
4. non-organic, such as hysteria or depression;
5. coincidental, such as a cerebral thrombosis from atheroma.

The most common and closely studied central nervous system disorders that present to the rheumatologist occur in systemic lupus erythematosus (Feinglass *et al*. 1976; Gibson and Myers 1976; Adelman *et al*. 1986) and the allied lupus-like and antiphospholipid syndrome (Hughes 1985; Asherson *et al*. 1989). Details are given in the appropriate chapters but how these concern the neurologist will be considered in depth here.

Neuropsychiatric systemic lupus erythematosus

The incidence of neuropsychiatric systemic lupus erythematosus may be as high as 50 per cent (Hanly *et al*. 1992) but the incidence of serious complications, as opposed to minor psychiatric disturbance, is far less. The most common features are depression, fits, and headaches, although virtually every manifestation of central nervous system disease has been described (Singer and Denburg 1990), including subtle cognitive defects in memory, intellect, and learning (Hanly *et al*. 1994). Most victims are young women. It usually occurs when the systemic lupus erythematosus is active and early in its course, though some patients have had seizures for years before the patient presents with other manifestations. (Details are given in Chapter 5.7.1)

Pathogenic factors

1. Antineuronal antibodies, directed notably against the cytoskeletal neurofilaments, tend to be associated with diffuse neuropsychiatric systemic lupus erythematosus (Robbins *et al*. 1988).
2. IgG anticardiolipin antibodies occur in patients with antiphospholipid syndrome and in 20 to 50 per cent with systemic lupus erythematosus. By their action on platelet and endothelial cells, they predispose to thrombosis of arteries, veins, and venous sinuses as well as cross-reacting with sphingolipids. They tend to be associated focal lesions in neuropsychiatric lupus (McHugh *et al*. 1988).

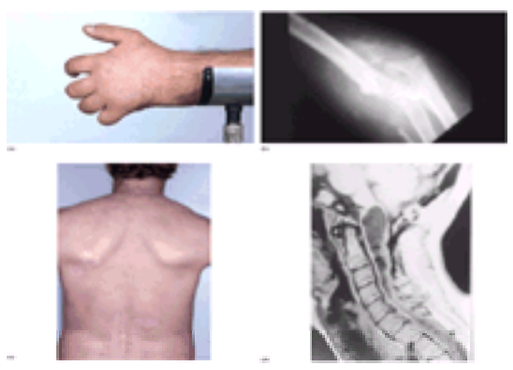

Fig. 1 Syringomyelia.

3. Vegetations on the aortic and mitral valves of some patients carrying anticardiolipin antibodies might be a source of emboli to the brain, causing transient ischaemic attacks, strokes, or dementia (Asherson *et al*. 1987; Asherson and Lubbe 1988).
4. Cerebral vasculitis, causing ischaemia, oedema, and infarction is rare.
5. Antiribosomal P antibodies might be associated with lupus psychosis and severe lupus depression. An initial study (Bonfa *et al*. 1987) found that 90 per cent of those suffering from lupus psychosis carried high levels of these antibodies, and that the levels of these antibodies rose before or during the psychotic episode, suggesting both a diagnostic and predictive value in measuring anti-P antibodies.

However, half of all the lupus patients in this study who carried anti-P antibodies did not suffer from lupus psychosis and six subsequent studies have given conflicting results (Derksen *et al*. 1990; Schneebaum *et al*. 1991; Nojima *et al*. 1992; Van Dam *et al*. 1991; Sato *et al*. 1991; Teh *et al*. 1992), either confirming or refuting the initial findings or suggesting an association of raised levels of these antibodies with severe lupus depression. Until the position is clarified, single or sequential measurement of anti-P antibodies is felt to be of no value (Teh and Isenberg 1992).

Fig. 2 Neuralgic amyotrophy with winging of the scapula.

Investigations

The diagnosis of neuropsychiatric lupus is based principally on symptoms and signs, but the most useful, generally available investigations (Schrieber *et al*. 1988) are listed below.

1. Formal neuropsychological testing may be the most sensitive and clinically useful measure of brain function in systemic lupus erythematosus; it measures function rather than structural abnormalities, it is non-invasive, objective, and it can be used serially (Ginsburg *et al*. 1992). Shortened versions of these tests are available (Jacobs *et al*. 1977).
2. Magnetic resonance imaging. Three distinct patterns detected by increased intensity of T_2 weighted images are recognized (Aisen *et al*. 1985; Molad *et al*. 1992).
   a. Small, multifocal lesions in the white matter, not detected on computed tomography probably represent microinfarcts or demyelination.
   b. Large lesions, also in the white matter and evident on computed tomography, are infarcts.
   c. Large lesions in the grey matter, not evident on computed tomography, are caused by oedema. The lesions may resolve or evolve to infarction (Sibbitt *et al*. 1989).

   Magnetic resonance imaging also detects intracranial catastrophes such as cerebral venous thrombosis, haematoma, abscess, and tumour. Patients with focal neurological findings or seizures are more likely to have abnormalities detected by magnetic resonance imaging than computed tomography, but it cannot diagnose neuropsychiatric lupus in the absence of clinical features.
3. Electroencephalography. Abnormalities are found in 80 per cent. Focal changes are associated with fits and focal neurological deficits, and diffuse changes with organic brain syndrome. Serial evaluation may monitor disease activity in response to treatment (Ritchlin *et al*. 1992).
4. Anticardiolipin antibody. This may be associated with thromboses or emboli that may warrant anticoagulation (Asherson and Lubbe 1988).
5. Echocardiography. Valvular vegetations as a possible source of emboli may be demonstrated if anticardiolipin antibodies are present.

Analysis of cerebrospinal fluid is important to exclude infectious meningitis. In acute, unstable, catastrophic central nervous system disease, computed tomography scanning will identify haemorrhage, large infarction, abscess, or tumour. Blood levels of anti-DNA antibody, complement, and immune complexes do not correlate with neuropsychiatric lupus. Less frequently available but useful investigations are positron emission tomography, which detects reduced cerebral metabolism (Stoppe *et al*. 1990), and single-photon-emission tomography which detects abnormalities of cerebral blood flow (Nossent *et al*. 1991).

Differential diagnosis

Exclusion of the many complications of systemic lupus erythematosus or its treatment which have central nervous system manifestations (Table 6) is imperative (Futran *et al*. 1986).

Septicaemia
Intracranial sepsis
Accelerated atherosclerosis
Hypertensive encephalopathy
Uraemic encephalopathy
Psychiatric disorders
Emboli from valvular vegetations
Drug side-effects, especially steroid psychosis[1]
Multifocal leucoencephalopathy

[1]See Table 1.

Table 6 Other complications of systemic lupus erythematosus or its treatment with central nervous system manifestations

Treatment

Most patients have mild, self-limiting disease that does not warrant treatment. Corticosteroids and cytotoxic drugs are often given for serious manifestations but their value is unproved. Patients receiving more than 100 mg/day of prednisolone for more than a month are at greater risk of dying from infection than neuropsychiatric lupus (Sargent *et al*. 1975). The evolution of irreversible lesions on serial magnetic resonance imaging could be an indicator for starting treatment, which should be early to prevent progression or new lesions developing (Sibbitt *et al*. 1989).

It is imperative to consider whether other factors are contributing to the clinical picture that would respond to different treatment (Table 7).

Subdural haematoma
Persistent intracerebral haemorrhage causing symptoms or signs
Some patients with chorea from antiphospholipid syndrome have strokes which may be prevented by prophylactic warfarin or aspirin
Multiple emboli associated with valvular vegetations in antiphospholipid syndrome causing transient ischaemic attacks or multi-infarct dementia also respond to the above regimen
Organic depression can respond to antidepressants

Table 7 Features of neuropsychiatric systemic lupus erythematosus requiring specific treatment

Antiphospholipid syndrome (see Chapter 5.7.3)

Anticardiolipin antibody appears to be responsible for the thrombotic and, possibly, embolic manifestations that occur in systemic lupus erythematosus, lupus-like syndromes, and antiphospholipid syndrome. Most patients have a history of a multiplicity of seemingly unrelated disorders, notably livedo reticularis, hypertension, and a history of deep venous thromboses (Asherson *et al*. 1989). Antiplatelet drugs or anticoagulation may be indicated. The principal neurological manifestations are:

1. cerebral thromboses;
2. progressive dementia, either in isolation or associated with repeated cerebrovascular accidents resulting from multiple emboli that arise from cardiac vegetations;
3. transient ischaemic attacks;
4. chorea, sometimes in pregnancy or as a harbinger of a stroke;
5. global amnesia;
6. transverse myelitis (see below).

Other connective tissue diseases

Central nervous system disease occurs in polyarteritis nodosa, Wegener's granulomatosis, mixed connective tissue disease, scleroderma, Sjögren's syndrome (Hietaharju *et al*. 1992), and giant cell arteritis, but far less frequently than in systemic lupus erythematosus or antiphospholipid syndrome. Cranial nerve lesions (see below) may predominate. Vasculitis, anticardiolipin antibodies, and overlap with systemic lupus erythematosus are the principal factors (Shannon and Goetz 1989). Other rheumatic disorders may have central nervous system manifestations (Table 8).

Behçet's syndrome	Recurrent neurological symptoms, principally brainstem (Table 9)
Hyperviscosity syndrome	The rheumatological associations are Sjögren's syndrome and rheumatoid arthritis; diverse symptoms occur often with confusion, ataxia, and visual symptoms; retinopathy may be marked with engorged tortuous veins
Lyme disease	Early: aseptic meningitis
	Late: 15 per cent develop a fluctuating meningoencephalitis with cranial nerve lesions
Sarcoidosis	Cranial nerve lesions, aseptic meningitis, fits, hydrocephalus
Takayasu's arteritis	Carotid or vertebrobasilar ischaemia (see below)
	Retinopathy with arteriovenous anastomoses around the disc
Whipple's disease	Slow progression of apathy, personality change, memory loss, or hypersomnia
	Occasionally, cranial nerve lesions, basal myelopathy, facial, motor, or sensory signs

Table 8 Other rheumatic diseases with central nervous system manifestations

Brain-stem syndromes

The brain-stem comprises the mid-brain, pons, and medulla. It conducts the major motor and sensory tracts and gives rise to all the cranial nerves except the olfactory and optic. The vertebrobasilar arteries supply the brain-stem and the cerebellum, as well as the cerebrum via the circle of Willis. The features of brain-stem disease are listed in Table 9. The principal rheumatological associations are:

Bilateral motor or sensory long-tract signs
Crossed (face/limb) motor or sensory signs
Dissociated pain and temperature loss
Cerebellar signs
Stupor or coma
Dysconjugate eye movements; nystagmus
Horner's syndrome
Unilateral deafness or pharyngeal weakness (these cranial nerves are not affected by single hemispheric disease)
Bulbar weakness

Table 9 Features of brainstem disease

1. vertebrobasilar insufficiency;
2. inflammatory conditions, notably Behçet's disease and connective tissue diseases;
3. platybasia from vertical and atlantoaxial subluxation or Paget's disease.

Vertebrobasilar insufficiency occurs in cervical spondylosis, atlantoaxial subluxation, giant cell arteritis, and Takayasu's arteritis. Its manifestations are myriad but the principal features are diplopia, circumoral numbness, dysarthria, and ataxia. Symptoms are often provoked by moving the head (Brust 1989).

Cranial nerve palsies

These occur in brain-stem disease or as a cranial neuropathy. They may be single or multiple, so only the notable associations are mentioned in (Table 10).

Brainstem disease (see above)
Connective tissue diseases: any nerve may be affected, in any combination, but notably trigeminal neuropathy in scleroderma and mixed connective tissue disease.
Giant-cell arteritis: optic; oculomotor
Lyme disease: multiple
Sarcoidosis: facial; optic chiasm
Whipple's disease: multiple

Table 10 Cranial nerve palsies in rheumatic diseases

Spinal cord disease

Only cervical myelopathy consequent to rheumatoid arthritis or cervical spondylosis presents to the rheumatologist with any frequency. Other causes (Table 11) usually affect the thoracic or lumbar cord. Most result from compression of the cord or its blood supply by vertebral structures, so neck or back pain are usually, but not always, found in association with spastic weakness of the limbs and radicular signs at this level.

Cervical disc prolapse
Cervical spondylosis
Paget's disease
Rheumatoid arthritis
Spinal tuberculosis
Staphylococcal discitis

Table 11 Rheumatic diseases complicated by myelopathy

Magnetic resonance imaging has major advantages over other forms of imaging as it distinguishes the cord from other structures and identifies compression from soft tissues, such as rheumatoid pannus. It can be performed with the neck in flexion, and axial views show irreversible changes such as myelomalacia. Magnetic resonance imaging uses non-ionizing radiation and the contrast medium, gadolinium, is not toxic.

Cervical myelopathy and rheumatoid arthritis

While subluxation of the cervical spine is common in rheumatoid arthritis (25–36 per cent) (Winfield *et al*. 1981) cervical myelopathy is rare and mostly in those with long-standing, crippling disease. Half will die within 5 years, often from unrelated causes (Nakano 1975). Compression is usually at the craniocervical junction from anterior or vertical atlantoaxial subluxation, and less frequently from subaxial subluxation. Compression may not occur with large displacements when the canal is roomy, or it may be caused by pressure from pannus, evident on magnetic resonance imaging (Komusi *et al*. 1985), with only small displacements. In half, the myelopathy progresses unless halted by surgery.

Recognition of this potentially fatal complication is often delayed for months, thereby jeopardizing surgical success, as functional decline is usually so insidious it may be dismissed as deterioration of the arthritis.

A high degree of suspicion is necessary and the principal indicators that should alert the rheumatologist are:

1. recent (less than 18 months) neck pain or occipital neuralgia;
2. paraesthesias or numbness in the limbs or trunk, 'electric-shocks' on neck movement such as lifting the head off the pillow or reading;
3. the patient's own account of diminished motor ability or documented change since the last examination (Crockard *et al*. 1985).

Paraesthesias may be in a glove-and-stocking distribution that could be mistaken for a peripheral neuropathy. Patients with spinothalamic involvement often describe sensations of heat or cold. Posterior column symptoms include sensations of the leg being encased in plaster or walking through quicksand. Spastic weakness may affect arms or legs. Compression of vertebral arteries may cause symptoms of vertebrobasilar insufficiency. Sphincter disturbance, usually urinary retention, occasionally occurs. An acute quadriparesis may follow a fall, whiplash injury, or forcible hyperextension during anaesthesia.

Manubriosternal joint subluxation in rheumatoid arthritis is associated with major deformities of the cervical spine, perhaps from the weight of the head causing chronic flexion of the neck (Khong and Rooney 1982).

Recognition of cord compression and assessment of its progression relies heavily on the history: evaluation of motor signs is difficult with destroyed joints and sensory symptoms are often patchy and transient. Demonstration of obscure 'textbook' signs of atlantoaxial instability may entertain, but do not guide management.

Surgical decompression may halt deterioration of the myelopathy and is recommended even in the relatively symptomless patient (Agarwal *et al*. 1992). Subaxial subluxation may need stabilization at the same time or may develop later (Henderson *et al*. 1993).

Other causes of atlantoaxial subluxation include Jaccoud's arthropathy complicating systemic lupus erythematosus (Babini *et al*. 1990), ankylosing spondylitis (Hunter 1989), juvenile chronic arthritis, Down's syndrome, Klippel-Feil malformation, multiple epiphyseal dysplasia, and rheumatic fever.

Myelopathy caused by cervical spondylosis

Complaints of difficulty climbing stairs, heaviness, stiffness or dragging of the legs, suggesting spastic weakness, in a patient with neck pain, should alert the rheumatologist to this complication. Other symptoms include paraesthesias, numbness or aching of the legs, or weakness of the arms. Sphincter disturbance is rare. A history of recurrent brachial neuralgia is uncommon in these patients.

Neurological signs are always present; 80 per cent have weakness, either of the arms or a para-, hemi-, or quadriparesis, with hyper-reflexia in most and an extensor plantar response in half. Hand muscles may atrophy and mimic syringomyelia. Fasciculation, attributed to interference with the descending blood supply to the lumbar segment, is sometimes present in the legs and can confuse the diagnosis with amyotrophic lateral sclerosis. The most useful clinical sign is sensory loss in the arms in a dermatomal pattern, but the usual picture is patchy sensory loss in the arms, together with a combination of dorsal column and/or spinothalamic tract involvement in the legs, usually without a clear sensory level. Cord damage is chiefly at levels C4–C7 and results from a combination of direct pressure from osteophytes, disc degeneration or ligamentous hypertrophy, trauma during neck movement, and interference with the spinal blood supply. Magnetic resonance imaging and computed tomography myelography are the preferred investigations.

Laminectomy should be recommended with caution; untreated most patients are little changed after many years. Alternative or additional disorders may be present (atheroma of the vertebral and carotid arteries, multiple sclerosis, amyotropic lateral sclerosis, neurosyphilis, spinal tumours). Surgery improves only half (Rowland 1989).

Transverse myelitis in systemic lupus erythematosus or antiphospholipid syndrome

The onset of this rare complication is dramatic with paraesthesias, numbness, and weakness ascending over hours to a thoracic level, and always associated with loss of sphincter function. Magnetic resonance imaging can be useful in the diagnosis and monitoring of these patients (Lavalle *et al*. 1990; Boumpas *et al*. 1990). Even high-dose prednisolone does not affect the poor prognosis, but improvement has been reported following pulse intravenous methylprednisolone followed by repeated pulses of intravenous cyclophosphamide (Barile and Lavalle 1992).

Cauda equina syndrome

This rare complication of ankylosing spondylitis develops after more than two decades, often when the disease is clinically inactive. Arachnoiditis causes adhesions

resulting in an enlargement of the caudal sac and arachnoid cysts causing pressure erosion of the adjacent bone and damage to the cauda equina. The principal presenting features are sensory with paraesthesias, pain or numbness in the perineum, buttocks, or lower limbs. Sometimes there is sphincter disturbance and, later, motor impairment. Computed tomography may be diagnostic. Decompression of the cyst, either at laminectomy or by shunting, has variable success (Tyrrell *et al*. 1994; Mitchell *et al*. 1990).

Peripheral nervous system involvement in rheumatic diseases

Radicular pain

The most common causes of radicular pain in rheumatological practice are cervical spondylosis and lumbar disc disease (Bland 1990), which are described in detail elsewhere. However, several points should be stressed.

1. Arm and leg pains associated with spinal disease are often wrongly attributed to nerve root (radicular) compression. In fact, the pain is commonly referred from muscles, tendons, joint capsules, and ligaments. This pain is perceived away from the site of origin; it radiates widely (from the cervical spine to the hand, arm, chest, and scapula regions; from the lumbar spine to the sacroiliac region, buttocks, and posterior thigh) in a poorly localized, non-dermatomal distribution, more proximally than distal. It is felt as a deep, aching pain and is not associated with neurological signs (Bland 1990).
2. Radicular pain is less common. It arises from compression (or ischaemia) of the dorsal roots or their ganglia from osteophytes, disc herniation, oedema, or fibrous tissue. Radicular pain follows a dermatomal pattern, it is perceived as sharp and lancinating, and is usually exacerbated by movement of the spine, coughing, or sneezing. Paraesthesias in a dermatomal distribution are often associated. Signs of nerve root compression or irritation are usually present (Fig. 4). Dermatomal numbness or myotomal weakness may occur.

Fig. 4 A right cervical 5th and 6th nerve root lesion with wasted biceps.

3. Soft tissue rheumatism in the arm (shoulder lesions, epicondylitis, carpal tunnel syndrome, de Quervain's tenosynovitis) are strongly associated with cervical spondylosis, possibly unmasked by radicular compression in the neck.
4. Compression of the lumbar nerve root from disc herniation is too frequently diagnosed. The straight leg raising test is specific, but only under the age of 30, and only for L5/S1 lesions; for higher lesions the femoral stretch test is indicated. The straight leg raising test is deemed positive only when it is restricted to less than 40° by the radicular pain. A crossed, straight leg raising test is even more specific; radicular pain is felt on the affected side when the contralateral leg is lifted. Loss, but not depression, of a reflex is a valuable localizing sign.
5. Radicular pain may be mistaken as arising from other structures sharing the same dermatomes; for example C5 as shoulder pain, thoracic nerves as angina or pleurisy, L3 as hip pain, L5 as knee or ankle pain.

Peripheral neuropathies

Several kinds of peripheral neuropathy (Asbury and Gilliatt 1984) complicate rheumatic diseases (Table 12, Table 13) but may be overlooked if the resulting pain or weakness is taken as reflecting joint disease. Neuropathies may also be manifestations of another complication, for example uraemic neuropathy in systemic lupus erythematosus, a side-effect of therapy such as gold salts, or coincidental such as diabetic or alcoholic neuropathy (Fig. 5). Subclinical neuropathy may be unmasked by a second insult, so dual pathology, such as entrapment neuropathy together with polyneuropathy, should be considered. Confirmation is by electrodiagnostic studies. A nerve biopsy occasionally aids diagnosis.

Type	Clinical features
Polyneuropathy (see Table 13)	Distal sensory (glove-and-stocking) and motor impairment; areflexia
Mononeuropathy including entrapment neuropathies	Loss of single peripheral nerve function
Mononeuritis multiplex	Involvement of two or more nerves; usually indicative of a systemic disease, notably vasculitis
Autonomic neuropathy	Postural hypotension, impotence, flushing, sweating, loss of sinus arrhythmia, loss of reactive tachycardia following the Valsalva manoeuvre, abnormal gut motility

Table 12 Classification of peripheral neuropathies

Sensory	Glove-and-stocking distribution of pain, paraesthesias or numbness; typically starts in the feet and only affects the hands when it has risen to the level of the knees
	The pain is spontaneous or touch-induced; often the threshold to pain or touch is delayed but has an exaggerated response
	Paraesthesias are usually perceived as tingling or as light bands
	Sensory loss may be all modalities, large fibres only (position and vibration), or small fibres only (pain and temperature)
Motor	Distal weakness, with depressed reflexes, wasting, and occasionally fasciculation

Table 13 Features of polyneuropathy (the deficit may be sensory, motor, or mixed)

Fig. 5 Painless ulcers in hereditary sensorineuropathy.

Entrapment neuropathies

In patients with joint disease, peripheral nerves may be damaged by pressure from deformed joints or periarticular structures, by callipers, or from the operating table. The onset is usually insidious, with pain, paraesthesias, or weakness. The differential diagnosis includes other causes of regional pain, such as brachial neuralgia, mononeuritis multiplex complicating vasculitis, and reflex sympathetic dystrophy. Confirmation is by electrodiagnosis.

Conservative treatment includes removal of the offending callipers, rest, splints, and steroid injections. Surgical decompression or transposition may be necessary for persistent pain or if motor signs develop.

Only those entrapment neuropathies relevant to the rheumatologist will be considered here (Dawson *et al*. 1983).

Median nerve

Pressure on the median nerve in the carpal tunnel causes tingling, pain, or numbness in the radial three and a half digits, sometimes radiating up to, or even above, the elbow. It is commonly present at night, which can be relieved by exercising the hand or hanging it out of bed. Symptoms sometimes persist through the day so the patient cannot manipulate small objects and drops things. Signs may be absent. When present, sensory loss is confined to the median nerve distribution, with blunting of touch and pinprick in the radial three and a half digits. Symptoms may be provoked by Tinel's sign (tapping the nerve at the volar surface of the wrist) or Phalen's sign (sustained flexion at the wrist). Thenar weakness or wasting is a late feature.

Common causes include obesity, fluid retention from pregnancy, arthritis, Colles, or scaphoid fractures. Acromegaly, hypothyroidism, amyloidosis, or chronic haemodialysis are rare.

Anterior interosseous nerve

Pressure at the elbow of this branch of the median nerve results in weakness of the deep flexors of the thumb, index, and middle fingers, with pain in the forearm but without sensory signs. The characteristic sign is loss of normal thumb-index pincer movement.

Ulnar nerve

Pressure behind the medial epicondyle of the elbow produces numbness in the ulnar one and a half digits and the corresponding side of the hand, but not proximal to the wrist, which differentiates it from a C8 radiculopathy. The intrinsic muscles of the hand and the deep flexors of the ring and little fingers may be weak (Fig. 6). Occasionally the ulnar nerve may be trapped in Guyon's canal at the wrist. Motor loss is then confined to the intrinsic muscles of the hand, and sensory loss to the palmar aspect of the ulnar side of the hand.

Fig. 6 Slight flexion of the 4th and 5th fingers in an ulnar nerve lesion at the elbow. (The sensory loss is indicated by the dotted line.)

Posterior interosseous nerve

Entrapment at the elbow causes weakness of extension of all fingers and may be mistaken for tendon ruptures. Sensory symptoms are absent.

Thoracic outlet compression syndrome

The lower elements of the brachial plexus, derived from the C8 and T1 roots, are compressed in isolation or together with the brachial artery and vein at the thoracic outlet. Various structures in this region have been implicated—cervical rib, scalenus anterior, pectoralis minor, and a costoclavicular band—each with its own name and operation. In reality, the evidence is usually lacking and the syndrome is far less common than is diagnosed (Bland 1990).

Presentation is with pain, paraesthesias, and numbness in the ulnar side of the hand and forearm associated with vasomotor changes. The various provocative tests described are now discounted. Confirmation requires arteriography and electrodiagnostic studies.

Sciatic nerve

This may be trapped by the piriformus muscle causing pain in the lateral thigh, foot drop, and an absent ankle jerk. Compression by a Baker's cyst gives only the motor signs.

Lateral cutaneous nerve of thigh

Tight clothes or obesity can compress this nerve as it passes under the inguinal ligament causing pain, paraesthesias, and numbness in the outer side of the thigh (meralgia paraesthetica) which may be mistaken for hip pain, an L3 root lesion, or trochanteric bursitis.

Common peroneal nerve

Where it winds around the head of the fibula, this nerve is vulnerable to pressure from the joint, callipers, or the operating table. Foot drop and weakness of eversion are associated with sensory loss on the dorsum of the foot.

Posterior tibial nerve

Compression occurs in the tarsal tunnel behind the medial malleolus causing pain and tingling in the sole on standing or at night.

Autonomic neuropathy

A mild and possibly clinically irrelevant autonomic neuropathy has been demonstrated in rheumatoid arthritis (Toussirot *et al*. 1993), systemic lupus erythematosus (Liote and Osterland 1994), CREST syndrome (Hermosillo *et al*. 1994), and systemic sclerosis (Dessein *et al*. 1992).

Peripheral neuropathies in particular diseases

Rheumatoid arthritis

Carpal tunnel syndrome may be the presenting feature of rheumatoid arthritis, but other neuropathies usually develop in established disease (Good *et al*. 1965). Entrapment neuropathies are the most frequent and may be multiple. An indolent pure sensory neuropathy is also common. The mechanism is unknown. The sensory loss in atlantoaxial subluxation may mimic a polyneuropathy in the arms. A rare but serious problem is mononeuritis multiplex, usually where there is also clinical and serological evidence of vasculitis. The nerves of the upper arm and thigh are vulnerable because of their sparse supply of nutrient arteries. The onset is usually sudden, with dermatomal pain and paraesthesias followed within hours by weakness. Additional nerves are involved asymmetrically over days or weeks.

Polyarteritis nodosa

Mononeuritis multiplex (see above) occurs in 50 to 70 per cent of patients, sometimes as a presenting feature, but typically in the systemically ill patient with multisystem disease (Conn and Dyck 1975). The kidneys are usually involved. Lesions may summate to resemble a polyneuropathy. Occasionally a peripheral sensory neuropathy slowly develops (see Table 13).

Sjögren's syndrome

Mild or subclinical, motor, or sensory neuropathy occurs in one-fifth of patients. Mononeuritis multiplex is rare and usually associated with frank vasculitis; anti-Ro is over represented in this group (Binder *et al*. 1988).

Scleroderma

A mild sensorineuropathy has been described (Schady *et al*. 1991). A parasympathetic autonomic neuropathy, evident on cardiovascular tests, is reported to be common and arguably related to the Raynaud's syndrome, oesophageal dysmotility, and bowel disturbance (Hermosillo *et al*. 1994). Carpal tunnel syndrome is the only other peripheral neuropathy reported with any frequency; fibrosis following surgical decompression may worsen the symptoms. Subacute combined degeneration of the cord is reported in vitamin B_{12} deficiency consequent to sclerodermatous bowel involvement (Lee *et al*. 1984).

Systemic lupus erythematosus

Mild peripheral neuropathies, mostly sensory, occur particularly during active disease. Mononeuritis multiplex is uncommon.

L-*tryptoph an toxiticy*

Before this drug was withdrawn, several cases were described of a vasculitis associated with eosinophilic myositis and neuropathy.

Other rheumatological disorders

Mixed connective tissue disease, Churg-Strauss syndrome, amyloidosis, sarcoidosis, Wegener's granulomatosis, cryoglobulinaemia, Lyme disease, and giant cell arteritis may all be complicated by peripheral neuropathies.

1.3.4 The cardiovascular system

Laura F. Wexler and Michael E. Luggen

Chest pain

Cardiac disorders that present as chest pain are almost invariably serious or potentially serious, requiring prompt diagnosis, close monitoring, and rapid initiation of treatment. Thus, it is critical that any patient with rheumatic disease who complains of chest pain be carefully and thoroughly evaluated. Chest pain of cardiac origin may be difficult to distinguish from the pain associated with costochondritis, arthritis, bursitis, or any other musculoskeletal disorder involving the chest and shoulders. More commonly, gastrointestinal symptoms exacerbated by medications used to treat rheumatic disorders may mimic cardiac pain.

Angina pectoris

Angina refers to the chest pain that results from imbalance of myocardial oxygen supply and demand; it occurs most commonly in patients with myocardial ischaemia secondary to coronary arterial disease but is also experienced by patients with acute myocarditis, chronic cardiomyopathy, severe systemic hypertension, or certain types of valve disease. The description of angina published by William Heberden (Heberden 1772) remains worthy of attention.

'... a disorder of the breast marked with strong and peculiar symptoms.

The seat of it, and sense of strangling, and anxiety with which it is attended, may make it not improperly called angina pectoris. They who are afflicted with it, are seized while they are walking, (more especially if it be up hill, and soon after eating) with a painful and most disagreeable sensation in the breast, which seems as if it would extinguish life, if it were to increase or to continue, but the moment they stand still, all this uneasiness vanishes.'

Patients frequently describe anginal pain as a band-like sensation around the chest or as pressure, tightness, squeezing, burning, or aching rather than as pain; the anxiety and sense of impending doom it elicits may seem out of proportion to the actual severity of the discomfort described. It is usually substernal but may radiate to either side of the chest or be isolated to the shoulders, arms (left, right or both), lower (but not upper) jaw, or epigastrium. It may thus be misinterpreted by the patient as bursitis, arthritis, toothache, or indigestion. An important feature distinguishing angina from rheumatic or gastrointestinal pain is that angina is almost never a sharp, localized pain that the patient can point to with one finger and it is not associated with tenderness over the area of pain. Unlike pericarditis (see below), angina is neither pleuritic nor positional. Although angina is often precipitated by exertion or stress (physical or emotional) and relieved by rest, it may occur solely or predominantly at rest. An episode of angina usually lasts several minutes and may recur many times in a day. However, it does not persist unchanged for hours or days. Angina is very often associated with dyspnoea; in some patients, dyspnoea may be the sole or predominant symptom associated with myocardial ischaemia. Although the quality and location of angina varies greatly from patient to patient, chronic, stable angina usually has a repetitive pattern in a particular patient.

Box 1 Cardiovascular complications of rheumatic diseases

Rheumatic disease	Coronary disease	Pericarditis	Myocardial disease	Conduction system disease	Valvular disease
Amyloidosis	+	–	++	++	–
Ankylosing spondylitis	–	–	+	++	++

+++ Occurs in >50% patients; ++ Occurs in 5–49% patients; + Occurs in <5% patients; – Occurs rarely if ever

Sublingual nitroglycerine almost invariably relieves angina within seconds or a few minutes and the response to nitroglycerine is sometimes considered a diagnostic test to help differentiate cardiac from non-cardiac pain. It should be noted that nitroglycerine is an effective smooth-muscle vasodilator and will also relieve epigastric pain associated with oesophageal spasm, which often mimics angina.

New-onset angina or angina that abruptly increases in severity or frequency, or that occurs at rest for the first time in a patient with previously stable exertional angina, is called unstable angina and is of particular significance because it is associated with a high risk of progression to acute myocardial infarction.

Acute myocardial infarction

Severe, unremitting anginal pain that lasts 30 min or more should suggest the possibility of an acute myocardial infarction, especially if the pain is associated with nausea, vomiting, diaphoresis, dyspnoea, light-headedness, or syncope. Contrary to common wisdom, an acute myocardial infarction is usually not precipitated by sudden exertion or stress (as musculoskeletal pain may be). Most often it occurs at rest, without warning. The mechanism of acute myocardial infarction is usually acute coronary thrombosis induced by endothelial injury or spasm in a coronary artery previously damaged by atherosclerosis or other inflammatory process. Rarely, spasm or embolus in a previously normal coronary artery can lead to acute infarction.

Pericarditis

The pain associated with pericarditis may closely mimic angina in quality and radiation pattern but it is not brought on by exertion or emotional stress and is not relieved by rest. It is usually located in the mid-anterior chest and is often pleuritic (exacerbated by deep inspiration or cough), positional, or aggravated by swallowing. Non-steroidal anti-inflammatory drugs frequently alleviate pericardial pain but are ineffective for anginal pain.

Acute aortic dissection

The pain associated with acute aortic dissection may mimic an acute myocardial infarction, but is often distinguished by its extreme severity and radiation to the back. The pain is usually so catastrophic as to bring patients to the emergency room promptly; in other words, aortic dissection would not present as a mild to moderate, repetitive anginal pain syndrome.

Dyspnoea

Dyspnoea is the cardinal symptom of congestive heart failure. Congestive heart failure associated with the rheumatic disorders can be the result of myocardial damage (from either primary involvement of cardiac muscle or from ischaemic damage resulting from coronary arterial disease) or valvular heart disease. However, dyspnoea may also represent an anginal equivalent, i.e., dyspnoea rather than chest pain may be the sole or predominant symptom of angina (myocardial ischaemia) in patients with obstructive coronary arterial disease.

Dyspnoea of cardiac origin may be difficult to distinguish from dyspnoea related to obstructive or restrictive lung disease but certain clues can suggest its origin. Paroxysmal nocturnal dyspnoea (nocturnal episodes of a sudden sense of suffocation that is relieved by sitting up) is more common in congestive heart failure than in pulmonary disease, as is orthopnoea. Dyspnoea on exertion is a feature of both cardiac and intrinsic pulmonary disease but cardiac dyspnoea is rarely precipitated by hot, humid weather or exposure to specific irritants, is not relieved by productive coughing or by bronchodilators, and, with the exception of severe pulmonary oedema, does not cause wheezing.

Dizzy spells and syncope

Dizzy spells are exceedingly common and may or may not indicate a significant cardiac arrhythmia, the most common cause being enhanced vagal tone leading to hypotension. Syncope or near-syncope may be a sign of cardiovascular involvement in patients with rheumatic disorders that affect the conduction system disease and cause heart block (see Table 4). Syncope may also occur in patients with coronary arteritis in whom myocardial ischaemia induces ventricular arrhythmias, sinus bradycardia, or heart block. Autonomic dysfunction, resulting in symptomatic postural hypotension (as occurs with amyloid), is another cause.

Rheumatic disease	Frequency[a]
Amyloidosis	++
Ankylosing spondylitis	++
Ehlers–Danlos syndrome	+
Lyme disease	++
Polymyositis/dermatomyositis	++
Reiter's syndrome	+
Rheumatoid arthritis	+
Rheumatic fever	+++
Sarcoidosis	++
Systemic lupus erythematosus	+
Systemic sclerosis	++

[a]Approximate frequency of clinically significant atrioventricular block in patients who have rheumatic disease. Atrioventricular block occurs rarely if ever in rheumatic diseases not listed.
+++ Occurs in >50% of patients; ++ occurs in 5–49% of patients; + occurs in <5% of patients.

Table 4 Rheumatic diseases causing conduction system disease

It is usually possible to distinguish cardiogenic syncope from transient neurological events, such as seizures or transient ischaemic attacks, on the basis of a careful history. Tonic–clonic movements and loss of sphincter tone, which characterize seizures, rarely occur with syncope. Recovery from a syncopal episode usually takes place within seconds or minutes and the patient returns promptly to an awake and alert state without the prolonged drowsiness and confusion characteristic of the postictal state. In contrast to cerebral ischaemic events, focal neurological deficits do not usually occur with syncope of cardiac origin.

Palpitations may indicate the presence of a significant arrhythmia but more often reflect anxiety and increased cardiac awareness, as there is a very poor correlation between the perception of palpitations and the presence of significant arrhythmias.

Specific cardiovascular syndromes associated with the rheumatic disorders

Coronary arterial disease

Several distinct patterns of coronary arterial disease occur in association with the rheumatic disorders (Fauci *et al*. 1978; Lie 1987) (Table 1): focal obstructive disease of the large extramural coronary arteries or ostial stenosis of the right or left main coronary artery in patients with giant cell or other forms of aortitis may mimic atherosclerotic coronary disease. Diffuse vasculitis and/or vasospastic disease of small intramural arteries is often asymptomatic but may lead to myocardial damage. Coronary artery disease may occasionally be the initial or sole manifestation of a rheumatic disorder; more commonly, clinical evidence of coronary artery disease will occur in the setting of diffuse systemic vasculitis or other evidence of the underlying rheumatic disorder.

	Size of artery[a]	
Rheumatic disease	Large	Small
Amyloidosis	–	+
Kawasaki's disease	++	–
Polyarteritis nodosa	++	+
Polydermatomyositis	+	+
Rheumatoid arthritis	+	+
Systemic lupus erythematosus	+	+
Systemic sclerosis	–	+
Takayasu's disease	+	–
Temporal arteritis	+	–
Wegener's granulomatosis	–	+

[a]Approximate frequency of clinically significant coronary arterial disease in patients with the rheumatic disorder. Coronary arterial disease of significance occurs rarely if ever in those rheumatic disorders not listed.
+++ Occurs in >50% of patients; ++ occurs in 5–49% of patients; + occurs in <5% of patients; – occurs rarely if at all.

Table 1 Rheumatic diseases involving the coronary arteries

Acute vasculitis involving the large epicardial coronary arteries is uncommon; it has been most often reported in association with systemic lupus erythematosus (Doherty and Siegel 1985; Mandel 1987), polyarteritis nodosa (Przybojewski 1981; Cassling *et al*. 1985), and rheumatoid arthritis (Pizzarello and Goldberg 1985; Van Albada-Kuipers *et al*. 1986). Clinically, it may result in acute obstruction of a coronary artery and exactly mimic obstructive, atherosclerotic, coronary arterial disease, presenting as unstable angina, acute myocardial infarction, congestive heart failure, or sudden death from an arrhythmia.

In addition to causing a true vasculitis, systemic lupus erythematosus has been associated with the development of premature atherosclerosis of coronary arteries. Doherty and Siegel (1985) reviewed the literature on 33 patients less than 35 years old who had systemic lupus erythematosus with evidence of coronary arterial

disease (angina, acute myocardial infarction, congestive heart failure, or sudden death); atherosclerosis was reported in twelve, coronary vasculitis in seven, and occlusive disease without clear distinction in six. The remainder had either embolic or thrombotic lesions or small-vessel hyaline arteriolar disease presenting as myocardial infarction.

Coronary atherosclerosis in young women with systemic lupus was rarely reported in the era before steroids. In 1975, Bulkley and Roberts (1975) reported finding coronary atherosclerosis at autopsy in 8 of 36 young patients with systemic lupus erythematosus and suggested that corticosteroids might be an aetiological factor in accelerated atherosclerosis. However, a subsequent review (Haider and Roberts 1981) of 22 patients with systemic lupus (all of whom had been treated with prednisone) submitted to autopsy revealed that only a subset (10 of 22) had truly accelerated coronary atherosclerosis, i.e., disease that was more severe than that found in age- and sex-matched controls. The subgroup with accelerated coronary disease had more severe hypertension and higher cholesterol concentrations, which are potent risk factors for coronary atherosclerosis and which are exacerbated by corticosteroids. However, they also had more severe lupus-associated pericardial and mitral valvular disease, suggesting that immunological factors related to the systemic lupus itself might predispose susceptible patients to accelerated atherosclerosis.

Coronary vasculitis and accelerated atherosclerosis in systemic lupus may be related, rather than distinct, processes since various types of vascular injury and/or immunological mediators have been implicated in the development of atherosclerosis in the general population. Acute vasculitis, as a form of vascular injury, may serve as an initiating factor for the development of atherosclerosis in susceptible patients, in whom the presence of other risk factors (hypertension, increased cholesterol levels) accelerates the process. In this schema, very early steroid therapy might be expected to reduce vascular injury and thus suppress or delay the development of atherosclerosis. Support for this hypothesis can be inferred from a report by Fukumoto *et al*. (1987), in which patients with systemic lupus treated with steroids had less intimal thickening in coronary vessels than patients with systemic lupus who had never been on steroids. In this autopsy study, age and the duration of the systemic lupus erythematosus correlated best with severity of intimal thickening.

In a patient with systemic lupus presenting with chest pain suggestive of acute unstable angina or possible myocardial infarction, the clinical or angiographic differentiation between atherosclerosis and pure acute vasculitis is difficult, but may be of considerable importance because of conflicting indications for and against the use of corticosteroids. In isolated cases, patients with systemic lupus and unstable angina reportedly responded to high-dose steroids, with resolution of chest pain and the disappearance of angiographically documented coronary stenoses (although this is not unequivocal evidence of vasculitis since coronary stenoses caused by coronary spasm or thrombosis in patients with atherosclerosis may also resolve spontaneously). On the other hand, steroids are generally considered to be contraindicated in patients with acute myocardial infarction, based on studies of experimental myocardial infarction (Hammerman *et al*. 1983; Vivaldi *et al*. 1987) in which high-dose steroids led to delayed healing of the infarct and thinning of the scar. The few, small, controlled clinical trials of steroid therapy (Madias and Hood 1982) in acute myocardial infarction have not demonstrated deleterious effects of steroids (none clearly demonstrates beneficial effects either) but numerous case reports (Bulkley and Roberts 1974; Silverman and Pfeifer 1987), most involving rather prolonged use of high-dose steroids for Dressler syndrome, have suggested a relation between early steroid therapy, the formation of ventricular aneurysms, and an increased risk of myocardial rupture. Patients who present with unstable angina are at high risk of progression to acute myocardial infarction; thus, the decision to try a course of steroids for possible coronary vasculitis in a patient with systemic lupus erythematosus with unstable angina or other evidence of acute myocardial ischaemia entails some potential risk. The duration of risk associated with steroid therapy after a myocardial infarction is not certain; in experimental studies, even a short course of steroids administered immediately after the infarct impaired scar formation for weeks after the initial event.

Coronary vasculitis can occur with or without evidence of extracardiac vasculitis so that absence of other evidence of systemic lupus activity is not helpful in excluding acute vasculitis involving a major coronary artery. Alternatively, absence of standard coronary risk factors does not exclude atherosclerosis in a young patient with systemic lupus erythematosus. While hypertension and hyperlipidaemia tend to be more prevalent in patients with systemic lupus who have accelerated atherosclerosis, severe atherosclerosis and acute myocardial infarction have been well documented in young female patients with few, if any, of the standard atherosclerotic risk factors (Bulkley and Roberts 1975).

Apart from biopsy of coronary arteries, there is no definitive way to differentiate coronary atherosclerosis from coronary arteritis. There is limited information on coronary angiography in patients with systemic lupus erythematosus (Heibel *et al*. 1976) and polyarteritis nodosa (Cassling *et al*. 1985) who have coronary disease. Unlike in Kawasaki disease (Suzuki *et al*. 1986) (see Chapter 5.11.8), there are no diagnostic radiographic features of vasculitis in coronary arteries in systemic lupus. Serial angiograms showing the abrupt appearance of an obstructive lesion in a previously normal vessel, aneurysmal dilation of the coronary arteries, and elongated smooth lesions have been suggested as radiographic features of coronary vasculitis, but all of these phenomena can also occur in atherosclerosis.

Treatment strategies in unstable angina and acute myocardial infarction

In a patient presenting with acute, unstable angina without evidence of infarction in whom there is a strong suspicion of acute coronary vasculitis, a short course of high-dose steroids may be appropriate in conjunction with standard treatment (antianginal drugs and aspirin and/or heparin) moving to early angiography in those who do not respond promptly to medical therapy.

The initial treatment of an acute myocardial infarction is the same regardless of the underlying coronary pathology (Suzuki *et al*. 1986). The patient should be under intensive care and treated with the usual medical regimen (nitrates, aspirin and/or heparin, and, if not contraindicated, a b-blocker). The current practice of administering thrombolytic therapy promptly to patients who present within the first few hours of a clearly documented acute myocardial infarction presents a dilemma in patients with systemic lupus as there are no data on the risk:benefit ratio of giving acute thrombolytic therapy to a patient with acute myocardial infarction caused by coronary vasculitis. The cases reviewed by Doherty and Siegel (1985) suggest that patients with systemic lupus and acute coronary syndromes have a fair likelihood of having intracoronary thrombus; anticardiolipin antibodies have been implicated as a contributory factor (Greisman *et al*. 1991). Whether or not the haemorrhagic risk associated with thrombolytic therapy (especially that of intracerebral haemorrhage) is in any way altered in patients with systemic vasculitis is unknown. Steroids should probably not be used if there is clear evidence of evolving myocardial infarction unless there are compelling reasons to do so, i.e., severe vasculitis involving other organs, in which case doses and duration of therapy should be minimal.

Vasculitis affecting the ascending aorta (giant-cell arteritis, Takayasu arteritis, temporal arteritis, non-specific aortoarteritis) will occasionally involve the proximal segment (ostium) of the right or left coronary artery, presenting as acute myocardial infarction, unstable angina, congestive heart failure, or sudden death (Holsinger *et al*. 1962; Cipriano *et al*. 1977; Save Soderbergh *et al*. 1986; Mitnick *et al*. 1990). In most reported cases other evidence of disease activity implicated arteritis as the cause of the coronary disease, but in several cases aortitis was a previously unsuspected finding discovered at the time of coronary bypass surgery for severe angina or at autopsy in a patient who died of an acute myocardial infarction. In a case reported by Mitnick *et al*. (1990), a patient with temporal arteritis developed ostial proximal coronary involvement despite low-dose steroid therapy that had been effective in controlling the systemic symptoms of the disease.

Vasculitis involving the small, intramural coronary arteries is commonly observed at autopsy in polyarteritis nodosa (Holsinger *et al*. 1962; Przybojewski 1981) and rheumatoid arthritis (15–20 per cent) (Haider and Roberts 1981; Lie 1987), but it is usually asymptomatic and only rarely presents as chest pain or an acute myocardial infarction (Morris *et al*. 1986). Small-vessel coronary arteritis may be responsible for diffuse, patchy areas of myocardial fibrosis leading to congestive heart failure or to clinical syndromes reflecting the specific area of damage, such as arrhythmia or heart block related to fibrosis of the specialized conduction tissues. In systemic sclerosis, diffuse narrowing of intramural coronary arteries secondary to intimal thickening and periadventitial sclerosis is occasionally found, and may be associated with myocardial infarction and sudden death (James 1974; Owens and Follansbee 1987; Nair *et al*. 1988). Diffuse coronary vasospasm is also thought to play an important part in this disorder and may be responsible for the fact that diffuse myocardial fibrosis, out of proportion to frankly obstructive coronary disease, is commonly observed in this condition. (Follansbee *et al*. 1993). Amyloidosis may involve small coronary arteries, and cause angina and myocardial infarction (Saffitz *et al*. 1983).

Evaluation of patients with suspected coronary disease

Patients with rheumatic disorders who develop angina, dyspnoea on exertion, or heart failure should be referred for a complete cardiovascular evaluation. Evaluation should include screening for risk factors for atherosclerosis and a stress test to aid in diagnosis and also to screen for high-risk profiles (early or profoundly positive tests implying the presence of severe or extensive disease). Patients with severe arthritis who cannot perform a bicycle or treadmill exercise test can be evaluated with pharmacological stress tests (dipyridamole, adenosine, or dobutamine thallium scintigraphy or echocardiography), which have comparable sensitivity and specificity for the detection of significant coronary arterial disease. Most young or middle-aged patients with objective evidence (abnormal electrocardiogram, positive stress test) or strong clinical evidence (classic symptoms, history of myocardial infarction, positive risk factors) of coronary arterial disease should undergo coronary angiography to define the severity of involvement and determine the appropriateness of medical as compared to revascularization therapy (angioplasty or bypass surgery). The decision in elderly or inactive patients who are limited by their rheumatological disease is more complex and should be based on the severity of their

cardiac symptoms and the efficacy of standard medical therapy.

Pericardial disease

Diffuse or focal inflammatory changes in the pericardium are found commonly at autopsy in many of the rheumatic diseases but clinically evident pericardial disease occurs less often (Table 2). Acute pericarditis, with or without effusions, occurs most often in systemic lupus erythematosus (Doherty and Siegel 1985; Mandel 1987), rheumatoid arthritis (John *et al*. 1979; Pizzarello and Goldberg 1985) and juvenile rheumatoid arthritis (Brewer 1977; Svantesson *et al*. 1983), and mixed connective tissue disease (Alpert *et al*. 1983) as well as in acute rheumatic fever (Stollerman 1988) (see also Chapter 5.3.12); systemic sclerosis (Owens and Follansbee 1987) is more often associated with chronic effusions. The clinical syndrome of pericarditis or pericardial effusion progressing to tamponade or constrictive pericarditis is rare, but has been reported in rheumatoid arthritis, systemic sclerosis, and systemic lupus.

Table 2 Rheumatic diseases causing pericardial involvement

Acute pericarditis

The pericardium has two layers, the visceral pericardium, which is adherent to the epicardial surface of the heart, and the parietal pericardium, which is separated from the visceral layer by a small amount of pericardial fluid (25–50 ml). Acute pericardial inflammation, which can result from a wide spectrum of pathological processes, usually results in a syndrome characterized by chest pain, a pericardial friction rub, and electrocardiographic changes. Two of the above are usually adequate to make the diagnosis. Pericarditis may or may not be associated with increased accumulation of fluid in the pericardial space.

Pericardial pain will be worsened by actions that increase the contact between the pericardial layers or between the parietal pericardium and the adjacent lungs or mediastinal contents. Thus, patients may complain of pain when changing position, coughing, deep breathing, or swallowing. The pericardial friction rub is produced by the rubbing together of the roughened, inflamed surfaces of the visceral and parietal pericardium during the cardiac cycle. It is a harsh, scratching, crunching or grating sound heard over the anterior precordium or left chest, and may be heard best with the patient leaning forward and holding forced expiration. Classically, the rub is triphasic, i.e., composed of three discrete sounds, corresponding to the motion of the heart in late diastole (atrial systole), early ventricular systole, and early diastole (rapid diastolic filling). The rub may also be biphasic with single late diastolic and systolic components or uniphasic with a single systolic component. The rub may be pleuropericardial, i.e., related to the cardiac cycle but present only during inspiration.

Electrocardiographic changes associated with pericarditis include depression of the PR segment, diffuse elevation of the ST segment, and diffuse inversion of the T wave (Fig. 1), which usually follow each other sequentially and resolve within a few days. Atrial arrhythmias, most commonly atrial fibrillation or flutter, are common. Ventricular ectopy is unusual unless there is associated myocardial involvement. The echocardiogram is not specifically helpful in making the diagnosis of pericarditis unless there is an associated pericardial effusion.

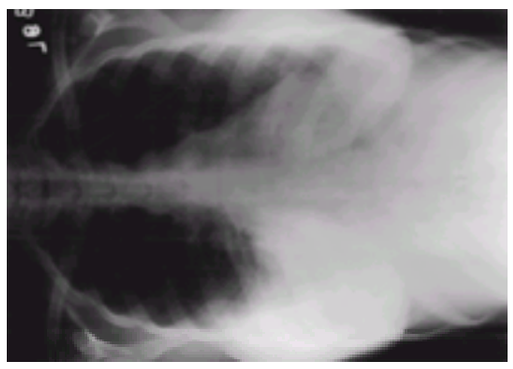

Fig. 1 A chest radiograph of a 23-year-old female with systemic lupus erythematosus and pleuropericardial disease.

Pericardial effusion

The signs and symptoms associated with a pericardial effusion are dependent on the size of the effusion and the rapidity with which it has accumulated. The pericardium has the capacity to stretch so that large collections of pericardial fluid may be tolerated without symptoms if the fluid has accumulated very slowly (Fig. 2). In contrast, small, rapidly accumulating effusion associated with, for example, an acute flare of systemic lupus erythematosus, can produce pericardial tamponade. When there is a large effusion, the electrocardiogram may show diminution in QRS voltage; changes characteristic of acute pericarditis may or may not be present. Echocardiography is the diagnostic technique of choice for identifying the presence of an effusion, assessing its size, and guiding pericardiocentesis. Diagnostic pericardiocentesis is indicated primarily to exclude treatable infections, particularly tuberculosis, or neoplasm. Purulent pericarditis has been reported (rarely) in rheumatoid arthritis. Characteristics which suggest that the effusion is rheumatic in origin are discussed below.

Fig. 2 A child with systemic-onset juvenile rheumatoid arthritis complicated by a large pericardial effusion. Note the 'water-bottle shape' of the cardiac silhouette.

Pericardial tamponade

Large or rapidly accumulating effusions may lead to tamponade, a condition in which diastolic filling of the heart is restricted by the pressure of fluid within the pericardial space. Once the pressure in the pericardial space exceeds that in the systemic and pulmonary veins emptying into the heart, diastolic filling ceases and there is a precipitous drop in cardiac output followed by hypotension, and, if not treated by immediate decompression of the pericardial space, cardiovascular collapse and death.

Signs of impending pericardial tamponade include evidence of obstructed venous inflow into the heart (elevated jugular venous pressure) and decreased cardiac output (sinus tachycardia, narrow pulse pressure, decreased urine output, cool extremities, altered mental status). Pulsus paradoxicus, a drop in systolic pressure of more than 10 mmHg during each inspiratory cycle, is a characteristic sign of impending tamponade. Electrical alternans, an electrocardiographic pattern of alternating increase and decrease in QRS voltage (and/or T-wave height) is another sign suggestive of impending tamponade.

Echocardiographic signs of pericardial tamponade include indenting of the right atrium or right ventricle during diastolic filling. (This sign may be obscured in patients with significant left ventricular dysfunction.)

If the diagnosis of pericardial tamponade is suspected but cannot be confirmed by echocardiogram, the patient should undergo a right heart catheterization. If the diagnosis of tamponade is confirmed, the patient should then undergo pericardiocentesis for relief of tamponade and for diagnostic evaluation of the fluid. Tamponade can occur with any type of inflammatory pericarditis and does not suggest a specific cause.

The risks of percutaneous pericardiocentesis are minimized when there is a large effusion and when echocardiographic or fluoroscopic guidance is available. Alternatively, a pericardial window may be created surgically or percutaneously using a balloon-tipped catheter. If the procedure is done in the setting of impending or suspected tamponade, a catheter should be left in the pericardial space for recurrent drainage since highly inflammatory, rapidly accumulating effusions are likely to recur. Steroid therapy is usually effective, and pericardial sclerosis or pericardial stripping is rarely required.

Constrictive pericarditis

Constrictive pericarditis refers to a state of chronic restriction of cardiac filling by a thickened, rigid pericardium. Recurrent or severe pericarditis associated with the rheumatic disorders very rarely leads to this complication; it has been reported occasionally in systemic sclerosis (Owens and Follansbee 1987) and rheumatoid arthritis (John *et al*. 1979). Restricted inflow into the right heart results in elevation of systemic venous pressure and a positive Kaussmaal sign (failure of the jugular venous pressure to fall or paradoxical elevation of the venous pulse wave with inspiration), peripheral oedema, and hepatic congestion. Inflow from the pulmonary veins into the left side of the heart is also impeded and patients are frequently dyspnoeic and fatigued. Electrocardiographic signs of acute pericarditis are usually absent, and instead of a rub a pericardial knock (a loud third heart sound corresponding to early diastolic inflow into the constricted, non-compliant ventricle) may be heard. Constrictive pericarditis may be difficult to distinguish from restrictive cardiomyopathy, a heart muscle disorder in which a similar pattern of impedance to cardiac filling results from diminished compliance of the myocardium, most often as a result of infiltrative diseases such as amyloid. The distinction can be critical since severe constrictive pericarditis responds poorly to medical therapy and usually requires surgical stripping for definitive relief. CT scanning or echocardiography can demonstrate pericardial thickening but neither establishes whether or not there is physiological constriction. While cardiac catheterization may show haemodynamic patterns suggestive of constrictive pericarditis, thoracotomy may be required to make a definitive diagnosis.

Differentiating pericarditis of rheumatic origin from other causes of pericarditis

The distinction between rheumatic pericarditis and other common causes of pericarditis is difficult to make on the basis of cardiac findings alone. In most large series of patients with clinical evidence of pericarditis, the rheumatic diseases account for less than 2 per cent of cases. Probably the most common cause of pericarditis in young patients is acute viral pericarditis, in which the pattern of chest pain, physical findings, and electrocardiographic changes are similar to those of pericarditis of rheumatic origin; leucocytosis and a raised erythrocyte sedimentation rate are also seen in both. Pericarditis associated with rheumatic diseases often occurs in the setting of an obvious flare involving other non-cardiac manifestations of the rheumatic condition; however, pericarditis is occasionally the sole or presenting finding, especially in systemic lupus erythematosus. In systemic lupus, rheumatoid arthritis, and mixed connective-tissue disease, an associated pleural effusion is common, but this can also occur in up to 60 per cent of patients with acute, non-rheumatic pericarditis.

The echocardiogram may help differentiate acute viral from rheumatic pericarditis in that certain of the rheumatic disorders are associated with echocardiographic findings other than effusion. In patients presenting with acute viral pericarditis, pericardial thickening is uncommon, but 10 to 15 per cent of patients with rheumatoid arthritis (Pizzarello and Goldberg 1985) and a somewhat smaller percentage of patients with systemic sclerosis (Owens and Follansbee 1987) have evidence of chronic pericardial disease; in patients with systemic lupus, echocardiographic abnormalities including pericardial thickening, valvular insufficiency, and sterile vegetation are present in 30 to 50 per cent (Doherty and Siegel 1985).

Analysis of the pericardial fluid is important in excluding infectious or malignant pericarditis, especially in patients on steroids or immunosuppressive agents. Pericardial biopsy may be required to make the diagnosis of tuberculous pericarditis. Pericardial fluid may offer some clues to the diagnosis of specific rheumatic disorders, although there are no pathognomonic features. Pericardial fluid glucose is low in rheumatoid arthritis (Pizzarello and Goldberg 1985) and systemic lupus erythematosus (Doherty and Siegel 1985) but is usually normal in viral pericarditis. Complement has also been reported to be low but difficulties in interpretation arise in that the amounts of complement have often been uncorrected for the protein content of the effusion and systemic complement levels. Moreover, the number of patients who have had these tests is small. The same is true of tests for antinuclear antibody in pericardial fluid; it is unclear whether they provide any significant information over and above that which can be obtained by testing the patients' blood. Furthermore, antinuclear antibodies have been reported in pericardial fluid from non-rheumatic pericardial effusions and it is likely that any condition which can produce a positive antinuclear antibody test in peripheral blood may produce a similarly positive test in an exudative pericardial effusion.

Myocardial disease

Primary myocardial disease includes acute inflammatory myocarditis and chronic cardiomyopathy, which is characterized as either dilated, restrictive, or hypertrophic.

Myocarditis

Autopsy series report histological evidence of myocarditis in many of the chronic rheumatic disorders (Table 3), with perivascular and interstitial inflammatory cells and focal fibrosis in up to 40 per cent of cases of systemic lupus erythematosus (Doherty and Siegel 1985; Mandel 1987) and 20 per cent of cases of rheumatic arthritis (Pizzarello and Goldberg 1985). However, there is generally a poor correlation between histological findings and clinical evidence of myocardial dysfunction. Acute, severe myocarditis presenting as heart failure is recognized clinically far less often. Acute myocarditis is characterized by rapid onset and progression of congestive heart failure, with pulmonary congestion and cardiomegaly on chest radiography, sinus tachycardia, diffuse, non-specific changes in ST and T wave on electrocardiograms, and atrial and ventricular arrhythmias. Dilation of all four cardiac chambers with markedly depressed systolic function of both ventricles is demonstrable on the echocardiogram or radionuclide ventriculogram. Severe, fulminant myocarditis may present as low cardiac-output state and shock. There is enzymatic evidence of myocardial necrosis (elevated serum creatine kinase-MB), and histological evidence of myocyte degeneration, as well as diffuse inflammatory infiltration on endomyocardial biopsy. Occasionally, acute myocarditis may be the sole or presenting sign of systemic lupus or rheumatoid arthritis and will mimic acute viral myocarditis, but, more commonly, other manifestations of rheumatic disease activity are present. Treatment includes bed rest, pharmacological support with positive inotropic agents, afterload-reducing agents, diuretics, and usually systemic anticoagulation to prevent venous thrombosis and systemic embolization from ventricular mural thrombi. There is anecdotal evidence supporting the use of high-dose steroids in severe myocarditis but few data on the use of immunosuppressive agents (Talwar *et al*. 1988).

+++ Occurs in >50% of patients. ++ occurs in 5–49% of patients. + occurs in <5% of patients.

Table 3 Rheumatic diseases causing myocardial disease

The role of myocardial biopsy in patients with rheumatic disorders who develop myocardial dysfunction is not clear as there has been a poor correlation between histological evidence of myocarditis and degree of myocardial dysfunction or response to corticosteroids. However, in patients with acute or progressive myocardial dysfunction in whom more common causes of heart failure have been excluded (myocardial infarction, valvular disease, severe anaemia), myocardial biopsy may be helpful in documenting the presence of inflammatory changes and excluding alternative, albeit rare, causes of myocardial failure (such as hydroxychloroquine toxicity, amyloid, sarcoid, or haemochomatosis) before starting a trial of corticosteroid therapy.

Acute viral myocarditis may be indistinguishable from other forms of inflammatory myocarditis. It has been suggested that steroids may be deleterious in the acute stages of viral myocarditis, based on studies in murine myocarditis in which viral replication was enhanced by steroid administration (Reyes and Lerner 1985). This observation has not been confirmed in human studies and there are anecdotal reports of marked improvement in patients with apparent viral myocarditis following administration of steroids and occasionally of cytotoxic agents. While it is not yet clear whether or not corticosteroids and immunosuppressive drugs are helpful in acute viral myocarditis (this is currently under investigation in a large clinical trial in the United States), there is no clear evidence that they are harmful. Thus, it appears reasonable to administer a course of steroids in acute myocarditis suspected of being associated with a rheumatic disorder, even if acute viral myocarditis cannot be ruled out.

Dilated cardiomyopathy

The term cardiomyopathy refers to any chronic disorders of cardiac muscle; cardiomyopathies are currently divided into dilated (congestive), hypertrophic, or restrictive types. Dilated cardiomyopathy is characterized by enlargement the four cardiac chambers with depressed systolic function. Myocardial dysfunction may involve all four cardiac chambers or may be isolated to either the left- or right-sided chambers. Atrial and ventricular arrhythmias are common. Patients usually present with insidious onset of dyspnoea on exertion and diminished exercise tolerance, or with new onset of atrial fibrillation; more rapid onset with progression to pulmonary oedema may also occur. Unlike acute myocarditis, extracardiac signs of acute vasculitis or inflammation are usually not present and there is neither serological nor histological evidence of acute inflammation. The aetiology of dilated cardiomyopathy associated with the rheumatic disorders is multifactorial. A picture of dilated cardiomyopathy may develop secondary to long-standing hypertension in systemic lupus erythematosus (Doherty and Siegel 1985) or in scleroderma (Owens and Follansbee 1987), or after extensive myocardial infarction in patients with coronary arteritis (Lie 1987), as a result of diffuse fibrosis in sarcoid (Shammas and Movahed 1993), or as a consequence of diffuse amyloid infiltration (Hamer *et al*. 1992). Diffuse ischaemic damage may also occur in small-vessel coronary vasculitis from obstruction, in situ thrombosis, or, in the case of scleroderma, coronary vasospasm (Follansbee *et al*. 1993). Long-standing mitral or aortic insufficiency leading to cardiac failure may also present as a dilated cardiomyopathy. Infiltrative myopathy, as in amyloid (Kyle and Bayrd 1975), may also cause a dilated cardiomyopathy.

In the absence of these underlying factors, clinically significant dilated cardiomyopathy as a primary consequence of the rheumatic disorders is uncommon, although many patients have histological evidence of patchy fibrosis and minimal chronic inflammatory reaction. Subclinical abnormalities of myocardial function, insufficient to cause frank congestive heart failure, have been described in several studies of patients with stable systemic lupus in the absence of hypertension or obvious coronary vasculitis (Doherty and Siegel 1985).

Restrictive cardiomyopathy

This is characterized by abnormal compliance of the heart leading to impaired diastolic filling with little or no impairment of systolic function. Clinically, patients present with signs and symptoms of biventricular heart failure (elevated systemic venous pressure and pulmonary congestion) and impaired cardiac reserve, including limited exercise tolerance, but without marked cardiomegaly. The most common cause of restrictive cardiomyopathy associated with the rheumatic disorders is primary or secondary amyloid (Chew *et al*. 1975). Although cardiac amyloid can cause dilated cardiomyopathy, the initial or predominant manifestation of amyloid infiltration of the myocardial walls may be restricted diastolic filling and impaired compliance, leading to depressed cardiac output reserve and elevation of systemic and pulmonary venous pressures (see also Chapter 5.13.1).

Little can be done to improve diastolic function in restrictive cardiomyopathy. Symptomatic pulmonary congestion can be relieved by diuretics, but these must be used with caution since underfilling of the left ventricle easily leads to low cardiac output with fatigue, hypotension, and renal insufficiency. It is essential to recognize that the signs, symptoms, and physiological consequences of restrictive cardiomyopathy may be virtually identical to those of constrictive pericarditis, which can be treated surgically. Clues to the differential diagnosis can be obtained by CT scanning, echocardiography, or cardiac catheterization, but thoracotomy is sometimes required to exclude constrictive pericarditis.

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy is a form of cardiomyopathy characterized by massive thickening of the ventricular walls and is not specifically associated with the rheumatic disorders. However, severe left-ventricular hypertrophy developing in response to hypertension in patients with systemic lupus or scleroderma may mimic it. Patients with severe left-ventricular hypertrophy often demonstrate abnormal diastolic properties of the left ventricle, such that inordinately high pressures develop during left ventricular filling, with resultant elevations in left atrial pressure and symptoms of pulmonary congestion. Systolic function is preserved initially, but long-standing untreated hypertension may eventually cause left ventricular dilation and contractile failure.

Conduction system disease

The cardiac conduction system consists of the sinoatrial node located in the high right atrium, the atrioventricular node located at the junction of the aortic root, anterior mitral leaflet and interventricular septum, the intra-atrial conduction fibres, which connect the two nodes, and the His–Perkinje system, which consists of specialized conduction fibres emanating from the atrioventricular node and spreading through the interventricular septum and ventricular walls. The conduction system is subject to damage by numerous mechanisms in the rheumatic disorders (Table 4) as it is intimately associated with, or surrounded by, dense connective tissue and receives its blood supply from small- to medium-sized arteries potentially affected by vasculitis. The proximity of the atrioventricular node to the aortic ring may result in conduction disorders in patients with inflammatory aortitis or connective tissue diseases involving the aorta. Thus, the conduction system of the heart may be damaged by fibrinoid necrosis of connective tissue or vasculitis of the atrioventricular or sinoatrial nodal arteries in systemic lupus erythematosus (Doherty and Siegel 1985; Mandel 1987), infiltration by rheumatoid (Pizzarello and Goldberg 1985) or sarcoid nodules (Shammas and Movahed 1993), or by amyloid infiltration (Mandel 1987), diffuse myocardial fibrosis in scleroderma (James 1974; Owens and Follansbee 1987), inflammatory myocarditis or degenerative myopathy in polydermatomyositis and Lyme disease (Steere *et al*. 1980; Askari and Huettner 1982; Haupt and Hutchins 1982), or extension of aortic root involvement to adjacent structures in ankylosing spondylitis (Nagyhegyi *et al*. 1988), Reiter's disease (Good 1974), and Ehlers–Danlos syndrome (Leier *et al*. 1980).

The presence of a first-degree atrioventricular block, Mobitz I (Wenkebach) atrioventricular block, or bundle branch block on electrocardiography in an asymptomatic patient with a rheumatic disorder suggests the possibility of conduction system involvement but does not necessarily predict progression to complete heart block and is not an indication for prophylactic implantation of a pacemaker. Periodic follow-up electrocardiograms are important and careful monitoring should be undertaken if the patient experiences near or actual syncope. Higher degrees of atrioventricular block (Mobitz II) or complete heart block imply advanced conduction system

disease and are a strong indication for prophylactic implantation of a pacemaker even if the patient is asymptomatic.

Patients who present with syncope or light-headedness in whom second- or third-degree heart block, or severe sinus bradycardia (pulse less than 40), or sinus pauses greater than 5 s can be documented are clearly candidates for the implantation of a permanent transvenous pacemaker. In symptomatic patients with less severe degrees of bradyarrhythmia or heart block, it is important to correlate the patient's symptoms with the occurrence of bradycardia during ambulatory monitoring or electrophysiological testing before implanting a pacemaker. Despite the potential for involvement of the conduction system, symptomatic bradyarrhythmias are uncommon in the rheumatic disorders and unless an arrhythmic cause is clearly documented, patients with syncope or light-headedness should be carefully investigated for other causes before permanent pacing is undertaken.

Aortic insufficiency

Aortic insufficiency can occur as a consequence of dilation or dissection of the aortic root, or as a result of damage or deformation of the aortic valve leaflets themselves (Table 5). Stretching of the aortic root with failure of the leaflets to coapt occurs in inflammatory diseases, especially ankylosing spondylitis (Nagyhegyi *et al*. 1988; O'Neill 1992), Reiter's disease (Good 1974), Takayasu disease (Ishikawa 1978), giant-cell arteritis (Pyeritz and Wappel 1983), Behçet's disease (James and Thomson 1982), and in the connective tissue diseases, especially Marfan syndrome (Marsalese *et al*. 1989), and Ehlers–Danlos syndrome (Leier *et al*. 1980). Disease of the aortic root in Marfan syndrome can be particularly treacherous in that acute aortic dissection can develop, which may present as fulminant aortic insufficiency. Marfan syndrome and the other connective tissue diseases are also associated with myxomatous degeneration of the aortic valve leaflets, which may contribute to aortic insufficiency. Scarring of the leaflets occurs occasionally as a result of Libman–Sachs endocarditis in systemic lupus (Doherty and Siegel 1985; Mandel 1987) (the mitral valve is affected more commonly). Deformation of the aortic valve by rheumatoid nodules is another rare cause of aortic insufficiency. Aortic valve disease is also reported in juvenile rheumatoid arthritis (Heyd and Glaser 1990).

[1] Approximate frequency of clinically significant valvular insufficiency in patients with rheumatic disease. Valvular insufficiency occurs rarely or even in those rheumatic diseases not listed.
[2] Due to either valvular pathology or aortic root dilatation.
+++ Occurs in > 50% of patients, ++ occurs in 15–49% of patients, + occurs in < 5% of patients, – occurs rarely if at all.

Table 5 Rheumatic diseases causing valvular insufficiency

The presentation and management of aortic insufficiency depends on whether the valve insufficiency develops slowly or abruptly. Slowly progressive aortic insufficiency is usually well tolerated and asymptomatic for many years as the left ventricular chamber is able to compensate by dilation and hypertrophy in response to the gradual imposition of the increased volume load. In contrast, acute aortic insufficiency presents the unprepared left ventricle with an acute volume overload, which results in severe heart failure. Acute, severe aortic insufficiency constitutes a medical emergency requiring early surgical replacement of the aortic valve. Chronic aortic insufficiency can usually be managed conservatively for many years, delaying valve replacement until the patient develops signs and symptoms of left ventricular dysfunction.

The characteristic, diastolic blowing decrescendo murmur of aortic insufficiency can be soft and is best detected with the bell of the stethoscope at the mid- to lower-left sternal border with the patient leaning forward and holding his or her breath in full expiration. In patients with aortic insufficiency secondary to dilation of the aortic root, the murmur is often heard best at the right upper sternal border. In addition to the diastolic blowing murmur, there is often a systolic ejection-type murmur at the base, reflecting the increased stroke volume in systole, and a low-frequency mid-diastolic rumble (Austin–Flint murmur) at the lower left sternal border that mimics mitral stenosis and is caused by premature closure of the anterior mitral-valve leaflet by the aortic regurgitant jet. Other characteristic physical findings in aortic insufficiency reflect the high stroke volume: the apical cardiac impulse is displaced to the left and is hyperdynamic, and the peripheral and carotid pulses are bounding. Echo-Doppler studies can best assess the severity and progression of aortic root- or valve-related aortic insufficiency.

The decision when to refer patients for aortic valve replacement is based on development of symptoms and evidence of deterioration of left ventricular function, ideally assessed by serial echocardiography. Asymptomatic patients with good left-ventricular systolic function (normal ejection fraction) do not require valve replacement. Patients who develop symptoms of congestive heart failure (dyspnoea on exertion) can usually obtain symptomatic benefit from medical therapy (digoxin, diuretics, and vasodilator therapy), but valve replacement is usually recommended early in such patients if there is evidence of systolic dysfunction, in order to offset progression to severe, irreversible, left ventricular dysfunction, which greatly increases the morbidity and mortality of valve replacement surgery and limits the benefits achieved.

Although most patients develop obvious symptoms when left ventricular systolic function deteriorates, members of a perplexing subgroup remain asymptomatic despite echocardiographic evidence of a decreasing ejection fraction. When to replace the aortic valve in an asymptomatic patient with left ventricular dysfunction demonstrated on echocardiogram remains controversial. However, there is agreement that careful periodic examination (history and physical examination) and serial studies of left ventricular function by echocardiogram should be routine for all patients with aortic insufficiency, with referral to a specialist for more detailed cardiac evaluation and consideration for valve replacement as soon as symptoms of heart failure or signs of left ventricular dysfunction on echocardiogram appear.

Mitral valve insufficiency

Clinically significant mitral valve insufficiency is uncommon in association with rheumatic disease except as a late consequence of acute rheumatic fever (see Table 5). Rheumatoid nodules may deform the mitral leaflets and result in mitral insufficiency (Pizzarello and Goldberg 1985), as can Libman–Sachs endocarditis and valvulitis in systemic lupus erythematosus (Doherty and Siegel 1985; Mandel 1987). The connective tissue disorders, especially Marfan syndrome, are associated with myxomatous degeneration of the mitral leaflets (Van Albada-Kuipers *et al*. 1986) and mitral valve prolapse, which occasionally causes significant mitral insufficiency but more commonly causes the characteristic mid-systolic murmur without haemodynamically significant valvular insufficiency. Occasionally, mitral valve prolapse results in acute rupture of the chordae tendineae, which causes acute, severe mitral insufficiency and presents as acute pulmonary oedema, requiring urgent valve replacement.

As in aortic insufficiency, slowly developing mitral insufficiency is usually well tolerated for long periods. The left ventricle undergoes gradual dilation and hypertrophy, enabling it to pump the increased stroke volume (normal diastolic filling from the pulmonary veins plus the additional load of blood regurgitation back into the left atrium through the incompetent mitral valve in systole). Dilation of the left atrium enables it to accommodate the mitral regurgitant volume without marked elevation in left atrial pressure. Left ventricular function may remain well compensated for many years. The onset of left ventricular dysfunction, or sudden worsening of the mitral insufficiency, will result in an increase in left atrial pressure and signs and symptoms of pulmonary congestion. Initially, symptoms can be ameliorated by a combination of digoxin, diuretics, and afterload-reduction (vasodilator) therapy, but severe or recurrent bouts of heart failure should prompt referral to a specialist for more detailed evaluation and consideration of valve replacement or repair, as is possible in some instances.

1.3.5 The respiratory system

Stephen G. Spiro and David A. Isenberg

Introduction

The lungs and chest wall are commonly affected by several of the rheumatological conditions. The involvement may be a direct manifestation of disease or it may be indirect as a result or complication of treatment. This chapter will detail the common symptoms of pulmonary diseases and show how often these are implicated in rheumatological conditions. The role of radiography and physiological tests in the assessment of these conditions will then be described. Finally, there is advice on which investigations should be carried out, together with a discussion on the treatment of pulmonary infections related to rheumatological disorders. A synopsis of how these disorders can affect the different respiratory structures is given in Table 1.

Rheumatoid arthritis	Bronchitis Bronchiectasis Obliterative bronchiolitis	Pneumonia Fibrosing alveolitis Rheumatoid nodules	Hypertension	Pleurisy Effusion Empyema	
Systemic lupus erythematosus		Pneumonia Fibrosing alveolitis Rheumatoid nodules	Hypertension	Pleurisy Effusion	Shrinking lungs with high diaphragms
Systemic sclerosis	Bronchiectasis	Fibrosing alveolitis Aspiration pneumonia	Hypertension		'Crossed' chest
Sjögren's syndrome	Bronchitis	Fibrosing alveolitis Lymphoma			
Dermatomyositis		Aspiration pneumonia			Myopathy
Polymyositis		Fibrosing alveolitis			
Ankylosing spondylitis		Upper lobe fibrosis			Costovertebral joint fixation
Behçet's syndrome		Haemorrhage	Aneurysm		
Pulmonary vasculitides		Nodules			
Relapsing polychondritis	Upper airway narrowing				

Table 1 Respiratory associations of the rheumatic disorders

Respiratory symptoms

Cough

Most rheumatological conditions that affect the lungs cause cough (Fig. 1). The airways can be involved in a variety of ways. It was once considered that asthma was more common in patients with rheumatoid arthritis, but there now seems no particular association except that of two relatively common conditions. Chronic bronchitis is likely to occur in patients who smoke.

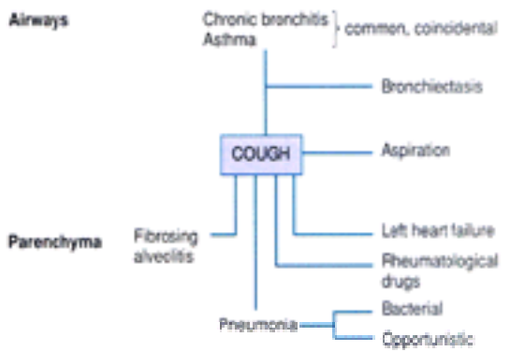

Fig. 1 The causes of cough.

Asthmatics will complain of waking during the night to cough, usually with a tight or wheezy chest. They will often be worse early in the morning and after exercise, exposure to cold air, pungent smells, and other chemical irritants. The diagnosis is seldom obscure and responds promptly to inhaled b_2-sympathomimetic agonists. In adults, asthma is associated more with cough and mucus (often yellow due to an increase in eosinophils) rather than wheezy breathlessness. The patient with chronic bronchitis will, by definition, have morning cough and sputum for 3 consecutive months for at least 2 years. He or she will be prone to acute exacerbations with infection, producing larger than usual quantities of yellow or green sputum, and needs antibiotics for control. Gradually deteriorating exercise tolerance will follow,

especially if smoking does not cease.

Chronic bronchial sepsis (or bronchiectasis) with persistent cough and the production of more than 30 ml of purulent sputum a day is found in some patients with rheumatoid arthritis. There is an increased incidence of bronchiectasis in these patients and the typical radiographic features are usually confined to just one or two lobes. Occasionally, cough with purulent sputum is an immunological reaction to the underlying condition, usually rheumatoid arthritis, but also occurs with inflammatory bowel disease. In these patients the symptoms respond dramatically to corticosteroids and not just antibiotics.

The development of parenchymal disease is almost universally associated with a persistent, dry, irritating cough, worse with exercise.

Fibrosing alveolitis occurs in association with several of the rheumatic disorders including rheumatoid arthritis, systemic sclerosis, Sjögren's syndrome, and systemic lupus (Table 1). There are no clinical, physiological, radiological, or histopathological differences between 'lone' cryptogenic fibrosing alveolitis (with or without associated rheumatoid factor) and the alveolitis in patients with rheumatic diseases. The pathogenesis is uncertain—it is possible that the alveolitis develops as a reaction to immune complexes deposited in the pulmonary capillaries. Limitations on exercise imposed by the joint disease may explain why some of these patients present relatively late with their respiratory symptoms, although florid fibrosing alveolitis with positive rheumatoid factor can herald the onset of rheumatoid arthritis and precede the joint manifestations by months or years. Usually, however, it is the patients with more severe rheumatoid arthritis who develop pulmonary fibrosis. In addition to cough, other clinical features include finger clubbing in up to 70 per cent of patients, bilateral inspiratory basal crackles, and, late in the disease, cyanosis.

The physiological and radiological features of fibrosing alveolitis are described below. However, the symptoms of cough together with infiltrates on the chest radiograph may also indicate a drug-induced pneumonitis (e.g. gold, cyclophosphamide, methotrexate), pneumonia (common in patients with chronic diseases, especially if also on corticosteroid or other immunosuppressive therapy), left ventricular failure (more likely on steroids or some non-steroidal anti-inflammatory drugs; and in old age), and opportunistic infections associated with the primary autoimmune rheumatic disorder or the consequence of its therapy.

The treatment of cough can be difficult but is helped greatly if the cause is identified. Asthma responds promptly and well to inhaled steroids with additional b_2-agonists when necessary. Chronic bronchitis improves on stopping smoking, and most exacerbations respond rapidly to conventional oral antibiotics. The treatment of fibrosing alveolitis is unsatisfactory, although initially oral corticosteroids improve the cough, but may be withdrawn if lung function does not improve in order to prevent long-term steroid side-effects. Cough suppressants such as pholcodeine or codeine linctus in sufficiently large doses are a boon at night. n the most refractory cases, nebulized bupivacaine local anaesthetic solution (0.03 per cent) can be helpful for a few hours, but patients risk aspiration and must avoid eating when their larynx is anaesthetized.

Cough, especially in association with purulent secretions and radiographic pulmonary infiltrations, can be caused by aspiration of stomach and oesophageal contents in systemic sclerosis. The high incidence of oesophageal reflux, especially when the patient is supine, can cause major problems with pulmonary infection, particularly by anaerobic organisms.

Breathlessness

Breathlessness is a common feature of most pulmonary conditions and causes associated with connective tissue disorders can be listed (Fig. 2).

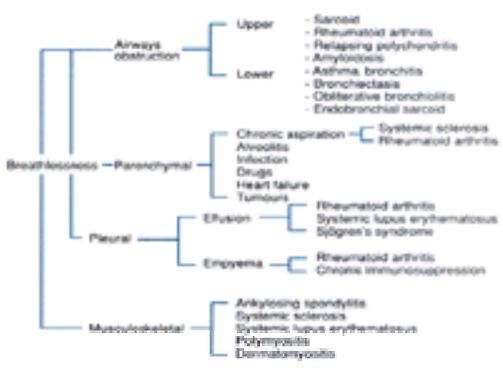

Fig. 2 The causes of breathlessness.

Airways

Asthma, chronic bronchitis, and bronchiectasis, if sufficiently severe, will result in breathlessness on exertion and in asthmatics at rest as well.

Upper airways obstruction will, because of its dominant effect on airways resistance, readily cause dyspnoea. Collapse of the cartilaginous support of the trachea and main bronchi in relapsing polychondritis can cause great difficulty with both inspiration and expiration and will be associated with loud, harsh wheezing and dyspnoea. This rare syndrome is often also associated with a deep, bovine cough. Endobronchial sarcoidosis or laryngeal infiltration by sarcoid can result in severe upper airways obstruction and breathlessness, particularly on exertion. Minor degrees of upper airways obstruction have been reported in up to 18 per cent of autopsies in patients with rheumatoid arthritis. Synovitis of the cricoarytenoid joint may cause supraglottic narrowing and also hoarseness and breathlessness.

Obliterative bronchiolitis has been recognized more recently to complicate rheumatoid arthritis. It is rare and can be rapidly fatal, although in most, whilst the condition seems to be of sudden onset and rapidly progressive, it becomes stable leaving the patient to suffer severe exertional dyspnoea with grossly reduced lung function. Pathologically the small airways (less than 3 mm in diameter) are narrowed or obliterated by a chronic inflammatory process with fibrotic scar formation. Wheezing is not a symptom but on examination high-pitched, end-inspiratory, basal squeaks are often readily audible. The condition responds poorly to corticosteroid or other therapy.

Parenchymal disease

These complications include fibrosing alveolitis, pulmonary infections, aspiration, drug-induced pneumonitis, heart failure, and acute manifestations such as acute lupus pneumonia. The history and the radiographic appearances are sometimes helpful but often frustratingly non-specific. The history may be of more importance, for example drug history, rate of onset of symptoms, and chest pain. Often a diagnosis is made only on lung biopsy (see below).

Sarcoidosis is often associated with widespread pulmonary infiltration, predominantly in the mid and upper zones. However, this is rarely accompanied by physical signs or breathlessness. Late progressive fibrotic changes in sarcoidosis cause shrinkage of the upper lobes with subsequent distortion of the lower lobes, and dyspnoea can develop.

Pleural disease

Pleural effusion

This is the most common respiratory sign in patients with rheumatoid arthritis. It is regarded generally as the only complication of rheumatoid arthritis to be more common in men. It is usually asymptomatic, although there can be pleuritic pain, dyspnoea, and fever. Although the effusions are usually small and unilateral, they can be large and bilateral. Large pleural effusions with dyspnoea are also occasionally seen in systemic lupus, although classically the effusions are small. It is more common in lupus to obtain a history of pleuritic chest pain and breathlessness with no visible effusion. Aspiration of an effusion is required usually to exclude infection or malignancy. The fluid is characteristically clear coloured, an exudate (protein greater than 30 g/l) with, in rheumatoid arthritis, a very low or unrecordable glucose concentration. The concentrations of lactate dehydrogenase and cholesterol are raised. Rheumatoid factor is detected frequently in the fluid. Pleural biopsy is rarely

helpful, with non-specific features of chronic inflammation only. If the effusions fail to resolve, or relapse after drainage, oral corticosteroids may be rapidly effective. It is rare to have to resort to surgical pleurectomy.

Empyema

Empyema is relatively common in patients with rheumatoid arthritis. This usually is secondary to long periods of corticosteroid therapy, but is seen less often in other autoimmune rheumatic disorders that are similarly treated. Breathlessness is common, as is a fever with malaise and weight loss. The diagnosis is established on aspiration of turbid fluid containing pus cells. The fluid should be cultured for aerobic and anaerobic organisms as well as tuberculosis. The empyema should be treated intensively, with local drainage as well as systemic antibiotics. Rib resection should be done early to facilitate drainage if intercostal tube drainage is not effective. A decortication may be necessary when the infection has resolved as a thick residual pleural cortex can cause severe restriction of movement of the underlying lung. Ideally, surgical decortication should be done at least 6 weeks after the infection has resolved, thus allowing the underlying lung tissue to heal and making surgery easier and less traumatic.

Chest wall disease

Breathlessness can be caused by the patient's inability to ventilate the lungs adequately. Gross restriction of the chest wall can occur in advanced systemic sclerosis and in ankylosing spondylosis. In the presence of normal lung fields on a chest radiograph, musculoskeletal causes of dyspnoea are often overlooked and psychogenic reasons may have to be considered. However, clinical examination of the patient and appropriate lung function tests should leave the physician in little doubt as to the correct cause.

Weakness of the respiratory muscles is often insidious and difficult to detect unless there is obvious wasting of other muscle groups such as in the upper limb girdle. Again, lung function tests are extremely helpful but the physician should be alert to the possibility of muscle weakness. In systemic lupus the contractile properties of the diaphragm are sometimes impaired, allowing it to keep its curved shape and resulting in lungs that look small radiographically on full inspiration. In polymyositis and dermatomyositis the well-recognized proximal myopathy often extends to involve the respiratory muscles.

Rarer causes of dyspnoea

These include pulmonary haemorrhage in Behçet's syndrome, usually due to a leaking aneurysm of a pulmonary artery, or bleeding from a pulmonary infiltration subsequent to the pneumonitis occasionally seen in this condition.

Tumours can develop in some autoimmune rheumatic disorders, particularly rheumatoid arthritis and Sjögren's syndrome, and less frequently dermatomyositis. Lymphoma can develop as a result of long-term immunosuppressive therapy.

Radiological aspects

There is a plethora of pulmonary abnormalities providing a large differential diagnosis for radiographic shadowing in association with connective tissue diseases (Fig. 3). Some of these are detailed next.

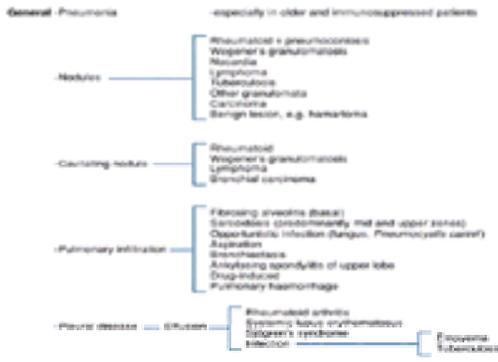

Fig. 3 The radiological abnormalities of rheumatic diseases.

Pulmonary nodules

Although the most common cause of a round lesion on the chest radiograph is a bronchial carcinoma and the next most common a benign lesion such as a hamartoma, there are several rheumatological causes or associations with such a lesion.

In rheumatoid arthritis, nodules histologically identical to subcutaneous necrobiotic nodules can occur. They tend to be peripheral, and can increase in size, remain static, or disappear (Fig. 4). They can also cavitate and they can occasionally cause a pneumothorax. When single, the differential diagnosis will include another benign lesion, a bronchogenic carcinoma, tuberculosis, or another granuloma (Fig. 3). The diagnosis is often elusive, although occasionally fine-needle aspiration of the lesion yields granulation tissue suggestive of a necrobiotic nodule.

Fig. 4 Necrobiotic nodules with bilateral effusions (the right is subpulmonary) in a case of rheumatoid arthritis.

Caplan's syndrome occurs when simple coal-workers' pneumoconiosis, or another pneumoconiosis, is complicated by the development of rheumatoid nodules, which are visible on the chest radiograph. These often arise in crops and may sometimes enlarge rapidly.

Nodular shadowing can occur in Wegener's granulomatosis, often as the only abnormality associated with malaise, fever, and a high erythrocyte sedimentation rate. The antineutrophil cytoplasmic antibody test is usually positive. The nodules can enlarge rapidly, become multiple, and cavitate producing relatively large, thin-walled lesions (Fig. 5). Diagnosis by fibreoptic transbronchial lung biopsy is unusual as a moderately large artery is required to provide evidence of vasculitis. Open lung biopsy is usually necessary if tissue for diagnosis is required.

Fig. 5 Multiple nodules of Wegener's granulomatoisis; some are cavitating.

Nocardia, a variety of the Actinomycetaceae, can develop as an opportunistic infection in patients on prolonged immunosuppressive therapy. They form single or multiple nodules, which may cavitate. Usually extrapulmonary lesions soon develop, as for example in joints and the subcutaneous tissues.

It is often impossible to distinguish a malignant from a benign nodule. This is particularly the case for pulmonary metastases, which are often spherical with smooth margins. If they are multiple and a range of sizes, then malignant disease is probable.

The classical malignant primary tumour will have an irregular margin with 'sun ray' spicules radiating out into the surrounding parenchyma. The presence of flecks of calcium cannot guarantee benign disease. Computed tomography (**CT**) often identifies subpleural nodules invisible on routine chest radiographs. The likelihood of malignant origin will increase if the nodules are greater than 10 mm in diameter. Most subpleural nodules are granulomata, that is old tuberculosis or sarcoid, and in the United States may often be due to fungal disease such as histoplasmosis or coccidioidomycosis.

Hyperinflated lungs

These occur only in some cases of obliterative bronchiolitis, unless there is emphysema as an independent feature in a patient who also happens to have a connective tissue disorder. The lung fields in obliterative bronchiolitis are clear, with no other specific features (Fig. 6). They are, however, often of normal size and appearance.

Fig. 6 The lungs are markedly overinflated, and there is a reduction in the vascular markings; these are non-specific findings but consistent with obliterative bronchiolitis. There is a necrobiotic nodule in the left lower lobe, behind the heart.

Small lungs

This appearance occurs in lupus; bilateral diaphragmatic weakness prevents the diaphragms from shortening and 'flattening' on inspiration, and both diaphragms remain elevated and deeply domed. There may be linear atelectatic shadows in the lower lobes, particularly above the diaphragm as a consequence of the basal hypoventilation. There is an apparent mediastinal widening in these patients but only as a consequence of the volume loss and not due to mediastinal disease.

Parenchymal shadowing

Diffuse, predominantly basal, reticulonodular shadowing, possibly with overall reduction in lung volume, is typical of fibrosing alveolitis. This occurs in association with rheumatoid arthritis, systemic lupus, systemic sclerosis, and Sjögren's syndrome (Fig. 7 and Fig. 8). The appearances are non-specific and identical to those cases of lone fibrosing alveolitis. Interstitial lung disease in rheumatoid arthritis correlates with the severity of joint disease, ranging from an incidence of just 1 per cent in mild rheumatoid arthritis to a 30 to 40 per cent association in patients with severe joint deformity. The interstitial infiltrates are depicted radiographically as small, irregular shadows or opacities, predominantly at the lung bases. These shadows are also termed reticulonodular densities, ground-glass densities, or increased interstitial markings. Eventually the infiltrates extend to the upper lung fields. They can occasionally respond remarkably well to treatment with corticosteroids (Fig. 9). If the interstitial fibrosis progresses, it can develop areas of honeycombing comprising round or polygonal air cysts with well-defined walls and measuring less than 5 mm in diameter. The cysts may eventually become confluent, forming large destructive cavities in the subpleural regions. Rupture can cause pneumothorax.

Fig. 7 Typical appearances of established fibrosing alveolitis with a reticulonodular pattern concentrated mainly in the lower lobes.

Fig. 8 Widespread coarse reticular shadowing mainly in the lower zones with associated loss of volume in a patient with rheumatoid arthritis. Note erosion of right humeral head. Tracheostomy in place.

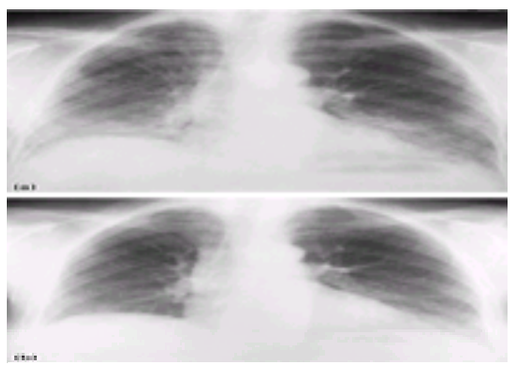

Fig. 9 (a) Reticulonodular and confluent shadowing at the lung bases; (b) 8 months later, almost complete resolution after corticosteroid treatment.

High-resolution CT scanning provides an 'early warning' means of assessing the lungs. In a study of 17 patients with early scleroderma it was shown that 15 (88 per cent) had a variety of abnormalities, especially subpleural cysts and honeycombing (Warrick *et al*. 1991). In contrast the plain chest radiograph was abnormal in only 10 cases (59 per cent). Similarly changes consistent with rheumatoid-associated lung disease, notably interstitial fibrosis, were detected in patients with rheumatoid arthritis at a time when the chest radiograph was often normal (Fewins *et al*. 1991). This form of scanning also facilitates the precise distribution of alveolitis and the extent of any lung fibrosis and destruction (Fig. 10 and Fig. 11).

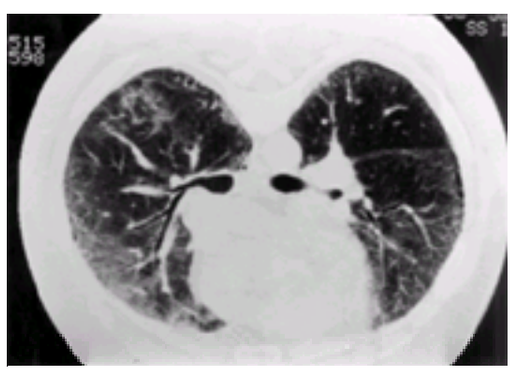

Fig. 10 Prone, high-resolution CT at the level of the carina. Diffuse parenchymal opacification in a subpleural distribution. This pattern is seen during the desquamative phase of fibrosing alveolitis.

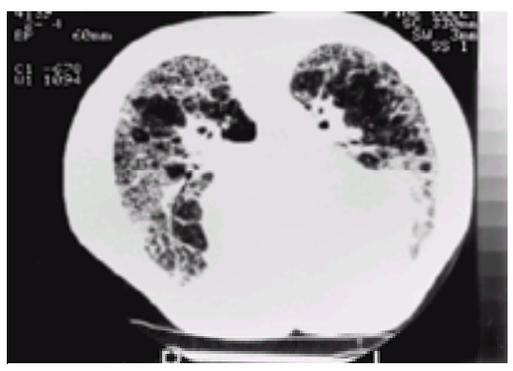

Fig. 11 Prone, high-resolution CT through the lower lobes. There is a reticular pattern in a subpleural distribution representing established fibrosis in a case of systemic sclerosis.

Other causes of diffuse pulmonary infiltrates include:

1. Sarcoidosis. The shadowing is usually more nodular and spares the lung bases. It is often associated with bilateral hilar lymphadenopathy, few symptoms, and commonly no decrease in lung size.
2. Infection. Opportunistic infection with fungi can also cause diffuse shadowing. However, the lesions are often more nodular and, although usually affecting more than one lobe, are often focal.
3. Polyarteritides. In polyarteritis nodosa a peripheral, soft, ill-defined, predominantly apical and/or midzone shadowing can develop, usually in association with an elevated peripheral eosinophil count. This 'pulmonary eosinophilia' can also be associated with pleural or pericardial effusions and is very responsive to corticosteroid therapy. It is similar to a hypersensitivity drug reaction within the lung such as occurs with gold salts (Fig. 12).

Fig. 12 Mild upper-zone consolidation, predominantly peripheral on the right, typical of pulmonary eosinophilia.

4. Upper lobe fibrosis is seen in ankylosing spondylosis, with contracture of the upper lobes and upward traction of the hilas. Eventually the upper lobes may cavitate. Apical pleural thickening may also develop and be extensive (Fig. 13).

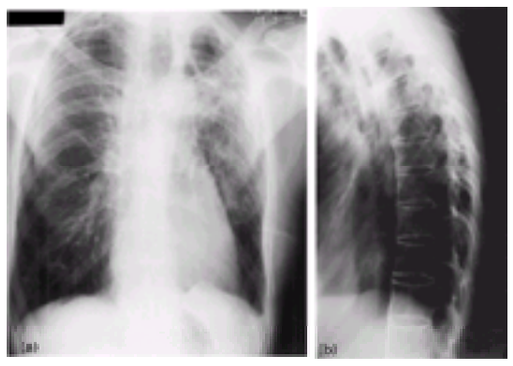

Fig. 13 (a) Linear shadows in upper zones with marked elevation of the hila consistent with upper-zone fibrosis in a case of ankylosing spondylosis. There is fusion of the costotransverse joints. (b) Lateral dorsal spine shadowing anterior syndesmophytes typical of ankylosing spondylosis.

5. Cavitation in the upper lobes, and to a lesser extent the mid zones, amongst florid scarring is also seen in sarcoidosis. This progressive course of sarcoid usually develops after the bilateral hilar lymphadenopathy has regressed. In both sarcoidosis and ankylosing spondylosis the cavities can become colonized by *Aspergillus* spp. to form mycetomata. These semisolid masses appear to 'sit' in the cavity surrounded by a halo of air, a characteristic appearance. Serum aspergillal precipitins will be strongly positive.
6. Focal intrapulmonary shadowing can occur after aspiration of gastric contents. Classically, aspiration happens when the subject is lying prone and the inhaled contents run posteriorly to the posterior segment of the upper lobes or apical segment of the lower lobes. Consolidation will be concurrent with the symptoms and signs of infection. Aspiration of anaerobic organisms is frequent and can cause pulmonary cavities. However, there can also be aspiration into basal segments, especially if it is associated with gross dysphagia as in advanced systemic sclerosis.
7. Bronchiectasis is recognized by peribronchial thickening causing 'tram-lines' on the chest radiograph due to a widened lumen and the thickened bronchial walls. Cystic changes can also be detected in cases where the damage is extensive. The lesions are patchy but usually confined to the middle and lower lobes.

Rare causes of pulmonary infiltrations will include acute exacerbations of lupus, a lymphoid tumour in, for example, Sjögren's syndrome, and intrapulmonary haemorrhage in a vascular disorder such as polyarteritis, Wegener's granulomatosis, or Behçet's syndrome.

Pleural disease

Pleural thickening is very unusual in autoimmune rheumatic disorders but pleural effusions are moderately common, especially in rheumatoid arthritis. They also occur in lupus and Sjögren's syndrome, and can reach considerable size.

Pulmonary function tests

Pulmonary function tests are not diagnostic but provide invaluable information as to the pattern and extent of an abnormality. They should be carried out early in any patient with pulmonary complications so that a baseline can be established and followed in order to evaluate the response to therapy, or assist in making decisions when to start therapy.

Spirometry

This is a simple test for almost any patient. It requires some co-operation for maximal inspiration and forced expiration until 'empty'.

The forced expiratory manoeuvre measures the forced expired volume in 1 s (**FEV_1**) and the forced vital capacity (**FVC**). The FEV_1/FVC ratio, expressed as a percentage, should be greater than 75 per cent, but falls with normal ageing to 65 per cent at 70 years. Figure 14 shows typical obstructive and restrictive patterns of spirometry. The obstructive pattern, with a proportionately greater decrease in FEV_1 than FVC, is found in all types of airflow obstruction. In pulmonary infiltrative conditions with or without fibrosis the FEV_1 is preserved relatively (although reduced) compared to the FVC. This results in an FEV_1/FVC ratio of greater than 80 per cent, but with reduced absolute values, the extent depending on the severity of the lesion.

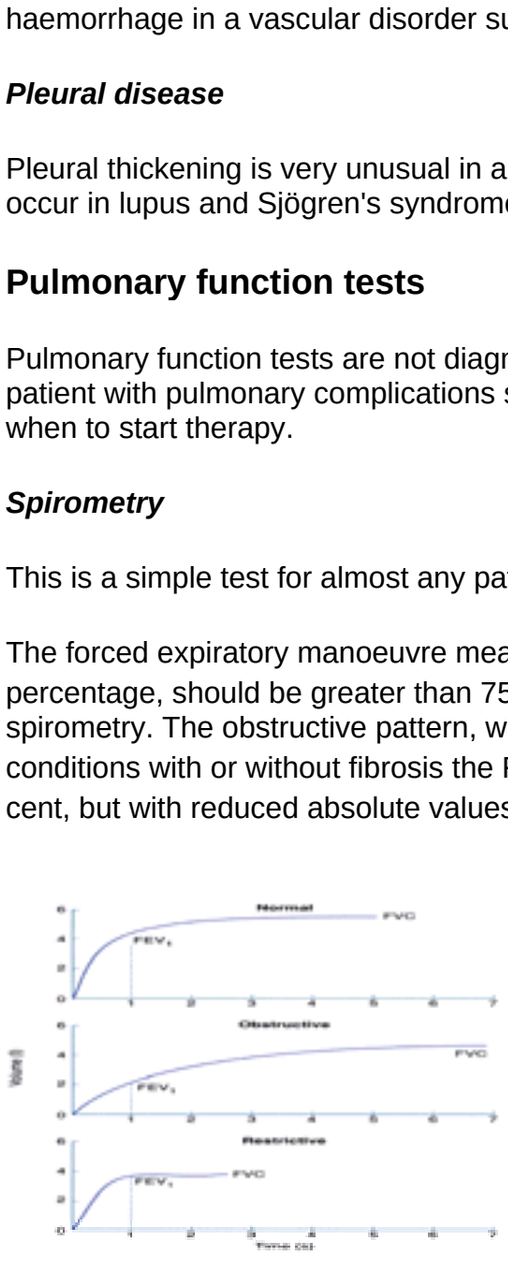

Fig. 14 Normal, obstructive, and restrictive patterns of spirometry.

In patients with stiff chest walls or weak muscles the pattern of spirometry is also restrictive, with reduction in both FEV_1 and FVC. The FEV_1/FVC per cent is not always increased as the elastic recoil pressures within the lung remain normal in contrast to parenchymal diseases.

Peak expiratory flow (PEF)

This is the most commonly tested lung function and yet is not particularly sensitive. The PEF is the instantaneous flow rate during the first 10 ms of expiration after a maximum inspiration. It is a measure of airflow obstruction, dominated by flow from the upper airways. The PEF is of little value in restrictive pulmonary conditions as the airways are normal. However, where upper airways obstruction is suspected the PEF is reduced severely. An indication that there may be obstruction in the trachea, carina, or main bronchi can be deduced if the ratio of FEV_1 (ml) to the PEF (l/min) is greater than 10.

Flow volume curves

The envelope of expiratory flow from total lung capacity (**TLC**) to residual volume (**RV**) and then back in again to TLC can be simply captured as flow versus volume (Fig. 15). This provides a sensitive measure of peak flow and expiratory flow. Flows along subsections of the vital capacity—usually at 25 and 50 per cent above the residual volume (V_{25}:V_{50}) are measured and compared to age- and sex-matched normal values. These flow rates represent flow in the small airways and are reduced especially when generalized obstruction predominates. In rheumatological medicine a good example is found in obliterative bronchiolitis (Fig. 15(b)) where flow at V_{50} and V_{25} is reduced especially compared to the FEV_1 and PEF when expressed as the percentage predicted. Pressure-dependent collapse (as in emphysema), that is decreased recoil causing collapse of major airways on forced expiration (Fig. 15(d)), is especially prominent in relapsing polychondritis where the trachea collapses during expiration. Flow volume curves give little information in patients with parenchymal disease.

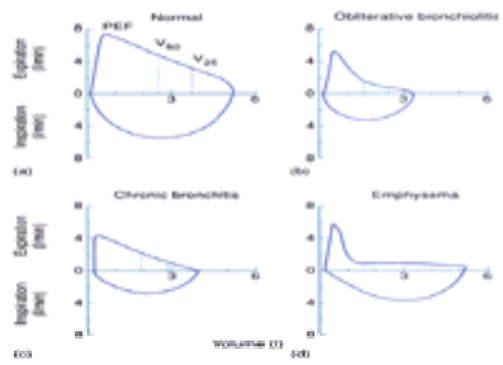

Fig. 15 (a) A normal flow volume curve. During expiration flow reaches an immediate peak (peak expiratory flow) and gradually falls to zero at residual volume. Flow rates at 50 and 25 per cent of the vital capacity are shown. (b) Reduced flows and small vital capacity in obliterative bronchiolitis. (c) 'Volume-dependent' reduction in expiratory flows in chronic bronchitis. (d) 'Pressure-dependent' reduction in expiratory flow in emphysema.

The flow volume loop is also particularly useful for detecting upper airways obstruction. The site of the lesion and whether it is fixed or variable will affect the shape of the flow volume loop (Fig. 16).

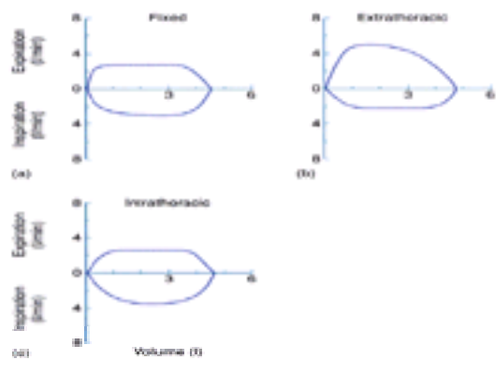

Fig. 16 Upper airways obstruction: (a) fixed airflow obstruction; (b) extrathoracic airflow obstruction, affecting inspiratory flow more than expiratory flow; (c) intrathoracic airflow obstruction, affecting expiratory flow more than inspiratory flow.

Total respiratory pressures

Classically patients with weakness of the respiratory muscles will show reduced spirometric and PEF values. However, this is not diagnostic as it fails to differentiate between muscle weakness and reduced lung volumes secondary to parenchymal disease. The strength of the respiratory muscles is best and simply measured by the maximum inspiratory and expiratory mouth pressures.

If pure diaphragmatic weakness or paralysis is suspected, then spirometry done with the patient first lying and then standing can be most useful. A drop in vital capacity by up to 40 per cent can occur when lying flat if the diaphragm is non-functioning. This is due to the abdominal contents moving towards the chest unopposed when the patient lies flat. This is a remarkably reproducible test.

Thoracic lung volumes

Measurement of TLC and RV in patients with restrictive lung disease is very important before treatment and should be closely followed during therapy. Lung volumes can be measured either by the wash-out (or wash-in) method of using an inert gas as by body plethysmography. In restrictive conditions both RV and TLC will be reduced. However, in patients with muscle weakness, RV may be reduced but TLC can be reasonably normal. Figure 17 illustrates these points.

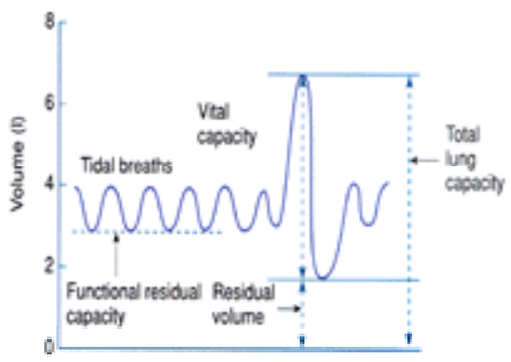

Fig. 17 The thoracic lung volume subdivisions.

Diffusing capacity

The magnitude of carbon monoxide gas transfer (*TL*CO) depends on the volume of the pulmonary capillary bed and the matching between the distribution of ventilation and perfusion within the lungs. The test is done with the subject inspiring a known concentration of carbon monoxide and of an inert gas, helium. As the helium is not absorbed, the change in its concentration in the expired sample will provide a measure of the volume of alveolar gas into which the gas mixture was inspired (alveolar volume, V_A). If the quality of uptake of carbon monoxide per unit of lung is desired, then dividing the *TL*CO by the V_A will provide the carbon monoxide transfer coefficient (*K*CO), a quantitative assessment of the efficacy of uptake by the lung and alveolar capillaries of carbon monoxide per litre of lung volume.

The *TL*CO is reduced when:

1. The alveolar capillaries are reduced in number, for example in emphysema, pulmonary fibrosis, pulmonary embolic disease, and pulmonary hypertension.
2. There is an increased ventilation/perfusion mismatch as occurs in pneumonia, infection, and infiltrates, and sometimes in pulmonary oedema.
3. There is a reduction in haemoglobin content in the blood.
4. The patient is a heavy smoker with high levels of carboxyhaemoglobin.

The *TL*CO is increased when:

1. There is a redistribution of ventilation/perfusion ratios enabling more capillary blood to come into contact with inspired gas as sometimes happens in asthma.
2. There is alveolar haemorrhage increasing the amount of haemoglobin available to carbon monoxide in the alveoli.
3. Polycythaemia increases the level of available haemoglobin in the capillaries.

Walking tests

Assessment of the functional ability of an individual in a manner that uses a normal, habitual activity is very useful. In patients with joint disease, formal treadmill or cycle ergometric exercise testing is often not possible. However, a walking test may be feasible. The subject is asked to walk up and down a corridor of known length or other suitable enclosed space for 2, 6, or 12 min watched by a technician who measures the distance walked and uses standard terms of encouragement at regular intervals. After a practice walk, a second walk distance is recorded. This is often up to 30 per cent longer than the initial distance walked, as the patient develops confidence in the test and his or her ability. Extra information can be obtained, for example, by attaching a portable pulse oximeter to the finger or ear to measure oxygen saturation during the walk. The test is highly reproducible after the test practice walk.

Differences in pulmonary function in the context of rheumatological diseases are summarized in Fig. 18. As indicated earlier, serial performance of these tests provides a useful way of assessing response to therapy. Thus, Akesson and colleagues demonstrated that cyclophosphamides increased vital capacity and static lung compliance in 18 patients with scleroderma who had lung disease (Akesson *et al*. 1994).

Fig. 18 A summary of pulmonary function in rheumatological diseases. PEFR, peak expiratory flow rate; FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity; TLC, total lung capacity; RV, residual volume; FRC, functional residual capacity; P_1 max, maximal inspiratory mouth pressure; P_E max, maximal expiratory mouth pressure.

Bronchoscopy, lavage, biopsy, and other diagnostic tests

Lung biopsy

Open lung biopsy remains the best method for providing tissue for histopathological diagnosis of chronic infiltrative lung diseases, and a review of several series gave a diagnosis in 94 per cent of cases (Gaensler and Carrington 1980). However, this procedure is by no means routinely performed, particularly when the association between the joint disease and the presence of pulmonary infiltration is both typical and as expected. The ultimate answer will be the response to any attempted therapy. A recent survey in the United Kingdom reviewed the case notes of 200 patients with cryptogenic fibrosing alveolitis, of whom 119 cases had only a clinical diagnosis—based on typical physical signs. Only 15 patients underwent an open lung biopsy, 35 bronchoalveolar lavage, and 66 transbronchial biopsy (Johnson *et al*. 1993).

If open lung biopsy is done, it is usually through a minithoracotomy and at least two areas of lung are sampled. In general the right middle lobe and the lingula are avoided as it is claimed by some that fibrosis occurs more readily in these areas. Similarly, there is little value in removing a piece of grossly fibrotic lung as it will be histologically less helpful. A moderately involved and an apparently uninvolved piece of lung should be sampled. The alternative to open lung biopsy is a transbronchial lung biopsy via the fibreoptic bronchoscope. While this is usually simple, with few complications (e.g. pneumothorax), the biopsies suffer from being very small and probably are not representative of a diffuse, chronic process. Four to six biopsies are recommended, all from one lung to avoid the risk of bilateral pneumothoraces, but from more than one segment whenever possible. Non-specific reactions and non-diagnostic microscopic appearances may be misleading (Wall *et al*. 1981).

Computed tomography

In patients who present with interstitial infiltration together with an obvious autoimmune rheumatic disease the need to obtain pulmonary histology is less urgent or potentially helpful. High resolution CT has been shown to be a good predictor of lung histology in systemic sclerosis, and can discriminate between fibrotic and inflammatory histology (Wells *et al*. 1992). Furthermore, high resolution CT in patients with systemic sclerosis can identify different patterns of the disease; that is ground-glass pattern, mixed, or predominantly reticular patterns—the latter being the most abnormal. These patterns correlate strongly with lung function, especially gas transfer (*TL*CO). Responses to therapy were seen most commonly in patients with a ground-glass appearance on high resolution CT, and least in those with a reticular CT appearance (Wells *et al*. 1993b).

Another potentially useful predictor of prognosis is the rate of clearance of technetium labelled diethylene-triamine-pentacetae (99mTc-DTPA) from the lung. Those patients with interstitial lung disease who had normal clearances had stable disease, whilst those with rapid clearances had deteriorating disease. There was no association between rates of clearance and the likelihood of responding to corticosteroid treatment (Wells *et al*. 1993a), and this was not influenced by any association of the fibrosing alveolitis with an autoimmune rheumatic disease.

Bronchoalveolar lavage

Lavage allows examination of the cellular and non-cellular elements present on the epithelial surface of the alveolar space. It does not truly sample the lung parenchyma; however, in some studies there has been good correlation between the type and the number of inflammatory cells obtained by lavage and those obtained by diagnostic lung biopsy (Reynolds 1987).

The technique does, however, have serious shortcomings both in its diagnostic value and as a tool for following disease activity. There is no satisfactory consensus on what constitutes a 'routine' analysis of fluid from bronchoalveolar lavage. Total and differential cell counts, frequently with identification of T-lymphocyte subsets by monoclonal antibody techniques, are usually made. Fluid from a non-smoker normally contains 85 to 90 per cent macrophages, 7 to 12 per cent lymphocytes, and 0.1 per cent neutrophils (Reynolds 1987). Patients may be classified as having a neutrophil alveolitis or a lymphocyte alveolitis based on an increase in the percentage of neutrophils or lymphocytes. A neutrophil alveolitis is often seen in cryptogenic fibrosing alveolitis, histiocytosis X, and in smokers; a lymphocytic alveolitis is commonly seen in sarcoidosis, hypersensitivity alveolitis, and granulomatous infections. However, there is marked overlap.

The value of bronchoalveolar lavage in the serial follow-up of lesions is not yet established with confidence. However, a study that included a subgroup of patients with rheumatoid arthritis associated with fibrosing alveolitis showed a link between a response to steroids and a decrease in neutrophils in the lavage (Turner-Warwick and Haslam 1987).

In patients suspected of pulmonary infections, especially by opportunistic organisms, bronchoalveolar lavage has a distinct role. On failing to make a diagnosis from sputum, or in the absence of sputum, a lavage via fibreoptic bronchoscopy in patients with pulmonary infiltrates can reveal fungi, *Pneumocystis carinii*, cytomegalovirus, Nocardia, tuberculosis, and other bacteria.

In patients suspected of drug-induced pulmonary shadowing, bronchoalveolar lavage may have a role but often the cell counts are non-specific. Data are too scanty to confirm the use of lavage as a diagnostic tool for drug-induced pathology.

Transbronchial lung biopsy also can provide findings suggestive of drug eruptions—with type I pneumonocyte desquamation and type II cell dysplasia. Hypersensitivity reactions may produce granulomas, interstitial eosinophilic infiltration, or granulation tissue as seen in some drug-induced organizing pneumonias.

Vascular studies

With the identification in the mid-1980s of clinical syndromes associated with the presence of antiphospholipid antibodies, much interest has focused on clotting abnormalities in the lungs of patients with underlying rheumatic disease. The widespread availability of ventilation/perfusion ratio (V/Q) scanning, CT and magnetic resonance imaging scans, and the more specialized pulmonary angiograms and digital subtraction angiography have greatly facilitated the ability to demonstrate the presence of pulmonary emboli and infarction. The association of antiphospholipid antibodies with deep venous thrombosis and thromboembolic pulmonary hypertension seems to be better documented in patients with the primary antiphospholipid antibody syndrome (Asherson *et al*. 1989) than in patients with systemic lupus erythematosus (Gulko *et al*. 1993).

Although much less common, pulmonary arterial aneurysms have been demonstrated in approximately 1 per cent of patients with Behçet's syndrome (Hamuryudan *et al*. 1994). Haemoptysis is the usual presenting symptom and the prognosis is often poor.

Pulmonary infections (Table 2)

Table 2 Pulmonary infections in rheumatology

The rheumatological conditions have a considerable association with pulmonary infection, probably because they induce host-defence defects within the immune system. In systemic lupus, many aspects of the immune system have been reported to be abnormal. These include the antibacterial activity of the alveolar macrophages, defects in the Fc receptor function of the macrophages, and diminished clearance of immune complexes by macrophages.

Defects have also been described in the chemotactic and phagocytic activity of both polymorphonuclear neutrophils and blood monocytes. Lymphopenia is common, and T lymphocytes, especially T suppressors, are decreased.

Patients with rheumatoid arthritis have a predisposition to pleuropulmonary infection. A twofold rise in pneumonia was found when patients with rheumatoid arthritis were compared to those with degenerative joint disease; deaths due to respiratory infection were four times more frequent than expected.

The drugs used to treat rheumatic diseases also adversely affect the host defence system; the complex and many effects of glucocorticoids have been described by Cupps and Fauci (Cupps and Fauci 1982). Cyclophosphamide affects virtually all components of the cellular and humoral immune response. The drug acts primarily during the S phase of the cell cycle and so all rapidly dividing cells are involved. B-lymphocyte depletion occurs early and antibody production can also be inhibited. Azathioprine also inhibits both humoral and cell-mediated immunity, and suppresses the numbers of both T and B lymphocytes. Methotrexate is a folic acid antagonist that interferes with transport of carbon fragments required for thymidine synthesis; DNA synthesis and cellular proliferation are inhibited.

Specific infections

Bacteria

Gram-negative bacteria (*Klebsiella pneumoniae, Escherichia coli*, and *Pseudomonas aeruginosa*) are frequent causes of pneumonias in patients with autoimmune rheumatic disorders. The high frequency of these infections is probably related to the ease with which Gram-negative bacteria colonize the upper respiratory tract in patients with serious or debilitating conditions.

As far as Gram-positive bacteria are concerned, the incidence of pneumococcal infections in this group of patients is probably no higher than in the general population. *Staphylococcus aureus* is a common cause of death in patients with systemic lupus (Hellman *et al*. 1987).

Infection with *Legionella* spp. is more frequent than normal in immunocompromised patients and those on immunosuppressive medication; 95 per cent will be caused by *L. pneumophilia*, and occasional cases by *L. micdadei*. The radiographic features of Legionella pneumonia will usually be indistinguishable from those of the other bacterial pneumonias. However, confusion, prostration, hyponatraemia, and disturbance of liver function are more common. Standard bacterial cultures will be unhelpful but cultures in specific media may provide a diagnosis within 2 to 7 days. Indirect immunofluorescence antibody techniques are positive in 70 to 90 per cent of cases at 10 days.

Fungal infections

Aspergillus

Aspergillus causes two types of infection in patients with autoimmune connective diseases. *Aspergillus* spp. frequently colonize cavities in patients with chronic fibrotic lung disease. In the autoimmune rheumatic diseases, these include sufferers from type III sarcoidosis and, occasionally, patients with upper lobe fibrosis secondary to ankylosing spondylosis. Usually the mycetoma remains asymptomatic but it can cause large haemoptyses. Should haemoptyses develop, resection will be difficult because of the surrounding fibrosis and scarring, with extensive adhesion to the chest wall, and the probability of poor overall lung function. Embolization of bronchial arteries by selective angiography is the treatment of choice and is successful in approximately half of cases.

Invasive aspergillosis is a much more lethal condition. Patients prone to this complication are those with severe defects in both cellular immunity and granulocyte neutrophil count and function. Other factors include cytotoxic or corticosteroid therapy, recent broad-spectrum antibiotic therapy, and severe neutropenia. Over 90 per cent of cases occur in association with the treatment of haematological malignancies or with organ transplantation. The most common initial finding is fever, usually with a patchy bronchopneumonia on the chest radiograph. However, the radiograph can also show nodular infiltration, lobar consolidation, cavitating lesions, or a diffuse miliary or interstitial pattern. Progressive parenchymal necrosis due to invasion of blood vessels by the fungus can cause cavitation with rapid colonization by a mycetoma. The propensity to invade vessels predisposes to death from massive haemoptysis.

The diagnosis of invasive aspergillosis is difficult. Bronchoscopy with lavage is seldom helpful but transbronchial biopsy will produce fungal hyphas in 40 to 70 per cent of cases. The mortality is in excess of 80 per cent, but starting treatment early and restoring the immune function may improve survival. Amphotericin B is the mainstay of therapy and the addition of 5-fluorocytosine is probably helpful. The renal toxicity of amphotericin is a serious potential problem, particularly if there is underlying renal disease. Liposomal amphotericin B with higher local deposition and activity is valuable in patients not tolerant of the conventional drug.

Phycomycetes

These non-septate fungi cause infection much less commonly than aspergillus. They also have a propensity to infect the lung and the central nervous system, and invade the vasculature. The diagnosis is usually by transbronchial lung biopsy. Untreated the mortality rate is nearly 100 per cent. Amphotericin B is the recommended treatment.

Cryptococcus neoformans

This organism usually invades the central nervous system but pulmonary involvement can arise, either in conjunction with infection of the central nervous system or in isolation (Kerkering *et al*. 1981). In up to a quarter of cases there may be no symptoms, only the incidental findings on a chest radiograph. A nodular lesion (single or multiple) is common but alveolar infiltrates are also often found. Sputum culture is positive in up to one-third of cases of cryptococcal pneumonia. Transbronchial lung biopsy is positive in up to half of cases presenting with infiltration, but nodular lesions usually require open lung biopsy for diagnosis.

(Histoplasmosis and coccidiomycosis also occur in endemic areas but are rare.)

Nocardia asteroides

Nocardiosis can complicate autoimmune rheumatic disease, particularly lupus. Prompt diagnosis is critical as the infection disseminates rapidly to cause death. Early treatment can cure up to 80 per cent of cases. Pulmonary involvement usually predominates, with an abnormal chest radiograph in 70 per cent of cases. Multiple nodular densities with or without cavitation are characteristic. A percutaneous fine-needle aspiration biopsy is diagnostic in up to 80 per cent of cases. Treatment with trimethoprim–sulphamethoxazole is highly effective.

Mycobacterial infections

Both typical and atypical mycobacterial infections occur in patients with autoimmune rheumatic disorders. The clinical features are often non-specific and pulmonary infiltration common, usually lacking the classical cavitating appearance found in the non-immunosuppressed. A high degree of suspicion is required. Sputum smears are the investigation of choice but, if negative, alveolar lavage can provide a diagnosis in up to 80 per cent of cases (Stover *et al*. 1984). *Mycobacterium tuberculosis* is sensitive to standard antituberculous therapy—rifampicin, isoniazid, and pyrazinamide—with the prospect of cure in more than 80 per cent. The cure rates for atypical mycobacteria infection are always considerably lower.

Pneumocystis carinii

Although the prevalence of *Pneumocystis carinii* pneumonia has increased dramatically in some populations over the last few years, it is still an unusual opportunistic pathogen in patients with autoimmune rheumatic disorders. Nevertheless, one should be aware of the small possibility of it arising and a bronchoalveolar lavage will almost invariably provide a positive diagnosis if the organism is present. Therapy comprises 2 weeks of intravenous trimethoprim, 20 mg/kg per day, with sulphamethoxazole, 100 mg/kg per day, followed by a week of conventional oral trimethoprim and sulphamethoxazole therapy. If trimethoprim and sulphamethoxazole therapy is not possible, then pentamidine isoethionate, 4 mg/kg per day intravenously for 3 weeks, is effective.

Viral infections

Infections with cytomegalovirus, herpes simplex, and herpes varicella zoster are more of a problem in patients with severe and sustained defects in cellular immunity, that is after organ transplantation, in human immunodeficiency virus-positive patients, and in sufferers from haematological malignancies. Nevertheless, these infections occasionally occur in people with connective tissue disorders, especially if taking immunosuppressive therapy.

Drug-induced pulmonary reactions

The disorders caused by the drugs used in autoimmune rheumatic disorders can be grouped as shown in Table 3. The range of such disorders is clearly wide and they mimic pulmonary reactions to the diseases themselves or other causes of pulmonary damage. There is very little that is helpful in the clinical manifestations, laboratory findings, or radiographic appearances specifically to suggest a drug-induced problem. Several patterns of radiographic abnormality occur, including increased interstitial markings, reticulonodular patterns, and alveolar infiltrates, often bilateral and most common in the lower lung fields.

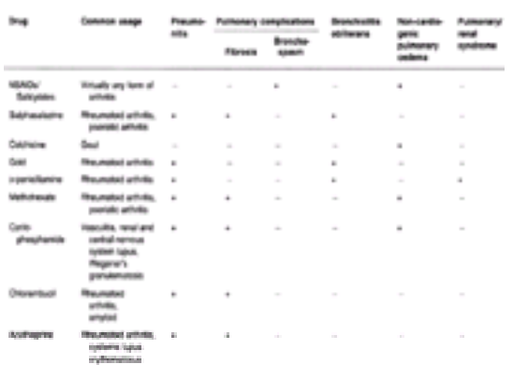

Table 3 Clinical manifestations of drug-induced pulmonary disease

Pulmonary function tests tend to show a restrictive defect with a reduced *TL*CO unless the drug causes a problem that purely affects the airways. Lung biopsy may demonstrate characteristic changes and exclude infection. Interstitial and alveolar inflammation is characterized by mononuclear cell infiltrates. Epithelial abnormalities include proliferation of both type I and type II pneumonocytes, with some dysplastic changes. In those with an acute hypersensitivity reaction, bronchiolitis, giant cells, granuloma formation, and an eosinophil infiltration may develop.

The precise prevalence of clinical manifestations that complicate drug therapy is not established. However, some associations are particularly well founded. For example Chakravarty and Webley reported that 46 per cent of patients treated with gold and 21 per cent treated with D-penicillamine developed a restrictive defect within 2 years of the onset of therapy (Chakravarty and Webley 1992). The chest radiographs often shows dense reticulonodular infiltrates, often basal, and occasionally with pleural fluid. Other features of gold toxicity may be evident elsewhere. Treatment is a combination of stopping therapy and adding corticosteroids and gives excellent results (Israel-Biet *et al*. 1991).

Of particular concern to rheumatologists given its current prominence in treating patients with rheumatoid arthritis and psoriatic arthritis, methotrexate may cause pneumonitis. This complication has been estimated to occur in 7 per cent of patients receiving methotrexate for either neoplastic or non-neoplastic disorders (Cooper *et al*. 1986). In a case–control study, however, no overt risk factors for the development of pneumonitis could be identified (Carroll *et al*. 1994). Even standard-dose regimens of methotrexate can cause pulmonary disease. Presentation of this complication is non-specific with cough, dyspnoea, and pulmonary crackles. Response is usual if the methotrexate is discontinued and high-dose steroids started. The steroids can be withdrawn once maximal improvement is achieved (Hargreaves *et al*. 1992).

Care should be taken if patients develop bronchospasm in relation to salicylates or non-steroidal anti-inflammatory drugs. These episodes usually arise early in treatment with these drugs and can even be seen after a single dose. The episodes can rapidly worsen and death may occur if the drug is continued.

Important points to remember (Table 4)

1. Rheumatoid diseases are associated predominantly with parenchymal infiltration, but airway, pleural, and musculoskeletal involvement are well recognized.
2. Breathlessness may be due to upper airways obstruction or weak muscles or an immobile chest wall. A normal chest radiograph does not eliminate a respiratory cause of dyspnoea.
3. High resolution CT provides clinical patterns of distribution of changes due to fibrosing alveolitis. The grading of those changes correlate to histological appearances and prognosis.
4. Lung function tests should include measurement of gas transfer, assessment of upper airway function (flow-volume curves) and, where indicated, measurement of total respiratory inspiratory and expiratory mouth pressures.
5. Open lung biopsy rarely provides information that is not intuitive from high resolution CT and lung function tests. It is more important where a non-associated cause is suspected, for example infection.
6. Drugs used by rheumatologists can cause pulmonary disease.
7. Infection is relatively common and a diagnosis should be sought, even if invasive tests are necessary.

1.3.6 The gastrointestinal system

Erkki Eerola and Reijo Peltonen

Introduction

Gastroenterology and rheumatology are associated in many ways and historically the idea of the association is not new. In 1672 Sydenham and in 1743 Ives described arthritis in patients with dysentery (Bollet 1981; Midvedt 1987). By the end of the nineteenth century the association between arthritis and shigellosis and inflammatory gut diseases had been recognized. The association can be of aetiological significance, as in enterogenic reactive arthritides, or without a causative link as in many gastrointestinal and rheumatic diseases with manifestations in both systems (Fig. 1 (a and b)). With some diseases it may even be difficult to decide in which category the disease should belong. The cellular and molecular mechanisms of inflammation and tissue damage are basically similar in both chronic inflammatory joint and bowel diseases (Parke 1993). The same drugs can sometimes be used to treat diseases of both systems or gastrointestinal and rheumatic manifestations of the same disease. An important facet is also the large number of gastrointestinal adverse effects of rheumatological medications.

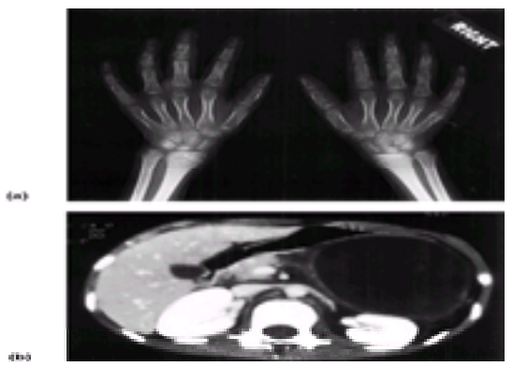

Fig. 1 Post-traumatic pancreatic cyst in a patient with associated lytic bone lesions secondary to lipase release.

Gastroenterological disorders with rheumatic manifestations

Gastrointestinal diseases with rheumatic associations are listed in Table 1. The closest association is in enteropathic arthropathies, which by definition are seronegative axial or peripheral arthropathies associated with gastrointestinal disorders. In patients with inflammatory bowel disease the overall prevalence of arthritic manifestations has been estimated to be approximately 30 per cent, but it seems to be increased (up to 62 per cent) when the patients are studied by rheumatologists (Scarpa *et al*. 1992; Parke 1993). On the other hand, an equally high percentage of patients with spondylitis have subclinical gut inflammation (Mielants *et al*. 1991b); in juvenile spondylarthropathy the prevalence may be even higher (Veys *et al*. 1993). In some of the enteropathic arthropathies rather convincing evidence of an aetiological association does exist. Antigenic material of intestinal microbial origin has been demonstrated in the synovial samples of patients with reactive arthritis after *Yersinia* and *Salmonella* enteric infections (Granfors *et al*. 1989; Granfors *et al*. 1990). Another aetiologically significant finding is the identification of the uncultivable causative agent of Whipple's disease (*Tropheryma whippelii*) from duodenal samples of the patients by using gene amplification techniques (Relman *et al*. 1992). Intestinal bypass surgery is a an example of an anatomical rearrangement which induces microbiological changes in the gut and leads to inflammatory joint symptoms in 6 to 35 per cent or even 52 per cent of the patients (Ross *et al*. 1989). There is a more definite aetiological link, however, in purulent or viral arthritis, when an intestinal pathogen is isolated in an affected joint.

Table 1 Gastrointestinal disorders with rheumatic manifestations

Gastrointestinal manifestations of rheumatic diseases

Gastrointestinal manifestations of rheumatic diseases are listed in Table 2.

Table 2 Gastrointestinal (GI) manifestations of rheumatic diseases (modified from Ryan and Sleisenger 1993)

Rheumatoid arthritis

The most common gastrointestinal manifestations in rheumatoid arthritis are gastric erosions and ulcerations caused by drug therapy. It is very difficult to assess whether the disease itself is an independent risk factor for them because of the widespread use of NSAIDs (Willoughby *et al*. 1986; Doube and Collins 1988). A common manifestation of the disease itself is oesophageal dysmotility, but it is usually benign and rarely causes serious complications or even dysphagia or heartburn. A potentially serious gastrointestinal manifestation is rheumatoid vasculitis, which has been estimated to affect 0.1 per cent of patients, but may be considerably more common. With complications such as ischaemic cholecystitis, appendicitis, pancolitis, bowel ulcerations, infarction, perforation and massive bleeding the mortality is high. In the treatment of vasculitis, cytoxic agents appear to be more effective than corticosteroids (Ryan and Sleisenger 1993). Amyloidosis has also been considered a rare complication although the prevalence appears to be increasing in rheumatoid arthritis. In autopsies, 21 per cent of patients were observed to have amyloidosis and 53 per cent of them had died because of it, although for other than gastrointestinal reasons (Susuki *et al*. 1993). In juvenile rheumatoid arthritis the trend may be the opposite. Amyloidosis as a cause of death is reported to have decreased from 42 per cent in the 1970s to 17 per cent in the 1980s (Savolainen and Isomäki 1993). Aggressive treatment with immunosuppressive agents may be the reason for this decline in mortality (David *et al*. 1993). Rectal biopsy or subcutaneous fat biopsy gives a 75 per cent diagnostic yield for amyloidoisis, but lip biopsy may be even better (86 per cent) (Bocanegra 1995). Interestingly, vasculitis and amyloidosis appear to exclude each other (Susuki *et al*. 1993).

Scleroderma

Gastrointestinal manifestations are common in scleroderma, occurring in 50 to 90 per cent of patients. They may precede the skin involvement, but usually, when the gastrointestinal tract is affected, the disease process is diffuse with multiple levels of involvement. The disease is characterized by mononuclear cell infiltrates, collagen deposition, and small vessel vasculitis in the skin and internal organs (Abu-Shakra *et al*. 1994). The most common symptoms are heartburn and dysphagia, and the most frequent manifestations of the disease include oesophageal dysmotility and lower oesophageal sphincter laxity. Small bowel involvement occurs in 17 to 50 per cent of patients. These manifestations often include segmental dilatation, atony, pseudo-obstruction, and bacterial overgrowth of the small bowel (10 per cent). The reported frequency of colonic involvement varies between 10 and 50 per cent; constipation in about 30 per cent and wide mouth diverticula in over 28 per cent. Other colonic complications such as telangiectasis, pseudo-obstruction, and volvulus are rare and each of them occurs in about 1 per cent of patients (Abu-Shakra *et al*. 1994).

Systemic lupus erythematosus

The most common gastrointestinal manifestation of systemic lupus erythematosus is abdominal pain. Nausea, anorexia, or vomiting affects over 50 per cent of patients. Diarrhoea affects 5 to 25 per cent of patients (Gutierrez *et al*. 1982). In systemic lupus, liver disease is not considered to be one of the most serious problems but it has been reported in 20 per cent and some biochemical evidence of hepatobiliary involvement in over 50 per cent of patients (Runyon *et al*. 1980). Ascites occurs in 10 per cent of patients and can be caused by peritoneal or mesenteric vasculitis, pancreatitis, serositis, nephrotic syndrome, or cardiac failure (Ryan and Sleisenger 1993). Vasculitis is one of the most serious gastrointestinal manifestations of lupus. It affects only 2 per cent of patients, but has a mortality rate of 50 per cent. It may result in colonic perforation, which has been reported to be responsible for about 27 per cent of deaths occurring in patients with lupus (Zizic *et al*. 1975).

Sjögren's syndrome

Xerostomia is one of the two major symptoms of Sjögren's syndrome. Dysphagia is reported in two-thirds of the patients. Abnormalities of oesophageal motility are seen in about 36 per cent and oesophageal webs in up to 10 per cent of patients. Impairment of pancreatic exocrine function is common. Sjögren's syndrome is associated with primary biliary cirrhosis (Tsianos *et al*. 1990) and has even been connected with hepatitis C infection (Haddad *et al*. 1992).

Vasculitides

Vasculitis is one of the pathogenetic mechanisms by which rheumatic diseases, such as rheumatoid arthritis and lupus, cause serious gastrointestinal manifestations. The frequency of gastrointestinal manifestations in diseases which in the first place are regarded as vasculitides varies widely. In Behçet's syndrome, vasculitic oral ulcers constitute a major diagnostic criterium. In Wegener's granulomatosis, the occurrence of gastrointestinal vasculitis is 5 per cent and in some other vasculitic diseases it is even lower. However, gastrointestinal vasculitis is common in polyarteritis nodosa (80 per cent), Henoch–Schönlein purpura (68 per cent), and Churg–Strauss syndrome (42 per cent) (see Fig. 2)

Fig. 2 Perforated lower oesophagus in a patient with dermatomyositis.

Gastrointestinal side-effects of antirheumatic drug treatment

Gastrointestinal side-effects of antirheumatic drugs are listed in Table 3.

Drug	Symptoms
NSAIDs (Hoy and Rooney 1988)	Nausea, oesophagitis, non-ulcer dyspepsia Peptic ulcer Hepatic enzyme abnormalities Steatorrhoea with malabsorption and protein-losing enteropathy Increased intestinal permeability Intestinal ulceration, stricture, obstruction and perforation
D-Penicillamine (Bergamini and Kaye 1988)	Dyspeptic admonitions, of nausea (2–20%) in the first 3–6 months Nausea, anorexia, abdominal pain (5–20%) Diarrhoea (occasional) Hepatic enzyme abnormalities (<5%), toxic hepatitis, hepatic necrosis, cholestasis jaundice Acute haemorrhagic colitis (rare)
Gold (Bergamini and Kaye 1988)	Buccal ulcers (5–20%) Hepatic enzyme abnormalities, cholestatic jaundice, hepatic necrosis Diarrhoea (50%, the most common gastrointestinal side-effect of gold) Gold enterocolitis (enteritis, diarrhoea, fever, eosinophilia, megacolon)
Sulphasalazine (Klotz et al. 1988)	Nausea, vomiting, dyspepsia, malaise, anorexia, abdominal pain, indigestion common, diarrhoea Colonic inflammation, mucosal ulceration, bloody diarrhoea (resembling ulcerative colitis) Hepatic enzyme abnormalities, granulomatous hepatitis, severe hepatitis and necrosis Cholestasis Pancreatitis (Braun and Hassell 1988)
Antimalarials	Anorexia, nausea, vomiting, diarrhoea
Azathioprine (McKendry 1981)	Nausea, vomiting (common), diarrhoea (~ 1%) Stomatitis Liver enzyme abnormalities
Cyclosporin (Kahn et al. 1982)	Nausea, vomiting, diarrhoea Abnormal liver function
Chlorambucil (Clemens 1981)	Nausea, vomiting Stomatitis
Cyclophosphamide (Clemens 1981)	Nausea, vomiting, diarrhoea Stomatitis Hepatic abnormalities
Methotrexate (Kemppainen and Furst 1986)	Nausea, vomiting, diarrhoea, stomatitis Liver enzyme abnormalities Hepatic fibrosis
Corticosteroids (Cooper and Kirwan 1988)	Peptic ulcer, pancreatitis

Table 3 Gastrointestinal side-effects of antirheumatic drug treatment

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs have improved the quality of life for patients with arthritis for over 90 years. More than 30 million people worldwide consume them daily, and the annual increase in prescriptions is 6 per cent (Giercksky *et al*. 1989; Gabriel and Bombardier 1990; Zeidler 1992). Unfortunately they also cause a higher number of adverse effects than any other class of drug. NSAIDs are able to induce mucosal damage in every part of the gastrointestinal tract from oesophagus to rectum, but most of the serious damage occurs in the gastroduodenal region. The mechanisms involved are believed to be direct topical injury and systemic prostaglandin inhibition (Schoen and Vender 1989). It is the prostaglandin inhibition which is also responsible for the anti-inflammatory effect of the drugs and therefore all NSAIDs have the potential to initiate serious gastrointestinal events. Endoscopic studies have shown that virtually every subject develops gastroduodenal mucosal injury after a single 650 to 1350 mg dose of acetylsalicylic acid. NSAIDs can cause ultrastructural damage of the gastric epithelium within minutes and gross subepithelial haemorrhages and erosions within hours of ingestion (Graham and Smith 1986) (Fig. 3). With long-term treatment 50 to 75 per cent of patients develop mucosal damage, and 10 to 37 per cent gastroduodenal ulcers, a value over 5- to 15-fold greater than would be expected in a healthy population (Larkai *et al*. 1987; Graham *et al*. 1988; Geis *et al*. 1991). The risk is directly dose-related (Griffin *et al*. 1988). However, only approximately 30 to 40 per cent of patients receiving long-term treatment with NSAIDs have symptoms of dyspepsia (Zeidler 1992; Lichtenstein *et al*. 1995) and in as many as 58 per cent of subjects with a life-threatening complication, the complication itself has been the presenting manifestation of NSAID injury without prior dyspepsia as a warning (Langman 1989). The incidence of serious gastrointestinal events is estimated to be 1 to 2/1000 users per year. At special risk are elderly people (nearly 40 per cent of the users, relative risk ratio 5.5), those on corticosteroid therapy (relative risk ratio 1.8), patients using high-dose or multiple NSAID treatment, and also anyone during the first 3 months of treatment (Gabriel *et al*. 1991; Lichtenstein *et al*. 1995). The risk may also vary among different formulations: meclofenemate has the greatest relative risk (8.7) and ibuprofen the lowest (2.3), while those for indomethacin, acetylsalicylic acid, and naproxen lie in between (Gabriel *et al*. 1991; Henry *et al*. 1993). This has some relevance for clinical practice, although the order may reflect mainly the relative anti-inflammatory potency of the drugs (Fries *et al*. 1991; Lichtenstein *et al*. 1995). Newer drugs such as etodolac and nabumetone with selective peripheral and low gastric prostaglandin inhibition may prove to be much safer. With these drugs incidence of ulcers is 0.3 to 0.7 per cent and serious complications occur only in 0.1 per cent of users (Jenner 1990; Schattenkirchner 1990). NSAIDs inhibit prostaglandin synthesis by blocking cyclo-oxygenase. At least two different cyclo-oxygenases exist, Cox-1 and Cox-2. Cox-1 is found mainly in the gastrointestinal tract, while Cox-2 seems to be responsible for peripheral inflammatory responses. By selectively inhibiting Cox-2, the newer NSAIDs may prove to have as good as or even better peripheral anti-inflammatory effect but considerably less gastrointestinal side-effects than the NSAIDs now in use (Hayllar and Bjarnason 1995).

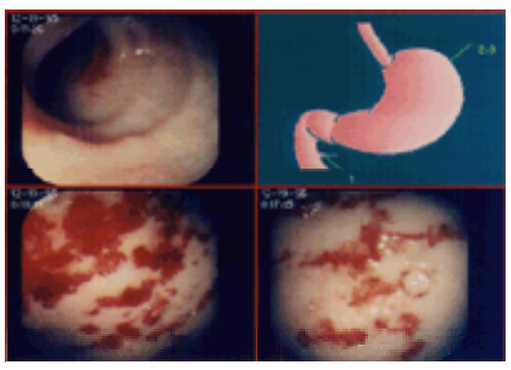

Fig. 3 Gastric lesions in a patient taking non-steroidal anti-inflammatory drugs (NSAIDs).

Oesophageal injury has been reported rarely and seems to come from direct topical irritation of NSAIDs (Minoch and Greenbaum 1991). Asymptomatic, small intestinal enteropathy is seen in 60 to 70 per cent of patients with long-term treatment (Bjarnason *et al*. 1993). It is associated with mild blood loss (1 to 10 ml per day) and increased intestinal permeability. Colonic injury occurs less frequently, but may be serious with perforations and bleeding. NSAIDs have been linked to development of collagenous colitis or colitis resembling inflammatory bowel disease. The drugs are also known to exacerbate pre-existing inflammatory bowel disease. Rectal administration may cause proctitis (Lichtenstein *et al*. 1995). Reversible elevations in liver enzymes are seen in about 5 per cent, and monitoring them may be necessary when NSAID therapy is initiated. Serious complications and deaths from hepatic damage are rare (Rabinovitz and Van Thiel 1992).

It should be realized that neither subjective symptoms nor endoscopic evidence of injury reliably predict the development of serious complications. In order to decrease the incidence of untoward gastrointestinal events induced by NSAIDs high-risk patients must be identified. Risk factors for gastroduodenal injury include age over 60 years, chronic use of NSAIDs, history of peptic ulcer, previous NSAID gastroduodenal intolerance, recent upper abdominal pain due to NSAIDs, multiple NSAID use, cardiovascular or other chronic disease in addition to arthritis, and use of multiple concurrent medications especially corticosteroids (Numo 1992). If high-risk patients must be treated with NSAIDs, either the lowest possible dose, an alternative non-NSAID analgesic, or the non-acetylated salicylate NSAID is recommended. If a NSAID is used, a coadministration of misoprostol should be considered. Misoprostol is a synthetic prostaglandin E_1 analogue and so far the only prophylactic agent that is unequivocally effective in protecting duodenal mucosa as well as the stomach from NSAID-induced injury. Prophylactic use of H_2 blockers and proton pump inhibitors (e.g. omeprazole) seems to offer some protection against duodenal ulcers only. However, even misoprostol cannot be relied upon to prevent more than 40 per cent of serious upper gastrointestinal complications (Silverstein *et al*. 1995), and the drug has not been proven to reduce the number of deaths. The results of the studies on the cost-effectiveness of coadministration of misoprostol with chronic NSAID use have so far been inconclusive. For patients with low risk of gastropathy, routine use of misoprostol is likely to be too costly and the drug is not always well tolerated (Scheiman 1994; Stucki *et al*. 1994). In the prophylaxis of ulcers, misoprostol is the only unequivocally effective agent, but even it has not been proven to reduce serious complications and deaths. The treatment of gastrointestinal injury includes withholding NSAIDs and administering H_2 blockers or omeprazole (Lichtenstein *et al*. 1995).

For a long time it was believed that disease-modifying drugs were many times more toxic than NSAIDs. In fact, because of the high frequency of gastrointestinal problems with NSAIDs, there are no substantial differences in toxicity between the two drug categories and the order in which the drugs are initiated in rheumatic diseases should be carefully considered (Fries *et al*. 1991).

Other antirheumatic drugs

Gastrointestinal side-effects of disease-modifying antirheumatic drugs occur most frequently in treatment with oral gold compounds, over 600 events per 1000 patient-years. With intramuscular gold the incidence is only one-tenth of that, but the complications appear to be more serious (Fries *et al*. 1991). Diarrhoea is the most common gastrointestinal manifestation of oral gold therapy (44 per cent). It responds well to dosage reduction and often declines even with continued use. Although serious gastrointestinal complications are rare, gold enterocolitis has been reported and may be fatal (Langer *et al*. 1987). Diarrhoea should therefore never be overlooked during any kind of gold therapy. In suspicious cases sigmoidoscopy may be required for the correct diagnosis. Stomatitis and mouth ulcers occur in

approximately 20 per cent of patients given intramuscular gold and in 5 to 10 per cent with oral gold compounds (Rangachari and Kean 1989).

Methotrexate and azathioprine have been reported to cause over 200 gastrointestinal adverse effects per 1000 patient-years (Fries *et al*. 1991). In a long-term study, methotrexate caused nausea and/or gastrointestinal distress in 65 per cent of patients, mouth sore or soreness in 55 per cent, and liver enzyme elevation in up to 88 per cent at some time during the treatment. The treatment also tends to lead to hepatic fibrosis verifiable by histology (Zizic *et al*. 1975; Kremer *et al*. 1989). Serious or potentially serious liver abnormalities have been reported in 12 per cent of patients (Augur *et al*. 1990). Hepatic and gastrointestinal toxicity has resulted in discontinuation of therapy in 16 per cent of patients treated with methotrexate (Alarcon *et al*. 1989).

Half of patients given cyclophosphamide complain of nausea, vomiting, or diarrhoea, and stomatitis also is common. Liver enzyme abnormalities are often seen. Serious hepatotoxicity, however, is uncommon; a few cases of hepatic necrosis have been reported when patients had previously been treated with azathioprine (Shaunak *et al*. 1988). Chlorambucil has a low frequency of gastrointestinal side-effects (only 4 per cent) (Clemens 1991).

Penicillamine is responsible for over 100 gastrointestinal adverse events per 1000 patient-years (Fries *et al*. 1991). Gastrointestinal pain or diarrhoea occurs in 8 to 35 per cent of patients. Taste abnormalities are experienced by 2 to 25 per cent of patients within the first 3 to 6 months. The symptom is dose related and usually subsides within a few months of treatment (Rangachari and Kean 1989). Haemorrhagic colitis has been reported (Hickling and Fuller 1979).

Sulphasalazine has a good gastrointestinal safety profile. Dyspepsia, nausea, abdominal discomfort, and mucosal ulceration are the most common side-effects of the therapy. Hepatic injuries, even massive liver necrosis, have been reported. Pancreatitis, cholestasis, and inflammatory diarrhoea are also rare complications (Amos *et al*. 1986).

Antimalarials and corticosteroids have a low number of gastrointestinal side-effects. The main gastrointestinal problems commonly associated with the use of corticosteroids are peptic ulceration (especially when used with NSAIDs), gastric haemorrhage, intestinal perforation, and pancreatitis. The risk of corticosteroids alone causing peptic ulcers is estimated to be very small or absent and this concern should not inhibit the use of small or moderate doses of steroids, for example in rheumatoid arthritis (Cooper and Kirwan 1990; George and Kirwan 1990). However, gastrointestinal problems when caused by corticosteroids tend to be serious and often require admission to hospital. For this reason corticosteroids are considered to be as toxic to the gastrointestinal tract as NSAIDs (Fries *et al*. 1991). Antimalarials appear to be the safest and best-tolerated disease-modifying drugs with respect to the gastrointestinal tract.

Diet and rheumatic diseases

Patients with rheumatoid arthritis often claim that certain foods provoke and certain diets alleviate their symptoms. In fact, the idea that dietary manipulation may alter the symptoms of rheumatoid arthritis is an intrinsic part of the folklore of the disease. In 1980, a large percentage (up to 94 per cent) (Wasner *et al*. 1980; Panush 1984) of patients in Western countries spent nearly one billion American dollars on diet and other similar unconventional therapies (Panush 1987; Buchanan *et al*. 1991; Darlington 1991); 37 to 50 per cent found them beneficial (Brown *et al*. 1980; Darlington *et al*. 1990), although there was no difference in disease progression or outcome between those reporting benefit or failure. In the past, dietary treatment of rheumatoid arthritis was generally considered as quackery (Lockshin 1981), but lately diet has become an important issue in rheumatology (Klinenberg 1985).

Diet therapy may be divided into three types: elimination, supplementation, and oral tolerance (Darlington and Ramsey 1993; Trentham *et al*. 1993). In a survey of 21 popular books (Darlington *et al*. 1990) the following supplements were advocated: vitamins, minerals, cod liver oil, New Zealand green-lipped mussel, kelp, evening primrose oil, devil's claw, yucca, and ginseng. Among other items tried by patients have been garlic, royal jelly, vinegar, honey, and alfalfa (Brown *et al*. 1980), while the following have been forbidden: alcohol, refined cereals, unrefined cereals, rice, acidic foods, fruits in general and especially citrus fruits, tomatoes, red meats, fish, chicken, egg yolks, egg whites, dairy produce, coffee (especially with caffeine), tea, chocolate, soft drinks, sugar (especially white sugar), processed foods, salt, pepper, monosodium glutamate, additives, preservatives, spices, and ice (Darlington *et al*. 1990). Thus, very often diets tried by patients, especially the health food diets, at the same time both supplementand eliminate individual foods. Most studies on pure supplementation diets concentrate on vitamins, minerals, fish oils, and plant oils. The idea that supplementation might be beneficial in rheumatoid arthritis is based on studies which show that patients have low serum levels of certain minerals and on the concept that certain oils, vitamins, and minerals have anti-inflammatory effect (Sköldstam 1989).

Supplementation therapy

Although patients with rheumatoid arthritis are susceptible to a number of dietary deficiencies including pyridoxine (vitamin B_6), histidine, vitamin C, zinc, and folic acid, dietary supplementation with these agents has not been found to improve the disease (Pike 1989). In their reviews of the literature on vitamin and mineral supplements in rheumatoid arthritis, Panush (1984) and Darlington (1991) observed that there is a lack of pertinent information. According to Panush, copper salts, although interesting (Banford *et al*. 1982), will probably not have any important role in the treatment of rheumatic disease. There is no clinical evidence that vitamin C has therapeutic effects in rheumatoid arthritis (Panush 1984; Sköldstam 1989). Tulleken *et al*. (1990) reported that the beneficial effects of fish oil supplementation cannot be ascribed to the antioxidizing properties of vitamin E (10 to 13 mg daily) *per se*. Machtey (1991) reported some benefit in osteoarthritis from vitamin E given at high doses (600 mg/day), and Scherak and Kolarz (1991) found in a multicentre, double-blind, crossover study using even higher doses of vitamin E (1200 mg daily) some benefit to patients with rheumatoid arthritis. There is no difference in the 25-OH-vitamin D concentrations between patients with rheumatoid arthritis and those with osteoarthritis (Bird *et al*. 1980). Although a low serum zinc concentration seems to be a non-specific feature of inflammation (Balogh *et al*. 1980), and the results in a preliminary study (Simkin 1976) did indicate some improvement in the symptoms of patients with rheumatoid arthritis who took oral zinc sulphate, later studies (Job *et al*. 1980; Kennedy *et al*. 1980; Mattingly and Mowat 1982) have not confirmed the result. Honkanen *et al*. (1991) observed that plasma copper and zinc levels correlated with the measures of disease activity, not dietary factors, and concluded that the plasma levels of these trace elements seem to be largely determined by the inflammatory process. A low selenium level was suggested by Tarp *et al*. (1985) as a possible factor in the pathogenesis of rheumatoid arthritis. However, other studies have not shown a correlation between plasma levels of selenium and disease activity (Möttönen *et al*. 1984; Peretz *et al*. 1987). Oral selenium therapy appears to have limited value in the management of rheumatoid arthritis, but glutathione peroxidase may play some role in the complex aetiology of the disease and possibly of other inflammatory disorders (Darlington and Ramsey 1993). Iron (and high concentrations of ferritin) may be associated with worsening of inflammatory joint diseases (Blake and Bacon 1981). All together, the results of therapeutic trials with vitamins and minerals in rheumatoid arthritis are controversial.

Fish oil

Bang *et al*. (1971) noted a low frequency of atherosclerosis among Eskimos, attributed this to the consumption of fish (Bang and Dyerberg 1980), and suggested that -3 polyunsaturated fatty acids, such as eicosapentaenoic acid and docosahexaenoic acid, may be responsible for the health benefit (Dyerberg and Bang 1979). Lucas and Power (1981) demonstrated dietary fat (vegetable oils and animal fat, but not fish oil) in amounts normally consumed in the Western diet to aggravate symptoms of rheumatoid arthritis. Kelley *et al*. (1985) showed that fish oil suppresses autoimmune disease. Lee *et al*. (1985) concluded that fatty acids derived from fish oils may have anti-inflammatory effects by inhibiting the 5-lipo-oxygenase pathway and the leukotriene B_4-mediated functions. A diet rich in fish oil can modulate the humoral and inflammatory components of the allergic response (Lee and Arm 1986) and may also be beneficial in several inflammatory conditions (Lee 1988). Human studies on diets rich in fish or supplemented with fish oil are listed in Table 4.

Table 4 Fish oil in the treatment of rheumatoid arthritis (RA)(a) Change in symptoms (b) Epidemiological evidence for beneficial effect of fish oil in rheumatoid arthritis

Plant oils

Polyunsaturated plant oils, such as g-linolenic acid may also be anti-inflammatory (Pike 1989). This fatty acid is metabolized to dihomo-g-linolenic acid which produces prostaglandins of the E series, such as PGE_1, which have potent anti-inflammatory properties (Mertin and Stackpoole 1981). It also does not lead to the formation of leukotrienes. Acute and chronic inflammation is suppressed by g-linolenic acid in animals (Tate *et al*. 1989). Attention has especially focused on the effects of evening primrose oil (Darlington and Ramsey 1993). Studies on the effects of plant oils on rheumatoid arthritis are listed in Table 5.

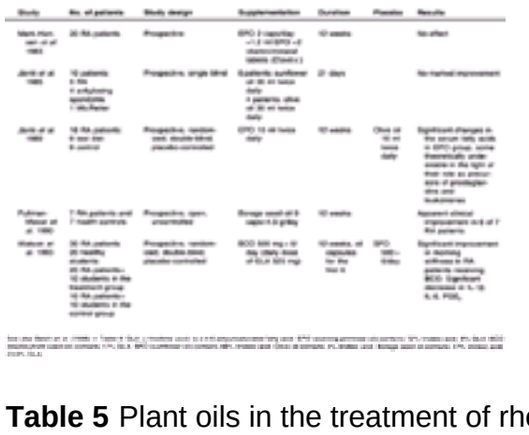

Table 5 Plant oils in the treatment of rheumatoid arthritis (RA)

Conclusions on oil supplementation therapy

Cathcart and Gonnerman (1991), in animal studies, found that fish oil can alleviate the symptoms of arthritis, and that the alteration in the severity of symptoms correlates with the decreased production of prostaglandins by peritoneal macrophages. Angelin and Palmblad (1988) concluded that the effects of fish oils in inflammatory diseases are interesting but, at best, modest, and Lee (1988) agreed that dietary supplementation with fish oil lipids may have anti-inflammatory effects. Kremer (1991) confirmed that fish oil supplementation is associated with clinical benefits in patients with rheumatoid arthritis. Improvement in the condition of the patient is not usually observed until after 12 weeks, but the improvement appears to increase as treatment is continued. Belch (1990) admitted that assessment of the literature does support a real, although modest, effect of fish oil in rheumatoid arthritis, without the production of serious side-effects. Most rheumatologists, however, would expect to achieve better relief of symptoms with NSAIDs. Pike (1989) agreed that some modest, but beneficial, effects of eicosapentaenoic acid consumption have been observed. Sperling (1991) noted that several small clinical trials have demonstrated a modest clinical effect of -3 fatty acids, but that larger, well-designed, randomized, double-blinded, placebo-controlled clinical trials are needed to determine the role, if any, of fatty acids in the treatment of rheumatoid arthritis. Buchanan *et al*. (1991) considered that there is a modest improvement of symptoms, but were of the opinion that it is unlikely that fish oil or evening primrose oil will make a major impact on the treatment of rheumatoid arthritis. Callegari and Zurier (1991) claimed that the potential capacity of particular fatty acids to regulate immune responses is exciting and called for long-term, multicentre, placebo-controlled studies with large numbers of patients to determine whether the plant oil therapy is useful in rheumatoid arthritis. According to Ringertz (1991), the trials on the effects of oil supplements on rheumatoid arthritis are characterized by a lack of improvement of the laboratory signs of inflammation. In a recent review, Darlington and Ramsey (1993) thought that the work on fish oils in the treatment of rheumatoid arthritis shows sufficient promise to justify further studies. The treatment appears to be safe, although long-term toxicity studies are needed, as are studies to determine whether low-dose fish oil is effective. The data on the effects of evening primrose oil for patients with rheumatoid arthritis are also promising, but need confirmation. Dietary supplementation with oils in the treatment of rheumatoid arthritis is of interest, because certain oils have, without doubt, some anti-inflammatory effect.

Elimination therapy

There are numerous reports connecting certain food items and arthritic symptoms (Hicklin *et al*. 1980; Mandell and Conte 1980; Coombs and Oldham 1981; Parke and Hughes 1981; Williams 1981; Bourne *et al*. 1985; Ratner *et al*. 1985; Panush *et al*. 1986; Lunardi *et al*. 1988; O'Farrelly *et al*. 1988; Panush 1990). It is known that food antigens are found in the serum after oral challenge (Paganelli *et al*. 1979). Regardless of the mechanism by which the arthritis is caused, be it called allergy (Williams 1981; Panush 1986), 'allergy' (Panush 1990), pseudo-allergy (Pearson 1991), immune response (Inman 1991), food antigens with molecular mimicry (Perez-Maceda *et al*. 1991), food hypersensitivity (Bahna and Kanuga 1991), or food intolerance (Parke and Hughes 1981), the idea of excluding the provocative item from the diet is delightful in its simplicity. If the item is unknown one may reason as follows: if a patient with constant symptoms fasts and consumes mineral water alone, his or her symptoms should clear completely if they are caused only by food intolerance (exclusion phase). Reintroduction of food items, one at a time, should reveal the item responsible for symptoms (reintroduction phase), and the rechallenge with it will confirm the finding. Some more palatable and nourishing modifications than a total fast also exist (cod and pear, lamb and pear, etc.) (Darlington 1985). Occasionally, diets believed to be beneficial in rheumatoid arthritis, such as certain vegetarian diets, may be combined with this method (Sköldstam 1986). Some diets may modify immunological responsiveness and thus affect the manifestations of rheumatic diseases (Panush 1986). Studies on exclusion and reintroduction of food items in patients with rheumatoid arthritis are listed in Table 6.

Table 6 Diets in the treatment of rheumatoid arthritis (RA)

Oral tolerance therapy

The idea of using oral tolerance in the treatment of rheumatoid arthritis is based on the fact that rheumatoid arthritis is an inflammatory synovial disease thought to involve T cells reacting to an antigen within the joint. The major protein in articular cartilage is type II collagen, and it is a potential autoantigen. Oral tolerance to autoantigens suppresses animal models of autoimmune disease mediated by T cells. In an experiment, oral administration of chicken type II collagen to patients with rheumatoid arthritis decreased the number of swollen and tender joints and some patients even had complete remission of the disease (Trentham *et al*. 1993). This approach appears exciting, but further confirmation from long-term studies is needed (Parke and Parke 1994).

Conclusions on diet therapy in rheumatoid arthritis

Studies on experimental animals have demonstrated that, without any doubt, modification of nutrition is able to delay, prevent, and even reverse the expression of genetically determined autoimmune defects. There is evidence which suggests that nutrition can also modulate the expression of autoimmunity in humans (Homsy *et al*. 1986; Trentham *et al*. 1993). The relationship between nutrition and rheumatic disease could be explained by two mechanisms that are not mutually exclusive:

dietary factors might alter immune and inflammatory responses, or food-related antigens might provoke hypersensitivity responses (Panush 1991). Some patients may also develop a type of allergic reaction to foods, but this is uncommon (O'Driscoll *et al*. 1985). This group of patients should benefit from a specific elimination diet (Sköldstam 1989). It has also been stated that total fasting may represent the most rapid and readily available way of relieving arthritic pain and swelling in rheumatoid arthritis (Palmblad *et al*. 1991). The benefit is usually lost soon after eating is resumed, and therefore total fasting is of little therapeutic significance in a chronic disease like rheumatoid arthritis (Sköldstam and Magnusson 1991). Ringertz (1991) notes that so far there have been no reports that show whether there may be any sustained positive effects in rheumatoid arthritis from dietary manipulations other than total fasting. However, Kjeldsen-Kragh *et al*. (1991) did report such an effect in patients who stayed on a vegetarian diet for 1 year, and Darlington and Ramsey (1991a), Maberly and Anthony (1991), and Seignalet (1992) also recorded similar effects with elimination diets in the treatment of rheumatoid arthritis.

The American College of Rheumatology position statement: diet and arthritis (American College of Rheumatology 1991) concludes that nutritional therapy for arthritis is experimental. Until more data are available, patients should continue to follow balanced and healthy diets, be sceptical of 'miraculous' claims, and avoid elimination diets and fad nutritional practices. Darlington and Ramsey (1993) state that it is essential for orthodox rheumatologists and research workers to continue to investigate the various ways in which patients' diets may influence the course of their disease, not only to find what may be useful in dietary manipulation for the patients' benefit and to keep them from the advice of the unscrupulous, but also so that patients do not adopt useless diets and thus deteriorate, when good medical advice to cease dietary therapy and to return to effective drug treatment would be of benefit. A summary of different diet trials in rheumatoid arthritis is listed in Table 6.

Intestinal microbiology and rheumatic diseases

The intestinal microbial flora is not essential for life (Shahani and Ayebo 1980), although it was once widely believed that Pasteur's work on the microbial nature of fermentation meant that without bacteria the food taken in would be passed unassimilated out of the body (Wilson 1983). Animals free from microbes and on adequate nutrition live more than 30 per cent longer than colonized animals (Drasar 1974; Parsonnet 1992). Although the relationship between host and normal flora is truly symbiotic (Parsonnet 1992), it is evident that intestinal bacteria may have either beneficial or harmful effects on the host, depending on the bacterial species and available substrates for their metabolism (Luckey 1977). It is surprising how well the epithelium of the gastrointestinal tract succeeds in allowing absorption of various nutrients and at the same time serving as a barrier against microbes and harmful antigenic structures. The number of bacteria in a human gut is estimated to be 10^{14}. Viable enteric pathogens may invade the blood stream and cause septic arthritis, but most often the arthritis is reactive (Ahvonen *et al*. 1969; Aho *et al*. 1974; Aho *et al*. 1976). Intestinal bacteria known to induce reactive arthritis include *Shigella, Salmonella, Yersinia, Campylobacter*, and *Clostridium difficile* (Gorbach 1986; Amor 1987; Aho 1989). Certain intestinal parasites such as *Giardia, Cryptosporidium, Strongyloides stercoralis*, and *Taenia saginata* have been associated with reactive arthritis (Bocanegra *et al*. 1981). The association between the gut and arthritis could be as follows: the increased permeability of the intestinal mucosa allows leakage of the antigens, either dietary or microbial in origin, which leads to an inflammatory reaction affecting the joints (Katz and Hollander 1989).

Patients with ankylosing spondylitis have a markedly elevated intestinal permeability (Katz and Hollander 1989), and more than 50 per cent of those with peripheral arthritis have inflammatory gut lesions (Cuvelier *et al*. 1987; Mielants *et al*. 1988). It has been suggested that intestinal *Klebsiella pneumoniae* may be a possible aetiological agent (Ebringer *et al*. 1988; Ebringer 1989; Ebringer 1991), although the cause still remains an open question (Russell 1988; Schwimmbeck and Oldstone 1989; van Kregten *et al*. 1991). It has even been suggested that many inflammatory arthritides may finally turn out to be reactions to microbial agents and thus these arthritides could and will be classified as reactive arthritis (Ford 1986).

Rheumatoid arthritis and intestinal bacteria

The idea that intestinal bacteria might be associated with rheumatoid arthritis is essentially derived from the association between gastrointestinal disease and arthritis (Wands *et al*. 1976; Katz and Hollander 1989; Sartor 1989), and from the fact that several intestinal bacteria cause reactive arthritis (Bennett 1978; Neumann and Wright 1983; Amor 1987; Atkinson and McLeod 1988; Aho 1989). Another reason for associating intestinal bacteria and rheumatoid arthritis is the fact that the genetic component of this disease is unlikely to be greater than 30 per cent, and there are no obvious environmental factors that explain the remaining 70 per cent of cases (Silman 1991). Furthermore, the gut flora can modify induction of arthritis induced experimentally by streptococcal cell wall extracts (van den Broek *et al*. 1992) and pristane (Thompson and Elson 1993). However, there is no definitive proof of a primary role for the gut in the pathogenesis of rheumatoid arthritis. If the link is substantiated, the therapeutic implications would be considerable (Zaphiropoulos 1986).

The main reasons for the difficulties encountered in studies on the association of rheumatoid arthritis and the intestinal microbial flora have been the enormous complexity of the latter (Finegold *et al*. 1974) and the inadequacy of traditional methods to study it (Hentges 1980; Hill 1981; Wayne *et al*. 1987; Woese 1987; Relman 1993). Each gram of wet faeces contains 10^{10} to 10^{12} bacteria recoverable by traditional bacteriological methods (Finegold *et al*. 1974; Moore and Holdeman 1974a; Moore and Holdeman 1974b; Moore and Holdeman 1975). The estimate of the number of bacterial species (more than 400 or 500) present in the intestinal tract of one person at any given time is calculated from the results obtained by culture methods (Moore and Holdeman 1974a; Moore and Holdeman 1975). Based on the studies which have relied on cloned or amplified 16S rRNA molecules using broad-range oligonucleotides (Giovannoni *et al*. 1990; Ward 1990; Schmidt *et al*. 1991; Liesack and Stackebrandt 1992), environmental microbiologists postulate that most of the extant micro-organisms (more than 80 per cent) remain unidentified, because of the insensitivity of bacterial cultures. The same may apply to the commensal microbial flora endogenous to humans (Relman 1993).

Culture-based studies dealing with the relationship between rheumatoid arthritis and bacterial species are presented in Table 7. Most often an initially positive report has been followed by several reports denying an aetiological role of the microbial species (Midvedt 1987), and no definite proof of any association between a change in the intestinal flora and rheumatoid arthritis has been produced. Recently, however, new data have been obtained by a new method—computed gas chromatography of bacterial cellular fatty acids, analysed directly from the stool samples (Peltonen *et al*. 1992). This method is probably the simplest way to establish whether there is a change, and if so the size of that change, in bacterial flora induced by any environmental factor such as diet, medication, or disease. The data show that the intestinal flora is changed in rheumatoid arthritis (Eerola *et al*. 1994), the change is mainly in the anaerobic flora (Eerola *et al*. 1994), and the beneficial effect of dietary treatment in rheumatoid arthritis is linked to changes in the intestinal flora (Peltonen *et al*. 1994).

Table 7 Studies on rheumatoid arthritis (RA) and specific bacteria often found in faeces

Another approach is based not on specific bacterial species or overall changes in the intestinal microflora but on the translocation of bacterial arthritogenic antigens from the gut (Bennett 1978). Non-viable bacterial antigens have been detected in rheumatoid synovial effusions (Bartholomew and Bartholomew 1979). As the translocation of viable bacteria from the gut to extraintestinal sites is not a rare phenomenon (Berg 1992), it is quite feasible that debris (including peptidoglycan) from bacteria normally present in the gastrointestinal tract also traverses the gut–blood barrier and stimulates the immune system. This idea is supported by experimental findings that bacterial cell wall material injected into rats can induce arthritis (Cromartie *et al*. 1977). Bacteria contain peptidoglycan within the capsule. Gram-positive bacteria contain ten times more of this substance than Gram-negative bacteria (Hazenberg *et al*. 1992). Growing evidence indicates that the arthritogenic properties of bacterial adjuvants reside within peptidoglycan dimers. Antibodies against peptidoglycan–polysaccharide polymers have been detected in the sera of patients with juvenile rheumatoid arthritis (Moore *et al*. 1989). Peptidoglycan has been shown to be absorbed from the gut (Lichtman *et al*. 1991). In the light of these observations, it is intriguing to note that past interest has focused mainly on Gram-positive bacteria (Olhagen and Månsson 1968; Svartz 1976), when the role of intestinal bacterial species in the aetiology of rheumatoid arthritis has been discussed (Midvedt 1987). The normal intestinal flora harbours a sufficiently diverse population of bacteria to produce the peptidoglycan–polysaccharide polymers capable of inducing arthropathic responses in the host. In a susceptible person, arthritis might result from the

accumulation of a certain threshold concentration of these arthropathic polymers in the joint. This accumulation might be accelerated greatly when the intestinal epithelium is damaged (Stimpson *et al*. 1986). As in the case of bacterial cell wall material, these peptidoglycan–polysaccharide complexes produced by the human intestinal flora also can induce arthritis when injected subcutaneously into rats (Kool *et al*. 1991). These bacterial cell wall polymers can also reactivate arthritis in rats (Lichtman *et al*. 1993). Several bacterial species of the normal flora contain peptidoglycan which is able to induce arthritis in experimental animals, these bacteria include *Peptostreptococcus productus, Propionibacterium acnes, Methanobacterium formicicum*, group A streptococci (Stimpson *et al*. 1986; Hazenberg *et al*. 1992), *Lactobacillus casei* (Lehman *et al*. 1987), *Eubacterium aerofaciens* (Severijnen *et al*. 1991), other *Eubacterium* species (Severijnen *et al*. 1990; Kool *et al*. 1992), *Bifidobacterium* species (Severijnen *et al*. 1989), and anaerobic coccoid rods (Severijnen *et al*. 1988). Although it is difficult to provide conclusive and persuasive evidence that peptidoglycans or other non-viable microbial components play any major role in rheumatoid arthritis, there is increasing evidence that these arthropathogenic polymers occur in the human intestinal lumen and that they can be released systemically (Schwab 1993).

Conclusions about the aetiological role of intestinal microbial flora in rheumatoid arthritis remain limited. Gullberg (1978) concludes that intestinal absorption of antigens and other noxious substances from intestinal microbes may play an important role in a multifactorial aetiopathogenesis of rheumatoid arthritis. Since arthropathies could be indirect consequences of change in the resident bacterial population in the gut, the same may be applicable to rheumatoid arthritis (Anonymous 1979). Midvedt (1987) states that alterations in the intestinal flora may play a role in the aetiopathogenesis of chronic aseptic inflammation in joints. The suggestion that the aetiology of rheumatoid arthritis lies in the intestine must continue to remain an unproven hypothesis (Doube and Collins 1988), and Phillips (1988) also indicates that at present there is little firm evidence to implicate microbial agents. In reactive arthritis the question is not so much 'do bacteria cause chronic polyarthritis', as 'how do they do it'. In rheumatoid arthritis the first question still remains: do bacteria cause it? (Phillips 1989). Microbially triggered arthritis is usually self-limited, but in some cases it develops into chronic arthritis (Leirisalo *et al*. 1982), and therefore reactive arthritides may serve as a model for studies on the pathogenesis of rheumatoid arthritis (Toivanen and Toivanen 1991). McCulloch *et al*. (1993) favour the hypothesis that rheumatoid arthritis may be a chronic form of reactive arthritis driven by the escape of primed T cells and microbial antigens from an extra-articular site of infection, possibly the gut, lungs, or skin nodules. Schwab (1993) concludes that peptidoglycan–polysaccharides, which are derived from a variety of bacterial species including intestinal bacteria, can be part of the aetiology of rheumatoid arthritis and other chronic inflammatory diseases.

At present there is interest on the subject but little firm evidence that intestinal microbes or their products are aetiologically important in rheumatoid arthritis.

NSAIDs and intestinal microbial flora

There are two reasons why the effects of NSAIDs on the intestinal bacterial flora may be interesting to rheumatologists. One is the pathogenesis of intestinal inflammation observed in patients with rheumatoid arthritis. NSAIDs are able to damage the intestinal mucosal integrity and increase permeability (Bjarnason *et al*. 1987; Mielants *et al*. 1991a). Nearly three-quarters of patients on long-term treatment with NSAIDs (more than 6 months) have small bowel inflammation (Bjarnason *et al*. 1987; Bjarnason 1990), and this may last for up to 16 months after discontinuation of the drug. It is possible that intestinal inflammation is caused by bacterial invasion into the damaged mucosa rather than by NSAIDs directly (Bjarnason *et al*. 1987).

The other reason is the question of the possible bacterial aetiology of rheumatoid arthritis. By altering the intestinal permeability and nutritional environment for bacteria in the gut, NSAIDs may favour the growth of certain bacterial species. It has been suggested that changes observed in the faecal flora of patients with rheumatoid arthritis (especially high counts of *Clostridium perfringens*) (Olhagen and Månsson 1968) might be an effect of NSAIDs (Shinebaum *et al*. 1987). This idea is supported by a finding that *Cl. perfringens* counts are higher both in patients with rheumatoid arthritis (who were all using NSAIDs) and those with osteoarthritis using NSAIDs than in patients with osteoarthritis not taking NSAIDs (Dearlove *et al*. 1992). Also, a similar difference in *Cl. perfringens* counts has been observed between rheumatoid arthritis patients taking NSAIDs and those patients not taking them (Bradley *et al*. 1993). On the other hand, it has been reported that 33 patients with rheumatoid arthritis in the mid-1960s without any medication had an abnormal *Cl. perfringens* flora (Olhagen and Månsson 1968), and that a short-term treatment with NSAIDs does not change faecal flora (Peltonen *et al*. 1993). The latter study is a human experiment where an actual attempt to change faecal flora with NSAIDs was made. The dose of naproxen was fairly high (500 mg twice day), but common in the treatment of rheumatoid arthritis. The treatment period was 2 weeks. Increased intestinal permeability has been induced with half that dose used for half that time (Bjarnason *et al*. 1984). No changes were observed, either in the faecal counts of *Cl. perfringens* or in the bacterial cellular fatty acid profiles of the stool samples. Only a long-term study (more than 6 months) with a similar controlled study design and with more participants will answer the question of whether NSAIDs actually change the faecal flora at the doses used in the treatment of rheumatoid arthritis. Furthermore, increased intestinal permeability and inflammation has been detected in patients with rheumatoid arthritis who were not given NSAIDs (Tagesson and Bengtsson 1983; Smith *et al*. 1985; Segal *et al*. 1986).

The question of the effects of NSAIDs on the intestinal microbial flora remains open as do so many other interesting aspects of associations between rheumatology and gastroenterology.

1.3.7 The endocrine system

Chad Deal

Many endocrine disorders are associated with well-characterized rheumatic syndromes. Some of the earliest descriptions of classical endocrine diseases, such as acromegaly and hypothyroidism, focused on bone, joint, and muscle manifestations. The principal elements of connective tissue are cells and products of those cells whose growth and metabolism are influenced by hormones. Thus, endocrine glands, through hormone action, directly affect the function of the musculoskeletal system.

Thyroid disease

Hypothyroidism

Rheumatic manifestations of hypothyroidism are listed in Table 1. A characteristic arthropathy has been described by Bland and Frymoyer (1970), Dorwart and Schumacher (1975), and Golding (1970). Of 38 patients with frank hypothyroidism (Bland and Frymoyer 1970), 11 had objective rheumatic findings. Joint involvement was concurrent with the onset of hypothyroidism in 6 of 11, hypothyroidism preceded the arthropathy in 3 of 11, and the arthropathy appeared first in 2 patients. The most characteristic pattern of arthritis resulted in synovial thickening and effusion of large joints, especially the knees. All the patients had stiffness, arthralgia, swelling, and synovial thickening; 10 had synovial effusions; 6 complained of joint pain; and 3 had carpal tunnel syndrome. The effusions had a non-inflammatory appearance (no erythema or warmth), although 1 patient had definite signs of inflammation in the knees.

1. Rheumatoid arthritis-like (large joints, especially prominent in knee)
2. Pseudogout-like
3. Hyperuricaemia/gout; hyperuricaemia common, gout rare
4. Flexor tenosynovitis of the hand
5. Carpal tunnel syndrome
6. Proximal myopathy—non-inflammatory with muscle hypertrophy (Hoffman's syndrome)
7. Skeletal abnormalities in children; slipped capital femoral epiphysis

Table 1 Rheumatic manifestations of hypothyroidism

Dorwart and Schumacher (1975) describe the characteristics of synovial effusions in patients with myxoedema. Of 12 patients with florid myxoedema, 7 had knee effusions, which were most often bilateral. Analysis of synovial fluid revealed volumes of 0.5 to 100 ml, with white blood-cell counts of 50 to 6550/mm ^{3}. There were calcium pyrophosphate dihydrate crystals (both intra- and extracellular) in 6 of 7, but none had acute pseudogout at the time of aspiration. One patient subsequently developed an acute pseudogout attack 5 weeks after thyroid hormone replacement had begun. Synovial biopsies showed mild inflammation with a thickened synovium (3 to 5 layers of synovial lining cells). On radiographs, the knees of 7 of 12 patients had chondrocalcinosis with initial chondral and subchondral erosions and large cyst-like structures. These findings have been reported in the metacarpophalangeal joints also. In summary, the findings in synovial fluid were:

1. usually less than 1000 white cells/mm^3;
2. calcium pyrophosphate dihydrate crystals often present;
3. high viscosity by string test;
4. increase in hyaluronic acid;
5. high total protein in 50 per cent.

The association of hypothyroidism, true pseudogout, and pyrophosphate arthropathy has been reviewed by Alexander *et al*. (1982). Of 105 consecutive patients with pyrophosphate arthropathy, 10.5 per cent had hypothyroidism, compared with 8.1 per cent of osteoarthritic controls. A study of 100 patients with hypothyroidism showed a 17 per cent prevalence of chondrocalcinosis, which was not significantly different from the 10 per cent prevalence in 100 controls (Job-Deslandre *et al*. 1993).

Erickson *et al*. (1994) evaluated 54 consecutive crystal-proven patients with gout, prospectively for hypothyroidism using an ultrasensitive assay for thyroid-stimulating hormone. Fifteen per cent of the patients with gout compared with 4 per cent of the controls ($p < 0.05$) had elevated levels of thyroid-stimulating hormone, an average of 2.5 times higher in women and 6 times higher in men than in controls. Although hyperuricaemia is common in hypothyroidism, gout attacks are rare. In a retrospective group of 137 patients on uric acid lowering agents, 20 per cent had elevated levels of thyroid-stimulating hormone. The occurrence of gouty arthritis in patients with hypothyroidism is unclear, although urate clearance is lower than in the same patients after treatment with thyroid hormone replacement therapy. Screening for occult hypothyroidism in patients with gout is recommended.

Although knees are the most frequently involved joints in hypothyroidism, hand joints may also be affected and this may lead to an initial diagnosis of rheumatoid arthritis. Wrist, metacarpophalangeal, and proximal interphalangeal joints may be affected. Morning stiffness usually lasts less than 30 min and only a minority have signs of acute inflammation. A characteristic feature of hand involvement is a flexor tenosynovitis, present in 4 of 12 patients described by Dorwart and Schumacher (1975). Flexor tenosynovitis and thickening of the transverse carpal ligament may result in carpal tunnel syndrome. While the arthropathy usually responds to thyroid hormone replacement within 2 weeks, the flexor tenosynovitis may persist for weeks after the joint signs have resolved.

In a review of all patients presenting with carpal tunnel syndrome over a 10-year period, 5 of 49 patients had myxoedema (Frymoyer and Bland 1973). Hypothyroidism was the reported cause of carpal tunnel syndrome in up to 7.6 per cent of patients in several other series (Phalen 1966; Phalen 1970). Similarly, approximately 7 per cent of patients with hypothyroidism may have compression of the median nerve. The aetiological background to carpal tunnel syndrome is multifactorial and includes

direct pressure on the nerve from an oedematous transverse carpal ligament, flexor tenosynovitis, infiltration of the perineurium and endoneurium, and neuronal metabolic dysfunction secondary to the hypothyroid state. Acroparaesthesisas are often a prominent component of hypothyroidism, and were present in 5 of 9 patients with arthropathy and hypothyroidism described by Golding (1970), suggesting a metabolic effect of thyroid deficiency on nerve function. Most studies of carpal tunnel syndrome caused by hypothyroidism stress the rapid resolution of symptoms with thyroid hormone replacement therapy.

The diagnosis of hypothyroidism should be considered in patients who have a polymyalgia rheumatica-like picture and a normal or only slightly elevated erythrocyte sedimentation rate. Patients may also present with a fibromyalgia-like picture. These presentations may be prominent in patients who have muscular symptoms as a component of the hypothyroid state.

McLean and Podell (1995) reviewed the skeletal consequences of hypothyroidism in children. These include short stature, retarded bone age, epiphyseal dysgenesis, and delayed dental development. The physeal growth plate is affected, resulting in premature closure and abnormal cartilage and bone, which may result in osteochondritis deformans and slipped capital femoral epiphysis. Crawford *et al*. (1977) reviewed 104 cases of slipped capital femoral epiphysis and found 4 cases of hypothyroidism.

Myopathy

Muscle disease may be an important component of hypothyroidism. In addition to generalized pain and stiffness, a proximal myopathy presenting like polymyositis may be a feature. Approximately 5 per cent of all acquired myopathy is due to hypothyroidism. It has been reported that 25 per cent of patients with myxoedema had proximal muscle weakness. A raised creatine phosphokinase is common, may be marked, and is felt to be secondary to membrane leakage, not membrane disruption as in inflammatory myopathies. A study of 11 patients with hypothyroidism and proximal weakness (Khaleeli *et al*. 1983) found elevations in creatine phosphokinase ranging from 54 to 4640 IU/l (concentrations were normal in 3 of 11; raised by less than twice the normal in 2 of 11; between 440 and 1000 in 4 of 11, and greater than 1000 in 2 of 11). Muscle biopsies were abnormal in 8 of 11. The most common finding was atrophy of type-II fibres; no biopsy showed inflammatory changes. Electromyograms were myopathic in 9 of 11, and showed smaller and shorter individual action potentials than normal, an increased proportion of polyphasic potentials, and increased insertional activity. Fibrillations occurred but were less common. Thyroid hormone replacement in 7 patients with an increased concentration of creatine phosphokinase ranging from 180 to 3000 revealed that the half-life for disappearance of this enzyme was 10 to 12 days (Klein *et al*. 1980). There was often worsening of muscle cramps and stiffness during the first 2 weeks of thyroid hormone replacement. All creatine phosphokinase levels were normal by 9 weeks; this return to normal often preceded the correction of serum levels of thyroid-stimulating hormone.

Weakness, muscular stiffness, and an increase in muscle mass in an adult with myxoedema has been referred to as Hoffman's syndrome (Klein *et al*. 1981). A similar state in children presenting with a striking increase in muscle bulk is referred to as Kocher–Debre–Semelaigne syndrome. The striking increase in muscle bulk may take 6 to 10 months to resolve with thyroid hormone replacement. Myxoedema pseudomyotonia is muscle weakness associated with delayed muscle contraction as well as relaxation (delayed deep tendon reflexes). The electromyogram does not show the high frequency after discharge seen in true myotonic disorders. A prominent feature of hypothyroid myopathy may be muscle cramps, leading to the term pseudotetany.

Thyrotoxicosis

Four types of rheumatic complaints arise in the hyperthyroid state and are listed in Table 2 (Kyle and Hazelman 1981). Myopathy is very common, occurring in 70 per cent of patients, although it is seldom a presenting manifestation. There was periarthritis of the shoulder in 6.7 per cent of 300 patients described by Skillern (1943). Thyroid acropachy (thickening of the extremities) is characterized by clubbing and soft tissue swelling of the hands and feet, often painful, and by radiographs that demonstrate periosteal new bone formation, best seen on the radial aspect of the second and third metacarpals (Fig. 1). A survey of 954 patients with thyrotoxicosis found 19 with acropachy (Gimlette 1960). The syndrome most often develops in treated patients who are hypo- and euthyroid. Osteoporosis is a frequent accompaniment of excess thyroid hormone, which causes accelerated bone turnover. A marked increase in faecal and urinary excretion of both calcium and phosphorus occurs.

1. Myopathy – proximal
2. Periarthritis (shoulder)
3. Thyroid acropachy (thickened skin with periosteal new bone)
4. Osteoporosis

Table 2 Rheumatic manifestations of hyperthyroidism

Fig. 1 Rheumatic manifestations of hyperthyroidism

Autoimmune thyroid diseases include Grave's disease and Hashimoto's thyroiditis. These diseases are associated with other disorders (rheumatoid arthritis, Sjögren's syndrome, systemic sclerosis, polymyalgia rheumatica/giant-cell arteritis, polychondritis) that are associated with HLA B8 and DR3 haplotypes. Antibodies to rheumatoid factor and DNA, as well as to thyroglobulin, are frequent in autoimmune thyroiditis. Petri *et al*. (1991) reviewed 26 patients with Grave's disease and 26 patients with Hashimoto's thyroiditis and compared them with 26 control patients for rheumatic disease symptoms and positive antinuclear antibodies (**ANAs**). No differences were noted in rheumatological symptoms when patients with thyroid disease were compared with healthy controls. Positive ANAs using either liver substrate or Hep-2 substrate were more common in patients with Grave's disease than in controls. Although 46.2 per cent of patients with Hashimoto's thyroiditis had positive ANAs using Hep-2 substrate, 26 per cent of controls had positive ANAs and the difference was not significant. Evidence for systemic autoimmune diseases was not found in patients and they did not have antibodies to DNA, SSA, SSB, Sm, or RNP. The development of hypothyroidism in patients with systemic lupus erythematosus has been reported and is often accompanied by antibodies to thyroid tissue. Although controversial, an association between autoimmune thyroid disease, systemic lupus erythematosus, rheumatoid arthritis, and Sjögren's syndrome has been reported.

Becker *et al*. (1963) found a 4 per cent incidence of rheumatoid arthritis in 506 patients with Hashimoto's thyroiditis, compared with 0.4 per cent in a control group with granulomatous thyroiditis. Mulhern *et al*. (1966) found a possible association of Hashimoto's thyroiditis with rheumatoid arthritis but not with systemic lupus

erythematosus or other connective tissue diseases.

LeRiche and Bell (1984) described a group of 15 patients with Hashimoto's thyroiditis and an inflammatory polyarthritis whose arthropathy did not respond to thyroid hormone replacement. Nine of 15 were negative for rheumatoid factor, and the other 6 were positive. These latter patients were positive for HLA DR4, had erosive diseases with nodules, and were felt to have coexistent rheumatoid arthritis and thyroiditis. The 9 patients negative for rheumatoid factor were positive for HLA DR2 and were felt to represent a distinct subset of an inflammatory arthritis associated with thyroiditis. Ninety-one consecutive women with rheumatoid arthritis were evaluated for thyroid dysfunction and compared with 93 controls with osteoarthritis or fibromyalgia. A similar prevalence of Grave's disease and multinodular goitre was seen in the patients and controls, but patients with rheumatoid arthritis had an excess of hypothyroidism and Hashimoto's thyroiditis (30 per cent compared with 11 per cent) (Shiroky *et al*. 1993).

Serological studies have shown an increased incidence of autoimmune thyroiditis in Sjögren's syndrome. Thyroid disease (defined as current or previous clinically overt disease requiring treatment) was found in 10 per cent of patients with primary Sjögren's syndrome and their family members (Foster *et al*. 1993). There are antithyroglobulin and antimicrosomal antibodies in 40 per cent of patients with Sjögren's syndrome (Block and Bunim 1963). Polymyalgia rheumatica or giant-cell arteritis were found in 7 of 250 patients with autoimmune thyroid disease by Dent and Edwards (1978). No association between autoimmune thyroid disease and giant-cell arteritis was discovered in a small prospective study (Barrier *et al*. 1993). In this study, one-quarter of patients with giant-cell arteritis had thyroid dysfunction and/or antibodies compared with one-third of controls. This is in contrast to a larger study by Bowness *et al*. (1991), who reported an increased prevalence of hypothyroidism in patients with polymyalgia rheumatica and giant-cell arteritis.

Hyperparathyroidism

The rheumatic manifestations of hyperparathyroidism are as follows:

1. arthritis/soft tissue:
   a. pseudogout/chondrocalcinosis;
   b. rheumatoid arthritis-like;
   c. azotaemic arthropathy;
   d. shoulder arthropathy;
   e. tendon, capsular, ligament laxity with rupture;
   f. hyperuricaemia (gout is rare);
2. bone/cartilage:
   a. resorption (subperiosteal most diagnostic);
   b. osteoporosis;
   c. chondrocalcinosis;
3. muscle—proximal myopathy.

Musculoskeletal symptoms are reported to be the initial manifestation in up to 16 per cent of patients with primary hyperparathyroidism.

Hyperparathyroidism, chondrocalcinosis, and pseudogout frequently coexist. McCarty *et al*. (1974) reported that 17 (7.2 per cent) of 238 patients with chondrocalcinosis had primary hyperparathyroidism. Conversely, chondrocalcinosis reportedly occurs in 18 to 40 per cent of patients with hyperparathyroidism (less frequently in secondary hyperparathyroidism), and clinical pseudogout occurred in only 1 to 10 per cent of these patients (Bland *et al*. 1979). Pseudogout attacks are frequent within the first few days after parathyroidectomy as the serum calcium falls, chondrocalcinosis persists and attacks of pseudogout continue. A second type of arthropathy has been described by Bywaters *et al*. (1963) in primary hyperparathyroidism and Rubin *et al*. (1984) in secondary hyperparathyroidism, both resemble rheumatoid arthritis. The arthropathy described by Bywaters resembled rheumatoid arthritis in that patients had articular symptoms in the knees, wrists, hand, and shoulders, and radiographic erosions. However, the radiographic changes differ from those of rheumatoid arthritis—as synovial proliferation is absent, the joint space is preserved, pericapsular calcifications are frequently present, erosions have a predilection for the ulnar side of the joint (radial in rheumatoid arthritis), and reactive bone formation with an osteoarthritic appearance eventually develops. The erosions are a result of the direct effect of parathyroid hormone on subchondral bone, and not of synovitis as in rheumatoid arthritis.

Patients with chronic renal failure and secondary hyperparathyroidism on dialysis, in addition to developing the classical changes of renal osteodystrophy, may develop erosive changes resembling rheumatoid arthritis (Fig. 2) Rubin *et al*. (1984) described their findings in 59 patients with chronic renal failure on dialysis; 12 had renal osteodystrophy and erosions, 11 had osteodystrophy without erosions, and 36 had neither. The rheumatoid-like erosions occurred with decreasing frequency in the metacarpophalangeal, distal interphalangeal, proximal interphalangeal, shoulder, wrist, and knee joints. These patients experiences episodes of subacute, often symmetrical, arthritis affecting the metacarpophalangeal, proximal interphalangeal, wrist, and knee joints. Swelling and synovial thickening were seen in 8 of 12 patients with erosive changes. Analysis of synovial fluid from the knees of 5 patients revealed white cell counts of 50 to 1000/mm ^{3}; no crystals were seen. Synovial biopsies showed mild hyperplasia of lining cells (2 to 6 layers).

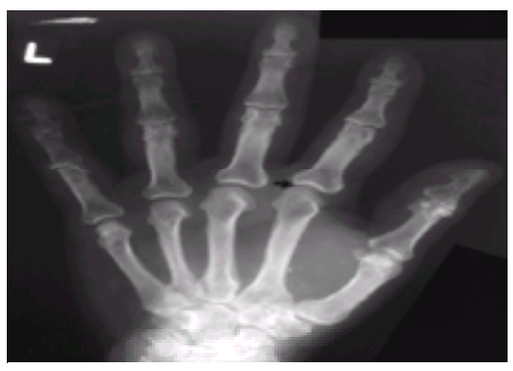

Fig. 2 Thyroid acropachy: note the characteristic lacy subperiosteal new bone in the diaphyses of short tubular bones of the hand.

A third type of arthropathy that may develop in primary or secondary hyperparathyroidism is a shoulder arthropathy with intra-articular and periarticular erosions of the head of the humerus (Nussbaum and Doppman 1982). No calcifications developed and some patients had radiographic findings without clinical symptoms. The effects of parathyroid hormone on soft tissue, capsule, and ligaments may lead to tenderness at the sites. There are numerous reports of hyperuricaemia and gouty arthritis in hyperparathyroidisim (Bland *et al*. 1979).

Neuromuscular disease is well described in primary hyperparathyroidism. Although subjective muscle weakness and fatigue are common, objective weakness is less frequent, and was present in 3 of 76 patients with surgically confirmed hyperparathyroidism reported by Frame *et al*. (1968). Patients have a symmetrical proximal myopathy, mostly in the lower extremities. Fatiguability is a common complaint. Muscle enzymes are normal, and muscle biopsy shows atrophy of type II fibres, often with a neurogenic component. The hallmarks of an inflammatory myopathy (necrosis, regeneration of muscle fibres, with inflammatory cells) are absent. Electromyographic findings are suggestive of both a myopathic (short polyphasic potentials) and neuropathic (long, amplitude polyphasic potentials) process; motor conductions are normal. Other neurological findings include hyperreflexia, tongue fasciculations, gait abnormalities, and paraesthesias (Patten *et al*. 1974). Patients with secondary hyperparathyroidism may have a similar picture. Those with mild, asymptomatic, primary hyperparathyroidism do not develop muscular weakness but do have muscle cramps (52 per cent) and paraesthesias (29 per cent).

Radiographic findings in hyperparathyroidism are as follows:

1. bone resorption:
   a. subperiosteal, intracortical, endoseal, subchondral, trabecular;

   b. subligamentous, localized (brown tumours);
2. bone sclerosis, periostitis;
3. chondrocalcinosis.

Subperiosteal resorption is virtually diagnostic of hyperparathyroidism and most frequently involves the radial aspect of the second and third phalanges. Brown tumours, representing large accumulations of osteoclasts–osteoclastomas and chondrocalcinosis, are most common in primary than secondary hyperparathyroidism, while osteocleosis and periostitis are less frequent.

Hyperparathyroidism is associated with accelerated bone loss, osteoporosis, and an increased fracture risk. However, patients with mild primary hyperparathyroidisim may not develop significant osteoporosis (Rao *et al*. 1988). Bone density measurements are useful in identifying those patients with primary hyperparathyroidism who are losing bone. In a study of 90 patients with primary hyperparathyroidism, fractures prior to the diagnosis of hyperparathyroidism occurred in 30 per cent of patients compared with 18 per cent of controls (Melton *et al*. 1992). Hyperparathyroidism may have differential effects on cortical and trabecular bone, with greater losses in cortical bone (Wishart *et al*. 1990). Surgery only partially reverses bone loss; in 14 patients undergoing parathyroid surgery, 13 showed an increase in bone mass in the lumbar spine (Minisola *et al*. 1993). Martin *et al*. (1990) followed 71 patients with primary hyperparathyroidism after operation. Bone mineral content increased during the first year after surgery, with the greatest gain in those with the lowest preoperative bone mass. However, bone mineral content of the radius remained more than 1 standard deviation below the mean in 61 per cent of patients at 1 year.

Hypoparathyroidism

Spondylitis has been described as a feature of hypoparathyroidism. However, sacroiliac involvement is absent and ankylosis is secondary to extensive calcification of paraspinal ligaments (anterior longitudinal ligament and posterior paraspinal ligament). Calvareal thickening and osteosclerosis have been described (Chaykin *et al*. 1969). Patients with pseudohypoparathyroidism and pseudopseudohypoparathryoidism, in addition to shortening of metacarpals and metatarsals, may have extensive soft tissue calcifications, exostoses, and bowing deformities.

Acromegalic arthropathy

Rheumatological manifestations of acromegaly are as follows:

1. arthropathy:
   a. bursal hyperplasia;
   b. synovial proliferation, prominent in knees;
   c. cartilage hyperplasia, widened joint spaces;
   d. bony proliferation;
   e. an osteoarthritis-like picture;
   f. backache;
   g. hypermobility;
2. carpal tunnel syndrome (50 per cent);
3. proximal muscle weakness (50 per cent);
4. Raynaud's phenomenon.

They are the result of chronic overstimulation of osteoblasts, osteoclasts, fibroblasts, chondrocytes, and muscle cells by growth hormone. Stimulation of chondroitin sulphate and collagen production by chrondrocytes is due to a hepatically derived serum factor called somatomedin (insulin-like growth factor) induced by growth hormone. Lieberman *et al*. (1992) reviewed the rheumatological and skeletal changes in acromegaly, including the effects of insulin-like growth factor 1 on articular cartilage and the effects of chronic somatotropism on the local production of insulin-like growth factor 1 in cartilage. Joint complaints usually arise well after the onset of clinical acromegaly, often 10 years after diagnosis. Large joints (knees, shoulders) are most often affected, and examination reveals synovial proliferation in knees and enlarged hands resulting from bony proliferation. Morning stiffness is not prominent, and joint swelling is present in less than one-half of patients. Back pain is frequent, and carpal tunnel syndrome is present in up to one-half and is usually bilateral. Bursas are often enlarged, especially prepatellar, olecranon, and subacromial.

Three large series of patients with acromegaly have been published by Kellgren *et al*. (1952), Bluestone *et al*. (1971), and Detenbeck *et al*. (1973). Bluestone described 42 patients, 16 with subjective complaints of joint pain (usually in shoulders, knees, hands, or hips) but without objective joint abnormality. While 26 had peripheral joint abnormalities on examination, only 9 of 26 patients had joint swelling, which was most prominent in the knees and consisted of synovial hypertrophy more often than effusions. Twelve had painless bony swelling of distal and proximal interphalangeal, and metacarpophalangeal joints. There was painful limitation of joint motion in 8 patients, often affecting the shoulders. Asymptomatic, coarse crepitance was present in over one-half of patients, usually affecting shoulders and knees. Twenty-two of 42 patients had carpal tunnel syndrome, which was bilateral in 20; 10 patients had mild Raynaud's phenomenon. Axial involvement was present in 20 patients who gave a history of non-traumatic backache, usually in the lumbar spine. Detenbeck evaluated 229 patients with acromegaly; 62 per cent had minor joint complaints; 16 per cent had symptoms that were severe and warranted radiographic evaluation. Kellgren found that 16 of 25 patients with acromegaly had joint complaints. Painless weakness of proximal muscles with normal muscle enzymes may occur in acromegaly. The electromyogram is usually normal; muscle biopsy reveals a myopathic pattern in one-half of patients (Khaleeli *et al*. 1984).

Radiographs are helpful, although the diagnosis is made on clinical grounds (Table 3). Characteristically, cartilage hypertrophy leads to widened joint spaces, most marked in the metacarpophalangeal joints, where the cartilage space is greater than 2.5 mm (Fig. 3). The distal tufts enlarge from the base and tip, and in advanced cases, the bone may meet and form a tunnel. Sesamoids may undergo hypertrophy, and in the thumb, a sesamoid index over 40 (obtained by multiplying the longest diameter by the width) suggests acromegaly. Lateral radiographs of the foot reveal a thickened heel pad (Fig. 4). A thickness of greater than 23 mm in men and 21.5 mm in women is abnormal. The diagnosis of acromegaly should be questioned in the absence of a thick heel pad. Obesity, infection, oedema, and myxoedema may also thicken the heel pad.

Measurement	Men	Women
Heel pad thickness (mm)	>23	>21.5
Sesamoid index (thumb)	>40	>32
Tuft width (mm) (3rd finger)	>12	>10
Joint space thickness (mm) (metacarpophalangeal)	>2.5	>2.5

From Resnick and Niwayama (1988).

Table 3 Bone and soft tissue measurements suggestive of acromegaly

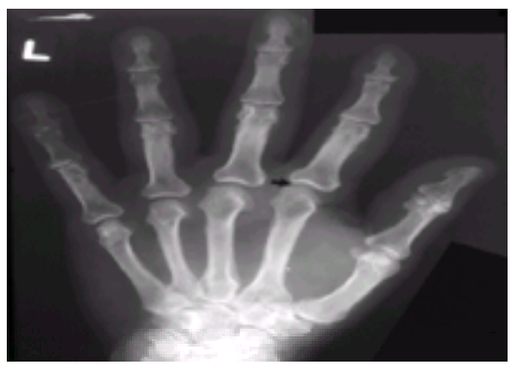

Fig. 3 Bone and soft tissue measurements suggestive of acromegaly.

Fig. 4 Bone and soft tissue measurements suggestive of acromegaly.

Correlation of radiographic and pathological findings in acromegaly has been summarized. Stimulation of endochrondral bone formation produces enlargement of costochondral junctions (acromegalic rosary) and thickened intervertebral discs. Stimulation of periosteal bone produces mandibular enlargement, a thickened cranial vault, prominent supraorbital ridges and facial structures, cortical thickening of tubular bones, enlargement of phalangeal tufts, and an increase in the anteroposterior diameter of vertebral bodies. Stimulation of subligamentous bone formation produces calcaneal spurs, and excrescences on the patella, trochanters, and tuberosities. Stimulation of bone resorption produces intracortical striations, widening of medullary cavities, and vertebral scalloping. Proliferation of articular cartilage causes widened articular spaces. Later, cartilage degeneration produces narrowed joint spaces and osteoarthritis with osteophytes. Connective tissue hyperplasia causes increased skin thickness (heel pad sign).

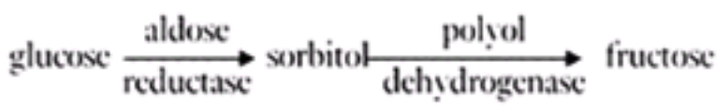
Pituitary

Pituitary and hypothalamic abnormalities may play a role in modulating autoimmune disease. Hyperprolactinaemia has been shown to exacerbate disease activity in the NZB × NZW mouse model of systemic lupus erythematosus. Jara-Quezada *et al*. (1991) reported elevated prolactin levels were associated with disease flares in pregnant patients with lupus. Elevated prolactin levels were found in 10 of 45 patients with lupus compared with 3 per cent of controls (Jara *et al*. 1992). A number of medications that elevate prolactin levels (chlorpromazine, aldomet, dilantin) have been associated with production of autoantibodies. Treatment with bromocriptine, an agent which lowers prolactin levels, has been used in NZB × NZW mice and in isolated case reports in humans with systemic lupus erythematosus, and may have immunosuppressive properties (McMurray *et al*. 1994).

Diabetes

Syndrome of limited joint mobility

The musculoskeletal manifestations of diabetes mellitus are diverse (Table 4), and divided into those that are related to the underlying pathological process of glycosylation of proteins and those that are secondary to the more primary diabetic complications. The syndrome of limited joint mobility, also called diabetic stiff-hand syndrome, was first described by Jung *et al*. (1971). It affects predominantly juveniles with type I diabetes mellitus but also adults with type I and II. Patients with this syndrome experience a slow decrease in mobility of the hands, characterized by a waxy thickening of the skin. The prevalence ranges from 8.4 to 58 per cent; in most series, 30 to 40 per cent of those with insulin-dependent diabetes mellitus develop the syndrome of limited joint mobility. While it occasionally may present before the onset of overt diabetes, the skin changes are more frequent in those with long-standing disease. Rheumatological interest in this syndrome relates to its scleroderma-like appearance, including occasional instances of pulmonary fibrosis and restrictive lung disease. Patients with the syndrome are more likely to have the microvascular complications of diabetes. The skin changes are felt to result from the enzymatic production of excessive sugar alcohols (polyols, such as sorbitol) in connective tissue, causing excessive tissue hydration and increased water content, which seems to parallel the increased stiffness of the skin. The sorbitol dehydrogenase pathway enzymes are saturated, resulting in increased production of sorbitol. Treatment with sorbinil, an inhibitor of the enzyme aldose reductase, has been reported to decrease skin thickening and improve mobility of the hands (Eaton *et al*. 1985):



Intrinsic complications of diabetes mellitus	Increased incidence in diabetes mellitus	Possible associations
Neuropathic joints	Dupuytren's contracture	Gout
Foot disease	Trigger finger	Calcium pyrophosphate deposition disease
Osteolysis	Carpal tunnel syndrome	
Syndrome of limited joint mobility	Shoulder periarthritis	Osteoporosis
Diabetic amyotrophy	Reflex sympathetic dystrophy	Osteoarthritis
Autoimmune insulin resistance		Autoimmune diseases
Diabetic muscular infarction	Diffuse idiopathic skeletal hyperostosis	

From Siebert (1988)

Table 4 Musculoskeletal complications of diabetes mellitus

The changes in skin texture predominate distally with finger involvement, but thickened palmar fascia (which may be misdiagnosed as Dupuytren's contractures, another problem in diabetes) also occurs. The skin changes have been likened to scleroderma and produce what is called the prayer sign; patients cannot closely appose the palms of their hands. They have mild morning stiffness but not synovitis; sensory abnormalities are mild or absent; and the electromyogram shows a mild decrease in conduction times. Radiographs are normal (Kapoor and Sibbitt 1989).

Several large reviews of the syndrome of limited joint mobility have been published. In a review of 137 patients aged between 1 and 24 years of age with

insulin-dependent diabetes mellitus (Seibold 1982), 47 (34 per cent) had palpable induration and thickening of the skin. Of these 47, only 6 had changes proximal to the metacarpophalangeal joints (thus meeting the American College of Rheumatology criteria for systemic sclerosis); 14 had changes at the metacarpophalangeal joints as well as distally, and 27 had changes distal to the proximal interphalangeal joints. Skin changes were graded slight in 25, moderate in 19, and severe in 3 patients. No patient had skin changes proximal to the wrists or on the face. Joint contractures were present in 26 of 47 (23 were symmetrical), were most common in the middle and ring fingers, and were usually angled at 5 to 10°. No patient had flexor tendon rubs as seen in systemic sclerosis. Rosenbloom *et al*. (1981) found the syndrome in 30 per cent of 309 cases of diabetes mellitus. Of those who had had the disease for longer than 4.5 years, 82 of 169 had skin changes. This report emphasized the association of microvascular changes with the syndrome. In the 82 patients with the syndrome and disease for longer than 4.5 years, one-half had the microvascular complications of diabetes (defined as nephropathy, retinopathy, or neuropathy), while only 10 of 87 without the syndrome had such complications. The usefulness of nailfold capillary microscopy was evaluated in a large group of patients with both insulin- and non-insulin-dependent diabetes mellitus, and found mild capillary enlargement and avascular areas in a few patients but no scleroderma-like changes were noted (Gertner *et al*. 1990). Light microscopic and ultrastructural features in skin biopsies were also different in diabetic thick skin and scleroderma. In this report, limited joint mobility was significantly correlated with neuropathy in patients with both insulin- and non-insulin-dependent diabetes and with retinopathy in insulin-dependent diabetes mellitus. No correlation was found between HLA types DR3 and DR4 and limited joint mobility.

Clark *et al*. (1990) reported the syndrome of limited joint mobility in 31 per cent of 70 children with insulin-dependent diabetes mellitus; no correlation was found between the syndrome and diabetic control, or the presence of retinopathy or microalbuminuria. Interestingly, on using HgbA1C as a marker for assessment of diabetes control, patients with the syndrome did not differ from those without it. Stiffening of connective tissue, as assessed by passive extension of the metacarpophalangeal joints, was shown to be associated with diabetic nephropathy in 205 patients with mature-onset diabetes (average age 61 years) (Aoki *et al*. 1993). In a series of 361 adult patients with diabetes mellitus (Starkman *et al*. 1986), 55 per cent of patients with insulin-dependent and 76 per cent with non-insulin-dependent disease had the limited joint mobility syndrome. The syndrome was related to duration of disease only in insulin-dependent diabetes with onset before the age of 35 years. Schulte *et al*. (1993) measured passive range of motion of the upper extremities in 70 adult patients with insulin-dependent diabetes mellitus and 79 non-diabetic controls for age, sex, and activity level. They concluded that the syndrome of limited joint mobility is a generalized phenomenon which occurs throughout the upper extremity including the shoulder and elbow, with the distal interphalangeal and metacarpophalangeal joints affected more than the proximal interphalangeal joints. Motion was significantly correlated ($p < 0.05$) with age, sex, duration of diabetes, and glucose control but not correlated with the presence of diabetic complications such as neuropathy, retinopathy, nephropathy, or peripheral vascular disease.

Articular syndromes and diffuse idiopathic skeletal hyperostosis (DISH)

Diabetes mellitus has been found in a significant number of patients with diffuse idiopathic skeletal hyperostosis (**DISH**). This association has been confirmed in African black patients; one-half of the patients with DISH had diabetes mellitus (Cassim and Rubin 1990). In one series of 510 patients with diabetes mellitus, 13 per cent had DISH (Karava and Viljanen 1966). By the age of 60 to 69 years, 21 per cent of diabetics and 4 per cent of controls had radiographic findings of DISH. One study of patients with DISH showed one-half with abnormal glucose tolerance. The high prevalence of abnormal glucose tolerance tests is partly a result of an association of obesity (present in 30 of 34 patients in one study), with DISH (Harris *et al*. 1974). Many patients have high insulin concentration after glucose challenge, suggesting insulin resistance. Insulin-like growth factors may play a part in stimulation of ligamentous calcifications seen in patients with DISH.

The prevalence of calcium pyrophosphate deposition disease in diabetes is reported to range from 8 to 73 per cent. A controlled trial by McCarty *et al*. (1974), who made glucose tolerance tests in 28 patients with pseudogout and 22 controls, found no difference in the two groups. The consensus is that there is no association between diabetes mellitus and gout, although hyperuricaemia may be more common. Joslin (1952) reported only 1 instance of gout in 1500 with diabetes mellitus.

Neuropathic joints/diabetic foot

Diabetes is the single greatest cause of neuropathic joints. In a review of 101 patients with Charcot joints and diabetes, the estimated prevalence was 1 in 680 patients with diabetes or 0.15 per cent (Sinha *et al*. 1972). Two-thirds of patients were in their fifth and sixth decades, and had had disease for more than 15 years. Diabetic control was often poor and all had peripheral neuropathy. Tarsal and tarsometatarsal joints were involved in 60 per cent, metatarsophalangeal joints in 31 per cent, and ankle in 9 per cent. Trauma and diminished pain perception and position sense appear to play a major part in the development of this arthropathy. The usual presenting complaint was swelling of one foot with vague or no pain. The earliest radiographic findings are joint effusions and subchondral lucency, followed by small fractures and irregular articular surfaces. Bony repair produces periosteal and endochondral ossification. Characteristic radiographic changes include 'sucked candy' appearances, and the balanced pagoda, 'mortar-in-pestle' and 'hour-glass' deformities (Fig. 5). Often patchy demineralization is present. The differential diagnosis of patients with radiographic changes consistent with neuropathic joints include neurosyphilis (common in hips, knees, and vertebral column), syringomyelia (upper extremity), leprosy (hands with calcification in nerves), and congenital indifference to pain (usually in children). Treatment of neuropathic joints usually consists of non-weight bearing, after which the joints may ankylose. Arthrodesis of ankle joints in patients with neuropathic arthropathy has a high incidence of complication (78 per cent) and should be considered with caution (Stuart and Morrey 1990).

Fig. 5 Diabetic neuroarthropathy. Anteroposterior and lateral views of the right foot will demonstrate extensive destruction of the intertarsal and tarsometatarsal joints. The patient illustrated has a neuropathic Lisfranc dislocation of the tarsometatarsal joint. There is both lateral and dorsal subluxation of the metatarsals in relation to the tarsal bones. The most sensitive place to look for Lisfranc dislocation is at the second tarsometatarsal articulation. Normally the medial border of the second metatarsal will align with the medial border of the intermediate cuneiform. The lack of osteoporosis with this extensive abnormality is suggestive of neuroarthropathy. This patient has been walking on this joint for some time. Diabetic neuroarthropathy predominates in the feet and is most commonly seen at the tarsometatarsal and metatarsal phalangeal joints.

Diabetic osteolysis is characterized by osteopenia, osteolysis, and resorption of the distal metatarsals and proximal phalanges. In contrast to neuroarthropathy, there is relative sparing of the joint (Griffiths 1985). The pathogenesis is unknown but may be secondary to microtrauma in a denervated extremity. Osteomyelitis is not uncommon in diabetes and must be differentiated from cellulitis, neuroarthropathy, and osteolysis. The three-phase bone scan may prove helpful in distinguishing between cellulitis, osteomyelitis, and neuropathic joints. With osteomyelitis, there is usually increased flow in the dynamic phase, with moderate to marked uptake in the immediate and delayed static phases. Cellulitis produces minimal uptake on the delayed images, while neuropathic joints demonstrate minimal activity on dynamic and immediate images and marked uptake on delayed images (Thomasson and Sundaram 1985).

Diabetes and soft tissue rheumatism

A number of soft tissue rheumatological syndromes are more frequent in patients with diabetes, including periarthritis of the shoulder, Dupuytren's contracture of the palmar fascia, carpal tunnel syndrome, and flexor tenosynovitis (Gray and Gottlieb 1976).

A review of 800 outpatients with diabetes mellitus compared with 600 non-diabetic controls showed that 10.8 per cent with diabetes and 2.3 per cent of controls had a history of significant periarthritis of the shoulder (Bridgman 1972). Of those with diabetes and periarthritis, 36 per cent were insulin dependent compared with 23 per cent of the entire group, suggesting an enrichment of periarthritis in type I diabetes. Over 40 per cent of cases were bilateral. In another review of 200 patients with diabetes mellitus compared with 100 controls, 22 per cent with diabetes had calcifications of the shoulder on radiographs compared with 8 per cent of controls. Half of patients with shoulder calcifications had a history of symptomatic periarthritis. Calcifications were often bilateral in multiple sites in patients with diabetes but were

usually unilateral and single in controls. Reflex sympathetic dystrophy of the hand may be a sequel of periarthritis of the shoulder.

Different series have reported varying prevalences of Dupuytren's contractures in diabetes mellitus. Bridgman (1972) found no increased prevalence; other series have reported a prevalence of 3 to 63 per cent (Bland *et al*. 1979). In those series reporting an association, prevalence increases with age and duration of diabetes, but does not appear to be related to the degree of diabetic control.

Phalen (1966) reported that diabetes mellitus was the most common systemic disease associated with carpal tunnel syndrome. Sixty-three of 379 patients (16.6 per cent) with diabetes had this syndrome. Other studies have shown that 5 to 8 per cent of patients with carpal tunnel syndrome have diabetes mellitus. The cause of carpal tunnel syndrome has been suggested to be either compression of the median nerve as a result of tissue infiltration, or ischaemia of the nerve secondary to microvascular disease of the vasa nervorum (carpal tunnel release would not be indicated in these patients). Diabetic hand syndromes secondary to neuropathies result in atrophy of intrinsic muscles of the hand, which may be confused with carpal tunnel syndrome. Electrodiagnostic studies will reveal both median and ulnar nerve involvement in these patients.

Although it is estimated that 10 per cent of adults with trigger fingers are diabetic, this association is poorly documented. MacKenzie (1975) reported on 63 patients with multiple flexor tenosynovitis of the fingers, 11 of whom had, or subsequently developed, diabetes mellitus. A survey of 250 patients with insulin-dependent diabetes mellitus reported that 5 per cent had trigger fingers and this was related to duration of disease. Almost one-half of the patients had the syndrome of limited joint mobility (Yosipovitch 1990).

Diabetic muscle infarction may present as a painful muscle mass, occurs in the setting of poorly controlled diabetes, and is the result of atherosclerotic arterial narrowing. Incisional biopsy may be required to make a definite diagnosis (Rocca *et al*. 1993). Ostrov *et al*. (1995) reviewed three cases of diabetic muscle infarction. Cases usually occurred in patients with poorly controlled diabetes mellitus or significant end-organ complications. This syndrome is often mistaken for thrombophlebitis, myositis, or vasculitis. The authors suggest using magnetic resonance imaging to evaluate diabetic patients with atraumatic, painful, swollen extremities which occur over the course of days to weeks; the images usually show asymmetry of muscle groups with high-intensity 12-weighted images. The painful swelling usually resolves spontaneously. The erythrocyte sedimentation rate is often elevated to over 100 ml/h but creatine phosphokinase and aldolase may be normal. This syndrome must be differentiated from focal myositis and localized nodule myositis; in these cases, biopsy shows normal vasculature without any evidence of atherosclerotic arterial narrowing.

Type I diabetes mellitus is associated with HLA alleles DR3 and DR4 (as are many of the classic connective tissue diseases); 95 per cent of patients with insulin-dependent diabetes mellitus are positive for these alleles. These patients will often have autoantibodies to other organs, and there is an increased incidence of organ-specific autoimmune diseases, usually in those that have HLA-DR3 alleles, such as autoimmune thyroid disease. The association of insulin-dependent diabetes mellitus with other connective tissue diseases has been reported. Thomas *et al*. (1983) found that 13.2 per cent of 295 patients with rheumatoid arthritis had a first- or second-degree relative with insulin-dependent diabetes compared with 3.8 per cent of 307 controls with degenerative joint disease. Other investigators have failed to find an increased prevalence of type I diabetes mellitus in rheumatoid arthritis.

Patients with insulin resistance often develop signs or symptoms of connective tissue diseases. Two types of insulin resistance have been described, A and B. Approximately 80 per cent of patients with type B insulin resistance are women aged 30 to 50 years. The syndrome is characterized by marked insulin resistance, acanthosis nigrans, and features of connective tissue disease including arthralgias, alopecia, enlarged salivary glands, leucopenia, proteinuria, hypergammaglobulinaemia, and high titres of antinuclear and anti-DNA antibodies. Features of connective tissue disease have preceded the appearance of diabetes mellitus in one-third of patients. Individual cases have been diagnosed as Sjögren's syndrome, systemic sclerosis, mixed connective tissue disease, and systemic lupus. A review of 14 patients with type B insulin-resistant diabetes mellitus revealed 12 with autoimmune features; 5 patients had four or more criteria for the diagnosis of systemic lupus erythematosus. Autoimmune features included speckled antinuclear antibodies in all 12 patients, double-stranded DNA in 7, alopecia/nephritis/malar rash in 4, and arthritis in 3 (Tsokos *et al*. 1985).

Polyglandular autoimmune syndromes

Polyglandular autoimmune syndromes are grouped into two distinct disorders. Type I begins at a mean of 12 years of age, and is characterized by hypoparathyroidism, primary adrenal insufficiency, and mucocutaneous candidiasis. Alopecia, chronic active hepatitis, pernicious anaemia, and malabsorption also occur. Type II, also called Schmidt's syndrome, has a mean age of onset of 30 years and is characterized by primary adrenal insufficiency, autoimmune thyroid disease, and insulin-dependent diabetes (Trence *et al*. 1984). These syndromes appear to be autoimmune; 80 per cent of patients have antibodies against one or more endocrine glands. In patients with polyglandular autoimmunity, there is an increased incidence of autoimmune diseases (usually as case reports) involving non-endocrine organs including alopecia, pernicious anaemia, vitiligo, Sjögren's syndrome, rheumatoid arthritis, myasthenia gravis, primary biliary cirrhosis, chronic active hepatitis, systemic lupus, and IgA deficiency (Table 5). Patients with type-II disorders have an increased incidence of the HLA B8, DR3 haplotype. Tucker *et al*. (1987) described 20 patients with type-II polyglandular autoimmune syndrome who had serositis (pleuritis and pericarditis) as a prominent component. Four patients were felt to have systemic lupus, based on the presence of antinuclear antibody titres ranging from 1:80 to 1:640, antibodies to DNA, antibodies to SS-A (Sjögren's syndrome-A), and rheumatoid factor. The 4 patients with systemic lupus had only autoimmune thyroid disease clinically, although 1 had antibodies to adrenal cortical cells.

Endocrinopathies	Non-endocrine disease
Graves' disease	Pernicious anaemia
Hashimoto's thyroiditis	Vitiligo
Addison's disease	Myasthenia gravis
Insulin-dependent diabetes mellitus	Sjögren's syndrome
Autoimmune oophoritis or orchitis	Rheumatoid arthritis
Autoimmune hypoparathyroidism	Idiopathic thrombocytopenic purpura
Autoimmune hypophysitis	Primary biliary cirrhosis

From Volpe (1986).

Table 5 Autoimmune endocrinopathies and non-endocrine organ-specific autoimmune disorders associated with them

Abonen *et al*. (1990) have termed type-I polyglandular endocrinopathy, APECED (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy), which emphasizes the three components of disease—endocrine failure, chronic mucocutaneous candidiasis, dystrophy of dental enamel and nails, alopecia, vitiligo, and keratopathy. A report of 68 such patients did not find systemic lupus or other classical connective tissue diseases. The largest series of polyglandular autoimmune syndrome, 71 patients with type I and 224 with type II, does not mention classical connective tissue disease in the patients (Neufeld *et al*. 1981).

POEMS syndrome (a multisystem disorder associated with polyneuropathy, organomegaly, endocrinopathy of various forms, production of a monoclonal antibody, and skin changes) was the subject of a review by Soubrier *et al*. (1994). In this retrospective study of 25 cases, scleroderma-like changes of the hands, mainly sclerodactyly, were noted in 4 of 25 cases. Two patients had Raynaud's phenomenon associated with scleroderma-like skin changes, with oesophageal hypomotility and restrictive pulmonary defect of renal failure, which were evocative of a scleroderma-like syndrome.

Diagnosis and endocrinology

Important points to remember when making a diagnosis are summarized in Box 1.

Box 1 Important points to remember

1. Rheumatic manifestations are common in endocrine disease

2. Polyarthritis, periarthritis tenosynovitis, myopathy, crystal deposition diseases, carpal tunnel syndrome, and osteoporosis are common accompaniments of endocrine disease

3. Differentiated diagnosis of rheumatic complaints should include endocrine disease and appropriate laboratory tests should be ordered (thyroid function tests, serum calcium, glucose)

1.3.8 Oncology and haematology

Michael Ehrenfeld and Yehuda Shoenfeld

Rheumatological manifestations of malignant diseases

Rheumatic symptoms and manifestations that may be clues to the existence of cancer may either be caused by direct invasion of the neoplasm or be due to an indirect cause, that is the paraneoplastic syndromes.

A wide range of neoplasia, both haematological and non-haematological, may be associated with rheumatic findings. As these patients may first present to the rheumatologist, he or she should be aware of the extent of these manifestations, thereby enabling earlier recognition and diagnosis. Furthermore, as there is an increased incidence of malignancy in almost all autoimmune rheumatic diseases, early recognition of a predictable malignancy is of great importance (see Chapter 5.19.1).

Direct association between rheumatological symptoms and cancer

Primary and secondary neoplasia may be responsible for this direct association.

Primary neoplastic diseases of bone or joints

Tumours of the joints, such as synovial sarcoma, are extremely rare. They are usually first encountered by orthopaedic surgeons or rheumatologists, as a result of symptoms suggestive of internal derangement of a joint, or in the evaluation of an articular or para-articular mass. Synovial sarcoma can appear at any age, although it is most common in young men. It usually occurs in the extremities, particularly around tendon sheaths and joint bursae, but it can also be found remote from joints. Santavirta *et al*. reviewed 31 cases of synovial sarcoma (Santavirta 1992). The 5-year survival rate was 55 per cent, and local and pulmonary metastases were found to be common. Treatment of choice was radical surgical excision with adjuvant radiotherapy and chemotherapy.

Para-articular involvement by malignant tumours arising from bone, such as osteogenic sarcoma, chondrosarcoma, or fibrosarcoma may give rise to a monoarticular synovitis with a mildly inflammatory fluid (Caldwell and McCallum 1986; Caldwell 1993). Occasionally, the tumour will invade the synovium and malignant cells may be found in the fluid. In a recent study of 47 cases of arthritis secondary to direct tumour involvement of joints, monoarthritis occurred in 45, with knee involvement in the majority (Schwarzer *et al*. 1990). Plain radiographs, tomography, and radionuclide bone scans provide helpful diagnostic information; however, any suspicious, slow-growing mass should be biopsied for diagnosis.

Occasionally, benign tumours such as osteoid osteoma, haemangioma, or lipoma may give rise to arthritis. Haemangiomas are most common in the young and are often associated with cutaneous angiomas. The knee is the joint most frequently involved. Recurrent attacks of acute pain and swelling of the joint, together with repeated aspirations of bloody fluid, are suggestive of the diagnosis. Pigmented villonodular synovitis may also present in a similar way. Radiographs may reveal phlebolites, which are diagnostic. Later findings are similar to those found in haemophiliac arthropathy. Arteriography and arthrography are complementary tests for assessing the size of the lesion before eventual surgical resection.

Secondary neoplasia

Lymphomas and leukaemias may simulate various rheumatic syndromes and cause synovitis (Fig. 1). The skeletal manifestations of leukaemia were reviewed extensively by Rennie and Auchterlonie (Rennie and Auchterlonie 1991). In children, these haematological malignancies may invade the synovium directly and thereby mimic juvenile or adult rheumatoid arthritis. Leukaemia, mainly acute, may present with arthritis in about 13.5 per cent of patients. Both acute and chronic leukaemia may be responsible for either monoarthritis or polyarthritis. In a study of 28 patients with leukaemic arthritis, Spilberg and Meyer found that acute leukaemia was more commonly polyarticular, asymmetrical, and part of the initial presentation (Spilberg and Meyer 1972). In chronic leukaemia the synovitis was usually a later manifestation and tended to be more symmetrical. Synovial biopsy and analysis of synovial fluid may confirm the presence of a leukaemic infiltration into the synovium. Immunocytological examination may facilitate diagnosis of leukaemic cells within the synovial fluid. Aside from migratory polyarthritis or arthralgias, other musculoskeletal manifestation of leukaemia include bone pain and tenderness, intra-articular or periarticular haemorrhage, synovial reaction to adjacent bony periosteal or capsular lesions, and crystal-induced synovitis. Back pain simulating a radiculopathy may be caused by diffuse leukaemic infiltration of the meninges.

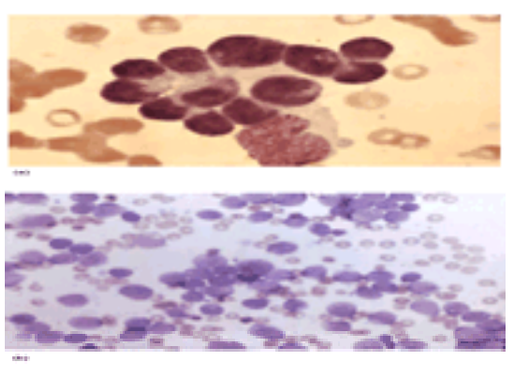

Fig. 1 (a) Neuroblastoma cells in the bone marrow of a patient presenting with musculoskeletal disease symptoms. (b) Acute lymphocytic leukaemia in a patient presenting with a monoarthritis.

Lymphoproliferative diseases may also present with a variety of musculoskeletal manifestations. Bone pain is the most common symptom of bone involvement. Lymphomas, though rare, may directly invade the synovium, with both monoarticular and polyarticular presentations. Radiographs may show bone destruction adjacent to the joints (Isenberg and Shoenfeld 1983).

Non-haematological metastatic disease

Direct invasion of the synovial membrane and the bone by non-haematological malignancy may lead to rheumatic presentations. The most commonly affected joint is the knee, with the hip, ankle, wrist, hand, and foot following. The malignancies are mainly carcinoma of the breast, bronchogenic carcinoma, gastrointestinal tumours, and melanoma (Caldwell and McCallum 1986). The joint disease is usually asymmetrical in distribution. Joint fluid is typically haemorrhagic, culture and crystal analysis are negative. The diagnosis of an underlying malignancy is most often made from a combination of radiographs, bone scan, and needle biopsy of the synovium, which may reveal the histological features of the tumour. Aspiration of synovial fluid may allow identification of malignant cells in some cases (Fam *et al*. 1980; Newton *et al*. 1984).

When radiographic films suggest a particularly destructive process accompanied by constitutional symptoms, a previous history of malignancy, and a protracted type of synovitis, metastatic carcinoma should be suspected.

Indirect associations between rheumatological syndromes and cancer

These paraneoplastic rheumatic syndromes can be subdivided into myopathies (particularly dermatomyositis and polymyositis) and arthropathies such as hypertrophic osteoarthropathy, amyloidosis in chronic haemodialysis, multiple myeloma and the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin change syndrome), secondary gout, carcinomatous polyarthritis, and the palmar fasciitis–polyarthritis syndrome. Miscellaneous indirect associations include: necrotizing vasculitis and polyarteritis nodosa-like syndrome; polymyalgia rheumatica; lupus-like syndrome; pyrophosphate arthropathy; cryoglobulinaemia; scleroderma; panniculitis, subcutaneous fat necrosis, and arthritis; relapsing polychondritis; and erythema nodosum with arthritis (see also Chapter 5.19.1). The syndrome of hypertrophic osteoarthropathy should be described in more detail. It consists of clubbing, periostitis of tubular bones, and an arthropathy ranging from mild arthralgia to a diffuse polyarthritis. If frank arthritis occurs, it usually involves the knees, ankles, wrists, and metacarpophalangeal joints. Diagnostic measures include a technetium bone scan, which may reveal an increased uptake around the shafts of the affected bones. Radiographs will usually reveal later periosteal elevation as a sign of new bone formation. Hypertrophic pulmonary osteoarthropathy (HPO) occurs as a presenting symptom in up to 20 per cent of primary lung tumours, though association with other malignancies is also known (Segal and Mackenzie 1982; Martinez-Lavin *et al*. 1993).

Malignancies in autoimmune rheumatic disease

Autoimmune rheumatic diseases and cancer are diagnosed with increasing frequency and there are many reports of an association between them, usually with lymphoreticular malignancies (Sela and Shoenfeld 1988) (see also Chapter 5.19.1). Rheumatoid arthritis, Sjögren's syndrome, systemic lupus, dermato-/polymyositis, systemic sclerosis, eosinophilic fasciitis, mixed connective tissue disease, lymphomatoid granulomatosis, and Paget's disease of bone have all been specifically associated with cancers (Haga *et al*. 1993; Gridley *et al*. 1993; Morel *et al*. 1993; Menon *et al*. 1993; Rosenthal *et al*. 1993).

Various autoantibodies have been identified in both haematological and epithelial malignancies. There are various methodological limitations in many of the studies that have tried to establish an association between autoimmune rheumatic disease and malignancy, leading to potential errors. These problems include the diagnostic criteria, the reliability of information on deaths, problems with follow-up data, inadequate confirmation of the histological type of the tumour, referral bias, imperfect selection of the control group in case–control studies, inadequate methods of analysis, therapy-related cancers, host susceptibility in both diseases, and environmental factors such as radiation, chemicals, or viral agents (Sela and Shoenfeld 1988). Even given these limitations, it is clear that some specific malignancies are still found more frequently than expected among most patients with autoimmune connective tissue diseases.

Malignancy as a complication of therapy

Immunosuppression

Immunosuppressive therapy has been used effectively in the treatment of autoimmune and rheumatic diseases because immune mechanisms are thought to be fundamental to the pathogenesis of these diseases. The drugs commonly used include the alkylating agents cyclophosphamide and chlorambucil, a purine analogue azathioprine, and the folic acid antagonist methotrexate.

The potential for the development of malignancy after the use of immunosuppressive drugs in non-malignant conditions has been a concern since 1970 when reticulum-cell sarcoma was documented to have developed in an unusual number of renal transplant recipients. Similarly, cancers have been described after the use of immunosuppressive drugs in rheumatic diseases; however, the actual frequency of these complications is difficult to determine because of methodological problems listed above.

In a long-term, retrospective, case–control study, Baker *et al*. have shown that prolonged daily treatment of rheumatoid arthritis with cyclophosphamide was associated with an increased risk of cancer of the urinary bladder, skin, or haematopoietic system (Baker *et al*. 1987). This risk was greatest in patients receiving the highest total dose and persisted for many years after the drug was discontinued. In a 7-year study of 61 cyclophosphamide-treated patients with rheumatoid arthritis and an equal number of controls, Baltus *et al*. reported malignancies in 25 per cent of treated patients and 7 per cent of the controls (Baltus *et al*. 1983). If data from Baker's and Baltus' studies are combined, there were haematological malignancies in 8 of 200 cyclophosphamide-treated patients versus 1 of 200 controls. It was later shown that regimens which involve the intensive use of cyclophosphamide followed by a drug-free period result in a reduced risk of untoward effects, including neoplasia and haemorrhagic cystitis. To date, there are only a few reported instances of malignancies in patients receiving pulse doses of cyclophosphamide.

Chlorambucil has become a popular alternative alkylating agent to cyclophosphamide, principally in Europe, in treating rheumatoid arthritis, systemic lupus, or vasculitis. This is primarily because of a lower incidence of bladder toxicity and alopecia, and its preferential lymphopoietic inhibition at low dosage. The potential for oncogenesis with chlorambucil is similar to that of cyclophosphamide, and of 1853 patients with rheumatoid arthritis treated mainly with chlorambucil or cyclophosphamide, 15 (0.85 per cent) developed acute leukaemia (Kahn *et al*. 1979).

Azathioprine appears to be the favoured alternative immunosuppressive agent to chlorambucil in the United States. The relatively high incidence of malignancies associated with azathioprine in renal transplant patients does not appear to apply to patients with rheumatoid arthritis, though there are occasional reports of lymphoreticular malignancies. Malignancies associated with azathioprine include non-Hodgkin's lymphoma, pancreatic sarcoma, reticulum-cell sarcoma and adenocarcinoma of the lung, squamous-cell carcinoma of the skin, acute myeloid leukaemia, transitional-cell tumour of the bladder, and carcinoma of the breast and the cervix.

Interestingly, Hazleman showed that the prevalence of neoplasia in patients with rheumatoid arthritis treated with azathioprine was less than in those who were treated with other drugs (Hazleman 1982). There have been similar results from other studies. It seems therefore that though the risk of azathioprine-induced malignancies exists, these are unlikely to achieve great importance for rheumatologists treating patients with rheumatoid arthritis (Lewis *et al*. 1980). Recently, Matteson *et al*. examined prospectively the safety of azathioprine and other disease modifying antirheumatic drugs (DMARDs) in the treatment of rheumatoid arthritis (Matteson *et al*. 1991). In a yearly follow-up over a 7-year period, 20 malignant conditions were diagnosed in 530 DMARD-treated adult patients with rheumatoid arthritis. Based on their results, the authors concluded that patients with rheumatiod arthritis requiring DMARD therapy may be at an increased risk of malignancy (particularly lymphoproliferative disorders) as compared with the general population.

The growing enthusiasm for the use of intermittent, low-dose methotrexate in rheumatoid arthritis has led to concern that the drug might carry an increased risk of associated neoplastic disease. There have been reports of malignancy occurring in psoriatic patients treated with methotrexate; to date, however, there is no convincing evidence implicating methotrexate as a cancer-causing agent in rheumatoid arthritis, though several cases of thymomas, lymphomas, and carcinomas have been reported in patients with rheumatoid arthritis treated with methotrexate. Though a relationship between methotrexate intake and various lymphoproliferative disorders has been suggested in several case reports, large studies in cancer and psoriasis, using both high- and low-dose methotrexate respectively, have not established a true relationship between methotrexate and cancer as has been shown for cyclophosphamide (Nyfors and Jensen 1983).

Arellano and Krupp recently calculated the relative risk of developing malignancies following treatment with cyclosporin (Arellano and Krupp 1993). Seventeen such patients were observed in over 1000 rheumatoid arthritis patients involved in clinical trials. The authors conclude that the use of cyclosporin, increases the already existing risk for malignancies by approximately the same degree as other DMARDs.

Because of potential toxicity and carcinogenicity, the decision to use immunosuppressive drugs in rheumatic diseases should be reserved for patients with active disease that is expected to be at least partly reversible.

Irradiation

X-ray therapy has been used in the past to treat ankylosing spondylitis, and this treatment may be implicated in the development of malignancy (Darby *et al*. 1987). Leukaemia, aplastic anaemia, and basal-cell carcinoma in the irradiated area may be late complications and this treatment has been abandoned.

More recently, total-lymphoid or total-body irradiation has been used in a small number of patients with rheumatoid arthritis refractory to all conventional therapy. This procedure has also been used as an immunosuppressive in patients with other autoimmune diseases. Though a few patients have been reported to develop a myeloproliferative or lymphoproliferative disorder, the overall incidence of malignancies in treated patients (with both rheumatoid arthritis and systemic lupus) was not found to be increased (Urowitz and Rider 1985).

Cancer therapy and musculoskeletal disorders

Loprinzi *et al*. recently described eight patients with a hitherto unrecognized new syndrome of myalgia–arthralgia developing within 1 to 3 months after completion of cyclophosphamide–5-fluorouracil combination chemotherapy for breast cancer (Loprinzi *et al*. 1993). Further cases of this 'postchemotherapy rheumatism' syndrome have been reported, also in association with other chemotherapeutic regimens and other malignancies, such as haematological malignancies. The symptoms usually clear within 4 to 9 months from their onset.

Haematological disorders in rheumatic diseases (seeChapter 4.2)

Anaemias

The rheumatic disease are commonly complicated by haematological abnormalities including those of all cell lines, coagulation abnormalities, and the haematological malignancies referred to above (Mowat 1971; Bennett 1977; Hamilton 1983). The most common finding is the anaemia of chronic disease, a mild anaemia that is generally asymptomatic. Its severity correlates with the activity of the disease. The two red-cell indices—mean corpuscular volume and mean corpuscular haemoglobin concentration—tend to be decreased, often to the range of values characteristic of microcytic and hypochromic anaemias. The serum ferritin rises while the transferrin and iron fall. Typically there is decreased iron absorption and impaired release of iron from the reticuloendothelial system (Baynes *et al*. 1987). Haemosiderin is usually found in the bone marrow. The cellularity of the marrow is usually abnormal, with plasma cells being increased in the majority of cases and associated with lymphoid aggregates. Marrow findings are, however, unpredictable, usually reflecting the diverse causes of cytopenias in patients with rheumatic diseases (Fig. 2).

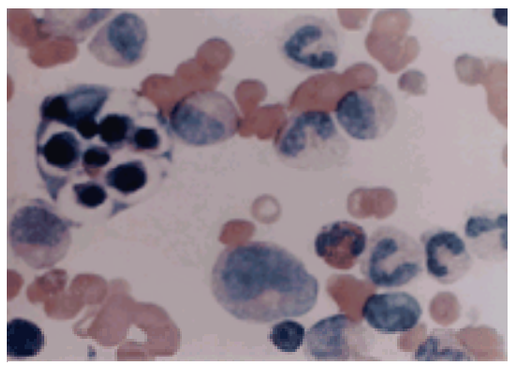

Fig. 2 Haemocytophagocytosis in a patient with juvenile rheumatoid arthritis.

The pathogenesis of the anaemia of chronic disease is still unclear. Inflammatory mediators, particularly the cytokines interleukin 1 and tumour necrosis factor, appear to be important in the impairment of erythropoiesis (Maury 1989).

One of the factors that could be related to the anaemia of rheumatoid arthritis appears to be a reduction in marrow response to erythropoietin as well as reduced erythropoietin levels. Patients in whom the hormone was measured by radioimmunoassay seemed to have a suppressed serum erythropoietin response to anaemia where the iron concentration was normal. Treatment with the human recombinant hormone resulted in improvement of the anaemia in a few of the patients, though no apparent changes in overall rheumatological status were noticed (Baer *et al*. 1990; Pincus *et al*. 1990).

In rheumatoid arthritis, more than one cause of anaemia is usually found and patients may simultaneously have true iron deficiency anaemia, which is found in up to 50 to 75 per cent of patients with chronic active disease, as well as anaemia of chronic disease. When these two conditions occur together, the haemoglobin drops, usually to below 9.5 g/dl, and the mean corpuscular volume is less than 80 fl. Iron deficiency is most often caused by chronic blood loss from gastritis induced by non-steroidal anti-inflammatory drugs, peptic ulcer, or from the diaphragmatic hernia frequently encountered in rheumatoid patients. An anaemia out of proportion to the clinical activity of the arthritis should therefore alert the physician to an unrelated cause.

Less frequently, a macrocytic megaloblastic anaemia may be found in rheumatoid arthritis with vitamin B_{12} deficiency. Folic acid deficiency has also been encountered, most often in iron-deficient patients with rheumatoid arthritis. The characteristic morphological changes in red blood cells may not always be present as they may be masked by the other common causes of anaemia.

Haemolysis with haemolytic anaemia is not a feature of rheumatoid arthritis, although antibody-mediated, Coombs'-positive, haemolytic anaemia has been described in rheumatoid arthritis and particularly in Felty's syndrome (see next subsection). Drug-induced haemolysis may also occur.

Pure red-cell aplasia is a rare but treatable cause of anaemia in rheumatoid arthritis and should be considered when there is severe normochromic anaemia in the absence of obvious blood loss or haemolysis. Autoimmune suppression of erythroid stem cells or antirheumatic drugs have been implicated in this complication, although single case reports suggest that pure red-cell aplasia could be an extra-articular manifestation of rheumatoid arthritis. Bone marrow hypoplasia may also complicate Felty's syndrome or renal failure.

As in rheumatoid arthritis, anaemia is the most common haematological abnormality in systemic lupus and occurs in over 50 per cent of the patients with active disease (Shoenfeld and Schwartz 1983). The most frequent cause is decreased production of red blood cells as a result of the chronic inflammation. The lupus

anaemia is usually normocytic, normochromic, with a reticulocyte count that is disproportionally low for the degree of anaemia. The bone marrow has a normal cellularity and normal or even increased iron. Iron studies are similar to those described in the anaemia of chronic disease in rheumatoid arthritis.

An unusual cause of impaired production of red blood cells in systemic lupus depends on a serum antibody that inhibits erythropoiesis. In these instances, the patients' serum suppresses *in-vitro* growth of autologous and allogeneic bone marrow cells. This type of immune-mediated anaemia can respond to either corticosteroids or plasma exchange.

Pure red-cell aplasia can be an unusual complication of systemic lupus. Antibodies directed against erythroblasts are present, and the condition may also respond to corticosteroid therapy. Although systemic lupus is often associated with anaemia, leucopenia, and thrombocytopenia, pancytopenia is present in only 5 per cent of these patients. Bone marrow findings in these patients show a variety of morphological abnormalities, that is hypoplasia, dyserythropoiesis, hyperplasia, gelatinous transformation, or lymphocytosis with or without plasmacytosis (Feng *et al*. 1991).

Autoimmune haemolytic anaemia may be the presenting sign of systemic lupus or one of its major manifestations. About 15 per cent of lupus patients will develop haemolytic anaemia at some time during the course of their disease. It is accompanied by a normal marrow response, reticulocytosis, a positive Coombs' test, hyperbilirubinaemia, and splenomegaly. Positive Coombs' tests are found in up to 30 per cent of patients, in half of whom there is no evidence of haemolysis. A positive Coombs' test may indicate the presence of circulating immune complexes but not necessarily of erythrocyte antibodies or autoimmune haemolytic anaemia. Systemic lupus patients with autoimmune haemolytic anaemia or immune thrombocytopenia probably make up two related subsets of lupus patients, who also have a high frequency of antiphospholipid antibodies. Corticosteroids, immunosuppressives, or splenectomy are the usual therapeutic measures employed, though newer therapeutic methods, such as plasmapheresis and high-dose intravenous gammaglobulin, have been proved to be beneficial in corticosteroid-resistant cases of autoimmune haemolytic anaemia (Miller 1990). When using prednisone or its equivalent, the initial dose should be 1.0 to 1.5 mg/kg, continued at that level for at least 4 to 6 weeks. Following a satisfactory response, the dose should be reduced gradually, generally at a rate of about 10 mg/week. The reticulocyte count is a reliable indicator of both responsiveness to therapy and relapse. A fall will indicate a response, whereas a rise signals a relapse. In cases of severe fulminant haemolysis, pulse methylprednisolone should be instituted at 1 g intravenously for 3 consecutive days.

As with rheumatoid arthritis, iron deficiency anaemia is not unusual in systemic lupus and is usually the result of either gastrointestinal drug-induced bleeding or menorrhagia. The anaemia is microcytic, hypochromic, with hypoferraemia and an increased serum iron-binding capacity with reduced iron stores.

Disorders of leucocytes

Leucopenia occurs in many rheumatic diseases (Bennett 1977; Hamilton 1983). In patients with rheumatoid arthritis several types of leucopenia have been found. The triad of neutropenia splenomegaly, and deforming rheumatoid arthritis (Felty's syndrome) occurs in about 1 per cent of patients with rheumatoid arthritis. Serious infections are frequent in these patients, most commonly skin infections and leg ulcers. Other factors associated with the increased incidence of infections are corticosteroid therapy and its dose, hypocomplementaemia, and high levels of immune complexes. These complexes coat granulocytes, leading to their sequestration and a reduced survival; furthermore, granulocyte-specific antinuclear antibodies are directed against white blood cell surface antigens, both contributing to the leucopenia. The neutrophil counts are usually between 500 and 2500/mm^3. In most patients, this may be accompanied by a mild anaemia of chronic disease and thrombocytopenia. The most common bone-marrow abnormality in Felty's syndrome is a maturation arrest of the granulocyte cell line. The neutropenia of Felty's syndrome as well as other rheumatic diseases is believed to be due to several mechanisms, including inadequate marrow granulopoiesis, accelerated disappearance of mature blood neutrophils often associated with antineutrophil antibodies, and splenic sequestration.

Treatment of Felty's syndrome is controversial and includes splenectomy, corticosteroids or immunosuppressives, and, to a limited extent, lithium salts. Leucopenia is not a contraindication to gold therapy and, when the leucopenia is mild, immunosuppressive agents may also be used when indicated. Gold may also improve the cutaneous vasculitis and may decrease the susceptibility to infection (Dillon *et al*. 1986).

Although haematological improvement is frequent after splenectomy, it does not always correlate well with reduction in the risk of recurrent infections or with ulcer healing. Plasmapheresis has also been used in these patients with some success.

Leucocytosis with proliferation of polymorphonuclear leucocytes can occur during an inflammatory flare of rheumatoid arthritis. In the differential diagnosis it is important to exclude a bacterial infection. In systemic lupus, leucocytosis is rare in the absence of infection or corticosteroid therapy; a depression of the total white blood-cell count to below 4500/mm^3 is characteristic, occurs in as many as two-thirds of lupus patients, and is mediated by immune complexes or complement-mediated aggregation. Other causes of granulocytopenia include drugs, decreased marrow production, and increased marginal or splenic pooling. Several mechanisms may exist at the same time in any given patient. Lymphopenia is possibly one of the most common manifestation of systemic lupus and is usually mediated by anti-T-cell autoantibodies. Other causes of granulocytopenia or lymphopenia in systemic lupus may be hypersplenism, or corticosteroids and immunosuppressive agents.

Eosinophilia

It has long been recognized that certain patients with rheumatoid arthritis show a significant eosinophilia; this usually correlates with the presence of vasculitis, pleuropericarditis, pulmonary fibrosis, and subcutaneous nodules. Eosinophilia also accompanies gold-induced skin rashes.

Platelet abnormalities

Thrombocytosis is common in rheumatoid arthritis and a positive correlation has been found between the platelet count and disease activity. Extreme thrombocytosis has been noticed with extra-articular manifestations of the disease—in particular, pulmonary involvement, peripheral neuropathy, and vasculitis. Thrombocytopenia is rare in rheumatoid arthritis, except when related to drug treatment or Felty's syndrome.

In systemic lupus, thrombocytopenia is the most common and important clinical disorder of haemostasis. Between 25 and 50 per cent of lupus patients will have mild, clinically negligible thrombocytopenia during the course of the disease, but only about 10 per cent will develop a marked reduction in platelets (less than 50 000/µl) and bleeding manifestations (Gladman *et al*. 1983). The bone marrow usually shows normal or increased numbers of megakaryocytes. Abnormalities of platelet function are commonly seen in patients with immune thrombocytopenia, and in patients with systemic lupus, whether or not they are thrombocytopenic.

At times, autoimmune thrombocytopenia develops simultaneously with autoimmune haemolytic anaemia. These instances, referred to as Evan's syndrome, almost always occur in patients with systemic lupus. In some patients autoimmune thrombocytopenia may precede other signs of lupus by months or years.

The finding of a positive antinuclear antibody test in a patient with an apparently idiopathic autoimmune thrombocytopenia thus warrants continued observation. An association between the presence of anticardiolipin and other antiphospholipid antibodies and thrombocytopenia in systemic lupus, as well as in chronic immune thrombocytopenic purpura, has been described. Antiplatelet antibodies are probably responsible for the observed thrombocytopenia, as well as for hypersplenism. Although complement-mediated lysis may occur, the major effector is the splenic macrophage, which opsonizes the antibody-coated platelets.

Corticosteroids are the mainstay of treatment. The initial dose in prednisone equivalents is usually 1 mg/kg, but 2 mg/kg may be required in more severe instances. An increase in the platelet count should occur within 1 to 3 weeks in responsive cases. The dose can be gradually reduced after 4 weeks, with careful monitoring of the platelet count. Clinical findings must guide the management. Petechiae and ecchymoses in the skin ('dry' purpura) are harmless, whereas 'wet' purpura with gastrointestinal bleeding or bleeding in the genitourinary system are much more dangerous. Bleeding in the central nervous system is rare. Steroid failures have been treated with splenectomy, immunosuppressive drugs, vinca alkaloids, cyclosporin, and high-dose intravenous gammaglobulin—all with varying degrees of success (Boumpas *et al*. 1990; Miller 1990).

Immune thrombocytopenic purpura has also been reported in mixed connective tissue disease, dermatomyositis, and systemic sclerosis.

Haemostatic changes in rheumatic diseases

The lupus anticoagulant and antiphospholipid syndrome (see also Chapter 5.7.3)

Various alterations in measures of coagulation have been described in association with most rheumatic diseases (Hamilton 1983). Most naturally occurring, circulating anticoagulants are antibodies to specific clotting factors. In systemic lupus specific antibodies against factors VIII, IX, XI, XII, and XIII have been reported. The discovery of the lupus anticoagulant has made this disorder the most studied in relation to haemostatic changes. Lupus anticoagulant was first described by Conley and Hartmann, who noticed that the addition of plasma from a patient with systemic lupus to normal blood prolonged the whole-blood clotting time but not the thrombin clotting time (Conley and Hartmann 1952). It was later shown that these *in-vitro* abnormalities can occur despite normal activity of the individual clotting factors. Furthermore, an association between a biological false-positive test for syphilis and the circulating anticoagulant became apparent. This anticoagulant, called the lupus inhibitor, is now known to be an antibody directed against the negatively charged phospholipid portion of the prothrombin activator complex. It is an immunoglobulin of the IgG or M class, which interferes with the phospholipid-dependent coagulation tests. It has recently been shown that a cofactor, b $_2$ glycoprotein I (apolipoprotein H), which is a normal serum protein, binds to negatively charged phospholipids and enhances autoimmune antiphospholipid binding (McNeil *et al*. 1990).

This lupus anticoagulant is one of a family of antiphospholipid antibodies. Others include anticardiolipin antibodies and an antibody that causes the false-positive result in reaginic tests for syphilis (VDRL, RPR, or Wasserman test). Whether antiphospholipid antibodies and the lupus anticoagulant are the same or two closely related but different antibodies is not yet known. Antiphospholipid antibodies probably cross-react with anti-DNA antibodies (Harris *et al*. 1985). Acidic phospholipids have now been recognized to bind to DNA-polymerase, topoisomerase I, and Z-DNA binding proteins. It has also been shown that low-avidity serum anti-DNA antibodies cross-react extensively with cardiolipin, whereas high-avidity antibodies do not (Smeenk *et al*. 1987). The lupus anticoagulant and anticardiolipin antibodies are highly correlated, although there are patients who have positive tests for one without the other. Passive transfer of anticardiolipin to naïve mice induces an experimental model of antiphospholipid syndrome, including thrombocytopenia and fetal loss (Blank *et al*. 1991). It seems, in general, that anticardiolipin antibodies are a more sensitive measure of antiphospholipid antibodies than the lupus anticoagulant. They are both associated with the clinical features listed below (Hughes 1993; Bick and Baker 1994; Kampe 1994).

1. Thromboembolic phenomena:
    a. venous; thrombosis, recurrent (deep vein, axillary, inferior vena cava, cerebral and retinal, Budd–Chiari syndrome, renal vein)
    b. arterial;
        i. cerebrovascular accidents, including transient ischaemic attacks and amaurosis
        ii. coronary thrombosis
        iii. iliofemoral artery-related peripheral arterial gangrene
        iv. mesenteric thrombosis
        v. retinal artery thrombosis
        vi. renal microangiopathy and renal failure
        vii. adrenal haemorrhage/failure
        viii. avascular necrosis.
2. Fetal loss: placental thrombosis and infarction (spontaneous recurrent abortion or miscarriage).
3. Thromboctyopenia: Coombs'-positive haemolytic anaemia.
4. Neurological disease:
    a. chorea and seizures;
    b. migraine headaches;
    c. progressive multifocal-infarct dementia;
    d. transverse myelitis;
    e. 'pseudomultiple sclerosis';
    f. pseudotumour syndrome.
5. Heart valve vegetations and endocarditis.
6. Pulmonary hypertension.
7. Livedo reticularis.
8. Chronic leg ulcers.

It has been suggested that many of these clinical associations are consequences of recurrent thrombosis. The incidence of lupus anticoagulant, the most common anticoagulant found in patients with systemic lupus, is not known but has been estimated at 5 to 10 per cent, though some series quote figures ranging up to 21 to 65 per cent. It has also been shown that lupus anticoagulant occurs in conditions other than systemic lupus and may be associated with drug administration, AIDS, or neoplasia. Diseases associated with antiphospholipid antibodies (anticardiolipin or lupus anticoagulant) are as follows:

1. Systemic diseases

    Autoimmune:

    a. systemic lupus erythematosus (frequent);
    b. rheumatoid arthritis (rare);
    c. vasculitis, including Takayasu's arteritis;
    d. systemic sclerosis and polymyositis;
    e. juvenile chronic arthritis;
    f. mixed connective tissue disease and 'overlap' syndromes;
    g. Sjögren's syndrome;
    h. autoimmune haemolytic anaemia;
    i. autoimmune thrombocytopenic purpura;
    j. Behçet's disease;
    k. hypothyroidism and Addison's disease.
2. Haematological disorders:
    a. Hodgkin's and non-Hodgkin's lymphomas;
    b. leukaemias, including hairy-cell leukaemia;
    c. Waldenström's macroglobulinaemia;
    d. bone marrow aplasia.
3. Liver disorders:
    a. cirrhosis;
    b. chronic active hepatitis;
    c. Budd–Chiari syndrome.
4. Drug associated:
    a. oral contraceptives;
    b. drugs associated with drug-induced lupus (procainamide, hydralazine, chlorpromazine, phenytoin, antibiotics).
5. Infections: bacterial, viral, fungal, and protozoa (e.g. AIDS).
6. Vascular thrombosis: recurrent venous or arterial.
7. Spontaneous abortions.
8. Neurological disorders:
    a. focal cerebral ischaemia;
    b. ocular ischaemia;
    c. chorea;
    d. migraines;
    e. dementia, psychiatric illness.
9. Others:
    a. epithelial malignancies;

b. psoriatic arthritis and osteoarthritis;
c. Raynaud's phenomenon;
d. ulcerative colitis;
e. rheumatic fever (acute);
f. normal population.

Paradoxically, patients with this antibody do not have a bleeding tendency unless they have another haematological abnormality such as thrombocytopenia or vascular deficiency. In contrast they are, as noted above, at increased risk of developing recurrent venous or arterial thromboembolic events. The explanation of this tendency to thrombosis in 5 to 30 per cent of patients with systemic lupus is still unclear. Thrombotic events have been considered to be related to the titre of the antibody, the isotype present (IgG), and perhaps the length of time the antibodies have been present. Several possible mechanisms have been proposed. One suggests that the reaction of lupus anticoagulant with platelet phospholipids may increase platelet adhesiveness, thus lowering the threshold for aggregation. Another possibility is the interaction of the anticoagulant with prostacycline, which is a potent vasodilator and inhibitor of platelet aggregation. In addition, the lupus anticoagulant can inhibit prekallikrein, thereby promoting clotting. Other options include interference with activation of protein C and antithrombin III (Triplett 1990).

The antiphospholipid syndrome is the disorder characterized by production of high levels of antiphospholipid antibodies in association with recurrent of venous or arterial thromboses, fetal wastage, and thrombocytopenia (Alarcon-Segovia *et al*. 1989). A variety of clinical features have been added to the initial definition of this condition. Though many of these patients are found to have systemic lupus or other connective tissue diseases, patients with the syndrome who do not have classical systemic lupus or other connective tissue disease may be classified as having 'primary' antiphospholipid syndrome (Asherson *et al*. 1989; Mackworth-Young *et al*. 1989). It appears that these patients do not have major clinical or serological features of systemic lupus. Otherwise there are no overt differences between primary antiphospholipid syndrome patients and those with antiphospholipid syndrome during the course of systemic lupus. In primary antiphospholipid syndrome there is, however, a lower incidence of heart-valve lesions, livedo reticularis, and chorea, and there is absence of acute illness with systemic symptoms and the typical lupus flares. These patients present with an idiopathic deep-vein thrombosis, pulmonary thromboembolism or thromboembolic pulmonary hypertension, transient ischaemic attacks or strokes, and myocardial infarctions or other arterial occlusions in the absence of systemic lupus or any other defined connective tissue disease. They are often antinuclear-antibody negative, and are always negative for typical serological markers of systemic lupus, such as antibodies to double-stranded DNA or to extractable nuclear antigen.

Recently, Vianna *et al*. published a European multicentre study, involving 114 patients with either primary antiphospholipid syndrome or secondary antiphospholipid syndrome (Vianna *et al*. 1994). They were able to show that patients with secondary antiphospholipid syndrome had a significant incidence of autoimmune haemolytic anaemia, endocardial valve disease, neutropenia, and abnormal C4 levels.

The 'catastrophic' antiphospholipid antibody syndrome

A few patients with antiphospholipid antibodies develop a sudden widespread organ failure with thrombocytopenia, wide spread thrombosis, and 'adult respiratory distress syndrome'. Prognosis is poor and the causes of the sudden catastrophe are unclear (Asherson 1992).

Obstetric complications (see Chapter 1.3.1.1)

The presence of lupus anticoagulant in pregnancy has been associated with recurrent early abortions and intrauterine death (Branch *et al*. 1985; Triplett 1989). It is most commonly associated with a first-trimester abortion or second-trimester fetal death. It has been suggested that placental infarctions are the cause of the fetal loss. However, fetal loss is now not thought to be as frequent as the published record suggests. Some women with high levels of lupus anticoagulant activity do not have thrombotic events or suffer fetal death. Prospective studies are needed to determine the true risk of a positive lupus anticoagulant test for the outcome of the pregnancy. An incidence of 5 to 48 per cent of lupus anticoagulant in women with histories of recurrent abortions has been recorded, compared with an incidence of less than 5 per cent in normal, uncomplicated pregnancies. However, prospective studies of normal pregnant women (using a high titre cut-off for antiphospholipid antibody) found that antiphospholipid antibody was rare (0–2.2 per cent). It seems, therefore, that screening for antiphospholipid antibody in unselected women is probably not indicated (Love and Santoro 1990).

Treatment of lupus anticoagulant (see Chapter 5.7.3)

The presence of lupus anticoagulant or antiphospholipid antibody in asymptomatic patients is not an indication for treatment. Some evidence suggested that patients with IgG antiphospholipid antibody of high titre are a high-risk group but other studies have not confirmed this. Patients with antiphospholipid antibodies who have recurrent venous or arterial thrombosis are best treated initially with heparin and then with oral anticoagulants such as warfarin or drugs that inhibit platelet aggregation (e.g. aspirin, dipyridamole). It is probably best to treat these patients as long as the antibody is present at high titre.

Although corticosteroids and immunosuppressive agents may lead to the normalization of the activated partial thromboplastin time, they are not recommended for long-term use as a preventive measure for recurrent thrombosis in patients with antiphospholipid antibody or lupus anticoagulant. On the other hand, for women with antiphospholipid antibody-associated fetal loss, relatively high doses of prednisone and low-dose aspirin have been used as treatment during pregnancy, with improved outcome (Parke 1989; Harris 1990). However, there are conflicting data that pregnant women receiving aspirin alone did not do worse than those on prednisone with low-dose aspirin (Lockshin *et al*. 1989). Though the optimal therapy for the fetal wastage syndrome has not yet been defined, the common practice in many institutions is to use low-dose aspirin (about 80 mg/day) in combination with low-dose heparin (2500 to 5000 u subcutaneously, twice daily).

The combination of low molecular weight heparin and low-dose aspirin has also been shown recently to be effective in the treatment of antiphospholipid antibody syndrome in pregnancy. Other forms of therapy, mainly for women with high-titre antiphospholipid antibodies and prior fetal death, include heparin, plasma exchange, intermittent intravenous high doses of immunoglobulin, and immunosuppressive agents.

The presence of antiphospholipid antibody or lupus anticoagulant in patients who are undergoing major surgery probably warrants the use of low-dose subcutaneous heparin prophylaxis.

Haematological effects of drugs

Non-steroidal anti-inflammatory drugs

A wide variety of adverse reactions in most body systems has been described with the use of non-steroidal anti-inflammatory drugs. Idiosyncratic blood dyscrasias are extremely rare among the adverse haematological effects of these drugs, even though they are used extensively and long term. The mechanism of action is either by exerting bone marrow toxicity or by direct toxic effects on circulating blood cells. Haemolytic anaemia (usually autoimmune in nature), aplastic anaemia, agranulocytosis, isolated neutropenia, and thrombocytopenia are the haematological disorders most frequently reported (O'Brien and Bagby 1985; Henry 1988).

Anaemia and agranulocytosis

Though it is difficult to be certain of the extent of association because of multiple drug exposures, cases of aplastic anaemia and agranulocytosis associated with the ingestion of non-steroidal anti-inflammatory drugs have been described with most of those available. In single cases, aspirin, indomethacin, sulindac, diclofenac, ibuprofen, fenoprofen, naproxen, and piroxicam have all been associated with aplastic anaemia.

Phenylbutazone and oxyphenylbutazone have long been known to be associated with a higher risk of aplastic anaemia and have therefore been abandoned in some countries and limited to hospital use only in others. In one large study of toxicity over a 17-year period in Denmark, 7 per cent of all reports were of haematological adverse reactions. About two-thirds of them dealt with bone marrow depression. Granulocytopenia and agranulocytosis were described in one-quarter of the reports on haematological disorders. Fatal agranulocytosis was particularly found in women over the age of 60 years (Kroman-Andersen and Pedersen 1988).

Pure red-cell aplasia, though extremely rare, has been described with phenylbutazone, indomethacin, and fenoprofen.

Effects on the blood-clotting mechanism

Non-steroidal anti-inflammatory drugs may prolong the bleeding time by inhibiting synthesis of prostaglandin endoperoxidase and thromboxane A_2 and consequently inhibiting platelet aggregation. This effect is usually also manifest at the lowest dosages used, i.e. antipyretic and analgesic doses. This effect has led to the use of aspirin in doses as low as 80 mg daily to prevent platelet aggregation and embolization in patients prone to transient ischaemic attacks. As a result of the effect on platelet function, most non-steroidals may rarely cause clinical bleeding of varying severity. However, blood loss from gastric lesions may be partially influenced by effects on platelet aggregation. A second mechanism by which protein-bound non-steroidals may effect coagulation is by displacing warfarin from plasma protein-binding sites. This in turn may increase warfarin's anticoagulant effect.

Thrombocytopenia

This has been described with most non-steroidal anti-inflammatory drugs, some of the cases being fatal. Fatal thrombotic thrombocytopenic purpura with acute renal failure has also been described. Thrombocytopenia was seen in one-quarter of the haematological adverse reactions in the large-scale Danish study (Kroman-Andersen and Pedersen 1988).

All non-steroidal anti-inflammatory drugs will interfere with platelet aggregation.

Autoimmune haemolytic anaemia

This anaemia induced by non-steroidals is extremely rare but may be severe. The condition tends to be reversible when the offending drug is withdrawn, although most patients require steroid therapy. In some cases the haemolytic anaemia is accompanied by signs of hypersensitivity.

Leukaemia

The possible induction of leukaemia by phenylbutazone was suggested in the early 1960s. Later, in the long-term Danish study, four male patients were reported to have died of leukaemia related to oxyphenylbutazone, phenylbutazone, mophebutazone, indomethacin, and ketoprofen, respectively. All were elderly, between 62 and 90 years of age.

Antimalarials

Various rare blood dyscrasias have been associated with antimalarials, including agranulocytosis, aplastic anaemia, leucopenia, and reversible toxic granulation. The agranulocytosis appears to be reversible (Maksymowych and Russel 1987).

A few of the antimalarials, particularly primaquine, have striking haemolytic effects when given to patients with glucose 6-phosphate dehydrogenase deficiencies. However, chloroquine and hydroxychloroquine have only a weak haemolytic activity.

Hydroxychloroquine has been suggested and used in some institutions as prophylaxis against thromboembolism after total hip replacement (Loudon 1988). In man, hydroxychloroquine can reduce red blood-cell aggregates without prolonging the bleeding time. A variable reduction in platelet aggregation and blood viscosity have been shown as well. Animal studies have shown a reduction in the size of the thrombus with hydroxychloroquine.

Gold compounds

The greatest concern when using these agents is bone marrow suppression (1–3 per cent), which may present as leucopenia, thrombocytopenia, agranulocytosis, or aplastic anaemia (Kean 1990). Blood dyscrasias are especially likely to develop after a total dose of approximately 300 mg of gold has been reached and exceeded, although agranulocytosis and aplastic anaemia may develop at any time during the course of treatment with gold. The untoward effects seen with intramuscular and oral gold are the same but their incidence differs. Because of these risks, full blood-cell and platelet counts must be made at least monthly.

The most common haematological side-effect of gold is thrombocytopenia, which occurs in up to 10 per cent of patients at some stage during gold therapy (Adachi *et al*. 1987). It is immune mediated with the production of platelet-associated IgG leading to peripheral platelet destruction. A second mechanism that has been proposed is complete marrow aplasia, which is usually associated with a gradual fall in platelet counts, as compared with the precipitous fall in the immune-mediated type. An association with HLA-DR3 has been demonstrated. The condition is usually responsive to corticosteroid therapy, although other modes of therapy may be as efficacious (i.e. *N*-acetylcysteine, penicillamine, vincristine, high-dose intravenous gammaglobulin, and splenectomy). Isolated thrombocytopenia usually has a good prognosis. It should be noted that oral gold preparations are safer and less toxic than injectable gold—thrombocytopenia being a rare side-effect with this medication.

Gold-induced neutropenia and marrow aplasia with pancytopenia are the most serious toxic effects of gold compounds, but these are rare. The mortality in this group is estimated at 60 to 75 per cent; there is a little evidence that corticosteroids, anabolic steroids, or D-penicillamine as a chelating agent, or plasmapheresis may be helpful.

Antithymocyte globulin and bone marrow transplantation have been used successfully in treating gold-induced aplastic anaemia. The condition has been associated in some patients with HLA-DR4, although earlier reports found an association with HLA-DR3. The findings are not conclusive.

Eosinophilia has long been recognized as an accompanying feature of gold therapy. If persistent and increasing, it may herald a more serious adverse drug reaction and is often associated with gold-induced dermatitis. The incidence of eosinophilia at the time of adverse reaction varies between 24 and 78 per cent.

D-*Penicillamine*

This drug has a rather high incidence (50 per cent) of adverse effects. Toxic side-effects are believed to be dose related, except for hypersensitivity reactions and autoimmune disorders. Haematological toxicity is the most serious of the untoward effects (Jaffe 1986; Kay 1986). Fatal reactions are associated predominantly with bone marrow aplasia. Other observed toxic effects include thrombocytopenia and neutropenia. These may be of two types. One is idiosyncratic and is most often seen within the first 12 months of treatment. It is independent of dosage and is acute in nature, similar to the aplastic anaemia. The second type, which is more common, is dose related and more gradual in its onset. Other rare side-effects include haemolytic anaemia, sideroblastic anaemia, transient eosinophilia, thrombocytosis, and polycythaemia. Frequent haematological monitoring is mandatory because recovery from bone marrow suppression is possible after prompt discontinuation of the drug (Howard-Lock *et al*. 1986).

Sulphasalazine

The adverse effects of sulphasalazine are well known because it has been used for over 40 years in the treatment of inflammatory bowel disease. A wide range of blood dyscrasias have been described over the years. These include agranulocytosis, leucopenia, aplastic anaemia, thrombocytopenia, haemolytic anaemia, megaloblastic anaemia with macrocytosis, and methaemoglobinaemia (Pinals 1988; Hopkinson *et al*. 1989). Agranulocytosis has most commonly occurred after a mean duration of treatment of 4 weeks, and appears to be sudden in onset and is a very serious complication. Dose-related adverse reactions appear to be related to acetylator phenotype in some studies.

Though fatalities have been described, withdrawal of treatment in cases of early neutropenia leads to restoration of the white-cell count to normal.

A rise in mean corpuscular volume is frequently seen during therapy, although true macrocytosis is less common, and macrocytic anaemia is even more rare, and is usually associated with low red-cell folate levels. However, when macrocytic anaemia does arise, it responds to folate supplements and treatment may be continued.

Methotrexate

This drug is an antimetabolite that acts as a folic acid antagonist. Its specificity toward rapidly dividing cells accounts for its adverse effects on the bone marrow and the gastrointestinal mucosa. Reported blood dyscrasias include leucopenia and thrombocytopenia (2–5 per cent and 1–2 per cent of treated patients, respectively) (Mackinnon *et al*. 1985; Weinblatt 1985; Furst and Kremer 1988). Although bone marrow toxicity, including pancytopenia, usually has a benign outcome and toxicity may be overcome by dose adjustment or temporary discontinuation of the drug, several instances of sepsis and death have been reported. Factors that increase the risk of blood dyscrasias include renal insufficiency, folate deficiency, and coadministration with trimethoprim sulphamethoxazole.

Other, less likely, risk factors for haematological toxicity include concomitant use of non-steroidal anti-inflammatory drugs or probenecid, competition for protein binding, or hypoalbuminaemia. The concomitant use of sulphasalazine, which is also a folate antagonist, require great caution. These haematological adverse reactions are usually dose related.

The use of weekly or daily oral folic or folinic acid in avoiding the cytopenia is controversial. In a double-blind, placebo-controlled trial, daily supplementation of low-dose methotrexate with 1 mg of folic acid significantly reduced the toxic manifestations without altering the efficacy (Morgan *et al*. 1990). The effect of weekly folic or folinic acid may simply be to correct subclinical folate deficiency, which has been shown to be associated with a higher incidence of severity of toxicity. Furthermore, if haematological toxicity is suspected, folinic acid should be given within 24 to 48 h of the methotrexate dose. However, the optimum dosing interval for the combination of folic acid and methotrexate has still not been determined.

Isolated case reports linking low-dose methotrexate therapy in rheumatoid arthritis and the development of cancer have been published over the last few years. Malignancies described include lymphoma, acute leukaemia, adenocarcinoma of the lung, and bladder cancer. Although still anecdotal, patients should be carefully followed for the possibility of the development of a malignancy.

Azathioprine

The main haematological side-effect of azathioprine is marrow suppression. Leucopenia (11–15 per cent) is more common than thrombocytopenia or anaemia, though pancytopenia may occur (Huskisson 1984; Singh *et al*. 1989). Leucopenia is generally mild and reversible. Haematological side-effects of azathioprine are dose dependent. When the usual dosage is given, the interval before maximal bone marrow suppression is about 2 weeks. If rapid agranulocytosis occurs, it is possibly an idiosyncratic reaction. Severe leucopenia may lead to serious infections. Thrombocytopenia rarely occurs without leucopenia.

Other haematological changes include macrocytosis and pure red-cell aplasia. When erythroid toxicity occurs, megaloblastoid changes are not related to the serum folate or vitamin B_{12} concentrations (McGrath *et al*. 1975).

The issue of azathioprine-related lymphoproliferative malignancies has been dealt with elsewhere in this chapter.

1.3.9 An anaesthetic perspective

Allan I. Binder and Frances Dormon

Introduction

Rheumatic diseases have important implications in anaesthetic practice (Binder and Isenberg 1989; Skues and Welchew 1993). Arthritis affecting the cervical spine, temporomandibular and cricoarytenoid joints, and involvement of the mouth, lips, nasopharynx, and oesophagus may result in increased risk and difficulty during intubation, maintenance, and the recovery from general anaesthesia. Constitutional illness, anaemia, and the involvement of specific organs are common and may complicate anaesthetic management. Medication, in particular systemic steroids, may also be important. The sedentary life-style of many patients with rheumatic disease accelerates atherosclerotic vascular disease and increases the risk of infection postoperatively.

This chapter will concentrate on the problems from the anaesthetist's point of view, so the rheumatologist can help by emphasizing the problems of an individual patient in relation to the particular procedure. We include discussion of alternatives to general anaesthesia, such as regional and local blocks, with their relative advantages and disadvantages. Newer techniques to increase the safety of intubation, including fibreoptic laryngoscopy and 'minitracheotomy' devices that can be used with jet ventilators, and anaesthetic drugs with specific advantages are mentioned. Finally, the role of the pain clinic, usually run by anaesthetists, is examined.

Systemic factors in rheumatic disease and their relevance to routine preanaesthetic assessment and anaesthesia

Autoimmune diseases such as systemic lupus erythematosus, juvenile chronic arthritis, scleroderma, and rheumatoid arthritis are multisystem diseases. As the emphasis of clinical features varies greatly from patient to patient, with many patients showing features of more than one autoimmune disease, preanaesthetic investigation needs to be tailored specifically to the individual patient. In some circumstances, such as the pregnant patient with systemic lupus erythematosus, the anaesthetist needs to consider the risks of anaesthesia to both the mother and fetus (Davies 1991). In order that the possible dangers of anaesthesia in patients with autoimmune disease may be anticipated and hence reduced, consideration will be given to the impact of the disease on major organs, with appropriate preanaesthetic investigation.

Cardiac disease

Patients with systemic lupus erythematosus, even if drug-induced (Goldberg *et al*. 1980), juvenile chronic arthritis (Goldenberg *et al*. 1992), scleroderma, and sometimes other autoimmune diseases can have serious cardiovascular pathology. The presence of valvular vegetations is associated with anticardiolipin antibodies (Leung *et al*. 1990; Metz *et al*. 1994) but also occurs in lupus patients without these antibodies (Gleason *et al*. 1993). Many other patients with autoimmune disease have subclinical cardiac abnormalities (Giunta *et al*. 1993; Corrao *et al*. 1995) which are unlikely to affect anaesthetic management, provided that the procedure is uncomplicated. However, they can prove important if the anaesthetist experiences difficulties with intubation and the delay leads to inadvertent hypoxia. For this reason, careful preoperative evaluation of the cardiovascular system should always be carried out.

Clinical assessment, electrocardiography, and chest radiographs will exclude major cardiac disease. Echocardiography and echo-Doppler cardiography (Cujec *et al*. 1991; Giunta *et al*. 1993) provide non-invasive methods to define the presence and severity of cardiac lesions, and so avoid unexpected difficulty during anaesthesia. If abnormalities are found, further investigation of cardiac reserve may be required. With a significant conduction defect, as occurs in some patients with spondylarthropathies (Tucker *et al*. 1982), the preoperative insertion of a temporary pacing wire is advisable or, as a minimum requirement, facilities should be available for pacing during surgery. Patients with reduced cardiac reserve need more detailed monitoring of their central venous pressure, arterial pressure, and sometimes cardiac output. In all cases, the cardiac status should be improved as far as possible preoperatively.

In patients with cardiac disease, general anaesthesia is often preferable. The modern technique of 'balanced anaesthesia' (Bailey and Stanley 1994) depends on the use of several drugs for induction. The smaller dose of each drug in the combination is associated with fewer undesirable side-effects. However, particular care still needs to be taken with the dosage of drugs during induction and reversal of anaesthesia. If the patient awakes too rapidly or has excessive pain, an endogenous surge of adrenaline may occur, which can destabilize the cardiac status.

If general anaesthesia is considered undesirable, local anaesthetic techniques can be considered. Limiting factors are the ability of patients to lie still for sufficiently long and the positioning required by the surgeon (Skues and Welchew 1993). A spinal block can cause a precipitous fall in the blood pressure in the compromised patient (Malmqvist *et al*. 1987). Although ephedrine and fluid will reverse this fall, the cardiac status may be too critical for these to be used. For these reasons, epidural blockade which develops more slowly, is safer.

Patients with suspected valvular abnormality, septal defect, or patent ductus arteriosus should be prescribed antibiotic prophylaxis (White 1985). The antibiotic should be started 1 h preoperatively if the oral or intramuscular route is used, or just before intubation if given intravenously.

Respiratory disease

Pulmonary disease may be of several types. Pulmonary fibrosis is the most characteristic and important for anaesthesia as it causes a progressive reduction in lung compliance and vital capacity. Impairment of gas transfer can lead to pulmonary hypertension (Winslow *et al*. 1995) and respiratory failure.

In systemic lupus erythematosus, pleuropulmonary complications are common and often severe, especially when associated with vascular abnormalities as a result of antiphospholipid antibodies (Asherson and Cervera 1995). Scleroderma also frequently has respiratory complications, resulting in complex abnormalities which

include a restrictive ventilatory defect, airflow obstruction, and a reduced diffusing capacity for carbon monoxide. Pulmonary vascular disease and restriction of chest expansion may also coexist, increasing the risk of respiratory failure and pulmonary hypertension (Arroliga *et al*. 1992). The severity of lung involvement in scleroderma does not always correlate with the extent of extrapulmonary disease (Tashkin *et al*. 1994), and can dominate the clinical picture.

Ankylosis of the thoracic spine and involvement of costovertebral joints typical of ankylosing spondylitis, as well as the seronegative spondylarthropathies, can seriously impair chest expansion. These patients usually maintain adequate ventilation, unless other factors such as bronchitis, pneumonia, or pneumothorax intervene (Radford *et al*. 1977).

Reduction in chest expansion can also be found in some patients with severe kyphosis due to advanced osteoporotic collapse of thoracic vertebrae or weakness of the respiratory muscle as a result of dermatomyositis (Schwarz 1992). In dermatomyositis, general anaesthesia is preferable, as respiration can be controlled with greater certainty by mechanical ventilation. After anaesthesia, pulmonary reserves may decline in all the above types of patients, leading to respiratory failure.

Preoperative assessment should identify significant respiratory disease. As a general rule, the ability to climb two flights of stairs without undue breathlessness suggests adequate respiratory reserve for general anaesthesia. If a problem is suspected, pulmonary function tests and baseline blood–gas analyses are necessary. The function tests should include transfer factor and a vitalograph, so the severity of restrictive and obstructive components of lung disease can be defined, and reversible elements treated. The baseline blood–gas analyses are especially helpful if respiratory failure develops in the postoperative period, where the preoperative carbon dioxide can indicate the level at which weaning off the ventilator can be attempted.

The choice of anaesthetic technique usually depends upon the surgical requirements, with some consideration to the likely postoperative course. For major thoracic and abdominal surgery, the postoperative period can be complicated by respiratory insufficiency, owing to pain and the residual effect of the anaesthetic (Catley *et al*. 1985). Regional techniques are often preferred to general anaesthesia in patients with serious respiratory disease, although long operations and the supine position may be particularly unpleasant for breathless and disabled patients. If sedation is added to a regional technique, great care is necessary to avoid oversedation and dangerous respiratory depression. A good method of analgesia is just as important following regional as general anaesthesia, as respiratory failure is as likely with either technique if pain control is inadequate.

Renal disease

Serious renal failure is a common finding in patients with systemic lupus erythematosus, but can occur in scleroderma and other autoimmune diseases. Subclinical renal dysfunction can also occur in lupus (Cottiero *et al*. 1995), rheumatoid (Pedersen *et al*. 1995), and other connective tissue diseases, and can be exacerbated by non-steroidal anti-inflammatory drugs (Segasothy *et al*. 1995), amyloidosis, or unrelated causes.

A mild reduction in renal function is not a problem to the anaesthetist, but if present should be noted so as to avoid prolonged perioperative fluid restriction. A drip will maintain hydration but fluid overload should be avoided if the patient also has cardiac disease.

With more serious renal failure, creatinine clearance and isotopic renograms (O'Malley and Ziessman 1993) help define the severity of the renal disease and residual reserve of renal function, although neither is accurate in advanced disease. In these patients, expert nephrological advice should be sought.

Monitoring of the central venous pressure is usually needed to help maintain the fluid balance in patients with renal disease, especially during and after major surgery, where there are large shifts of fluid complicating the fluid balance. Whichever technique of anaesthesia is used in patients with autoimmune diseases, the plasma concentration of anaesthetic drugs may be affected by the degree to which they are protein-bound (Wood 1986) or by the presence of renal dysfunction.

Haemopoietic disease

Anaemia is a common feature of rheumatic diseases and can result from many varied causes. The 'anaemia of chronic disease', typical of inflammatory diseases such as rheumatoid arthritis, results from ineffective erythropoiesis (Vreugdenhil *et al*. 1990), and rarely drops the haemoglobin to below 9 g/100 ml. Ideally, anaemia should be assessed, and where possible treated, before elective surgery. A haemoglobin of 10 g/100 ml is considered adequate for general anaesthesia, although lower levels are acceptable for simple surgical procedures which are unlikely to cause appreciable blood loss, provided the anaemia is chronic and physiological adaptation has been achieved. Preoperative oximetry is very helpful in the assessment of anaemic patients as it demonstrates the presence of desaturation without cyanosis.

If preoperative transfusion is necessary, it should be completed at least 24 h before surgery to allow the transfused red cells to replenish the levels of 2,3-diphosphoglycerate and function in oxygen transfer. If a delay in surgery is not possible, the transfusion should be delayed until the time of the surgery, to avoid inadvertent fluid overload developing preoperatively.

Complex haematological abnormalities can develop as a result of systemic lupus erythematosus, Felty's syndrome, and occasionally other rheumatic diseases. The drugs used in treatment can also cause abnormalities. Full haematological assessment in these patients should include white blood count, platelet count, and a coagulation screen. Anticardiolipin antibodies and cryoglobulins should also be measured in some cases. Anticardiolipin antibodies increase the risk of intravascular coagulation during surgery (Menon and Allt-Graham 1993) and paradoxically also occasionally cause excessive bleeding, especially when hypoprothrombinaemia and/or thrombocytopenia are also present (Shaulian *et al*. 1981). In these patients, fresh frozen plasma and platelet packs should be available for the surgery. Expert haematological advice should be sought if complex abnormalities are found.

Low white-cell counts as a result of systemic lupus, Felty's syndrome, or some rheumatic drugs increase the risks of postoperative sepsis, and decrease the white cell response and hence identification of infection. Prophylactic antibiotics should be prescribed in susceptible patients.

Prophylaxis against deep venous thrombosis is increasingly important, especially in patients undergoing elective surgery for total hip and knee arthroplasty (Lieberman and Geerts 1994) and other conditions with a high risk of venous thrombosis and pulmonary embolism (White 1985). Adjusted-dose heparin, low-dose warfarin, or the low molecular weight heparins all significantly reduce the risks of thromboembolism following hip arthroplasty. Although less thoroughly assessed, low-dose warfarin, the low molecular weight heparins, and pneumatic compression boots have similar value in the prevention of thromboembolism after knee arthroplasty. The optimum duration of thromboembolic prophylaxis has yet to be determined, with recommendations varying from discontinuing therapy when the patient begins to mobilize, to maintenance for as long as 3 months after the arthroplasty. This issue is especially relevant in view of the current trends toward earlier discharge from hospital and the concern about thromboembolic events following discharge (Trowbridge *et al*. 1994).

Gastrointestinal disease

Oesophageal fibrosis and hypomotility are common in scleroderma and, even when not clinically apparent, markedly increase the risk of reflux of gastric contents after anaesthesia (Orringer *et al*. 1976; Smith and Shribman 1984). Extubation should be delayed in these cases until the patient is able to maintain an independent airway. Positioning and careful observation should be continued well into the postoperative period to avoid aspiration and identify cricoarytenoid inflammation (Funk and Raymon 1975), both of which could result in respiratory embarrassment after extubation.

Skin and joints

Particular care is necessary in the handling, positioning, and movement of patients with generalized arthropathy who undergo surgery. Corticosteroid therapy and rheumatoid nodules increase the risks of pressure-induced skin damage. Unusual parts of the body may become weight bearing during surgery and will require additional padding and support. All patients with significant arthritis should be sent to theatre wearing a soft collar, as this serves to remind the anaesthetist and other theatre staff to avoid excessive movement of the neck and to handle the patient with extreme care. Dry eyes need to be protected with regular methylcellulose eyedrops during surgery. The application of petroleum jelly to the lips and nose will provide similar protection to oral and nasal mucosa.

Antirheumatic drugs

Prolonged corticosteroid therapy is associated with osteoporosis, deficient wound healing, reduced resistance to infection, and accelerated atherosclerosis. However,

the suppressive effect on the hypothalamic–pituitary–adrenal axis is the most important complication to the anaesthetist, as it can persist for up to a year after corticosteroid therapy has ended. The levels of cortisol do not show whether the axis has recovered and other functional tests of the axis are complicated and unreliable. Steroid cover should therefore be given to these patients. Intravenous hydrocortisone is started with surgery, the doses being tapered over the next 2 to 4 days and returned to the maintenance levels within a week. For major surgery, 200 mg of intravenous hydrocortisone is given with anaesthetic induction. The dosage of hydrocortisone infused is then reduced by 25 per cent each day untill the maintenance dose is reached. For lesser procedures, half the initial dose, that is 100 mg of hydrocortisone, is adequate (Roizen 1994). The trend is to shorten the period of steroid cover, because of its adverse effect on wound healing and increased risk of infection (White 1985).

The anaesthetist must minimize the risks of infection by maintaining scrupulous cleanliness of all equipment used. Bacterial filters should be incorporated into the breathing circuits to reduce the risk of pulmonary infection. Preoperative dental hygiene is particularly important in scleroderma and Sjögren's syndrome and prophylactic antibiotics are sometimes needed.

Azathioprine, methotrexate, and other immunosuppressive drugs are also associated with an increased risk of infection and similar precautions to those for steroids should be adopted. A reduction in the white blood count and platelet counts, and possible adverse effects on wound healing, may also be associated with immunosuppressive drugs. Bridges *et al*. suggested some reduction in early infection rates if methotrexate was stopped 4 weeks before elective orthopaedic surgery, but Kasdan and June and Sany *et al*. failed to confirm this, and advocated continuation of methotrexate through the surgical period, until larger prospective studies have clarified the relative infection risks of continuing immunosuppression (Bridges *et al*. 1991; Kasdan and June 1993; Sany *et al*. 1993).

Emergency work-up for anaesthesia

Ideally there should be plenty of time for a full anaesthetic work-up to assess potential risks in patients with rheumatological disease (Binder and Isenberg 1989; Skues and Welchew 1993) and this has been considered above. However, these patients often require emergency surgery, precluding an ideal work-up. Under these circumstances, general assessment of mouth opening, neck movement, and laryngeal function at the bedside may help predict a difficult intubation. Two simple tests which may be helpful in predicting a difficult direct laryngoscopy are:

1. an inability to visualize the soft palate or uvula when the mouth is opened as widely as possible and the tongue is protruded (Mallampati *et al*. 1985);
2. an inability of the patient to protrude the lower teeth beyond the upper incisors suggesting reduced temporomandibular joint movement (Calder 1992).

If the patient has serious peripheral arthritis, instability of the cervical spine can be assumed and radiological assessment of the neck should be made. If there is serious concern about the neck, awake intubation (Sinclair and Mason 1984), especially via a fibreoptic laryngoscope (Sidhu *et al*. 1993), should also be considered. A soft collar to protect the vulnerable neck and careful handling have been mentioned earlier.

To avoid serious danger to the patients, the anaesthetist must be alerted to the presence and severity of systemic ill-health, anaemia, and the cardiac, respiratory, and renal complications of their rheumatic disease. Details of drug therapy such as corticosteroids and immunosuppressive agents should also be provided. All these factors may influence the approach to anaesthesia and the choice and dosage of anaesthetic agents.

Intubation difficulties

Rheumatoid arthritis

Rheumatoid arthritis is by far the most common autoimmune rheumatic disease presenting to the anaesthetist. The advent of joint replacement has markedly increased planned surgical intervention, even in patients with advanced disease. Emergency operations are also frequently needed, especially for upper gastrointestinal bleeding induced by non-steroidal anti-inflammatory drugs. Rheumatoid arthritis can affect any synovial joint and often affects the cervical spine (Crosby and Lui 1990), temporomandibular (Ericson and Lundberg 1967; Redlund-Johnell 1988), and cricoarytenoid joints (Funk and Raymon 1975; Lawry *et al*. 1984).

Adequate extension at the cervical spine is important for direct laryngoscopy and endotracheal intubation, and can be compromized by rheumatoid neck involvement. Cervical subluxation, which usually occurs at the atlantoaxial joint, can affect any level. While subluxation can cause cervical myelopathy or radiculopathy, it is often asymptomatic. Atlantoaxial subluxation usually occurs anteriorly but can also occur posteriorly, as a result of odontoid peg erosion (Castro *et al*. 1994). Progressive subaxial cervical subluxation affecting multiple levels, the so-called 'stair-case spine', typically occurs in seropositive rheumatoid patients with severe deforming peripheral arthropathy (Yonezawa *et al*. 1995). With progressive cervical disease, the neck becomes short and rigid, with superior migration of the dens, further complicating intubation. While neurological changes in rheumatoid patients usually results from subluxation, soft-tissue pannus formation can contribute to spinal cord compression (Castro *et al*. 1994). Temporomandibular joint involvement which limits mouth opening can also complicate direct laryngoscopy and intubation (Aiello and Metcalf 1992).

A hoarse voice, a sense of fullness in the throat, dysphagia, exertional dyspnoea, and rarely stridor may indicate disease of the cricoarytenoid joints which, if suspected, may require further investigation. Indirect laryngoscopy or fibreoptic examination of the cords may reveal rheumatoid nodules on the cords (Bridger *et al*. 1980) or cricoarytenoid joint involvement, with decreased cricoarytenoid movement, bowing of the cords during inspiration, fixed adduction of the cords, or glottic stenosis. In extreme cases, these findings indicate the need for elective tracheostomy or consideration of alternative methods of anaesthesia. The presence of such findings necessitates particular vigilance for signs of postextubation airway obstruction (Funk and Raymon 1975).

The anaesthetic work-up should identify potential problems with the airway and those patients likely to present difficulties during intubation (Macarthur and Kleiman 1993), although this assessment is notoriously unreliable (Wilson 1993). Bedside examination of neck and jaw movement, as described above, should be routinely carried out on all patients. Even under ideal circumstances, unexpected problems may arise (Keenan *et al*. 1983) and the anaesthetist needs to anticipate the possibility of a failed intubation.

In rheumatoid arthritis, radiographs of the cervical spine in flexion/extension with a through-mouth view of the odontoid peg are helpful in defining the presence and severity of any spinal instability, although the routine use of this investigation in all asymptomatic rheumatoid arthritis patients has been questioned (Campbell *et al*. 1995). Magnetic resonance imaging (**MRI**) (Castro *et al*. 1994; Yonezawa *et al*. 1995) is the investigation of choice in defining the presence and severity of subluxation and soft-tissue pannus affecting the cervical spine (Fig. 1).

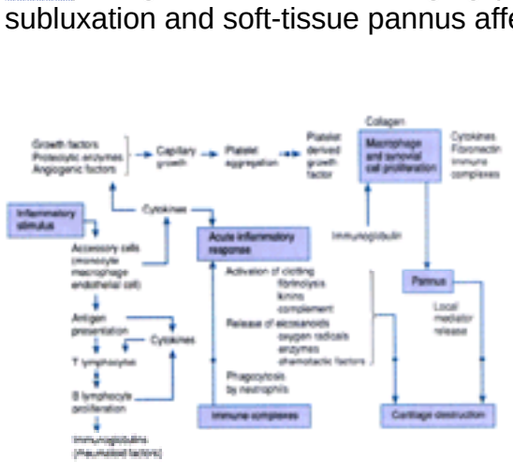

Fig. 1 Magnetic resonance scan of a rheumatoid patient showing atlantoaxial subluxation and compression of the spinal cord.

Having made a full assessment, the anaesthetist will choose to anaesthetize the patient in one of the ways listed in Table 1. The choice of anaesthetic approach is

often based on individual preference and, with some of the techniques, the level of individual expertise (Vaughan 1991).

No relaxant needed
Intravenous induction
Inhalational induction: with/without Guedel airway with/without laryngeal mask airway
Relaxant needed
Intravenous induction: delay relaxant until positive-pressure ventilation (PPV) is established with mask; intubate under (i) direct vision, or (ii) with introducer, or (iii) blind oral/nasal, or (iv) with a fibreoptic 'scope
Inhalational induction: delay relaxant until PPV established with mask intubate as for intravenous induction
Awake intubation: using fibreoptic laryngoscope
Awake insertion of 'minitracheotomy': ventilate with jet ventilator through minitracheotomy for induction and intubation
Elective tracheostomy in the awake patient

Table 1 Methods of airway maintenance during anaesthetic induction

Juvenile chronic arthritis

Juvenile chronic arthritis, particularly of polyarticular or systemic onset, often results in serious and early involvement of the cervical spine (Hensinger *et al*. 1986). In addition to instability, growth abnormalities of the vertebral bodies, bony fusions, and sometimes torticollis add to the intubational difficulties. Development of the temporomandibular joint is similarly affected, with micrognathia and reduced mouth opening giving clues to the severity of temporomandibular involvement (Stabrun *et al*. 1988). MRI scanning of the temporomandibular joints is also valuable in their assessment (Taylor *et al*. 1993). Serious disease of the cricoarytenoid joints can also occur (Jacobs and Hui 1977).

The younger patient (below the age of 14 years) with potential for a difficult intubation presents the anaesthetist with a far greater problem (Smith 1990). There are fewer anaesthetic options in the small child because techniques such as awake intubation are unsuitable and venous access may be difficult to achieve before induction of anaesthesia. The anatomy of the child is different from the adult, making visualization of the larynx more difficult. Sizes of the tracheal tube need to be scaled down according to age, and adult equipment cannot be used, increasing the hazards for anaesthetists unfamiliar with young patients. The physiological differences include a reduced respiratory reserve which leads to more rapid onset of cyanosis if there is a delay in intubation or difficulty in maintaining the airway.

For all these reasons, very young children with significant arthritis should be treated in specialist paediatric centres where expertise with difficult intubation techniques is greater. However, the options listed in Table 1 still generally apply. The laryngeal mask (see Techniques for difficult intubation below), can be used in all age groups and there is a paediatric version of the 'minitracheotomy' for awake intubation or airways maintenance during induction and intubation in children aged 6 years or older. Furthermore, intubation can be achieved using a smaller fibreoptic laryngoscope or a guide wire technique with the adult fibreoptic laryngoscope.

For certain procedures where intubation is unnecessary, ketamine can be used for anaesthesia (D'Arcy *et al*. 1976). This drug usually results in the maintenance of adequate respiration and a clear airway. However, it does not guarantee a safe airway and should not be used unless full intubation facilities and equipment for emergency tracheostomy are available. Ketamine is also unsuitable for older children, who are more liable to suffer from troublesome hallucinations during the recovery phase.

Ankylosing spondylitis and seronegative spondylarthropathies

Significant ankylosis of the cervical spine is common in ankylosing spondylitis, and can occur in psoriatic arthritis (Salvarani *et al*. 1992) and any of the seronegative spondylarthropathies (Dekker-Saeys *et al*. 1978; Olivieri 1988). Disease of the cricoarytenoid joints can also be present. Ankylosis is rarely missed during the preanaesthetic assessment in patients with severe involvement, although these patients often generate more anxiety than is warranted. While difficult to intubate because of the rigidity of the neck, the airway is easy to maintain without intubation or manipulation. The laryngeal mask airway (Brain 1983) is easy to insert and, provided that the intercostal joints are not severely ankylosed, it is possible to ventilate the patients with the mask. If intubation is considered essential, it should be achieved with minimal manipulation in the awake patient (Sinclair and Mason 1984) or using a 'blind' technique. Care must be taken in these patients as atlantoaxial subluxation or vertebral fracture can occur from relatively minor trauma (Murray and Persellin 1981; Suarez-Almazor and Russell 1988).

Sjögren's syndrome and scleroderma

These conditions, alone or in conjunction with other autoimmune states, can cause problems with intubation because of their specific effects on the mouth and nose.

In Sjögren's syndrome, xerostomia may result in poor mouth opening, and dryness and friability of the oral and nasal mucosa, making it difficult to insert the laryngoscope. The poor dental state may also result in loose teeth, which could dislodge during intubation, or single-standing teeth, which could impede laryngoscopy.

In scleroderma, the reduced mouth opening can be even more severe and further complicate an intubation made potentially difficult by abnormalities of cervical and mandibular joints. Poor dental hygiene is almost invariable in patients with severe scleroderma and patients need to be warned that if teeth are electively removed for anaesthesia, dentures may be impossible to fit. Whether the oral or nasal route is used for intubation, severe lacerations or bleeding from telangectasia may follow (Davidson-Lamb and Finlayson 1977).

Pulmonary fibrosis is commonly found in patients with scleroderma, Sjögren's syndrome, and other autoimmune diseases and progressive reduction in lung compliance and vital capacity can also result from sclerodermatous involvement of the chest wall.

Venous access is often a problem in scleroderma, limiting the choice for induction of anaesthesia (Smith and Shribman 1984). Vasospastic abnormalities are also common and vasodilatation must be anticipated after induction of anaesthesia (Eisele 1990), with plasma expanders or blood being available to maintain the blood pressure after induction. Infused fluids must be warmed to prevent vasospastic irritability in these patients. Intravenous induction may provoke a painful cyanotic reaction, similar to that experienced by patients with Raynaud's phenomenon (Davidson-Lamb and Finlayson 1977). Intra-arterial cannulation should be avoided, as gangrene of the limb can result from thrombosis. The maintenance of the ambient temperature in theatre and throughout the postoperative period is another important consideration in these patients.

If local anaesthetic techniques are to be used, vasoconstrictors should be avoided, as the blood supply may be further compromized (Eisele 1990). Regional anaesthesia can also result in prolonged but reversible sensory blockade, which is useful as analgesia, but can be associated with prolonged vasospastic change (Neill 1980; Smith and Shribman 1984).

Techniques for difficult intubation

Table 1 lists the range of techniques available to the anaesthetist. Not all patients require intubation, particularly for short procedures on the limbs, and local anaesthetic techniques may be more suitable in these cases. Repeated attempts at endotracheal intubation can increase the risk of neurological damage (Hastings and Kelley 1993) and incidence of airway obstruction due to glottic trauma in the postoperative period.

Induction of general anaesthesia can be achieved smoothly with an intravenous or inhalational agent. If the airway is difficult to maintain, an oral or nasal airway may help. The laryngeal mask airway (Brain 1983; Calder *et al*. 1990) passed orally, fits snugly over the larynx (Fig. 2), and is of proven value in the safer management of anaesthesia in arthritic patients. However, the laryngeal mask airway does not protect the airway from soiling by gastric contents and is therefore not a replacement for intubation in all cases. Intubation is essential if the surgery requires muscle relaxation, the operation is longer, the patient needs to lie prone, or there is pulmonary

disease.

Fig. 2 (a) Laryngeal mask airway. (b) Diagram of a laryngeal mask airway in place.

Despite careful assessment, it is not always possible to predict what will happen to the airway after induction (Wilson 1993). Sometimes, even with mild disease, the airway becomes obstructed soon after induction and the use of airway devices does not help. On other occasions, despite apparently adequate mouth opening preoperatively, problems arise after induction. Therefore, with all these patients, induction of anaesthesia is undertaken slowly, allowing repeated reassessment of the adequacy of the airway. Inhalational anaesthesia is the safer option in these cases, as induction can be halted if the patient obstructs. After induction, and before any muscle relaxants are given, the anaesthetist must ensure that it is possible to ventilate the patient manually with a bag, mask, and airway. Provided this is possible, there is then enough time to try the several available techniques. If laryngoscopy is only moderately difficult and a grade 3 view of the larynx is obtained (Cormack and Lehane 1984) (Fig. 3), it is possible to intubate directly or by use of a soft bougie as an introducer over which the tracheal tube is passed. If this proves impossible, some anaesthetists are sufficiently experienced with blind-nasal intubation. The use of a small, fibreoptic intubating laryngoscope (Fig. 4) has radically altered the management of rheumatoid patients with cervical spine disease (King and Adams 1990), and may also reduce the risk of life-threatening postoperative complications, especially in patients undergoing posterior cervical spine surgery (Wattenmaker *et al* 1994). Several other methods of intubation have been described. A 'minitracheotomy' (Matthews *et al*. 1986) can be made and a catheter passed through the larynx from below. This can then be used as a guide through the oral route. The laryngeal mask airway can also be used as a guide, either for the blind passage of a soft-bougie introducer or to guide the fibreoptic intubating laryngoscope towards the larynx. Once the larynx has been identified, a tracheal tube can be 'railroaded' over the laryngoscope.

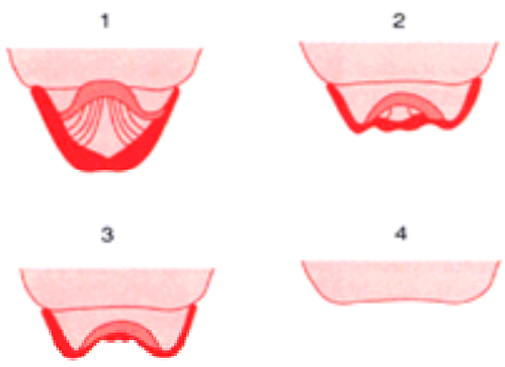

Fig. 3 Diagrammatic classification of the four grades of view of the larynx obtained at laryngoscopy in a difficult intubation: grade 1, most of the glottis visible; grade 2, only epiglottis and posterior commissure seen; grade 3, only epiglottis seen; grade 4, not even the epiglottis can be exposed.

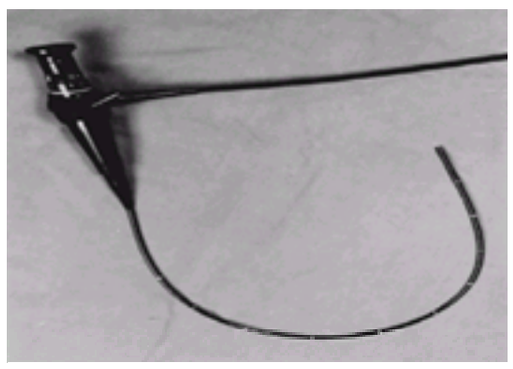

Fig. 4 Fibreoptic intubating laryngoscope.

If intubation is considered too hazardous following induction of anaesthesia, the patient should be intubated before induction, that is 'awake' (Sinclair and Mason 1984; Sidhu *et al*. 1993). This technique can be learnt with relative ease but should not be attempted unless the operator is familiar with the fibreoptic intubating laryngoscope in normal patients (Vaughan 1991).

Preoperative explanation of the procedure will reassure the patient and anticholinergic premedication can help by reducing secretions. Anxiolytic agents should be used with care because respiratory depression may occur or the airway may become obstructed. Several methods have been described to achieve analgesia of the pharynx and upper trachea but care must be taken to avoid toxicity if a 4 per cent lignocaine spray is used.

A 'minitracheotomy' device inserted under local anaesthesia can be used with a jet ventilator to ensure adequate ventilation (Matthews *et al*. 1986) but should only be used by those familiar with the jet, because a failure to maintain a clear airway for expiration through the larynx would result in pneumothorax.

Finally, if intubation is considered impossible by any other route, and surgery can only be carried out under general anaesthesia, an elective tracheostomy should be performed under local anaesthesia. New kits are now available for percutaneous dilational tracheostomy, which is quicker to perform with no increase in the complication rate (Bodenham 1993)

Postoperative care

Immediately following extubation prolonged observation is necessary to ensure that airway obstruction does not develop, especially in patients with serious cricoarytenoid (Funk and Raymon 1975), temporomandibular, or cervical spine pathology. In some cases, postoperative ventilation may be necessary for 24 to 48 h, to ensure adequacy of the airway and oxygenation. Aspiration of gastric contents, which can lead to respiratory embarrassment, is a particular risk in scleroderma patients where gastro-oesophageal reflux is common (Orringer *et al*. 1976; Smith and Shribman 1984).

The main challenge facing the anaesthetist immediately following major surgery is the provision of effective analgesia without respiratory depression. Ventilatory insufficiency in the postoperative period can be precipitated by a number of causes such as restrictive lung disease, infection, obesity, diaphragmatic splinting due to

pain, and the residual effect of the anaesthetic (Catley *et al*. 1985) superimposed on pre-existing borderline respiratory function. If the carbon dioxide is significantly raised preoperatively, then postoperative ventilation is usually necessary, although weaning off the ventilator should be attempted with a higher carbon dioxide than normal.

Early and regular chest physiotherapy, bronchodilators, and antibiotics are important in postoperative management. If the retention of sputum becomes a problem, a 'minitracheotomy' (Matthews *et al*. 1986) should be inserted to assist in the removal of secretions before the patient tires and develops respiratory failure.

Adjuvant epidural analgesia, cryotherapy to the intercostal nerves during thoracotomy, or patient-controlled intravenous opioid analgesia are all methods that optimize postoperative pain control and hence reduce the risk of respiratory failure. Patient-controlled analgesia systems may not be appropriate in rheumatoid patients with severe hand involvement (Jani and Trujillo 1994) and catheter techniques of regional blockade using local anaesthetic agents (see below) may be more effective.

Opioid drugs need to be used with particular caution in rheumatoid patients as obstructive sleep apnoea (Mahowald *et al*. 1989) may occur, especially in patients with temporomandibular joint involvement (Redlund-Johnell 1988). Non-steroid anti-inflammatory drugs given by the suppository, intramuscular, or buccal routes have particular value in postoperative pain control, by limiting the need for opioids which often cause vomiting and respiratory depression.

After major abdominal or thoracic surgery there are large shifts of fluid into the interstitium, thoracic cavity, and bowel, complicating the fluid balance. The high incidence of renal and cardiac abnormalities may result in early cardiac or renal failure with only minor variations in fluid balance and therefore continuous monitoring of the central venous pressure may need to be extended well into the recovery period.

Careful positioning with additional padding and support to weight bearing parts of the body should be maintained, with pressure relieving mattresses used soon after surgery if indicated. However, passive exercises and mobilization also need to be started as early as possible to help prevent joint contracture, pressure sores, and other postoperative complications which are common in severely disabled patients. Rheumatoid therapy should also be reinstituted as soon as feasible and prophylaxis to prevent deep vein thrombosis, infection, and peptic ulceration should be continued in appropriate cases.

Alternatives to general anaesthesia

Local anaesthetic techniques, often combined with sedation, have gained increasing popularity in recent years. Improvement in education of the general public has contributed more to the increased usage than the introduction of new drugs or techniques. There are numerous techniques (Table 2) ranging in complexity from simple infiltration to blockade at the spinal level (Wildsmith and Armitage 1993).

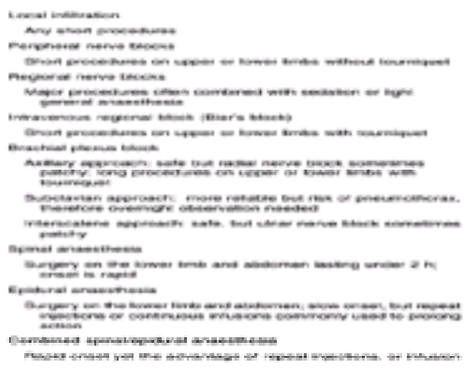

Table 2 Alternatives to general anaesthesia

Local infiltration

Careful explanation, with or without anxiolytic premedication, is all that is required before local infiltration. The appropriate use of sedative drugs enables fairly complex operations to be undertaken. The combination of 1 to 2 mg of midazolam and 10 to 30 mg of propofol (see Table 3) provides sedation and amnesia with relative safety. Full monitoring and anaesthetic facilities should however be available, because of the rare (1–2 per cent) occurrence of respiratory depression in especially sensitive patients.

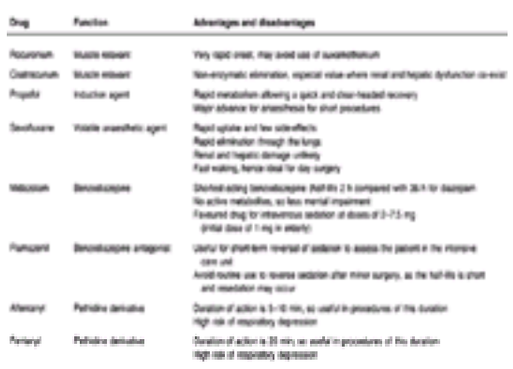

Table 3 Newer drugs of value in anaesthesia

Peripheral nerve blocks

These techniques are suitable for many surgical procedures on the limbs, especially where a tourniquet is unnecessary. Several texts list the individual blocks (Wildsmith and Armitage 1993).

Regional nerve blocks

These are useful for many major procedures, sometimes in combination with sedation or even light general anaesthesia without intubation.

Intravenous regional anaesthesia (Bier's block)

This form of anaesthesia is safe, simple, and useful for a wide range of procedures, given the necessary expertise. The local anaesthetic is injected intravenously into an arm or leg that has been isolated from the general circulation by a tourniquet. Care is necessary to ensure that the cuff is not inadvertently deflated for at least 20 min to avoid risks associated with the release of a bolus of local anaesthetic. Furthermore, full resuscitation facilities should be available. This type of anaesthesia is suitable for operations lasting about 40 min, as tourniquet pain occurs after this time. However, a major advantage is that patients can be discharged within an hour of the procedure.

Brachial plexus blocks

The brachial plexus can be approached by three distinct routes, each having some advantages and disadvantages.

The axillary approach

The axillary approach is the safest and therefore the most commonly used route. However, the axillary block has the disadvantages that the success rate is variable and supplementary peripheral nerve blocks are often required. The block of the radial nerve is often patchy and, if a tourniquet is used, nerve blocks may be needed for the tourniquet area.

The subclavian approach

The subclavian approach is more reliable, particularly in the upper arm and tourniquet areas, but is associated with a greater risk of pneumothorax, making overnight observation in hospital desirable. A bilateral block should not be attempted because slow development of pneumothoraces may occur.

The interscalene approach

The interscalene approach is also reliable but the ulnar block may be patchy. It should be reserved for patients with emphysema or chronic obstructive airways disease, where the risk of pneumothorax is high, and for operations on the upper arm.

Spinal anaesthesia

Increased use of this form of anaesthesia has followed the introduction of narrow-gauge needles, which have reduced the incidence of spinal headache to under 5 per cent, and obviated the need for 24 h of bed-rest after the procedure. The block, which is established within 10 min, is more reliable and complete than an epidural block and lasts for up to 2 h. The time limit can be extended by the insertion of a fine-bore catheter for continuous spinal anaesthesia, although the introduction of the combined spinal/epidural technique has reduced the use of spinal catheters. This type of block should be used with great care in patients with poor myocardial reserve, as its rapid onset can lead to sudden hypotension due to peripheral vasodilatation (Malmqvist *et al*. 1987).

The use of a hyperbaric mixture of anaesthetic, such as bupivacaine in 4 per cent dextrose, allows the establishment of a unilateral block for surgery on one leg. For this type of block, the spinal needle is inserted with the patient lying on the side requiring surgery for at least 10 min while the block is established. The drop in blood pressure is far less with a unilateral block.

Epidural anaesthesia

This has gained wide usage even in the presence of extensive spinal disease. The wider-bore epidural needle allows a catheter to be inserted easily for continuous infusion. The block takes longer to establish and there is a small chance of 'unblocked' segments, where nerve roots are left unaffected by the anaesthetic. If the needle is advanced too far, the dura may be pierced producing a dural leak which can cause severe headache and very rarely complications such as arachnoiditis (Sklar *et al*. 1991) have been reported.

Combined spinal and epidural anaesthesia

Using a special needle pack, the epidural space is identified and a long spinal needle is used to pierce the dura and perform a spinal block. The spinal needle is then removed and a catheter inserted into the epidural space. This combined technique offers the advantages of a rapid onset spinal block with the facility to administer 'top-ups' or a continuous infusion for longer operations or to provide postoperative analgesia.

Newer drugs of value in anaesthesia

A few agents recently introduced into anaesthetic practice have improved the safety and efficiency of anaesthesia for patients with multisystem disease. These drugs are shown in Table 3 with their relative advantages and disadvantages.

The pain clinic

Pain clinics are being established in large numbers because of their value in the management of patients with intractable pain (Butler and Murphy 1989). Treatment is tailored to the individual need of each patient and includes physical and psychological measures to reduce pain, and, where this is impossible, to help patients to cope with their pain and modify their life-styles accordingly. Pain clinics are usually run by anaesthetists, assisted by a multidisciplinary team. Detailed evaluation of these clinics is outside the scope of this chapter but the major treatment options are shown in Table 4. Although a large variety of conditions are referred to pain clinics, chronic mechanical backache, neck and shoulder pain, and reflex sympathetic dystrophy are the most commonly referred by rheumatologists.

Multidisciplinary team	Anaesthetist, other physicians, social worker, physiotherapist, occupational therapist, psychologist
Drug therapy	Conventional analgesics, e.g. non-narcotic, analgesics
	Narcotic analgesics as a last resort
	Centrally-acting, pain-modifying drugs: tricyclic antidepressants, antiepileptic agents
Nerve blocks	Local, regional, spinal blocks
	Autonomic blocks: stellate ganglion, coeliac plexus and lumbar sympathectomy
	Facet joint injection or cryotherapy
Other	Guanethidine blocks
	Calcitonin injection therapy
	Clonidine injection
	Percutaneous cordotomy and other rare neurosurgical techniques

Table 4 The approach of a 'pain clinic' and its therapeutic modalities

Intractable back pain, having failed to respond to conventional treatment, may benefit from the approach of the pain clinic. Transcutaneous nerve stimulation, acupuncture, nerve blocks, epidural and facet-joint injections are some of the mechanical means of achieving pain control. Where the pain continues despite these measures, psychological assessment and treatment of depression may be valuable. Behaviour modification and other techniques to improve coping can also be taught.

Reflex sympathetic dystrophy (algodystrophy) is often intractable and when unresponsive to physiotherapy may benefit from guanethidine blocks, continuous epidural infusion, calcitonin injections, and chemical sympathectomy.

Patients with rheumatoid arthritis and inflammatory arthropathies at present form a very small proportion of referrals to pain clinics. However, there is increasing recognition of the value of pain specialists in the amelioration of pain from some sources. An example of this is the treatment of pain arising from the cervical spine, whether due to inflammatory or mechanical causes. Cervical epidural injection should be considered where the cervical spine pain is severe and unresponsive to physiotherapy but without any serious neurological abnormality. This treatment is particularly effective where muscle spasm and radicular pain are prominent features (Ferrante *et al*. 1993; Castagnera *et al* 1994). Suprascapular blocks for intractable shoulder pain, and local injection around the hip, can have similar value. Moreover, the multidisciplinary approach of the pain clinic may help in the management of pain and development of coping mechanisms in patients with generalized inflammatory arthropathies whose pain is inadequately controlled despite optimal medical and surgical treatment.

The true value of the pain clinics to rheumatology patients has not yet been fully explored. The marked improvement in postoperative pain control achieved by pain specialists over recent years suggests that there could be similar advances in the control of some types of pain in patients with inflammatory arthropathies.

Conclusions

This chapter has considered the systemic and joint abnormalities in patients with rheumatic disease from the perspective of the anaesthetist. The preanaesthetic assessment and techniques for general and regional anaesthesia have been described, with an insight into the difficulties often encountered and methods used for solving these problems. Finally, the role of the pain clinic has been considered.

Acknowledgement

The authors wish to thank Mr Alan Crockard for kindly providing the MRI of a rheumatoid neck, shown in Fig. 1.

1.3.10 The eye

Elizabeth M. Graham and Alison M. Leak

Introduction

The ophthalmologist has many roles in the management of patients with rheumatological problems. Most rheumatological diseases have ocular complications, many of which are specific to the disease, and consequently the ophthalmologist has an important diagnostic role. Many ophthalmic complications require specific therapy and in some cases may actually dictate the systemic therapy for the disease, giving the ophthalmologist a therapeutic role. Rheumatological diseases require a wide range of drugs and several of these have important ocular side-effects; the ophthalmologist therefore has a guardian's role in monitoring the eye and preventing complications.

Most rheumatological diseases affect either the uvea, sclera, retina, or optic nerve, and produce symptoms and signs that confirm both their nature and aetiology. Involvement of the uvea or sclera usually produces painful red eyes with preserved vision, whereas involvement of the retina or optic nerve causes profound visual loss without pain or redness. Fortunately, with the particular exception of juvenile chronic arthritis, most of the ocular complications that can affect the sight are symptomatic, so that the rheumatologist can at once alert the patient to the possibility of future eye disease and then await events.

The ocular examination

All patients referred to the ophthalmologist undergo the same routine examination, whether or not they are symptomatic. Visual function is assessed by testing visual acuity via a pinhole to obtain the effects of refractive error. The visual field is assessed using a red pin, as red is the most sensitive colour for elucidating disease of the optic nerve. Colour vision, changes in which may indicate early disease of the optic nerve or severe macular disease, is tested with Ishihara colour plates.

The eyes are examined in detail for evidence of redness or squint, and then with a slit lamp to observe any medial opacity (e.g. uveitis, cataract) and to measure the intraocular pressure. Pupillary reactions and eye movements are tested before the pupils are dilated for examination of the fundi.

Eye symptoms and signs

The more common eye symptoms encountered in patients with rheumatological diseases are dry, gritty eyes, photophobia, watering, redness, pain, floaters, and, most importantly, blurring or actual loss of vision. The differential diagnosis of the painful red eye and of sudden loss of vision is outlined in Table 1 and Table 2.

Ocular pathology	Vision	Pain	Distribution of redness	Extra signs	Likely systemic disease
Conjunctivitis	Good	Mild	Diffuse	Purulent sticky exudate	Reiter's syndrome
Dry eyes	Good	Gritty	Mild diffuse	Schirmer test Reduced tears Rose Bengal stain	Rheumatoid arthritis Systemic vasculitis Sjögren's syndrome (primary and secondary)
Episcleritis	Good	Irritation	Diffuse or nodular	Mobile nodules	Rheumatoid arthritis Systemic vasculitis
Scleritis	May be reduced	Very severe	Diffuse or nodular	Keratitis	Rheumatoid arthritis
Anterior uveitis	Reduced	Mild to severe	Circumcorneal	Keratic precipitates Small pupil Abnormal intraocular pressure Swollen optic disc	Seronegative spondylo-arthropathy Sarcoidosis Behçet's disease Vogt–Koyanagi disease

Table 1 The differential diagnosis of painful red eye

Cause of visual loss	History	Field	Pupil reaction	Media	Fundus	Likely systemic disease
Vitreous haemorrhage	Sudden	Generalised constriction	Normal	Hazy (blood)	Not seen or new vessels Retinal vascular occlusion	Systemic vasculitis Behçet's disease
Macular oedema	Gradual, with distortion	Small, relatively central scotoma	Normal	Hazy Cells in anterior chamber and vitreous	Swollen disc	Behçet's disease Sarcoidosis Seronegative arthropathy
Central retinal artery occlusion	Sudden	Dense, large, central scotoma	Afferent pupillary defect	Clear	Normal or pale optic disc Cherry-red spot at macula Dark blood in arterioles	Systemic vasculitis, especially giant-cell arteritis Polyarteritis nodosa
Ischaemic optic neuropathy	Sudden	Dense altitudinal defect	Afferent pupillary defect	Clear	Pale, swollen, optic disc	Giant-cell arteritis Systemic vasculitis
Inflammatory optic neuropathy	Progressive	Central scotoma	Afferent pupillary defect	Clear or hazy	Optic disc oedema Optic atrophy	Sarcoidosis Whipple's granulomatosis

All these are painless and occur in white eyes, except occasionally inflammatory optic neuropathy.

Table 2 The differential diagnosis of sudden loss of central vision

The combination of symptoms with ocular signs indicates the site of the eye disease, and this may reflect both the nature and severity of the joint disease.

Common eye disorders encountered in rheumatological disease

Conjunctivitis

Bacterial conjunctivitis commonly presents as sore, red, sticky eyes with a purulent discharge. Patients complain of being unable to open their eyes in the morning and of blurred vision. Viral conjunctivitis is very common. It presents with red, watering, irritable eyes and only minimal discharge, but often excessive photophobia as the cornea may become secondarily infected.

Dry eyes

Patients with dry eyes may complain of a foreign-body sensation, dryness, redness, grittiness, and excessive secretion of mucus. Their symptoms are aggravated by hot, dry, polluted atmospheres. Dry eyes may be due to local eye disease, particularly blepharitis and allergic eye disease, or keratoconjunctivitis sicca, which is associated with systemic disease. Keratoconjunctivitis sicca occurs when secretion of the lacrimal gland is of insufficient quality or quantity to maintain the tear film and ocular surface. It may be caused by reduction of tear secretion, destruction of the lacrimal glands or scarring of the ducts. The systemic diseases associated with dry eyes are primarily autoimmune diseases, for example primary Sjögren's syndrome, systemic lupus erythematosus, rheumatoid arthritis and systemic sclerosis, but also include infiltrative disorders including lymphoma, sarcoidosis or amyloidosis.

Slit-lamp examination is the essential investigation for patients with dry eyes. Offending local ocular disease can be diagnosed. The tear film is examined, particularly the break-up time of a fluorescent dye and the integrity of the cornea, which indicates adequacy of lubrication. In the absence of a slit lamp, Schirmer's test will identify patients with bone dry eyes but is otherwise not helpful. Rose Bengal stain denotes areas with an incomplete tear film. In early cases of keratoconjunctivitis sicca the stain is limited to the conjunctiva and in severe cases can be seen all over the cornea.

Treatment of dry eyes requires patience from the sufferer and the physician. Frequent regular tear supplements are the mainstay and these range from viscous preparations to normal saline. Temporary or permanent canalicular ablation is rarely required. Modern treatments which are under investigation are epidermal growth factor, aldose reductase inhibitors or cyclosporin eye drops (Tsubota 1994).

Episcleritis

The episclera is the thin layer of transparent tissue lying between the conjunctiva and the white sclera. It has its own blood supply and is incompletely fixed to the underlying sclera. This is in contrast to the conjunctiva, which is freely mobile over the episclera. Episcleritis is a benign, self-limiting condition that is usually unilateral and often nodular, involving only a small segment of the eye's surface. Patients complain of irritation and redness rather than pain, although the nodules may be tender to the touch. The affected episcleral vessels are dilated, within a swollen episclera. The condition subsides spontaneously within 4 to 6 weeks.

Scleritis

Scleritis is a serious, potentially sight-threatening condition, which in contrast to episcleritis is painful and does not subside spontaneously. Pain is the most constant feature and may be excruciating. The inflamed area is red and may produce a nodular, diffuse, or necrotizing pattern. If adjacent tissues are involved in the inflammatory process, additional signs and symptoms develop: spread to the cornea produces peripheral ulceration, keratitis and photophobia, whereas involvement of the posterior sclera causes proptosis, serous retinal detachment, a swollen optic disc, and, rarely, angle-closure glaucoma.

An unusual variant of scleritis is scleromalacia perforans, which occurs in elderly women with severe rheumatoid arthritis (see also below). This is characteristically painless and the affected sclera becomes dead white because the underlying lesion is arteritic infarction (Watson and Hazleman 1976). Eventually the sclera becomes atrophic and the blue, underlying choroid can be seen bulging through it. Actual perforation of the globe is very rare, despite the name. All forms of scleritis are very important to recognize for both the ophthalmologist and rheumatologist because they often herald activity of the systemic disease and may require systemic immunosuppression to prevent permanent ocular damage and blindness.

Acute anterior uveitis

Anterior uveitis is inflammation within the anterior chamber of the eye. The patient complains of an acutely painful, red eye with photophobia, sometimes associated with blurred vision. The pain is exacerbated by close work because the inflamed iris is stretched when the pupil constricts. The condition is generally unilateral and frequently recurrent. The ophthalmological signs, easily seen with the slit lamp, consist of circumcorneal redness and keratic precipitates on the endothelial surface of the cornea with flare and cells in the anterior chamber, looking like a cinema projection beam with specks of dust. In severe cases the cells gravitate to form a fluid level called a hypopyon. The pupil is small and poorly reactive; the intraocular pressure is often low in the acute stage and high in the convalescent stage.

Retinal vasculitis and posterior uveitis

The pattern of retinal disease in systemic inflammatory disease frequently reflects the nature of the disease and consequently may have important diagnostic value (Sanders 1987; Graham *et al*. 1989). In patients with seronegative arthropathies, Behçet's disease, and sarcoidosis, there may be inflammation in the posterior chamber of the eye (cells in the vitreous); the patient complains of floaters and of blurred or distorted central vision if the macula is oedematous. In mild cases, fundoscopy reveals focal or diffuse white sheathing of the retinal veins; in severe cases there are also scattered haemorrhages. Actual occlusion of the retinal veins and new vessels on the optic disc or peripheral retina may develop. The new vessels, similar to those in diabetes mellitus, generally develop as a consequence of retinal ischaemia secondary to occlusion of retinal veins. Their walls are fragile and vitreous haemorrhage is an important cause of visual morbidity in these patients.

By contrast, patients with systemic vasculitis do not develop inflammation within the eye but the vasculitic process affects the retinal capillaries and arterioles to produce retinal ischaemia, sometimes resulting in new vessels and vitreous haemorrhage. The ophthalmoscopic features range from asymptomatic, cotton-wool spots (due to occlusion of the retinal capillaries) to complete occlusion of the retinal artery causing blindness.

Optic neuropathy

Disease of the optic nerve invariably causes profound visual loss. Symptoms range from vague, blurred central vision and difficulty in differentiating colours to complete blindness. The cardinal ophthalmological signs of optic nerve disease are reduced visual acuity, impaired or absent colour vision, a central scotoma, and an afferent pupillary defect. The optic disc may look swollen, pale, or even normal. The pattern of visual loss varies from sudden, complete blindness, as experienced by

patients with giant-cell arteritis in whom the optic nerve undergoes infarction, to a slowly progressive loss in patients with granulomatous disorders when the optic nerve becomes compressed by abnormal tissue. All patients who develop disease of the optic nerve require urgent investigation and treatment.

Specific ocular manifestations of systemic inflammatory diseases

The ocular manifestations of systemic inflammatory disease vary according to the size and type of vessel predominantly affected by the disease process. As a general rule, diseases that affect arterioles involve the cornea, episclera, sclera, and retinal arterioles, whereas those affecting the venules produce uveitis (intraocular inflammation), macular oedema, and retinal venous disease.

Giant-cell arteritis

Giant-cell arteritis is an ophthalmic emergency and an important cause of preventable blindness in elderly people. Twenty-five per cent of patients develop ocular disease and the majority experience sudden loss of vision in one eye, with a dense, inferior, altitudinal field defect (Ross Russell 1959; Ross Russell 1986). The cause of the blindness is usually infarction of the optic nerve (ischaemic optic neuropathy) (Fig. 1), and occlusion of the central retinal artery in a minority of cases. Treatment is immediate, high-dose systemic steroids (e.g. prednisolone 1–2 mg/kg daily) to produce symptomatic relief of headache and, most importantly, to prevent blindness in the other eye, as recovery of vision is very unusual. If the patient has experienced symptoms of fluctuating vision in the good eye, treatment with intravenous steroids, heparin, and plasma expanders is indicated.

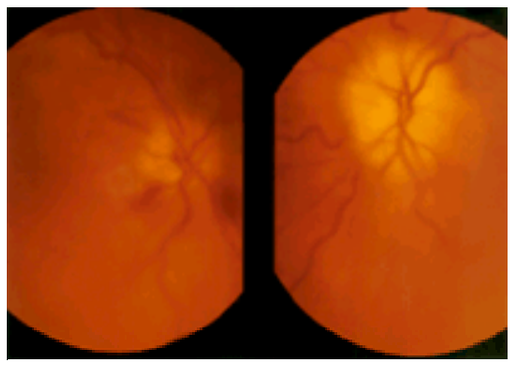

Fig. 1 Giant-cell arteritis. An 81-year-old lady with severe scalp tenderness woke up blind in her left eye, followed 3 days later by blindness in her right eye. The right fundus (left) has a swollen optic disc with peripapillary haemorrhages. The left optic disc (right) is swollen and pale, typical of ischaemic optic neuropathy.

Unusual neurophthalmological complications of giant-cell arteritis include oculomotor palsies, Horner's syndrome, cortical blindness (due to embolization from affected vertebral arteries), internuclear ophthalmoplegia, and visual hallucinations (Cullen and Coleiro 1976).

Systemic lupus erythematosus

Eye symptoms are very common in patients with systemic lupus erythematosus and range from minor, external problems (Frith *et al*. 1990) to severe retinopathy. Five per cent of patients will develop scleritis some time during the course of their disease, and this is occasionally seen at presentation (Fig. 2). As usual, active scleritis indicates active systemic disease and may require adjustment of systemic therapy. Uveitis is very rare in systemic lupus and only occurs in association with severe scleritis.

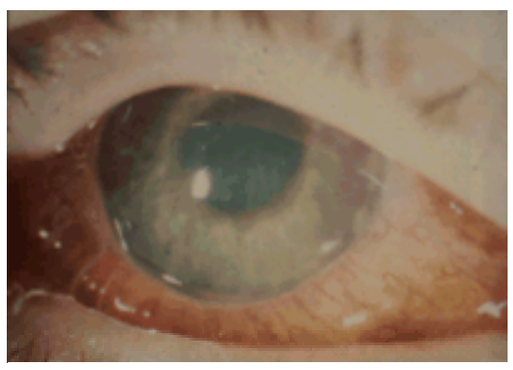

Fig. 2 Scleritis. A 32-year-old Caucasian woman presents with a 3-week history of general malaise and fever and a 1-week history of loss of vision associated with severe pain. The eye is red, the sclera is inflamed, the conjunctiva is chemosed. The cornea appears lazy because of corneal folds caused by hypotension in the eye secondary to severe ischaemia. Investigations confirmed acute, fulminant systemic lupus erythematosus.

The most important ophthalmic manifestation is the retinopathy described by Maumenee (1940). The hallmark of this is the cytoid body, which is the descriptive term used in systemic lupus for cotton-wool spot. Retinal haemorrhages and occlusions of central and branch retinal arteries may also occur; these are due to deposition of immune complexes rather than vasculitis (Graham *et al*. 1985). Occlusions of branch retinal veins are usually secondary to hypertension. Serous detachment of the retina and choroidal infarcts (Fig. 3) are seen in patients with active disease due to vasculitis of the choroidal vessels (Eckstein *et al*. 1993). The presence of anticardiolipin antibodies may be a marker for the development of retinal vascular occlusion (Levine *et al*. 1988) (Fig. 4).

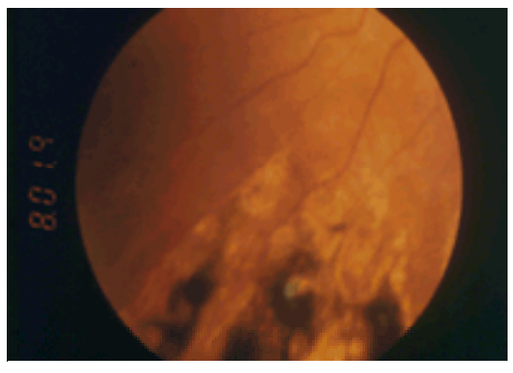

Fig. 3 Choroidal infarcts in systemic lupus erythematosus. A 22-year-old female presents with headaches and confusional state. Systemic lupus is diagnosed. 10 years later she has further thrombotic events when antiphospholipid antibodies were identified and these infarcts observed. They are asymptomatic.

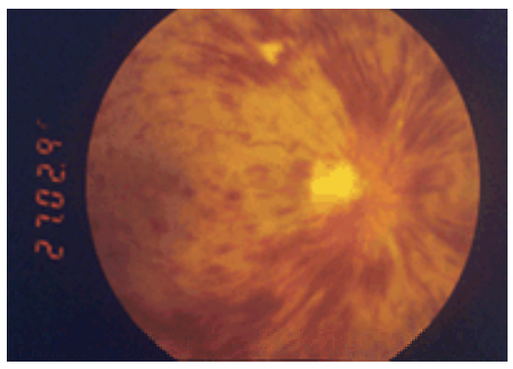

Fig. 4 Retinal vein occlusion in a woman who suffers with systemic lupus erythematosus and has antiphospholipid antibodies.

Polyarteritis nodosa

This disease has similar ophthalmic manifestations to those of systemic lupus. However, necrotizing scleritis with peripheral corneal ulceration is relatively common. The retinopathy is usually secondary to accelerated hypertension and therefore characterized by arteriovenous nipping, cotton-wool spots, and flame-shaped haemorrhages. The appearance of isolated cotton-wool spots or branch-artery occlusion is unusual; sudden visual loss, due to either ischaemic optic neuropathy or occlusion of the central retinal artery, rarely occurs. The development of scleritis or retinal vascular disease in the absence of hypertension warrants investigation of the systemic disease.

Wegener's granulomatosis

Eye problems develop in about half of patients with Wegener's granulomatosis, particularly those with limited disease (Spalton *et al*. 1981). This is the only systemic inflammatory disease that commonly presents with orbital disease, which is due to infiltration of the orbit with granulomatous tissue (Fig. 5). The patient complains of proptosis, which is caused by the orbital mass, red eyes from the scleritis, and loss of vision from compression of the optic nerve by the granulomatous tissue, often accompanied by oedema of the optic disc and choroidal folds.

Fig. 5 Wegener's granulomatosis. A 32-year-old man presented with fever, malaise, sore red right eye, and blurred vision. The right eye was proptosed with dilated scleral vessels and an incidental finding of extensive xanthelasmas (top). A CT scan revealed a 'dirty' right orbit where the muscles and optic nerve could not be identified due to extensive granulomatous tissue.

Systemic sclerosis

The most common eye complaint is dryness. A minority develop retinopathy similar to that seen in the other systemic vasculitides, with cotton-wool spots, haemorrhages, and occlusion of retinal arteries and also with choroidal infarction (Grennan and Forrester 1977).

Rheumatoid arthritis

One-third of patients suffer with dry eyes and in 10 per cent this is combined with a dry mouth (Sjögren's syndrome). Five per cent of patients presenting with episcleritis and 30 per cent presenting with isolated scleritis have rheumatoid arthritis (Watson and Hazleman 1976). Patients with scleritis associated with rheumatoid arthritis more commonly have bilateral scleritis than patients with scleritis due to other systemic immune disease (Sainz de la Meza *et al*. 1994). The scleritis is associated with an occlusive vasculitis; this may be very severe and cause corneal melt and occasionally perforation requiring surgical repair. Scleromalacia perforans affects elderly women predominantly (Fig. 6). Advancing scleral disease in these patients almost always heralds a flare-up of the systemic disease, particularly the vasculitic complications. Uveitis is not a feature of rheumatoid arthritis and involvement of the retinal vessels is very unusual.

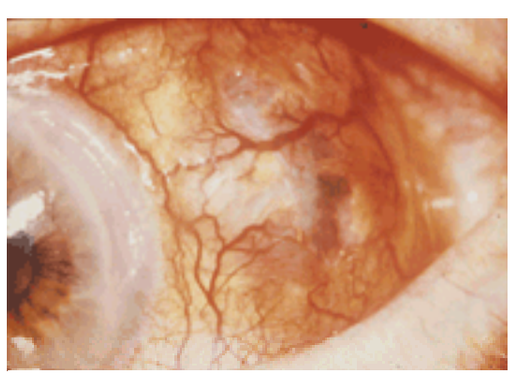

Fig. 6 Scleromalacia perforans. A 75-year-old man has suffered with severe rheumatoid arthritis and scleritis for many years. He now has an area of very thin sclera due to ischaemia and ulceration of the adjacent peripheral cornea.

Ankylosing spondylitis and the seronegative arthropathies

Acute anterior uveitis is the most important ocular disease in this group of patients. It occurs in 25 per cent of patients with ankylosing spondylitis and in 10 to 15 per cent of patients with other causes of seronegative arthropathy. The clinical symptoms and signs are identical, regardless of the accompanying disease. Attacks are usually unilateral but both eyes become affected during the course of the disease (Rothova *et al*. 1987). In severe cases, slit-lamp examination reveals a sticky, fibrinoid aqueous in the anterior chamber; posterior synechiae (adhesions between the iris and the lens) are common and raised intraocular pressure occurs. Patients who are HLA-B27 positive tend to be younger at the time of the first attack, have more severe ocular inflammation, and a longer duration of the acute attack than those who are HLA-B27 negative, in whom uveitis may be milder but sometimes more chronic (Linssen 1990). Conjunctivitis occurs in one-third of patients with

Reiter's disease but there is no increased incidence in the other groups (Fig. 7).

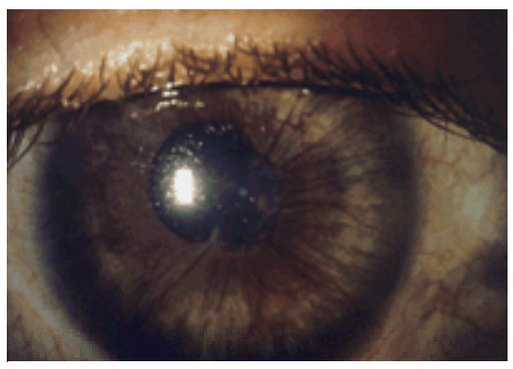

Fig. 7 Uveitis associated with ankylosing spondylitis. A 24-year-old man is blind from chronic anterior uveitis. The eye is white but the pupil is irregular due to posterior synechiae and abnormal new vessels are present on the iris.

Interestingly, the posterior segment of the eye is rarely affected in seronegative arthropathies: only 10 per cent of patients develop cells in the vitreous from retinal vasculitis affecting predominantly the capillaries and the postcapillary venules, but the consequence of this may be cystoid macular oedema and oedema of the optic disc. In very severe cases, serous retinal detachment ensues (Rodriguez *et al*. 1994).

Sarcoidosis

Eye involvement occurs in 30 to 40 per cent of patients with systemic sarcoidosis (Jabs and Johns 1986; Karma *et al*. 1988). The most common ocular manifestation is acute or chronic, relapsing uveitis, often in the absence of active pulmonary disease. The anterior uveitis is characterized by granulomatous, 'mutton fat', keratic precipitates and nodules on the iris (Fig. 8). Patients may complain of dry eyes from involvement of the lacrimal glands, which can be very dramatic, particularly in patients of African ethnicity. Asymptomatic conjunctival and scleral nodules may develop and are of diagnostic use.

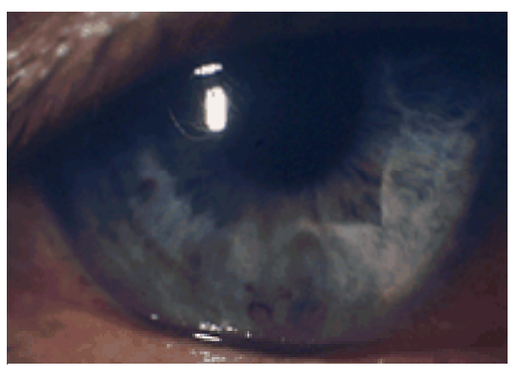

Fig. 8 Granulomatous anterior uveitis. A 58-year-old man presents with episodes of breathlessness and red eyes, due to sarcoidosis. The conjunctiva is injected; large, grey, keratic precipitates are seen inferiorly on the corneal endothelium.

Twenty-five per cent of patients with ocular sarcoidosis develop posterior uveitis with cells in the vitreous, and retinal vasculitis. The diagnostic retinal features of sarcoidosis are periphlebitis, focal cuffing of the retinal veins, new vessels on the optic disc or in the peripheral retina (often in the absence of retinal ischaemia), choroidal nodules (Fig. 9), and pigment epithelial lesions (Spalton and Sanders 1981).

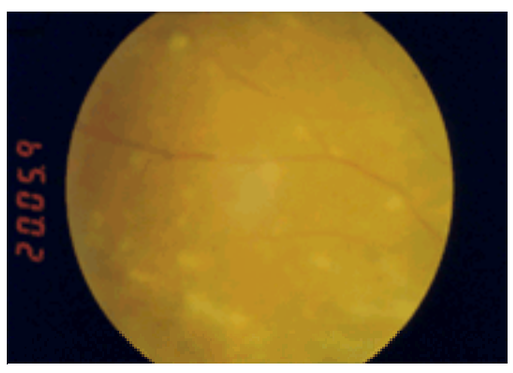

Fig. 9 Sarcoidosis. A 40-year-old Asian man has suffered with uveitis and sarcoidosis for 15 years. He has sheathing of his retinal veins and multiple pale areas in the pigment epithelium and choroid, which probable represent granulomas.

Five per cent of patients develop granulomatous optic neuropathy with profound visual loss (Graham *et al*. 1986). This may mimic acute demyelinating optic neuritis, with pain and rapid visual loss, or it may produce progressive visual loss owing to a granuloma compressing the optic nerve (Fig. 10). Both types may be acutely steroid-sensitive and therefore it is important to make the diagnosis rapidly.

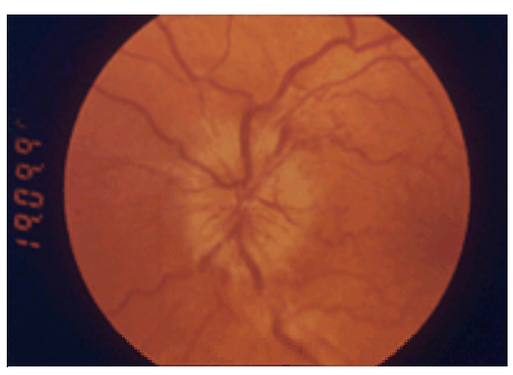

Fig. 10 Optic nerve infiltration by sarcoidosis. A 24-year-old Caucasian man presents with sudden loss of vision associated with pain in the left eye. Investigations reveal a lymphopenia, a high angiotensin-converting enzyme, raised protein, and 11.0 million lymphocytes in the cerebrospinal fluid.

Behçet's disease

Ocular manifestations in Behçet's disease occur in 70 per cent of patients and are very important as 25 per cent of patients will go blind (Michelson and Chisari 1982). Together with orogenital ulceration and thrombophlebitis, uveitis forms the major triad described in 1937 by Hulusi Behçet.

Severe anterior uveitis, often in a white eye, is common, with hypopyon formation in extreme cases. The anterior uveitis is typically recurrent but can resolve spontaneously. The high incidence of blindness in patients with Behçet's disease is due to the severity of the retinal changes. The pathognomonic features are sequential occlusions of branch retinal veins (Fig. 11) and retinal infiltrates. The recurrent nature of the venous occlusions results in progressive retinal ischaemia and eventually the entire retinal vasculature becomes obliterated and the optic disc atrophic (Atmaca 1989). Retinal infiltrates, which are due to collections of polymorphs in the superficial retinal layers, are pathologically similar to a hypopyon and will resolve spontaneously over the course of a week.

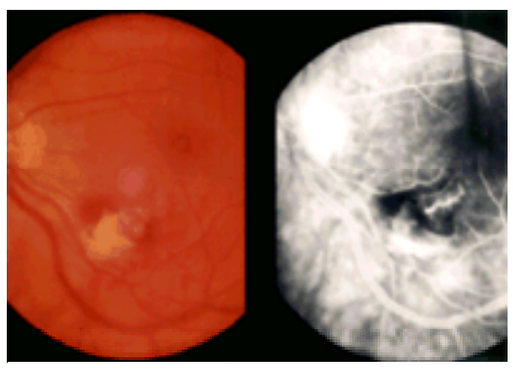

Fig. 11 Behçet's disease. A 24-year-old woman with a history of severe orogenital ulceration and thrombophlebitis suddenly developed blurred central vision in her left eye. An area of haemorrhage and infiltrate was present inferior to the macula (left) and a fluorescein angiogram (right) revealed occlusion of a small retinal vein.

Ocular involvement in rheumatic conditions of childhood

Introduction

Uveitis occurring before the age of 16 years is approximately four times less common than uveitis in the general population (Perkins 1966). In two reviews of uveitis in childhood, systemic illnesses such as sarcoidosis, Behçet's disease, and vasculitis accounted for less than 8 per cent of patients (Perkins 1966; Kanski and Shun-Shin 1984). The most common associated disorder in Kanski's series was seronegative juvenile chronic arthritis. Ocular complications of rheumatic diseases in childhood were reviewed by Petty (1990).

Juvenile chronic arthritis

The chronic anterior uveitis that occurs in association with juvenile chronic arthritis deserves special mention, particularly as it does not occur in adults. Affected children are mostly girls, and are usually young at onset of arthritis (mean age, 3 years). Joint involvement is usually pauciarticular, although it may spread to become polyarticular. Most patients have associated antinuclear antibodies in their serum.

Arthritis generally predates the eye involvement by 1 to 3 years or sometimes much longer, but 5 to 10 per cent of cases present with uveitis and the ophthalmologist should therefore ask for a rheumatological opinion in any young child with chronic anterior uveitis. Similarly, because the eye disease is usually asymptomatic until complications occur, the rheumatologist must arrange for an early slit-lamp examination on all children. The ophthalmologist will then arrange suitable follow-up screening at regular intervals (Leak 1992).

The non-granulomatous iridocyclitis runs an uncomplicated course in only one-third of affected children (Petty 1987). Although the majority of cases develop the complications of band keratopathy, posterior synechiae, cataracts, or glaucoma, only 10 to 20 per cent of affected eyes become blind (Rosenberg 1987; Wolf *et al*. 1987). Early onset of uveitis, either symptomatic or when picked up in routine screening within the first year of arthritis, and particularly if associated with posterior synechiae at this first examination, is associated with a significantly worse prognosis for vision (Wolf *et al*. 1987)). Most eye involvement develops for the first time within 5 years of the onset of arthritis, and after this the risk is much less, unlike the acute symptomatic anterior uveitis in ankylosing spondylitis, which may occur for the first time very many years later than the original musculoskeletal symptoms.

Spondylarthropathies

As many as 8.6 per cent of patients with ankylosing spondylitis have their onset before the age of 16 years (Bennet and Wood 1968), frequently in an adolescent boy with pauciarticular arthritis of the legs, or enthesitis. Acute anterior uveitis probably occurs as frequently in juvenile-onset spondylitis as in adult ankylosing spondylitis, and over long follow-up up to 27 per cent of such children develop episodes of uveitis.

Bilateral, painless conjunctivitis is common in Reiter's syndrome but, in addition, acute anterior uveitis and keratitis with corneal ulcers have been described in children. Chronic anterior uveitis is only described in occasional children with juvenile spondylitis or Reiter's disease and always requires reconsideration of the diagnosis.

Although juvenile psoriatic arthritis is often grouped with the spondarthropathies, acute uveitis is uncommon and ocular involvement is usually chronic and clinically indistinguishable from that which occurs in association with early-onset juvenile chronic arthritis.

Multisystem systemic illness

Many systemic rheumatic diseases with ocular involvement in adults have counterparts in childhood, including systemic lupus erythematosus, Sjögren's syndrome, and systemic sclerosis (Leak and Isenberg 1989). Behçet's disease is rarely diagnosed before adolescence, although a history of oral ulcers may predate the appearance of other major manifestations by more than 8 years (Kim *et al* 1994).

Sarcoidosis beginning under the age of six years with rash and arthropathy may be associated with chronic anterior uveitis (Hoover *et al* 1986, Sahn *et al* 1990). Features distinguishing this from juvenile chronic arthritis include the iris nodules, posterior eye involvement, and rather painless, non-evasive, boggy tenosynovitis. Blau syndrome is a familial form of granulomatous arthritis, uveitis, and rash with similar features to sarcoidosis in childhood (Blau 1985).

In childhood, classical polyarteritis nodosa and Kawasaki disease are the most common forms of systemic vasculitis. Bilateral, non-suppurative, bulbar, conjunctival injection is a recognized diagnostic criterion in Kawasaki disease, occurring in virtually all cases in the early stages of the illness; acute, bilateral uveitis is also very common (Ohno *et al*. 1982; Smith *et al*. 1989).

Differential diagnosis of coexistent ocular and arthritic problems in childhood includes infections such as Lyme disease, infantile-onset, multisystem inflammatory disease (Yarom *et al*. 1985), and lysosomal storage diseases (Cassidy and Petty 1990).

Infective arthropathies and eye disease

Secondary syphilis may be accompanied by an acute panuveitis with an active anterior uveitis, cells in the vitreous, and retinal changes involving predominantly the capillaries, which produce oedema of the macula and optic disc, and also subretinal fluid in the inferotemporal quadrant, leading to a characteristic pale appearance.

Other infectious diseases that must be considered in undiagnosed patients presenting with arthritis and ocular inflammation include those involving Epstein–Barr virus, Lyme disease, Whipple's disease, brucellosis, and human immunodeficiency virus (Nussenblatt and Palestine 1989).

Temporal relationship of ocular involvement with other disease manifestations in specific conditions

The chronic anterior uveitis associated with juvenile chronic arthritis usually runs an intermittent course that is not associated with the current activity of the arthritis, although it is common for their onset to be within 1 to 2 years of each other. The severity of ocular and joint involvement is also independent such that blindness may occur in a child with minimal arthritis and no residual deformity. By contrast, in adult rheumatoid arthritis, scleritis indicates generalized, active disease.

The acute attacks of unilateral anterior uveitis that characterize the seronegative spondarthropathies occur randomly, whereas ocular involvement in Reiter's syndrome occurs as part of a symptom complex, usually within the first 2 to 3 years (Lee *et al*. 1986).

In Behçet's disease and sarcoidosis, uveitis is frequently found with other systemic manifestations at presentation, but subsequent flare-ups frequently occur in isolation such that eye and joint disease are not significantly associated.

In Kawasaki disease, eye involvement occurs as part of the acute inflammatory process, and Ohno *et al*. (1982) found a strong statistical correlation between the activity of uveitis, as measured by the numbers of inflammatory cells in the anterior chamber, and the erythrocyte sedimentation rate (**ESR**) and C-reactive protein.

Diagnostic and laboratory tests

The initial history and examination will provide the diagnosis in the majority of patients. The use of radiological or laboratory tests in the assessment of a patient with eye disease is limited. A useful screen for a patient with uveitis would be a full blood count, ESR, chest radiographs, and serology for syphilis. Further tests such as HLA-B27, angiotensin-converting enzyme, and antinuclear antibodies would be indicated by clinical evidence of disease elsewhere. In a prospective study of 865 patients, intensive investigation established a specific diagnosis in 628 patients (73 per cent) but an associated systemic disease was found in only 220 patients (26 per cent) (Rothova *et al*. 1992).

Evidence of an acute-phase response, for example a raised ESR or C-reactive protein, suggests a generalized systemic illness with active ocular involvement. However, in diseases in which the activity of eye and joint disease do not run in parallel, active uveitis alone is usually not associated with a raised ESR.

Autoantibodies

Rheumatic diseases such as rheumatoid arthritis and systemic lupus erythematosus are often associated with serum autoantibodies but in this situation the antibodies are not of diagnostic use as the systemic disease would usually be obvious clinically.

Amongst a mixed group of patients with uveitis, antibodies to tissue antigens do not occur more frequently than in controls, except in children with juvenile chronic arthritis in which 80 per cent or more have antinuclear antibodies (Murray 1986). Patients with retinal vasculitis may have circulating immune complexes and/or antiretinal antibodies. The presence of antibodies alone may be associated with more severe disease (Kasp *et al*. 1986). Antineutrophil cytoplasmic antibodies have been found in 'fit' patients with severe necrotizing scleritis and may indicate an underlying systemic vasculitis that requires persistent vigilance by the ophthalmologist (Talks *et al*. 1994).

Immunogenetics

Determination of HLA-B27 in patients with acute anterior uveitis is valuable because B27-positive patients are more likely to have an associated spondarthropathy and should be referred for a rheumatological opinion (Feltkamp 1990).

Treatment of the ocular complications of systemic inflammatory disease

Mild, anterior-segment complications such as conjunctivitis, dry eyes, and episcleritis will invariably respond to local treatment.

Treatment of scleritis, anterior uveitis, retinal vasculitis, and optic neuropathy depends firstly on the severity of the eye disease and its effect on vision, and secondly on the activity of the systemic disease. In general, systemic therapy is dictated by the eye disease if the vision is reduced or potentially threatened by inflammation.

Scleritis

Scleritis is an indication for systemic therapy. Adequate doses of non-steroidal, anti-inflammatory drugs may suffice (e.g. flurbiprofen, 50 mg, three times a day), but if corneal or retinal involvement develops or the inflammation is uncontrolled, systemic steroids are indicated. In rare instances it is necessary to supplement the steroids by pulse cyclophosphamide (Meyer *et al*. 1987) or cyclosporin (Wakefield and McCluskey 1989). If the scleritis coincides with activity of the systemic disease, adjusting the treatment for the latter is usually sufficient.

Uveitis

The treatment of uveitis depends primarily on the visual acuity and the site of the inflammatory process. The rationale of treatment of uveitis is set out in Table 3. In the majority of cases, anterior uveitis can be treated topically with steroid eye drops (prednisolone betamethasone/dexamethasone) and a dilating agent (tropicamide/cyclopentolate/atropine), occasionally supplemented by a subconjunctival injection. A trial of systemic steroids may be necessary in selected patients with frequent persistent relapses of anterior uveitis. If the inflammation involves the posterior segment and the visual acuity drops below 6/12 (0.5), due either to cystoid macular oedema or vitreous cells, a subtenons injection of steroid or systemic steroids are indicated. If the vision drops because of occlusion of the retinal vessels or involvement of the optic nerve, systemic immunosuppression is immediately indicated. Corticosteroids and cyclosporin are effective (Towler *et al*. 1990; Howe *et al*. 1994), but these may be used in conjunction with azathioprine (Lightman 1991) or methotrexate (Shah *et al*. 1992).

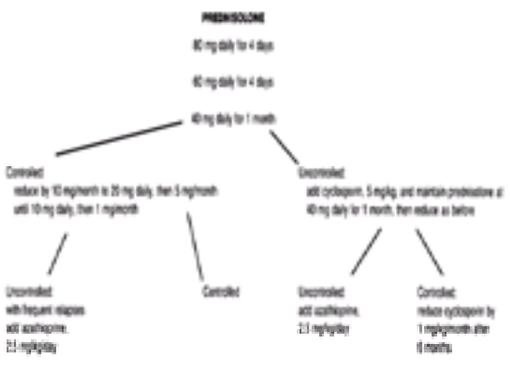

Table 3 Changing course of systemic steroids for patients with posterior uveitis

The most difficult management problem is Behçet's disease because of the severity and frequency of the attacks of uveitis, which almost invariably affect the retinal vessels. A combination of prednisolone, cyclosporin, azathioprine, and colchicine appears to be most effective in refractory patients. However, there are no controlled trials of these drugs in Behçet's uveitis and therefore the perplexing problem of benefits of treatment versus side-effects must be continuously evaluated. The management of Behçet's disease is discussed in Chapter 5.11.7.

Antirheumatic therapy with ocular side-effects

Most antirheumatic drug therapy causes no significant ocular side-effects but attention is drawn to toxicity of antimalarial drugs prescribed for rheumatoid arthritis, systemic lupus erythematosus, and related disorders, and to corticosteroids, widely used in many rheumatic conditions.

Antimalarial drugs

Use of these compounds in patients with rheumatic diseases has been hindered by fears about ophthalmological toxicity and the need for frequent monitoring by an ophthalmologist. Corneal deposits and poor contraction of the ciliary body are minor, reversible problems and the real worry is the development of retinopathy.

Chloroquine has a high affinity for the melanin-containing tissue of the eye, including the retinal pigment epithelium (Maksymowych and Russell 1987). The pathophysiology of the retinal damage is related to malfunction of the phagolysosomes, resulting in faulty clearance of ageing photoreceptor membranes. The build-up of lamellar myelin bodies disturbs the metabolism of the retinal pigment epithelium.

In the advanced stage with an absolute scotoma and loss of visual acuity, there is granular pigmentation of the macula surrounded by a 'bull's eye' of rings of depigmentation and pigmentation. However, in the early stages, fundoscopy and other standard optic screening tests are normal despite the presence of a scotoma on a red Amsler grid (Fig. 12). Identification at this stage is the goal of screening programmes, as cessation of treatment will usually prevent progression.

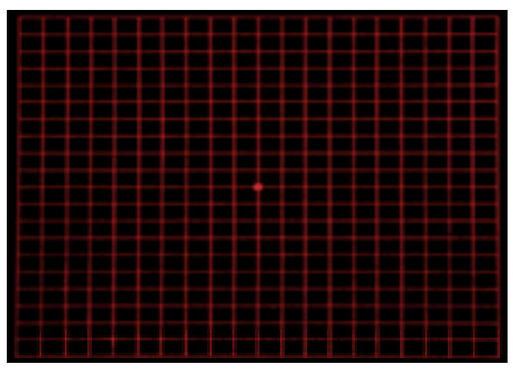

Fig. 12 The red Amsler grid.

Evaluation of published reports on retinal toxicity is difficult because of the differences in dosage over variable periods of time and the exact criteria used to define retinopathy, as well as lack of baseline data in some patients.

The total dose of drug used before development of retinopathy is very variable whereas the daily dosage in relation to the patient's weight now seems to be the important factor. At daily doses of 250 mg for chloroquine or 400 mg for hydroxychloroquine, there are few cases of mild, reversible retinopathy. Reports of progressive retinopathy at 250 mg/day of chloroquine contain insufficient information on patients' weight.

Several reviewers are agreed that the risk of toxicity is very small at the recommended daily dosages: chloroquine 3.5 mg/kg; hydroxychloroquine 6.5 mg/kg (Maksymowych and Russell 1987; Rynes 1987; Easterbrook 1988; Lozier and Friedlaender 1989). In practical terms, for a patient of 65 kg, 400 mg of hydroxychloroquine are safe, or 225 mg of chloroquine (not 250 mg). However, smaller patients must take a reduced dose, as should those with renal or hepatic impairment. Current opinion favours hydroxychloroquine as having the best safety record (Berstein 1991; Easterbrook 1993; Spalton *et al*. 1993).

An adequate, baseline ophthalmological examination is the ideal and should include visual acuity (corrected for distance and near), colour vision, red Amsler chart, and fundoscopy. Detection of coexistent eye disease such as age-related macular pigmentation will necessitate regular follow-up at 6-monthly intervals. In the absence of ocular abnormalities, opinion is divided as to the necessity and frequency of repeat tests. Some suggest no other ophthalmological review is necessary (Morsman *et al*. 1990), although the prescribing physician may wish to recheck the Amsler grid test every 6 months (Benstein 1991). By contrast, Easterbrook (1993) still recommends annual ophthalmological assessment, whereas Spalton *et al*. (1993) feel this is only necessary after 5 years on antimalarial therapy. Self-testing by the patient with an Amsler grid at 2-weekly intervals is an inexpensive and reproducible test that is both simple and sensitive (Easterbrook 1988; Lozier and Friedlaender 1989). Detection of faded or distorted areas should prompt early evaluation with field testing by the ophthalmologist.

Corticosteroids

Both oral and topical corticosteroids may cause a variety of ophthalmic side-effects:

1. Corneal and scleral thinning can occur with topical steroids and lead to perforation.
2. Cataracts are common, especially after higher doses of systemic steroids. Their development in chronic uveitis is partly related to the treatment but the advantages of topical therapy in particular far outweigh the side-effect.
3. Raised intraocular pressure is another common side-effect of steroids. Five per cent of the population are termed 'steroid reactors' because of a significant but asymptomatic increase in pressure. The frequency, duration, and type of topical or oral steroid all influence this effect, and use of an alternative steroid should be considered, for example from dexamethasone to fluoromethalone.
4. Infectious problems: herpes simplex can cause an acute, unilateral anterior uveitis and topical steroids risk exacerbating such eye infections; topical steroids should not be used indiscriminately on an undiagnosed red eye.

Immunosuppressives

Patients on long-term systemic immunosuppression may develop viral retinitis (herpes simplex, herpes zoster, cytomegalovirus) causing retinal necrosis and eventual blindness (Fig. 13). Early symptoms include red eyes, floaters, and field defect, and require an urgent ophthalmological opinion.

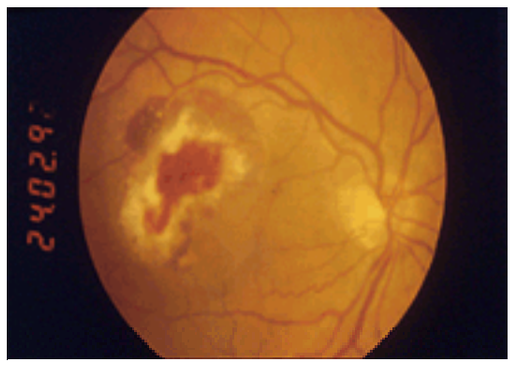

Fig. 13 Cytomegalovirus retinitis. A middle-aged man has Wegener's granulomatosis controlled with prednisolone and azathioprine. After 12 months' treatment he develops blurred vision. The area of retinal necrosis with haemorrhage and satellite lesions is typical of cytomegalovirus retinitis. The retinitis resolved with ganciclovir and reduction of immunosuppressive therapy.

Box 1 Important key points for ophthalmologists to remember

1. Examine all children suspected of juvenile rheumatoid arthritis as soon as possible. It takes seconds!
2. Visual loss due to ischaemic optic neuropathy with cotton wool spots and/or minor retinal arteriolar occlusion is due to systemic vasculitis.
3. Uveitis associated with choroidal or pigment epithelial disease suggests sarcoidosis..
4. Uveitis and retinal infiltrates or retinal vein occulsions suggests Behçet's disease.
5. Scleritis associated with peripheral corneal ulceration indicates systemic vasculitis, particularly Wegener's granulomatosis or polyarteritis nodosa.

1.3.11 The kidney

Carolyn P. Cacho, Jay B. Wish, Frances B. Wheeler and Gary M. Kammer

Introduction

Renal involvement is often the most catastrophic and potentially lethal complication of systemic rheumatic diseases. As such, it is vital for the rheumatologist to be familiar with the pathophysiology and clinical manifestations of renal disease. Many renal diseases are rapidly progressive and, therefore, the rheumatologist should recognize the early signs and symptoms, and have a framework for determining when consultation with a nephrologist is indicated. In many cases, urinary abnormalities such as haematuria and proteinuria will predate the onset of renal insufficiency, giving the rheumatologist an opportunity to determine the nature and severity of the renal lesion in consultation with the nephrologist. Similarly, the acute onset or worsening of hypertension may indicate renal involvement, warranting collaboration with the nephrologist for establishing both diagnostic and therapeutic strategies.

Several rheumatic disorders have a relatively high incidence of renal involvement (Table 1). It is appropriate for patients with these illnesses to undergo a thorough initial assessment of renal function as well as frequent reassessments of renal parameters, even when the initial nephrological examination is negative. Renal involvement in the systemic rheumatic diseases is variable and unpredictable. For example, systemic lupus erythematosus may present with proteinuria without hypertension or abnormalities of renal function; the proteinuria may or may not progress to renal failure over time. At the other extreme, lupus nephritis may present as a rapidly progressive glomerulonephritis, characterized by haematuria, proteinuria, severe hypertension, and advanced renal insufficiency. Other rheumatic diseases with a relatively high incidence of renal involvement also show marked variability of signs and symptoms of kidney disease (Table 1). Furthermore, it is often difficult to differentiate rheumatic diseases either on the clinical or pathological basis of renal involvement. In many instances, the presentation of the renal disease and even the findings from renal biopsy may be identical. Thus, diagnoses of rheumatic disorders are defined on the basis of the clinical range of extrarenal findings and on serological analyses. The overlap of rheumatic and renal diseases further underscores the advantages of close collaboration between the nephrologist and the rheumatologist in their evaluation, diagnosis, and treatment. The following sections seek to provide a broad perspective of the interaction between nephrologist and rheumatologist in the evaluation and management of renal complications in systemic rheumatic diseases by focusing on proteinuria, haematuria, acute renal failure, and hypertension.

Systemic lupus erythematosus	60–70
Mixed connective tissue disease	6–47
Henoch–Schönlein purpura	30–70
Sjögren's syndrome	40–50
Systemic sclerosis	45
Wegener's granulomatosis	50
Classic polyarteritis	30–60
Microscopic polyarteritis	60–70

Numbers are percentages.

Table 1 Rheumatic disorders with a relatively high incidence of renal involvement

Proteinuria

Definitions

The upper limit of protein excretion in healthy adults is approximately 150 mg/day. Functional proteinuria describes proteinuria without intrinsic renal disease. Such protein excretion is usually less than 500 mg/day and may be associated with high fever, strenuous exercise, or exposure to cold. Although proteinuria up to 1 to 2 g daily has been recorded during severe congestive heart failure without intrinsic renal disease, proteinuria greater than 500 mg daily is strongly suggestive of intrinsic renal disease. Abnormal protein excretion of less than 3 to 5 g/day can occur in both glomerular and tubular interstitial diseases; however, more than 2 g of protein daily implicates glomerular disease. When proteinuria greater than 3.5 g daily is sufficient to lead to hypoalbuminaemia, hypercholesterolaemia, and peripheral oedema, the patient is said to have the nephrotic syndrome. Protein excretion of greater than 3.5 g daily can be found in the absence of hypoalbuminaemia, lipid abnormalities, and/or peripheral oedema. This is called nephrotic-range proteinuria, and protein excretion less than 3.5 g/day is termed non-nephrotic range proteinuria.

The quantity of proteinuria as a result of glomerular disease does not correlate with the nature or severity of the glomerular lesion. Proteinuria of greater than 20 g daily may be associated with minimal histological changes on renal biopsy and may be exquisitely sensitive to treatment with corticosteroids. By contrast, 3 to 5 g of proteinuria daily can be found in the presence of active lesions that are poorly responsive to therapy.

The prolonged presence of nephrotic-range proteinuria often leads to progressive renal insufficiency. While persistent proteinuria does not invariably progress to chronic renal failure, patients with a partial (less than 1 g daily) or complete (less than 150 mg daily) resolution of proteinuria in response to therapy have a lower rate of progression to endstage renal disease (Appel *et al*. 1987). Although remission of proteinuria is a favourable prognostic sign, rheumatic diseases do have periodic exacerbations and remissions. Thus, there is a risk for recurrence of proteinuria, which may become persistent and ultimately progress to chronic insufficiency in disorders such as systemic lupus erythematosus or systemic sclerosis.

The monitoring of proteinuria and renal function over time can be done by the nephrologist, but the rheumatologist must be kept informed in order to adjust therapy.

Patients receiving therapy aimed at reducing proteinuria should undergo serial determination of protein excretion in order to assess the response to therapy and to determine a prognosis for renal survival. Patients with complete resolution of proteinuria also should have close follow-up by urinalysis approximately 3 to 4 times per year. In addition, screening for proteinuria, examination of the urinary sediment, and measurement of renal function should be undertaken whenever patients present with an extrarenal exacerbation of a rheumatic disorder. Monitoring of certain serological factors may also yield useful information that suggests the exacerbation of renal disease. An increase in the concentration of antinative-DNA antibody and a decrease in C3 and/or C4 complement levels often predate the onset or exacerbation of renal disease in systemic lupus (Garin *et al*. 1979; Pillemer *et al*. 1988). However, as the serum C3 and C4 may or may not be chronically decreased, an isolated low complement level is not necessarily predictive of active disease. In this circumstance, both the blood pressure and renal function must be closely monitored.

Diagnostic studies in the patient with proteinuria

The onset of proteinuria in a rheumatic disease does not necessarily implicate renal involvement from the systemic illness. None the less, when it complicates a systemic rheumatic illness that has a high incidence of renal involvement (Table 1), the onset of proteinuria is certainly of concern. It is in this circumstance that it is appropriate to consult a nephrologist in order to begin a well-conceived and thorough diagnostic evaluation. Moreover, there are many patients under the care of the rheumatologist in whom the diagnosis of a systemic illness has not yet been made. With this in mind, the onset of proteinuria should trigger a more complete diagnostic evaluation. This should include quantification of urinary protein excretion and a careful microscopic examination of the urine sediment and an estimation of renal function. Additional diagnostic studies for the new onset of proteinuria should include antinuclear antibodies, serum complement (C4 and C3), hepatitis B surface antigen, and anti-HCV antibodies. As long-standing diabetes remains one of the most common causes of secondary nephrotic syndrome, an evaluation of proteinuria should include measurement of serum glucose and/or glycohaemoglobin. The increasing prevalence of human immunodeficiency virus (**HIV**) infection in the general population and the association of this infection with focal segmental glomerulosclerosis and heavy proteinuria warrants an anti-HIV antibody determination. Finally, paraproteinaemia is a significant cause of nephrotic syndrome due to glomerular amyloidosis and 'light chain nephropathy', a glomerular and tubular interstitial disorder. Therefore, a serum protein electrophoresis as well as the urine immunoelectrophoresis for the measurement of Bence-Jones proteins should be done in patients with unexplained proteinuria.

Differential diagnosis of proteinuria in systemic rheumatic disease

The main causes of heavy proteinuria in rheumatic illnesses are divisible into two groups. The first group presents with isolated nephrotic range proteinuria with or without renal insufficiency. Systemic lupus erythematosus commonly presents in this manner and, indeed, presentation with the nephrotic syndrome may precede the diagnosis of lupus. The renal biopsy generally shows a non-inflammatory form of lupus nephritis, characterized either by (a) membranous nephropathy (WHO classification type V) with thickening of the glomerular basement membrane and subepithelial deposition of immune complexes; or (b) mesangial proliferative disease (WHO classification type II) with increased mesangial cellularity and matrix but without significant proliferation of glomerular endothelial or epithelial cells and inflammatory infiltration. Patients with mesangial proliferation will generally have extensive deposition of immune complexes within the mesangial matrix.

Renal amyloidosis occurs in up to 15 per cent of patients with rheumatoid arthritis and may also complicate Sjögren's syndrome, scleroderma, and long-standing systemic lupus. This entity typically presents with heavy proteinuria in the absence of haematuria, hypertension, or renal insufficiency. The diagnosis is often inferred by the demonstration of amyloid in a biopsy from an extrarenal site, such as the rectum, gingiva, or abdominal fat pad. However, in some cases, renal biopsy is required for the diagnosis. Renal amyloidosis may be associated with massive proteinuria of greater than 20 g daily and generally leads to progressive renal insufficiency that is unresponsive to treatment.

Several therapeutic agents frequently used for connective tissue diseases have been associated with the development of heavy proteinuria. Non-steroidal anti-inflammatory drugs (**NSAIDs**) can induce heavy proteinuria, acute renal failure, and electrolyte disorders. Renal dysfunction associated with these agents is most frequently the result of haemodynamic changes within the glomerulus secondary to inhibition of prostaglandin synthesis, but these drugs may also produce acute interstitial nephritis and significant renal failure. Unlike other forms of drug-induced interstitial nephritis, peripheral eosinophilia, fever, and eosinophiluria are generally absent with NSAIDs. Proteinuria is variable but may be as high as 20 g/day. Renal biopsy, when done, has usually revealed minimal-change glomerular disease and acute interstitial nephritis. Immunofluorescence staining is negative. Recent studies have indicated that 75 to 80 per cent of the mononuclear interstitial infiltrate is composed of T lymphocytes. It has been speculated that inhibition of cyclo-oxygenase by NSAIDs shunts arachidonic acid to the lipoxygenase pathway, with subsequent production of mediators of inflammation, such as the leukotrienes. The development of heavy proteinuria with or without renal insufficiency in a patient treated with these drugs should prompt discontinuation. In most cases, the proteinuria and renal insufficiency have resolved after elimination of the offending drug (Levin 1988).

Approximately 3 to 4 per cent of patients treated with gold for rheumatoid arthritis develop proteinuria; however, only one-quarter of these show the nephrotic syndrome. Renal biopsy of these individuals has generally revealed a classic membranous glomerulopathy, a non-inflammatory lesion characterized by thickening of the glomerular basement membrane resulting from presumptive *in situ* immune-complex deposits. The pathogenesis of this lesion is poorly understood. The development of increasing proteinuria or nephrotic syndrome during gold therapy should prompt discontinuation of the drug. In over 80 per cent of patients, the proteinuria resolves within 1 year, and steroid therapy does not appear to be warranted (Katz *et al*. 1984).

Administration of penicillamine is associated with proteinuria in about 10 per cent of cases. There is no clear relationship between the development of proteinuria and either the daily or cumulative dose of the drug, suggesting an idiosyncratic reaction. As with gold therapy, renal biopsy in patients with penicillamine-associated proteinuria generally reveals a membranous glomerulopathy. Although the pathogenesis is unknown, the renal lesion usually resolves after discontinuation of the drug, but the proteinuria may persist for as long as 2 years. Renal insufficiency rarely develops, even when complicated by heavy proteinuria (Stein *et al*. 1980).

The second type of presentation is that of proteinuria of variable quantity accompanied by haematuria and possibly renal insufficiency. Systemic rheumatic illnesses which may present in this manner include polyarteritis nodosa, Wegener's granulomatosis, Henoch–Schönlein purpura, and cryoglobulinaemia. Systemic lupus erythematosus may also fall into this category, especially when it is associated with a focal or diffuse proliferative glomerular lesion (WHO classification type III to IV). Cryoglobulinaemia, also an immune-complex disease, is characterized by deposition of circulating immune complexes within the glomerulus and a proliferative glomerular lesion not unlike that seen in the more severe cases of lupus nephritis. Henoch–Schönlein purpura more often presents with haematuria (which may be gross) than with proteinuria; impairment of renal function may or may not complicate this type of purpura. Renal insufficiency, if it does occur, may be self-limiting or progressive. Polyarteritis nodosa is associated with two relatively distinct renal syndromes. In classical polyarteritis nodosa, there is a vasculitis involving the large and medium-sized vessels of the kidney and this results in hypertension as the primary presenting symptom. When present, glomerular lesions are the result of ischaemia, not inflammation, and manifest primarily as haematuria, not proteinuria. In microscopic polyarteritis, a rapidly progressive glomerulonephritis is characterized by red blood cell casts, proteinuria, acute renal failure, and hypertension. Wegener's granulomatosis, also associated with inflammation of the small vessels of the kidney including the glomeruli, presents with a similar clinical picture. Although the **c-ANCA** (antineutrophil cytoplasmic autoantibody; see below) is present in probably 90 per cent of patients with active, untreated systemic Wegener's granulomatosis (Jennette and Falk 1995), the only definitive way to distinguish these various forms of acute necrotizing glomerulonephritis is to perform a renal biopsy (Madaio 1990).

Haematuria

Definitions

Haematuria is defined as the presence of red blood cells in the urine. The normal urine should be negative for haem pigment on dipstick examination and should reveal less than three red blood cells per high-power field on examination of the sediment. Haematuria is said to be microscopic if the urine colour is normal and blood can be detected only by microscopic examination or a urine dipstick method. The haematuria is termed gross if red blood cell excretion is large enough to cause a visible reddish or brownish discoloration of the urine. Significant bleeding from the lower portions of the urinary tract such as the bladder or urethra usually produces a red discoloration of the urine. Bleeding from the kidney, on the other hand, and especially from glomeruli, results in denaturation of haem proteins as the red blood cells traverse the urinary tract; this produces a 'tea-coloured' or 'cola-coloured' urine. The dipstick haem test is not specific for intact red blood cells and will register positive if any haem pigment, including haemoglobin or myoglobin, is present in the urine. Free haemoglobin may be present in the urine as a result of massive intravascular haemolysis due to an immune mechanism in patients with severe systemic lupus or a non-immune mechanism in severe microangiopathies. Myoglobin may be present in the urine as the result of lysis of skeletal muscle. This is usually seen in traumatic or non-traumatic rhabdomyolysis but rarely can be seen with chronic inflammatory muscle diseases in exacerbation, such as dermatomyositis and polymyositis. When the haematuria is accompanied by red blood cell casts, hypertension, and oedema, the patient is said to be nephritic. Nephritic patients have a variable amount of proteinuria and decrement in renal function.

Anatomical sources of haematuria in a patient with systemic rheumatic disease

Subjects with rheumatic disease may develop bleeding at various sites along the urinary tract either as a result of the underlying systemic disease or as a result of therapy for the rheumatic disorder. Lower urinary tract (bladder and urethra) bleeding most commonly results from urinary tract infection. Chronic immunosuppressive therapy and underlying renal insufficiency predispose to urinary tract infections, which can also present with either painless or painful microscopic or gross haematuria. The presence of white blood cells, leucocyte esterase, or nitrates on urinalysis is suggestive but not diagnostic. Therefore, a urine culture should be included in the evaluation of unexplained haematuria. In addition, cyclophosphamide, a pharmacological agent used in the therapy of several rheumatic diseases, can induce haemorrhagic cystitis and has been associated with transitional cell tumours of the uroepithelium and occasionally squamous cell carcinoma of the bladder. Haemorrhagic cystitis can present as painless microscopic or painful gross haematuria. This side-effect may be prevented by hydration and the use of mesna (2-mercaptoethane sulphonate).

Bleeding from the upper urinary tract (ureters and urinary collecting system) is most often associated with long-term ingestion of non-narcotic analgesic agents. Renal papillary necrosis occurs with the accumulation of large doses of analgesic agents containing a combination of aspirin and phenacetin or with sustained use NSAIDs. The process may present with either painless microscopic or gross haematuria. Papillary necrosis can also induce renal colic, owing to ureteral spasm as the sloughed papilla passes down the ureter to the bladder. Occasionally the diagnosis can be made by detecting the passage of gross tissue into the urine or from the presence of fragments of the sloughed papilla in the microscopic examination of the urine sediment. More commonly, the diagnosis is made from radiographic studies. The complications of renal papillary necrosis are pain and the potential for urinary tract obstruction. Papillary necrosis itself is generally not associated with a decline in renal function, although chronic interstitial nephritis is often associated with this process and may lead to progressive renal failure. Recently, chronic heavy use of over-the-counter analgesics including NSAIDs and acetaminofen, but not aspirin, has been associated with the development of endstage renal disease (Sandler *et al*. 1991; Perneger *et al*. 1994). Whether this association is due to analgesic nephropathy or to the increased prevalence of analgesic ingestion among patients with diseases which predispose them to endstage renal disease remains unclear. NSAIDs can also produce an acute interstitial nephritis, which usually presents with proteinuria and renal dysfunction. Associated inflammatory changes within the renal interstitium usually resolve, but interstitial fibrosis, which may also occur, is irreversible. The key to treatment in either case is to recognize the diagnosis and to eliminate the offending agent (Levin 1988). Occasionally, microscopic haematuria can complicate interstitial nephritis. A special case of this phenomenon may occur in the interstitial nephropathy which is associated with Sjögren's syndrome. In this entity, the haematuria may be secondary to nephrocalcinosis resulting from the distal renal tubular acidosis not infrequently encountered in patients with this disease (Moutsopoulos *et al*. 1991).

Aside from the presence of a malignancy, the greatest concern in the patient with haematuria associated with systemic rheumatic illness is the development of glomerulonephritis. Glomerular haematuria, as opposed to isolated proteinuria, generally reflects an inflammatory process of the glomerulus, often resulting from the deposition of immune complexes or antiglomerular basement membrane (**anti-GBM**) antibody. Rheumatic disorders associated with this entity include systemic lupus erythematosus, Henoch–Schönlein purpura, Wegener's granulomatosis, and cryoglobulinaemia. Non-nephrotic or nephrotic-range proteinuria, cellular casts in the urinary sediment, and a deterioration of renal function may be present. The immediate danger from acute glomerulonephritis is deterioration of renal function.

Vascular diseases of the kidney can lead to haematuria by induction of ischaemic glomerular damage. Such injury causes destruction of the glomerular filtration barrier and leakage of red blood cells into Bowman's space. This mechanism occurs in both classical and microscopic polyarteritis as well as the microangiopathic syndromes such as systemic sclerosis, malignant hypertension, thrombotic thrombocytopenic purpura, and haemolytic uraemic syndrome. Finally, renal vein thrombosis, which may occur in the nephrotic syndrome, may also lead to gross or microscopic haematuria. It should be pointed out that renal vein thrombosis is not a cause of heavy proteinuria but, rather, a consequence of it. Nephrotic syndrome, especially that due to membranous glomerulonephropathy, predisposes to the development of renal vein thrombosis because of a hypercoagulable state induced by the urinary loss of certain natural anticoagulants, including antithrombin III, and increased plasma fibrinogen resulting from accelerated liver synthesis.

Diagnostic studies

It is important to point out that the presence of a known rheumatic illness does not exclude a malignant cause of haematuria. One of the greatest concerns with the new onset of haematuria in the presence or absence of rheumatic disease is the possibility of a tumour of the urinary tract. Therefore, in contrast to the evaluation of isolated proteinuria, the work up of haematuria should prompt both a urological and a nephrological evaluation. Normal urinary tract imaging with intravenous pyelography or renal ultrasonography and cystoscopy essentially rule out the bladder, ureters, and collecting system as the source of bleeding, while the coexistence of haematuria and significant proteinuria or the presence of red blood cell casts in the urine sediment offer reasonable security that the haematuria is of glomerular origin and not due to neoplasm. Protein excretion should be quantified and a baseline measure of renal function obtained. Once non-glomerular sources of the haematuria have been excluded, the exact nature of the glomerular disorder may be determined from the results of the serological tests and laboratory examination as previously described for the proteinuric patient. In addition, the ANCA test may be helpful in diagnosing a vasculitis or, in the patient with an established vasculitis, may distinguish between vasculitic disease activity and complications of cytotoxic therapy. A renal biopsy may be indicated to establish the diagnosis or to ascertain the nature, activity, or chronicity of the glomerular lesion. These may be important in determining prognosis as well as potential response to therapy.

Role of renal biopsy in the evaluation of proteinuria and haematuria

The role of renal biopsy in the evaluation of proteinuria and haematuria has been controversial. The decision to perform a renal biopsy in a specific clinical setting varies with the practice style of the nephrologist involved. Inferences can be made about the nature and activity of the renal lesion on the basis of renal functional abnormalities, the activity of the urine sediment, and the presence or severity of hypertension. Often, a diagnosis can be established from the extrarenal manifestations of the disease and its serological abnormalities. A therapeutic decision can then be made from this clinical information. The response of the renal lesion to therapeutic intervention can be assessed by changes in renal function, reduced cast excretion in the urine sediment, diminished quantity of proteinuria, and improvement in serological abnormalities. Such an approach can certainly be defended in the patient who may be at higher than usual risk for renal biopsy because of obesity, coagulation abnormalities, or the presence of a solitary kidney.

On the other hand, there are clinical circumstances in which a renal biopsy may be essential to establish a diagnosis. Neither serological studies nor the pattern of extrarenal involvement are specific for a particular renal pathology and, therefore, renal biopsy is a fundamental diagnostic procedure. Although the presence of the C-ANCA strongly supports the diagnosis of Wegener's granulomatosis, the identification of immune deposits on a renal biopsy specimen in a patient with rapidly progressive glomerulonephritis is still the 'gold standard' and an important determinant of whether corticosteroids, immunosuppressive agents, or plasmapheresis are the most appropriate course of therapy.

An intermediate circumstance occurs when the diagnosis of systemic disease is established and a renal biopsy is being considered to ascertain the nature and severity of the glomerular lesion. The most typical case would be that of lupus nephritis, in which some nephrologists might recommend renal biopsy because of the prognostic implications of certain renal lesions. In addition to classifying patients with lupus nephritis according to the pattern of glomerular involvement (minimal, mesangial, focal proliferative, diffuse proliferative, and membranous), renal pathologists make note of the extent of activity (inflammatory, potentially reversible changes) and chronicity (sclerosing, irreversible changes) within the kidney (Balow and Austin 1988; Esdaile *et al*. 1989). Thus, given a patient with moderate renal failure, the presence of a high chronicity index may be considered a relative contraindication for intensive corticosteroid or immunosuppressive therapy because the likelihood of a therapeutic response would be outweighed by the potential toxicity. By contrast, a high activity index may prompt the nephrologist to institute aggressive treatment because of the potential for reversal of the underlying pathology (Boumpas *et al*. 1995). The more conservative nephrologist might defer renal biopsy, attempt a limited trial of corticosteroid or immunosuppressive therapy, and then, if the renal disease fails to respond, consider renal biopsy at a later date to investigate a pathological explanation for the lack of response. Both approaches can be justified, and in fact, decision-analysis studies of this issue have failed to reveal any clearly favourable approach. The rheumatologist may, therefore, wish to choose the nephrology consultant on the basis of compatibility of their practice styles in this context.

Acute renal failure

Definitions

Acute renal failure is defined as a sudden decline in renal function, usually measured by an increase in serum creatinine and blood urea nitrogen (**BUN**) or a decrease in glomerular filtration rate. The serum creatinine is a reliable marker of changes in the glomerular filtration rate if its limitations are understood. The BUN is a less reliable marker of changes in renal function, primarily because it may be elevated in several conditions where renal function is stable. These include

gastrointestinal bleeding and steroid administration. As a result, rises in the BUN are best interpreted in relation to changes in the serum creatinine. Approximately 20 per cent of urinary creatinine excretion under physiological conditions is due to tubular secretion. Therefore, as glomerular filtration declines and tubular secretion of creatinine contributes a greater fraction of creatinine excretion, increases in the serum creatinine and a fall in the creatinine clearance tend to underestimate the true decrease in glomerular filtration rate that has occurred. Furthermore, therapeutic agents such as cimetidine and trimethoprim may competitively inhibit tubular creatinine secretion, leading to increases in the serum creatinine in the absence of any changes in glomerular filtration rate. Finally, because the serum creatinine is roughly inversely proportional to creatinine clearance or glomerular filtration rate, at relatively normal levels of renal function, changes in the serum creatinine tend to be relatively insensitive. For instance, an increase in the serum creatinine from 1 to 2 mg/dl would represent a halving (50 per cent decline) of the glomerular filtration rate. Once such a change has occurred, substantial renal function has been lost, despite what appears to be only a modest increase in the serum creatinine. An increase in the serum creatinine from 1.0 to 1.1 mg/dl, if real, represents a 9 per cent decline in glomerular filtration rate, also rather significant. However, the standard laboratory assay for serum creatinine has a variation of plus 10 per cent, meaning that any change of 0.1 mg/dl in the serum creatinine could correctly or incorrectly be attributed to laboratory variation. Therefore, it is important that even seemingly small changes in the serum creatinine should not be discounted and, if a more reliable indicator of renal function is required, creatinine clearance or radionuclide studies (such as iothalamate clearance) should be considered.

Patients with acute renal failure are generally described as being oliguric or non-oliguric. Oliguria is defined as a daily urine output of less than 400 to 500 ml. This quantity represents the smallest volume of urine that can serve as a vehicle for the excretion of a typical daily osmotic load of waste products, assuming that the urine is maximally concentrated throughout the 24-h period. Therefore, a urine volume of less than 400 to 500 ml/day will necessarily imply an incomplete excretion of waste products, and will be accompanied by an increase in the concentration of some of those waste products in the blood, such as the blood urea nitrogen and serum creatinine. Oliguric renal failure has traditionally been divided into prerenal, renal, and postrenal or obstructive causes. Prerenal acute renal failure is a physiological decrease in the volume of urine in response to a true decrease in intravascular volume or an effective decrease in circulating volume. This is an appropriate response by the kidney because it preserves the extracellular fluid volume while sacrificing solute excretion. It does not represent intrinsic renal disease and, by definition, should be reversed upon restoration of an adequate effective circulating volume. Prerenal azotaemia is characterized by a blood urea nitrogen-to-creatinine ratio greater than 20, a low urinary sodium, and high urine osmolarity.

In the nephrotic syndrome, hypoalbuminaemia results in transudation of fluid from the vasculature into the interstitial space. Baroreceptors in the renal vasculature then 'sense' a decreased circulating volume. Sodium and water reabsorption increase and the volume of urine declines. Similarly in congestive heart failure, as may complicate systemic lupus erythematosus, low cardiac output is 'sensed' by the kidneys and a low urine output state develops. NSAIDs, by inhibiting renal vasodilatory prostaglandins, may also produce adverse haemodynamic changes and a decline in renal function independent of their potential to produce interstitial nephritis or proteinuria. It has been reported that sulindac has a 'renal sparing' effect because the enzyme that converts sulindac to its active form is not present in the kidney. However, the sparing effect of sulindac appears to be lost at daily dosages of greater than 300 mg. Volume depletion, hepatic disease, and lupus nephritis predispose to the adverse renal haemodynamic changes associated with the NSAIDs. The alterations in renal function are reversed upon discontinuation of the offending drug. The angiotensin-converting enzyme (**ACE**) inhibitors, including captopril, enalapril, and lisinopril, can induce decreased renal perfusion and an acute decline in renal function. Such alterations in renal function are enhanced when there is underlying volume depletion, renal vascular disease, or pre-existing glomerular disease. Although this group of drugs may be the treatment of choice for the malignant hypertension associated with scleroderma renal crisis and the microangiopathies, renal function must be monitored closely because the ACE inhibitors can dilate intrarenal efferent arterioles, leading to a decline in intraglomerular pressure and glomerular filtration rate.

Cyclosporin, a potent immunosuppressive agent used extensively in solid-organ transplantation, has been shown to be effective in selected cases of rheumatoid arthritis. The drug has also been used in a number of other autoimmune diseases including Sjögren's syndrome and psoriasis. Cyclosporin's major liability is its nephrotoxicity, which may manifest as an acute, subacute, or chronic decline in renal function. Cyclosporin produces a dose-related decline in renal blood flow and glomerular filtration rate, which usually is reversible upon decreasing or discontinuing the drug. The mechanism for this effect is not well understood but is felt by some investigators to be related to the stimulation of vasoconstrictor prostaglandins within the kidney. The NSAIDs, which inhibit the vasodilator prostaglandins within the kidney, may have an additive effect on cyclosporin nephrotoxicity.

This deleterious dose-dependent effect of cyclosporin was confirmed in another study in which renal biopsy specimens from 192 patients with autoimmune diseases treated with cyclosporin were analysed to determine the effect of cyclosporine therapy. The investigators found that cyclosporin toxicity could be minimized by limiting the cyclosporin dose to no more than 5 mg/kg body weight per day and by adjusting the medication dose to avoid increases in the serum creatinine of more then 30 per cent of baseline (Feutren *et al*. 1992). In a study comparing high- and low-dose cyclosporin therapy in rheumatoid arthritis, glomerular filtration rate declined by an average of 40 per cent in patients receiving 10 mg/kg body weight per day and by an average of 17 per cent in patients receiving 1 mg/kg body weight per day (Yocum *et al*. 1988). Other, less common, forms of cyclosporin nephrotoxicity include a renal microangiopathy and chronic interstitial nephritis, both of which are irreversible. Close monitoring of renal function is vital in all patients receiving cyclosporin so that dosage modifications can be made as soon as nephrotoxicity is detected.

Postrenal failure is oliguria caused by an intrarenal or extrarenal obstruction to urine flow. Intrarenal obstruction may be due to crystallization of a substance within the renal tubules. This might be endogenous, such as uric acid or a calcium salt, or exogenous, such as crystals of methotrexate or a sulphonamide. Extrarenal obstruction to urinary flow most commonly involves the lower urinary tract because the obstruction of only one of two functioning kidneys will allow the non-affected kidney to continue to make urine, so oliguria and renal failure will not result. Severe haemorrhagic cystitis complicating cyclophosphamide therapy may produce enough blood clot within the bladder to obstruct the flow of urine and acute oliguric renal failure develops. Bilateral papillary necrosis could lead to obstruction of the upper urinary tract through occlusion of both ureters, but this would be a most unusual event. Postrenal failure can be reversed if the site of obstruction is identified, and the obstruction is relieved before onset of renal parenchymal damage. Postrenal failure is characterized by low-to-absent urine output. Urinary sodium concentration and urine osmolarity are variable. In the acute phase, the urine electrolytes and osmolarity may mimic a prerenal picture with a low urine sodium concentration and high urine osmolarity, however, as the obstruction becomes chronic, increasing tubular dysfunction is reflected by a high urine sodium concentration and low urine osmolarity. Obstruction is best diagnosed by renal ultrasound, which may reveal hydronephrosis, and cystoscopy, which could identify the presence of clots or tissue in the bladder.

Of most concern in the patient with acute renal failure is renal parenchymal disease, because this is most likely to lead to irreversible renal damage if appropriate diagnostic and therapeutic procedures are not undertaken. Acute renal failure due to renal parenchymal disease may be oliguric or non-oliguric, the latter term meaning that, despite an apparently normal daily volume of urine, solute clearance continues to decline as measured by serum creatinine or clearance techniques. The presence of normal urinary volumes may make patient management somewhat easier. Fluid and sodium restrictions may not have to be as severe, and not as much fluid may have to be removed on dialysis. However, non-oliguric renal failure may be just as ominous as oliguric renal failure with regard to prognosis and potential response to therapy. Therefore, attention only to urinary volume without consideration to changes in the serum creatinine or creatinine clearance is misguided because severe, progressive renal insufficiency may develop without an oliguric phase. Serial tests of the serum creatinine must be done in the unstable patient to assess adequately any changes in renal function. An estimation of creatinine clearance using the Cockroft–Gault formula can then be made in order to adjust medication dosing. Urine collections of 24-h duration for creatinine clearance are less helpful in the assessment of acute renal failure because, aside from being cumbersome, the large changes in the serum creatinine over a relatively short period of time render the test inaccurate. The Cockroft–Gault formula for the estimation of endogenous creatinine clearance is calculated as follows:

Creatinine clearance = (140 – age) (ideal body weight, kg) for men
(× 0.85 for women)
(72) (serum creatinine, mg/dl)

Anatomical sources of acute renal failure in the patient with systemic rheumatic disease

Acute renal failure has several pathophysiological mechanisms in systemic rheumatic diseases.

A. Prerenal:
    1. True decreased circulating volume
        a. overdiuresis
        b. dehydration
    2. 'Effective' decreased circulating volume
        a. nephrotic syndrome
        b. congestive heart failure
        c. non-steroidal anti-inflammatory drugs

        d. cyclosporin
        e. angiotensin-converting enzyme inhibitors
B. Intrinsic renal:
    1. Acute interstitial nephritis
        a. non-steroidal anti-inflammatory agents
        b. Sjögren's syndrome
    2. Acute tubular necrosis
        a. sepsis
        b. pigment
            i. haemoglobin
            ii. myoglobin
        c. toxins/drugs
            i. antibiotics
            ii. radiocontrast media
    3. Rapid progressive glomerulonephritis
        a. immune complex disease
            i. systemic lupus erythematosus
            ii. Henoch–Schönlein purpura
            iii. cryoglobulinaemia
        b. anti-GBM disease
        c. pauci-immune
            i. polyarteritis
            ii. Wegener's granulomatosis
    4. Microangiopathic
        a. scleroderma
        b. thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome
        c. cyclosporin
C. Postrenal/obstructive:
    1. Extrarenal
        a. cyclophosphamide-induced haemorrhagic cystitis
        b. bilateral papillary necrosis
    2. Intrarenal
        a. Methotrexate-induced intratubular crystallization

The NSAIDs, used very often in patients with rheumatic disease, may be associated with the development of heavy proteinuria and acute renal failure. Renal biopsy reveals an inflammatory infiltrate in the interstitial or tubular portion of the kidney parenchyma which is called an interstitial nephritis. Interstitial nephritis induced by NSAIDs appears to be unique among the drug-induced tubular interstitial nephritides in its association with heavy proteinuria. Tubular interstitial nephritis generally occurs after prolonged exposure (mean, 5 to 6 months) to the offending agent. The propionic acid derivatives—fenoprofen, ibuprofen, and naproxen—have accounted for three-quarters of the cases reported, with fenoprofen alone accounting for over one-half of the incidence of tubular interstitial disease induced by NSAIDs. The lesions have also been found after the self-administration of over-the-counter ibuprofen and may recur after exposure to different NSAIDs of the same group or upon re-exposure to the same agent. The onset of nephrotic syndrome generally precedes that of renal failure. Approximately 10 per cent of cases have only nephrotic syndrome, about 15 per cent have only renal failure, and the remainder develop both (Abraham and Keane 1984). Wright's or Hansen's stain of the urinary sediment may rarely reveal eosinophiluria. Supportive dialysis becomes necessary in about one-third of patients. An improvement in renal function occurs within days of discontinuing the offending agent, although proteinuria may persist for weeks to months. There appear to be no definite predisposing factors that identify subjects prone to developing nephritis induced by these drugs. Alternative agents infrequently associated with nephrotoxicity include meclofenamate and sulindac.

Sjögren's syndrome is associated with a chronic inflammatory infiltrate of the renal interstitium that may lead to a progressive deterioration in renal function. More common renal manifestations are those related to tubular dysfunction, including distal renal tubular acidosis and nephrogenic diabetes insipidus. Glomerular obsolescence with sclerosis may occur in association with severely damaged tubules; heavy proteinuria is uncommon. Renal involvement is generally inferred from a rising creatinine and tubular dysfunction, which may present with metabolic acidosis, hypokalaemia, hypophosphataemia, hypouricaemia, aminoaciduria, or polyuria (El-Mallakh *et al*. 1985). However, renal involvement is generally not a limiting factor in Sjögren's syndrome. A specific medical therapy for the renal lesion is not available.

Acute tubular necrosis has several potential pathophysiological mechanisms in systemic rheumatic diseases. Perhaps the most common is sepsis complicating chronic immunosuppression. Sepsis with endotoxaemia may lead to substantial renal dysfunction, even in the absence of overt septic shock, because local release of vasoactive substances in the kidney produces vasoconstriction and shunts blood flow away from the kidneys. While early acute renal failure of sepsis may resemble prerenal azotaemia and may be characterized by a low urinary sodium and a high urinary osmolarity, it is more often associated with high urinary sodium and a low urinary osmolarity. Aggressive hydration often fails to reverse the oliguria and rising serum creatinine, which indicates that the defect is not merely a function of decreased renal perfusion. Sepsis-associated renal failure may respond to the renal vasodilator dopamine. None the less, the treatment of choice is eradication of the infection with appropriate antibiotic therapy.

Large loads of haem pigment can result in renal tubular toxicity and acute renal failure with acute tubular necrosis. Severe intravascular haemolysis, which can occur in systemic lupus and the microangiopathic diseases, can result in the formation of haemoglobin casts within the tubules, intratubular obstruction, and direct tubular toxicity. There is considerable experimental evidence that red cell stroma contributes to the nephrotoxicity of acute haemolysis by inducing vasoconstrictive changes within the kidney. Such alterations in vascular tone promote tubular reabsorption of fluid, thereby further concentrating and enhancing the precipitation of haemoglobin within the tubular lumens. Polymyositis and dermatomyositis are rarely associated with myoglobinuric acute renal failure, because these diseases tend to be chronic rather than acute diseases of muscle.

The clinical course of pigment-induced nephropathy is similar to that of other forms of acute tubular necrosis with oliguria and (because of cell breakdown) significant hyperkalaemia. Mannitol may be useful in the early stages of the renal failure to increase urine flow, thereby washing out obstructing tubular casts, producing direct renal vasodilatation, and possibly preventing swelling of glomerular cells. Once renal failure due to pigment nephropathy becomes established, management is similar to that of other forms of acute renal failure. The electrolyte disorders, such as hyperkalaemia, that may be associated with cell lysis may necessitate early dialysis.

Rapidly progressive glomerulonephritis is a catastrophic form of inflammatory renal disease that sometimes complicates systemic rheumatic disease. It is a syndrome characterized by hypertension, proteinuria, haematuria with red blood cell casts, and a rapid decline in renal function. The pathological correlate of rapidly progressive glomerulonephritis is the formation of epithelial cell crescents in Bowman's space, often accompanied by a necrotizing vasculitis of the arterioles and glomerular capillaries. There are a number of systemic rheumatic diseases that can be associated with this type of glomerulonephritis, including systemic lupus erythematosus, polyarteritis nodosa, Wegener's granulomatosis, and cryoglobulinaemia. If the diagnosis can be established on the basis of the extrarenal manifestations of these diseases, then the cause of a rapidly progressive glomerulonephritis should be apparent. However, the glomerulonephritis can be the initial manifestation of disease. At times, its extrarenal manifestations are not sufficiently specific to allow for a diagnosis. In such circumstances, the immunopathology of the renal lesion has traditionally been the basis for classifying the various forms of the rapidly progressive disease. The detection of deposits within the glomerular capillaries by immunofluorescence microscopy, or of subepithelial or subendothelial deposits by electron microscopy, suggests an immune-complex pathogenesis that is characteristic of lupus nephritis, postinfectious glomerulonephritis, or cryoglobulinaemic nephritis. The presence of linear immunofluorescence along the glomerular basement membrane is diagnostic for glomerulonephritis mediated by anti-GBM antibody which, in the presence of pulmonary haemorrhage, is termed Goodpasture's syndrome.

Much less well defined, however, are the forms of rapidly progressive glomerulonephritis that are not associated with immune-complex deposits or anti-GBM binding within the glomerulus, which have been termed pauci-immune glomerulonephritis. The diagnosis usually depends upon the pattern of extrarenal manifestations and includes polyarteritis nodosa in the presence of systemic necrotizing arteritis, Wegener's granulomatosis in the presence of pulmonary necrotizing granulomas, and idiopathic crescentic glomerulonephritis when no extrarenal disease is present. A scheme for the differential diagnosis of rapidly progressive glomerulonephritis is summarized in Table 2.

Group	Glomerular immunofluorescence	Serological markers	Extrarenal manifestations	Diagnosis
Immune complex	Granular	Antinuclear antibodies	Skin, joints, haematological	Systemic lupus
		Cryoglobulins	Skin, joints	Cryoglobulinaemic glomerulonephritis
		Antistreptococcal antibodies	None	Poststreptococcal glomerulonephritis
		HBsAg	Skin, joints	Hepatitis-associated glomerulonephritis
		Increased IgA	Skin, joints, abdominal pain	Henoch–Schönlein purpura
Anti-GBM[a]	Linear	Anti-GBM antibodies	Lung haemorrhage	Goodpasture's syndrome
			None	Anti-GBM glomerulonephritis
Pauci-immune	None	Mostly c-ANCA[b]	Lungs, sinuses, joints	Wegener's granulomatosis
		c-ANCA or p-ANCA[c]	Skin, joints, lungs, nerves	Polyarteritis nodosa
		Mostly p-ANCA	None	Idiopathic crescentic glomerulonephritis

[a]Antiglomerular basement membrane. [b]Cytoplasmic, and [c]perinuclear antineutrophil cytoplasmic autoantibodies.

Table 2 Differential diagnosis of rapidly progressive glomerulonephritis

It has now been demonstrated that idiopathic, rapidly progressive glomerulonephritis and vasculitis-associated glomerulonephritis may share a common serological marker, antineutrophil cytoplasmic autoantibodies (**ANCA**). However, the ANCA test has also been associated with other systemic disorders in which renal disease may be absent. The ANCA test produces three patterns of indirect immunofluorescent staining: fine granular cytoplasmic (**c-ANCA**), perinuclear (**p-ANCA**), and a diffuse, atypical ANCA (**a-ANCA**) (Gross and Csernok 1995). The c-ANCA and p-ANCA immunofluorescent patterns are shown in Fig. 1.

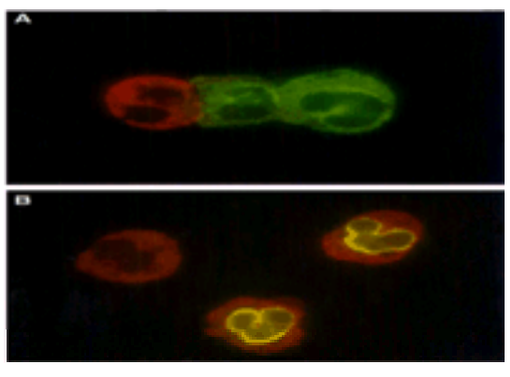

Fig. 1 Antineutrophil cytoplasmic autoantibody (ANCA) indirect immunofluorescence patterns on neutrophils (× 1000). (a) Cytoplasmic (c-ANCA) pattern with antigen specificity for proteinase 3 (PR3-ANCA), and a negative eosinophil (as seen on both ethanol- and formalin-fixed neutrophils). (b) Artefactual perinuclear (p-ANCA) staining on ethanol-fixed neutrophils, with a negative eosinophil. p-ANCA immunofluorescence due to myeloperoxidase antibodies (MPO-ANCA) appears cytoplasmic on formalin-fixed neutrophils.

c-ANCA reflects an autoantibody response against a 29-kDa serine protease, known as proteinase 3 (**PR3**), which is localized within the azurophilic granules of quiescent neutrophils (Niles *et al*. 1989) as well as on the cell surface of activated neutrophils (Csernok *et al*. 1990). Localized in lysosomes, PR3 is a bifunctional protein with both enzymatic and antimicrobial functions. Acting as a proteinase, it hydrolyses naphthol-ASD-chloracetate.

Although several azurophilic granule enzymes can drive the p-ANCA response, the principal autoantigen is myeloperoxidase (**MPO**) (Falk and Jennette 1988; Wiik *et al*. 1995). MPO is a 140-kDa cationic protein of azurophilic granules of neutrophils and certain granules of monocytes that generates chlorinated oxygen species upon activation of the cell by a microbe.

The autoantigen(s) stimulating the a-ANCA response has not been identified. PR3 and MPO are the most commonly-identified autoantigens triggering the c-ANCA and p-ANCA responses, respectively, and therefore the terms PR3-ANCA and MPO-ANCA are coming into more common usage.

PR3-ANCA (c-ANCA) is a sensitive and specific autoantibody for active Wegener's granulomatosis. Although the frequency of this autoantibody in all patients with Wegener's granulomatosis approximates 90 to 95 per cent (Kallenberg *et al*. 1994), the overall sensitivity is estimated to be 66 per cent and the overall specificity is 98 per cent (Rao *et al*. 1995). During active disease, the pooled sensitivity increases to 91 per cent and the pooled specificity rises to 99 per cent. It remains uncertain, however, whether or not disease activity correlates directly with autoantibody titres. Based on an estimated 5 per cent prevalence of Wegener's granulomatosis, 37 per cent of patients with a positive c-ANCA may have a false-positive test result. These data underscore the importance of employing the c-ANCA test as corroborating evidence for the diagnosis of Wegener's granulomatosis in patients with the appropriate clinical stigmas and disease activity.

The p-ANCA is most commonly associated with microscopic polyangiitis, Churg–Strauss syndrome, and pauci-immune glomerulonephritis. These disorders tend to be associated with MPO-ANCA. The p-ANCA pattern occurs in less than 5 per cent of subjects with Wegener's granulomatosis and classic polyarteritis nodosa.

At a recent consensus conference, the idiopathic vasculitides were reclassified into large, medium, and small vessel vasculitis (Jennette *et al*. 1994). Although Wegener's granulomatosis, microscopic polyangiitis, and Churg–Strauss syndrome were the small vessel vasculitic disorders predominantly associated with a positive ANCA test, it is also known that other non-renal and non-vasculitic processes, including ulcerative colitis and primary sclerosing cholangitis, are often associated with a positive p-ANCA.

Perhaps the most malignant form of renal involvement in the systemic rheumatic diseases is the microangiopathy that may be seen in systemic sclerosis, the thrombotic thrombocytopenic purpura/haemolytic uraemia syndrome, and with the use of cyclosporin. The presence of microscopic renal lesions in patients with systemic sclerosis may be as high as 80 per cent, although only 40 to 50 per cent will present with clinical renal involvement, including hypertension, proteinuria, or azotaemia. Hypertension is very ominous in patients with systemic sclerosis, with the death rate among hypertensive patients being about 2.5 times greater than among those with normal blood pressure. There are two distinct forms of hypertension seen in patients with systemic sclerosis. Mild to moderate hypertension associated with some degree of proteinuria may lead to the slow development of renal failure, and the extrarenal manifestations of systemic sclerosis usually dominate the clinical picture. However, in 15 to 20 per cent of patients who develop hypertension in the setting of systemic sclerosis, the onset is abrupt with severe elevation of blood pressure to greater than 130 mmHg diastolic, usually associated with cardiac failure and rapid deterioration of renal function (Steen *et al*. 1984). In some patients, severe hypertension may be the presenting feature of systemic sclerosis, with little involvement of skin, peripheral vessels, or joints. Classically, the small arterioles of the kidney in patients with the malignant form of hypertension in systemic sclerosis show extensive fibrinoid necrosis and microthrombus formation. Glomerular changes are variable and show varying degrees of thrombosis and necrosis secondary to ischaemia. Obviously, the accelerated hypertension and rapidly progressive renal failure of systemic sclerosis are life-threatening and demand prompt, intensive intervention. The initial priority is to bring the blood pressure under control, and the ACE inhibitors have been the mainstay of therapy in this regard (Asher and Murray 1991). Even if oliguria and progressive renal failure supervene despite control of blood pressure, antihypertensive therapy should be continued because it will protect other organs from the damaging effects of severe hypertension and renal function may return after months of dialysis support (Chapman *et al*. 1986).

Thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome are classical examples of microangiopathic haemolytic anaemia and have many features in common including anaemia, thrombocytopenia, and renal involvement. The two syndromes are similar in most of their clinical and laboratory findings, differing primarily in age of onset and extent of renal involvement. An abnormal urinalysis characterized by haematuria, haemoglobinuria, proteinuria, hyaline, and granular casts is seen in the vast majority of patients with either disease, but those with haemolytic uraemic syndrome have a 90 per cent incidence of associated renal function abnormalities compared with a 50 per cent incidence in patients with thrombotic thrombocytopenic purpura. The classical pathological finding in the kidney in both syndromes is occlusive lesions or arterioles and glomerular capillaries with fibrin, platelets, and red blood cells. Glomerular capillaries also show hyaline thrombosis with areas of infarction. The pathogenesis of these diseases is not completely understood, but it appears that some form of endothelial injury may be the

underlying insult. Patients with systemic lupus erythematosus have been known to progress to thrombotic thrombocytopenic purpura (Gelfand *et al*. 1985), and it is also seen in the setting of severe disseminated intravascular coagulation, sepsis, and other vasculitides including polyarteritis nodosa and Wegener's granulomatosis. Plasma exchange has become the mainstay of therapy in thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome. Renal failure with its associated complications remains the most common cause of death (Eknoyan and Riggs 1986).

Principles of treatment

Several general principles of evaluation and management of acute renal dysfunction in systemic rheumatic diseases should be emphasized. Deterioration of renal function is usually associated with moderate to severe hypertension. If incompletely treated, hypertension will further compound the renal injury by producing more intrarenal vascular damage. Therefore, intensive control of blood pressure is imperative. Malignant hypertension associated with renal vasculitis, systemic sclerosis, or microangiopathic disease results from extremely high concentrations of renin and angiotensin, released in response to focal areas of renal ischaemia. The ACE inhibitors, therefore, may be the only oral agents effective in the sustained reduction of blood pressure. Severe hypertension complicated by stroke, hypertensive encephalopathy, coronary ischaemia, pulmonary oedema, or aortic dissection requires concentrated intervention with confinement to an intensive care unit and use of a rapidly acting, parenteral, antihypertensive agent. There may be a further decline in renal function after hypertension has come under control, because of decreased renal perfusion pressure in the setting of high renal vascular resistance. However, once renal autoregulatory processes have stabilized, gradual return of renal function to physiological levels takes place after the successful control of blood pressure.

The chief cause of complications in the setting of acute renal failure is not the azotaemia but the associated fluid and electrolyte abnormalities. The rheumatologist should manage these abnormalities with the nephrologist. In the acutely ill, highly catabolic patient with systemic illness, early and frequent dialysis may be required. Fluid overload may compound hypertension, leading to further renal injury, and should be managed intensively with high-dose diuretics. The rheumatologist and nephrologist should review the prescribed medications critically as soon as acute renal insufficiency is recognized. The dosage schedule for potentially nephrotoxic agents such as NSAIDs, aminoglycoside antibiotics, and amphotericin B should be adjusted for the level of renal failure or discontinued if possible. Intravascular radiocontrast procedures should be avoided during acute renal insufficiency. If it is necessary to use a diagnostic procedure requiring contrast, a minimal dose should be employed and the patient intensively hydrated before, during, and after the procedure to promote excretion of the radiocontrast. The presence of a highly catabolic state caused by corticosteroid therapy, gastrointestinal bleeding, parenteral nutrition, or septicaemia can induce a rise in the blood urea nitrogen by as much as 50 mg/dl per day in the setting of acute renal failure. Such levels of azotaemia are clearly detrimental to platelet and neutrophil function and may potentiate a bleeding diathesis or further compromise host defenses. Therefore, intensive daily or continuous dialysis may be warranted.

Course and prognosis

The prognosis of acute renal failure is determined both by the underlying disease and by the quality of medical management. Subjects with renal dysfunction complicating a rheumatic disorder should be followed-up jointly by a rheumatologist and nephrologist.

Hypertension

Introduction

Hypertension is a very common finding in the adult population, affecting as many as 20 to 30 per cent of individuals over the age of 40. Raised blood pressure may be an incidental finding in the patient with systemic rheumatic illness and does not necessarily represent renal involvement from their disease. However, the onset of acute hypertension in a patient who was previously normotensive or whose blood pressure was well controlled may suggest renal involvement and may predate the onset of haematuria, proteinuria, or renal insufficiency. Anyone with a rheumatic disease who develops severe hypertension should be intensively investigated for the cause, and referral to a nephrologist should be considered. Intensive control of the blood pressure is important to minimize the renal and extrarenal complications of the severe hypertension, and a nephrologist may be best equipped to choose appropriate antihypertensive therapy in this setting.

Specific diseases

Classical polyarteritis may produce hypertension through involvement of medium-sized arteries within the kidney, leading to distal areas of decreased perfusion and the release of potent vasoconstrictor substances. The glomeruli may not be directly affected in this polyarteritis and, therefore, the presence of minimal haematuria, proteinuria, or other abnormal urinary sediment findings may presage abnormal results from renal function tests. Severe hypertension is, in fact, the most common renal manifestation of classical polyarteritis, affecting as many as 35 per cent of subjects with no other clinical renal manifestations of the disease. The diagnosis of classical polyarteritis in this setting is generally made from the extrarenal manifestations, most commonly mesenteric vasculitis with abdominal pain, abnormal liver function, and mononeuritis multiplex. Up to one-third will have a positive serology for hepatitis B surface antigen. In the absence of proteinuria or haematuria suggesting active glomerular involvement, renal biopsy is not helpful in the confirmation of the diagnosis. However, even without hypertension, polyarteritis nodosa is often found to involve medium-sized arteries on renal arteriography, characterized by segmental narrowing and aneurysmal dilatation.

Rapidly progressive glomerulonephritis can be associated with severe hypertension in the setting of acute glomerular injury. Intensive control of the blood pressure should be the objective, even before a specific diagnosis of the glomerular disease has been established. Inflammation is often compounded by ischaemia and, therefore, the hypertension will often prove refractory. High doses of multiple antihypertensive agents may be required for its control. A further decline in renal function may be anticipated as blood pressure control is achieved, because profound abnormalities in autoregulation of renal blood flow can occur, impairing the ability of the glomeruli to adapt to a fall in renal perfusion pressure. None the less, a rise in the serum creatinine does not obviate the necessity to reduce the diastolic pressure to between 90 and 100 mmHg.

Summary and conclusions

The purpose of this chapter has been to provide the rheumatologist with a survey of the most important renal manifestations of systemic rheumatic illnesses, grouped according to the presentation most likely to be encountered in clinical practice. Table 3 is a list of important points to remember. Proteinuria, haematuria, acute renal failure, and hypertension can be ominous signs of direct renal involvement in systemic rheumatic diseases. However, they may also represent indirect involvement by complications of the primary disorder or its treatment, in which case the prognosis tends to be more favourable. The role of the rheumatologist here is to be familiar with the diseases most likely to affect the kidney and their renal manifestations, and to obtain the appropriate screening tests so that renal involvement can be identified promptly and appropriate intervention initiated without delay. When the patient does develop urinary abnormalities, decreasing renal function, or severe hypertension, the nephrologist should be involved early to assist the rheumatologist in the diagnosis and treatment of the renal disorder. Renal biopsy is a useful tool in many of these settings, but it should be understood that the information gained from it is more likely to be helpful in establishing the pathophysiological background, extent of activity, and chronicity of the renal lesion than it is to provide a specific diagnosis. The diagnosis of most of these systemic diseases is more likely to be established from the nature and pattern of extrarenal manifestations, and from serological abnormalities. Findings on renal biopsy can be helpful in choosing therapy in certain individuals, based on the confirmation of a suspected diagnosis, the activity compared with the chronicity of the lesion, the likelihood of responsiveness to therapy, and occasionally, an unexpected finding such as drug nephrotoxicity or amyloidosis.

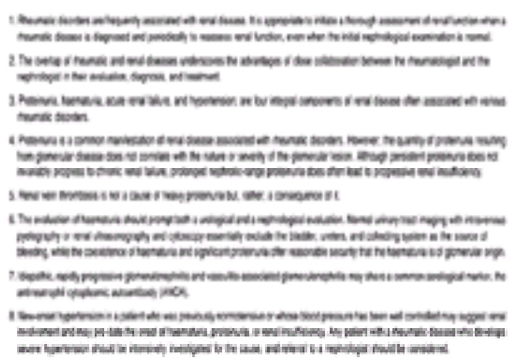

Table 3 Important points to remember

Many deaths associated with systemic rheumatic disease are due to renal involvement. The improvement in diagnosis and treatment as well as the widespread availability of dialysis for chronic conditions have significantly reduced fatality for many of these illnesses. None the less, the presence of renal involvement remains an ominous prognostic sign in many of these diseases and should be treated seriously. Relatively recent discoveries concerning the immunopathogenesis of the renal involvement in some of these illnesses are promising but also reminds much that yet remains unknown about these disorders.

1.3.12 Psychiatric issues in rheumatology

Malcolm P. Rogers and Simon Helfgott

Introduction

The practice of rheumatology is not unlike the practice of psychiatry. Relationships with patients tend to be long term, most of the diseases are chronic and unpredictable in course, and the treatments available seldom cure but often are effective in increasing function and controlling the underlying disease. Function is an important focus of both specialties. The two disciplines have avoided a high-technology, disease-orientated approach in favour of a more comprehensive view of the patient's illness, open to relevant psychological and social data. Interestingly, a study by the Rand Corporation on the effects of six chronic disorders, including major depression and rheumatoid arthritis, showed that both had a similarly adverse affect on quality of life (Stewart *et al*. 1989). The number of days of missed work and time spent in bed at home were roughly equivalent for both disorders.

Stress and psychoneuroimmunology

While most of this chapter will concentrate on the recognition and treatment of the psychiatric complaints and disorders that occur frequently among patients with rheumatic disease, it is worthwhile first briefly discussing the topic of psychoneuroimmunology. There is an extensive literature on the possible effects of psychological stress and other emotional states on the onset and the course of rheumatic disease, particularly rheumatoid arthritis and systemic lupus erythematosus (Rimon 1989). For years, experienced clinicians and patients frequently connected flare-ups of disease with stressful life events. It is fair to say that the issue is not fully settled from a scientific point of view, despite many years of effort. The principal difficulty has been the practical necessity of relying on retrospective analyses. Some of the more imaginative approaches have included studies of identical twins discordant for rheumatoid arthritis (Meyerowitz *et al*. 1968), and attempted quantitation of the amount of life stress during the 6 months immediately before a flare-up of disease (Heisel 1972). These and other studies have provided some suggestive evidence for a link between stress and illness but there have been negative results as well. These questions helped to stimulate what has now become the new and evolving field of psychoneuroimmunology (Kiecolt-Glaser and Glaser 1989). George Solomon was one of the first to ask whether psychological stress might influence rheumatoid arthritis by its effect on the immune system (Solomon 1969). Using an animal model of inflammatory arthritis he demonstrated that stress could indeed alter parts of the immune response. Subsequent studies with the model of arthritis induced by type II collagen in rodents have shown that various kinds of psychological stress have important but often conflicting effects on inflammation in joints, apparently without directly affecting antibody or cellular immune responses (Rogers *et al*. 1980).

Psychoneuroimmunology has also explored the effects of bereavement, depression, and relaxation on immunity in a variety of clinical states (Ader 1991). In simple terms, experimental and naturally occurring stress has been associated with altered measures of both cellular and humoral immunity. However, there is no clear demonstration as yet that these altered measures are biologically significant in the sense that they cause or adversely affect human disease. Certain forms of psychological intervention in cancer, for example, have been shown positively to affect the incidence of illness and death. Whether the psychological mechanism responsible for this clinical benefit acts through an immunological pathway remains unanswered.

Psychiatric manifestations of rheumatic diseases

The psychiatric manifestations of rheumatic diseases fall into three basic categories: (i) organic diseases caused by central nervous involvement of the underlying condition (primary disorders); (ii) psychiatric disturbances that are psychological 'reactions' to the impairments of rheumatic disease (secondary disorders); (iii) drug-induced psychiatric disorders (tertiary disorders). Each group is outlined below in Table 1, Table 3, and Table 4, respectively. The difficult task for the rheumatologist or psychiatrist is to define which of the three groups best describes the underlying cause of the psychiatric impairment or whether there is an independent, primary psychiatric disorder. This chapter will attempt to outline an approach to the evaluation of psychiatric illness in the patient with rheumatic disease.

Systemic lupus erythematosus	Affective disorders Psychosis Organic mental disorder
Primary Sjögren's syndrome	Affective disorders Paranoid ideation Personality changes
Rheumatoid arthritis	Organic mental disorder (rare)
Giant-cell arteritis/polymyalgia rheumatica	Organic mental disorder Depression
Granulomatous angiitis of the central nervous system	Organic mental disorder
Systemic necrotizing vasculitis–polyarteritis nodosa/ Wegener's granulomatosis	Organic mental disorder Seizures
Cogan's syndrome	Seizures
Wegener's disease	Organic mental disorder Hypersomnia
Behçet's syndrome	Organic mental disorder Seizures
Sarcoidosis	Organic mental disorder Psychosis Affective disorder, hyper-controllable Confusion
Lyme disease	Organic mental disorder Cognitive impairment Sleep disturbance
Amyloidosis	Organic mental disorder

Table 1 Rheumatic diseases with primary psychiatric involvement

Anti-double-stranded DNA antibodies
Depressed complement levels; C3, C4
Lymphopenia
Antineurofilament antibody
Anticardiolipin antibody
Antiribosomal-P antibodies
Antineuronal antibodies

Table 3 Proposed laboratory correlates of neuropsychiatric systemic lupus erythematosus

Disease	Psychiatric manifestations
Rheumatoid arthritis Juvenile chronic arthritis	Mood disturbance (from endogenous depression to grief), anxiety
Spondyarthropathies Osteoarthritis Polymyalgia rheumatica Systemic sclerosis Systemic lupus erythematosus Primary Sjögren's syndrome Myositis	

Table 4 Rheumatological disease with secondary psychiatric involvement

Rheumatic disease with primary psychiatric involvement (Table 1)

Organic mental syndromes occur frequently in this category. They include dementia, delirium, cognitive impairment, and sometimes more subtle changes of personality and affect. A disturbance of orientation, memory, language, or attention (and obviously specific motor and sensory symptoms) all strongly suggest organic disease of the central nervous system, and therefore help to identify primary psychiatric involvement.

Systemic lupus erythematosus

Systemic lupus can have major effects on the central nervous system, producing a variety of neuropsychiatric symptoms (see Chapter 5.7.1). Nearly a century ago Sir William Osler described these central nervous symptoms, including delirium, aphasia, and hemiplegia, and speculated that they may relate to vascular changes in the brain (Osler 1903). Daly (1942) was the first to emphasize the varied psychiatric presentations seen with systemic lupus, reporting 'toxic delirium' with confusion and disorientation as well as psychoses with paranoid features. Other psychiatric features include affective disorders, dementia, phobias, and autistic behaviour (Adelman *et al*. 1986). The true incidence of psychiatric symptoms is difficult to ascertain; most large series report an incidence of 15 to 20 per cent (Hay *et al*. 1992).

Clinical features

The psychiatric manifestations can sometimes predate the other clinical manifestations of systemic lupus. Most patients show some 'organic' symptoms suggestive of an organic mental disorder. However, a schizophrenic-like picture with hallucinations and paranoia and a grossly clear sensorium is sometimes found. Autistic behaviour has been seen, but infrequently. About half of the psychiatric episodes in the Johns Hopkins' study were accompanied by neurological signs or symptoms, with seizures being significantly associated (Feinglass *et al*. 1976). One-third of patients had no neurological features at any point in the course of the disease.

Using standardized neuropsychological tests, a number of investigators noted significantly more cognitive impairment in patients with systemic lupus than in those with rheumatoid arthritis and in controls (Carbotte *et al*. 1986; Hanly *et al*. 1992a; Denburg *et al*. 1993). Neuropsychological testing has the advantage of being more directly relevant to the functional and behavioural capacity of the patient. Easily administered tests include the Bender Gestalt (with immediate and delayed recall), trail making, verbal fluency, and the Wechsler Adult Intelligence Scale–Revised.

Psychiatric assessment

Psychiatric assessment consists of a careful history, including the history of pre-existing psychiatric disorders or substance abuse (Table 2). It is very useful to ascertain the patient's usual baseline of psychological functioning, including educational background, coping mechanisms, and view of their current illness. Particular investigation should focus on possible somatoform symptoms, such as conversion reactions, hypochondriasis, and frequent procedures or surgical interventions without evidence for organic disease. In addition, mental status should be carefully examined, with particular attention to orientation, memory (both remote and short-term), attention, language, reasoning, and visuospatial disturbance. Tests should include memory for remote events, such as names of political figures and the detail of historical events, as well as for repetition and retention of new information, such as four random words. Attention can be tested by having the patient repeat digits backward and forward, by naming the days of the week in reverse, or by subtracting serial 3s or 7s. Brief tests of naming objects in the room, reading, repeating a phrase, and writing a sentence should be given. Having the person copy a simple geometric figure or drawing a clock and putting in the time are effective screening techniques for visuospatial deficits. The best way to elicit symptoms of psychosis is to inquire about any unusual occurrences, unusual perceptions, the hearing or seeing of things that seem strange or unreal, or of possible fears that others are trying to hurt them.

History
Prior psychiatric illness
Prior substance abuse
Educational level
Family support
Mental status
Appearance and behaviour
Mood and affect
Speech
Thought content and process: rationality, delusions, hallucinations
Attentiveness (digit span, serial 7 subtraction, days of the week)
Orientation (time, person, place)
Memory (remote: political, historical, personal dates, etc.); new: remember four random words after 5 min)
Judgement
Intellect (abstraction, comprehension)

Table 2 The bedside psychiatric examination

Patients who show clear difficulties with such 'bedside' screening tests are most probably experiencing some organic brain disturbance. Others who do well on such tests yet still report prominent subjective difficulties may be suffering from more subtle organic disturbances. Both should have more detailed neuropsychological tests from experienced neuropsychologists.

The psychiatric disturbances may be due to failure of other organs. For example, uraemic encephalopathy may ensue, and renal failure or vasculitis with secondary severe hypertension can also result in hypertensive encephalopathy with the development of headaches, disorientation, coma, and seizures. Occult central nervous infections, especially in the immunocompromised patient, can lead to an organic mental syndrome. As mentioned later, high doses of corticosteroids, the mainstay of therapy for systemic lupus, can directly cause psychiatric disturbances.

Establishing the diagnosis of neuropsychiatric systemic lupus erythematosus

This remains a difficult task, even for the most astute clinician. The diagnosis should be considered in a young woman presenting with psychotic features, even if no other clinical or laboratory features of systemic lupus are present, as these psychiatric signs and symptoms may well be the initial presentation. In a study of 296 patients admitted to an acute psychiatric ward in Nottingham, United Kingdom, approx. 1 per cent of the patients met criteria for the diagnosis of systemic lupus (Hopkinson and Powell 1990). There is no consensus on the association between systemic and psychiatric lupus; most series have failed to document any relation

between the two.

A number of immunological tests have been proposed as useful in the evaluation of neuropsychiatric systemic lupus (Table 3). In a series of 70 female patients (Hanly *et al*. 1993), antineuronal antibodies were detected in 34 per cent, lymphocytotoxic antibodies in 47 per cent, anti-P antibodies in 17 per cent, and anticardiolipin antibodies in 24 per cent. However, there was no significant difference in the prevalence of any of these antibodies in patients with and without cognitive impairment. On the other hand, work by Denburg and colleagues (Denburg *et al*. 1994) has suggested a relation between specific cognitive deficits, namely visuospatial dysfunction, and the presence of lymphocytotoxic antibodies.

Anticardiolipin antibodies can be found in patients with systemic lupus erythematosus or with the primary antiphospholipid syndrome (Love and Santoro 1990). Cerebrovascular thrombotic events, particularly stroke, can develop. An organic mental syndrome may arise, although isolated psychiatric disease without overt neurological signs is probably rare.

Concentrations of interferon-a were increased in the cerebrospinal fluid in 5 of 6 patients with lupus psychosis (Shiozawa *et al*. 1992); these decreased when the psychosis subsided and they did not rise following seizures alone. These limited findings suggest that interferon-a, possibly synthesized in the brain, may play some part in the pathogenesis of psychosis in systemic lupus.

One study measured a variety of cytokines, prostaglandins, and autoantibodies in the cerebrospinal fluid of patients with systemic lupus and infection (Tsai *et al*. 1994). The results suggested that high levels of interleukin (**IL**)-6 and prostaglandin E_2 in the cerebrospinal fluid favoured a diagnosis of infection of the central nervous system while modestly elevated IL-6, high IgG, and autoantibodies against calf thymus antigens in the cerebrospinal fluid suggested a diagnosis of neuropsychiatric systemic lupus.

The autopsy findings in lupus of the central nervous system have recently been reviewed. Ellison *et al*. (1993) described small-vessel hyalinization and thickening, with fragments of platelet membrane found in the wails of small cortical and meningeal vessels. Concurrent thrombus formation, possibly related to antiphospholipid antibody formation, may facilitate the incorporation of platelet fragments into small-vessel walls, with resultant thickening and irregularity of the vessels. In another series of seven patients with confirmed neuropsychiatric systemic lupus (Hanly *et al*. 1992b), four were found at autopsy to have multifocal cerebral cortical microinfarcts associated with microvascular injury. These studies suggest a vascular basis for neuropsychiatric systemic lupus in many, but not all patients.

Electroencephalography

The electroencephalogram may help to confirm the presence of an abnormal seizure focus that manifests as episodic changes in behaviour and mentation (e.g., temporal lobe epilepsy). It may help to distinguish delirium from a primary mental disorder with cognitive dysfunction such as acute mania. Clinically, delirium is characterized by diminished attention and sometimes diminished level of consciousness, associated with disorientation, agitation, reversal of the sleep-wakefulness cycle, perceptual distortions and misinterpretations, and impairment of short-term memory. Most patients with delirium have diffuse slowing of the background electroencephalogram, unlike in most primary mental disorders (McNamara 1991). Ritchlin *et al*. (1992) found that using neurometric quantitative electroencephalography as an indicator of cerebral dysfunction in patients with systemic lupus produced a diagnostic sensitivity of 87 per cent and specificity of 75 per cent.

Brain imaging

Advances in technology have resulted in four imaging techniques that may be helpful in evaluating neuropsychiatric systemic lupus; these four are outlined next.

Computed tomography (CT)

This technique initially described the presence of steroid-induced cortical atrophy (Bentson 1978) and calcification of the paraventricular areas (Daud and Norudin 1988) seen in systemic lupus. For the most part, CT has been supplanted by MRI. However, CT scans continue to serve an important diagnostic role in identifying emergent haemorrhage or cerebral infarction. They are also considerably less expensive than MRI.

Magnetic resonance imaging (MRI)

MRI is far more sensitive than CT for detecting disease of the central nervous system, and can demonstrate the reversal of some of the brain lesions in lupus (McCune *et al*. 1988). Three different patterns of disease can be demonstrated by MRI: cerebral infarction, multiple small areas of increased signal intensity secondary to microinfarctions, and focal areas of increased intensity in the cerebral grey matter (Bell *et al*. 1991).

A recent study (Baum *et al*. 1993) highlights the possibilities and difficulties in interpreting the MRI in neuropsychiatric systemic lupus. Twenty-one consecutive outpatients with systemic lupus were studied: 12 had focal lesions, primarily in the frontal lobes. Patients with focal neurological signs were more likely to have lesions on MRI. Ten patients had paraventricular hyperintensities, a finding noted in several other series as well. Yet seven patients with abnormal MRI had no neuropsychiatric symptoms, and eleven had neuropsychiatric symptoms and signs that did not correlate with MRI findings.

To summarize, MRI may fail to detect abnormalities in diffuse, non-focal, or mild lupus of the central nervous system. It is sensitive to focal lesions that are large enough to produce clear-cut localizing signs on neurological or cognitive examination.

Single photon-emission CT (SPECT)

SPECT appears to have limited value in the evaluation of neuropsychiatric systemic lupus. Rogers *et al*. (1992) noted abnormal findings in 8/18 patients with subtle cognitive and affective changes, including a diffuse bilateral temporal-parietal pattern previously noted only in Alzheimer's disease. Another study (Rubbert *et al*. 1993) found normal SPECT scans in 90 per cent of those with overt neurological signs. SPECT may have a useful role in patients with diffuse symptoms, such as cognitive dysfunction and psychosis, in which MRI may be insensitive.

Positron-emission tomography (PET)

PET assesses cerebral blood flow and glucose metabolism. Carbotte *et al*. (1992) described an intensive longitudinal study of three women with neuropsychiatric systemic lupus. Fluorodeoxyglucose uptake indicated abnormalities in all three that had not been identified on plain CT, yet corresponded well with localizable cognitive deficits. Changes in each patient's cognitive profile on reassessment paralleled changes on PET. The high cost and limited availability of the necessary equipment has precluded more widespread use of PET.

Treatment of the psychiatric symptoms

The usual treatments, ranging from antidepressants to antipsychotic medications and psychotherapy, have an important role. However, one must treat the underlying biological cause, the systemic lupus, as well. If the patient develops a frank psychosis on corticosteroids, the first task would be to define the aetiology of the change in mental status; is this drug-induced or a manifestation of the lupus or, less commonly, due to an occult infection of the central nervous system in an immunocompromised host? Generally, doses of prednisone in the range of 1 to 1.5 mg/kg per day have been given orally or systemically with variable results. Although steroid-induced psychosis can occur, the neuropsychiatric manifestations in patients taking corticosteroids are much more likely to be due to the disease than to the drug.

Patients who fail to respond to corticosteroids have been treated with cyclophosphamide: one study from the National Institutes of Health suggests the use of monthly pulse administrations of 0.75 to 1.0 g/m^2 of cyclophosphamide (Boumpas *et al*. 1991). The sample in most of these studies of treatment is too small for any meaningful extrapolation. In a retrospective study of 31 patients (Neuwelt *et al*. 1995) with severe neuropsychiatric systemic lupus refractory to corticosteroids and other oral immunosuppressive agents, intravenous cyclophosphamide was associated with substantial improvement in 18 patients, and stabilization of the condition in nine others. Patients with an organic brain syndrome or a large number of neuropsychiatric manifestations had a poorer outcome. The treatment of anticardiolipin-related thrombotic events remains controversial; recent studies suggest that warfarin appears to be superior to low dose aspirin in the management of this condition

(Khamashta *et al*. 1995)

Sjögren's syndrome

One study found a high incidence of psychopathology in a group of patients with primary Sjögren's syndrome, in particular, high levels of hostility and paranoid ideation (Angelopoulos *et al*. 1988). Other studies have identified an increased incidence of affective disorders, cognitive impairment (in attention and concentration), and a correlation between neurological and psychiatric symptoms suggestive of an organic mental disorder (Malinow *et al*. 1985). An increased incidence of neuropsychiatric symptoms may also accompany secondary Sjögren's syndrome.

Rheumatoid arthritis

The only primary neuropsychiatric syndrome in rheumatoid arthritis, described in two cases, is an organic mental disorder caused by rheumatoid nodules in the choroid plexus (Kim *et al*. 1982). Rarely, rheumatoid cranial vasculitis also appears as an organic mental disorder.

The vasculitides

The vasculitides associated with neuropsychiatric factors are listed in Table 1. Granulomatous angiitis of the central nervous system is a rare condition that presents with non-specific signs and symptoms including acute or subacute onset of confusion, headache, personality change, paresis, cranial neuropathy, or loss of consciousness (Sigal 1987). An elevated erythrocyte sedimentation rate may be the only abnormal laboratory finding. Cerebral angiography may reveal changes including vascular beading or aneurysms, but a definite diagnosis can only be made by brain or leptomeningeal biopsy. Pathological changes include an inflammatory process involving small arteries, with intimal proliferation, fibrosis, and multinucleated giant cells (Sigal 1987). A few cases have followed herpes zoster ophthalmicus.

Systemic vasculitides such as polyarteritis nodosa or Wegener's granulomatosis can involve the central nervous system. Psychiatric disturbances are rarely seen without neurological signs or symptoms. Depression and changes in mental status are not uncommon presentations for giant-cell arteritis. Helpful clinical clues for establishing this diagnosis include the presence of jaw claudication, new onset of headaches, visual changes, and proximal myalgias. An elevated erythrocyte sedimentation rate is generally found. Biopsy of the temporal artery is recommended for the patient with a new onset of depression and any of the aforementioned features. Improvement is noted after treatment with corticosteroids.

Behçet's syndrome

The central nervous manifestations of Behçet's syndrome consist of subacute, haemorrhagic, and necrotizing meningoencephalitis, most typically affecting the brainstem and hypothalamus. In addition to the focal neurological symptoms associated with these lesions, organic mental disorders, disorders of consciousness, and seizures have all been described (Bousser *et al*. 1988).

Whipple's disease

Behavioural changes, hypersomnia, memory disturbance, and dementia, which may antedate its usual gastrointestinal or joint manifestations, characterize some of the central nervous manifestations of Whipple's disease (Fleming *et al*. 1988). One case report described dementia partially reversed by antibiotic therapy (Tarter *et al*. 1990).

Sarcoidosis

Involvement of the central nervous system occurs in 5 per cent of patients with sarcoidosis (Stoudemire *et al*. 1983). Delirium, dementia, personality change, hypersomnolence, depression, and psychosis have all been described. Steroids have reversed at least some of these neuropsychiatric manifestations.

Lyme disease

Lyme disease, caused by the tick-borne spirochaete *Borrelia burgdorferi*, is associated with a wide variety of neurological and some psychiatric manifestations. Logigian *et al*. (1990) studied 27 patients with signs of earlier Lyme disease, current evidence of immunity to *B. burgdorferi*, and chronic neurological symptoms with no other identifiable cause. Twenty-four of them had a mild encephalopathy, which had begun 1 month to 14 years after the onset of the disease and was characterized by memory loss, mood changes, or sleep disturbance. Fourteen had memory impairment on neuropsychological testing and 18 had increased protein in cerebrospinal fluid, evidence of intrathecal production of antibody to *B. burgdorferi*, or both. Associated symptoms included fatigue, headaches, arthritis, and hearing loss. After a 2-week course of intravenous ceftriaxone, two-thirds of the patients had improved, one other had improved and then relapsed, and the remainder had no change in their condition.

A long-term follow-up (mean of 6 years) of a cohort of patients revealed significantly more verbal memory deficits in patients with higher IgG Lyme antibody titres who received treatment later (mean of 3 years) (Shadick 992; Shadick *et al*. 1994**)**. Similarly, Krupp *et al*. (1991) noted more memory impairment on formal testing of Lyme patients than healthy controls.

Sigal (1995) has described the medical challenges associated with 'pseudo-Lyme' disease. Subjective complaints such as chronic fatigue, headaches, or memory deficits may be incorrectly attributed to Lyme disease. It is of utmost importance that the diagnosis of Lyme disease be made using accepted serological techniques. The entity of 'seronegative' neuropsychiatric Lyme disease is probably quite rare.

A recent review of experience with Lyme disease in children (Adams *et al*. 1994) found no differences between disease and control groups for a number of neuropsychological measures. These data contrast with a number of case reports in the literature suggesting the existence of Lyme-related psychiatric disease, including paranoia, dementia, schizophrenia, bipolar disorder, panic attacks, major depression, anorexia nervosa, and obsessive–compulsive disorder (Fallon and Nields 1994).

Amyloidosis

Some of the types of primary amyloidosis may involve the blood vessels of the central nervous system. Cerebral amyloid angiopathy can produce a variety of organic mental disorders including dementia, a fact of increasing interest because of the isolation of b-amyloid protein in both plaques and skin in patients with Alzheimer's disease. It is unclear whether secondary amyloidosis may also be associated with brain pathology.

Rheumatological disease with secondary psychiatric involvement (Table 4)

Depression in rheumatoid arthritis

Estimates of the incidence of depression in rheumatoid arthritis have varied widely, from 30 per cent (more typically) to as high as 70 per cent. The variability has resulted from differences in the definition of depression as well as differences among the populations studied. Some studies have found that the prevalence of depression is no higher in rheumatoid arthritis than in other chronically ill medical patients (Wolfe and Howley 1993).

Frank *et al*. (1988a) made one of the few studies using current operational criteria for depression in the context of rheumatoid arthritis. By using a structured diagnostic interview of predominantly male patients, they found a prevalence of major depressive disorder of 17 per cent. A much larger number, 41 per cent, met the criteria for dysthymic disorder, a less severe but more chronic form of depression in which symptoms must be present for at least 2 years and for more than half of the time. These diagnostic categories are not mutually exclusive: almost all of the patients with major depressive disorder met criteria for dysthymic disorder, so-called double depression. Overall, 41 per cent of this sample of 137 outpatients with rheumatoid arthritis were found to be depressed, with either of the two major depressive disorders or both. No correlation was found between the presence of a history of depression and higher levels of reported pain, as has been found in other studies.

Contrary to intuition, most studies have not found a significant correlation between depression and measures of disease activity, but rather with socioeconomic

factors, such as decreased social support and economic deprivation. One of the most comprehensive investigations of the origins of depression in rheumatoid arthritis found that a wide range of factors, including disability measures, duration of disease, social isolation, and economic deprivation, all made significant contributions to the explanation of depressed mood, together accounting for 44 per cent of the variation in depressed mood. Others have confirmed the complexity of determinants for depression in rheumatoid arthritis (Blalock and DeVellis 1992), indicating that loss of valued activities (Katz and Velin 1995) and social relationships (Crotty *et al*. 1994) may be as important as disease activity or functional status.

While most studies have found an increased incidence of depression in patients with rheumatoid arthritis, a few reports have not borne this out (Cassileth *et al*. 1984; Wolfe and Howley 1993). Cassileth measured, on psychological rating scales, the psychological health of patients with a variety of chronic medical disease including rheumatoid arthritis. They showed that these persons were overall indistinguishable from the general population and significantly healthier mentally than a population of psychiatric outpatients (Cassileth *et al*. 1984). However, they did not use the standard, operationalized definitions of clinical depression.

Systemic lupus erythematosus

Because of the potential life-threatening nature of systemic lupus and the alteration in appearance, both from the underlying disease and from use of corticosteroids, the psychological toll can be enormous (Omdal *et al*. 1995). Given the younger age of onset and the female predominance, issues related to family planning and pregnancy are of foremost concern to both patient and physician. Most observers have found an increase in clinical depression and anxiety (Liang *et al*. 1984). Providing patients with information relating to their disease and its management may increase their knowledge base but does not affect their psychological response (Konttinen *et al*. 1991). Peer support groups for systemic lupus may have a beneficial role to play (Peterson *et al*. 1993).

Juvenile chronic arthritis

Measurement of pain behaviours may be especially useful in studies of treatment outcome because these behaviours are relatively independent of depression (Jaworski *et al*. 1995). One recent survey found no correlation between scores on psychological testing and measures of functional status (Baildam *et al*. 1995), whereas another found that the proportion of patients demonstrating an anxious preoccupation with their disease increased with the degree of disability (David *et al*. 1994).

Miscellaneous disorders including systemic sclerosis, inflammatory myositis, spondylitis, severe osteoarthritis

The main connecting link in these conditions is the impairment in function due to joint and muscle problems and changes in appearance. These changes produce sadness, grief reactions, social isolation, and economic hardships. Some patients emphasize the positive, character-building aspects of these diseases and their potential for strengthening marital and family relationships.

Drug-induced psychiatric manifestations (Table 5)

Medication	Psychiatric manifestations
Corticosteroids	Mania, depression, organic mental disorders, insomnia
Hydroxychloroquine	Psychosis, organic mental disorders, personality change, insomnia
Cyclosporin	Mania, depression, lethargy, organic mental disorders
Non-steroidal anti-inflammatory drugs	Depression, organic mental disorders
Methotrexate Azathioprine Gold salts D-Penicillamine	Mood changes, headaches
Monoclonal antibodies (e.g., anti-TNF, anti-IL-2)	Fatigue, headaches

IL, interleukin; TNF, tumour necrosis factor.

Table 5 Drug-induced psychiatric manifestations

Corticosteroids

Major psychiatric side-effects have been well described (Table 6), occurring in approx. 6 per cent of all patients on steroids (Kershner and Wang-Cheng 1989). Female sex appears to be an important risk factor (Boston Collaborative Drug Surveillance Program 1972). Starting treatment with corticosteroids often results in euphoria. This may be due to a direct central nervous effect of the drug, or may relate to the psychological sense of well being from the beneficial effects of treatment on the disease process. Occasionally, steroids can induce a depressive state, especially with doses exceeding 0.5 mg/day or when rapidly tapered off after prolonged use. Wolkowitz *et al*. (1990) found that healthy volunteers given either a single, 1-mg dose of dexamethasone or 80 mg/day of prednisone for 5 days made significantly more errors of commission in verbal memory tasks, suggesting the possibility of specific, corticosteroid-related, cognitive impairments. Psychiatric symptoms are generally reversible when the drug is reduced or stopped. One prospective study found a good response to prophylactic treatment with lithium carbonate (Falk *et al*. 1979).

Depression	40
Mania	27
Psychosis	14
Delirium	10
Mixed depression and mania	8

Table 6 Steroid-induced psychiatric manifestations (percentages)

Cyclosporin

Cyclosporin produces its anti-inflammatory activity by binding to the interleukin-2 receptor on T cells. The observed psychiatric side-effects have included mania (Wamboldt *et al*. 1984), depression, and lethargy (Adams *et al*. 1987). With the higher doses (5-15 mg/day) given after organ transplantation, irreversible dementia, encephalopathy, and fatal progressive neurological deterioration have been seen (Bertoli *et al*. 1988). Cyclosporin can attenuate the opiate withdrawal syndrome precipitated by naloxone in morphine-dependent animals and this effect can be adoptively transferred by splenic mononuclear cells (Dougherty and Dafny 1987). The drug can also alter the electrophysiological properties of discrete brain nuclei (Dougherty *et al*. 1987).

Antimalarials

Chloroquine and to a lesser extent hydroxychloroquine have associated toxic psychiatric reactions including personality change, depression, depersonalization,

neurotic symptoms, confusional states, psychosis, and suicide (Mohan *et al*. 1981; Good and Shader 1982). Chloroquine is concentrated in brain and spinal cord. The psychiatric effects may be related to acetylcholinesterase inhibitory activity (Mustakillio *et al*. 1962).

Others

Gold salts, D-penicillamine, and azathioprine are not associated with any psychiatric findings (Rogers 1985). Methotrexate, given orally or parenterally in low weekly doses (i.e. 20 mg or less) for rheumatic diseases can be associated with headache, light-headedness, and mood swings.

Non-steroidal anti-inflammatory drugs

These are a class of agents distinguished by their ability to inhibit cyclo-oxygenase and thereby impair prostaglandin biosynthesis. Prostaglandins are synthesized in the brain and can modulate the effect of various neurotransmitters. In addition, these non-steroidal agents can cross the blood–brain barrier, which may explain their analgesic and antipyretic effects. These might be mediated by a direct effect on hypothalamic structures.

Indomethacin is the most potent inhibitor of cyclo-oxygenase among the non-steroidal anti-inflammatory drugs: it caused central nervous disturbances, including headache, light-headedness, dizziness, and vertigo, in almost one-half of the patients studied. These manifestations of toxicity can also occur, to a lesser extent, with virtually any of these drugs. More profound changes, including depression, confusional states, visual hallucinations and suicides, are reported with indomethacin (Tollefson and Garvey 1982). Interestingly, indomethacin contains an indole moiety similar to that in serotonin, which may explain its frequent psychiatric manifestations. Sulindac, structurally related to indomethacin, has been linked, in case reports, to delirium (Thornton 1980) and paranoid psychosis (Kruis and Barger 1980). Tolmetin reportedly induced mania in a patient with a prior history of psychiatric disturbances (Sotsky and Tossell 1984). We speculate that its pyrrole moiety, also found in porphobilinogen, which is excreted in acute porphyria, a condition associated with intermittent psychosis, may be responsible.

Propionic acids such as ibuprofen, naproxen, and fenoprofen have been associated with depression and cognitive dysfunction, especially in elderly people (Goodwin and Regan 1982). Insomnia and nightmares have been described with several of the non-steroidal, anti-inflammatory drugs.

Salicylates and salsalate in the therapeutic range have been associated with visual hallucinations (Greer *et al*. 1965), and confusion, especially in elderly individuals (Anderson *et al*. 1976), in whom these can be misinterpreted as signs of Alzheimer's disease (Vivian and Goldberg 1982). Tinnitus and impaired hearing have also been encountered, even with subtherapeutic blood concentrations of salicylates.

Treatment

When should a patient with rheumatological disease be referred to a psychiatrist or other mental health professional? When functional impairment seems out of proportion to the underlying medical disorders, when there are cognitive changes, hallucinations, delusions, bizarre behaviour, confusional states, or when there are questions about the use of psychotropic medications as in patients with depression or significant anxiety states, referral to a psychiatrist should be considered. It becomes more urgent when the possibility of suicide or psychosis arises.

Support groups should be considered for patients who are more isolated as a result of their disorders and seeking more information than can reasonably be provided by the rheumatologist, or more social support than that currently available.

Managing depression

The word depression, to the confusion of some, has been used to describe conditions ranging from grief and adjustment reactions to the more serious and potentially life-threatening major depressive disorder (unipolar depression). In general, antidepressants are indicated for treatment of the more severe depressions.

By current consensus as defined in the Diagnostic and Statistical Manual of Mental Disorders IV (1995) , a major depressive syndrome consists of at least a 2-week period during which at least five of the following nine symptoms will have consistently occurred, representing a change from a previous level of functioning.

1. depressed mood;
2. markedly diminished interest or pleasure;
3. ignificant weight loss or gain;
4. insomnia or hypersomnia;
5. agitation or psychomotor retardation;
6. fatigue;
7. feelings of worthlessness or excessive guilt;
8. diminished ability to think or concentrate;
9. suicidal ideas.

A further stipulation is that one of the five symptoms is either (1) depressed mood, or (2) loss of interest or pleasure.

A contemporary epidemiological study has found that the lifetime prevalence of major depressive disorder in the normal population is 4.4 per cent. If treated with antidepressant medications, approx. 60 to 70 per cent of patients will respond with resolution of the episodes within a few weeks. If untreated, it is estimated that a typical episode of major depression will last from 6 to 12 months and then usually resolve spontaneously. However, depression may persist and present as a chronic depressive disorder in 20 per cent of individuals.

Accurate diagnosis of depression in medically ill patients is confounded by the overlap between symptoms of the medical disorder and symptoms of depression, particularly the neurovegetative symptoms. For example, fatigue, insomnia, and anorexia may all be directly related to medical conditions such as rheumatoid arthritis. For this reason, some investigators have suggested substituting the more cognitive/affective symptoms, such as guilt and low self-esteem, for the neurovegetative ones when diagnosing depression in patients with medical illness.

Psychological interventions and the course of rheumatic diseases

The belief that one can manage and control a specific stressful situation (so-called self-efficacy) is probably an effective antidote to the helplessness so often found at the core of depression in chronically ill patients. In a longitudinal study, Parker *et al*. (1988) demonstrated that increases in self-efficacy could be taught to patients with rheumatoid arthritis, in turn leading to improvements in pain, and in psychological and health status. Using a self-management course for patients with arthritis that emphasizes cognitive, behavioural, and stress management skills, together with mutual support groups, Strauss *et al*. (1986) demonstrated improvements in health status and specifically in measures of arthritis activity.

Muller *et al*. (1987) made a meta-analysis of 15 studies on the effects of psychoeducational interventions on disability, pain, and depression in individuals with rheumatoid arthritis or osteoarthritis. The results indicate that patient education and group psychotherapeutic support can improve the health status of patients with chronic arthritis.

The participation of patients with lupus in a specifically designed self-help course correlated with subsequent lower levels of depression, and greater enabling skills and use of relaxation and exercise (Braden *et al*. 1993).

Psychotropic medications

Mood stabilizers

Lithium is the mainstay of treatment for manic depressive or bipolar affective disorder. It is helpful as an adjunct in treatment-resistant depression and as a prophylaxis against corticosteroid-induced mania. Alternative drugs recently introduced for treatment of acute mania, such as carbamazepine and valproic acid, may

also prove useful in this disorder (Small 1990).

Electroconvulsant therapy

This remains an effective treatment for major depression but is indicated only if the antidepressants are unsuccessful or not tolerated, or if there is an acute risk of suicide that necessitates immediate treatment.

Antidepressants

The four major categories of antidepressants include the serotonin-specific reuptake inhibitors (**SSRI**s), tricyclics, monamine oxidase inhibitors, and others. In general, the therapeutic response rate for all of the antidepressants is similar—approx. 70 per cent in major depression.

SSRIs

Over the past decade or so a number of new antidepressant agents have been introduced. The most important and widely used of these groups are the SSRIs. They are generally now the first-line agents used in the treatment of depression. Fluoxetine (Prozac) was introduced first, in 1987. It has received the most attention and controversy. Two others in the same class, sertraline (Zoloft) and paroxetine (Paxil), quickly followed. More recently, fluvoxamine (Luvox) has been added to the list (Wilde *et al*. 1993). The SSRIs have been so widely used and accepted because of their relatively limited side-effects. They have a highly specific action on serotonin reuptake and, as such, lack the anticholinergic side-effects, sedation, orthostatic hypotension, and cardiotoxicity that can be problematical with other antidepressants. Because of their potentially stimulating properties, they are the only antidepressants given in a single dose in the morning (Table 7). Nausea, jitteriness, insomnia, and headache are among the more common side-effects. Approximately 30 per cent of men will experience sexual dysfunction in the form of delayed ejaculation. All of the SSRIs have long half-lives, with fluoxetine the longest because of the activity of its metabolite. For this reason, medically ill patients should probably be treated with a non-fluoxetine SSRI.

Agent	Dosage range (mg)	Distinction
Fluoxetine (Prozac)	10–40	Longest half-life
Sertraline (Zoloft)	50–100	
Paroxetine (Paxil)	20–40	
Fluvoxamine (Luvox)	20–40	

Table 7 Serotonin-specific reuptake inhibitors

As with virtually all of the other antidepressants, there is an approximately 2- to 6-week lag time at therapeutic dosage before the antidepressants begin to exert their maximum effect on depression.

Tricyclics

Tricyclic antidepressants have been used in clinical practice for over 30 years. There is no evidence that one is more effective than another. Table 8 lists the tricyclic antidepressants and their usual ranges of dosage. The tertiary amines imipramine, amitriptyline, and doxepin are converted to their demethylated secondary amine metabolites desipramine, nortriptyline, and protriptyline, respectively, which retain pharmacological effectiveness and are used clinically as separate agents.

Tertiary amines
Imipramine (100–200 mg)
Amitriptyline (100–200 mg/day)
Doxepin (100–200 mg/day)
Trimipramine (100–200 mg/day)
Clomipramine (100–225 mg/day)
Demethylated secondary amines
Desipramine
Nortriptyline (75–150 mg/day)
Protriptyline (15–40 mg/day)

Table 8 Tricyclic antidepressants and usual dosage ranges

The tricyclics, and for that matter all of the antidepressants, are thought to exert their antidepressant effects through modulation of the availability of biogenic amines at receptor sites in the brain, particularly serotonin and noradrenaline, and through their effect on the responsiveness of adrenergic and serotonergic receptors. The side-effects of these medications also arise from receptor blockade. For example, sedation stems from antihistaminic effects, postural hypotension from a-adrenergic receptor blockade, and blurred vision, dry mouth and constipation from the anticholinergic effects. The demethylated secondary amines, desipramine and nortriptyline, have been increasingly used, especially in elderly patients, because of their relatively low anticholinergic side-effects as well as less sedation and orthostatic hypotension.

A clinical advantage of the tricyclics is the ready availability of methods for measuring their plasma concentration, which can be used to determine compliance and to titrate the dosage for maximum therapeutic effect.

It is useful to start at a low dosage, generally between 10 and 25 mg, about an hour before bedtime, and then to increase gradually (approximately every 3 days) by the same amount, working up to a total dosage range of 50 mg/day. The 10-mg dosage increment is usually prudent in geriatric practice, while an increment of 25 to 50 mg is usually tolerated in the patient under 60 years of age. Once having gradually worked up to 50 mg it is usually easier to increase the dosage the rest of the way up to 150 mg/day or higher.

Patients respond to tricyclics at different dosages. This is probably due to individual biological variability and the rate at which the individual metabolizes the antidepressant. If a lower dosage does not result in remission or results in subtherapeutic blood concentrations, the dosage may need to be increased to 200 to 300 mg. Many patients with chronic rheumatic diseases may benefit from lower doses from the sedative and analgesic effects of the tricyclics.

Other antidepressants

Bupropion (Wellbutrin), a structurally unique compound, has minimal anticholinergic and antihistaminic properties. Its major contraindication has been in patients with seizure disorder. On the plus side, unlike the SSRIs, it does not disrupt ejaculation and other sexual function. Maprotiline (Ludiomil) and trazodone (Desyrel) have

side-effects similar to the tricyclic antidepressants. Venlafaxine (Effexor) is a relatively new addition that has been promoted on the basis of its combined serotonin and norepinephrine reuptake blockade (Feighner 1994). This can be associated with sustained increases in blood pressure in approx. 5 per cent of cases when dosages were maintained above 200 mg/day.

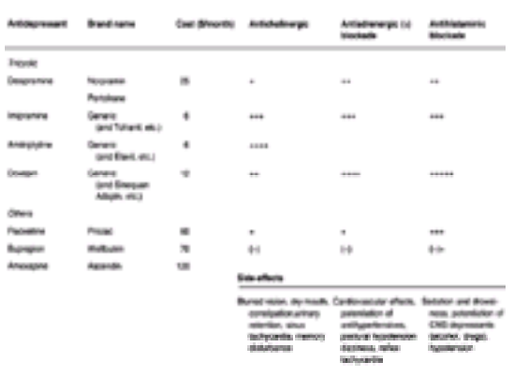
Another antidepressant recently approved by the United States Food and Drug Administration is nefazodone (Serzone) (Anton *et al*. 1994). Like the SSRIs and venlafaxine, the more common side-effects are nausea, lack of appetite, insomnia, nervousness, and sexual dysfunction. These do not have the prominent anticholinergic side-effects and hypotension so characteristic of the tricyclics. They also have the advantage of being non-lethal in overdoses, in contrast to the tricyclics.

Monoamine oxidase inhibitors

The monoamine oxidase inhibitors (imipramine, desipramine tranylcypromine, phenelzine) were the first effective antidepressant drugs but because of tyramine-induced hypertensive episodes their use was limited. These drugs appear to have a special role in the treatment of atypical depressions characterized by hypersomnia, hyperphagia, and a reversed diurnal variation with symptoms typically worse at night than in the morning. They can often be effective in tricyclic-resistant patients and for the treatment of panic disorders. Concomitant ingestion of tyramine-containing foods, sympathomimetic agents, and meperidine (Demerol) must be avoided.

Treatment strategies

The choice of an antidepressant is often determined by its side-effects. Currently SSRIs are likely to be the first drug of choice because of their relatively benign side-effects. Table 9 compares the most commonly used antidepressants in relation to a variety of factors: cost, receptor blockade, and side-effects.



Antidepressant	Brand name	Cost ($/month)	Anticholinergic	Antiadrenergic (α) blockade	Antihistaminic blockade
Tricyclic					
Desipramine	Norpramin	25	+	++	++
	Pertofrane				
Imipramine	Generic (and Tofranil, etc.)	6	+++	+++	+++
Amitriptyline	Generic (and Elavil, etc.)	6	++++		
Doxepin	Generic (and Sinequan Adapin, etc.)	12	++	++++	+++++
Others					
Paroxetine	Paxil	60	+	+	+++
Bupropion	Wellbutrin	70	(+)	(+)	(+)
Amoxapine	Asendin	120			

Side-effects		
Blurred vision, dry mouth, constipation, urinary retention, sinus tachycardia, memory disturbances	Cardiovascular effects, potentiation of antihypertensives, postural hypotension, dizziness, reflex tachycardia	Sedation and drowsiness, potentiation of CNS depressants (alcohol, drugs), hypotension

Table 9 Cost, blockade, and side-effects of commonly used antidepressants

The most frequent reason for failure to respond to antidepressant treatment is inadequate dosage, so monitoring of the plasma concentration is an important step in guiding the clinician (Table 10).

Drug	Therapeutic plasma concentration (mg)
Amitriptyline	150–250*
Doxepin	100–250*
Imipramine	200–300*
Amoxapine	150–500
Desipramine	150–300
Maprotiline	100–300
Nortriptyline	50–150
Protriptyline	100–250
Bupropion	50–100
Fluoxetine	100–300
Sertraline	100–300
Paroxetine	100–300
Trazodone	800–1600

*Drug and metabolite.

Table 10 Antidepressant plasma concentrations

After a satisfactory response has been obtained, the patient is generally continued on the medication for another 9 months before the dose is gradually tapered off. It is now clear that patients who have had a history of two or more depressions in the past should be kept on a maintenance dosage equal to the initial therapeutic dosage (Kupfer 1991).

How does one proceed with the 10 to 40 per cent of patients who fail an initial trial of the medication? The main causes of a poor response are inadequate dosage, non-compliance, often associated with inability to tolerate side-effects, and inadequate duration of treatment. There are no precise guidelines in determining how to proceed after an initial full trial of an SSRI or tricyclic fails. It is important to allow an adequate trial of 4 to 6 weeks. Most clinicians choose another agent with a different pattern of side-effects or biochemical profile, for example in a non-responder to an inhibitor of serotonin reuptake. If the second trial of an antidepressant fails, then the usual choice is between a newer agent, a combination of agents such as an SSRI boosted by a lower dosage of a tricyclic, or with a booster effect from lithium, or a monoamine oxidase inhibitor. For unclear reasons, individual patients may respond to one but not another of these agents. The addition of lithium is an adjunct may be effective in a subgroup of patients, especially those with a family history of bipolar illness.

Analgesic effects of antidepressants

Since their introduction over 30 years ago, tricyclics and, to a lesser extent, monoamine oxide inhibitors have found a role in the treatment of chronic pain syndromes, particularly for neuropathic pain, but also in the treatment of headaches, arthritis, low back, and facial pain. Approximately 50 to 60 per cent of patients with a chronic pain syndrome will benefit from the adjunctive analgesic effects of the antidepressants (Blackwell 1987). The analgesic action of the antidepressants cannot be entirely explained as a placebo effect, nor can it be indirectly related to the drug's effect on depression. In a review of 28 placebo-controlled studies, Magni (1991) concludes that antidepressants are helpful in a wide range of chronic pain syndromes, including fibromyalgia and rheumatoid arthritis, in addition to neuropathic pain, headache, migraine, and facial pain. Several studies of the use of antidepressants in chronic pain have shown pain relief in the absence of measurable changes in depression. Furthermore, structural congeners of imipramine such as carbamazepine and phenothiazine, which are not antidepressants, also have analgesic properties. Animal studies using antidepressants have also demonstrated some reduction in pain behaviour (Butler *et al*. 1985). Although the mechanisms of analgesia of the antidepressants remain unknown, their regulatory effects on serotonin and other biogenic amines, and their potential effect on opiate receptors, provide a theoretical basis.

Most of the antidepressants appear to have these analgesic effects. One must weigh the side-effects of the particular drug against the clinical setting. A patient with chronic pain and insomnia, for example, could benefit from a sedating antidepressant such as amitriptyline or trimipramine. These are generally described once daily, an hour or two before bedtime, and generally at a dose that is half of that used for the treatment of depression. It is wise to start with a low dose, either 10 or 25 mg, and gradually increase, similar to the approach in depression.

Antidepressants in rheumatoid arthritis

In the early 1960s both anecdotal reports and uncontrolled studies suggested that antidepressants might have a role in providing pain relief to patients with rheumatoid arthritis. In the first controlled study of antidepressants in chronic pain, McDonald Scott (1969) demonstrated a significant improvement in rheumatoid arthritis with the use of imipramine. At a dosage of 75 mg daily, imipramine was compared to placebo in a double-blind, cross-over study of 22 patients with arthritis. Patients with a history of depression or other psychiatric disturbance were excluded. A significantly higher proportion of patients receiving imipramine improved both in subjective ratings of pain and in grip strength, and decreasing morning stiffness in 55 per cent of patients with various chronic arthritides.

Subsequent studies in patients with arthritis have suggested that not all antidepressants have similar analgesic properties. For example, Ganvir *et al*. (1980) failed to demonstrate a significant analgesic effect with 25 mg of clomipramine daily as compared to placebo, although they subsequently questioned whether the dosage was adequate. More recently, Frank *et al*. (1988b) compared amitriptyline, desipramine, trazodone, and placebo in a 32-week, double-blind, cross-over trial in 47 patient with rheumatoid arthritis. Although all of these drug regimens, including placebo, produced significant changes in pain measures, only amitriptyline was associated with a significant reduction in the number of painful and tender joints. Intriguingly, a study of the effects of amitriptyline or imipramine in rats with adjuvant-induced arthritis has suggested that the tricyclic antidepressants may have direct anti-inflammatory effects because of a reduction in the physical signs of inflammation (Butler *et al*. 1985).

Managing anxiety disorders

Anxiety disorders are common in the general population and may be more frequent in patients with rheumatic disorders. Acute anxiety reactions may benefit from short-term use of benzodiazepines if they do not interfere with balance or cognitive function. It is important to be alert to more specific kinds of anxiety disorder, such as panic disorder with agoraphobia, obsessive-compulsive disorder, and social phobia. Panic disorder with agoraphobia may benefit from a benzodiazepine, such as aiprazolam or clonazepam, or a tricyclic with antipanic effects, such as imipramine or desipramine. Pharmacotherapy should be given in conjunction with cognitive and behavioural approaches to the phobias. Obsessive-compulsive disorder specifically benefits from clomipramine (Anafranil) and the SSRIs. Patients with social phobia seem to do best with either imipramine or monoamine oxidase inhibitors. All of these disorders are significant problems in their own right and should be differentiated from the more non-specific and transient adjustment reactions seen with anxiety.

Patients needing 'anxiolytic' medications such as benzodiazepines who have a history of alcohol or substance abuse generally are better treated with buspirone (Buspar), which is non-addicting.

Managing sleep disturbances

These are common, particularly in patients with systemic lupus, rheumatoid arthritis, and fibromyalgia (see Chapter 5.7.1). Some patients with lupus may develop insomnia secondary to the use of prednisone. When prednisone is producing manic or hypomanic symptoms associated with loss of sleep, a mood stabilizer such as lithium should be considered. The pain and inflammation of rheumatoid arthritis may be associated with more frequent night-time awakenings. Anti-inflammatory medication is probably more helpful than sedative hypnotic medication at night.

Summary

Finally, some essential clinical guidelines that may be helpful when evaluating rheumatological patients for psychiatric illness are shown in Table 11.

1. Neuropsychiatric illness is a common manifestation of many rheumatic diseases, particularly systemic lupus, where it may be associated with multiorgan involvement or as an isolated condition.
2. The neuropsychiatric manifestations of patients with systemic lupus on corticosteroids are much more likely to be due to the disease than to the steroids.
3. End-organ failure, for example renal or hepatic, and occult infection in the immunocompromised host should be excluded as causes for organic mental syndromes.
4. Consider potential drug toxicities, especially corticosteroids, as a cause of organic brain syndromes.
5. Depression complicating chronic rheumatic disease should be identified and when appropriate treated with antidepressant drugs.

2.1 Molecular genetics and its relevance in rheumatology

Patricia Woo

Introduction

The term 'new genetics' was first coined by editor of the *American Journal of Human Genetics*, commenting on an article that described a new DNA analytical approach to mapping the human genome. In general the term is used to describe the study of inheritance at the molecular level, including that of single-gene disorders, which can be traced clearly through families (as in the haemoglobinopathies), and of common (probably polygenic) disorders, such as coronary heart disease, mental illness, and autoimmune diseases. An understanding of underlying genetic factors is important because epidemiological studies of putative environmental factors have not revealed the cause of common diseases such as diabetes and rheumatoid arthritis. Although there is no clear evidence of their Mendelian inheritance, the inflammatory rheumatic diseases do cluster in families. Presumably this reflects the action of environmental factors against a background of genetic susceptibility. If we were able to define the main genes involved, and determine how their products differ from those of unaffected individuals, we would be in a better position to understand how these conditions arise, and eventually how to prevent or manage them.

Because of the successful control of environmental diseases in the developed world, diseases that are wholly or partially controlled by genes are assuming increasing importance in paediatric and adult medicine. Considerable resources have been invested not only in defining genes that may cause or confer susceptibility to human diseases but also in mapping the human genome. 'Reverse genetics' has proved a powerful tool (see below) for pinpointing the gene(s) involved with a particular disease. The genome mapping project will facilitate the identification of the disease-associated gene(s), once the relevant region of the chromosome has been identified. Understanding the biological activity of specific disease-associated genes requires knowledge of their control, functions, and products. Understanding the disease requires additional knowledge of the mutations and how they disrupt the function of the gene in question.

The human genome, gene structure, and expression

Structure of genes

Biologically important proteins are synthesized from a specific code carried within the DNA inside the nucleus of a cell. The code consists of different combinations of four nucleotides. This information is transcribed by copying the DNA into a messenger RNA (**mRNA**), which passes into the cytoplasm (Fig. 1). The mRNA is then associated with ribosomes and amino acids are then synthesized according to the mRNA sequence, that is, the mRNA forms a template for the translation of the genetic code into protein (Fig. 2).

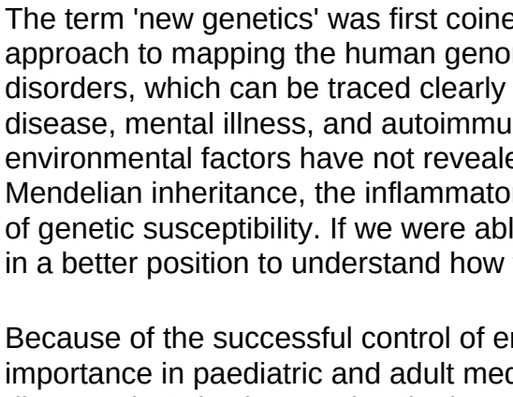

Fig. 1 Transcription and mRNA processing (adapted from Weatherall 1991).

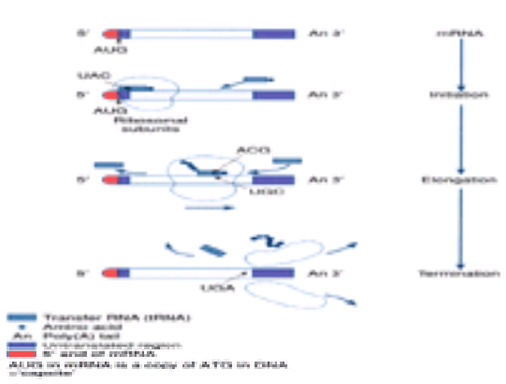

Fig. 2 Translation of mRNA (adapted from Weatherall 1991). AUG, initiation codon for methionine; UGA, termination codon.

A gene contains DNA nucleotide sequences that have their coding regions (exons) interrupted by sequences of unknown function (introns or intervening sequences). Though the role of introns is unclear, it is thought that they may have evolutionary importance. The direction of transcription of the coding sequence is usually controlled by a stretch of sequences upstream—the 5'-promoter region—containing the triplets ATG, which initiate transcription. Termination of transcription is denoted by another triplet, TAA, TAG, or TGA, at the 3' end of the gene. Within the promoter region, there are also sequences that regulate the gene's transcription rate (see below).

Control of gene expression

Every cell has a full complement of all the genes within the genome. Not all of them are actively expressed; the stage of development, the sex, and the cell types are

some of the important determining factors in expression. The mechanisms by which gene expression are regulated in eukaryotes (multicellular organisms) are not completely understood. In general, genes are switched on by the attachment of nuclear proteins to DNA with the appropriate recognition sequence, followed by the unfolding of the helical structure of the double-stranded DNA and also of chromatin. It is thought that this process allows the enzyme RNA polymerase II to gain access to the start site of the gene, the 'cap site', and initiate transcription by synthesizing a mirror image of the DNA coding strand, that is, a nuclear RNA. This RNA strand is edited or spliced to a final template (mRNA) for the synthesis of amino acids (see Fig. 1).

Transcription factors are DNA-binding proteins that mediate transcription of the DNA sequence (Mitchell and Tjan 1989). Certain common structures of these proteins have emerged; there are four types of transcription factors described so far. The first type contains a helix–loop–helix structure, as in homeoboxes of *Drosophila* DNA. The second type is a group of proteins with 'zinc fingers'—loops of the protein with a characteristic amino-acid sequence bound centrally by a zinc ion (Fig. 3). The first such protein described was the ribosomal transcription factor TFIIIA. These 'fingers' bind to the major groove of the DNA double helix. The third group of factors are the so-called leucine zippers (Fig. 4). These are dimeric proteins bound together at the N-terminal, which is leucine-rich. The C-terminals of these polypeptides bind DNA along the helical grooves. These proteins can be homo- or heterodimers, as in the oncogene complexes c- *fos*/c-*Jun*. The fourth type of proteins constitutes the NFkB family, which has in common 'rel' domain(s) that bind DNA as well as other nuclear proteins. The mechanism by which the DNA strand is activated is unclear. It may be a change in the tertiary structure of the DNA that will allow contact with other transcription factors crucial to the recruitment of RNA polymerase, as well as further protein interactions.

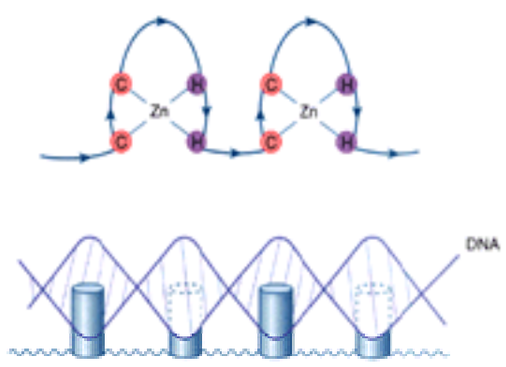

Fig. 3 Zinc-finger DNA-binding motif. C, cysteine; H, histidine.

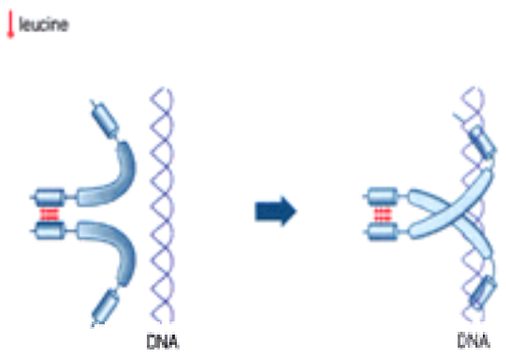

Fig. 4 Leucine zipper.

Transcription factors may be produced constitutively or may require an external stimulus such as cytokines and growth factors to be synthesized and/or activated. The inducible proteins tend to bind to enhancer elements in the 5' region of the gene. The enhancer elements are so called because they increase or facilitate transcription. The effect of the binding of enhancer proteins to DNA may be to cause further unfolding of the chromatin to allow easier access to DNA by RNA polymerase, or they may interact directly with the transcriptional apparatus, which consists of a series of essential DNA-binding proteins in addition to RNA polymerase II.

During development, sections of the chromatin are methylated to prevent activation of the genes within this region (Cedar 1988). Methylation is thought to both change the chromatin structure and prevent the binding of transcription factors. Recent work by Bird and colleagues shows that methylated CpG islands bind a protein, MeCP1, that can prevent binding of activated transcription factors (Meehan *et al*. 1992). Mutations in these regions can lead to demethylation, and activation of 'silent' genes. Another general mechanism of suppressing whole chromosomes is sex determination. Recent work has located a region of the X chromosome that can inactivate the second X chromosome in mice to prevent expression of double copies of genes on the X chromosome (Ashworth *et al*. 1991). The X-inactivation gene has now been identified (Penny *et al*. 1996). The third method of suppression of gene expression is gene-specific and relates to sequences, usually 5' to the gene, but possibly within the introns or the 3'-untranslated region, that interact with cell-specific nuclear factors. In this way, tissue-specific expression is precisely regulated.

The control of gene expression is not confined to transcription. The stability of mRNA and the storage and secretion of the newly synthesized protein can also be regulated. For example, the half-lives of mRNAs for interleukin (**IL**) 1 and tumour necrosis factor-a are very short because the AT repeats in their 3'-untranslated regions confer instability, presumably by allowing processing enzymes to act. The length of the poly(A) tail of the mRNA confers stability to the half-life of mRNA. But this is only one of the stabilizing mechanisms, as there are mRNA species without poly(A) tails. This area of investigation is expanding but there are few answers as yet.

Control of the protein secretion rate is another method of regulation by external agents. For example, apolipoprotein (**apo**) B is regulated by the fatty acid oleates, albumin and insulin in tissue-cultured cells via alteration of its secretion rate (Pulinger *et al*. 1989). Secretion of C-reactive protein is increased by the presence of IL-1 in tissue culture (Macintyre *et al*. 1985).

So far it has been assumed that one DNA template produces one peptide, but there are exceptions to this rule. As described above, the DNA exons are separated by intervening sequences or introns, and these allow different assemblies of exons, as with genes in the immunoglobulin superfamily (Hood *et al*. 1985). Also, mRNAs can have different lengths if there are several start sites for transcription; the mRNAs for calcitonin and calcitonin gene-related peptide are good examples (Edbrooke *et al*. 1985). Alternatively the mRNA can be edited, as demonstrated for apoB by Powell *et al*. (1987). A stop codon is introduced through a C®U conversion in the pre-mRNA of the intestine, resulting in a shorter peptide (B48 from B100), which is also functional. Another example of post-transcriptional modification is a chimerical protein in the absence of a fusion mRNA, for example, one of the subunits of glucose 6-phosphate dehydrogenase (Borst *et al*. 1989).

An apparent exception to Mendelian inheritance has been described. The expression of certain genes is determined by whether they are inherited from the male or female parent, a phenomenon known as parental imprinting (Swain *et al*. 1987). A good example is the inheritance of Angelman syndrome ('the happy puppet') from the mother only. Little is known at present about the molecular mechanisms involved in this fascinating phenomenon.

Coordinated gene expression

Activation and suppression of genes by external signals are the central mechanisms whereby growth, differentiation, metabolism, and inflammation occur. The pathways of extracellular control can be one of three types: endocrine signalling (control molecules acting from a distance), paracrine signalling (where target cells are close to the signalling cells), and autocrine signalling (where cells respond to their own secreted polypeptides). All these extracellular regulatory polypeptides can act in one of two ways: diffusion across cell membranes (e.g. steroids, which are lipid-soluble) or interaction with specific receptors (e.g. all cytokines and growth

factors). Receptor-binding proteins rely on a series of intracellular messenger molecules to be activated once they have bound to their specific receptors, a process called signal transduction. These second-messenger systems are all dependent on protein kinases, transferring the phosphate group of ATP on to threonine, serine, or tyrosine of cytosolic proteins. Many of these are likely to be precursors of DNA-binding proteins. The study of signal transduction is important, providing insight into how genes are coordinated by external signals. Although there are millions of genes, there are clearly common transduction pathways utilized by different external signals. It follows therefore that if there is mutation in the regulatory molecules, be they growth factors, receptors, intracellular messengers, or DNA-binding proteins, the consequences for cell growth and differentiation can be very serious.

The concept of gene families

Many human genes have been shown to belong to gene families. The criteria for family membership are DNA-sequence and/or protein-structural homologies, and similarity in function. There are many good examples of these gene families; in the study of inflammation and rheumatic diseases, the supergene family of immunoglobulins and related genes is one. Diversity of immunoglobulin genes is achieved by shuffling or rearrangement of the many exons by the B lymphocytes, and immunoglobulin- and T-cell-receptor genes are unique in this method of generating diversity. The membrane molecule has a characteristic structure within this gene family (Fig. 5). Related genes include those coding for several leucocyte surface antigens, growth-factor receptors, as well as the T-cell-receptor genes. T-cell receptors recognize antigens coded for by the major histocompatibility complex (**MHC**) from antigen-presenting cells (see Chapter 3.3). It is interesting that the MHC genes also belong to this immunoglobulin superfamily. Thus the proteins involved in antigen presentation and recognition are all part of this family.

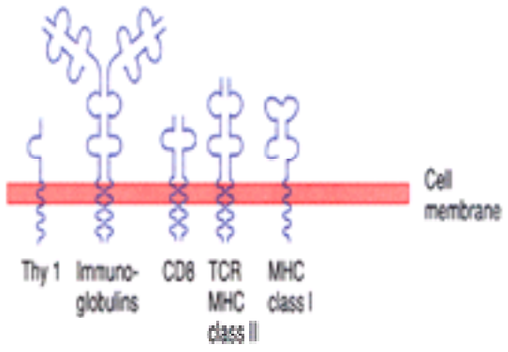

Fig. 5 The immunoglobulin superfamily. Thy 1/CD8, leucocyte antigens; TCR, T-cell receptor.

Another example is the group of growth/cytokine receptor families: the tumour necrosis factor/Fas (CD95) receptor family (see Chapter 3.1) and the IL-6/growth hormone-receptor families. The former use similar ligand-binding domains and the latter have common signalling domains.

There are increasing numbers of examples of gene families, for example the transforming growth factors and bone morphogenetic proteins (see Chapter 2.4), and the proteinases within the serpin family (Carrell *et al*. 1989) and the transcription factor families. All these examples strongly suggest that specialized genes are evolved from a primordial or ancestral gene.

The human genome

It is important for us to define the genes that are involved in human disease, and an estimate of the number of functional genes or gene clusters has been calculated (see Weatherall 1991). There are approx. 3×10^9 nucleotide pairs in the human haploid genome, but half would be repetitive sequences. Of the rest the coding ratio may be approx. 1:30 in each gene cluster, and it was estimated by Weatherall that the total number of clusters (of about 15 genes or so) will be 3000 to 15 000. Thus it is a feasible proposition to attempt to sequence the functional genome, as is the policy of the human genome projects in Europe and the USA. These projects should expedite the location of disease-associated genes once close linkage has been established by reversed genetics (see below).

Principle of reverse genetics

This has been a very useful approach to the identification of genes that cause clinical disease in single-gene disorders such as muscular dystrophy, cystic fibrosis, and retinoblastoma, to name but a few. The first step in the chromosomal localization of the gene is to study gene markers in affected families, multicase families or sibling pairs, and establish linkage between the gene markers and the disease gene—that is, cosegregation of the gene and disease in family studies over three or more generations. This method is often called gene mapping: the technique first used was restriction fragment length polymorphism but now DNA amplification by polymerase chain reaction (see Chapter 4.7). There are clusters of nucleotides of CG repeats, known as microsatellites, scattered on all chromosomes. Some 300 primer pairs are currently available to provide markers at 10 cM apart. This technology is semi-automated and a physical map of the human genome has been produced (Adams *et al*. 1995).

Once the region of the chromosome has been identified, the disease gene can be identified by assessing the segregation of known genes in this region with disease—the candidate-gene approach. Techniques used include extensive DNA cloning to define the gene, its sequence, its derived-protein sequence, and finally its function. At present the identification of a disease gene is very time-consuming, labour-intensive, and expensive; the genome mapping project will speed up this process.

Reverse genetics has been also very useful in unravelling genetic variability in clinical disorders, as well as providing a measure of genetic contributions to common diseases that are usually polygenic (see below).

Examples of single-gene disorders in rheumatology

It is clear that gene action is regulated by a series of steps that finally lead to a protein product. Mutations in single-gene disorders can act at all these steps (Table 1). Most single-gene disorders characterized so far are the result of the synthesis of a structurally abnormal protein, reflecting single-base mutations in the parent gene. Collagen accounts for approx. 25 per cent of total body protein. It is essential for the integrity of cartilage, bone, tendon, blood vessels, heart valves, and many other tissues. Genetic disorders of collagen leading to clinical diseases such as Ehlers–Danlos and Marfan syndromes are clearly set out in Chapter 2.2. The mutations include deletions of parts of the gene, and nucleotide change(s) leading to critical amino-acid substitutions.

Reduced output of gene product
Transcription
Insertions
Deletion or partial deletion
Promoter-box mutations
Other regulatory mutations
Processing of mRNA
Mutations involving splicing
Poly(A) addition-site mutations
Translation
Mutations involving initiation, elongation, or termination
Synthesis of an abnormal gene product
Mis-sense mutations (point mutations)
Fusion genes
Insertions
Deletions
Elongated products
Chain-termination mutations
Frameshift mutations
Defective post-transcriptional modification

Reproduced from Weatherall (1991) with permission.

Table 1 Types of mutations that underlie single gene disorders

Amino acid substitutions in the structural protein can lead to abnormal metabolites, and some of these single-gene disorders are seen in the paediatric rheumatology clinics. For example, the storage diseases such as Hurler's, Scheie, other mucopolysaccharidoses, and mucolipidoses are all the result of defective enzymes, leading to an accumulation of abnormal metabolites in tendons and subcutaneous tissues over joints (see Chapter 5.17.4).

Apart from the production of an abnormal protein, many genetic disorders are caused by the reduced production of a protein, that is, reduced gene expression. The a- and b-thalassaemias are good examples (Weatherall *et al*. 1988). This type of defect has been shown particularly in subgroups of systemic lupus erythematosus, where the absence of the genes for complement C2 or C4 are clear disease-susceptibility factors because of the defective handling of immune complexes in these patients. In C1 esterase-inhibitor deficiency, the defect can be a combination of the production of an abnormal non-functional protein and reduced production of the normal protein. The clinical picture is hereditary angioedema but the patients may also have features of systemic lupus.

Even if a single-gene defect has been defined for a particular disease, the phenotypic expression, as a result of the different types of mutations and deletions of that gene, can be heterogeneous, and therefore so can the resultant clinical disease manifestations. Good examples include the thalassaemias, haemophilia A, and cystic fibrosis. In these single-gene disorders, other genes and environmental factors may also alter the phenotypes, but the main influence is the mutant gene.

Genetics of common diseases (see review by Lander and Schork 1994)

In contrast to the single-gene disorders, common conditions, such as heart disease, diabetes, rheumatic diseases, psychiatric illness, and cancer, appear to be the result of a complex interaction between environmental factors and several genes at different loci. In order to understand the underlying cause of such diseases, we need to define both environmental and genetic factors. In the case of rheumatoid arthritis, which is prevalent among many racial groups, epidemiological studies have clearly shown that it is not like an infectious disease with a single causative agent. Twin studies of the *HLA-DR* locus have shown that the contribution from this is about 15 per cent of the total genetic susceptibility to rheumatoid arthritis. Thus rheumatoid arthritis is an example of polygenic disease, where it is likely that the combined effect of several genes can allow a number of environmental triggers to produce a similar clinical condition. The drive to unravel the genes that are important in polygenic diseases is because their identification will allow us to understand the biochemical basis of why these diseases occur (e.g. complement deficiencies and immune-complex disease). As a result, more rational methods of disease prevention and management can be developed.

There are two general approaches to defining the genes involved in a particular disease: the candidate-gene approach and the establishment of linkage using large families—the techniques of reverse genetics as mentioned above. These are formidable tasks, especially when gene mapping will be confounded by factors such as genetic heterogeneity, incomplete penetrance, and gene interaction. Once again, as in single-gene disorders, this task will be a great deal easier once we have a reasonable map of the human genome.

As far as the inflammatory rheumatic diseases are concerned, the candidate-gene approach has been favoured historically and considerable effort has been expended in the analysis of the MHC genes and, more recently, the T-cell-receptor genes. The hypothesis is that the trimolecular complex of HLA, peptide, and T-cell receptor in presenting antigen is central to the pathogenesis of disease. More detailed descriptions of current findings can be found in Chapter 3.3 and Chapter 4.7. Table 2 illustrates the polygenic influences in four groups of diseases. Examples of the linkage approach include mapping of the gene for familial susceptibility to psoriasis to 17q (Tomfohrde *et al*. 1994) and familial Mediterranean fever to chromosome 16 (Pras *et al*. 1992).

	HLA	Non-HLA	Sex	Chapter no.
Rheumatoid arthritis	DRβ	TCR	F	4.7

IL, interleukin; TCR, T-cell receptor; TNF, tumour necrosis factor.

Table 2 Polygenic influences in rheumatic diseases

A more recent area of study concerns candidate genes other than those coding for the antigen-presenting trimolecular complex. For example, the inflammatory cytokines are mediators of the inflammatory and immune responses seen in inflammatory rheumatic diseases, particularly rheumatoid arthritis and systemic juvenile chronic arthritis (see Chapter 3.1). Two approaches are used in the study of these candidate genes. One is to define genetic polymorphisms in multicase families, both in the coding and control regions of the genes. An example is the search for polymorphisms of cytokine genes and their associations with autoimmune diseases. This is reviewed in Chapter 3.1. The regulation of these genes appears to be variable according to the genotype, thus providing evidence for the concept that these genes can be modifiers of disease and contribute to its severity rather than being crucial to its development.

A brief discussion of the regulation of gene expression has already been given above. In rheumatic diseases, the interaction between environmental infectious agent(s) and genes may be at the level of the antigen presentation and antigen recognition, that is, the trimolecular complex of MHC, peptide, and T-cell receptor. But intracellular perturbation of the transcriptional apparatus of important cellular genes can also be important. Molecular virology has shown that a number of viruses use cellular transcription factors for their own expression (e.g. human immunodeficiency virus is activated by NFkB). They can activate cellular transcription factors that will also act on other cellular genes; for example, human T-lymphotrophic virus (**HTLV-1**) activates IL-2 through NFkB. In addition, their own transcription/transactivating factors could act on cellular genes; for example, the Tax protein of HTLV-1 can transactivate the genes for IL-2 and IL-2 receptors (Greene *et al*. 1986).

Tumour viruses have long been known to cause neoplastic proliferation of cells. They can achieve this either by insertion into the host genome, causing increased expression of adjacent host-cell genes (insertional mutagenesis), or they may carry genes with transforming properties (viral oncogenes of retroviruses). The viral oncogenes have homologous DNA within the cell and these are part of the its normal transcriptional apparatus. A good example is the NFkB family of DNA-binding proteins, related to the v-*rel* oncogene family (Kieran *et al*. 1990; Ruben *et al*. 1991), which are responsible for transcription of the k light chain of immunoglobulin, MHC, acute-phase genes such as those for serum amyloid A and angiotensinogen, and cytokines. Oncogene products may be involved in many aspects of cellular regulation. They may be growth factors or their receptors (e.g. c-*sis* and the a-chain of platelet-derived growth factor; c-*fms* and the receptor for colony-stimulating factor 1), enzymes associated with these receptors, tyrosine kinase (e.g. c-*fms* and v-*fms*), or DNA-binding proteins. Some of these cellular oncogenes, such as Bcl-2, are important in delaying programmed cell death (apoptosis), and others such as p53 and *myc* hasten apoptosis. The membrane protein Fas also enhances apoptosis when bound by its ligands. Since cell proliferation is related intimately to apoptosis, irregularity in apoptosis of immune-reactive cells can lead to disease. When a single base mutation was found in the Fas–protein in MRL-lpr/lpr mice, which possess features of systemic lupus and rheumatoid arthritis (Watanabe-Fukunaga *et al*. 1992), apoptotic defects were suspected as a mechanism for autoimmune diseases such as systemic lupus and rheumatoid arthritis. Recently, human lymphoproliferative disease has been found in children with mutations in Fas (Rieux-Laucat *et al*. 1995). Thus the role of the oncogenes in apoptosis needs to be characterized in autoimmune disease.

Conclusion

The study of common polygenic diseases is a formidable challenge to the researcher, but the potential benefits are enormous. Recombinant DNA technology is a powerful tool for unravelling this problem. Understanding the function of the products of the genes involved will allow more specific management the diseases. Environmental risk factors can be studied again in the light of genetic subgroups, and preventative measures should then become possible.

2.2 Molecular abnormalities of collagen and connective tissue

F. Michael Pope

Introduction

Collagen is a major connective-tissue protein family with crucial mechanical and scaffolding functions. Other important components of the extracellular matrix include fibrillin, elastin, microfibrillar-associated protein, and certain other skeleton-associated products such as PAX1 to –9, SOX9, FGFR1 to –3, and bone morphogenetic protein, which all have tissue-regulating properties. These various substances occur in a variety of connective tissues such as bone, cartilage, muscle sheaths, ligaments, joint capsules, skin, vascular structures (e.g. veins, arteries, heart valves), lungs, pleuroperitoneal linings, intestinal walls, hernial sacs, and glomeruli (Pope and Nicholls 1986; Pope *et al*. 1988a, Pope *et al*. 1988b). Furthermore, there are numerous subtle molecular interactions with other connective tissue elements such as laminin, elastin, heparin or chondroitin sulphate, other proteoglycans, and fibronectin. Each of these substances can react with other proteins and also bind to a variety of cellular components. These are more specific interactions between types I, II, III collagens and types V, VI, IX, and X collagen, which together form compound fibrils. They also probably influence embryogenesis and fetal development so that errors and mutations interfering with their quantity and quality cause congenital fetal deformities. Thus, mouse embryos deficient in type I collagen may be genetic lethals with death as early as the 12th day, whilst less destructive errors cause disorders such as osteogenesis imperfecta. Various mouse models have been created, including those with errors in collagens I, II, III, V, IX, and X. Mice with rhizomelic dwarfism and cleft palates caused by *COL2A1* mutations have been known since 1990.

Since the review by Vuorio and de Crombrugghe (1990), another six collagen proteins and 10 equivalent genes have been described. Currently this family contains at least 19 proteins and 32 genes (Prockop and Kivirriko 1995). Mutations have been known in some for 15 years or more; thus *COL1A1* and *COL1A2* mutations of type I collagen cause either osteogenesis imperfecta or Ehlers–Danlos syndrome type VII (Byers 1990; Pope 1991). Collagen type II (*COL2A1*) mutations clearly cause certain chondrodysplasias (Kuivaniemi *et al*. 1991); type III collagen (*COL3A1*) mutations usually cause the arterial form of Ehlers–Danlos syndrome (type IV) or occasionally types I or III. An X-linked, a5(IV) collagen, basement-membrane protein coded by the *COL4A5* gene is implicated in X-linked Alport syndrome (Barker *et al*. 1990). In other cases, *COL4A1*, *–4A2*, *–4A3*, and *–4A4* genes have been implicated in autosomal-dominant and -recessive Alport syndrome. Collagen V (*COL5A1*) has recently been implicated in Ehlers–Danlos syndrome types I and II, which are most probably allelic, whilst abnormalities of the *COL11A1* and *–11A2* genes have been implicated in the Stickler syndrome (Nicholls *et al*. 1994; Li *et al*. 1995; Loughlin *et al*. 1995; Snead *et al*. 1994; Vikkula *et al*. 1995). There is also biochemical overlap between the Stickler syndrome and multiple epiphyseal dysplasia (Vikkula *et al*. 1995), with mutational position and the clinical phenotype rather closely related. *COL11A1* and *–11A2* have also been implicated in multiple epiphyseal dysplasia. Defects of type X collagen cause Schmid-type metaphyseal chondrodysplasia (Wallis *et al*. 1994). Nevertheless, mutant mice null for *COL10A1* show normal growth and development of long bones. This suggests that *COL10A1* mutations act as dominant negatives (Rosati *et al*. 1994). Type VII collagen mutations frequently cause dystrophic epidermolysis bullosa (Dunnill *et al*. 1994a, Dunnill *et al*. 1994b; Eady and Dunnill 1994; Eady *et al*. 1994). Recent new collagens include the bullous pemphigoid antigen gene (*BPAG2/COL17A1*). Here mutations have already been detected in generalized atrophic benign epidermolysis bullosa (McGrath *et al*. 1995). Another interesting substance is MARCO, a novel macrophage receptor with a large intracellular collagenous domain, one of the scavenger receptor-protein family. Diseases caused by other similar genes are highly probable. Other important candidate genes for connective tissue disease include those for collagen VI, present in skin, blood vessels, and fibrocartilage, and for type VIII, which is an endothelial collagen. Collagens IX, X, XI, and XII are important components of cartilage and bone, whilst type XIII collagen is keratinocyte-associated (Vuorio and de Crombrugghe 1990). Subsets of common disorders such as osteoporosis, osteoarthritis, and congenital berry aneurysm (Pope *et al*. 1988a; Ala-Kokko *et al*. 1990) are sometimes caused by mutations of collagen types I, II, and III, and resemble those of osteogenesis imperfecta, certain chondrodystrophies, and vascular Ehlers–Danlos syndrome. Other diseases likely to be implicated include Ehlers–Danlos syndrome types I, II, and III (the benign hypermobile syndrome), Ehlers–Danlos syndrome VIII, and dystrophic epidermolysis bullosa, which is usually caused by *COL7A1* mutations. Defects of cartilage or bone morphology caused by connective-tissue gene mutations include achondroplasia, pseudoachondroplasia, and the spondyloepiphyseal dysplasias. Some forms of pseudoxanthoma elasticum may be caused by certain elastin and/or collagen errors. The Marfan syndrome is caused by abnormalities of fibrillin 15 (Godfrey *et al*. 1994). In the same year as Blanton *et al*. (1990) and Kainulainen *et al*. (1990) linked it for the first time to chromosome 15, the fibrillin –5 and –15 genes were cloned. Subsequently, numerous mutations have been detected and the genomic organization of fibrillin 15 established (Corson *et al*. 1993; Nijbroek *et al*. 1995). In contrast, the fibrillin gene on chromosome 5 causes a slightly different disorder (congenital contractual arachnodactyly). There have also been rapid advances in the analysis of defects of elastin and various other microfibrillar elements that cause diseases such as Williams syndrome. The clinical range of the diseases is wide and includes various inherited single-gene diseases, the common forms of which cause significant morbidity and mortality. For example, osteoporosis affects up to 50 per cent of otherwise normal adult women by the age of 75 years (Lewis 1981). Similarly, osteoarthritis is discovered in 10 per cent of routine autopsies, whilst aneurysms in the circle of Willis are found in 2 per cent of autopsies and cause 4000 deaths per annum in the United Kingdom (Mortality Statistics 1977). Similar gene defects may also participate in other common abnormalities, such as varicose veins, inguinal and femoral hernias, and in common forms of familial joint hypermobility syndromes, which affect up to 10 per cent of Caucasians in the United Kingdom.

The molecular analysis of human genetic disease proceeds in one of two ways. Most often a faulty candidate gene is suspected from structural (histological) finding or the protein chemistry, and is subsequently cloned, sequenced, and then analysed for mutations. This approach has been impressively successful in inherited abnormalities of collagens I, II, and III, but in other cases all obvious candidate genes have been excluded, leaving the cause completely unknown. Other diseases worthy of consideration include common forms of myopia, corneal abnormalities, emphysema, mitral-valve prolapse, periodontal disease, and certain disorders of the myotendinous junctions, any or all of which might be caused by connective tissue mutations.

Modern recombinant DNA technology

The recent spectacular advances in recombinant DNA technology include methods for cutting DNA into fragments suitable for insertion into transmissible, extrachromosomal DNA elements (plasmids), which are easily grown in bacteria, thus facilitating the purification and amplification of any desired DNA fragment. Subsequently, progressively larger DNA fragments have been amplified whilst vectors such as l-phages, cosmids, and yeast artificial chromosomes (Watson *et al*. 1987) have increased the length of clonable DNA from tens to hundreds of kilobases (gene sequencing). Similarly, the preferential amplification of any DNA segment by the polymerase chain reaction (**PCR**) (Saiki *et al*. 1986) has revolutionized human molecular genetics.

Two approaches commonly have been used. The first, reverse genetics, identifies the gene locus and then works backwards from gene sequencing to protein structure and function. Early examples were the cloning of genes for Duchenne muscular dystrophy (Monaco *et al*. 1986), cystic fibrosis (Rommens *et al*. 1989), and neurofibromatosis type I (Fountain *et al*. 1989a; Fountain *et al*. 1989b), and also chronic granulomatous disease. Another striking example was in Huntington's disease, which was extraordinary difficult to clone despite being first mapped in 1984 (Gusella *et al*. 1985). Similarly, Alzheimer's disease was first mapped in 1987 but now has several different causative genes (St George-Hyslop *et al*. 1987). Other examples include schizophrenia (McGillivery *et al*. 1990), myotonic dystrophy, fragile X, and the class of neurological defects characterized by unstable triplet repeats. The Marfan syndrome, which was only mapped to chromosome 15 in 1990 (Kainulainen *et al*. 1990), is an excellent example in the genetics of connective tissues. In the alternative approach a candidate protein is identified in various ways and the gene subsequently cloned, followed by mRNA, cDNA, or genomic analysis.

Collagen genes

The gene analysis of collagen or other connective tissue proteins is amenable to both the approaches outlined above. In the classical approach the candidate collagen protein is identified and cloned from cDNA or genomic libraries. Alternatively, a suitable autosomal-dominant disease such as osteogenesis imperfecta can be tested for linkage to *COL1AI* or *–1A2* gene markers or to other restriction fragment length polymorphisms (**RFLP**) nearby (Sykes *et al*. 1990).

The conventional approach has defined at least 30 genes coding for some 20 collagen (compound) proteins. In humans these are rather widely distributed, lying on chromosomes 1, 2, 6, 7, 10, 12, 13, 17, 21, and the X chromosome. There are multiple genes on chromosomes 2 (three), 6, 13, and 21 (two on each) (Vuorio and de Crombrugghe 1990). All code for extended triple helices of Gly–XY polymers (where X and Y are often proline or hydroxyproline). Thus collagen types I, II, III, V, and XI, which form the so-called interstitial collagens, have N- and C-globular extensions with uninterrupted Gly–XY triple helices coded by 52 exons. All other collagens have either globular N- and/or C-terminal extensions, with varyingly large globular interruptions of the triple helix (Kuivaniemi *et al*. 1991). Bending of the rigid helix at such globular interruptions may be important in different tissues such as basement membranes, cartilage, and cornea, and probably allows interaction with other associated macromolecular and cellular components. Cartilage also contains conventional, cross-striated, interstitial type II collagen fibres.

Historically the genes for collagens I, II, III, and V were identified in numerical order of discovery (the numbering system originally arose from protein analysis 20 years earlier). Thus the a1(I) and a2(I) genes *COL1A1* and *COL1A2* of type I collagen were originally cloned in chickens and then in man. These vertebrate proteins have well-defined N- and C-terminal extensions essential for fibril alignment and formation, and the central triple helices are coded by regular GlyXY subunits in cassettes of exon (coding) sequences, which are always multiples of 9 bp, commonly 45, 54, 63, 81, 108, and 162 (Prockop and Kivirriko 1984). Such base-pair combinations suggest that there is duplication of the original 9-bp multiples in various combinations and permutations (Vuorio and de Crombrugghe 1990). Alternatively, an ancestral 54-bp exon with surrounding introns could produce 108 and 162 bp by intron loss and 45 and 99 bp by recombination.

Thus type I collagen is a heteropolymer of two distinct a-chains that spontaneously self-assemble in a 2:1 ratio to form $a1(I)_2a2$ triple helices. Although, rarely, there may be $a1(I)_3$ trimers in skin, a2 trimers cannot assemble and are thermodynamically unstable. Types II and III collagens form homotrimers: $a1(II)_3$ and $a1(III)_3$, respectively. The latter has two cysteine bonds in the a-helix, as well as the normal inter- and intrachain disulphide bonds within the C-propeptides found in other interstitial collagens. Type II collagen is confined to cartilage and the vitreous humour of the eye, whilst type III collagen is widely distributed in skin, ligaments, tendons, pleuroperitoneal linings, the intestinal wall, and blood vessels (arteries, veins, and capillaries) particularly. It plays an especially important part in arterial strength and stability. These four collagens all have a central helix of $(GlyXY)_{333}$ with proline or hydroxyproline (10 per cent) and lysine or hydoxylysine (4 per cent) in the second and third positions (Prockop and Kirivikko 1984). The Gly–XY cassettes are crucial to the normal biophysical properties and correct winding of the collagen triple helix (as will be self-evident from patterns of mutations). The 3' end of the gene codes for a C-terminus of between 243 and 247 amino acids (depending upon collagen type). It has a short telopeptide sequence but is mostly globular with a highly conserved exon structure for all interstitial collagens (Yamada *et al*. 1984; Vuorio and de Crombrugghe 1990). It is coded by exons 49 to 52; exons 49 and 50 vary in size and exons 51 and 52 are constant for the various interstitial genes. In most of the interstitial families, exon 49 codes for between 45 and 63 bp but in a2XI it has reduced to only 15 bp.

The N-propeptides are more divergent, with substantial differences. *COL1A1*, *–1A2*, *–2A1*, and *–3A1* genes have cysteine-rich regions missing in *COL1A2*. The triple helical region of the N-propeptide also varies, being most complex in the *COL2A1* gene, where there are several extra exons.

Other similarities at the 5' and 3' ends of the gene include regulatory sequences upstream of the gene, such as CCAAT between -80 and -100 in the *COL1A1* and *–1A2* genes, respectively. There are also multiple binding sites upstream of this site for proteins such as transforming growth factor-b. There is also a highly conserved enhancer sequence within the first intron of *COL1A1, COL1A2*, and *COL3A1* collagens, sited between +418 and +1524 of *COL1A2* and +820 and +1602 of *COL1A1*. Deletion of certain promoter sequences causes positive or negative effects (Vuorio and de Crombrugghe 1990). There may also be enhancer sequences analogous to those b-globins, downstream of the 3'-coding sequences. The genes for non-interstitial collagens, whilst somewhat different, also have family resemblances to the interstitial collagens. Thus the *COL4* genes (*4A1, 4A2, 4A3, 4A4*, and *4A5*), which all contain several globular interruptions within the triple helix, are highly homologous to each other. They all possess long, C-terminal, globular domains (NC1) with smaller N-terminal globular domains (NC2). Electron-microscopic and biochemical evidence shows that N- and C-terminal interactions between adjacent type IV molecules produce a chicken-wire model (Vuorio and de Crombrugghe 1990). There are more than 20 globular interruptions to the Gly–XY triple-helical repeat, 12 of which are single amino-acid deletions whilst others are globular inserts of up to 24 amino acids, depending upon the particular chain type. Nevertheless, exon sizes conform reasonably well to the 9-bp model. The *COL4A1* and *COL4A2* genes run in opposite orientation and direction from head-to-tail contiguous promoter sequences.

Type VI collagen is highly disulphide-linked and has a short triple helix with globular ends forming microfibrils of antiparallel dimers that are laterally associated. Three distinct genes *COL6A1, 6A2*, and *6A3* code for a1, a2, and a3(VI) collagens. They are situated respectively on chromosomes 2 and 21. Again the helical exons are multiples of 9 bp.

Type VII collagen (*COL7A1*) has globular N- and C-terminal extensions with a central helix of 320-kDa monomers packed as antiparallel fibrils. The C-terminus forms almost half of the molecule. Collagen VIII is an endothelial protein, collagens IX, X, and XI are all components of cartilaginous matrix, whilst the vitreous humour of the eye contains collagens II, V, and XI. In the Stickler syndrome, abnormalities of the vitreous structure and function are combined with myopia and osteoarthritis (degenerative joint disease) caused by mutations of the *COL2A1* or *COL11A1* and *–A2* genes. Fibrillin 15 and collagen VI have also been identified in the vitreous humour. Other important interactions include the decoration of collagen I/III by collagen V. There are strong hints that disturbances of such ordered structures produce distinctly abnormalities. A good example is the cauliflower fibrils that occur in the skin of patients with Ehlers–Danlos syndrome I or II. In other cases, certain molecular components that might fit into the gaps between the quarter-staggered fibrils include calcium (collagen I), collagen V (collagen I and III), or proteoglycans or glycosaminoglycans and other compound fibres. Similar constraints also apply to the NC1 (N-propeptide) of collagen IX. Here, site-directed mutagenesis of this region impairs chain registration, selection, or helical stability. The function of the C- and N-propeptide in those collagens with significant non-helical interruptions is clear, as evidenced by the fibrillogenesis of collagens IV, VI, VII, VIII, and X.

Collagens IX, X, and XI also form components of cartilaginous matrix. In that regard the vitreous humour has proved to be an especially interesting tissue and disorders of the vitreous, of which Stickler's syndrome is a good example, are caused by either homogeneous or heterogeneous anomalies of collagen II, V, and XI. Here the homo- or heterogeneous primers of each or all components are all capable of producing a disorder of fibrillogenesis and collagen triple helices, and resultant vitreous disorder or fragility. The latter usually occurs in combination with myopia or osteoarthritis or degenerative joint disease. Furthermore, other unexpected components have also been identified in the vitreous, such as fibrillin 15 and collagen VI, and defects of both these genes are potentially pertinent to eye disorders. Other important mechanisms include the decoration of collagen I/III fibrils by collagen V (see above). Compound heterozygosity of collagen type I and III and *COL1A1*, *–1A2*, and *–3A1* mutations and collagen I/II and III genetic compounds *COL1A1, 1A2, 3A1*, and *2A1* could produce clinical disease, though no convincing examples have so far been observed. Lastly, enzyme deficiencies such as of lysylhydroxylase (Wenstrup *et al*. 1989) and lysyloxidase (Byers *et al*. 1980) have been described, though the procollagen peptidase deficiency in humans originally postulated by Lichtenstein *et al*. (1974) has only very recently been identified (Smith *et al*. 1992; Nusgens *et al*. 1992). The animal equivalent, in contrast, is very well known (Lapiere *et al*. 1971). The disturbed morphology of the human fibril is virtually identical to that of the cow, sheep, and cat, and is produced by persistence of the N-terminal propeptide sequence in each component of the triple helix of collagen type I. Here the inheritance is autosomal-recessive. In contrast the autosomal-dominant, N-terminal, structural mutants *of COL1A1* and *COL1A2*, although allowing PNa components to persist in one or two a-chains, produce much less severe structural consequences than the triple a-chain enzyme defect.

The molecular analysis of *COL2A1* mutations lagged initially because of the inherent difficulty in culturing chondrocytes and obtaining cartilage samples from which the mutant proteins could be isolated. Those mutations characterized to date closely resemble type I and III mutants, both in the pattern of the protein changes (Murray *et al*. 1989) and from gene-sequencing data (Lee *et al*. 1988; Tiller *et al*. 1990; Kuivaniemi *et al*. 1991). They are usually helical glycine substitutions or deletions. Collagen type II defects cause a variety of inherited disorders including spondyloepiphyseal dysplasia congenita, Stickler syndrome, and osteoarthritis (Palotie *et al*. 1989; Anderson *et al*. 1990; Knowlton *et al*. 1990).

Type IX and XII collagens are highly homologous in both exon structure and protein folding, whilst collagen type XIII is secreted by keratinocytes but also occurs in skin, bone, intestine, and muscle. Collagens IV, VI, IX, X, XII, and XIII have all been cloned and sequenced. Type VIII and XIII still await more detailed analysis. Interesting supramolecular interactions of collagen types (at the fibrillar level) have been observed. Thus collagens I and III and I and V form compound fibrils, whilst collagens II and XI coassociate with collagen IX, which coats the surface of type II. Similarly, collagen XII decorates the surface of type I collagen. Such complex combinations presumably interact with themselves and other connective components. Collagens XIV to XVII have also been recently described. The latter is the so-called bullous pemphigoid-associated antigen, mutations of which produce a relatively mild variant of dystrophic benign epidermolysis bullosa.

Collagen folding and self-assembly

The collagen triple helix forms an unique protein structure containing multiple repeating polymers of (GlyXY) $_n$. The flexible lysine bonds are interspersed with inflexible proline or hydroxyproline to confer a specific helical conformation as defined by hydrogen bonding and water bridges linking individual a-chains to each other (Prockop and Kivirriko 1984; Byers 1990). Furthermore, for proper triple-helix formation it is essential that each of the three a-chains is in correct register. If not, then redundant loops and mismatches could seriously impair the processing of the procollagen extensions. When the triple helix is correctly wound it can be incorporated into mature collagen fibrils. This process may be faulty at several biosynthetic steps: for example, in precursor pro-a-chains with N- and C-terminal propeptides the charged interactions between the C-propeptides are largely stabilized by interchain disulphide bonds. This ensures the correct alignment of individual a-chains to one another, so ensuring that the first few GlyXY triplets adjacent to the C-terminus are correctly aligned (in the three separate a-chains). It is also essential that each component of the triple helix be properly aligned if proper superhelical winding is to take place. Helical winding next propagates towards the N-terminal end, twisting the three chains into a tightly wound, rod-like structure (Byers 1990).

There are also several important post-translational modifications, such as changing of GlyXPro to GlyXhydroxyproline by the enzyme prolyl-4-hydroxylase (Kivirriko and Myllyla 1982). This stabilizes the collagen helix at ambient body temperature, delaying crystallization of the 'in-register', C-propeptide-associated (potential) triple helix. Other important steps include limited lysyl hydroxylations, some of which have galactose or glucosylgalactose residues added. Hydroxylysine stabilizes the cross-links between collagen monomers. The chains cannot be efficiently folded without hydroxylation but the act of folding inhibits this modification, the process therefore being self-regulatory. It having been wound into an optimal configuration, various cleavage enzymes (Byers 1990) dramatically alter the solubility of the precursor molecule. Spontaneous polymerization into fibrils (of individual triple-helical collagen a-helices) then follows in a highly ordered, structured fashion. Quite possibly the self-assembly of collagen fibrils is also affected by other components of the extracellular matrix.

The information outlined above has been accumulated from basic biochemistry, biophysics, molecular biology, and studies of certain specific collagen mutations. It applies especially to the interstitial collagen types I [a1(I) and a2(I)], II (a1(II) $_3$, and III (a1(III)$_3$ proteins. Very probably, similar considerations and constraints apply to other interstitial collagens, such as collagen V (a1- and a2-chains) and collagen XI (a1- and a2-chains). It is also now apparent that defects of *COL5A1*, *–5A2*, *–11A1*, and *–11A2* also produce clinically detectable disease. More recently the *COL5A1* gene has been linked to both Ehlers–Danlos syndromes I and II (Burrows *et al*. 1996; Loughlin *et al*. 1995), and a convincing mutation of *COL5A1* demonstrated in a single patient with Ehlers–Danlos syndrome II (Nicholls *et al*. 1994). Latterly a translocation through the middle of the *COL5A1* gene has also been shown to cause Ehlers–Danlos syndrome II (Torriello *et al*. 1996). Similarly, *COL4* mutations are being categorized in Alport syndrome. Deletions and substitutions of *COL4A5* cause sex-linked recessive Alport syndrome (Barker *et al*. 1990). It is obvious that much still remains to be discovered. In the context of rheumatology there are at least three other cartilage collagen genes (apart from collagen II) with the potential to produce cartilage-related inherited diseases.

Mutation of collagen genes and resulting proteins

Mutations of the genes coding for interstitial collagens type I, II, and III are extremely diverse, and, with certain rare exceptions, virtually private to each family. Amino acid substitutions are particularly disruptive when altering triple-helical glycines, but both the location and type of substitution are important. To date only occasional second- or third-position (X + Y) mutations have been detected and even then their effects are not completely clear. Splice-junction point mutations (Watson *et al*. 1987; Weatherall 1991) are an important mechanism for collagen deletions (analogous to haemoglobin and other splice mutations). Other rarer abnormalities include large (Superti-Furga *et al*. 1988) and small inframe deletions, also nonsense or frameshift mutations (Nicholls *et al*. 1984b; Pihlajaniemi *et al*. 1984). The latter are less common than helical substitutions (Byers 1990; Beighton *et al*. 1991; Kuivaniemi *et al*. 1991). All dramatically affect protein structure or secretion, although overmodified secreted products are, in general, common in type I defects (Bonadio and Byers 1985) whilst overmodified retained protein is common in *COL3A1* mutations (Pope *et al*. 1988a, Pope *et al*. 1988b). Generally speaking the clinical phenotype is much more variable in mutations of collagen type I, ranging from virtual normality (with mild osteoporosis) to congenital fractures with lethal disease in babies (Sillence *et al*. 1984). Defects of collagen type III, on the other hand, whilst more often lethal, exert their main effects in late adolescence, adult or middle life when lethal or life-threatening arterial rupture is commonplace (Pope *et al*. 1988a, Pope *et al*. 1988b; Pope *et al*. 1996). Beighton *et al*. (1992) have attempted to correlate clinical chemical and molecular phenotypes.

Although there are strong clinical (phenotypical) similarities between the different subgroups [except for Ehlers–Danlos syndrome type VII, in which exon-6 splicing defects of a(I) and a2(I) have so far been consistent] (Weil *et al*. 1989a; Weil *et al*. 1989b; Weil *et al*. 1988; Nicholls *et al*. 1991; Pope 1991; Vasan *et al*. 1991), most families with mutations of collagen type I and III (with only one or two rare exceptions) have private mutations (Byers 1990; Kuivaniemi *et al*. 1991). To date nearly all type I mutations have been observed in osteogenesis imperfecta/Ehlers–Danlos syndrome VII; only 5 per cent are recurrent between families. No *COL3A1* mutants have recurred (i.e. so far each family is unique). The molecular analysis of *COL2A1*, which (as outlined above) had previously lagged behind the others, has recently advanced spectacularly with more than 50 recorded mutations (Vikkula *et al*. 1994). Again, private mutations are the norm. As in collagen type I and III mutants, many are glycine substitutions or deletions, with similarly disturbed protein patterns (Murray *et al*. 1989) and gene-sequencing data (Lee *et al*. 1988; Tiller *et al*. 1990; Kuivaniemi *et al*. 1991). There is also impressive evidence that associates *COL2A1* mutations to various inherited disorders such as spondyloepiphyseal dysplasia congenita, the Stickler syndrome, and osteoarthritis (Palotie *et al*. 1989; Anderson *et al*. 1990; Knowlton *et al*. 1990;).

There have been equally spectacular advances in the analysis of Alport syndrome. These are in the linked *COL4A5* gene and also in the autosomal *COL4A3* and *COL4A4* genes. Similarly, gene linkage and mutational analysis of *COL7A1* mutants have rapidly advanced, with linkage of the gene to both the autosomal-dominant and -recessive epidermolysis bullosa dystrophica, and *COL7A1* mutations in both variants. Studies include combinations of cDNA and genomic sequencing of amplified gene fragments (Al-Imara *et al*. 1992; Dunnill *et al*. 1994a; Hovnanian *et al*. 1994). Usually cDNA is amplified as four or five fragments, whilst the 118 *COL7A1* genomic exon sequences are amplified with 70 pairs of separate primers followed by a combination of HDE, SSCP or DGGE analysis. Various null alleles (usually stop-codon mutants), but relatively few glycine helical substitutions or splice junction deletions, have been detected.

There has also been rapid progress in the analysis of collagen IX and X mutants, which cause disorders such as spondylometaphyseal and Schmid-type chondrodysplasias, respectively. Other important recent advances include the identification of a collagen Va1 and -a2 error in either mice or man (*COL5A1* and *COL5A2* mutants), each of which produces specific connective-tissue diseases. For example, the common disease (Ehlers–Danlos syndrome II) is caused by an exon skip of the *COL5A1* (Nicholls *et al*. 1994), whilst the mouse model is homozygous for an N-terminal deletion of the *COL5A2* gene (Andrikopoulos *et al*. 1995). Recently, any doubts about the sporadic nature of the original *COL5A1* mutant have been resolved with the demonstration of linkage to *COL5A1* in a very large British pedigree (Loughlin *et al*. 1995). Also recently, we have linked *COL5A1* to families with mixed Ehlers–Danlos syndrome I/II phenotypes, suggesting that Ehlers–Danlos syndrome I and II are allelic (at least some of the time) (Burrows *et al*. 1996).

Type I collagen mutations

Type I collagen is widespread in bones (particularly the metaphyses and diaphyses of long bones), where it is the major matrix protein. It also occurs in tendons, joint capsules, the dermis, and blood vessels. Not surprisingly, clinical abnormalities include weakened bones with variably diminished bone matrix proportional to the severity of the osteogenesis imperfecta (Fig. 1), which ranges from mild, barely detectable familial osteoporosis to lethal, short-limbed dwarfism (Pope *et al*. 1988b). Sometimes ligaments, joint capsules, scleral thickness, dentine, heart valves, and dermal thickness are affected as judged by joint laxity, blue sclerae, dentinogenesis imperfecta, and prolapsed or incompetent heart valves, respectively. Very severe joint laxity, with or without skin fragility though usually without osteoporosis, is more typical of Ehlers–Danlos syndrome VII, which is accompanied by short stature. In heterozygotes, mutations outside the main collagen helix produce either mild osteogenesis imperfecta or osteoporosis, but may be very severe in homozygotes (Byers 1990). One unusual patient with Marfan syndrome with an abnormal a2(I) collagen protein had a second-position mutation (Phillips *et al*. 1991) affecting her father and herself [a second, somewhat similar patient was briefly mentioned (Godfrey *et al*. 1990)]. It is unclear whether the father in the former family is a true Marfan or a mosaic (Phillips *et al*. 1991). Furthermore, the general relevance is also unclear as no other Marfan family has been linked to the *COL1A2* or any other collagen gene. There are three possible explanations: the a2 genotype produces a phenocopy closely similar to authentic Marfan syndrome, the a2 association is coincident, or the a2 association is genuine and Marfan syndrome is allelically heterogenous. There is very little evidence of the last, however, and with one exception all Marfan syndrome families so far tested have been linked to fibrillin (Blanton *et al*. 1990; Kainulainen *et al*. 1990; Kainulainen *et al*. 1991; Tsipouras *et al*. 1991; Dietz *et al*. 1995; Kainulainen *et al*. 1994; Nijbroek *et al*. 1995). The one exception is highly controversial (Dietz *et al*. 1995; Boileau *et al*. 1995): a very large French family is linked to 3p24.2–p25 (Collod *et al*. 1995) but whether or not the family has Marfan syndrome is hotly debated (Dietz *et al*. 1995; Boileau *et al*. 1995).

Clinical features of osteogenesis imperfecta

The clinical and pathological changes are those of an inherited osteoporosis, and in the worse forms of the disease the bone matrix is severely disorganized and

depleted (Pope *et al*. 1989) (Fig. 1). The periosteum persists normally under these conditions but there is often minor distortion and disorganization of the epiphyseal plates. Radiological changes range from mild osteoporosis with occasional fractures to a widespread and severe skeletal abnormality with absent skull calcification, multiple rib fractures, polyspondyly with spinal collapse, and distorted, multiply fractured bones that are either modelled or unmodelled depending upon clinical subclassification (Pope *et al*. 1989) (Fig. 2).

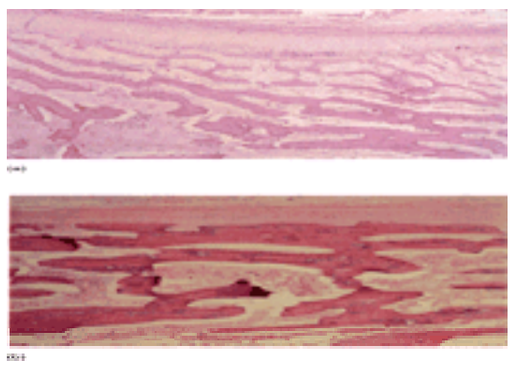

Fig. 1 Histological features of fetal bone in mild osteogenesis imperfecta (a) compared with normal control (b) at 24 weeks' gestation. The trabecular bone is obviously thinner in the osteogenesis imperfecta sample. Original magnification × 4.

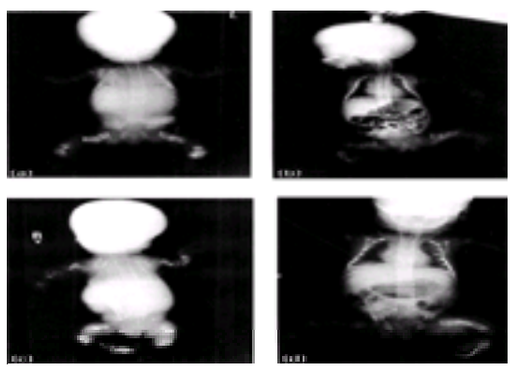

Fig. 2 Radiological phenotype of babies affected by osteogenesis imperfecta ranging from (a) lethally affected, generalized involvement of ribs and unmodelled long bones (Sillence type IIa) to various combinations of unmodelled long bones and nodular or unbroken ribs (b–d). The least severe phenotype (sometimes called Sillence type IIc or III) has gracile, generally unfractured bones but considerable distortion and fractures of the lower limbs (d).

The clinical phenotype reflects these facts, so that affected patients vary from normal-looking children with occasional fractures beginning in infancy to severely crippled, short-limbed dwarves (dying either *in utero* or perinatally). Their variability is recognized by the Sillence classification (Sillence *et al*. 1979), which separates two mild and autosomal-dominant disorders (types I and IV) from two lethal or severely crippling disorders (types II and III) (Fig. 3). Both autosomal-dominant and -recessive inheritance occurs.

Fig. 3 (a) Many patients with Sillence type I osteogenesis imperfecta have generalized joint laxity (shown here at finger tips); (b) here, this was associated with premature corneal arcus caused by the osteogenesis imperfecta. (c) Severely crippling Sillence type II osteogenesis imperfecta—this patient has a relatively normal face, shortened upper-limb segments, a broadened and distorted chest, and convex, distorted lower limbs: he had a Gly–Cys mutation at position 415 of the collagen a1(I) chain. (d) Severely affected patient with Sillence type IIb osteogenesis imperfecta. (e) Lethally affected patient with Sillence type IIa osteogenesis imperfecta.

Types I and IV osteogenesis imperfecta

Generally both are mild disorders presenting in infancy or childhood with occasional fractures. Although the defect can present at birth, childhood fractures that improve at puberty are more usual. Type I osteogenesis imperfecta differs from type IV only by the deep blue sclerae, which in patients with type IV are pale grey or white. Common features include autosomal-dominant inheritance (multiple affected generations with transmission through either sex), variably short stature, and childhood fractures improving at adolescence but recurring after the menopause. There are occasional, rarer variants in which fractures are more common in females but rare in males. Rather than improve (in number) in adolescence they continue unabated throughout adulthood. In these families, males have fractures only rarely. Many different mutations have now been observed (Fig. 4). Deafness or dentinogenesis imperfecta segregate separately, sparing some families whilst rampant in others. In families with dentinogenesis imperfecta the primary dentition is uniformly opalescent (slate or brownish coloured), whilst the changes in the secondary dentition are usually patchy with the lower incisors and first permanent premolars particularly prone. Dental radiographs characteristically show short, tapering roots and expanded crowns. Histologically, there are sparse or agglomerated dentinal tubules, both by light and electron microscopy (Fig. 5). The dentinogenesis imperfecta/osteogenesis imperfecta disorder is separate from isolated dentinogenesis imperfecta, which affects the primary and secondary dentition equally. More rarely it is associated with minor joint laxity similar to Ehlers–Danlos syndrome III (Komorowska *et al*. 1989) and is also probably a connective tissue disorder. The gene has been located to chromosome 4.

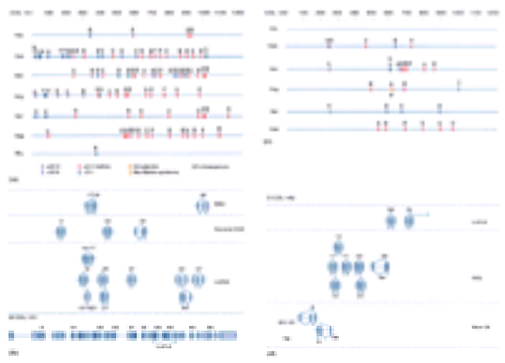

Fig. 4 Distribution of type I collagen mutations arranged by glycine substitutions for COL1A1 and COL1A2 (a and b) and by exon skips (c and d). (Updated from information by Byers (1990), Kuivaniemi *et al.* (1991), and Cole and Dalgleish (1995).) Different colours indicate the severity of osteogenesis imperfecta and exon skips are denoted by superscripts. OI = osteogenesis imperfecta, ED = Ehlers-Danlos syndrome, op = osteoporosis.

Fig. 5 (a) Typically patchy distribution of dentinogenesis imperfecta in adolescent teeth of mild Sillence type I osteogenesis imperfecta; the lower incisors and premolars are particularly affected. (b) Dental radiographs in typical osteogenesis imperfecta showing shortened, tapering roots, obliterated pulp cavities, and tulip-like crowns. (c) This mother and baby both have mild Sillence type I osteogenesis imperfecta. Note mother's triangular head. Both individuals have blue sclerae.

Sillence type II osteogenesis imperfecta is a severely crippling and often lethal disease (Fig. 2(a, b) and Fig. 3(b). Affected babies die either *in utero* or perinatally from a variety of causes such as cerebral haemorrhage, strangulated hernias, or chest infections. Some of them occasionally have severe congenital heart disease. The majority who die early do so from chest infections and pulmonary restriction, which complicate the widespread fractures. Sillence described three main types, IIa, IIb and IId, of which the first two have unmodelled, rectangular limb bones, especially the femurs and humeri. Osteogenesis imperfecta type IIa has characteristically widened and multiply fractured ribs, which have a generalized, feathered appearance. Osteogenesis imperfecta type IIb, in contrast, shows either nodules (from callus formation) or unbroken but thinned and slightly misshapen ribs. After slight modification of Sillence's classification by Thompson *et al*. (1987) (Fig. 2(a,b)), this type was called osteogenesis imperfecta III instead of type IIc as originally proposed by Sillence. Osteogenesis imperfecta IIc (Thompson *et al*. 1987) describes babies with very much more severely twisted (sometimes modelled) limb bones, distinct from osteogenesis imperfecta IIa and b. Similarly, the ribs are thinned, nodular, or sometimes contain multiple fractures but are always thinner and more distorted than those of IIa and b. With the thin-boned infantile variant, osteogenesis imperfecta III, most will survive to adulthood. Here there are slightly distorted ribs that are gracile rather than widened, whilst there are well-modelled limb bones often with angulated, U-shaped tibiae. This subset might be better named Sillence IId osteogenesis imperfecta in babies but osteogenesis imperfecta type III in surviving adults (and some certainly die in infancy or early childhood). Osteogenesis imperfecta type IIa is invariably lethal, as are many forms of IIb and IIc, so there are insufficient data to classify adult survivors. Probably osteogenesis imperfecta type III would be an appropriate designation for most of them. In practice the Sillence IIa–c classification is a useful guide for what is actually a continuous spectrum of clinical changes with broad-boned lethal osteogenesis imperfecta at one extreme and thin-boned osteogenesis imperfecta at the other. Such clinical variability is quite consistent with a wide range of individual and unique collagen mutations. Inheritance is usually autosomal-dominant, and most affected babies have arisen from sporadic new mutations, some of which (10 per cent) have parents with somatic gonadal mosaics. Multiple reoccurrences in this circumstance simulate autosomal-recessive inheritance (Byers 1990). Authentic autosomal-recessive inheritance is also well documented (Nicholls *et al*. 1984; Byers 1990) but distinguishable from mosaicism only if the gene defect is fully sequenced. There is also suggestive evidence that some osteogenesis imperfecta type IId phenotypes are unlinked to both *COL1A1* and *COL1A2*. Proteins other than type I collagen must therefore participate.

Collagen type I mutations in osteogenesis imperfecta

Bone matrix protein is made largely of type I collagen, with small amounts of type V and with smaller traces of type III. The last comes from vascular structures such as arteries, veins and bone marrow, stroma, and capillaries (Pope *et al*. 1988a, Pope *et al*. 1988b). To date nearly 150 mutations of type I collagen have been detected, which include point mutations, deletions, insertions, and a number of splicing mutations, as outlined below (Byers 1990; Kuivaniemi *et al*. 1991; Cole and Dalgleish 1995) (see Fig. 4(a,b)). The Sillence classification only roughly correlates with the molecular pathology. Thus milder, Sillence type I and IV osteogenesis imperfecta is caused by silent alleles, point mutations or exon skipping of *COL1A1* or *–1A2* in relatively harmless parts of the molecule. Lethal and severely crippling osteogenesis imperfecta mostly arises from glycine substitutions of either *COL1A1* or *–1A2* genes. These severely disrupt the collagen helix either by producing homozygous, C-terminal mutations or much more commonly by forming disruptive helical substitutions that consequently impair helical conformation (or even produce kinking distant to the substitution site). A good example is Gly–Cys748 of *COL1A1* in which processing of the distant N-propeptide is subsequently severely compromised (Vogel *et al*. 1988). Thus glycine substitutions are often position-specific, either interfering with helical folding (as measured by proteinase susceptibility) or impairing protein crystallization with normal folding. Mutations also produce the so-called protein suicide effect, in which the presence of one or more abnormal proa chains within triple helices causes both normal and abnormal products to be intracellularly degraded (Prockop and Kivirriko 1984; Prockop 1990). Thus either one or two mutant molecules in a heterotrimer of wild-type and mutant products destroy their companion normal components too. Only wild-type a1(I)2a2 heterotrimers (12 per cent of the whole) survive to be successfully secreted. Occasionally both mutations (shortened and normal heterotrimers) escape. Domains of micro-unfolding present as ladders of varying molecular size after proteinase digestion. This implies heterogeneity of protein function within the triple helix.

Point mutations (see Fig. 4(a))

Gly–Cys substitutions clearly illustrate how mutational location affects clinical phenotype. Thus two similar Gly–Cys substitutions, both within the C-terminal, CNBr fragment a1(I)CB6, cause widely disparate clinical phenotypes. The one causes very mild, autosomal-dominant Sillence type I whilst the other causes lethal, Sillence type II osteogenesis imperfecta. The effect of the two errors correlates precisely with their location. Both produce a novel, higher molecular-weight, disulphide-linked dimer running above normal collagen a1(I) chains. Both individual peptide maps showed a pattern derived from collagen a1(I) chains, with a1(I)CB6 running as a dimer; after reduction the dimer disappeared whilst a1(I)CB6 reappeared (Steinmann *et al*. 1984; Pope *et al*. 1988b) (Fig. 6). The lethal a1(I) dimer melted at 38°C whereas the dimer from the mild osteogenesis imperfecta melted normally at 41°C (Fig. 7). This disturbed helicity in the lethal but not the mild mutation. At the time the location of both mutations to *CB6* belied their very different clinical phenotypes. Possible explanations included a Gly–Cys substitution in the severely affected patient and a second- or third-position Arg or Ser–Cys substitution in the milder case. Alternatively, a second silent mutation might have produced a combined lethal effect. Cloning and sequencing the relevant gene fragments showed that both mutations were GCG–TCG; the lethal at position 988 and the mild at position 1017 only 30 bp (10 amino acids) away. The mild mutation substituted the first glycine outside the collagen triple helix (with unimportant biophysical effects), whilst the 988 mutation changed the tenth glycine from the C-terminus of the a1(I) helix and is consequently lethal. Whereas the 988 substitution produced a protease-susceptible collagen that melted at 2°C lower than normal, the 1017 mutation produced an a1(I) collagen protein that melted normally (Fig. 7). Subsequently, at least 13 other cysteine substitutions have been identified at scattered locations ranging from near the N-terminus to as far 3' as from the C-terminus (see Fig. 4(a)). Substitutions at the C-terminus of amino acid 690 to the end of the helix have been lethal, with those between amino acids 391 and 559 severely crippling. In contrast, N-terminal ('left-hand') mutations between 94 and 223 have been uniformly mild (Byers 1990; Kuivaniemi *et al*. 1991; Cole and Dalgleish 1995). This is consistent with two other mutations that we have studied, the one at residue 19 close to the N-terminus producing premature osteoporosis, and the other at amino acid 415 producing a mixed Sillence type III/IV phenotype. Those cysteine substitutions of a2(I) collagen produce less predictable phenotypes. Thus, one at position 259 had an osteogenesis

imperfecta type III phenotype whilst at position 472 there was a genetic lethal and at position 646 a severe type IV phenotype (Byers 1990; Kuivaniemi *et al*. 1991). Such differences are partly due to ascertainment bias. For example, whether severe crippling affects survivors or premature lethality kills younger babies is partly determined by randomly encountered respiratory pathogens or other complications such as respiratory restriction, cerebral haemorrhage, or congenital heart disease.

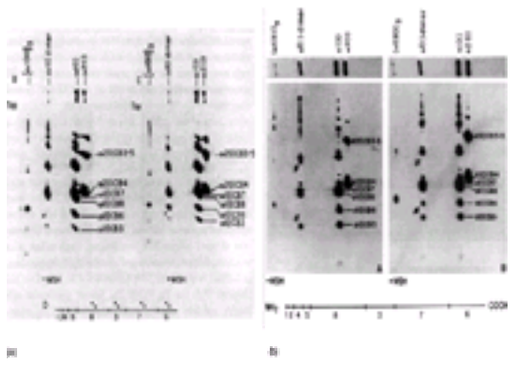

Fig. 6 Two-dimensional gel electrophoresis of radiolabelled collagens from (a) a lethally affected patient described by Steinmann *et al*. (1984) and (b) a mildly affected patient described by Steinmann *et al*. (1986). The lethally affected individual has tilted 'smiling' of all CNBr peptides and the mildly affected has horizontal, 'non-smiling' gels, yet both have mutations localized to a1(I)CB6 and produce an additional, higher molecular-weight dimer running heavier than the a1(I) chains. This is obvious when the gels are compared before (-MSH) and after (+MSH) reduction with mercaptoethanol. The order of peptides from N- to C-termini is shown diagrammatically.

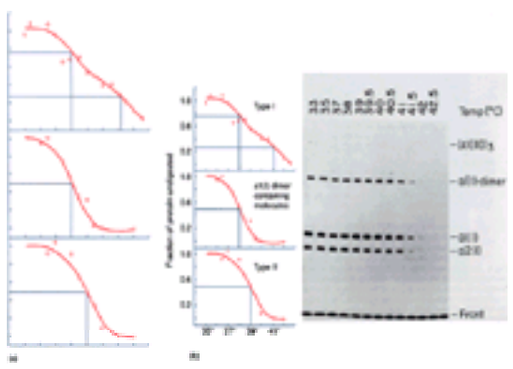

Fig. 7 Comparison of the melting profiles of the lethal and mild osteogenesis imperfecta (from Steinmann *et al*. 1984 and Steinmann *et al*. 1986). The lethally affected patient has differing melting curves for the cysteine-containing and normal a1(I) chains (shown as a graph). (a) The cysteine-containing a1(I) chain melts at 2°C earlier than its wild-type; in contrast, the cysteine-containing chain from the mildly affected individual melts identically to the wild-type a1(I) chains. The mutational position therefore influences the proteinase susceptibility of the two different mutant chains. Whereas the melting curve is plotted as a ratio in (a), similar data are shown at each time point in (b).

Other substitutions (see Fig. 4)

To date, there are more than 150 mutations of type I collagen a1 or a2 genes (*COL1A1* and *COL1A2*), including those already discussed. The same broad generalization applies, that is, alterations closest to the C-terminus are the most disruptive (Byers 1990; Kuivaniemi *et al*. 1991). Glycine to cysteine, alanine, serine, arginine, valine, and aspartate have all been identified in the *COL1A1* gene and glycine, valine, arginine, and aspartate in the *COL1A2* gene. Severity varies with the position and also the type of substitution (Fig. 4(a)). For example, Gly–Asp mutations are universally lethal, even at position 97, which lies close to the N-terminus of a1(I) collagen up to position 883 much nearer the C-terminus. Similarly, the two recorded a2(I) Gly–Asp substitutions at positions 547 and 976 are also lethal. Somewhat paradoxically, since they are such small amino acids Gly–Ser mutations can be lethal if located at the C-terminus. Gly–Val substitutions (also rather rare) are lethal wherever they occur. Up to 1991, no Gly–Glu substitutions had been recorded for either type I gene nor have any appeared subsequently. On the other hand, several have now been identified in the *COL3A1* gene (see below). Clinical severity is therefore determined by helical position, the nature of the substitution, and other less tangible influences such as local interaction with neighbouring molecules or local domain effects, whereby neighbouring changes can have widely disparate clinical consequences (Byers 1990). Many questions still remain and the distant consequences of specific mutations (perhaps caused by three-dimensional protein-folding effects) also require clarification. For example, as mentioned earlier, the Gly–Cys748 mutation introduces a local kink at this position, yet mysteriously interferes with the function of the N-propeptide more than 500 amino acids away (Vogel *et al*. 1988).

Similarly, studies of collagenase A and B fragments have identified areas of micro-unfolding between 637 and 775 of collagen a1(I). Two nearby Gly–Ser substitutions in positions 598 and 631 show an adjacent region between amino acids 500 to 631 (Westerhausen *et al*. 1990). Very probably others lie elsewhere in the collagen helix.

Other important questions include the mechanisms for chain selection. Thus, why should a1(I) $_2$a2 be formed in preference to a1 trimer? Presumably, but for no clear reason, a2 is required for bone calcification and organization but is less essential in tissues such as skin or sclerae.

Exon-skipping deletions (Fig. 4(b))

Most vertebrate structural genes, including those for collagen types I and III, are interrupted by non-coding introns of between 80 and 10000 bp. Collagen introns lie at the lower end of this scale. The primary mRNA transcript is transcribed from genomic DNA. It is then very precisely processed and the 52 constituent exons rejoined correctly. These include the 42 triple-helical exons, the four C-terminal exons, and the six exons of the N-propeptide. The 5' and 3'ends of each intron have invariant splice-junction donor sites (at the 3' end of the 5'-most exon) and acceptor sites at the 5' end of the 3'-most exon. The former is usually GT (in genomic sequence) and the latter AG. Some pre-mRNA transcripts are spliced into several independent transcripts by exon shuffling. Examples include pituitary hormones, viral proteins, and the immunoglobulin variable regions (Watson *et al*. 1987). Mutations of the conserved junctional sequences disrupt correct splicing of those complicated genes, with many introns. Collagen demonstrates many such examples. Single nucleotide changes can destroy a normal splice site or activate hidden (cryptic) alternatives. Thus shortened, extended, extra, or missing exons result. If the 3' polyadenylation sequence is missing, the translation continues to the next downstream 3' equivalent. Such variability is a potent means of evolutionary change.

The gradient of collagen exon-skipping deletions (Fig. 4(b)) lies along the collagen genomic sequence in a similar fashion to point mutations (Byers 1990; Kuivaniemi *et al*. 1990, Kuivaniemi *et al*. 1991). Thus several C-terminal *COL1A1* mutations have been lethal (exons 43 and 44), whilst mid-gene defects are severe or lethal (exons 27 and 30). In contrast, N-terminal skipping can be either mild (17) or lethal (14), and similar considerations apply to the *COL1A2* exon skips. Up to 1991 there had been 18 *COL1A1* and *COL1A2* exon skips and now (in 1995) there are 36 skips (Byers 1990; Kuivaniemi *et al*. 1991; Cole and Dalgleish 1995). We have observed an atypical, large family with autosomal-dominant osteogenesis imperfecta who have mis-splicing of exon 9 of the *COL1A2* gene with a shortened a2-protein (Nicholls *et al*. 1991). Protein mapping was unhelpful but amplification by PCR showed there was an 11-bp insertion spanning the intron–exon junction of both exon and intron 9. This caused mis-splicing of exon 9, with a shortened a2(I) protein missing 18 amino acids.

Null alleles commonly cause Sillence type I osteogenesis imperfecta (Willing *et al*. 1992) and mouse models with *COL1A1* mutations have a phenotype similar to human osteogenesis imperfecta (Khillan *et al*. 1991).

Mutation with milder phenotypes that are neither deletions nor caused by exon skipping

Many Sillence type I osteogenesis imperfecta patients produce less type I collagen than normal. This is easily detectable by polyacrylamide gel electrophoresis as a relatively higher abundance of type III collagen protein (Fig. 8(a)). Type I collagen is normally secreted and not overmodified, and has no structural abnormalities. Theoretically, mutations affecting gene expression, translational efficiency, stability of proa chains, and molecular assembly could all produce relatively low amounts of type I collagen protein, though in practice stop-codon mutations are common. Steady-state levels of cytoplasmic mRNA are often lowered but may also be normal (Byers 1990). Gene linkage to *COL1A1* is commonplace in up to 95 per cent of this phenotype (Sykes *et al*. 1990). Occasionally, point mutations occur (as in our Gly–Cys family). Willing *et al*. (1990) observed complete failure of incorporation of the proa1(I) chain in a patient with a small deletion, causing abnormal chain elongation. Occasionally, these are structural *COL1A1* alterations occurring with a very similar protein analysis to those causing lethal, Sillence type II osteogenesis imperfecta (Fig. 8(b)). Presumably, abnormalities of protein migration indicate more subtle underlying changes that determine other crucial differences in the clinical phenotype. Null mutants are distinguishable from wild-type genes by reverse transcriptase-PCR of allele-specific, intragenic cDNA polymorphisms. This allows confident discrimination between expressed or non-expressed alleles (Willing *et al*. 1990).

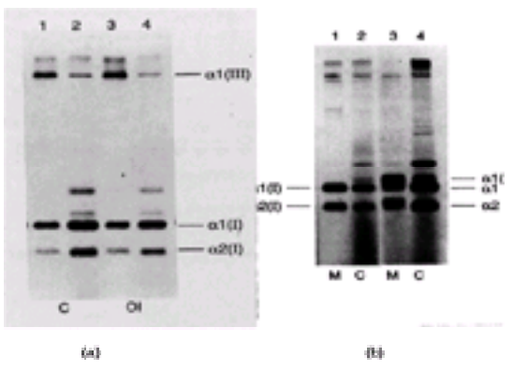

Fig. 8 Radiolabelled collagen profiles. (a) Low type I collagen producing mild osteogenesis imperfecta: the intensity of the unreduced a1(III) band distinguishes affected individuals [relatively more type III collagen secreted into the medium (track 3) from unaffected (track 1)]. There is no difference in the cell-layer collagens (tracks 2 and 4). C, control; OI, osteogenesis imperfecta. (b) Double a1(I) components [one a1(I)H, of higher molecular weight] that occur in some rare, mild OI families. In this instance a double a1(I) band is secreted into the medium (M) whereas in the cell layer(C) mainly a1(I) is retained (tracks 3 and 4). The equivalent band retained in the cell layer of the control (track 2) is type V collagen.

COL1A2 mutations that lower the synthesis of a2(I) will also affect the ratio of collagen III to I. Here the a1:a2 ratios will exceed 2, in contrast to depletion of a1(I), with ratios near to 1. Those a chains not incorporated into heterotrimers could either form a1(I) trimers [a1(I) chains] or self-degrade (a2 chains). Exceptionally chains with apparent a2 dimers can form anomalously. It is unclear whether these are stabilized by inter- or intramolecular cross-links, but the clinical phenotype is not osteogenesis imperfecta.

A unique, 4-bp deletion in *COL1A2* was clinically silent in the heterozygote male whilst the carrier female manifested premature osteoporosis. In contrast, the homozygous affected child had very severe, Sillence type III osteogenesis imperfecta. Both heterozygous parents also showed increased joint laxity and slightly thin bones (Nicholls *et al*. 1984b). The 4-bp deletion produced a frameshift with a nonsense downstream sequence resulting in a defective sequence of the last 31 amino acids. It is also possible that deletions at a2 might cause entirely different (non-osteogenesis imperfecta) clinical phenotypes.

Gonadal mosaicism

There are now many examples of single *COL1A1* or *COL1A2* mutations causing lethal osteogenesis imperfecta. Usually, these are sporadic, new, autosomal-dominant mutations with negligible risks for recurrence. Occasionally, there are extraordinary families with four or more affected children but normal parents, suggesting the possibility of germ-line mosaicism (Byers 1990). Such families were previously considered autosomal-recessive Compound heterozygosity for two separate collagen mutations is also possible. Thus both Sillence osteogenesis imperfecta types IIb and c were considered in this category. Most are gonadal mosaics, as judged by the clinical expression of a milder (non-lethal) phenotype in the carrier parent, the properties of the mutant protein and expression of the mutant gene in fibroblasts, hair bulbs, saliva, lymphocytes, seminal fluid, or ovarian biopsies. A good example is Gly–Cys at position 472 of the *COL1A2* gene. Here a man with clinically mild osteogenesis imperfecta fathered separate children with osteogenesis imperfecta from two different mothers. The mutant gene occurred in 33 per cent of sperm, 67 per cent of lymphocytes, and 100 per cent of dermal fibroblasts. A second example is Gly–Cys904 in *COL1A1*. Here, the overmodified collagen was protease-susceptible at a low denaturation temperature. The proband's mother was a mixed somatic/gonadal mosaic with mild, Sillence type I osteogenesis imperfecta (including a triangular face and blue sclerae). A third example is Gly–Arg550. Here a lethally affected fetus had a mildly mosaic father with the osteogenesis imperfecta type IV phenotype.

Mouse models

Mice with severe disruption or severely shortened forms of collagen type I reproduce a clinical phenotype very similar to or identical with osteogenesis imperfecta (Jaenisch *et al*. 1983; Khillan *et al*. 1990).

Osteogenesis imperfecta with neither *COL1A1* nor *COL1A2* mutations

We have observed several examples, some with Sillence type IId osteogenesis imperfecta. One osteoporotic but otherwise normal mother partially expressed a doublet of normal and overmodified mutant a1(I) chains; she has had three children lethally or severely affected by osteogenesis imperfecta. In a second family of osteogenesis imperfecta, two clinically normal parents have produced six consecutively affected children with type IId (D. A. Gibbs *et al*., 1991; personal communication). Here, both an overmodified and a normal protein are produced. Mapping data imply a defect at the 3' end of either the *COL1A1* or *COL1A2* gene, and the protein overmodification was sufficiently distinctive for prenatal diagnosis (Fig. 9(a)) In the absence of such changes, ultrasonographic monitoring of limb length can be very useful (Fig. 9(b)). Both compound heterozygosity and autosomal-recessive inheritance are unlikely (with odds of 4096/1 against), and cloning and sequencing of the a1(CB6) region and the homologous region of *COL1A2* followed by allele-specific hybridization of parental tissues seems to exclude collagen type I, with the implication of mutations of genes other than *COL1A1* or *COL1A2*.

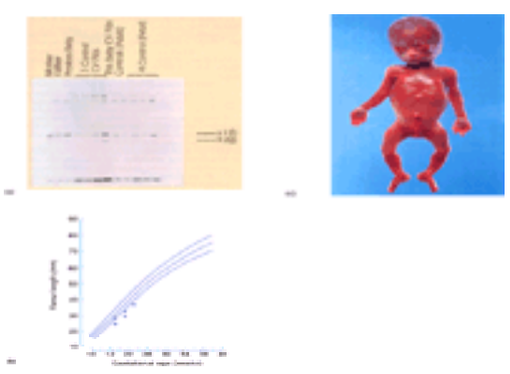

Fig. 9 (a) Patterns of overmodified a(I) and a2(I) collagen profiles in two consecutively affected siblings. The seriously previously affected baby is compared with the current pregnancy in various parental normal and fetal controls. (b) The ultrasound calculation of femoral length was used as a back up. It consistently fell near or below the third percentile. (c) The terminated fetus had obvious deformities of his lower limbs.

Osteogenesis imperfecta with normal collagen type I protein

Some patients with osteogenesis imperfecta have no obvious abnormalities of a1(I) or a2(I) collagen proteins but still have abnormal *COL1A1* and *–1A2* genes. Genetic linkage studies are a valuable alternative in suitable families and will often pinpoint the mutant gene. Several RFLPs are now available, including *Msp*I and two *Rsa*I sites for a1(I) and *Eco*RI, *Msp*I, *Stu*I, and *Rsa*I for the *COL1A2*. All of them are suitable for analysis by Southern blotting or PCR (Sykes *et al*. 1990), with at least a 95 per cent probability that over 90 per cent of families with osteogenesis imperfecta will be linked to either *COL1A1* or *COL1A2* markers. Most Sillence type IV pedigrees have segregated with *COL1A2* markers, whilst families with Sillence type I osteogenesis imperfecta are three times more likely to be linked to a *COL1A1* marker.

Linkage in autosomal-recessive osteogenesis imperfecta

Such linkage data have been consistent for autosomal-dominant families but not for autosomal-recessive inheritance. For example, we have studied an unusual Irish 'traveller' family with three consecutive children lethally affected by type IId osteogenesis imperfecta. Here, two first cousins had married. In this family, linkage data suggested that neither the *COL1A1* nor *COL1A2* gene was to blame yet the protein mapping data showed clear overmodification of collagen type I peptides. The latter usually would indicate C-terminal mutations of either the *COL1A1* or *COL1A2* genes. To date this paradox remains unresolved. We have also observed at least three similar Asian Indian or Middle European families. Possible explanations include unusual somatic mosaicism, compound heterozygosity, or the involvement of unidentified matrix gene other than *COL1A1* or *COL1A2*.

Ehlers–Danlos syndrome type VII

Whether collagen type I (*COL1A1*/*COL1A2*) mutations cause osteogenesis imperfecta or Ehlers–Danlos syndrome VII depends entirely upon the location of the error. Type VII is a distinct subset of Ehlers–Danlos syndrome typified by extreme early joint laxity, increased skin fragility (similar to Ehlers–Danlos syndrome I/II), and misshapen collagen fibrils by transmission electron microscopy (Fig. 10(b)). Ehlers–Danlos syndrome VII overlaps clinically those with osteogenesis imperfecta mutations caused by N-terminal helical mutants, but patients with Ehlers–Danlos syndrome VII rarely break bones whilst the osteogenesis imperfecta group lacks skin fragility. There are distinctive genetic subsets of Ehlers–Danlos syndrome VII: one group with structural abnormalities of type I collagen (*COL1A1* and *COL1A2*), and another in which the enzymes responsible for peptide cleavage (the N- and C-propeptidases) are faulty. The former (structural) group usually has errors in exon 6 of either the *COL1A1* or *COL1A2* genes (Fig. 10a). The latter group has specific errors in the N-terminal propeptidase that cleaves the N-propeptide from both pro-a1(I) and pro-a2(I) chains. Very probably (see below), intraexonic mutations of exon 6 and other more complex deletions of this region can also produce similar disorders. Here the subtleties of the protein chemistry will depend upon whether the N-proteinase or pepsin/trypsin cleavage sites, or lysine hydroxylation sequences, are omitted. (Fig. 10(c))

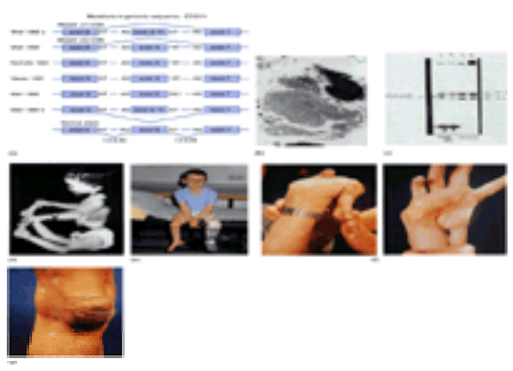

Fig. 10 (a) Diagrammatic representation of certain published mutations in Ehlers–Danlos syndrome VII affecting the splicing of exon 6 of either the *COL1A1* or *COL1A2* genes. (b) Collagen fibril patterns in our Dutch patient (Pope *et al*. 1991). (c) Radiolabelled collagen profiles from Ehlers–Danlos syndrome VII patients (tracks 1 and 2) compared with normal control (tracks 3 and 4) with persistent pNa2 chains after pepsinization. (d) Affected patient with Ehlers–Danlos syndrome VII (after McKusick 1972)—note extreme rotation of hips and knees. (e) British patient with *COL1A1* splice-junction mutation. Note early premature cutis laxa and joint laxity sufficiently severe to require bracing of the unstable knees. (f) Laxity of finger joints and (g) abnormal scarring of knees and shins from the Dutch patient whose fibres are shown in (b) and (c). These changes resemble Ehlers–Danlos syndrome I/II (see also Fig. 20 and Fig. 21).

Ehlers–Danlos syndrome type VIIC also closely resembles the peptidase deficiency of cows, sheep, and Himalayan cats (Pope *et al*. 1988b) in which failure to remove any precursor N-propeptides causes lethal or severe skin fragility. Skin from these animals has very characteristic hieroglyphic fibrils when examined by transmission electron microscopy. Recently, equivalent human mutations have shown identical changes (Nusgens *et al*. 1992; Smith *et al*. 1992). Other notable features of these patients with Ehlers–Danlos syndrome VIIC include identical biochemical changes, with disordered removal of the faulty N-propeptides, and various novel clinical features including premature, generalized cutis laxa with severe blepharochalasis, severe joint dislocation particularly of the hips, and unusually wrinkled skin of the dorsum of the hands and feet as well as the palms and soles.

Types VIIA and B are possibly the most individual of the phenotypes of Ehlers–Danlos syndrome. Biochemically the molecular defect is remarkably consistent and so far, in published families, has involved a splicing failure of exon 6 of either the *COL1A1* or *COL1A2* collagen (Weil *et al*. 1989a, Weil *et al*. 1989b; Nicholls *et al*. 1991; Cole *et al*. 1993) (Fig. 10(a)). This specifically deletes the peptidase cleavage site from one or two of the three a-chain components of collagen type I heterotrimers, with consequent slippage and disruption of collagen helical packing and faulty formation of fibrils, visible as highly irregular, angulated fibrillar patterns (Fig. 10(b)). At the protein level, inefficient processing of procollagen to collagen causes persistence of pNa1 or pNa2 molecules after pepsinization (Fig. 10(c)).

The clinical features include extreme, persistent joint laxity, presenting as congenital dislocation of the hips in infancy and later joint laxity in childhood (Fig. 10(d,e,f)), short stature, scarring of the knees (Fig. 10(g)), forehead, and shins as severe or even worse than in Ehlers–Danlos syndrome I, with a typical criss-cross patterning of the palms. Inheritance is autosomal-dominant. Surprisingly, fractures and osteoporosis are rare, although they commonly accompany nearby N-terminal helical, *COL1A1* or *–1A2*, point mutations in severely loose-jointed variants of osteogenesis imperfecta with osteoporosis and short stature (see Fig. 4(a)). Mutated sequences 5' of exon 6 might also cause phenocopies of Ehlers–Danlos syndrome VII. As mentioned earlier, more subtle mutations within exon 6, such as insertions, deletions or point mutations, might also produce similar phenotypes, especially if highly conserved residues are changed. Perhaps mutation of the adjacent exons (3, 4, and 5) might also produce similar diseases but with variable severity of structural or fibrillar packing. Certainly, mutations of the first few helical exons of the *COL1A1*, *–1A2* or *–3A1* genes regularly produce the expected skeletal or arterial phenotypes of osteogenesis imperfecta and Ehlers–Danlos syndrome IV, which nevertheless are distinct from Ehlers–Danlos syndrome VII. Mutations of the N-terminal propeptidase of *COL3A1* could presumably still produce hieroglyphic fibrils but with vascular rather than predominantly ligamentous pathology (Karl Kadler, personal communication).

Chondrodystrophies and chondrodysplasias

Until very recently the mechanisms of the chondrodystrophies have been extremely difficult to unravel (Maroteaux 1970; Beighton 1995). They are very heterogeneous, with more than 100 recognized non-allelic disorders. Bone and cartilage matrix is also biochemically diverse and contains numerous structural proteins including collagen types I, II, III, V, VI, IX, X, and XI, proteoglycans such as chondroitin sulphate, proteoglycan link protein, hyaluronic acid, and certain other minority components such as osteopontin, osteonectin, and the Gla proteins. All are therefore potential candidate genes. As recently as 1989 knowledge of the molecular pathology of these disorders was primitive. In the first version of this chapter (1993), a few *COL2A1* (cartilage collagen II protein) mutations had been detected in disorders such as achondrogenesis, Kniest dysplasia, certain spondyloepiphyseal dysplasias, and Stickler syndrome (Ahmed *et al*. 1990). Since 1994 the field has exploded to include other unexpected genes such as the segmentation genes, *HOX, PAX* and *SOX*, certain connective tissue components such as morphogenetic proteins (e.g. bone morphogenetic protein 5), and other skeletal regulators such as the fibroblast growth factors and their receptors, the *FGFR* genes. Other important substances have included glycosaminoglycan sulphation proteins and the sulphate transport proteins (see below). Simultaneously there has been

consolidation and expansion in the analysis of more conventional connective-tissue scaffolding genes such as *COL9A1*, *–2*, and *–3* (collagens IX) and *COL10A1* (collagen X), all of which cause skeletal dysplasia. Other unexpected candidates are the thrombospondin gene family, a good example of which is the *COMP5* gene on chromosome 19, which causes multiple epiphyseal dysplasia. In men and mice the *COL11A1* and *–11A2* genes have been separately implicated, causing autosomal-recessive chondrodysplasias (with abnormal cartilage, limbs, ribs, mandible, and trachea) in mice, and, in humans, autosomal-recessive Stickler syndrome with spondyloepiphyseal dysplasia, osteoarthritis, and deafness but without ophthalmic changes, caused by homozygous Gly–Arg substitutions (the so-called otospondylomegaepiphyseal dysplasia syndrome). Here there was severe, degenerative osteoarthritis of hips, knees, and elbows; other features included mid-facial hypoplasia with shortened noses and supraorbital ridges, and sensory neural deafness. Some Stickler families unlinked to *COL2A1* or *–11A2* have been linked to *COL11A1* (Snead *et al*. 1994) whilst in others the gene locus is unknown. The phenotype of the *COL11A1* families includes vitreoretinal detachment, premature myopia, joint laxity (lessening with age), and skeletal disproportion, but without short stature or facial hypoplasia. There has been rapid progress in work on *COL2A1* mutations, with convincing abnormalities now demonstrated in achondrogenesis, Kniest syndrome, the Stickler syndrome, and certain spondyloepiphyseal dysplasias including Strudwick-type spondyloepimetaphyseal dysplasia. The field has also been greatly enriched and illuminated by the creation of transgenic mouse models for several chondrodystrophies. Occasionally these have provided unforeseen and unexpected information. Thus, mice with *COL11A1* deletions have convincing chondrodysplasia, with shortened snouts, stunted limbs, and tracheomalacia (Li *et al*. 1995). Mice homozygous for *COL5A2* mutations have kyphoscoliosis and cutaneous fragility, and resemble humans with Ehlers–Danlos syndrome type II (Andrikopoulos *et al*. 1995). [*COL10* knock-outs are clinically normal (Rosati *et al*. 1994), although human, autosomal-dominant negative, glycine substitutions in *COL10A1* cause Schmid metaphyseal dysplasia. Here a faulty protein is much more disruptive than a missing component.]

Other important clues include the location of chondrocalcinosis with osteoarthritis to chromosome 8q and the implication that proteoglycan sulphation is disturbed in diastrophic dwarfism and certain types of achondrogenesis (Hastbacka *et al*. 1994; Superti-Furga 1995). Studies of mutations in the *FGFR* gene family have revolutionalized the molecular pathology of the craniofacial dysplasias of Apert, Crouzon, and Pfeiffer syndromes as well as of apparently unrelated disorders such as achondroplasia, hypochondroplasia, pseudoachondroplasia, and thanatophoric dwarfism, which are therefore allelic to the craniofacial dysplasias and one another.

Collagen mutations causing chondrodysplasias

The major connective tissue protein of cartilage collagen is coded by the *COL2A1* gene. It is also present in the vitreous humour of the eye. Other important structural proteins include collagen IX (a1, a2, and a3 chains), collagen X, which forms in hypertrophic cartilage in the metaphyses, and more unexpected elements such as cartilage-specific matrix protein, a member of the thrombospondin family. Cartilage is therefore a complex connective tissue that is phylogenetically ancient. Whilst typical in containing cell matrix and fibrous elements, it differs from other tissues such as skin, ligament, and bone in having a higher proportion of cells and matrix relative to the fibrous elements. During fetal life the entire protoskeleton is initially cartilaginous, remaining so until birth, when only fragments have differentiated into more mature bone. Later, except for certain articular surfaces, most of original cartilaginous protoskeleton changes into bone, a continuing process that in humans is not complete until well into adolescence. Even then, cartilaginous elements persist in the ears, nose, ribs, articular surfaces, and respiratory tracts, and at other unexpected sites such as the vitreous humour, where a more gelatinous form of cartilage matrix persists and is crucial for the optical properties of the posterior eye. Since it adheres closely to the retina, abnormalities and fibrous contractions result in retinal detachment and blindness.

Cartiliginous matrix has several variants including hyaline and fibrocartilage. The latter includes white fibrocartilage, which is rich in collagen, and yellow elastic cartilage, which is rich in elastin. Articular hyaline cartilage lines the articular ends of bones within synovial cavities. Here it provides a robust and stable surface lubricated by synovial fluid. Collagen bundles align tangentially near the articular surface but thicken if running vertically or more deeply. Chondrocytes tend to be flattened superficially but form distinctive vertical columns as they approach the bony metaphyses. Chondrocytes are firmly embedded in the cartilaginous matrix containing several collagenous proteins, such as collagens II, VI, IX, X, and XI; whole genes have all been cloned and sequenced. Many other cartilaginous components have also been located, cloned, and sequenced. This has allowed rapid progress in the molecular pathology of various chondrodysplasias and, since 1992, specific mutations in *COL2A1, COL5A2, COL11A1*, *–11A2*, *–9A1*, *–9A2*, and *–10A1* genes have been shown to produce a wide range of skeletal disorders (Table 1).

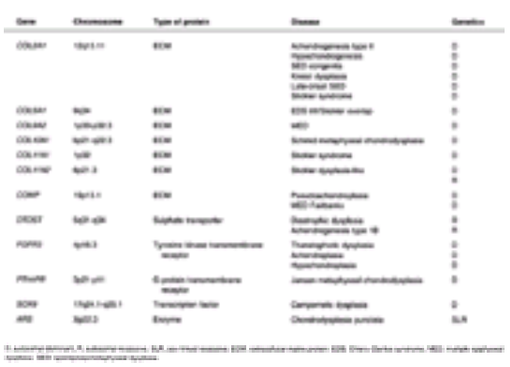

Table 1 Collagen gene mutations and their skeletal manifestations

Abnormalities of other components combine to produce an impressive range of chondrodysplasias. Thus, abnormalities of the *COMP5* gene produce a cartilage-specific glycoprotein that has a five-armed structure similar to thrombospondin. Here the clinical phenotype causes spondyloepiphyseal or metaphyseal dysplasias, similar or identical to those caused by *COL9A1* and *–9A2* mutations, respectively. Probably shared structural interactions of the two molecules produce common organizational changes and pathology. Mutation of *COL10A1* produces Schmid metaphyseal dysplasia in which the hypertrophic cartilage of the metaphyses is abnormal.

Since 1993 there have been other quite unexpected advances, implicating components that are shared by bone and cartilage alike, such as the *FGFR* genes. These bind certain fibroblast growth factors that orchestrate the expression and differentiation of numerous other mesenchymal growth factors. Their receptors are diverse but homologous and include FGFR-1, -2, and -3. All have extracellular, immunoglobulin-like, binding regions with transmembranous tyrosine kinase-like domains and intracellular sequences that transmit certain cytoplasmic signals. Mutations of either the IgG or transmembranous regions of FGFR-1, -2, and -3 have been implicated in achondroplasia (FGFR-3), Crouzon, Apert, Pfeiffer, and Jackson–Weiss syndromes (FGFR-1 and -2), and disorders such as achondroplasia, hypochondroplasia, and thanatophoric dwarfism. Although unexpected, this provides a convincing rationale for disorders in which the orchestration and timing of skeletal function are impaired. These molecules are quite separate from, and upstream (in hierarchical terms) of, disorders caused by faulty structural proteins such as collagens II, X, and XI, of which collagen II only had been implicated as recently as 1993. The three years to 1996 produced a revolution in the molecular pathology of skeletal dysplasia in which a whole hierarchy of faulty products clearly participates (including defects of pattern, structural, organizational and mechanical errors, or changes in structural elements with scaffolding functions).

Hyaline cartilage is translucent though slightly opaque because of scattering by transmitted light. In polarized light it is fibrillar and, by electron microscopy, contains permeating fibrils of 10 to 20 nm. The *COL2A1* gene has the typical organizational structure of a fibrillar collagen comprising a central helix with N- and C-terminal extensions (Vuorio and de Crombrugghe 1990). The C-terminus is conventionally organized and coded by four exons (49–52), with exons 51 and 52 identical (in size) to those of other fibrillar collagens. The N-terminus is more variable, especially in the short triple helix, which in the *COL2A1* gene has several additional exons (and one non-helical interruption). Part of exon 3 and two extra exons (4B and 5B) code for the 79 amino-acid sequence of the N-terminus. The central triple helix is coded by exons 7 to 48 inclusive, and exons 49 to 52 encode the C-propeptide. The gene of 28 Kbp maps to chromosome 12.

COL2A1 polymorphisms

Various intragenic and flanking polymorphisms have been described (Francomano *et al*. 1987, Francomano *et al*. 1988; Wordsworth *et al*. 1988). They include *Hind*III and *Pvu*II variants detectable with a 9.2 kb *Eco*R1 fragment. In a large, autosomal-dominant, Finnish pedigree the *HindIII* RFLP was tightly linked to familial osteoarthritis Palotie *et al*. 1989. Similarly, a *Bam*H1, intragenic, RFLP is more common in Caucasian patients with osteoarthritis than in normal controls (Hull and Pope 1989), although in other examples *COL2A* is not involved (Baldwin *et al*. 1995). The *Eco*R1/*Bam*H1 hypervariable region in the 4.3-kb, *Eco*R1 3' flanking region of *COL2A1* has a useful variable repeat, which is deleted or duplicated in 30 bp multiples. More recently, the 5' *Hin*fI RFLP has also been informative in

spondyloepiphyseal dysplasia congenita (Anderson *et al*. 1990).

Many suitable markers for the *COL5A1*, *–5A2*, *–9A1*, *–9A2*, *–9A3*, *–11A1*, and *–11A2* genes have also been recently identified, all of which can now be tested in skeletal abnormalities. Here the 'educated guess' strategy is useful when the candidate gene is unknown, but other biochemical and structural information provides strong hints. Otherwise a systematic search of the genome becomes necessary and, in that regard, the recent Human Genome Mapping Initiative has produced a very dense map of human gene markers such as $(CA)_n$ sequence-tagged sequences. Any of these markers can firmly locate faulty human loci. A good recent example is the unexpected identification of the *COMP5* locus on chromosome 19 in multiple epiphyseal dysplasia (Briggs *et al*. 1995). Here, two separate lines of research converged: one had located the megaepiphyseal dysplasia locus whilst the other pursued the basic structure, function, and biology of the *COMP5* gene and protein. No doubt many other examples are destined to appear in the future.

Studies of human disease

Type II collagen predominates in cartilage but also forms the vitreous humour (of the eye). Several lines of evidence combine to suggest that cartilage collagen genes can cause specific skeletal dysplasias in man and other animals. Thus McKusick (1972), in categorizing inherited defects of connective tissue as a specific subset of human disorders, noted that chondrodystrophies were unusually diverse and variable examples. They form natural subgroups, which Spranger (1985) has very clearly delineated and which are likely to share common abnormalities in relevant cartilage components. For example, the distribution of collagen type II in articular cartilage, epiphyseal plates, and the vitreous humour strongly implies specific pathological patterns. Similarly, achondrogenesis I and II, hypochondrogenesis, and spondyloepiphyseal dysplasia are excellent candidates for *COL2A1* mutations as they all share the features of severe joint degeneration, variable skeletal deformities, and myopia. Furthermore, all have disordered cartilage organization with degenerative joint disease. The Kniest/Stickler and Wagner syndrome(s) also share similar clinical features. All show severe degeneration of hyaline cartilage and progressive myopia with or without retinal detachment. Other milder disorders with similar mechanisms include familial myopia with premature osteoarthritis and subsets of common osteoarthritis. The combined anatomical, biochemical, and molecular evidence implicates *COL2A1* mutations in most of these diseases.

To detect the mutations, three main approaches were used: (a) the ascertainment of suitable autosomal-dominant or -recessive pedigrees for studies of linked genetic markers; (b) the detailed analysis of cartilage collagen from tissue samples such as iliac crest or chondrocortical junctions or femoral heads; and (c) the amplification by PCR of mutant alleles detected by (a) or (b), followed by indirect or direct sequencing of mutated gene fragments. This strategy has been extremely efficient and informative, and is now largely comparable in outcome with similar studies of type I and III collagen mutations, differing only in that usually protein has been purified from tissue samples rather than cultured cells. Chondrocytes are more difficult to maintain in culture, but can be successfully grown in agarose suspension (Benya and Shaffer 1982; Horton 1988; Byers 1990). Evidently, many lethal or severe *COL2A1* mutants secrete the faulty product and, like patients with severe osteogenesis imperfecta or vascular Ehlers–Danlos syndrome IV, cannot incorporate mutant or even wild-type protein into their hyaline cartilage, instead retaining or degrading the faulty/wild-type heterotrimers intracellularly (Eyre *et al*. 1986). Another useful and important technique is the amplification of *COL2A1* gene transcripts from non-collagenous tissues such as lymphocytes or fibroblasts. This has obviated both the need for difficult cartilage biopsies and the vagaries of chondrocyte culture. Disadvantages include the artefactual amplification of non-cartilage sequences in genes that are alternatively spliced in different tissues and also the lack of any supporting studies of cartilage histology or protein chemistry.

The 'illegitimate transcription' of the very small traces of *COL2A1* mRNA produced by immortalized lymphocytes or cultured skin fibroblasts can be used for the amplification by PCR of *COL2A1* cDNA. Thus cartilage gene sequences can be usefully analysed from non-cartilaginous samples such as skin or blood. This greatly simplifies the opportunities for testing affected individuals from whom cartilage samples are difficult to obtain (Chan and Cole 1991; Chan *et al*. 1993; Cole *et al*. 1993). Similarly, other minority cartilage components, such as the *COL5A1*, *–A2*, *–11A1*, and *–11A2* genes, can be explored in other cartilaginous disorders such as the Stickler syndrome.

Evidently, the hierarchical nature and complexities of skeletal development, growth, and repair also requires other developmental orchestrators such as the *HOX* and *PAX* genes. These are similar to the so-called segmentation genes of *Drosophila*. Others include bone morphogenetic protein (transforming growth factor-b gene family), the FGFR receptor and fibroblast growth factor genes, and other unexpected components such as the thrombospondins. The development and maintenance of bone and artery is very probably just as complex but is much less well understood.

Evidence that *COL2A1* mutations cause chondrodystrophies

Wordsworth *et al*. (1988) observed discordant segregation between RFLP markers for *COL2A1* and diseases such as achondroplasia, pseudoachondroplasia, multiple epiphyseal dysplasia, autosomal-recessive spondyloepiphyseal dysplasia tarda, diaphyseal aclasis, and the trichorhinophalangeal syndrome. He concluded that *COL2A1* was not a common candidate gene for these chondrodysplasias. Unfortunately, families with autosomal-dominant spondyloepiphyseal dysplasia tarda or metaphyseal chondrodysplasia were uninformative (so that linkage could be neither confirmed nor rejected). We now know that chondrodysplasias that share the features of distorted hyaline cartilage, epiphyseal dysplasia, premature osteoarthritis, and vitreoretinal detachment or myopia frequently have *COL2A1* mutations.

The latter form two distinct but related groups. Firstly, the Stickler/Wagner group is autosomal-dominant. Clinical signs include vitreoretinal degeneration, myopia, cataracts and retinal detachment with premature osteoarthritis, epiphyseal dysplasia, and facial abnormalities such as mid-facial hypoplasia with a large philtrum and micrognathia with occasional cleft palate. These disorders are heterogeneous, some patients being marfanoid whilst others are short (McKusick *et al*. 1990), though joint laxity is abnormal in both groups (see Fig. 12(a–d)) The Kniest syndrome is also part of the Wagner/Stickler phenotypical complex. There are at least two types (of Kniest syndrome): one relatively mild and autosomal-dominant (or sporadic), the other genetically lethal and sporadic. The milder overlaps with metatrophic dysplasia, which also shows disproportionate short stature, prominent eyes, and mid-facial hypoplasia (Jones 1988; McKusick *et al*. 1990). Radiographs show epiphyseal irregularity, metaphyseal flaring, late ossification of the femoral heads, and platyspondyly. Histologically the cartilage resembles Swiss cheese (McKusick *et al*. 1990). Other generalized abnormalities include inguinal and umbilical hernias, kyphoscoliosis, odontoid hypoplasia, and retinal detachment and myopia. There was clear linkage of *COL2A1* markers such as *Hind*III RFLP and the variable tandem repeat at the 3_ end of the gene (Knowlton *et al*. 1990). Two families showed tight linkage to *COL2A1* whilst another did not (Nunez *et al*. 1985). Schwartz *et al*. (1989) were the first to show non-allelic genetic heterogeneity in both Stickler and Wagner syndromes. They suggested that the Wagner syndrome (retinal or vitreoretinal degeneration with minimal systemic features) was unlinked to *COL2A1*, whilst the Stickler syndrome was clinically and genetically more heterogeneous (and only sometimes linked).

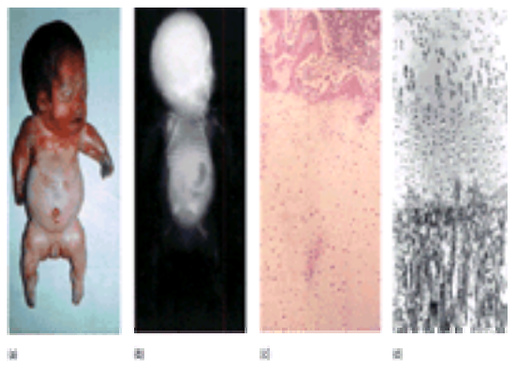

Fig. 11 (a) Typical clinical appearance of patient with lethal achondrogenesis II—note the rhizomelia and abdominal distension with the constricted small chest. (b) The radiographs show shortened ribs, metaphyseal flaring, and shortened long bones. (c) The histological appearance of the femur shows bulbous hyperplasia of the epiphyses and disorganization of cartilage columns, including a fibroblastic inclusion at the epiphyseal plate, compared with the normal control. (d) The bony trabeculae are also disorganized in the achondrogenesis bone. Original magnification × 157.

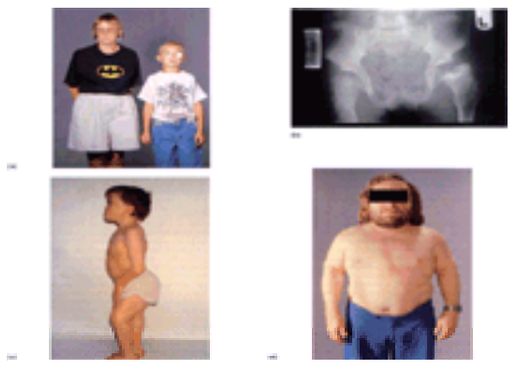

Fig. 12 Collagen II associated mutations. (a) Affected mother and son with *COL2A1*-linked Stickler syndrome. Note the high myopia. (b) Premature degenerative joint disease in similar patient. (c) Another Stickler variant; note the lumbar lordosis and mid-facial hypoplasia. (d) Spondyloepiphyseal dysplasia with rhizomelic shortening of the upper segments of the upper limbs.

Subsequently, we have described genetic heterogeneity as well as distinctive vitreoretinal features that allow us to separate *COL2A1* families from all of the others. Sometimes non-*COL2A1* families are linked to relevant genes such as *COL11A1*, whilst in others the candidate genes are so far unknown. Nevertheless, it is noteworthy that vitreous humour contains heterologous molecules made of collagens II, Va2, XIa1 or XIa2 chains, which can be interchangeable. Consequently the *COL5A1*, *–5A2*, *–1A1*, and *–11A2* genes are also strong candidates for the Stickler/Wagner complex (Snead 1995; Vikkula *et al*. 1995).

Spondyloepiphsyeal dysplasia congenita is also linked to *COL2A1* (see Fig. 12(d)). Here, notable clinical signs include odontoid hypoplasia, ovoid vertebrae with narrowed spaces, kyphoscoliosis, lumbar lordosis, chest deformities, poorly mineralized epiphyses, poorly calcified femoral heads, and myopia. It is a clear autosomal-dominant and has a good prognosis. This contrasts with achondrogenesis, which is a severe, short-limbed dwarfism with highly disorganized cartilage matrix causing death *in utero* or in the neonatal period (McKusick *et al*. 1990). Affected infants are born prematurely with large heads, a short trunk, and severe micromelia (Fig. 11).

Achondrogenesis types I and II (Langer–Saldino; Parente–Fraccaro) are distinguished by rather subtle radiological features that are separated into types IA, IB, and II (similar to the Sillence type II osteogenesis imperfecta classification) by subtle differences in rib and limb morphology and fracture pattern. Generally, types IA and IB have stubby ribs and distorted limbs, whilst babies with type II have straighter limbs and ribs (McKusick *et al*. 1990). Grebe-type achondrogenesis is a separate, extremely severe subtype. McKusick accepts Borochowitz's suggestion that further subdivides the Parente–Fraccaro classification. Achondrogenesis–hypochondrogenesis is at the milder end of this spectrum.

Histologically the affected bone shows disorganized endochondral ossification and severely distorted growth plates. (Fig. 11(c,d)). Cartilage vascularity is increased and chondrocytes are dilated, with granular inclusions within the endoplasmic reticulum. These features strongly suggest a morphological, structural disturbance of collagen II. Other mechanisms are also possible. For example, Superti-Furga (1994) and Superti-Furga (1996) have identified an abnormality in the metabolic activation of sulphation in achondrogenesis type IB, and also demonstrated a number of mutations of this gene

Finally, linkage to *COL2A1* has been demonstrated in three exceptional osteoarthritis families. In particular, two large Finnish families with premature osteoarthritis (without chondrodysplasia) had combined lod scores exceeding 3 (Palotie *et al*. 1989). This suggests that *COL2A1* mutations can cause non-syndromic osteoarthritis without chondrodysplasia. Subsequently, Knowlton *et al*. (1990) also showed tight linkage to the *COL2A1 Hind*III RFLP in a second osteoarthritis family. Many affected family members had both Heberden's nodes and typical radiographic signs of osteoarthritis in hips, shoulders, wrists, and hands. There were also flattened metatarsal heads with irregular flattening of vertebral end-plates, suggesting a mild chondrodysplasia. Another mild chondrodysplasia with premature osteoarthritis (Naquamaland hip dysplasia) was also linked to *COL2A1* (Sher *et al*. 1991), but subsequently these workers excluded *COL2A1* as the candidate for Benkes familial osteoarthritis (Beighton *et al*. 1994). However, in both American and South African families the extrapolation to osteoarthritis 'vulgaris' is unproven, in contrast to the Finnish evidence. Nevertheless, both studies illustrate the potential for analysing the pathogenesis of osteoarthritis. Further support has been forthcoming from associated studies: for example, certain RFLPs for *COL2A1* are twice as frequent in patients with osteoarthritis as in normal controls (Hull and Pope 1989). Contrastingly, in another study of segregation in eight osteoarthritic patients with a slightly different phenotype including Heberden's nodes, the evidence for *COL2A1* skewing was borderline. Most probably, therefore, osteoarthritis is genetically heterogenous with a common histological expression but variable mechanisms, some of which are *COL2A1*-related. Any of the other structural genes expressed in cartilage would also be strong candidates in the causation of osteoarthritis (Dieppe *et al*. 1987).

Collagen protein analysis in the chondrodysplasias

Over the past 10 to 15 years the analyses of type I and III collagen mutations have been very straightforward since such abundant radiolabelled proteins can readily be separated, mapped, and melted from cultured skin fibroblasts. Both secreted and intracellularly retained mutant proteins from the majority of cell lines of severe osteogenesis imperfecta or arterial Ehlers–Danlos syndrome can be characterized (Pope *et al*. 1988a, Pope *et al*. 1988b; Byers *et al*. 1990; Kuivaniemi *et al*. 1991) Until recently, similar analyses of the chondrodysplasias were greatly hindered by the technical difficulties of chondrocyte cell culture. Not only was primary culture difficult but the cells were unstable in agarose suspension (Benya and Shaffer 1982; Horton 1988). Chondrocytes are now readily derived from simple iliac-crest biopsies (Chan *et al*. 1993), and they can be routinely redifferentiated with semisolid alginate beads. Furthermore, immortalized lymphocytes (Chan and Cole 1991) or cultured skin fibroblasts produce traces of *COL2A1* mRNA from which cDNA can be amplified. Tissue from biopsies of the iliac crest or chondrocostal junction can also be used to purify collagen type II proteins, which can then be analysed conventionally by peptide mapping or temperature denaturation in a similar fashion to radiolabelled type I or III collagens in osteogenesis imperfecta and Ehlers–Danlos syndrome (Byers 1990; Kuivaniemi *et al*. 1991; Tiller *et al*. 1995).

Two very important pioneering papers clearly illustrate this approach. Godfrey and Hollister (1988) described a lethally affected, short-limbed fetus with collagen type II achondrogenesis/hypochondrogenesis. Cartilage was histologically abnormal, with disorganized growth plates and overvascularized, fibrotic, hypercellular cartilage similar to that illustrated in Fig. 11(c). Collagen extracted from cartilage of the femoral head was then analysed either by a-chain or gene analysis of *COL1A1* or *COL1A2* mutations in osteogenesis imperfecta (see above). Proteolytic thermal denaturation studies were also undertaken, and the extractability of cartilage collagen and the amounts of hexosamine and proteoglycan examined. Affected patients possessed both normal and overmodified a1(II) collagen detectable as abnormal doublets (Fig. 13(a)). Similarly, CNBr cleavage in one and two dimensions confirmed overmodification of the whole collagen a1(II) helix as measured by doublets in one-dimensional gels and 'smiling' or tilted bands in the two-dimensional gels (Fig. 13(a,b)). Furthermore, only collagen type II was overmodified whilst collagen a1(I), a2(I) or a1(III) chains (as expected) were not. By extrapolation to analysis of lethal osteogenesis imperfecta this located the mutation at the C-terminus of a1(II) collagen. Such accurate mapping also provided a means of cloning and sequencing the mutant gene just as in osteogenesis imperfecta and Ehlers–Danlos syndrome IV mutations. Even though defective at the C-terminus, much of the mutant protein was still secreted and could easily be isolated from cartilage biopsies. In contrast, the patient studied by Eyre (1986) could not secrete the faulty mutant collagen II protein.

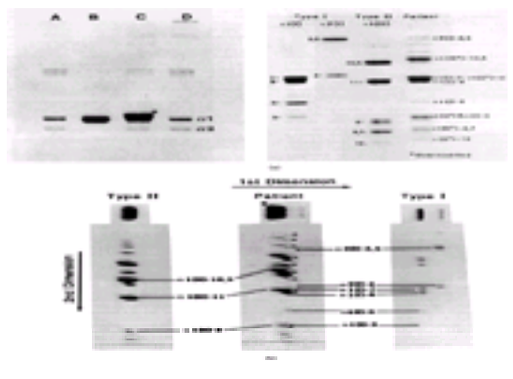

Fig. 13 (a) Collagen a1(II) chains derived from a patient with achondrogenesis: compared with the control a1(II) chains (track B) the mutant produces normal and overmodified (*) forms; similarly (right panel) all a1(II) cyanogen bromide fragments are overmodified (Godfrey and Hollister 1988). (b) The two-dimensional peptide

maps of forms excised from (11a) showed typical 'smiling' of all cyanogen bromide peptides in an affected patient. These are analogous to the a1(I)CB6 mutations causing osteogenesis imperfecta as illustrated in Fig. 7(b), and normal and overmodified species together form a diagonal 'smile'.

Murray *et al*. (1989) then described very similar studies in nine patients with spondyloepimetaphyseal and spondyloepiphyseal dysplasias. As expected, all were dwarfed and had abnormal epiphyses, varying metaphyseal irregularities, flattened vertebral bodies, and myopia. Here, costal cartilage was sampled from the more mildly affected children under general anaesthesia. Using standard procedures with 4M GuCl and proteinase inhibitors, type II collagen was extracted with pepsin or acetic acid, and whole collagen a1(II) chains or CNBr-cleaved a-chains characterized by polyacrylamide gel electrophoresis. All affected patients had abnormal mobility of collagen a1(II) chains with variable overmodification of CNBr-derived peptides. As expected, and by analogy with *COL1A1*, *–1A2*, and *–3A1* mutants (Bonadio and Byers 1985; Byers 1990; Kuivaniemi 1995), the extent of overmodification varied with position, being least severe near the N-terminus (mild) and worse towards the C-terminus (increasingly severe). Thus the least affected patients were the least modified and vice versa. These pioneering studies paved the way for more detailed mutant analysis by RFLP analysis combined with protein mapping, gene amplification, and sequencing (see also Fig. 4 and Fig. 19). Very substantial progress has occurred since the first edition of this chapter.

Fig. 14 Diagram of COL2A1 (type II collagen) mutations, substitutions (grey), deletions (blue), duplications (yellow), and 'stops' in red.

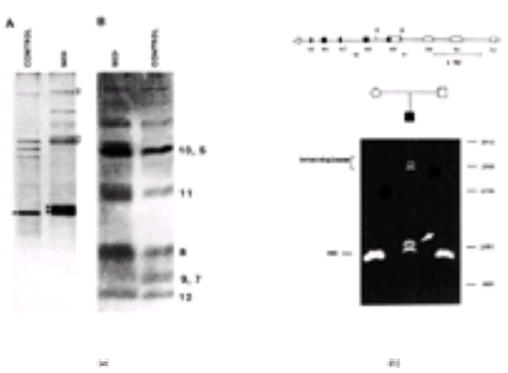

Fig. 15 Collagen a1(III) chains and CNBr peptide pattern of extracted cartilage components from a control and a patient with spondoepiphyseal dysplasia (Tiller *et al*. 1990). (a) Whole a1(III) chains from the patient are overmodified compared with the control and after cleavage with CNBr show overmodification of each CNBr fragment—very similar to Fig. 15(a). This is analogous to the overmodified a1(I) components shown in Fig. 6(a). (b) Amplification of the relevant portions of exons 48–49 showing normal and lengthened mutant fragments with heteroduplex formation between wild-type and mutant copies; at the bottom is a sequence of mutated and wild-type fragments showing 30 amino acids (90-bp duplication) of the mutant allele, situated in exon 48.

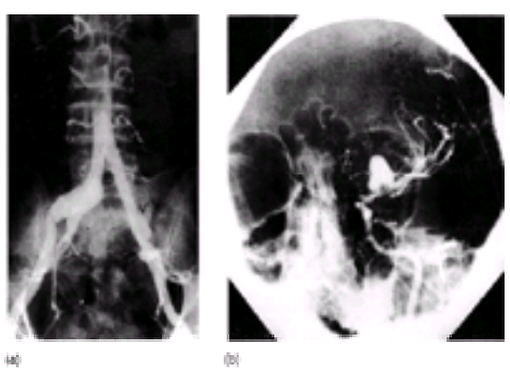

Fig. 16 (a) Aortogram showing fusiform right femoral aneurysm, and (b) large middle-cerebral aneurysm from two different patients with Ehlers–Danlos syndrome IV.
