The gradient-echo contrast can be advantageous for studying the trabecular bone structure and detecting haemorrhage (Sebag and Moore 1990) (Fig. 26). The use of the gradient-echo sequence is particularly useful in detecting osteolytic areas but can be problematic when identifying bone marrow oedema (Fig. 26). With certain gradient-echo parameters, epiphyseal, physeal, and articular cartilage appears brighter and better defined than it does on spin-echo images (Fig. 26). This contrast allows a very good demonstration of cartilage abnormalities in children. Fast spin-echo produces in a shorter time images with contrast similar to spin-echo. Fast spin-echo is especially advantageous for obtaining rapid, high resolution, heavily T_2-weighted images with a high signal-to-noise ratio. This is very useful for spinal studies with a myelographic effect (Georgy and Hessenlink 1994) (Fig. 25).

The transfer magnetization technique allows the contrast between joint fluid and articular cartilage to be increased, with an arthrogram-like effect (Wolf and Balaban 1994).

The fat-suppression technique by decreasing or eliminating the signal from fat is also increasingly used in musculoskeletal MR. It allows a good study of cartilage structures (which appear bright) and cartilaginous abnormalities, a better detection of gadolinium enhancement, and a better differentiation of subacute haemorrhage from fat (Peterfy *et al*. 1994).

Finally the short-TI inversion recovery (**STIR**) fat-suppressed sequence is a very sensitive screening method for detecting musculoskeletal disorders and especially marrow diseases in older children and teenagers (Fig. 29).

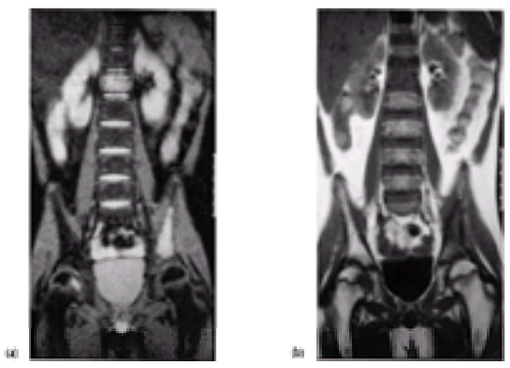

Fig. 29 Acute leukaemia relapsing in a 9-year-old boy with normal plain films. (a) Frontal T_1-weighted MR image. (b) Frontal STIR image. Infiltration of the T12 vertebral body, of the right femoral head, and of left iliac wing.

Normal and abnormal MR musculoskeletal appearance in children

It is important when assessing a joint that the observer is familiar with the appearance of a normal MR in the growing child. In the near-term fetus, the epiphyses are entirely cartilaginous. As ossified epiphyses develop with increasing age, there is gradual thinning of the epiphyseal cartilage. Therefore, the ossification centres have a bright signal representing the fatty marrow content. Growth plates and epiphyseal cartilage have an intermediate signal intensity on both T_1 and T_2 spin-echo sequences (Fig. 26 and Fig. 27). They have a bright signal on T_2* gradient-echo sequences and on fat-suppressed T_1 sequences (Fig. 26). Furthermore in children, the epiphyseal cartilage that surrounds the ossification centre, has a non-uniform signal pattern. A non-homogeneous hypointense zone is seen lying between the articular cartilage and the hemispherical growth zone of the ossification centre (Jaramillo and Hoffer 1992). This hypointense area is thought to represent a broad zone of poorly organized chondrocytes. With increasing age, the growth plate is reduced to a narrow zone between the epiphysis and the metaphysis, which shows an intermediate signal on T_1 and T_2 images and a high signal on T_2* and fat-suppressed images (Harcke *et al*. 1992) (Fig. 26).

Physiological closure of the growth plate begins centrally. Gadolinium-enhanced substraction MRI depicts the increased vascularization and perfusion of the metaphyseal growth zone (Debaert *et al*. 1992; Saifuddin *et al*. 1994) (Fig. 28).

The distribution of fatty and haematopoietic marrow changes in the paediatric skeletal system from infancy to adulthood (Moore and Sebag 1990). The high fat content of fatty marrow results in an increased signal on T_1-weighted sequences and a lower signal on T_2-weighted sequences. In contrast, the higher water and protein content of haematopoietic marrow results in a signal on T_1-weighted sequences that is low in neonates and slightly increased in the older child, together with a signal that is intermediate or increased on T_2-weighted sequence. After injection of contrast material, haematopoietic marrow shows a greater enhancement than fatty marrow, especially in small children and infants (Sze *et al*. 1991).

Starting in infancy, the haematopoietic marrow is converted progressively to a fatty marrow. This begins in the distal appendicular skeleton and progresses to the axial skeleton. In an individual bone, the conversion begins in the diaphysis and then extends to the metaphysis, reaching the adult pattern by 25 years. Knowledge of the type of marrow that is normally present in a given bone at a given age is essential to recognize any local or diffuse marrow abnormality in children (Sebag *et al*. 1993). T_1-weighted spin-echo sequences are optimal for showing the status of marrow conversion, while STIR and T_2-weighted sequences are better at distinguishing an abnormal marrow (Moore and Sebag 1990) (Fig. 29).

The articular surfaces are smooth and show up well on T_2 and T_2* sequences, with an arthrographic-like appearance (bright joint fluid) (Fig. 26 and Fig. 27).

The synovium is not seen in the normal joint. Without contrast enhancement, proliferative synovial tissue (i.e pannus) has a variable signal and cannot be distinguished reliably from joint effusion and cartilage (Hervé-Somma *et al*. 1992) (Fig. 27). After injection of a paramagnetic agent (gadolinium), proliferative synovium which is extremely vascular may be enhanced. Enhancement is indicative of disease activity and allows a precise assessment of pannus extension, joint effusion, and cartilage loss (Hervé-Somma *et al*. 1992).

Contrast enhanced MR is the most sensitive modality to determine an arthritis is present, but rarely helps in establishing a specific diagnosis (Fig. 30).

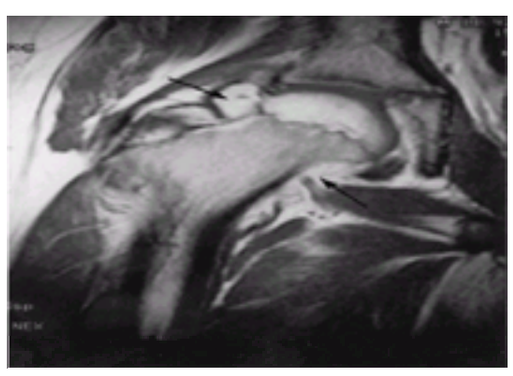

Fig. 30 Tuberculosis of the hip in an 11-year-old boy. Enhanced T_1-weighted MR image shows a non-specific intense enhancement of a dramatic synovial proliferation in the right hip (arrow).

In haemarthrosis and lipohaemarthosis, MR imaging can document the presence of haemorrhage owing to a predictable sequence in the chemical degradation of haemoglobin in extravasated blood (Fig. 27). Decreased signal intensity resulting from haemosiderin deposition can be demonstrated within an abnormal synovial proliferation (Fig. 27) However, although this finding is suggestive it is not specific and can be seen in haemophilia, bleeding disorders, pigmented villonodular synovitis, and intra-articular neoplasms such as haemangiomas (Kottal *et al*. 1987; Jelinek *et al*. 1989) (Fig. 31).

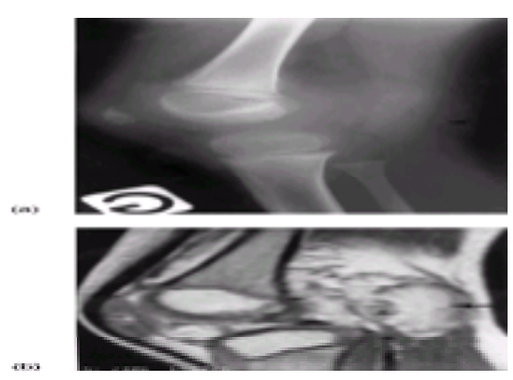

Fig. 31 Synovial haemangioma affecting the knee in a 5-year-old boy. (a) Plain film demonstrates a phlebolithis and a popliteal mass. (b) Enhanced T_1-weighted MR

image shows the extension of the synovial haemangioma.

Role of MRI in paediatric musculoskeletal system

MRI is an extremely sensitive modality for bone marrow imaging; however the pattern of MR changes is non-specific and the diagnosis may be dependent on clinical information (Bonnerot *et al*. 1994).

Joints are ideally suited for investigation by MRI in children (Recht and Resnick 1994). In many centres arthrography and CT arthrotomography have been replaced by MRI, which is currently used to evaluate congenital, traumatic, and inflammatory processes involving various joints. While the knees and hips are the joints most commonly examined with this modality, MRI of ankles, shoulders, wrist, elbow, and C1 to C2 are being performed with increasing frequency. Within the knee, MRI is ideal for determining internal derangement; discoid menisci and meniscal tears are easily visualized (Zobel *et al*. 1994) (Fig. 21). In osteochondritis dissecans, the extent of involvement can be evaluated as well as the status of the overlying cartilage (Rogers and Poznanski 1994).

In Legg–Calvé–Perthes' disease, MRI allows the detection and definition of the extent of necrotic bone, which is essential for the diagnosis, prognosis, and successful treatment of this condition (Ducou le Pointe *et al*. 1994) (Fig. 26 and Fig. 28).

Within the hip, MRI allows detection of vascular changes and assessment of femoral head incongruity. It is useful to evaluate femoral head containment within the acetabulum even in abduction (Fig. 26). The role of MRI compared with that of scintigraphy is still under study (Henderson *et al*. 1990; Conway 1993; Uno *et al*. 1995). MRI also allows early detection of osteonecrosis in children at risk and, especially, complications of steroid therapy (Mulliken *et al*. 1994). MRI is also useful in demonstrating late changes of congenital hip dislocation including deformity of the femoral head, acetabular dysplasia, infolding of the labrum, hypertrophy of the pulvinar, invagination of the ilio psoas tendon, and superimposed osteonecrosis (Johnson *et al*. 1988; Bos *et al*. 1988; Bos *et al*. 1991).

MRI is essential for preoperative planning in congenital limb deficiency by showing the unossified structures connecting the hypoplastic bone.

MRI is the most satisfactory modality for diagnosing possible growth plate abnormalities prior to the osseous abnormality (Norton *et al*. 1991; Rogers and Poznanski 1994).

The early detection of any damage (most often acute or chronic trauma) is essential to avoid severe growth deformity and long-term sequella (Jaramillo *et al*. 1990). MRI is very useful in the evaluation of sports injuries, showing occult fractures and trabecular bone impaction, which are seen increasingly in children and adolescent (Kapelov *et al*. 1993).

Inflammatory and synovial diseases in children are increasingly being studied by MRI, though its roles in these conditions have not yet been defined (Resnick 1988; Kaye 1990). In juvenile chronic arthritis, clinical evaluation of symptomatic joints is frequently supplemented with plain radiographs; but radiographic changes represent late and indirect signs of synovial disease.

Contrast-enhanced MRI can be used to evaluate precisely the extension of synovial proliferation, the status of articular cartilage, joint effusion, and bone erosion in juvenile chronic arthritis (Hervé-Somma *et al*. 1992) and haemophilic arthropathy (Fig. 32).

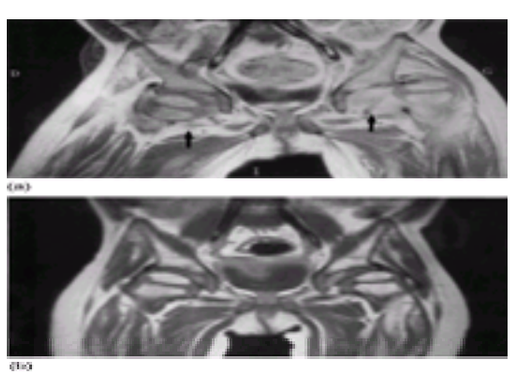

Fig. 32 Juvenile chronic arthritis. Systemic onset disease with hip involvement in a 3-year-old girl. Enhanced T_1-weighted MR image: (a) Prior to intra-articular injection of steroid: bilateral, active enhancing pannus is seen (arrow) with left hip dislocation. (b) After intra-articular injection of steroid: bilateral decrease in volume and enhancement of pannus with normal femoral head containment.

Cartilage loss is detected better on MRI than on plain films, especially in young children with thick, growing cartilage and at the early stage of the disease (Senac *et al*. 1988; Hervé-Somma *et al*. 1992).

Contrast-enhanced MRI is promising in the evaluation of the effectiveness of intra-articular therapy in juvenile chronic arthritis (Hervé-Somma *et al*. 1991; Eich *et al*. 1994). Enhanced MRI allows better evaluation of residual anatomic lesions after treatment. MRI may be used to predict subsequent therapeutic failure (fluid loculations) or early relapse (persistence of pannus enhancement) (Fig. 32). It is particularly valuable for hip appraisal in which clinical evaluation is difficult.

MRI is now the preferred approach for evaluating children for lesions of the spine and spinal cord (either congenital, traumatic, inflammatory, or tumorous).

Finally, as in the adult, MRI has proved to be essential in the evaluation of :

- extent of soft tissue tumours and bone tumours (Norton et al.1991)
- evaluation of the response to treatment of musculoskeletal tumours (Debaert *et al*. 1992)
- musculoskeletal infection (acute and chronic osteomyelitis)

In osteomyelitis, MRI should be performed in cases that may require surgical drainage including infections of the spine or pelvis, infections extending into the growth plates of long bones, and infections that fail to respond to antibiotics (Dangman *et al*. 1992; Jaramillo *et al*. 1995) (Fig. 1).

In conclusion

Selection of the appropriate sequence of imaging studies for a given child and a given diagnostic problem has become a complex undertaking. Investigations have to be tailored to the individual need of the child, and radiologists and paediatricians have to work together to ensure that the needs of all are best matched. Clinical examination and/or plain films remain the initial investigations (see Boxes 1, 2, 3, and 4). The need for radiation protection must remain a priority in children. Finally, in this era of advancing imaging technology, a knowledge of the relative value of available imaging techniques is necessary to optimize the management of children with musculoskeletal disease.

4.10 Histopathology

Patrick J. Gallagher and Janice R. Anderson

Most chronic rheumatological disorders affect multiple tissues and organ systems (Fig. 1 and Fig. 2). In turn, this generates a wide variety of different histological biopsies. Here, the problems associated with the handling, processing, and interpretation of the more specialized rheumatological biopsies are considered. The value of skin, gastrointestinal, renal, hepatic, pulmonary, marrow, and other biopsies have been considered in various chapters in Section 1.

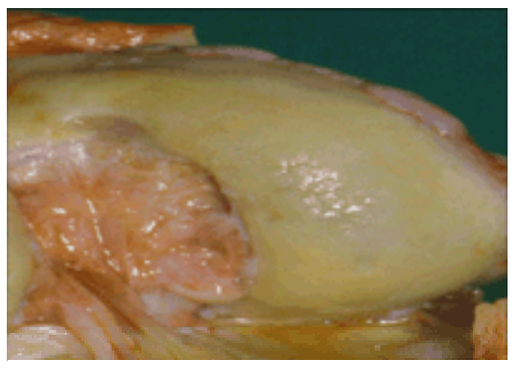

Fig. 1 Early rheumatoid disease. There is a synovial hyperplasia in the intertrochanteric area and a small erosion on the medial aspect of the condyle.

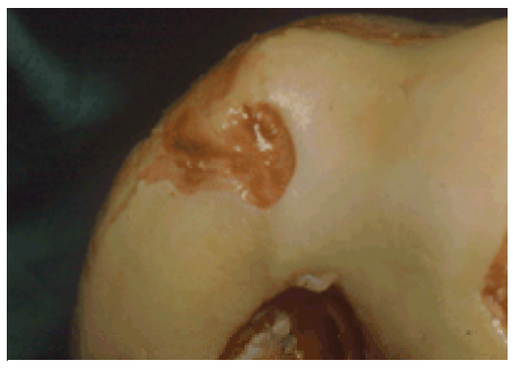

Fig. 2 Rheumatoid disease. An erosive lesion with a base of pannus.

Synovial biopsies

Methods of closed synovial biopsy were described over 50 years ago and, even before the introduction of the narrow-gauge biopsy needle, there were comprehensive accounts of the histological changes in a variety of rheumatic disorders. In everyday practice most synovial biopsies are reported non-specifically in descriptive terms. This is unsatisfactory for both rheumatologists and pathologists, and has generated mutual scepticism as to the value of the procedure. In response to this, computerized methods have been used to assess the importance of many different histological features in large series of synovial biopsies (Soren 1978; Rosenberger *et al*. 1981). These detailed studies have clarified exactly which alterations are most common in each disorder. However, as the range of histological changes is limited, the precision with which diagnoses can be made in individual patients has not necessarily increased.

Technical aspects

Most biopsies obtained with a needle or during arthroscopy are 5 to 10 mm in maximum dimension and ideally three or more fragments are required. It has been

calculated that at least 2.5 mm^2 of synovial tissue are needed to reflect the variation in cellular density expected in rheumatoid synovium (Kennedy *et al*. 1988a).

Formalin fixation is satisfactory for routine histology and an increasing number of simple immunohistochemical techniques. However, many monoclonal antibodies directed against leucocyte antigens only give good results in frozen sections and these may be required in experimental studies. If this is the case, one fragment should be snap frozen in liquid nitrogen and kept at as low a temperature as possible. Urate may be dissolved out by formalin and alcohol is the ideal fixative if gout is suspected.

No special processing techniques are required but multiple levels should be examined and spare sections reserved for additional staining methods.

Evaluation of biopsies

Pathologists who do not work closely with rheumatological units may have difficulties in interpreting synovial biopsies. This is usually ascribed to the limited range of changes that develop in synovium and the paucity of diagnostic features. At least 10 per cent of biopsies are unsatisfactory, either because the material retrieved is too small for evaluation or only collagenous joint capsule has been biopsied. Comparatively large biopsies of synovium can be obtained during joint replacement operations and are an invaluable source of material for investigation. As more 're-do' replacements are performed an increasing number of abnormal synovial samples are submitted for evaluation (see below). Although stereological methods of quantification are used increasingly in assessing bone biopsies, they have not been routinely applied to synovial biopsies (Artacho-Perula *et al*. 1994).

Synovial lining cells

In a normal biopsy the synovial lining is a thin monolayer of flattened or cuboidal basophilic cells, closely applied to the underlying fibroadipose tissue (Fig. 3). Although ultrastructural studies have defined at least two distinct cell types, these cannot be distinguished at the light microscopic level, at least in routine needle-biopsy material. The larger A, or M for macrophage-like, cells have a phagocytic function. The B cells (not B lymphocytes) resemble fibroblasts and have ultrastructural appearances that indicate active synthesis.

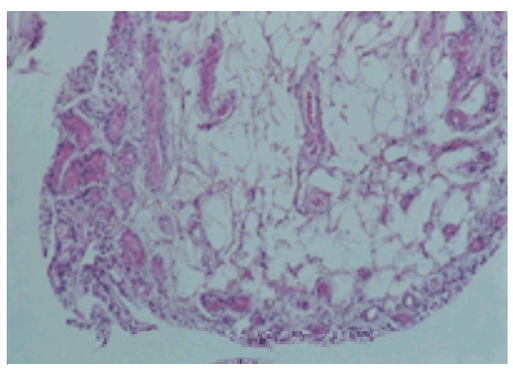

Fig. 3 A normal biopsy. The bulk of the biopsy is loose fibroadipose tissue. Blood vessels are prominet but the appearances are within normal films.

Synovial hyperplasia is diagnosed easily when the lining cells form a clear multilayer but if the villous pattern is accentuated, even hyperplastic synovium may have a monolayered appearance (Fig. 4). Normal synovial lining cells are only slightly larger than underlying fibrocytic nuclei but in most reactive conditions they enlarge and may show considerable variation in size and shape. Areas of synovial ulceration and fibrin deposition are common features in many different forms of acute synovitis (Fig. 5 and Fig. 6).

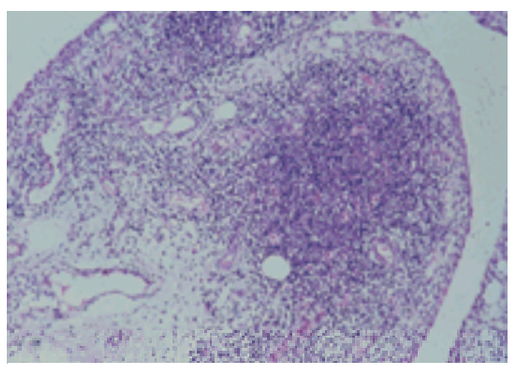

Fig. 4 Chronic rheumatoid arthritis. The synovium shows villous hypertrophy and there is a prominent lymphoid aggregate

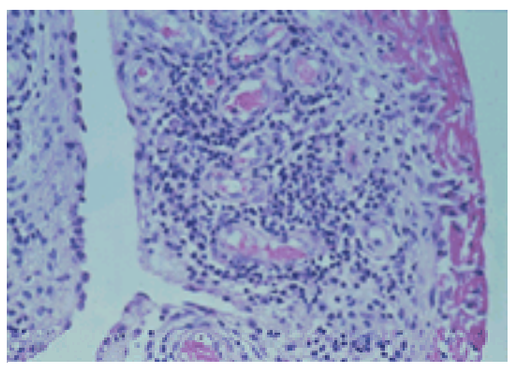

Fig. 5 Chronic rheumatoid arthritis. There is a diffuse lymphocytic infilltration, the synovial membrane is ulcerated, and there is a superficial layer of fibrin (right hand side)

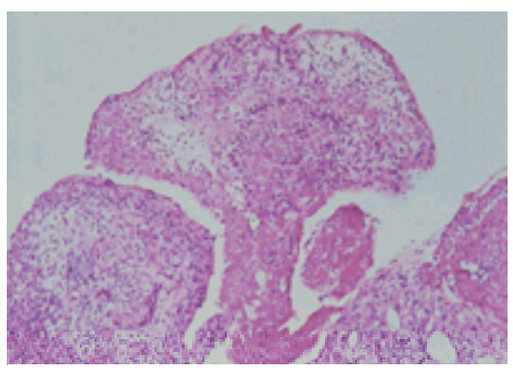

Fig. 6 Early Rheumatoid arthritis. There is a mass of fibrin in the centre and the underlying synovium is infiltrated with acute and chronic inflammatory cells.

Inflammation

Inflammatory infiltration and increased vascularity are the most important histological features that should be evaluated in synovial biopsies. Occasional groups of chronic inflammatory cells may be seen in synovial biopsies from healthy young subjects or early in the clinical course of post-traumatic synovitis. Immunohistochemical studies have shown that most of these cells are T lymphocytes and there is clearly an overlap with mild chronic synovitis (Lindblad and Hedfors 1987). More extensive inflammation must be regarded as pathological, especially if there is an admixture of cells or the pattern of infiltration is diffuse. Large nodular aggregates of lymphocytes and macrophages are commonly seen, especially in rheumatoid disease and related disorders. In contrast, true granulomatous lesions are rare and usually indicate a specific disorder such as sarcoidosis.

Synovial vasculature

In acute synovitis, increased vascularity with perivascular margination and emigration of leucocytes may be prominent. Although hyperaemia is a major clinical and pathological feature of acute synovitis, its histological expression is highly variable. The normal synovial membrane has a rich blood supply and it can be very difficult to assess a marginal increase in vascularity (see Fig. 3). In the most acute stages the appearance resembles granulation tissue, with associated haemorrhage and fibrin deposition. The capillaries are often distended and engorged, and there may be focal endothelial necrosis. In chronic inflammatory synovitis, small and medium-sized arteries and veins may be prominent and show fibrous intimal thickening. A uniform, eosinophilic or hyaline appearance in the vessel wall should suggest amyloidosis but we stain routinely all synovial biopsies with Congo red.

Histological changes in individual disorders

Although histopathologists rarely make a definitive diagnosis on a synovial biopsy, there are some general features that suggest particular disorders and a few changes that indicate specific diseases (Table 1).

Frequent changes, no specific diagnostic value
Hyperplasia of synovial lining cells
Villous synovial hyperplasia
Synovial ulceration and fibrin deposition
Acute and chronic inflammatory cell inflammation
Chronic inflammatory aggregates, with germinal centre formation
Less frequent changes, possible diagnostic value
Granulomatous lesions in joint capsule (rheumatoid arthritis) or synovium (sarcoidosis)
Dense acute inflammatory infiltration with micro-organisms (infective arthritis) or urate crystals (gout)
Subsynovial deposits of amyloid
Dense haemosiderin deposits (repeated haemorrhage, e.g. haemophilia)

Table 1 Histopathological changes in synovial biopsies

Rheumatoid disease

The histological changes in rheumatoid arthritis have been described in numerous reports but there are no specific diagnostic features. Non-committal histological reports may be annoying to rheumatologists but there are many reasons why these must be the norm. The knee is usually biopsied but this may not be the most severely affected joint. Within the knee itself there is some variation in the pattern of histological change (Hutton *et al*. 1987), though in general terms there is a good association between the macroscopic and microscopic features of inflammation (Lindblad and Hedfors 1985). In individual joints the clinical severity of synovitis can be correlated with the degree of histological change, particularly in the early stages of disease (Rooney *et al*. 1988). Pathologists should be told what treatments have been given, especially if second-line drugs were used before the biopsy was taken.

The chief microscopic features in classical rheumatoid arthritis are mononuclear cell infiltration, villous synovial hyperplasia (Fig. 7), synovial ulceration and fibrin deposition, fibrosis, and increased vascularity (Fig. 5 and Fig. 6). Although there are no features that allow a specific diagnosis of rheumatoid disease, there is some value in grading the density of synovial hyperplasia, vascularity, and inflammation. Patients with substantial abnormalities early in their clinical course tend to develop persistent disease (Gallagher *et al*. 1985). Disease activity can be correlated with the intensity of ferritin staining within synovial macrophages. The amount of ferric iron, as shown by Perls' staining, is some guide as to how the disease might progress (Blake *et al*. 1984).

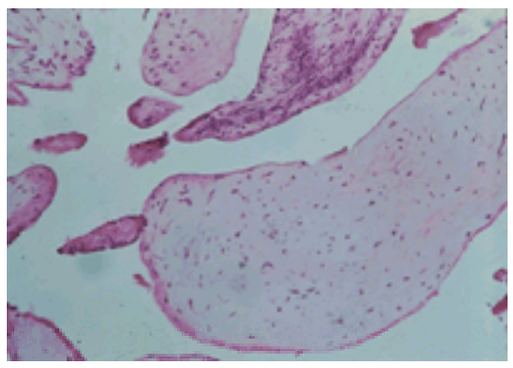

Fig. 7 Vilous synovial hyperplasia in long-standing rheumatoid arthritis. In this field there is no associated inflammation.

Studies with monoclonal antibodies have shown that T-helper lymphocytes are the most numerous of the mononuclear cells in active rheumatoid disease. The density of the inflammatory infiltrates and the ratio of helper to suppressor lymphocytes is reduced in patients who respond to treatment (Rooney *et al*. 1989). There is some evidence that mast cells have a role in the pathogenesis of inflammatory joint disease. They are difficult to recognize in routine sections but paraffin sections stain well with antibodies to mast cell tryptase.

As immunohistochemistry is not of proven diagnostic value, frozen sections are probably superfluous in routine practice. However, if abundant tissue is available, a small sample should be kept frozen. Recent experimental studies of rheumatoid synovium have clarified the ways in which inflammatory cells and regulatory peptides interact in rheumatoid disease (Edwards and Cambridge 1995) (see Chapter 3.1). At present there is no role for specialized molecular investigations in routine synovial biopsies. This may change as instruments are developed that allow combined techniques, such as polymerase chain reaction (PCR) and *in situ* hybridization, to be performed on tissue sections.

Osteoarthritis

Although osteoarthritis is primarily a degenerative disorder there can be substantial inflammatory cell infiltration in severely affected joints (Fig. 8). When osteoarthritic and rheumatoid synovium are compared morphometrically, marked inflammation can be seen in both groups of patients but well-developed lymphoid follicles and significant numbers of plasma cells are restricted to rheumatoid disease. Nevertheless, in one study, 40 per cent of osteoarthritic samples could not be differentiated from rheumatoid biopsies and half of all osteoarthritic synovia had moderate or marked inflammation (Goldenberg *et al*. 1982). Immunohistochemical studies suggest that, in contrast to rheumatoid disease, the numbers of subsynovial CD4 and CD8 cells are about equal (Kennedy *et al*. 1988b). In needle biopsies of osteoarthritis associated with chondrocalcinosis there are no histological features that reliably distinguish them from needle biopsies obtained from cases of uncomplicated osteoarthritis.

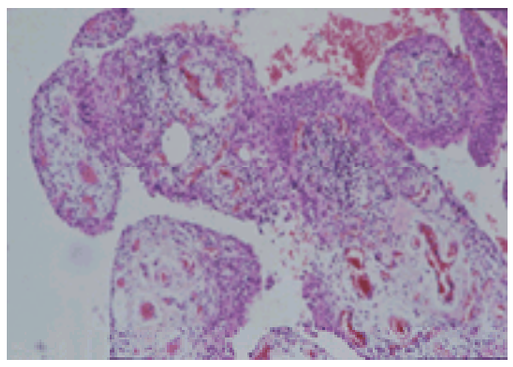

Fig. 8 Villous synovial hyperplasia and moderate associated chronic inflammation in osteoarthritis. Inflammation of this degree is not uncommon.

Other arthropathies

Non-specific inflammatory changes are seen in most of the less common forms of chronic joint disease such as psoriatic or enteropathic arthropathy, juvenile chronic arthritis, Reiter's disease, Behçet's syndrome, or ankylosing spondylitis. There is no single histological feature that is in any way diagnostic or even suggestive of an individual disorder. In both adults and children the density of the inflammatory infiltrates is usually less than in typical, long-standing rheumatoid disease. In a comparative study of patients with ankylosing spondylitis and rheumatoid arthritis the histological features were similar but the lymphocyte helper to suppressor ratios were only increased in patients with rheumatoid disease (Kidd *et al*. 1989).

Acute purulent inflammation is seen in infective arthritis, gout, some reactions to intra-articular foreign bodies, and the early stages of rheumatoid disease (see Fig. 6). In unusual disorders, such as sarcoidosis or amyloidosis, a specific histological diagnosis is sometimes possible.

Prosthetic joints

Metallic debris and fragments of polyethylene or methacrylate bone cement are phagocytosed by synovial macrophages and may accumulate in the synovium. An exuberant reaction may be seen in synovial biopsies taken during 're-do' joint replacements. Abraded polyethylene fragments may stimulate a marked macrophage and foreign body giant cell reaction. The material is strongly birefringent.

Salivary gland biopsy

Inflammatory cell infiltration of the lacrimal and salivary glands may occur as an isolated event or in association with a variety of autoimmune diseases. Together with the associated fibrosis and loss of glandular tissue, production of saliva and tears is reduced. This causes dryness of the mouth and eyes and in turn may progress to a sicca syndrome with keratoconjunctivitis.

The typical, well-developed lesions in major salivary glands in Sjögren's syndrome have been termed 'benign lymphoepithelial lesions' or 'myoepithelial sialadenitis'(MESA). Although glandular tissue is lost, larger salivary ducts may be preserved and the subsequent proliferation of their lining epithelium and myoepithelial covering produces typical nodular masses—'myoepithelial islands'. There is considerable interest in the nature of the associated lymphocytic infiltrates, which range from patchy and histologically innocuous aggregates to malignant lymphoma. Patients with Sjögren's syndrome and MESA have about a 40-fold risk of developing malignant lymphoma, either in affected salivary glands or other nodal or extranodal sites. Furthermore, they have an increased incidence of lymphoproliferative abnormalities such as lymphocytic interstitial pneumonitis and unusual forms of atypical hyperplasia in lymph nodes. There is also an increased risk of malignant lymphoma in patients with MESA without the clinical features of Sjögren's syndrome (Isaacson and Norton 1994).

Technical aspects

Malignant lymphoma should be suspected in any patient with an autoimmune rheumatic disease who presents with salivary gland enlargement or cervical lymphadenopathy. If biopsy is undertaken it is essential that fresh tissue is sent to an immunopathology laboratory as quickly as possible. Although an increasing range of antibodies give satisfactory immunohistochemical staining in formalin-fixed, paraffin-processed tissues, many important monoclonal antibodies require frozen sections for optimal demonstration of reaction product. Furthermore, fresh tissue is essential for chromosomal studies and may be more suitable for the detection of immunoglobulin and T-cell-receptor gene rearrangements.

In Sjögren's syndrome both major and minor salivary glands are involved (Greenspan *et al*. 1974) and the small glands on the inner aspect of the cheek and lower lip are biopsied easily (Fig. 9). The lower lip is everted and a 15- to 20-mm incision is made under local anaesthesia, parallel to the vermilion border in the labial mucosa. Some four to seven nodules of minor salivary gland are required. In normal subjects the procedure is relatively innocuous; occasionally a feeling of numbness around the biopsy site remains. In patients with severe stomatitis the biopsy site may become infected and ulcerate.

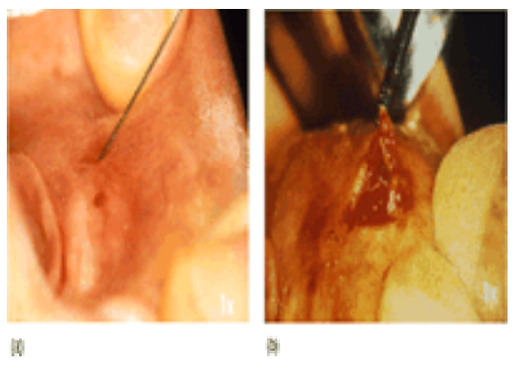

Fig. 9 (a), (b) Biopsy of a minor salivary gland on the inner aspect of the lower lip.

Evaluation of biopsies

Major salivary glands

Ideally, salivary gland biopsies in which there is a suspicion of a lymphoproliferative disorder should be referred to centres with considerable experience of oncological pathology. Specialized laboratory techniques are continually adding to our knowledge of basic aspects of the biology of malignant lymphomas and a general pathologist is rarely able to follow the changes in terminology that these advances necessitate. Furthermore, oncologists are seldom willing to treat these patients until the histology has been reviewed formally by pathologists with whom they have a close working relationship. In the most detailed accounts of the histological and immunohistochemical changes in Sjögren's syndrome, several different groups have emphasized the difficulties encountered in assessing and classifying the changes in myoepithelial sialadenitis (McCurley *et al*. 1990). Immunohistochemical and molecular hybridization techniques have demonstrated the clonal nature of the B-cell infiltrates in many of these lesions (Fishleder *et al*. 1987). Isaacson and his colleagues suggest four histological categories (Hyjek *et al*. 1988):

1. early myoepithelial sialadenitis with focal lymphoid infiltration;
2. established myoepithelial sialadenitis with dense lymphoid infiltration but no evidence of light-chain restriction (i.e. monotypic immunoglobulin staining);
3. established myoepithelial sialadenitis with histological and immunohistological evidence of early lymphoma;
4. frank malignant lymphoma.

Early diagnosis of malignant lymphoma requires careful cytological analysis of the lymphoid infiltrates and good quality immunohistochemical preparations. Virtually all of these are B-cell MALT-type lymphomas, some with a characteristic monocytoid appearance (Shin *et al*. 1991). In the International Lymphoma Study Group Classification (Harris *et al*. 1994) these are grouped under marginal zone B-cell lymphomas.

Minor salivary gland biopsies

Labial gland biopsies from patients with a sicca syndrome show a variety of histological changes, which have been quantified and contrasted with the appearances of glands obtained from control subjects at autopsy (Daniels 1984). Some are entirely free of inflammation and others contain only occasional, small aggregates of 50 or more lymphocytes. For convenience results are sometimes expressed as the number of these aggregates per 4 mm^2. When there are multiple or confluent foci there is usually some loss of glandular tissue. In the most inflamed glands, very little acinar tissue remains and there can be marked duct distension and fibrosis (Fig. 10). Multiple lymphoid aggregates are most unusual in autopsy samples from previously healthy subjects but areas of diffuse inflammation with associated loss of glandular tissue may be seen.

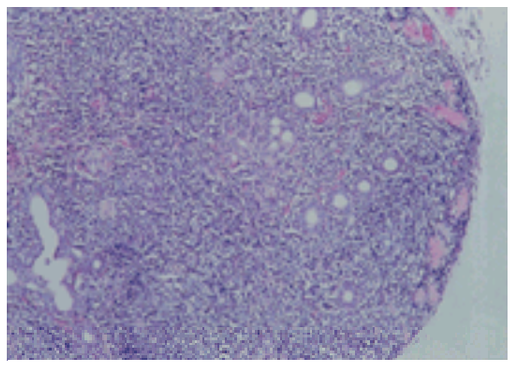

Fig. 10 Labial salivary gland biopsy in a patient with sicca syndrome. The normal architecture of the gland has been effaced by diffuse lymphocytic infiltrate.

Biopsies are most often taken in the investigation of patients with an obscure sicca syndrome. In a study of over 360 cases, Daniels demonstrated that multiple lymphoid aggregates (>1 focus/4 mm^2) in adequate biopsies of labial salivary glands were better indicators of a Sjögren's syndrome than reduced salivary flow from the parotid or subjective symptoms of a dry mouth (Daniels 1984). The technique has also been used in the diagnosis of sarcoidosis. In a study of 40 consecutive biopsies from patients with rheumatological disorders, 10 were entirely normal, 9 had advanced inflammation and fibrosis, and the remainder slight or moderate changes (Harvey *et al*. 1989). There was no evidence of malignancy or granuloma formation. In contrast, non-caseating granulomas (Fig. 11) were present in 5 of 25 patients in whom there was a strong clinical suspicion of sarcoidosis.

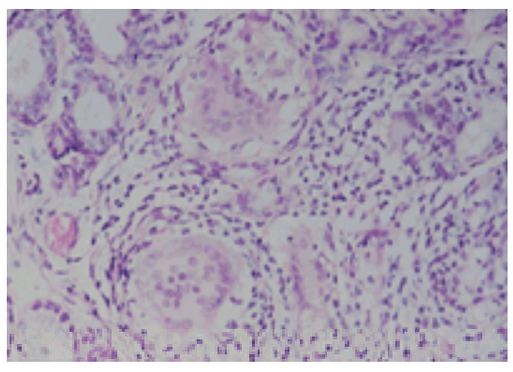

Fig. 11 A non-caseating granuloma, with prominent giant cells, in the labial salivary gland of a patient with sarcoidosis.

Labial salivary gland biopsy could be used more widely. There is no reason why the newer, molecular techniques should not be applied to material extracted from these glands, as comparatively little tissue is required for extraction of enough DNA. A recent study used *in situ* hybridization to demonstrate that 13 of 70 of patients with Sjögren's syndrome had light chain restriction in labial gland biopsies. Four of these 13 patients later developed extra salivary lymphomas (Jordan *et al*. 1995).

Bone biopsy

In systemic bone disorders, such as osteomalacia, renal osteodystrophy, and hyperparathyroidism, bone biopsy can be a valuable aid in establishing a diagnosis and in assessing the severity of the disease process and the response to treatment. The role of biopsy in the common forms of osteoporosis is less clear but it certainly has a place in the investigation of patients less than about 50 years old and in those with associated abnormalities of calcium metabolism (Eriksen *et al*. 1994). Biopsies should only be referred to pathologists whose laboratories have the technical expertise to process and section undecalcified bone and who have sufficient experience to evaluate and quantify the histological changes.

Technical aspects

Eriksen and his colleagues have produced an excellent short guide to bone biopsy which is required reading for pathologists and rheumatologists with an interest in metabolic bone disease (Eriksen *et al*. 1994). The terminology can be confusing but an international group has attempted to standardize the nomenclature and specialist journals, such as *The Journal of Bone and Mineral Research*, give succinct guidelines in their instructions to authors. Virtually all biopsies are from the ilium,

usually within 20 to 30 mm of the anterior superior iliac spine. The iliac crest should be avoided as the demarcation between cortical and trabecular bone can be indistinct (Vigorita 1984). A core should be taken in a horizontal plane through the full thickness of the gluteal surface. An ideal biopsy should, therefore, include the inner and outer cortical plates and the full width of trabecular bone. A 5-mm Jamshidi needle produces a more than adequate biopsy. Cores of 10 mm are less likely to fragment but in our experience this advantage is offset by the added difficulties in processing and sectioning.

Tetracycline is a naturally fluorescent antibiotic that binds to immature bone at the 'calcification front'—the interface between osteoid and mineralizing bone. Tetracycline fluorescence can therefore be used to estimate how much of the bone surface is undergoing mineralization. If two doses are given at a fixed interval the rate of bone calcification can also be calculated (Fallon and Teitelbaum 1982). Two separate 3-day courses of oxytetracycline are given (250 mg, four times a day) at least 10 days apart. The biopsy should be taken no less than 3 days after the end of the second course. The results are unpredictable, especially in severe osteomalacia, when it may be difficult to identify two clear lines of fluorescence. If there is strong clinical evidence of osteomalacia or renal bone disease, it is advisable to increase or prolong the doses of tetracycline and to extend the intervals between the two courses of antibiotic, and between the second dose and the biopsy, as described below. When tetracycline has been given the biopsies should be fixed in 70 per cent alcohol rather than formalin.

Bone that has not been decalcified is difficult to section especially if it has been routinely processed into paraffin wax. Trabecular bone tends to tear and shatter during cutting and the alignment of marrow with the bony trabeculae can be lost. Bone biopsies can be dehydrated satisfactorily in modern tissue processors and we use a kit (JB4; Polysciences Inc.) to embed the samples in 2-hydroxyethylmethacrylate. Sections are then cut with glass knives at 3 µm. It is sometimes possible to distinguish osteoid from mineralized bone in haematoxylin and eosin stains but better definition is obtained with Goldner's trichrome method or the Van Kossa stain for calcium phosphate.

Histopathological assessment

Although simple histological assessment can allow a confident diagnosis in florid cases of osteomalacia (Fig. 12) and renal osteodystrophy, quantitative microscopy is required when osteoporosis is suspected or the changes of osteomalacia are more subtle. Almost all histological features can be measured with a suitable range of eye-piece graticules and highly reproducible results can be obtained by experienced observers. Most large laboratories now have some form of computerized measuring system and even the simplest of these can be adapted for bone histomorphometry. At low magnifications we use a drawing arm to produce a map of the trabecular architecture and shade in any important additional features. The drawings are then placed on a graphics tablet and the relevant areas outlined with a cursor. Well-focused, low-power photomicrographs with good contrast are notoriously difficult to produce and they have few advantages over good line drawings. If a darkroom is available, a projecting microscope can be used to shine a high-power image directly on to the graphics tablet. This is especially useful for measuring osteoid and osteoblastic or resorptive surfaces, and for counting osteblasts or osteoclasts. Fully automated image analysis systems have been adapted for bone histomorphometry but their cost is many times greater than an interactive system.

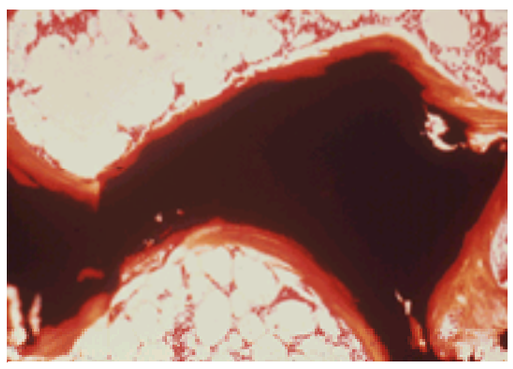

Fig. 12 Bone biopsy from a patient with osteomalacia. The material was not decalcified and was stained by the von Kossa method. An abnormally thick rim of non-calcified osteoid (orange-yellow colour) surrounds the mineralized trabeculum (black). The relative osteoid volume in this patient was 11.2 percent (normal range approximately 1.5–3.2 per cent).

Most pathologists assume that the information obtained from a two-dimensional image is a reflection of the results that would be obtained from the full three-dimensional structure. This is not necessarily true but recent reviews have outlined mathematical methods by which three-dimensional measurements can be estimated from a small number of sections taken at known intervals in a carefully defined plane (Cruz-Orive and Weibel 1990). These methods can be applied to bony tissue (Gundersen *et al*. 1988) and are especially useful for estimating trabecular bone volume.

Many different measurements can be made in bone biopsies (Melsen *et al*. 1978) but comparatively few of these are used in the diagnosis of osteoporosis and the various forms of osteomalacia (Table 2). The histological features of some variables, such as trabecular bone volume, are clear cut, at least if the sections are free of artefactual tears or fissures. If the measurements are made from a hard copy, usually a drawing or photograph, even an inexperienced pathologist should obtain reproducible results. There is much more variation when subtle microscopic changes are evaluated. For example trabecular resorptive surfaces are defined on the basis of their irregular or scalloped surfaces but the identification of these is highly subjective.

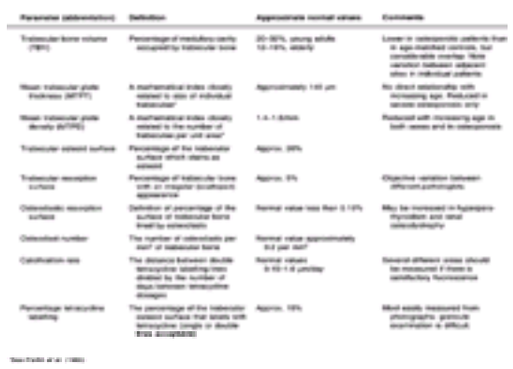

Table 2 Histological measurements in bone biopsies

Osteoporosis

As there are no reliable, qualitative features that distinguish osteoporotic from normal bone, some form of quantitation is essential for diagnosis. The comprehensive approach used in recent long-term studies of bisphosphonate treatment sets an ideal standard but is impractical in most routine laboratories (Storm *et al*. 1993). As a first step we measure trabecular bone volume and osteoid volume. Trabecular bone volume is defined as the percentage of the medullary cavity occupied by trabecular bone. In most studies of this volume there are differences between groups of patients with osteoporosis and healthy controls, but in elderly people there may be a considerable overlap. Furthermore, measurements of trabecular bone volume in biopsies taken from different sites in the same patient can vary by as much as 80 per cent (Chavassieux *et al*. 1985). Healthy young adults have trabecular bone volumes in the range 20 to 32 per cent but mean results in elderly subjects have been quoted as 11.9 and 19.9 per cent (normal) and 8.7, 9.6, and 13.3 per cent (osteoporotic patients). Patients with trabecular bone volumes of 20 per cent or greater are most unlikely to have osteoporosis, but volumes as low as 6 per cent can occasionally be recorded in elderly subjects with no clinical or pathological evidence of osteoporosis (Ashton-Key and Gallagher 1992).

Mean trabecular-plate thickness and mean trabecular-plate density can be derived from the trabecular bone volume using simple formulas (Parfitt *et al*. 1983). The

plate thickness is an indication of the size, and the density an index of the number of trabecular plates per unit area. By using these three measurements together it is possible to determine whether bone loss has resulted from loss of complete trabeculae, by thinning of trabeculae, or a combination of both. In non-osteoporotic controls there is an almost linear decline in both trabecular bone volume and mean trabecular-plate density with increasing age, and this is accentuated in patients with vertebral fractures. It is now accepted that the underlying cellular mechanisms in age-related and postmenopausal osteoporosis are different (Dempster and Lindsay 1993) (see also Chapter 5.17.1). In postmenopausal disease enhanced osteoclastic activity during the erosive phase of bone remodelling may cause deep perforations of trabeculae with a generalized loss of 'connectivity'. In contrast, in age-related osteoporosis there is a reduction in trabecular plate thickness but the trabeculae retain their 'connections' with each other. At least two methods have been described to assess this—the marrow star volume (Eriksen *et al*. 1994) and node-strut analysis. The value of these measurements is illustrated clearly in a recent report of hyperparathyroidism in postmenopausal women (Pariesen *et al*. 1995). The principles of these methods are illustrated in Fig. 13.

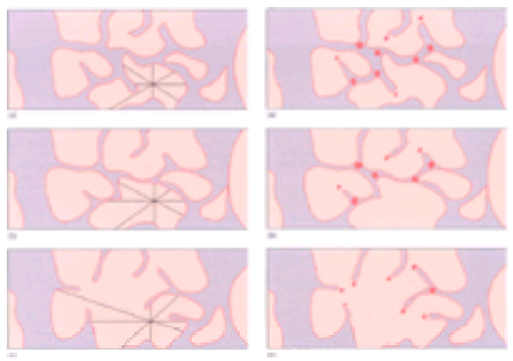

Fig. 13 Histopathalogical assessment of osteoporosis. The top panels (a) depict normal bone. Interconnecting bony trabeculae are in the centre and cortical bone at the edges. For illustrative purposes the proportion of cortical bone has been exaggerated. (b), in the centre, is age-related osteoporosis. The trabeculae are thinned out but remain connected. The trabecular bone volume (TBV) would be reduced. The lower panels (c) are severe postmenopausal osteoporosis. The trabeculae are thinned and, because they have been deeply eroded, have lost connectivity. The star volume (left hand panels) is obtained by measuring and adding the distances from a random point to the nearest bony trabeculum. It is slightly increased in age-related osteoporosis (b, left) but markedly increased when connectivity has been lost (c, left). In practice, several random histological levels would be examined and the results would be expressed volumetrically (see text). Node-strut analysis is illustrated in the right hand panels. A node (red circles) is a junction between three (or more) trabeculae, a strutis a connection between two nodes, and a terminus (red dot) is a blindly endingtrabeculum. In severe postmenopausal osteoporosis the number of nodes and struts are decreased and termini are increased. For full details refer to Pariesen *et al*.(Pariesen *et al*. 1995).

There is no evidence that osteoid volume is increased in either the 'postmenopausal' or 'senile' form of osteoporosis. Furthermore, most reports indicate that osteoid volume is not affected by increasing age. If a high osteoid volume is recorded in an osteoporotic patient, an additional form of metabolic bone disease should be suspected.

Osteomalacia

The histological appearances of florid cases of osteomalacia are characteristic (see Fig. 12) and histomorphometry is not strictly necessary for immediate diagnosis. Trabecular bone volume, osteoid volume, and osteoid surface should be measured in all cases, along with an index of hyperparathyroidism such as percentage trabecular or osteoclastic resorption surface. When tetracycline has been given it is usually possible to calculate the calcification rate and percentage tetracycline labelling. In practice a perfect pattern of fluorescence is seldom obtained. If severe osteomalacia or renal osteodystrophy is suspected the interval between the two courses of antibiotic should be increased and the biopsy taken 1 or 2 weeks after the last dose. Even if this is possible the number of true double lines may be small and the real value of this technique may be doubtful. Nevertheless, we use tetracycline in all adults in whom there is a suspicion of osteomalacia or renal osteodystrophy. It should not, of course, be used in children. Confocal laser microscopy can produce excellent fluorescent images of tetracycline-labelled bone biopsies but the instruments are expensive and not generally available to diagnostic histopathologists.

Biopsies from patients with renal bone disease or hyperparathyroidism should be handled in much the same way. Reabsorption surfaces should be measured. Some form of 'hard copy'—good drawings or well-prepared photomicrographs—makes these measurements easier. Nevertheless, with practice, consistent results can be obtained by direct microscopy. Osteoblasts and osteoclasts should be counted when there is any suspicion of hyperparathyroidism. Their distribution is not random in these disorders, nor even in normal bone. Because of this a set of measurements made from a single section may be imprecise. Gundersen and his colleagues have described simple techniques that allow more accurate estimation of irregularly distributed histological features (Gundersen *et al*. 1988). By examining a comparatively small number of sections it is possible to volumetrically, rather than in two dimensional terms.

Vascular disorders (see also Chapter 5.11.1, Chapter 5.11.2, Chapter 5.11.3, Chapter 5.11.4 Chapter 5.11.5, Chapter 5.11.6, Chapter 5.11.7, Chapter 5.11.8 and Chapter 5.12.1)

Temporal artery biopsy

Despite many detailed clinical, pathological, and epidemiological studies, very little is known about the cause of cranial ('giant-cell' or 'temporal') arteritis (see Chapter 5.11.6). Although medium-sized arteries of the head and neck are frequently involved, almost any area of the body, including the aorta, may be affected. It is disease of the posterior ciliary and ophthalmic arteries that leads to blindness but biopsies are usually taken from the superficial temporal branch of the external carotid or the terminal branches of the occipital artery.

Technical aspects

Many patients with the classical, clinical features of temporal arteritis have normal biopsies and this is often ascribed to focal involvement of the artery by disease (Klein *et al*. 1976). To minimize the incidence of these false-negative biopsies, samples removed for histological examination must be as long as possible and should be taken from areas that are tender. Scalp necrosis is a rare complication of cranial arteritis but it is safe to remove a 2- to 3-cm length of the superficial temporal artery. Biopsies must be handled gently and should not be trimmed for processing until they are fully fixed. Histological artefacts can be produced if fresh biopsies are squeezed or cut transversely, and in the most curious of these the artery appears to intussuscept on itself. All of the biopsy should be processed, cut at multiple levels, and stained by haematoxylin and eosin and a connective tissue method, such as elastic–van Gieson.

Evaluation of biopsies

The microscopic features of acute and resolving cranial arteritis and the arterial changes associated with ageing are summarized in Table 3. The classical picture of granulomatous acute and chronic inflammation, with multinucleated giant cells in close relationship to an extensively fragmented internal elastic lamella, is seen in approximately 60 per cent of typical clinical cases (Table 4, Fig. 14 and Fig. 15)). Giant cells are not a prerequisite for diagnosis. However, there must be evidence of inflammation within the muscular wall, for adventitial chronic inflammatory infiltrates are a feature of common disorders such as atherosclerosis. In some biopsies from patients with acute cranial arteritis there is florid intimal oedema (and it may be the rapid resolution of this that underlies a prompt response to anti-inflammatory drugs).

'Ageing changes' (arteriosclerosis)	Active cranial arteritis	Subacute or healed cranial arteritis
Concentric intimal and inner medial fibrosis	Acute and chronic transmural inflammation, often in relationship to small branches	Focal aggregates of lymphocytes and macrophages in the media
Focal fragmentation and apparent reduplication of internal elastic lamella	Prominent giant cells in relation to destructed internal elastic lamella	Bizarre, irregularly arranged intimal fibrous tissue
Focal calcification, especially around elastic lamellae and adjacent media	Marked intimal fibrosis and oedema	Fragmentation of elastic lamella, usually involving more than one-quarter of the arterial circumference
Hyalinization of muscular media	Focal areas of intimal and medial necrosis; not extensive necrotizing change with fibrin deposition and luminal thrombus formation unusual	Medial scarring with ingrowth of new blood vessels (neovascularization)
Aggregates of lymphocytes and macrophages in adventitia, especially in association with atherosclerosis		

Table 3 Histological changes in temporal artery biopsies

	[illegible]	[illegible]
No. of biopsies suitable for study*	130	91
No. of patients (%) with clear clinical evidence of cranial arteritis	57 (43%)	39 (43%)
Histological results (on review)		
Typical cranial arteritis	23 (17%)	21 (23%)
Atypical arteritis†	5 (3%)	2 (2.2%)
Healed arteritis	2 (1.5%)	3 (3.3%)
Arteriosclerosis	91 (67.5%)	55 (60.5%)
Normal	9 (4.5%)	0 (0.0%)
Percentage of patients with clear clinical cranial arteritis who had positive biopsies	58%	49%
Histological errors		
No. of patients (%) with arteriosclerosis erroneously diagnosed as healed or atypical arteritis	8 (5.0%)	5 (5.5%)
No. of cases in which a histological diagnosis of arteritis was missed	0	1

*Cases in which both histology and clinical records were available for study.
†No giant cells but inflammatory lysis of cranial arteritis.

Table 4 Histological results in temporal artery biopsies, Southampton University Hospitals

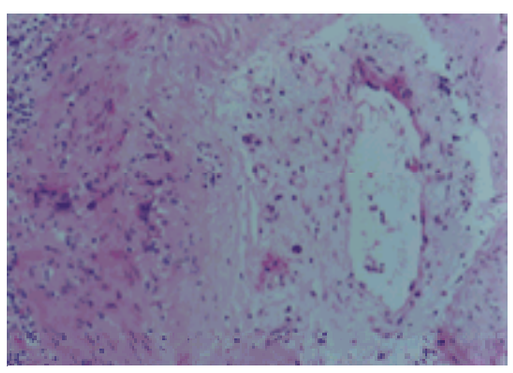

Fig. 14 A positive temporal artery biopsy. Note the florid intimal oedema and mixed chronic inflammatory infiltrate.

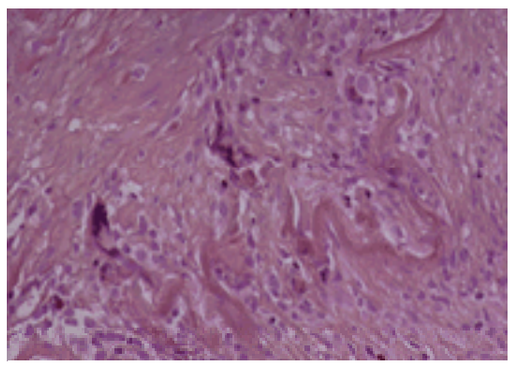

Fig. 15 Cranial arteritis. Note the close relationship between the internal elastic lamella and giant cells. Not all positive biopsies contain giant cells.

Surgical pathologists must be familiar with the full range of ageing changes that occur in the aorta and muscular arteries. These alterations can be misinterpreted and, in reviewing 91 biopsies taken over a 5-year period, we identified five cases reported as healed arteritis that showed only ageing change (Ashton-Key and Gallagher 1991). These alterations, sometimes termed arteriosclerosis, include intimal and inner medial fibrosis, concentric intimal thickening by bands of collagenous tissue resembling the internal elastic lamella, focal fragmentation and calcification of elastic tissue, hyalinization of the medial muscle, and small aggregates of lymphocytes and macrophages in the intima and media. In contrast, in genuine cases of healed arteritis there are extensive breaks in the internal elastic lamella and areas of irregular or coarse scarring involving much of the thickness of the media. On occasions a bizarre pattern of intimal fibrosis is recognized (Fig. 16). If these changes are present, a diagnosis of healed arteritis can be made even in the absence of inflammation.

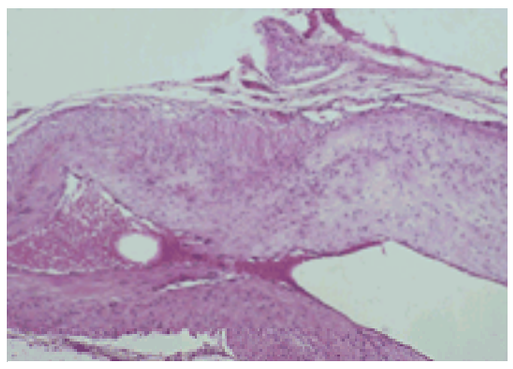

Fig. 16 Healing temporal arteritis. On the right there is irregular inimal thickening and oedema but at the left the structure of the arterial wall is almost normal.

Indications for biopsy

About 20 per cent of temporal artery biopsies show acute, subacute, or healed arteritis but between 10 and 20 per cent of patients with negative biopsies have classical signs and symptoms of cranial arteritis and respond well to steroid treatment (Hall *et al*. 1983; Ashton-Key and Gallagher 1991). Some rheumatologists and ophthalmologists do not routinely take a biopsy from patients who they intend to treat with steroids and the results shown in Table 5 provide some support for this practice (Allison and Gallagher 1984). In one group of patients we studied, 18 per cent of those with a clinical diagnosis of cranial arteritis developed a complication associated with long-term steroid treatment and in cases such as these a positive biopsy report is invaluable.

	No steroids before biopsy (n=41)	Steroids for 7 days or less (n=31)	Steroids for more than 7 days (n=22)
Positive biopsy			
Typical cranial arteritis	42 (59%)	26 (52%)	2 (10%)
Atypical arteritis	8 (14%)	4 (8%)	–
Healed arteritis†	–	–	2 (10%)
Negative biopsy	11 (19%)	21 (40%)	18 (80%)

*These results demonstrate that the chance of a positive biopsy diminishes after steroid therapy is started. Adapted from Allison and Gallagher (1984).
†Giant cells absent but otherwise typical of cranial arteritis.

Table 5 Temporal artery biopsy and the duration of steroid treatment before biopsy in patients with good clinical evidence of cranial arteritis*

Larger arteries are involved in a proportion of cases. Disease of the proximal aorta may be associated with dilatation of the proximal aorta, aortic incompetence, or aortic dissection. In some cases the diagnosis is only made when cardiac surgeons biopsy an unusually thick aortic wall. As in the temporal artery, the histological changes in the aorta may be focal. Any inflammation within the aortic media, as opposed to the adventitia, is pathological and must not be dismissed. The erythrocyte sedimentation rate and acute phase reactants should be measured preoperatively in all patients with proximal aortic disease.

There is no doubt that steroid treatment produces a rapid improvement in clinical symptoms and appears to be associated with a higher incidence of 'false negative' biopsies. It is unlikely that complete resolution of histological changes can occur in steroid-treated patients in days or even weeks. The low incidence of positive biopsies may be the result of sampling error—and when steroid treatment has already been started it is particularly important to take biopsies from areas of tenderness. Not all patients with genuine temporal arteritis have a raised erythrocyte sedimentation rate or plasma viscosity, and normal values (Wong and Korn 1986) are not a contraindication to biopsy.

Granulomatous arterial diseases

Three other chronic inflammatory diseases of large vessels have superficial similarities to cranial arteritis but each is a distinct clinical and pathological entity. Granulomatous angiitis of the central nervous system affects small and medium-sized arteries of the meninges and cerebrum. As in cranial arteritis, giant cells may be prominent but, if anything, the inflammatory infiltrates are denser and there may be extensive necrosis of the muscular wall (Fig. 17). Patients present with a variety of focal or diffuse neurological symptoms but visual symptoms are not especially common and the scalp vessels do not appear to be affected. If cerebral angiography is performed, a characteristic beaded appearance may be seen; on occasions the diagnosis has been confirmed by meningeal biopsy. Some patients have responded to cyclophosphamide and corticosteroids (Frayne *et al*. 1986). The cause of this disorder is unknown but there is an association with a form of amyloid angiopathy distinct from the usual pattern seen in Alzheimer's disease (Shintaku *et al*. 1986).

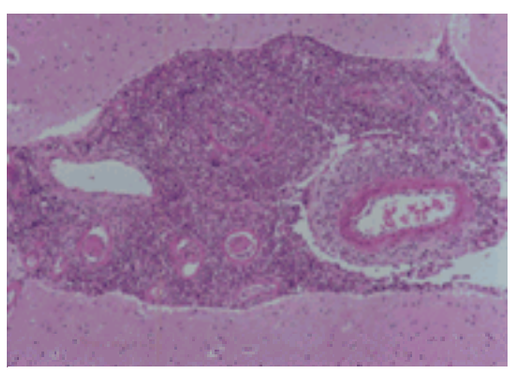

Fig. 17 Granulomatous angiitis of the central nervous system. There is florid transmural chronic inflammation with prominent giant cells. In contrast to cranial arteritis there is extensive necrosis of the vessel wall.

Takayasu's arteritis affects the aorta and its larger branches and, at least in the early stages, it is a granulomatous chronic inflammatory disease (Hall *et al*. 1985). The usual presenting symptoms are upper limb claudication or hypertension but the diagnosis is often difficult and aortography is usually required. Most biopsies are taken from completely obstructed arteries and these may show only intimal fibrosis, medial scarring, and patchy chronic inflammation. In active cases the histological appearances closely resemble those of cranial arteritis but the clinical features are so different that this is seldom a source of confusion. The same may be said of Buerger's disease, a distinctive peripheral vascular disorder, in which there may be granulomatous inflammation of the lower limb arteries. Histological confirmation of the diagnosis is usually made in amputation specimens but cerebral and gastrointestinal arteries can be affected (Rosen *et al*. 1985). The disease has no important rheumatological complications.

Histological diagnosis of systemic vasculitis

The term 'vasculitis' is applied loosely to non-infectious inflammatory disorders of blood vessels. There is some direct and some circumstantial evidence that the inflammation is a result of an immunological reaction at the endothelial surface or in the wall of the affected vessel. In the early stages the clinical diagnosis may be uncertain. Screening for autoantibodies is an essential investigation and circulating autoantibodies to neutrophil cytoplasmic antigens are strongly associated with the development of several forms of systemic vasculitis (Savage *et al*. 1991). A wide variety of tissue biopsies may be submitted in order to establish a histological diagnosis (Table 6).

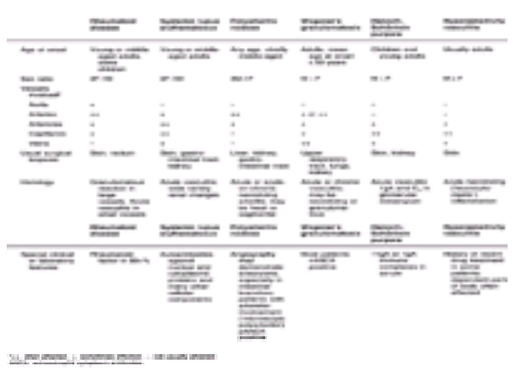

Table 6 Histological and immunopathological features of vasculitis

Evaluation of biopsies

No single microscopic feature is diagnostic of a particular disorder and there is considerable overlap between the appearances in the different forms of vasculitis. A careful assessment of the nature of the inflammatory reaction, the type and size of the diseased vessel, and the site of the tissue biopsy may provide a correct diagnosis. The most characteristic histological features of a true vasculitis are necrosis of the media of the vessel wall, transmural and adventitial inflammation, and a granulomatous reaction (Travis *et al*. 1991) (Fig. 17 and Fig. 18). In contrast, in other chronic inflammatory processes, inflammatory cells are usually restricted to the adventitia. Although the intima and media may undergo reactive thickening ('endarteritis obliterans'), there is no significant necrosis or inflammation of the wall itself. The inflammatory changes are often more marked in veins than in arteries and this would be unusual in a true vasculitis. These are useful guidelines but in practice there are many exceptions. Not all biopsies from undoubted cases of vasculitis will show full-thickness inflammation or necrosis of the vessel wall. On the other hand, arterial haemorrhage is a well-recognized complication of disorders such as peptic ulceration or tuberculosis and this could not occur without extensive medial necrosis.

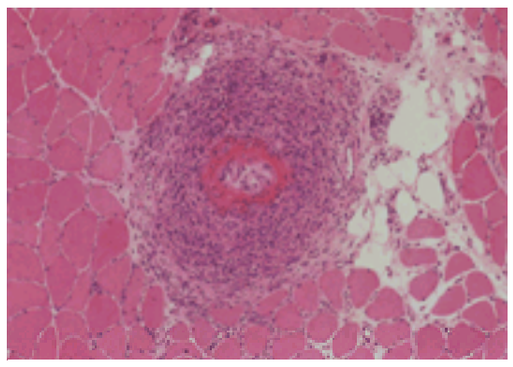

Fig. 18 Polyarteritis nodosa in a muscle biopsy. There is fibrinoid necrosis of the inner media and the inflammatory infiltrate extends through the full thickness of the wall.

Immunohistochemical methods have not found a place in the routine diagnosis of systemic vasculitis. In small vessels, such as arterioles and capillaries, it is comparatively easy to demonstrate pathological deposits of immunoglobulins. This is especially true of skin, where simple immunofluorescent methods with frozen sections are at least as satisfactory as more modern methods in paraffin-embedded material.

There are substantial technical problems in larger vessels, where the reaction product may be obscured by heavy background staining (Gallagher 1991). Although it is assumed that many forms of vasculitis are the result of immune complex deposition, in most instances the nature of the antigenic component is uncertain. Nevertheless, if substantial deposits of immunoglobulin can be demonstrated in diseased vessels the process is more likely to be true vasculitis than a reactive.

Muscle biopsy in the rheumatic disorders

Technique

Muscle biopsy, obtained by either needle or open biopsy, is a minor procedure that can be done under local anaesthesia in almost all patients. An open biopsy requires a small skin incision but has the advantage that a larger specimen is obtained, often giving more diagnostic information in a patchy inflammatory disorder such as polymyositis. In comparison, a needle biopsy provides a smaller sample but several biopsies in different directions can be obtained through the same small incision, and it is much less likely to leave a scar. In addition, the patient is more likely to tolerate repeat biopsies. With either method, careful handling and freezing of the specimen is essential to obtain maximum histological information. It is best to orientate the specimen before freezing and then to snap-freeze in isopentane cooled in liquid nitrogen. This rapid freezing eliminates ice-crystal artefact, which can grossly distort the muscle fibres and obscure pathological changes. A simple technique for freezing biopsy specimens is illustrated (Fig. 19). It is important to keep the specimen completely frozen and to avoid contact with fingers or metal instruments at room temperature, as these may cause thawing at the periphery. For diagnostic purposes, transverse sections generally yield the most information. Fibre atrophy is one of the more common pathological changes in the rheumatic disorders and fibre size can be accurately assessed from fibre diameter, but only in genuine transverse sections (Fig. 20). If there is enough material, it is always sensible to store a small frozen sample for biochemical analysis and to put a tiny strip into glutaraldehyde for electron microscopy, lest either of these investigations prove necessary.

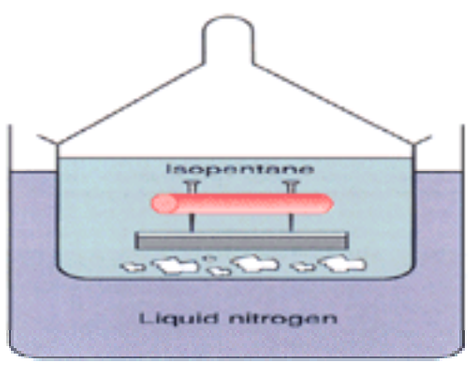

Fig. 19 A small cylinder of muscle under slight tension is pinned to a piece of rubber and prevented from sticking to it by a layer of plastic. When dropped into isopentane, cooled by liquid nitrogen until crystals appear on the bottom of the beaker, the specimen freezes instantly.

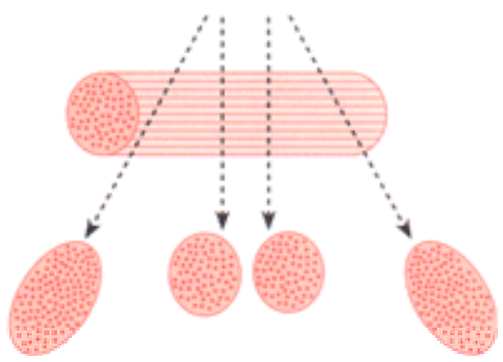

Fig. 20 Fibre size can be reliably assessed from fibre diameter or area, but only in true transverse sections. Poor orientation results in larger elliptical sections and

erroneous measurements of fibre size.

Site

A positive muscle biopsy is an important diagnostic criterion of polymyositis and dermatomyositis (see Chapter 5.9.1), where skeletal muscle is the main and often sole pathological target. In other systemic rheumatic disorders, muscle biopsy may assist in primary diagnosis, but more often is done to elucidate the cause of muscle symptoms, particularly to detect an active myositis. The site of biopsy is best determined by the clinical picture. A severely wasted muscle in a patient with a chronic disorder should be avoided. A tender muscle may yield a positive result in inflammatory disorders; electromyographic abnormalities on one side in symmetrical muscle disease may assist localization of an appropriate muscle to biopsy in the opposite limb.

Muscle fibre types and staining reactions

A wide variety of enzyme histochemical and tinctorial stains is available, but only a few are necessary for initial screening (Fig. 21). Differences in physiological properties, that is differences in twitch speed and fatiguability, correlate with differences in enzyme profile of individual muscle fibres. One fibre category may be selectively involved in disease; therefore identification of fibre types and their variation from the normal pattern are important diagnostic criteria. The myosin ATPase histochemical reaction is the best and most readily reproducible method, by which three types can be distinguished: slow-twitch, fatigue-resistant type-1, and fast-twitch type-2 fibres, which are subdivided into 2A with intermediate fatiguability and 2B that fatigue rapidly (Fig. 22). The muscle fibres within a motor unit are of uniform type but fibres from adjacent units are intermingled, creating a normal mosaic pattern in all normal human limb muscles. A fourth type, 2C fibres, are immature fibres found only in fetal, neonatal, or regenerating muscle. Other stains give additional information about sarcoplasmic contents, the arrangement of myofibrils, and other organelles. Immunocytochemistry may be used to identify and type infiltrating lymphocytes and macrophages in inflammatory disease. Electron microscopy has played an important research role in muscle disorders but has little diagnostic value in the rheumatic disorders.

Myosin ATPase *	Fibre typing
Oxidative enzymes *	Intermyofibrillar network
Gomori trichrome	Mitochondria
Acid phosphatase *	Lysosomes, macrophages
Periodic acid Schiff	Glycogen
Oil Red O	Lipid

* *Histochemical reaction*

Fig. 21 Basic panel of special stains for muscle biopsy interpretation

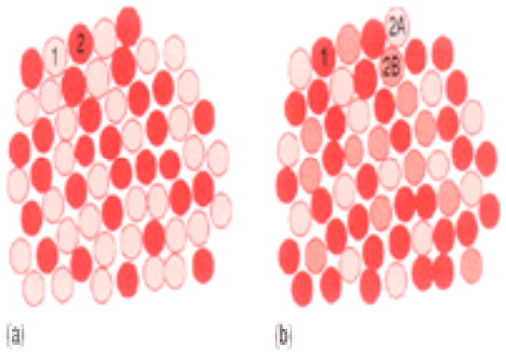

Fig. 22 Fibre types. (a) Myosin ATPase at pH9.4 shows strong reactivity in type 2 fibres (dark), but enzyme activity is inhibited in type 1 fibres (pale). (b) At acid pH 4.6 there is a reversal of this pattern. The type 1 fibres are dark and the type 2 fibre subtypes are revealed, type 2A (pale) and 2B (intermediate). The intermingling of fibres of adjacent motor units creates the normal mosaic pattern.

Clinicopathological correlation

Histological abnormalities in a muscle biopsy are rarely pathognomonic of a single disorder. Rheumatic diseases and conditions with totally different pathogeneses, such as dystrophies or neurogenic atrophy, may not always be distinguished by histological features alone. Close clinicopathological correlation is essential to obtain the maximum diagnostic information from a muscle biopsy. For detailed descriptions of the pathology of neuromuscular disease and biopsy interpretation the reader is referred to larger, comprehensive works (Anderson 1985; Engel and Banker 1986). This section seeks to correlate histopathological abnormalities in muscle with pathogenetic mechanisms in the rheumatic disorders. As with the clinical picture, there is considerable histological overlap in the various rheumatic disorders, and the different diseases are discussed under the headings of key pathological features.

Inflammation

Inflammatory myopathies are disorders in which muscle cell injury is directly or indirectly attributable to the inflammatory reaction and mononuclear chronic inflammatory cells are usually present in the muscle (see also Chapter 5.9.1).

Infectious agents

Infective myositis due to active proliferation of bacterial, fungal, or parasitic organisms in muscle may elicit a vigorous inflammatory response, but it is rare except in the tropics and unlikely to be confused with the immunological disorders. Acute viral myositis is attributable to viral invasion of muscle cells, for example by influenza or enteroviruses, but is a self-limiting disorder. Infectious agents have long been incriminated as trigger factors of the immunologically mediated destruction of muscle in polymyositis and dermatomyositis, but micro-organisms are consistently absent in muscle examined by light and electron microscopy or tissue culture. In addition, a steroid-responsive inflammatory myopathy, indistinguishable from idiopathic polymyositis occurs in patients infected with human immunodeficiency virus (**HIV**) (Calabrese 1989; Wrzolek *et al*. 1990), and retroviral antigens have been identified in sparse macrophages in muscle biopsies (Nordstrom *et al*. 1989; Dalakas 1990).

Mononuclear cells

Whilst there is no absolute distinction, polymyositis and dermatomyositis generally show differences in distribution and character of the inflammatory cells, which probably reflect different immune effector mechanisms (Engel and Arahata 1986). In both disorders the cellular infiltrate is predominantly lymphocytic, but in polymyositis it is chiefly endomysial and focal (Fig. 23(b)). Individual, apparently healthy muscle fibres are surrounded and invaded by lymphocytes, shown by immunocytochemistry to be cytotoxic T cells accompanied by macrophages. This invasion of non-necrotic muscle fibres implicates cell-mediated cytotoxicity in polymyositis. In contrast, in dermatomyositis the infiltrate is dispersed in the perimysial connective tissue surrounding fascicles and frequently forms perivascular aggregates (Fig. 23(a)). Endomysial inflammation is less conspicuous. B cells are more numerous in dermato-than in polymyositis, but the character of the infiltrate

changes from B-cell dominance in the perivascular location to increasing numbers of T cells, mainly CD4, approaching the endomysium. The relative abundance of B cells suggests local humoral immune mechanisms have a more important role in dermatomyositis. Polymyositis and dermatomyositis are the archetypal disorders, but the same patterns of inflammation may occur in any of the autoimmune rheumatic disorders.

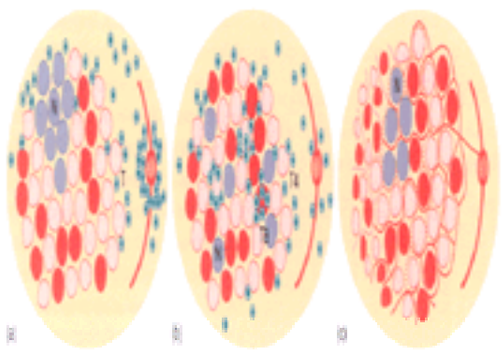

Fig. 23 Immunological injury. (a) Pattern of lymphocytic (T and B cell) infiltration in dermatomytosis. Necrotic fibres (N) in small groups suggesting microinfarcts. (b) Pattern of lymphocytic infiltration in poliomyositis. Invasion of non-necrotic fibres by cytotoxic T cells (T8) and spotty fibre necrosis (N). (c) Membrane attack complex (MAC) deposition of capillaries (dotted line) precedes capillary loss. Reduction of flow in capillary bed causes microinfarcts (N) and atrophy of fibres at the pperiphery of the vascular field.

Invasion by cytotoxic T cells and destruction of non-necrotic muscle cells also occurs in inclusion-body myositis (Engel and Arahata 1986). Histological distinction from polymyositis depends on the presence of numerous vacuoles rimmed by basophilic material, and eosinophilic cytoplasmic inclusions (Lotz *et al*. 1989). The vacuoles are acid phosphatase-positive, lysosomal vacuoles containing cytoplasmic debris. The eosinophilic inclusions are found within or closely associated with vacuoles and electron microscopy reveals they are composed of masses of electron-dense filaments, 14 to 18 mm in diameter, of unknown origin and composition. Despite resemblance to paramyxoviral nucleocapsids, negative findings for viral DNA by *in-situ* hybridization refute the possibility that mumps virus is an aetiological agent (Nishino *et al*. 1989). Furthermore, neither the filaments nor vacuoles are disease specific but occur in a wide variety of chronic wasting neuromuscular disorders. The autophagic lysosomal system plays a central role in muscle cell degradation in all these conditions, but the trigger factors are unknown.

Eosinophils

Skeletal muscle may be involved in the spectrum of hypereosinophilic disorders, in which eosinophil-derived toxins probably contribute to tissue damage. These disorders encompass eosinophilic fasciitis (Shulman's syndrome), where a mixed chronic inflammatory infiltrate containing many eosinophils is present in an oedematous and sclerotic fascia, often spreading deeply into the perimysium (Serratrice *et al*. 1990). In some cases the infiltrate involves the endomysium and is associated with spotty necrosis of muscle fibres, an eosinophilic polymyositis. Indistinguishable eosinophilic inflammation of fascia and muscle may be found in the eosinophilia–myalgia syndrome attributable to tryptophan ingestion (Silver *et al*. 1990).

Granulomatous inflammation

The 'tuberculoid' granuloma, a histological marker of cell-mediated immunity, is a tight focus of epithelioid histocytes and multinucleate Langhans giant cells. Granulomas are rare, inconspicuous components of the predominantly lymphocytic inflammation of muscle fascicles in polymyositis. In contrast, sarcoidosis involving skeletal muscle shows discrete, non-caseating tuberculoid granulomas, chiefly in the interstitium, but without accompanying endomysial inflammation or necrosis of muscle fibres.

Necrosis

All stages of necrosis and regeneration may be seen in a single biopsy in the active phase of the idiopathic inflammatory myopathies. Initially a necrotic segment is pale staining and structureless. Invasion by macrophages that engulf cytoplasmic debris rapidly follows and subsequently small basophilic segments containing large nuclei indicate regeneration from satellite cells. Different patterns of fibre necrosis are observed in polymyositis and dermatomyositis. In polymyositis there is frequently spotty, single-fibre necrosis (see Fig. 23(b)). These necrotic fibres are not surrounded by T lymphocytes but contain the membrane-attack complex, indicating a different method of immunological destruction, probably humoral antibody-dependent, complement-mediated cytotoxicity. In a minority of patients with an idiopathic inflammatory myopathy clinically compatible with polymyositis and with no drug exposure, the muscle biopsy is completely devoid of inflammatory cell infiltration and shows only segmental necrosis. The same picture is seen in a proportion of patients with AIDS-related myopathy (Wrzolek *et al*. 1990) and is recorded in Lyme disease (Schoenen *et al*. 1989).

In dermatomyositis necrotic fibres are frequently in small clumps, with the appearance of microinfarcts (see Fig. 23(a)). Primary immunological attack upon the vasculature may be responsible for these ischaemic foci. Capillary vessels positive for the complement membrane-attack complex and decreased capillary density are consistent findings and present early in the disease (Emslie-Smith and Engel 1990) (see Fig. 23(c)). Microtubular inclusions of uncertain nature revealed by electron microscopy in endothelium in dermatomyositis, and also in systemic lupus erythematosus, may be a cellular response to injury. In addition to microangiopathy, fibrinoid necrosis, attributable to immune complex deposition in vessel walls, is occasionally seen in arterioles and venules in dermatomyositis, particularly the juvenile form.

A necrotizing inflammatory myopathy, histologically indistinguishable from either poly- or dermatomyositis, may occur in association with any of the systemic autoimmune rheumatic diseases, that is in overlap syndromes. In systemic sclerosis, necrosis of muscle fibres is unusual, and inflammatory cell infiltration, predominantly T cell, is largely confined to the perimysium, supporting the likelihood of a cell-mediated immune response directed against connective tissue components rather than muscle cell antigens.

Necrosis of muscle fibres in patients with a rheumatic disorder is occasionally attributable to drug therapy. Many different drugs, with different modes of action, can cause a necrotizing myopathy but D-penicillamine, which induces a wide range of autoimmune phenomena, is probably the most frequently encountered in rheumatological practice. A florid, necrotizing inflammatory myopathy is histologically identical to idiopathic poly- or dermatomyositis. Zidovudine toxicity may contribute to muscle cell necrosis in HIV-positive patients (Dalakas *et al*. 1990).

Atrophy

Muscle fibre atrophy is invariably present in patients with muscle weakness. Different causes and pathogenetic mechanisms give different patterns of atrophy (Fig. 22). Atrophy may be selective, affecting only one fibre type, usually type-2, or involve groups of fibres, or be confined to the periphery of fascicles (Fig. 24). Regenerating fibres are also smaller than normal, but can be recognized by their cytoplasmic basophilia and type-2C ATPase reaction. Selective atrophy of the fast-twitch type-2, particularly type-2B, fibres is a frequent but by no means specific finding in patients with rheumatoid disease and muscle symptoms. Whilst often seen in association with myositis, type-2 atrophy may be the only abnormality. The cause is often multifactorial and selective type-2 atrophy alone is insufficient for diagnosis of active inflammatory myopathy. Disuse atrophy, and hence immobility, associated with joint pain, malignancy, cachexia, and steroid therapy may all induce type-2 atrophy. Muscle biopsy is often used in an attempt to distinguish between steroid-induced myopathy and exacerbation of myositis. If the only abnormality is type-2 atrophy, the many possible contributory factors and the patchy nature of the inflammatory process make distinction impossible.

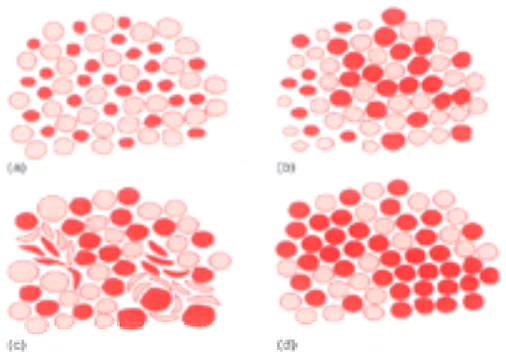

Fig. 24 Patterns of atrophy. For simplicity only two fibre types are illustrated. (a) Selective type-2 fibre atrophy, a non-specific change encountered in many disorders. (b) Perifasicular atrophy involving both fibre types, as in dermatomyositis. (c) Neurogenic atrophy, small group atrophy affecting individual motor units of both fibre types. Some residual innervated fibres show compensatory hypertrophy. (d) Reinnervation reverses atrophy and may result in type grouping, i.e. large groups of uniform fibre type.

Perifascicular atrophy, involving type-1 and type-2 fibres, is particularly characteristic of dermatomyositis, both juvenile and adult (Fig. 24(b)). It is attributed to ischaemia, secondary to the microangiopathy of this myositis. The distribution coincides with the periphery of the vascular field, where effects of reduced blood supply are most severe.

Grouped atrophy, affecting type-1 and type-2 fibres in any proportion, is characteristic of denervation. The muscle fibres of each motor unit are in fairly close proximity within the belly of the muscle. Denervated fibres slowly shrink and the muscle fibres within a denervated motor unit shrink simultaneously, creating the grouped pattern (Fig. 24(c)). Denervated fibres assume an angular outline, as though moulded by adjacent healthy contracting fibres. Grouped atrophy is most evident in the motor-neurone diseases, but denervation may be a component of a rheumatoid disorder, usually as a consequence of ischaemic motor neuropathy secondary to vasculitis. It is also another frequent muscle abnormality in AIDS patients, secondary to HIV infection of peripheral nerves (Gabbai *et al*. 1990).

Denervation atrophy may be accompanied by a change in the fibre type distribution due to reinnervation. Distribution of fibre type is not an intrinsic property of muscle cells, but is determined by the motor nerve. Reinnervation of denervated fibres may induce a change in fibre type and create enlarged motor units, which appear as clumps of fibres of uniform type (Fig. 24(d)).

Hypertrophy

Hypertrophy of muscle fibres is a normal physiological response to physical training and the fibres of healthy active young adults are generally slightly larger than those of inactive elderly persons. Hypertrophy also occurs in pathological conditions, when it is most often a compensatory change in residual, healthy, over-stressed fibres alongside atrophic and damaged fibres. Hypertrophy is not seen in early or acute phases of inflammatory myopathies, nor in muscle of patients disabled and immobilized by arthritis, but it may be found in chronic, insidious or burnt-out disease, when patients remain active. Limb-girdle forms of muscular dystrophy and chronic spinal muscular atrophy may enter the histological differential diagnosis of chronic polymyositis.

Disturbances of internal cell architecture

A variety of alterations in the normal, regular arrangement of myofibrils, the peripheral situation of nuclei, and the normal distribution of other cell organelles indicate sublethal cell injury. The oxidative enzyme reaction and Gomori's trichrome stain are particularly valuable for detecting these changes. These minor abnormalities are not disease specific and on their own serve only to confirm an occult organic basis for the patient's muscle symptoms.

Myofibrillar disarray

Myofibrillar disarray, frequently seen in the inflammatory myopathies, is responsible for a patchy staining reaction, a so-called moth-eaten pattern with the oxidative enzyme reaction. In polymyalgia rheumatica, despite the severity of myalgia, a few moth-eaten fibres and a very mild degree of type-2B atrophy is generally all that is seen on biopsy. Inflammation is conspicuously lacking and there is no vasculitis in muscle.

Vacuoles

Empty cytoplasmic vacuoles, derived from dilated organelles such as sarcoplasmic reticulum or the T-tubule system, are an occasional finding and rarely numerous in inflammatory myopathies. The numerous lysosomal or rimmed vacuoles of inclusion-body myositis have already been described. A few may be found in steroid-sensitive poly- or dermatomyositis, together with the eosinophilic inclusions; it is the very large number that separates inclusion-body myositis. Identical vacuoles are also characteristic of chloroquine-induced myopathy, where in addition, electron microscopy may reveal short, curved, lamellar cytoplasmic bodies, identical to the inclusions in Batten's disease.

Mitochondria

The wide clinical spectrum of myopathies due to mitochondrial enzyme deficiencies encompasses patients with symptoms indistinguishable from polymyositis. A diagnostic biopsy in mitochondrial myopathy reveals numerous 'ragged red' fibres with Gomori's trichrome stain, an appearance created by aggregates of large, structurally abnormal mitochondria. There is no inflammation. In contrast, secondary mitochondrial injury may be responsible for an occasional 'ragged red' fibre amongst the more characteristic changes of the idiopathic inflammatory myopathies, and may be a manifestation of zidovudine myotoxicity in HIV-positive patients.

Fibrosis

Increase in interstitial connective tissue—perimysial and endomysial fibrosis—only occurs in chronic rheumatoid disorders, preceded by considerable atrophy and destruction of myofibres.

Vasculitis in muscle

Vasculitis—inflammation directed against blood vessels of almost any calibre in many different tissues—is a pathological component of most rheumatic disorders and may contribute to fibre atrophy and necrosis in skeletal muscle. Acute necrotizing arteriolitis and arteritis are not uncommon in juvenile dermatomyositis and may on occasion be seen in skeletal muscle in systemic lupus and rheumatoid arthritis. However, in polyarteritis nodosa, fibrinoid necrosis of medium-sized arteries is the essential diagnostic feature; muscle fascicles in the territory of an affected vessel may show ischaemic atrophy, or a pattern of denervation atrophy because the motor nerve is ischaemic, but there is no endomysial inflammation. Muscle infarcts due to arteritis in the absence of associated microangiopathy are very unusual, probably because there is a good collateral supply and the full capacity of the capillary network is only required during strenuous exercise.

The histological aspects of vasculitis are sometimes given undue diagnostic weight. Large-vessel vasculitides, such as polyarteritis nodosa, Wegener's granulomatosis, and rheumatoid arthritis, may all involve arteries in skeletal muscle and cannot be distinguished on this basis. The microscopic appearances are largely determined by the structure and calibre of the vessel, and the time-course of the reaction. Thus, in the acute phase of inflammatory destruction of an artery, which has an intima, internal elastic lamella, and smooth muscle coat, there is a fibrin thrombus, fibrin seepage into the wall, and inflammation is predominantly neutrophilic. At a later stage there is intimal hyperplasia and the inflammation obliterating the wall becomes more granulomatous, with a predominance of lymphocytes, histocytes, and occasional giant cells.

Peripheral nerve biopsy in the rheumatic disorders

Definition of the peripheral nervous system

The peripheral nerves include all the neural structures external to the pial sheath of the central nervous system, that is the axons and sheaths of all cranial nerves except optic and olfactory, all spinal and autonomic nerves, and the dorsal root and autonomic ganglia.

Factors that influence the decision to biopsy

Peripheral nerve biopsy is not an investigation that should be undertaken lightly. Not only is it an invasive procedure, with inevitable scarring and not insignificant postoperative sensory disturbance, but the diagnostic yield is negligible unless there are specialist laboratory facilities for processing the nerve and a pathologist experienced in interpretation. Furthermore, only a tiny, possibly unrepresentative, section of an extensive network can be examined. There are no histological criteria that differentiate motor and sensory fibres, and patterns of degeneration are limited and stereotyped. Only rare disorders, such as leucodystrophies, exhibit disease-specific fine-structural changes. In most peripheral neuropathies, molecular pathogenetic mechanisms are unknown. Morphological clues may incriminate the axon or myelin sheath as the primary target but, inevitably, because of structural and metabolic interdependence, secondary changes will occur. In a single biopsy, the sequence of events is not always easy to reconstruct and diagnostic interpretation must be amplified by close correlation with clinical and electromyographic data.

Indications for biopsy

Biopsy is unnecessary in a large proportion of patients with a peripheral neuropathy because they have a known cause, such as diabetes, or a family history and recognized pattern of hereditary disease. Diseases that selectively involve motor neurones, namely motorneurone disease and hereditary motor neuropathies, manifest as muscle weakness. Muscle biopsy and electromyography, rather than nerve biopsy, are more appropriate methods of investigation. Nerve biopsy is generally only applicable to peripheral neuropathies with a definite sensory component. In the rheumatoid and autoimmune rheumatic diseases, a diagnostic quest for vasculitis, which is not only the most common cause of peripheral neuropathy in these disorders but also potentially treatable, is the foremost indication for nerve biopsy. Entrapment neuropathies and neuropathy due to drug toxicity occur but are usually recognized without biopsy.

Site

Certain factors dictate the site of nerve biopsy.

1. It must be easily accessible through a small skin incision made under local anaesthetic, therefore superficial, but not subject to repetitive trauma in everyday life, as this alone will injure the nerve.
2. Biopsy must not give rise to unacceptable deficit; therefore cutaneous sensory nerve is preferable to a motor or mixed sensory–motor nerve.
3. The nerve selected must be involved and in most polyneuropathies, the lower legs are earliest and most severely affected.

Hence, the sural nerve, which is purely sensory and easily identified subcutaneously at the ankle, is most often appropriate, but the superficial peroneal and radial nerves are useful alternatives. After exposure the proximal end of the nerve should be incised first. The distal end can then be handled without the patient experiencing abnormal sensations. To minimize discomfort during and deficit after surgery, only partial transection of the nerve and excision of several fascicles is necessary (Fig. 25) but, ideally, these should be at least 3 cm long. The success of biopsy relies heavily on careful surgical technique. Artefactual disruption of delicate axons and myelin sheaths is easily produced by stretching or pinching with forceps. The specimen is best transferred immediately, fresh and unfixed, to the laboratory where a skilled technician can subdivide it for the most appropriate methods of study—generally resin-embedded transverse sections, teased fibre preparations, and electron microscopy. Quantitation of internodal length and nerve fibre diameter and density has an important role in the interpretation of the nerve biopsy (Fig. 26 and Fig. 27). Normal values are essential for comparison, and these are best documented for the sural nerve, although some data for other nerves are available (Dyck *et al*. 1984; Vital *et al*. 1990).

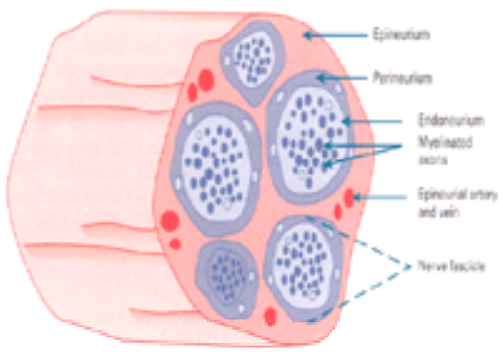

Fig. 25 Diagram of transected nerve to show the arrangement of fascicles bounded by connective tissue sheaths. The sural nerve at the ankle contains five or six fascicles and thus partial transection may be adequate. Full thickness is preferable for detection because arteries, most often invlved, lie within the epineurium.

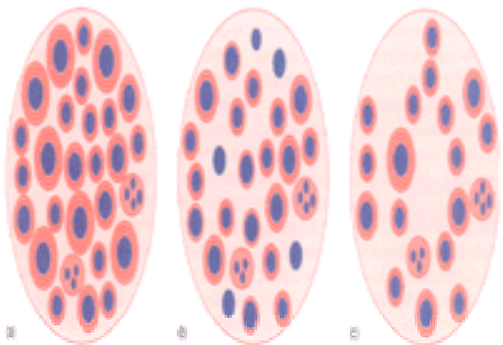

Fig. 26 Transverse sections are required for measurement of nerve fibre density and fibre diameters. (a) The normal nerve has three major populations: (i) large myelinated fibres; (ii) small myelinated fibres; (iii) unmyelinated axons—the smallest fibres. (b) Demyelination and remyelination. No axonal loss. Large fibres with abnormally thin myelin sheaths indicate remyelination. (c) Axonal loss. Decreased fibre density, chiefly due to loss of large diameter fibres.

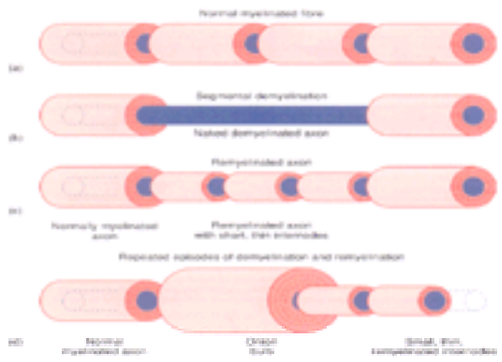

Fig. 27 Teased fibre preparations permit examination of the thickness of several consecutive internodes and are particularly valuable for recognition of demyelination and remyelination. (a) Normal myelinated fibre. (b) Segmental demyelination. (c) Remyelinated axon. (d) Repeated episodes of demyelination and remyelination.

Interpretation of the biopsy

Pathological changes are related to the neuronal components principally involved, with an attempt to explain resulting clinical and electrophysiological abnormalities.

Wallerian degeneration

Wallerian degeneration refers to the chain of events initiated by transection of the axon. Whilst trauma is an obvious cause, the pathology is identical when a segment of nerve is destroyed by ischaemia and infarction, and thus it occurs in vasculitic neuropathies.

The changes are greatest in the distal axon, where total dissolution of the axon and fragmentation of the myelin sheath occur, with formation of myelin ovoids (Fig. 28(a)). The debris is phagocytosed by Schwann cells and invading macrophages, and Schwann cells in the vicinity proliferate. The proximal axonal segment swells, owing to accumulation of cytoplasmic organelles; the myelin sheath is retracted from internodes. The extent of proximal change depends on proximity to the cell body. If injury is very close to the cell body, the neurone may die, but if at a distance, recovery and regrowth of the distal axon may occur by sprouting from the proximal segment. The recently formed Schwann cells remyelinate the new axon (Fig. 28(b)). Although the axon may grow to achieve its original diameter, the internodes of a remyelinated axon remain smaller and thinner than the original and can thereby be recognized in teased fibre preparations (Fig. 27(a-c)). The size of each internode appears to be determined by the area of axon in contact with the Schwann cell (Thomas and Ochoa 1984). More Schwann cells make contact with new axon than with the original, therefore the territory of each is smaller and the internodes are smaller.

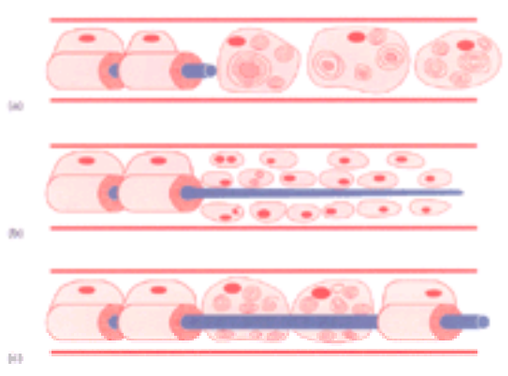

Fig. 28 The role of Schwann cells. (a) Wallerian degredation—breakdown of distal axon and myelin sheath—formation of myelin ovoids within original Schwann cell basement membrane. (b) Axonal regeneration—axonal sprouting from proximal stump accompanied by proliferation of Schwann cells that will remyelinate new axon. (c) Segmental demyelination—myelin debris engulfed by Schwann cells. Schwann cell proliferation and remyelination follows as above.

The neurone

The cell body is the metabolic power house of the cell. Normal structure and function of the axon are maintained by continuous supply of factors transported centrifugally; if the mechanism is impaired the distal ends of the longest axons are the most vulnerable. Consequently, morphological changes of neuronal injury frequently appear first in the distal axon. Distal glove-and-stocking sensory impairment, together with muscle weakness of extremities, is characteristic of many polyneuropathies.

The severity of pathological insult probably determines the time course of events. In acute axonal degeneration attributed to metabolic failure, of which uraemic neuropathy is an example, changes in the distal axon are indistinguishable from Wallerian degeneration. In more chronic insidious forms of degeneration, such as alcoholic–nutritional neuropathy, the distal axon shrinks, but axonal atrophy is accompanied by wrinkling of the myelin sheath and paranodal retraction. This is followed by demyelination, that is fragmentation of the myelin sheath and remyelination to form a thinner sheath around the atrophied axon. Complete axonal degeneration may eventually occur. Fine structural changes often provide evidence of decreased axonal transport in the form of axonal spheroids—an accumulation of neurofilaments and other organelles which create a focal axonal swelling.

Myelin sheath and Schwann cells

Demyelination is destruction of the myelin sheath with preservation of the axon. This may be a primary event or secondary to axonal atrophy, as described above. Provided the axon survives, demyelination is followed by remyelination and the formation of smaller, thinner myelin internodes (Fig. 27(c)). Chronic disorders, exemplified by the hereditary motor and sensory neuropathies, are characterized by repeated episodes of segmental demyelination and remyelination. The repetitive focal proliferation of Schwann cells and formation of new basement membranes creates localized, circumferential thickening of nerves, histologically likened to an onion bulb (Fig. 27(d) and Fig. 29). These thickened nerves may become clinically palpable, hence the term 'hypertrophic neuropathy'.

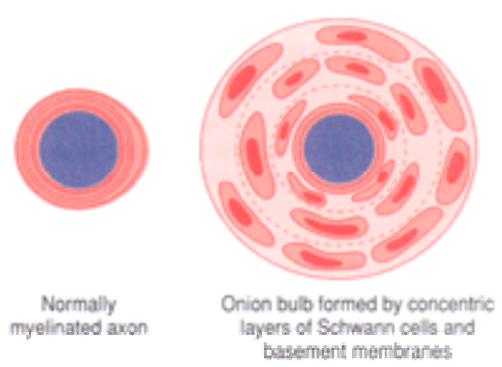

Fig. 29 Onion bulb—the result of repetitive remyelination as seen in transverse section.

The principal pathogenetic mechanisms of primary demyelination are inflammatory, immunological, and toxic. The Guillain–Barré syndrome is the prototype of acute inflammatory demyelinating polyneuropathy (**AIDP**). Small numbers of sensitized, cytotoxic T lymphocytes infiltrating the myelin sheaths effect patchy segmental myelin breakdown, particularly involving nerve roots; this corresponds clinically with asymmetrical, sensorimotor radiculopathy. With severe, widespread acute demyelination, the physical signs can be almost symmetrical. However, in this apparently random attack on peripheral nerves, a clear anatomopathological explanation for the frequent predominance of motor deficits is lacking. Myelin sheaths fragment and are degraded within macrophages (Fig. 28(c)), but although some are shrunken, the axons are largely preserved. Conduction velocity is proportional to the thickness of the myelin sheath, and thus extensive demyelination results in slowing of conduction velocity or complete conduction block, but electromyographic changes may be absent at early stages, before fragmentation has begun. AIDP is seemingly triggered by infection and is a form of neuropathy associated with HIV infection and may coincide with seroconversion (Chaunu *et al*. 1989). The virus has occasionally been cultured from peripheral nerve but is not detectable by any microscopical technique, suggesting that very few virions are present (Monte *et al*. 1988).

Chronic inflammatory demyelinating polyneuropathy (**CIDP**) is due to repeated episodes of demyelination that give relapsing or progressive neurological deficit. Histologically, mononuclear cell infiltration of the nerve is accompanied by evidence of remyelination and often onion-bulb formation. CIDP also occurs in AIDS (Leger *et al*. 1989), where it is associated with a greater degree of axonal loss than in the idiopathic cases.

In peripheral neuropathy associated with paraproteinaemias, segmental demyelination occurs in the presence of circulating antibody, most often of IgM class, specifically directed against myelin-associated glycoprotein (Gosselin *et al*. 1991). Antibody deposition in the myelin sheath is demonstrable by immunoelectron microscopy (Mata *et al*. 1988) and myelin lamellas may be widely spaced (Takatsu *et al*. 1985). Nevertheless, there is poor correlation between level of antibody and severity of neuropathy, and a primary tissue damaging role for the antibody has yet to be established (Gosselin *et al*. 1991).

Chloroquine-induced neuropathy may be encountered in patients with autoimmune rheumatic disease. Biopsy shows segmental demyelination and remyelination, and distinctive lamellar phospholipid lysosomal inclusions can be found in Schwann cells by electron microscopy (Tegner *et al*. 1988). The lipid-combining property of the drug may impede lipid degradation and promote its accumulation.

Interstitium

Ischaemia due to vascular disease is responsible for peripheral neuropathy in a variety of disorders. The clinical picture is governed by the territory and calibre of vessels involved, irrespective of the nature of the vascular pathology. Large-vessel, arterial occlusion invariably causes focal infarction and distal Wallerian degeneration, clinically evident as abrupt onset of mononeuritis and mononeuritis multiplex (Said *et al*. 1988). Arteriolar occlusion, frequently due to vasculitis, may have similar clinicopathological manifestations, but a high proportion of patients present with symmetrical distal polyneuropathy (Harati and Niakan 1986; Kissel *et al*. 1989). Most probably, this represents summation of the effects of small, multifocal, ischaemic lesions. Very mild ischaemia may only damage the myelin sheath of the distal axon. Electrophysiological studies reflect this range of changes. Segmental infarction can cause conduction block (Ropert and Metral 1990); on the other hand, provided some large myelinated fibres are spared, conduction velocity may be maintained. Inevitably, severe axonal loss will lead to conduction slowing and the compound action potential, a summation of all the impulses transmitted, is diminished.

Vascular disease (artery and arteriole)

Mononeuritis occurring in any of the autoimmune rheumatic disorders, not only polyarteritis nodosa, but also, for example, in rheumatoid disease (Said *et al*. 1989), temporal arteritis (Caselli *et al*. 1988), Sjögren's syndrome (Mellgren *et al*. 1989), systemic lupus (Omdal *et al*. 1991), suggests large-vessel vasculitis. Necrotizing arteriolitis is partly responsible for cryoglobulinaemic neuropathy (Garcia-Bragado *et al*. 1988) and the multifactorial pathology of neuropathies associated with HIV infection (Chaunu *et al*. 1989). It is one cause of carcinomatous neuropathy and a probable cause of peripheral neuropathy in Lyme disease (Meier *et al*. 1989). Nerve biopsy is not a very fruitful diagnostic test in sarcoidosis, but vasculitis and epineurial epithelioid granulomata may be found in symptomatic patients.

Large-vessel vasculitic lesions are sought in the epineurium (Fig. 25) and therefore a full-thickness rather than fascicular nerve biopsy will give a greater yield. Although florid fibrinoid necrosis may not be detected, perivascular lymphocytes and plasma cells are positive clues to adjacent foci; haemosiderin deposition, perivascular fibrosis, and recanalization of thrombus are all gravestones of previous episodes. In the absence of any vascular pathology, focal axonal degeneration, with asymmetry between adjacent fascicles, strongly suggests proximal ischaemia. In all these disorders, neuronal vasculitic injury is attributed to an immune mechanism. Immune complex deposition has been detected, but a T-cell mediated attack is also invoked (Kissel *et al*. 1989). In contrast, mononeuropathy in diabetes mellitus is due to the combination of arterial atherosclerosis and diabetic microangiopathy.

Microvascular disease (capillary and venule)

The only vessels to penetrate the endoneurium are capillaries and venules. Leucocytoclastic vasculitis frequently occurs in skin and other organs in many autoimmune rheumatic diseases, but is rare within the endoneurium (Kissel *et al*. 1989). Perivascular lymphocytes may be associated with adjacent florid epineurial vascular disease but not endoneurial vasculitis. Occlusion of the capillary venules results from other pathologies. Small-vessel occlusion in cryoglobulinaemia may be due to sludging of the paraprotein and endothelial cell swelling (Vital *et al*. 1988). In diabetes mellitus, diversion of glucose into non-insulin dependent metabolic pathways leads to capillary basement thickening. Whilst not the sole cause, this microangiopathy undoubtedly contributes to the axonal atrophy that underlies the distal sensory and autonomic neuropathy of diabetes.

Amyloid (see also Chapter 5.13.1)

Intraneural amyloid deposition is a cause of rare hereditary neuropathies and may occur in myeloma. Large endoneurial deposits undoubtedly have a direct pressure effect on fragile myelin sheaths, but ischaemia resulting from deposition in walls of small vessels is a contributory mechanism. Despite the high incidence of secondary systemic amyloidosis in chronic rheumatoid disease, it is not a cause of peripheral neuropathy. This serum AA protein-derived amyloid is rarely, if ever, deposited in peripheral nerves.

Eosinophils

The endoneurial capillaries maintain the blood–nerve barrier. In inflammatory demyelinating and vasculitic neuropathies, endoneurial oedema is a subsidiary event reflecting increased permeability. Breakdown of the barrier is probably a key event in the neuropathy of the hypereosinophilic syndrome. Nerve biopsy reveals endoneurial oedema and distal Wallerian-type degeneration, but no eosinophil infiltration. Eosinophils do not penetrate the endoneurium, but substances released by their degranulation both impair the integrity of the endoneurial barrier and exert a neurotoxic effect (Sunohara *et al*. 1989).

In conclusion, the role of nerve biopsy is limited. It should not be performed without clear objectives and, whilst obvious, it cannot be overstated that prior liaison between physician, surgeon, and pathologist is a fundamental prerequisite of success.

4.11 Electrophysiology

Adam Young

Modern nerve conduction studies and electromyography provide unique quantitative information about the function of nerves and muscles. These investigations can be an invaluable aid to both the diagnosis and management of musculoskeletal and neuromuscular disorders. The general aims of electrical tests in these disorders are to:

1. detect and distinguish between disorders of:
   a. anterior horn cells
   b. nerve roots
   c. plexi
   d. peripheral nerves
   e. neuromuscular junctions
   f. muscles
2. define location, extent, and severity;
3. relate neurophysiological abnormalities to clinical features;
4. infer pathology if possible.

The principal application of electrical studies to rheumatic disease is in the diagnostic and prognostic assessment of the neurological and myopathic features that complicate several of the inflammatory arthropathies and autoimmune rheumatic disorders and some of the mechanical and soft tissue conditions. The usual features are muscle weakness or wasting, sensory symptoms, pain or deformity, or a combination of these, in a patient with an established autoimmune rheumatic disorder or presenting for the first time with a rheumatic complaint for diagnosis. The most frequently encountered indications, possible pathophysiological processes and some examples for electrodiagnosis in rheumatology are shown in Table 1.

Clinical feature	Pathophysiology	Examples
Muscle weakness or wasting	Atrophic	Rheumatoid joint
	Myopathic	Polymyositis
	Neuropathic	Rheumatoid or entrapment neuropathy
Sensory symptoms	Peripheral neuropathy	Rheumatoid arthritis
	Entrapment neuropathy	Ulnar neuropathy
Pain	Entrapment neuropathy	Carpal tunnel syndrome
	Nerve injury	Causalgia
Deformity	Hereditary or rare neuromyopathies	Muscular dystrophy
	Entrapment neuropathy	Ulnar nerve claw hand

Table 1 Indications for electrodiagnosis in rheumatic disorders

There are several and varied procedures available and good clinical information is essential for planning an individual examination. The answer to a specific clinical question depends on the interpretation of the appropriate choice of a number of laboratory, radiological and electrical investigations and the requesting clinician should consider carefully the diagnostic and prognostic yield of the electrical study with respect to inevitable discomfort to the patient during this procedure. It is, however, a safe investigation and, except when needle sampling of muscles is required, is non-invasive.

The following points should be considered when an electrical test is planned:

1. The optimum diagnostic yield depends on thorough clinical evaluation of the patient's symptoms and signs.
2. It only provides physiological information but will complement other studies of pathological (e.g. biopsy) or structural disturbances (e.g. radiology).
3. Biopsy and electromyography must not be done in the same muscle, and muscle enzymes (e.g. creatine phosphokinase) should be assayed either before or after 2 weeks of muscle sampling.
4. It is uncomfortable for the patient.
5. It requires expensive equipment and expertise.

General principles and methods

Technical details of the methods used are outside the scope of this chapter and if required can be found in the specialized literature (Ludin 1980).

Nerve conduction studies

Motor nerve conduction velocity

This is measured by stimulating a motor nerve with a surface (skin) electrode and recording the response from the appropriate muscle with preferably a surface electrode placed over the muscle belly (only occasionally is a concentric needle electrode inserted into the muscle belly required). A supramaximal stimulus is delivered at a minimum of two sites along the peripheral nerve. The onset of the muscle response, the motor action potential (MAP) gives the terminal or distal motor latency (DL). If the distance between the two stimulating sites is measured, the motor nerve conduction velocity (NCV) of that segment of nerve can be calculated from the formula:

Speed (m/s) = distance (cm) / time (ms)

The amplitude, duration and shape of the MAP is examined and all these findings are compared with the contralateral side and other peripheral nerves, and also to the normal values available in standard tables (Ludin 1980) or developed by the user's own laboratory. Figure 1 and Figure 2 show the stimulation and recording sites and traces obtained in an evaluation of the ulnar nerve.

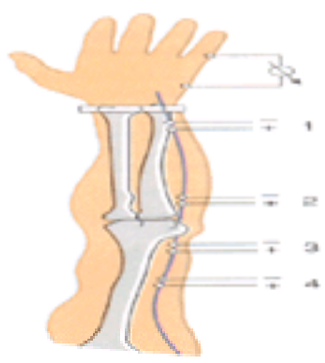

Fig. 1 Stimulation and recording sites of ulnar nerve. The stimulation points of the ulnar nerve are shown by numbers and are at the wrist, below and above the elbow, in the axilla, and at Erb's point in the supraclavicular fossa. Recordings of the muscular response are over the adductor digiti minimi (ADM). The distance between the stimulation and recording sites is measured in centimetres. This examination will demonstrate a localized slowing at a particular part of the ulnar nerve (for example compression by Osborne's band at the elbow) or a more generalized slowing of the ulnar nerve if axonal or wallerian degeneration is present as a result of a more proximal lesion. This is widespread and involves other nerves, it may be part of a peripheral neuropathy.

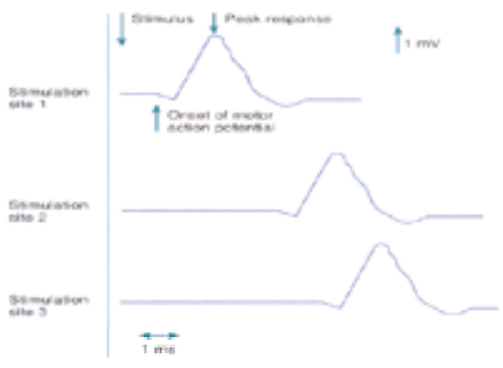

Fig. 2 Recordings of ulnar nerve study. This patient presented with pain, sensory symptoms and slight weakness of the little finger on the right. The referring clinician suspected an ulnar nerve lesion and planned ulnar nerve exploration. MAPs were recorded from the ADM following stimulation of the ulnar nerve at the first three sites previously shown in Fig. 1. The amplitude is calibrated at 1 millivolt (mV) per vertical scale mark, and the latency in 1 millisecond (ms) per horizontal mark. With modern machines cursors are placed at the onset of the responses and the velocities calculated from the formula speed (m/s) equals distance over time. In this example the distal latency recorded in the ADM following stimulation of the ulnar nerve at the wrist was 2.5 ms, and velocity in the forearm and at the elbow was 59.3 m/s and 58.1 m/s respectively. These are normal results for ulnar nerve studies. The findings of normal peripheral ulnar motor nerve conduction studies in the presence of clinical abnormalities suggest a lesion other than in the ulnar nerve itself and indicate performing some of the other procedures descibed further on in this chapter, for example, sensory nerve studies, needle sampling and reflex studies. In this example normal sensory studies but electrical evidence of denervation in the ADM would be highly suggestive of a preganglionic lesion of the T1 nerve root or in the anterior horn cell.

Sensory nerve conduction velocity

This is measured normally by stimulating the sensory nerve and recording the sensory nerve action potential (SNAP) with surface electrodes distally, i.e antidromically, because this is technically easier to do. The responses are of much lower amplitudes (normally measured in microvolts) and more difficult to elicit, and may require averaging techniques. The amplitude, shape and duration are recorded. The velocity is calculated in the normal way, and/or the distal latency standardized for distance. An example of a median nerve sensory study is shown in Fig. 3.

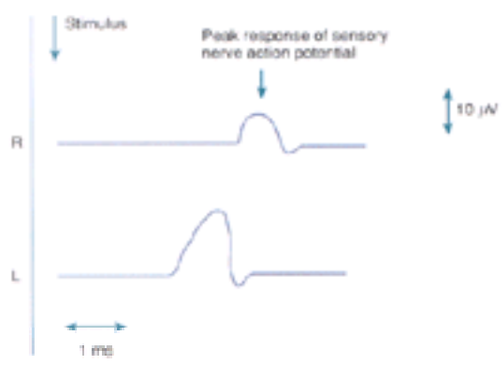

Fig. 3 Sensory nerve conduction study in median nerve. This patient was referred by a clinician who suspected carpal tunnel syndrome which had not responded to conservative measures of therapy. It shows the tracings of right and left median nerves. The recording electrodes are placed over the index finger as shown in Fig. 1 and the median nerve is stimulated at the wrist. The SNAP is measured in microvolts (vertical scale) and DL in milliseconds (horizontal scale). The DL for the right median nerve is delayed and there is a significant difference between the right (symptomatic) and left sides. Although not shown here, in this case the motor conduction studies of the median nerve over the right wrist were abnormal but those performed in the forearm were normal thus confirming the clinician's diagnosis and the patient was referred for surgical decompression.

Mixed nerve potential

The mixed motor and sensory nerves are tested by stimulating a mixed fibre nerve proximally (e.g. in median fossa for median nerve) and recording the amplitude and latency of the compound nerve action potential distally (at the wrist for median nerve).

Reflex latencies

Specific involvement of a nerve root may be indicated from conduction studies of the central segments of peripheral nerves by measuring the latencies of limb reflexes (Malcom 1951). A technique using an electronically triggered patella hammer has made reflex studies easier to perform and more comfortable for the patient. The ankle jerk is elicited in the usual way, the response recorded with a surface electrode over the medial belly of the gastrocnemius. The latency is recorded in milliseconds and compared with the other side. Its absence or a delay of 2 ms or more is found in conditions which clinically affect this reflex. For example it is

particularly useful in patients who present with back pain and sciatica but no evidence of tension signs or abnormal neurology. A delayed ankle jerk latency in the presence of normal conduction of the peripheral segments of sciatic and peroneal nerves is suggestive of an S1 root lesion.

Similarly, the 'H' reflex is mediated through the monosynaptic reflex arc of the first sacral (S1) root and increased latencies in the presence of normal peripheral conduction imply dysfunction of this root (Deschuytere and Rosselle 1973). The posterior tibial nerve is stimulated at below threshold strength in the popliteal fossa and the motor response in the medial head of the gastrocnemius in the calf is recorded with a surface electrode.

When a motor nerve is stimulated impulses travel proximally to the anterior horn cells followed by recurrent conduction back down the nerve where the small muscle response (known as the 'F-wave') can be detected over muscles of the appropriate root distribution. This latency is measured and compared with the other side or height-related normal values. They are sometimes technically difficult to elicit but a delayed F-wave in the presence of normal peripheral conduction implies slowing of proximal motor fibres at plexus or root level.

Neuromuscular function

Repetitive nerve stimulation and recordings of motor action potentials can reveal abnormalities of neuromuscular transmission. In myasthenia gravis a significant decrement occurs in about 60 per cent if one muscle is sampled but this can be improved to 95 per cent if many other muscle groups are included (Oh *et al*. 1982).

Electromyography

Electromyography (EMG) is the recording and study of spontaneous and voluntary electrical activity of muscle. It almost always requires the sampling of muscles with a concentric needle electrode (CNE) and is normally performed in conjunction with the electrical studies described above. The first objective is to distinguish between primary muscle disease and secondary changes as a result of neurogenic disorders. A normal muscle at rest has no detectable electrical activity, apart from the initial insertional activity or if the CNE is placed very close to the motor end plate. If a motor unit loses its nerve supply, sensitivity to acetylcholine increases and spontaneous discharges can be detected by the CNE when amplified and displayed on a cathode ray oscilloscope as small spontaneous fibrillation (SF) potentials (less than 300 microvolts; see Fig. 4). They may be confused with normal motor end plate potentials, an important distinction because spontaneous fibrillation is characteristic of denervation. Positive sharp waves are another electrical sign of denervation. The interpretation of these changes requires considerable skill and experience and is largely a matter of personal judgement, despite the recent improvements in developing objective measurements of the motor unit.

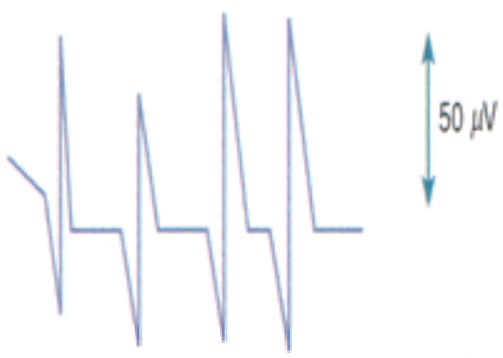

Fig. 4 Electrical signs of spontaneous activity – spontaneous fibrillation. Small units (usually less than 100 μV) seen in muscle at rest often coming in bursts. Several depths and areas of a muscle need to be sampled. When found they are characteristic of denervation.

When the motor unit fires the action potentials which are conducted along the muscle fibre cell membranes are much larger (Fig. 5). If there is loss of motor units (e.g. primary myopathy), or muscle fibres cannot be activated (e.g. myasthenia gravis) the recorded potentials are smaller. In axonal degeneration, sprouting of surviving axons in an attempt to reinnervate nearby denervated muscle fibres results in a larger motor unit which is detected electrically by the appearance of large amplitude motor action potentials (Fig. 5). When the force of contraction is increased more units are activated, and these recruitment patterns vary with different conditions. The analysis of interference pattern is normally subjective and computer based methods are not generally available.

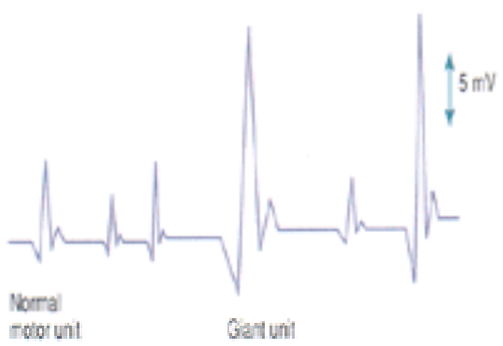

Fig. 5 Electrical signs of voluntary motor units. The amplitude of a normal action potential of a motor unit on voluntary contraction varies from 1 to 8 mV depending on the muscle. Giant motor units exceed this and are a sign of attempted reinnervation.

Various other features are recognized and include the complex repetitive discharges seen in polymyositis, fasciculation potentials characteristic of denervation, and the myotonic discharges of myotonia. Single fibre techniques (Stalberg and Trontelj 1979) can be useful in detailed examination of the motor unit, particularly in the diagnosis of motor end plate disorders and reinnervation. This was initially a very time consuming refined method, but has been simplified to some extent by modern methods. The 'blanket technique' described by Payan (1978) bridges the gap between single-fibre and conventional electromyography.

Sensory evoked potentials

Very small potentials, evoked by repetitive percutaneous stimulation of peripheral nerves can be detected with averaging techniques by surface electrodes over the skin of spinal cord or scalp. These are known as somatosensory evoked potentials (SEPs) and have been used extensively in the investigation of patients with multiple sclerosis, particularly in suspected cases and in revealing clinically silent lesions (Jones 1982). The SEP has also been used in investigations of peripheral neuropathies, and is particularly well suited to the investigation of proximal lesions of the brachial plexus and spinal nerve roots which are so inaccessible to normal recording methods (Jones *et al*. 1981). The dermatomal somatosensory evoked potential (DSEP) is an adaptation of this technique and found a place in the assessment of lumbar spinal disease, especially compressive disc and degenerative lesions (Katifi and Sedgwick 1987).

Clinical application

How can electrical methods assist the clinician in rheumatological practice? The answer to this depends very much on the nature, site and chronicity of the lesion, the clinical information available, and the knowledge of other features which may affect the electrical findings, for example the presence of neurological anomalies or dual pathology. In some cases this investigation can be crucial in decisions regarding surgery, but in others the diagnostic and prognostic yield may be minimal.

Three main pathological processes result in the electrical abnormalities seen in conduction studies:

- demyelination
- axonal degeneration
- metabolic effects

It is customary to use the term demyelination for neuropathies with a primary disorder of the myelin sheath. Prolonged distal latencies and conduction velocities are the characteristic electrical findings, the best known examples being the hereditary neuropathies. The degree of slowing parallels the degree of demyelination, and conduction velocities are usually reduced by at least 30 per cent. Segmental demyelination is found localized to one segment of a nerve in the entrapment neuropathies. More prolonged compression of a peripheral nerve results in further damage to the axons distal to the lesion causing wallerian degeneration (Lewin 1993). Normal or slightly reduced conduction velocities in the presence of reduced amplitudes or absent sensory, motor and/or mixed action potentials are characteristic of axonal degeneration. This is seen typically in amyloidosis, and alcohol and drug abuse. Motor conduction velocities of less than 40 m/s are unusual (McLeod *et al*. 1973). In rheumatological practice axonal degeneration is typical of the vasculitides, for example mononeuritis multiplex seen in polyarteritis nodosa and rheumatoid arthritis. Certain conditions result in a mixed pattern of electrical findings, for example in diabetes mellitus and Guillain–Barré syndrome. The rapid improvement in conduction times after renal transplants is explained by certain metabolic effects.

The degree and site of these changes (Table 2) are an indication of the presence of axonal degeneration or widespread or segmental demyelination and this helps to narrow down the differential diagnosis. Electrical studies help distinguish the relative importance of the coexistence of these processes, for example localized entrapment neuropathies in the presence of generalized neuropathies of rheumatoid arthritis or diabetes. Timing of the investigation may be important, and serial studies may be helpful. For example, because the amplitude of the motor action potential reflects the number of surviving axons, the response in the thenar muscles on stimulating the median nerve at the wrist is a useful prognostic indicator in the early stages of a polyradiculitis (Miller *et al*. 1988). Significant demyelination in the childhood and hereditary neuropathies can be a useful predictor of response to steroid treatment.

Electrical features	Axonal degeneration	Segmental demyelination
Amplitude	Markedly reduced	Normal/slight reduction
Distal latency	Normal/slight delay	Marked delay
Velocity	Normal/slight delay	Marked delay
Examples	Vasculitis	Diabetes

Table 2 Summary of electrical findings of conduction studies in neuropathy

Common clinical conditions

Acute nerve injury

This subject is well covered in surgical texts and the great deal that has been learnt from studying traumatic nerve lesions can be applied to other lesions of the peripheral nerve. The basic principles of damage are taught early in medical school and summarized in Table 3.

Type of injury	Pathophysiology	Recovery
Neurapraxia (contusion)	No axonal degeneration	Days to weeks
Axonotmesis (trauma)	Wallerian degeneration Endoneural tubes survive	Variable Months to years
Neurotmesis (division of nerve)	Complete degeneration of nerve	None without surgery

Table 3 Classification of nerve injury (after Seddon 1972)

A surgical opinion should be sought early in these cases because the timing of surgery can be crucial to recovery. Early referral for rehabilitation may be necessary and the planning of this can be helped by the prognostic information obtained from electrical methods. Wallerian degeneration requires nerve regrowth and if present the timescale of recovery is inevitably longer and dependent on the length of nerve and degree of damage.

Acute compression neuropathies

Sudden but prolonged compression of a peripheral nerve leads to mild focal demyelination affecting large fibres preferentially, and nerve conduction studies reveal motor and sensory conduction block at the damaged site, but normal conduction distally because the nerve is electrically still intact (Ochoa *et al*. 1973). This is followed by gradual electrical and clinical recovery accompanied by wallerian degeneration which may be detected by evidence of electromyography features of denervation. The clinical syndromes most often seen in rheumatological practice are shown in Table 4.

Clinical sign	Nerve	Condition
Wrist drop	Radial nerve palsy	Saturday night palsy Tourniquet palsy
Weak hand	Ulnar nerve	Tourniquet palsy
Foot drop	Common peroneal nerve	Crossed leg palsy Tight plaster cast Tourniquet palsy
	Sciatic nerve	Total hip replacement Haematoma in haemophilia or poor anticoagulation control

Table 4 Acute nerve entrapment syndromes

The so-called 'tourniquet palsy' may in fact be the result of prolonged pressure because of poor positioning of a limb during prolonged anaesthesia. Similar clinical and electrical features are sometimes seen following the reduction of difficult fractures and the removal of tight plaster casts. Bonney (1986) has recently reviewed iatrogenic nerve damage, all of which may be seen in rheumatology clinics and includes traction of peripheral and cervical nerve roots during anaesthesia, damage to the superficial radial nerve following surgery for De Quervain's syndrome, digital nerve damage during surgery for Dupytren's contracture, and sciatic nerve damage during total hip replacement. The changes detected electrically depend critically on when they are performed after injury. Spontaneous fibrillation so characteristic of denervation does not appear for at least ten days. The appearance of this or other electrical signs of axonal degeneration indicate a slow recovery (Bolton and McFarlane 1978). Table 5 summarizes these changes.

Time after injury	Sensory conduction	Motor conduction
Immediate	Absent across injury	None proximal to injury Normal distal response
1–10 days	Progressive decline in SNAP and CNAP	Progressive decline in MAP
	Normal NCV	Normal NCV
10–21 days		Spontaneous fibrillation may be detected on EMG

Table 5 Electrical changes after injury

Chronic or subacute compressive (entrapment) neuropathies

Mononeuropathies developing after prolonged mechanical damage to a nerve at a site of anatomical constriction are common, the most familiar of which is the median nerve in the carpal tunnel. Following localized demyelination, segmental demyelination occurs and progresses to wallerian degeneration. Varying degrees of slowing of nerve conduction velocities are found and in early or mild cases sensory nerves studies are more sensitive (Buchtal and Rosenfalk 1971). Needle sampling may reveal denervation in the relevant muscles in more severe cases. Dawson *et al*. (1983) have described entrapment neuropathies in detail, but the common lesions encountered in rheumatological practice are summarized in Table 6.

Nerve	Site of entrapment
Median	Carpal tunnel at wrist
Ulnar	Palm, wrist or elbow (cubital tunnel)
Radial	Spiral groove in upper arm
Cervical nerve root/plexus	Cervicothoracic outlet
Common peroneal	Head of fibula
Posterior tibial	Tarsal tunnel
Lumbar sacral roots	Lumbosacral spinal canal or foramina

Table 6 Common entrapment neuropathies

Not only can electrical studies determine the exact site and severity of a lesion in these conditions, they may also help to assess prognosis and response to treatment, depending on the nature and site of lesion. However, correlation of clinical and electrical findings are not always straightforward as shown by the lack of uniformity in reported studies of electrical assessment and monitoring of recovery following injury and surgical decompression. These are best discussed on an individual basis later. For diagnosis it is important to demonstrate that delay in conduction distal to the site of compression is disproportionate to any mild proximal slowing (Simpson 1956). Electrodiagnostic demonstration of an isolated motor nerve root lesion can be achieved by finding evidence of denervation in a group of muscles corresponding to the distribution of the spinal segment rather than the peripheral nerve. A preganglionic root lesion will not affect the distal sensory action potential whereas a postganglionic lesion may do so because the integrity of the peripheral nerve fibre may be affected. This may be vital information in differentiating between a lesion of the anterior horn cell (e.g. motor neurone disease) and a localized postganglionic lesion (e.g. in brachial plexus).

Median nerve

Mild cases of carpal tunnel syndrome usually respond initially at least to conservative measures (Le Quesne 1978). Electrodiagnosis is generally indicated if the diagnosis is not secure or the lesion appears progressive as in the following circumstances:

1. If motor neurone disease is suspected because thenar muscle wasting is marked or progressive and sensory symptoms absent or minimal.
2. Osteoarthritis of the hand, especially in the carpometacarpal joint of the thumb, or the presence of reflex sympathetic dystrophy can make a clinical diagnosis uncertain.
3. Dual pathology is suspected, that is both at the cervical spine and at the wrist, the so-called double crush syndrome (Upton and McComus 1982). This information may affect treatment.
4. If surgical exploration and/or decompression is considered.
5. Recurrent symptoms following surgery for median nerve decompression may be because of inadequate surgery which can be better demonstrated electrically in comparison with a preoperative result.

The minimal diagnostic criterion is a prolonged median sensory conduction velocity with a normal ulnar sensory velocity. The distal motor latency to the abductor pollucis brevis is normally also determined. Using these criteria, Boniface *et al*. (1994) reported that nerve conduction studies excluded the clinical diagnosis of carpal tunnel syndrome in 36 per cent, and most of these patients (72 per cent) responded to conservative treatment at follow-up. In this study, it was clear that decisions whether to perform decompressive surgery were influenced greatly by positive electrical findings, and the authors highlighted the importance of the investigation for this clinical condition as part of good clinical practice as well as health service costs.

Postoperative electrical studies are not always easy to interpret. Goodman and Gilliat (1961) reported normalization of conduction velocities within a few months but Melvin *et al*. (1968) reported persistently abnormal sensory latencies in 60 per cent of patients one year after decompression of the median nerve at the wrist. Surgeons still report patients with typical carpal tunnel symptoms who respond to decompressive surgery in the presence of normal electrical findings. Refinements of electrodiagnosis reported by Mills (1985) in which the median nerve is stimulated in the palm and recorded at the wrist should obtain correct results in 95 per cent of cases.

Ulnar nerve

The common indications for ulnar nerve studies are:

1. the degree and exact site of damage at the elbow;
2. whether the lesion is in the ulnar nerve or the 1st thoracic root;
3. whether an ulnar nerve lesion of the hand is proximal or distal to the bifurcation into deep muscle and superficial sensory branches.

Conduction studies of ulnar nerve lesions at the elbow correlate well with clinical severity and localization is correct in 95 per cent of cases (Payan 1969). Mild symptoms and no objective signs can usually be best treated conservatively, but surgery should be considered in patients with moderate symptoms and neurological signs which progress, and electrical tests are often the best way of assessing this. Decompression of the ulnar nerve without transposition is often all that is needed, especially in patients with a short history, associated with mild weakness only, and with mild abnormalities of sensory nerve action potentials (Miller and Hummel 1980). Transposition of the ulnar nerve is still being performed purely on clinical grounds. It should be reserved for patients with objective evidence of ulnar nerve damage. Repair or mobilization of peripheral nerves can produce causalgia and become a long-term treatment problem (Withrington and Wynn Parry 1984). Occasionally the nerve can be trapped in Guyon's canal at the wrist.

Radial nerve

This nerve can be injured in the axilla (e.g. pressure from a crutch), in the spiral groove (Saturday night palsy) or by fracture of the humerus or radius, and thorough clinical examination is sufficient usually for initial diagnosis and monitoring recovery. As with the ulnar nerve it may occur postoperatively from faulty positioning or prolonged tourniquet pressure. If there is any dispute about the cause or timing of such a lesion, electrodiagnosis may be required for medicolegal reasons. Surgery is rarely indicated.

Cervicothoracic nerve roots and brachial plexus

Cervical disc prolapse, cervical ribs and bands in the thoracic outlet syndrome, neuralgic amyotrophy, tumours and irradiation are all relatively uncommon conditions and electrical studies may contribute to diagnosis if there is clinical progression and surgery is considered. Unfortunately the use of F-waves and somatosensory evoked potentials have not helped as much as was hoped originally in the diagnosis of lesions of the proximal segments of these nerves. Electrical studies are still often needed to exclude lesions of these nerves at more peripheral sites and in patients with unusual presentations or poor response to treatment, because the demonstration of dual pathology may alter management. Common clinical situations are carpal tunnel syndrome and cervical nerve root involvement from cervical spine degeneration, rheumatoid involvement of both cervical spine (often silent) and hand or elbow, and multiple nerve entrapment syndromes. The diagnosis and planning of treatment for traction lesions of the brachial plexus has been shown to be helped greatly by expert electrical examination in special centres (Jones *et al*. 1981; Wynn Parry 1988).

Sciatic and common peroneal nerves

The sciatic nerve may be injured following traction during hip surgery. The common peroneal nerve is vulnerable at the level of the fibula head as the nerve enters the peroneus muscle. Electrical studies are indicated when:

1. ecovery is poor;
2. decompressive surgery is considered;
3. here is difficulty distinguishing between an isolated palsy or a lesion of the 5th lumbar nerve root or both.

If the lesion is complete and recovery is not apparent or appears very slow, decisions about the amount of physiotherapy actually required, planning of rehabilitation and type of leg appliances all require prognostic information early which can often only be obtained by electromyography. In distinguishing between an L5 root lesion and peroneal nerve palsy causing a foot drop, it is worth noting that the weakness of foot eversion which is found in peroneal nerve palsies is not always easy to demonstrate. The posterior tibialis is one of the few muscles innervated by the L5 root and not via the peroneal nerve and therefore an important muscle to examine in distinguishing these two lesions. It is a difficult muscle to examine clinically but ideal for needle sampling.

Posterior tibial nerve

The tarsal tunnel syndrome is not common and the electrophysiological findings reported in the limited series are generally disappointing (Kaeser 1970). It is a rather painful area to examine electrically but denervation found on needle sampling proves reliable and treatment can be rewarding.

Back pain and sciatica

Electrical studies do not have a place in the routine work up of acute or chronic mechanical back pain with or without sciatica. Over 90 per cent of prolapsed disc disorders are diagnosed successfully after careful clinical examination followed by radiological studies. These methods have in the past been less successful in correctly diagnosing and localizing chronic nerve root involvement from bony entrapment because water-soluble dyes do not extend far enough laterally into the lateral recesses and exit foramina where impingement of the nerve roots in an often narrowed canal occurs (McNab 1977). Development of electrodiagnostic methods was invaluable in these patients, and successful localization of segmental nerve root damage in 70 per cent or more can be achieved (Young *et al*. 1983). Modern magnetic resonance and computerized scanning methods of the lumbosacral spine have improved greatly the visualization of the spinal canal and its recesses, and electrical investigation is now less often needed. Electrical methods can still be useful in the following circumstances:

1. the problem of failed surgery (Young and Wynn Parry 1988);
2. clinical and radiological signs which do not correspond;
3. in isolating single nerve root involvement by epidural fibrosis in patients with extensive arachnoiditis (Leyshon *et al*. 1981).

Electrical changes remain for more than a year postoperatively both in the peripheral muscles (Young *et al*. 1983) and in the paraspinal muscles (See and Kraft 1975) and must therefore be interpreted carefully.

Other less commonly affected nerves

Anterior and posterior interosseus nerves in forearm

Lesions in these nerves can be confirmed with motor conduction studies and by finding abnormalities in the appropriate muscles on needle sampling.

Facial nerve

Conduction studies are difficult and needle sampling uncomfortable and a problem to interpret. Apart from the method, prognostic information from electromyography is limited. Needle sampling can determine whether loss of motor units is complete or not.

Peripheral neuropathies

Motor, sensory and mixed conduction studies in both arms and legs are essential if a generalized neuropathy is suspected. Sensory investigations are more sensitive than motor studies, and particularly the sural sensory and peroneal mixed action potentials in sensory neuropathies. The differential diagnostic possibilities are narrowed by a careful appraisal of the clinical features, the degree of slowing, and amplitude response, and which sensory and/or motor nerves are affected. Differentiation between the numerous possible causes of peripheral neuropathies on the basis of electrical findings alone is possible in only a few cases. The common causes of peripheral neuropathy such as diabetes, drug and alcohol effects, vitamin deficiencies, metabolic and autoimmune rheumatic disorders, malignancy, and Guillain–Barré syndrome can usually be diagnosed by means of detailed and full clinical, radiological, laboratory and electrical investigations.

Two varieties of peripheral neuropathy are well recognised features of rheumatoid disease (Pallis and Scott 1965). Low amplitudes and slowing of sensory conduction suggest segmental demyelination found in the more common mild distal sensory neuropathy, which has a good prognosis. Widespread denervation in the presence of

relatively normal conduction suggests axonal degeneration found in the more severe sensorimotor neuropathy. This may start as an isolated neuropathy and progress as part of a vasculitic process as in mononeuritis multiplex. Electrical studies are clearly valuable in distinguishing the two and demonstrating the extent of involvement, which may not be apparent clinically because of joint deformity or widespread synovitis.

It is not unusual for normal electrical values to be recorded in patients who present with features of a peripheral neuropathy, and these cases can be explained on the basis of very early mild disease, involvement of small diameter fibres only, central lesions of the nerve root, or non-organic disorders (Payan 1985). Most series record that as many as 50 per cent of cases remain undiagnosed, but in a very detailed study Dyck *et al*. (1981) reported that 42 per cent of patients proved to have an inherited disorder when careful family studies were performed, 21 per cent had an inflammatory demyelinating polyradiculopathy and 13 per cent had other acquired neuropathies.

Myopathies

The electrophysiological diagnosis of many myopathies is based on needle sampling. Conduction studies are required to exclude neuropathic lesions and are usually normal. Electrodiagnosis is most rewarding in the acute phases of the inflammatory myopathies. The classic changes in acute polymyositis are those of myopathic degeneration and acute denervation. Fibrillation potentials have been reported in 74 per cent of polymyositis and 33 per cent of dermatomyositis patients (Bohan *et al*. 1977), but are not an essential prerequisite for the diagnosis of an inflammatory myopathy. Other changes include myopathic motor potentials (low amplitude short duration motor unit potentials) and polyphasic potentials. These changes allow successful diagnosis in about two-thirds of all cases of myopathy, including the other inflammatory arthropathies that can be complicated by myopathy, such as rheumatoid arthritis and systemic lupus erythematosus. The diagnosis depends on the typical clinical features, an elevated creatine phosphokinase (CPK), electromyography abnormalities and histological changes seen on muscle biopsy. In practice, treatment is usually recommended if two of the four features are present (Bohan and Peter 1975). Prognosis has improved with the earlier and judicious use of steroids and immunosuppressive agents, and electromyography can be important in this respect although MRI is being used as a less invasive alternative, especially for children.

The most common drug-induced myopathy is caused by steroid treatment, which is at least partially dose dependent, often subclinical and frequently electromyography and CPK level are normal. Sometimes it is very difficult to distinguish between the changes of polymyositis and the myopathic changes seen in chronic steroid treatment (particularly the fluoridized corticosteroids) which many of these patients are in fact taking for their condition. However, florid spontaneous activity makes an inflammatory aetiology a high probability. A muscle biopsy is usually the only way to make the distinction safely. The other causes of myopathy, for example metabolic myopathies and the muscular dystrophies, require other more detailed investigations in addition to electromyography for a definitive diagnosis (Hudgson 1983). The assessment of treatment of these myopathies is mainly a clinical skill and, although occasionally helpful in some instances, electrodiagnosis has not found a place in the routine management of these cases.

Multifocal pathology

This may be suspected clinically for example in mononeuritis multiplex, but more often is revealed by the appropriate electrical tests. Certain conditions characterized by mild generalized neuropathic changes which are often subclinical, are also prone to localized entrapment neuropathies because of mechanical pressure as in diabetes, hypothyroidism, chronic alcoholism, inflammatory arthritis, and familial pressure palsies. Change in multiple cervical and/or root pathology although mild is not uncommon, particularly in the older patient and may be found during investigation for other conditions. In a series of patients with carpal tunnel syndrome reported by Murray-Leslie and Wright (1976) , 33 per cent also had humeral epicondylitis and cervical spine dimensions were significantly smaller in this group. A full clinical summary is vital to explain unusual electrical findings resulting from dual pathology.

Pitfalls in electrodiagnosis

The normal ranges for motor nerve conduction were first established by Hermann von Helmolz in the summer months of the early 1850s. Subsequent studies by him in the winter demonstrated the significant effect of temperature on nerve conduction (Helmolz and Baxt 1867) and present-day electromyographers are well aware of the necessity to provide standard temperatures (preferably warm ones) for this examination. In some circumstances cold patients need to be warmed up to obtain real results, for example in peripheral neuropathy. Another factor which can influence electrical readings is age, with maximal conduction velocities seen in the teens. Full-term neonates have half the normal adult ranges, and there is a reduction of 0.5 to 1.8 m/s every ten years after the age of 20. Amplitude decay increases with age. Anomalies of neurological arrangements occasionally make the life of an electromyographer difficult, the most common of which is the Martin–Gruber anastomosis between ulnar and median nerves, which probably occurs more frequently than the 6 per cent quoted by Hopf and Hense (1974). Conventional electrical tests will be essentially normal in patients with upper motor neurone lesions or with non-organic signs. In the latter, when the hysteria-conversion reaction or malingering posture makes clinical examination so difficult, electrical testing can be very reassuring, but occasionally reveals a genuine underlying pathological lesion.

5.1.1 Epidemiology and the rheumatic diseases

Alan J. Silman

Introduction

Epidemiology can be defined broadly as the study of the occurrence of diseases in human populations. Occurrence can be considered in terms of the demographic, genetic, and environmental influences and thus, in addition to 'counting', the epidemiological investigation of a disorder aims to uncover risk factors in disease causation. Additionally, and increasingly, epidemiological method is being applied to the study of the natural history of disease and to those factors that influence prognosis.

The term clinical epidemiology refers to a different area of endeavour and describes the application of epidemiology to clinical practice. Areas in this regard of specific relevance to rheumatology are:

1. the derivation of criteria for diagnostic or classification purposes;
2. the evaluation of clinical data in terms of their accuracy (validity) and reliability (reproducibility);
3. the design, conduct, and analysis of intervention studies (clinical trials).

In other areas of medicine (for example, cardiovascular disease), the application of epidemiology to the evaluation of strategies for primary prevention and screening is of much interest. Such activities are, unfortunately, of little relevance in rheumatology, given current knowledge, and will not be considered further. This review will concentrate on the application of epidemiology to understanding the occurrence and causation of disease. Examples are taken, where appropriate, from some of the principal disorders to illustrate the particular points to be made. Detailed epidemiological information of relevance to specific disorders will also be found in the appropriate chapters in this volume.

Criteria for diagnosis

There is no single diagnostic test for most of the major rheumatological disorders. Further, there is considerable overlap, both clinically and pathologically, between the various conditions. As a consequence, sets of criteria covering the main clinical and other facets of each disorder have been formulated with the aim of separating 'cases' from 'non-cases'.

Purpose of criteria

Criteria are useful in so far as they allow like to be compared with like, such that results of clinical and other studies may be compared directly. The American College of Rheumatology has taken an important lead in formulating criteria for most of the principal disorders. It prefers the term 'classification' to 'diagnostic' when applied to the criteria generated for specific disorders, to take account of the atypical case.

Criteria are developed for a number of purposes including population studies of occurrence, aetiological studies, and clinical trials (Fries *et al*. 1994). In trials, there is a need for considerable stringency, i.e. only patients with clearly established disease are eligible for study to prevent dilution of an effect. In that case, the aim of the criteria is maximal specificity (no false positives). By contrast, if the aim is the investigation of familial clustering one would not wish to miss even mild disease in the first-degree relatives of affected probands. Criteria in this situation should opt for maximal sensitivity (few false negatives). In practice, published criteria take no account of the different applications and, as a consequence, they are not always appropriate to the desired task.

Derivation of criteria

Historically, there are three approaches to deriving criteria (Table 1). These are (i) expert consensus, (ii) quasianalytical, and (iii) analytical. The first approach results from the deliberations of a group of 'experts' who reach an agreement between themselves as to what constitutes a case. The second starts as a consensus, but the criteria developed are thereafter tested in patients with and without the disease (determined in an independent manner), and then subjected to subsequent refinement. The third approach is to collect data on the major, potentially diagnostic features and, using a number of statistical approaches (Bloch *et al*. 1990), derive the most discriminatory criteria. The main advantages and disadvantages of these approaches are summarized in Table 1. Diseases for which criteria have been published are listed in Table 2, with their methods of derivation.

Approach	Advantages	Disadvantages
Consensus	Criteria based on clinical good sense and likely to be acceptable	May not maximize discrimination between cases and non-cases
Quasi-analytical	As above but discriminatory power stated	Assumes that appropriate individual items were included in criteria sets; may not maximize discrimination
Analytical	Maximal discrimination between cases and non-cases; excludes bias from preconceived notions	May not reflect clinical sense and thus have difficulty in acceptance

Table 1 Approaches to deriving criteria for rheumatic diseases

Disease	Reference	Approach	Common name
Rheumatoid arthritis	Kellgren (1962)	Consensus	The 'Rome' criteria
	Bennett and Wood (1968)	Consensus	The 'New York' criteria
	Arnett et al. (1988)	Analytical	Revised ARA*
Ankylosing spondylitis	Bennett and Wood (1968)	Consensus	'New York' revision of 'Rome' criteria
	van der Linden et al. (1984)	Quasi-analytical	'Revised New York'
Systemic lupus erythematosus	Cohen et al. (1971)	Consensus	'Preliminary ARA'
	Tan (1982)	Quasi-analytical	'Revised ARA'
Raynaud's syndrome	Wilkins et al. (1982)	Quasi-analytical	
Systemic sclerosis	Masi et al. (1980)	Quasi-analytical	Revised ARA
Osteoarthritis			
Knee	Altman et al. (1986)	Analytical	ARA
Hand	Altman et al. (1990)	Analytical	ARA
Vasculitis (various types)	Hunder et al. (1990)	Analytical	ARA
Fibromyalgia	Wolfe et al. (1990)	Analytical	ARA

*ARA, American Rheumatism Association

Table 2 Publications of criteria for rheumatic diseases

The constitution both of cases and the comparison group used for deriving criteria is of fundamental importance for their interpretation. This is best illustrated by example. The 1987 American Rheumatology Association (**ARA**) revised criteria for rheumatoid arthritis (Arnett *et al*. 1988) allow the following subset of signs to satisfy the criteria: either positive rheumatoid factor test or typical radiological erosion, plus swelling in three or more groups of appropriate joints of which at least one should be either a wrist or metacarpophalangeal joint. Such a subset might not be specific enough for routine clinical practice. The sensitivity of the criteria as a whole were, however, very high in the case series studied because they were all current attenders at a specialist hospital facility and had had disease for a mean of 7.7 years. The application of the same criteria to patients attending with early disease to a non-specialist could give a much reduced sensitivity (Silman and Symmons 1995).

The preliminary criteria for the diagnosis of scleroderma (Masi *et al* 1980) show an extremely high specificity for the major criterion of proximal skin tightness against the comparison group chosen for study from rheumatological practice. Their performance against patients without scleroderma attending a dermatology practice with swollen or tight skin would be substantially different. The purpose of emphasizing this point is not to devalue the criteria themselves, but to argue for caution in their use in circumstances different to those from which they were derived.

Occurrence of disease

The occurrence of diseases is expressed as the number of cases arising in the population 'at risk'. The latter is multiplied by an appropriate power of 10 to yield a sensible number. Thus, it might be appropriate to express the annual incidence of new episodes of back pain as a percentage, whereas the incidence of scleroderma is more conveniently expressed per million population. Frequently there are reports of 'epidemiological' studies that present the relative proportions of diagnoses seen, for example, in a clinical practice, with the interpretation that the proportions represent the relative occurrence of those diseases in the catchment population of the clinic. Such data relying totally on numerator ascertainment, without consideration of the population base, are subject to considerable error. Thus it is difficult to interpret reports from Chinese populations that systemic lupus erythematosus is more frequent than rheumatoid arthritis, suggesting that either the lupus is more frequent than in the West or that the arthritis is less frequent. There may also be selective differences in attendance at hospital between these two disorders.

Measures of occurrence

A number of measures of occurrence are used in the epidemiology of the rheumatic diseases and these are listed in Table 3. Broadly, prevalence, which describes the proportion of existing cases in a population, is less useful than incidence, which describes the rate of occurrence of new cases. Prevalence is dependent on duration, so the longer a disease persists the greater the likelihood that it will be included in a prevalence estimate.

Measure	Description	Appropriate example
Incidence	Rate of occurrence of new cases arising in population conveniently expressed per unit time interval (e.g. per year)	Incidence of rheumatoid arthritis is 0.3 new cases/1000/year
Episode incidence	Rate of occurrence of new episodes of a disease arising in population; usefully applied to conditions where previous episodes may only be weakly related	New episode incidence of painful shoulder is 10/1000/year
Cumulative incidence	Similar to incidence but time interval expressed as fixed period	Cumulative incidence of juvenile chronic arthritis by age 16 is 1/1000
(Point) prevalence	Describes the occurrence of current cases, i.e. those with evidence of disease; implication is based on a particular point in time (notional prevalence day)	Point prevalence of radiographic osteoarthritis of the hip is 1%/1000 (on 1 January 1991)
Period prevalence	Similar to episode incidence in so far as it expresses the rate of individuals displaying evidence of disease in a fixed period (e.g. 1 year) but they may not be continually affected during this period; unlike episode incidence does not require development of new episode during that period	One-year period prevalence of low back pain is 50/1000
Cumulative prevalence	Summation of disease occurrence during fixed period; similar to cumulative incidence but would exclude those who had died from disease prior to investigation	Similar to cumulative incidence

Table 3 Measures of disease occurrence

There are considerable problems in assessing prevalence in rheumatic diseases, because they frequently go into remission without any residual clinical sign of disease. Thus a population prevalence survey can only detect either those with currently active disease (e.g. inflamed joints) or those with evidence of past disease (e.g. joint deformity). Those individuals whose disease resolved without damage will remain undetected. To overcome this investigators may try to assess the existence of past disease, for example by taking a detailed history or reviewing available medical records. This is acceptable, but if such an approach is comprehensive, then it is not point prevalence that is being ascertained (see Table 3) but cumulative prevalence (MacGregor and Silman 1992). Further, the problem with such an approach is that cases who died before being ascertained would obviously be missed. Thus such a cumulative prevalence would underestimate cumulative incidence.

Approaches to estimating disease occurrence in rheumatology

The approach to be used (Table 4) depends both on the frequency of the disease (Safavi *et al*. 1990) and its severity. Population surveys are prohibitively expensive for rare diseases, but necessary for common ones. Thus it would not be appropriate to ascertain back pain by review of hospital attenders as many cases will not seek medical attention. Conversely it would be reasonable to assume that the majority of cases with scleroderma will seek medical care and thus a population survey is not necessary. The complacency of such an approach, however, was displayed by a population survey from South Carolina suggesting that there is a considerable,

unrecognized prevalence in the community of previously unrecognized scleroderma and 'scleroderma spectrum' disorders (Maricq *et al*. 1989) and that expensive population surveys may be necessary.

Measure	Approach
Incidence	(i) Retrospective review of diagnosed cases from medical facilities
	(ii) Prospective notification or registration scheme
	(iii) Measurement of cases occuring in interval between two population surveys
Episode incidence	(i) Retrospective population survey*
	(ii) Prospective notification or registration scheme
Cumulative incidence	(i) Retrospective review of diagnosed cases
	(ii) Retrospective population survey*
Point prevalence	(i) Cross-sectional population survey*
	(ii) Estimate based on current diagnosed clinic attenders
Period prevalence	(i) Retrospective* population survey
	(ii) Prospective population survey

*A retrospective population is based on recall for past events whereas a cross-sectional survey aims to investigate current disease status. In practice, both methods can be adopted concurrently, e.g. 'Have you ever had or do you now have painful joints?'

Table 4 Approaches to measuring disease occurrence

It is virtually impossible to derive incidence data from cross-sectional population surveys, as a single survey will miss cases that went into remission or died before the survey. Lawrence (1977) in his classical work in Leigh and Wensleydale in the North of England, undertook a second survey five years after the first and calculated the rate of development of new cases from those that developed the disease in the interval. Again, this approach would miss those that developed the disease and either died or went into remission between the two surveys.

The only realistic options for assessing incidence (see Table 4) are, first, some form of prospective notification system whereby newly developing cases are continuously and prospectively notified to a central source in a similar fashion to cancer registration. Such a scheme is logistically difficult and expensive, although a recent example of its use in rheumatoid arthritis is encouraging (Symmons *et al*. 1994). Alternatively, all relevant clinical facilities used by the target population may be reviewed to determine the rate of newly diagnosed cases. The disadvantages of this second approach are, first, its retrospective element relying on sufficient information being recorded in the case records to allow a subsequent diagnostic opinion. Second, such an approach requires an excellent information system with few mistakes in diagnostic coding, entry, or retrieval. Such systems are infrequent, with the Rochester Epidemiology Program being a notable exception.

Rochester Epidemiology Program

The Mayo Clinic in Rochester, Minnesota, together with the Olmsted Medical Practice, provides apparently the only source of medical care to the local population, which was approximately 60 000 in 1980. The record system at the Mayo Clinic is almost unique in being able to extract diagnostic data from the records over at least the past 50 years and as a consequence any diagnosis made on a resident of the County can be retrieved. These data have been used to generate estimates of the incidence of many rheumatic diseases such as rheumatoid arthritis (Linos *et al*. 1980), systemic lupus erythematosus (Michet *et al*. 1985), ankylosing spondylitis (Carbone *et al*. 1992) and temporal arteritis (Chuang *et al*. 1982). There are problems, however, in interpreting the results. First, the population is really too small for reliably assessing the incidence of some rare disease. Thus there were no male cases of scleroderma recorded in their incidence series (Michet *et al*. 1985), although males with this disorder do exist. Second, the Olmsted population is unusual both in having heavy over-representation of the professional middle classes and also (compared with the rest of the United States) having a relative excess of those of Scandinavian origin.

In most other parts of the world, it is impossible to rely on one clinical facility to ascertain all cases and an obvious alternative approach is to review as many different sources of data as possible. The greater the degree of overlap between the sources, the greater the confidence that ascertainment is complete. Such an approach has been applied to both scleroderma (Silman *et al*. 1988) and systemic lupus erythematosus (Jonsson *et al*. 1990), both studies using many different sources of data. Statistical methods are available which use the amount of overlap to assess the likely range of the true occurrence (McCarty *et al*. 1992).

Overview of the occurrence of the major rheumatic diseases

Table 5 summarizes the typical available estimates of the occurrence of the rheumatic disorders for Western populations. For some diseases, such as rheumatoid arthritis, there have been many studies and the aim has been to produce a 'ball park' figure.

Disease	Annual incidence per 1000	Point prevalence per 1000
Rheumatoid arthritis	0.5	8.0
Psoriatic arthritis	Not available	0.2
Systemic lupus erythematosus	0.05	0.4
Systemic sclerosis	0.01	0.1
Ankylosing spondylitis	0.07	2.0
Knee osteoarthritis	Not applicable	100*
Juvenile chronic arthritis†	0.1	0.7
Gout	1.0	Not applicable

Rates are based on consensus of most recently available data.
*Rates variable and age dependent; this prevalence in age-range 35–74 years.
†Rates refer to children under 15 years of age.

Table 5 Occurrence of major rheumatic diseases: Western populations aged 15+ years

There are a number of points of note. First, in terms of incidence, the inflammatory arthropathies are very rare disorders. Thus less than one new case of rheumatoid arthritis occurs in an adult population of 1000 every two years. Even the prevalence is relatively low at approximately 0.6 to 0.8 per 100, meaning that population surveys of less than 2000 are unlikely to give robust estimates of occurrence. There are, however, considerable differences in the reported prevalence and incidence of many of the rheumatic diseases and it is tempting to ascribe the differences to underlying differences in the populations studied. As an example, the range of incidence rates observed is shown for giant cell arteritis (temporal arteritis) in Table 6. It seems unlikely that these differences represent true biological variation in geographical or temporal occurrence. It is more likely that there is an artefactual explanation for such differences and some of these are:

Country	Incidence rate per 100 000 (both sexes, age 50+ years)
Israel	0.5
Scotland	4.2
France	9.4
USA	11.7
USA	17.0
Sweden	28.6
England	40.0
USA	54.0
USA	70.0
Denmark	76.6

Source: Silman and Hochberg (1993).

Table 6 Variation in reported incidence of polymyalgia rheumatica/giant cell arteritis

1. small sample size leading to random error;
2. differences in age and sex structure of populations surveyed;
3. high non-response rate with selective differences in occurrence between responders and non-responders;
4. differences in completeness of case ascertainment;
5. differences in case definition;
6. observer variation in use of case definition.

Small-denominator population size increases the risk of denominator error. Differences in the ascertainment procedure for cases are a principal source of variation. Even when the same apparent source is used (for example, referrals to a specialist rheumatologist), there is likely to be large variation between populations in the threshold for referral. Sources of this variation include the availability of health care services and physician and population perception of disease severity. Lack of standardization in case definition is a major problem. Thus, in the data in Table 6 some studies restricted inclusion to those with a positive biopsy, others relied on a broader clinical diagnosis.

Generally in rheumatology, it is perhaps easy to declare that cases satisfied 'the ARA Criteria' for the relevant disease, but there may be considerable differences in observer interpretation of the various individual constituents of the particular criteria used. The timing of a report is of interest. The effect of time trends on disease is considered below, but differences in diagnostic fashion will obviously have an effect on the reported occurrence rates in different years. Thus reported prevalence rates of up to 20 per cent for rheumatoid arthritis in a survey undertaken 25 years ago (Engel 1968) are more likely to represent a perception of what was then rheumatoid arthritis and what now would be considered unacceptable.

Factors affecting occurrence of the major rheumatic diseases

Age and sex

It is impossible to compare the results from different studies without considering the age and sex structure of the population studied. Differences in crude (i.e. all age and sex combined) estimates of occurrence rates between populations may well be explained by differences in demographic structure. There are very striking effects of age and sex in virtually all the rheumatic diseases, as shown in Table 7. Extreme examples are the very low incidence of ankylosing spondylitis at age 65 and the virtual absence of knee osteoarthritis at age 25. In all disorders considered, a 5-year shift in the mean age or a 10 per cent difference in the proportions of the two sexes in the population studied can have a large effect on the crude estimates. One problem in surveys is that males and those at the two extremes of the age distribution are less likely to participate, resulting in a 'skewed' estimate of occurrence.

Disease	Ratio ages 65:25 years	Sex (F/M)
Rheumatoid arthritis	6:1	2.5:1
Ankylosing spondylitis	0[a]	1:3
Gout	2:1	1:6
Systemic sclerosis	3:1	4:1
Systemic lupus erythematosus	1.5:1	3:1→9:1[b]
Juvenile chronic arthritis (pauciarticular)	N/A	2:1→7:1[b]
Knee osteoarthritis (prevalence)	0[a]	2:1

Data are typical
[a]No incident cases at this age
[b]Range given as ratio varies considerably in published studies
Source: Silman and Hochberg (1993).

Table 7 Effect of age and sex on incidence of rheumatic disease

There are two approaches to overcoming this problem. First, the data can be presented separately for each age and sex group (e.g. Table 8), although this is frequently not possible or desirable as the numbers in individual age and sex 'strata' may be too small for precise estimates. The data presented on the prevalence of knee osteoarthritis and on the incidence of rheumatoid arthritis are unusual by virtue of having large sample sizes for the disorders considered. Frequently in publications this is not the case. Alternatively, adjustment may be made to some notional standard population to produce a standardized rate. For example, in the Symmons *et al*. study of rheumatoid arthritis incidence (Symmons *et al*. 1994), male and female crude rates of 14.0 and 35.6 per 100 000 were standardized to the United Kingdom 1991 population to produce standardized rates of 12.7 and 34.3 per 100 000 respectively. The only problem is that other reports do not standardize to the same population and readers rarely make the necessary calculations themselves to obtain comparable results.

Age (years)	Prevalence			
	Males		Females	
	Number studied	%	Number studied	%
40–44	395	0.0	428	0.0
45–49	362	0.3	386	1.6
50–54	312	2.2	298	2.7
55–59	220	1.4	229	0.4
60–64	178	5.6	186	4.8
65–69	116	6.9	183	9.8
70–74	85	7.1	122	16.4
75–79	59	8.5	117	14.5
80+	27	7.4	77	29.9

Source: Van Saase et al. (1988)

Table 8 Age- and sex-specific prevalence rates for grade 3 osteoarthritis of the right knee

With the exception of the HLA B27-associated spondylarthropathies and gout, there is a striking female excess (even after age adjustment) in most of the rheumatic diseases for reasons that are mainly unexplained. Such an excess is always a useful starting point for considering aetiological hypotheses and the effect of hormonal and reproductive factors (e.g. Silman and Black 1988; Brennan and Silman 1994). In disorders with an increased occurrence with age then a degenerative aetiology, perhaps as a consequence of a sustained environmental insult, is likely (e.g. osteoarthritis in the presence of obesity). By contrast, disease with a young age at onset may represent a greater genetic contribution or more short-lived environmental influence (e.g. Reiter's syndrome).

Time trends

It is of considerable interest to monitor the trends over time in the occurrence of diseases. From an aetiological view changes in the incidence of disease may represent changing levels of exposure to putative risk factors. From a public health perspective the appropriate health service provision requires knowledge of both current and future levels of occurrence. Trends in prevalence rates are difficult to interpret because improvement in survival will lead to an increase in prevalence. Thus it is really only appropriate to consider changes in incidence over time, and regrettably, there are few data on incidence at different time periods for most of the major rheumatic diseases, the notable exception being rheumatoid arthritis.

Time trends for rheumatoid arthritis

The earliest reliable data on trends in the incidence of rheumatoid arthritis come from estimates based on cross-sectional surveys of population samples from Leigh and Wensleydale, studied in the 1950s and 1960s. A follow-up survey was undertaken after 5 years in the 620 individuals who had participated in the initial survey in 1954 to 1959. This found that 36 (6 per cent) of the population originally free of rheumatoid arthritis had developed it during the follow-up period (Lawrence 1977). This however, is equivalent to an annual incidence of 12 per 1000, which was six times the rate estimated during the first survey (based on recalled age at onset). It is not likely that the incidence increased sixfold during this period and the data probably seriously overestimate the true occurrence of the disease and probably reflect a case definition of low specificity.

The accurate determination of trends requires the continual monitoring of a population, with access to contemporary medical records; these permitting retrospectively correct diagnostic assignment. Such a system can only work if the monitoring can detect all the cases in a defined population as in the Rochester Epidemiology Program discussed above. Although retrospective examination of medical records will omit those who never seek medical attention for their symptoms and standardization of diagnosis is difficult, the utility of such a system in documenting trends in new cases is clear. Figure 1 shows published results from 1950 to 1975 in the Rochester studies (Linos *et al*. 1980). These show an increasing incidence in the first part of this period, with a marked subsequent decline in females but not in males. Although there have been considerable changes in diagnostic practice over this period, with increasing recognition of the need to separate out the HLA B27-related seronegative arthritides, such an explanation is unlikely, given the patterns observed. Such a diagnostic reassignment would have been expected to alter the trends in both sexes equally. Possible reasons for the difference between the sexes will be considered later in this review. A more recent study from Seattle (Dugowsen *et al*. 1991) aiming to 'capture' all incident cases in women in 1987 in a fixed population, yielded an annual incidence rate of 0.23 per 1000 women aged between 18 and 64 years compared with a rate of 0.46 per 1000 in the same age group in the Rochester population during the period 1950 to 1974, i.e. the rate had halved over the past decade. This decline in the United States is not restricted to white groups. Over the past 25 years there has been a halving in incidence in Pima Indians, a group with one of the world's highest rates (Jacobsson *et al*. 1994).

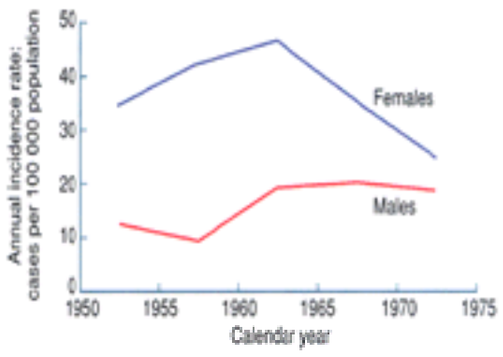

Fig. 1 Published results from 1950 to 1975 in the Rochester studies (reproduced with permission from Linos *et al*. 1980).

There are also supporting data from the United Kingdom. The Royal College of General Practitioners conducted morbidity surveys involving a large group of general practitioners who were required to make a diagnosis for every patient consultation. These surveys in 1955, 1970 to 1972, 1981 to 1982, and 1992 all relied on the recorded diagnosis from the general practitioner and were not standardized. The results comparing the two middle surveys show (Hochberg 1990) (Table 9) that there was no significant decline in incidence between these surveys. The other data from this source are from an ongoing survey of all patients attending one of 30 participating general practitioners, who send back to the 'central' unit a 'weekly return' of the numbers attending with a list of specific diagnoses (Royal College of General Practitioners 1976 to 1987). These include rheumatoid arthritis. Analysis of these data (Fig. 2) (Silman 1988) showed a statistically significant decline of approximately 7.5 per 100 000 per year between 1976 and 1987, equivalent to a halving in the incidence rate during this time. Although most of the participating doctors had remained the same during the period of observation the possibility cannot be excluded that there was a decline in completeness of recording during this period.

Source: Hochberg (1990)

Table 9 Incidence rate of rheumatoid arthritis in the United Kingdom

Whole population data are also available from those countries that have a population morbidity register for specific disorders. Interpretation of trends from such sources is difficult as, in addition to the persistent problem of changes in completeness of registration, there may be selective changes in the severity of cases recorded. Such registers are extensively available in Scandinavia, and data from Finland (Isomaki 1989) have recently been published. This source demonstrated an annual incidence of newly registered patients with seropositive rheumatoid arthritis of 0.46 per 1000 in 1980, which was unchanged from that recorded in the early 1970s.

Time trends for other rheumatic diseases

There are fewer data for the other diseases. There are suggestions that symptomatic osteoarthritis is increasing in incidence, based on an increase in consultations to general practitioners from the Royal College of General Practitioners data (Croft 1990) (Fig. 3). Similar data have shown a 30 per cent increase in the incidence of

gout between 1971 and 1981 (Stewart and Silman 1990). There has been a marked increase in the incidence of scleroderma, based on a number of studies covering 35 years of observation of the population of Allegheny County, Pennsylvania (Fig. 4) (reviewed by Williams and Silman 1991). Giant cell arteritis has also doubled in incidence in some countries in the past two decades (Rajala *et al*. 1993). However, there is always a problem with such diseases in that increasing incidence may only represent better case ascertainment as physicians become more confident at making the diagnosis. By contrast, there has been a decline in the incidence of ankylosing spondylitis over six decades in the Olmsted County population (Carbone *et al*. 1992).

Trends in birth cohorts

The onset of many of the rheumatic diseases is difficult to define in time and thus trends in calendar year of presentation or diagnosis may not reflect true temporal patterns of disease. Further, if the presumed environmental exposure which triggers a particular disorder occurs early in life, it might be more appropriate to examine trends in disease in successive generations defined by their cohort of birth. An illustrative example of this in rheumatoid arthritis is that contemporary studies of its incidence demonstrate a marked increase in risk with increasing age (Symmons *et al*. 1994). Although this might represent a true age effect on incidence, an alternative explanation is that the oldest groups in that population were at highest risk based on their year of birth and that follow-up over a long period would confirm that the age-specific incidence rates would fall.

Lawrence (1977) was the first to point out the possibility that the risk of rheumatoid arthritis could be related to the period in which an individual was born. In a prospective study in Oberhörlen (West Germany) in the 1960s the maximal incidence was found to be in those aged 65 years and over, whereas the maximal prevalence of existing cases in the cross-sectional survey in the same population was in the decade below that age.

More interesting perhaps, are the data from the Leigh and Wensleydale population surveys (mentioned above) on the prevalence of rheumatoid factor positivity in relation to period of birth (Lawrence 1977). In brief, there were three observations: (i) in urban populations, positivity increases with age in cross-sectional studies; (ii) over a 10-year follow-up period in that urban population there was a tendency for individuals to have a fall in titre; (iii) on analysis by year of birth, the rate of positivity fell in successive cohorts from those born between 1885 and 1894; indicating perhaps that the 1885 to 1894 groups had a peculiarly high risk. Lawrence suggested that the reduction in titre in the older age groups was consistent with an effect of improvement in atmospheric pollution resulting from the Clean Air Acts in 1956.

Clustering in time

A further approach to considering the influence of time on the onset of disease is to look for clustering of disease, i.e. the non-random distribution in time. The most classical example of this was the initial description of the apparent epidemic of juvenile arthritis in Lyme (Steere *et al*. 1977), where both the parents' and the physicians' feelings were that the number of cases seen was greater than would be expected by normal random distribution of sporadic cases. Although there are complex statistical methods available for confirming the non-randomness, it is normally obvious that such a cluster exists, as was the case in Lyme. The ultimate consequence from the follow-up of this cluster was the incrimination of *Borrelia burgdorferi* as the causative organism.

The reporting of apparent clusters of cases in time has occurred in other rheumatic disorders with no well-defined cause. One interesting example is polymyalgia rheumatica/giant cell arteritis, although the role of increased awareness and changes in diagnostic sensitivity in producing such clusters is unknown. A cluster of five cases in Jerusalem was reported in a 7-week period, where their expected annual referral rate was one case. A study in general practice in the United Kingdom was also suggestive of a cluster with six cases of polymyalgia rheumatica and two of giant cell arteritis presenting in 7 months in a population of 4400. Further, one of the most unusual aspects of the epidemiology of polymyalgia rheumatica/giant cell arteritis is the suggestion of seasonality in incidence. The results are confusing, however. Thus, an initial report of clustering in summer (Kinmont and McCullum 1965) was followed by two of a definite winter peak (Coomes *et al*. 1976; Jonasson *et al*. 1979), one with a marked summer peak (Cimmino *et al*. 1990), and one suggesting both a summer and a winter peak (Mowat and Hazleman. 1974). Two more studies showed no such seasonality (Chuang *et al*. 1982; Omland *et al*. 1986) but the results from the positive studies do suggest that clustering in time and indeed in space might be responsible for some of the variable incidence of this disease.

Racial influences

A summary of the principal racial influences in the rheumatic diseases is given in Table 10. The consideration of racial influences is of interest, although any differences that do emerge are inevitably difficult to interpret. The reasons for this are first that there may be racial differences in symptom perception, physician consultation, and physician bias in diagnosis, all of which could lead to apparent differences in incidence. Second, ethnic groups differ in both genes and environment, the latter both at a macro level—there may be geographical differences due to area of residence—and at a micro level, perhaps due to differences in nutrition or other lifestyle factors. The classical epidemiological method of attempting to distinguish between these explanations is the migrant study. Thus, one aims to compare the incidence of a disease in members of an ethnic group who migrate with that seen in the population who remain in their original environment. One example of this is the study of rheumatoid arthritis in black African populations. Thus a very low prevalence of rheumatoid arthritis was seen in a rural African population in South Africa, but the prevalence approximated to the white persons' rate among those black people who had migrated to an urban environment (Solomon *et al*. 1975). The suggestion is that it is the rural environment rather than the negro race that is protective. However, there has to be caution in interpreting the results of such studies. First the migrants are unlikely to be representative of the 'parent' population in respect of their lifestyle and other factors. Second, the occurrence of disease may lead to migration, thus an individual with rheumatoid arthritis may seek to move nearer to a city for greater access to medical care. One

problem in considering comparative studies of racial differences is that one may not be comparing like with like, and different study methods may be involved.

	Racial groups with rate:	
	Increased*	Decreased
Rheumatoid arthritis	Pima Indians	Black Africans Chinese
Ankylosing spondylitis	Haida Indians	
Systemic lupus erythematosus	American blacks Chinese	
Osteoarthritis	Blackfeet Indians	Caribbean blacks
Juvenile chronic arthritis	Native Americans	Chinese
Gout	Filipinos Tamils Malaysians	Pima Indians

*Compared with 'European' group.

Table 10 Racial differences in the occurrence of rheumatic diseases

Rheumatoid arthritis is rarer in both developed (Lau *et al*. 1993) and rural (Beasley *et al*. 1983) Chinese groups and in both developed (MacGregor *et al*. 1994a) and rural (Silman *et al*. 1993) black groups than in white populations. Examples of racial differences in a few other selected diseases are considered below.

Osteoarthritis

A single-observer study comparing rural Jamaica with rural England showed a similar overall prevalence of osteoarthritis, although there was a difference in the distribution of affected joints. Jamaicans were more likely to have knee and hand involvement and less likely to have hip and metatarsophalangeal joint involvement (Bremner *et al*. 1968). By contrast, involvement of the distal interphalangeal joint is very common in Pima and Blackfeet Indian groups in North America, with rates of Heberden's nodes as high as 30 per cent in some Blackfeet communities (Bennett and Burch 1968). In North American black populations, radiographic changes in the knee are more common in women but similar in men when compared with a similarly surveyed white population (Felson 1988). Differences in the prevalence of osteoarthritis of the hip are more common, with a relative rarity of disease at this site in Asian Indians, Chinese, and black African populations (Felson 1988).

Juvenile chronic arthritis

The incidence of juvenile chronic arthritis in native Americans in British Columbia, Canada is three times that of a comparable white population (Hochberg 1981). By contrast no cases were found in an extensive survey of 20 000 Chinese children in the same population (Hill 1977). There do not appear to be any differences between black and white children in North America.

Systemic lupus erythematosus

This is up to five times more common in black than in white races, although this excess is more predominant in the United States and West Indian populations than in black African groups (Symmons 1991). South Asians are also at double the risk of white populations (Hopkinson *et al*. 1994). The other at-risk group would appear to be the Chinese, with a number of anecdotal hospital series reporting a relative excess of systemic lupus erythematosus compared with rheumatoid arthritis, in contrast to the normal state in Western Caucasoid populations. There may be environmental factors relevant here however, as the excess is seen in Chinese populations in Malaysia but not in 'Westernized' Chinese for example in San Francisco (Frank 1980). It is likely in this, as in other disorders, that the effect of race is not limited to disease susceptibility but also applies to disease severity.

Geographical influences

The racial distribution of disease can, as was explained above, be interpreted on the basis of geographical differences related to environmental factors. Some of the differences that affect the Third World are considered in Chapter 5.1.2. Geographical, like racial, differences can be useful in framing hypotheses for further testing. Geographical differences may be between countries or even within countries to the level of small, area clusters, in an analogous manner to the clustering in time discussed above for Lyme disease. Clustering without an obvious explanation has been described for connective tissue diseases in general in Georgia, United States (Arnett *et al*. 1990) and for scleroderma in South and West London, where one hypothesis was that this was due to proximity to airports (Silman *et al*. 1990).

Geographical differences between populations for the various diseases have been considered and many of these were well described at a conference nearly 25 years ago (Bennett and Wood 1968), relating particularly to gout and rheumatoid arthritis.

Rheumatoid arthritis

Rheumatoid arthritis has been subject to more population studies than any other rheumatic disease and the breadth of these studies across all five continents is shown in Table 11. The points listed above on methodological explanations for differences in results are relevant in interpreting these studies. Most of the studies are very small and with a disease, such as rheumatoid arthritis, with a less than 1 per cent rate of prevalence, population studies of under 2000 are unlikely to yield useful data. The precision with which the studies were conducted varies, and the published reports do not always allow an accurate appreciation of the methods used, particularly the diagnostic criteria. Despite these caveats, the most striking feature from these numerous studies is the overall similarity in prevalence between populations, with a standard rate of between 0.5 and 1.0 per cent. This consistency is most unusual in human chronic diseases and may reflect the ubiquity of the causative factors, genetic and/or environmental.

Table 11 Geographical variation in prevalence of rheumatoid arthritis

Other rheumatic diseases

Ankylosing spondylitis varies in prevalence according to the underlying population frequency of the HLA-B27 gene. Rates of the disease are substantially higher in Scandinavian than in other European or American Caucasian populations (Rigby 1991). Gout is a disease with a very marked geographical variation in prevalence, probably related to the underlying population levels of serum uric acid. Filipino and Polynesian populations in the Pacific Rim have shown the greatest excess in prevalence compared with that in Caucasoid populations (Decker *et al*. 1968). Interestingly, even within relatively homogeneous populations, there are differences in

prevalence. For example, there is a higher rate of gout in England than in either Wales or Scotland (Currie 1979). Juvenile chronic arthritis has also been extensively studied with no major difference found in Western populations or what was the Soviet Union. There have also been a number of prevalence and incidence studies of polymyalgia rheumatica in different populations, although many of the these studies were from populations of the same ethnic origins, mostly either from Scandinavia or from the largely originally Scandinavian population in Olmsted County served by the Mayo Clinic. There are no consistent differences between the populations studied in Scandinavia or the United States. One study from Israel (Friedman *et al*. 1982) had the lowest recorded incidence (0.5 per 100 000), although it is always difficult to be sure as to the role of under-ascertainment. Similarly studies from Southern Europe—France (Barrier *et al*. 1982) and Italy (Salvarani *et al*. 1987)—yielded incidence estimates substantially lower than those from most of the major studies in Northern European and the United States. The one exception is the study from the Southern United States (Smith *et al*. 1983) which, at 2.4 per 100 000 in the white population, had the lowest incidence rate for giant cell arteritis (apart from the Israeli study).

Aetiological models

Most of the rheumatic diseases have a combination of genetic and environmental factors implicated in their aetiology; it is frequently the role of epidemiology to define the nature of these factors and consider their involvement quantitatively. The problem is not a simple one, however, for two reasons: first, there is not a single aetiological model for the majority of the rheumatic diseases. However, knowledge about genetic factors has increased exponentially as data on gene products is replaced by information from DNA sequencing. Thus it is likely that there is an infinite number of point mutations that explain the occurrence of such wholly genetic disorders as the Ehlers–Danlos syndrome, rather than a single genetic cause.

It is, however, useful to consider models for disease causation according to whether a cause is necessary, i.e. the disease for all practical purposes cannot occur in its absence, and/or sufficient, i.e. the disease can occur in the presence of that risk factor alone, as shown in the diagram below.

		Cause necessary	
		Yes	**No**
Cause sufficient	**Yes**	*Borrelia burgdorferi* and Lyme disease	Organic solvents and scleroderma
	No	HLA B27 and ankylosing spondylitis	HLA DRB1*04 and rheumatoid arthritis

Thus Lyme disease follows infection by *Borrelia burgdorferi* and this organism (probably) alone can cause the disease (Steere *et al*. 1983). By contrast, organic solvent exposure is not necessary for the development of scleroderma but is sufficient for some cases (Black *et al*. 1986). It is (almost) true that HLA B27 is necessary for the development of ankylosing spondylitis but it is not sufficient, as the majority of individuals with this antigen will not develop the disease. The most frequent pattern of causation is, however, the last quadrant (bottom right) where a risk factor is neither necessary nor sufficient. Thus the overwhelming majority of individuals with HLA DR4 (HLA DRB1*04) will not develop rheumatoid arthritis and a significant proportion (30 per cent) of individuals with rheumatoid arthritis will not have HLA DR4 (HLA DRB1*04).

It is obvious to most observers that for most of the rheumatic diseases there is not, as in the Lyme model, a single cause, and one is searching for risk factors that may be relevant but are poor discriminators between those who will and will not develop a particular disease. One useful strategy is to describe clinically or pathologically derived subsets within a clinical entity that may allow the better derivation of causes, the so-called splitting approach. This is particularly useful in relation to juvenile chronic arthritis, where such factors as pattern of joint involvement at onset and the production of antinuclear antibodies have been associated with different immunogenetic backgrounds to an increasingly specific level (Fernandez-Vina *et al*. 1990)

Genetic factors

There are a number of epidemiological approaches to assessing the genetic contribution to disease and these are shown, with their advantages and disadvantages, in Table 12.

Approach	Advantages	Disadvantages
Comparison of occurrence in different ethnic groups	Data may be readily available	Differences between ethnic groups may be more related to environment than genes
Assess whether there is an increased risk in relatives	Families normally willing to participate and provide good data	Environmental factors also cluster within families
		Often difficult to obtain data from correct families
		Need to adjust for age and sex as younger members have not had time to develop disease
Comparison of concordance in identical and non-identical twins	Good matching for environmental factors	Twin pairs not available in rare diseases Identical twins may share closer environment than non-identical (especially if of unlike sex)
Comparison of frequency of genetic marker in probands and controls	Data easy to obtain Accurate definition by DNA techniques of markers may enhance specificity	Such population associations do not prove causation Difficult to obtain strength of genetic contribution or type of inheritance
Studies of linkage between marker and disease in multicase families	Strength of genetic contribution and inheritance are possible to determine	Linkage difficult to show and large number of families needed Results from multicase families may not be applicable to sporadic cases

Table 12 Approaches to studying genetic factors in disease aetiology

Family studies

It is obvious from Table 12 that the study of family members of probands with a disease is an important tool in genetic epidemiology, but there are specific problems in relation to the rheumatic diseases which have been summarized for rheumatoid arthritis (Silman 1986); these are listed below.

1. Categorization of relatives into affected and non-affected is frequently difficult as relatives may show some features of the syndrome under investigation but not sufficient to satisfy the relevant criteria. As an example the relatives of probands with ankylosing spondylitis frequently have either clinical or radiographic evidence of sacroiliitis but not both (Burns and Calin 1983) and to categorize them as affected or unaffected would both be wrong. The answer is to use all the available data and analyse subsets, and thus in family studies not to be bound by rigid criteria.
2. Many of the rheumatic diseases may not become evident until the seventh or subsequent decades and misclassification of those yet to develop the disease may occur. This is different to, for example, the situation with type I diabetes, where development of the disease has normally occurred by the end of the third decade. Some have suggested adjusting for the age of the proband as a suitable method, i.e. if a sibling has not developed the disease by the age at which his or her affected proband developed the disease then he or she can be categorized as non-affected. This is erroneous, as data (for example, in rheumatoid arthritis) have shown that there are considerable differences in the age of onset between affected sibling pairs (Silman *et al*. 1987) and even between concordant monozygotic twins (MacGregor *et al*. 1994b).
3. By contrast for some of the inflammatory joint diseases there is also the problem of misclassification, because the disease has undergone complete remission by the time of the family survey and there is no evidence of past disease either clinically or radiologically. Unless contemporary notes are of high quality, it may be impossible to determine the significance of self-reported past history.
4. It is well recognized that probands derived from hospital series are more likely to have a 'positive' family history than unselected probands chosen from a community survey. This is likely to be due to selection for referral to hospital of an individual with symptoms in the face of a family history, thus explaining the greater familial clustering in hospital series (for example, in rheumatoid arthritis; Wolfe *et al*. 1988). An alternative, but less likely explanation is that hospital cases are more severe, and that the 'genetic contribution' is considered to be one of severity as opposed to susceptibility.

Genetic contribution to specific diseases

In this review it is impossible to provide the detailed data of the genetic contribution to the various rheumatic disorders. A summary of the data from some of the major disorders is shown in Table 13, from which it can be seen that the various strategies outlined above have yielded very different estimates of the role of genetic factors for the different disorders. Recent advances in molecular biology are refining the genetic factors to be considered. An excellent example of this is the 'shared epitope hypothesis' (Gregerson *et al*. 1987), which provides an explanation for the population association between rheumatoid arthritis and different, serologically defined class-II antigens at the DR locus on the basis of the shared possession of a short sequence of amino acids in the third, hypervariable region of the DRB1 gene. Unfortunately for the epidemiologist, although this shared epitope is observed in some 90 per cent of rheumatoid arthritis, it is also found in 50 per cent of the normal population. A quick calculation of the relevant 2 × 2 table gives the results that positive predictive value for the epitope is less than 2 per cent and the specificity is around 50 per cent; in other words, it is a poor discriminator for those destined to develop rheumatoid arthritis.

Disease	Familial clustering (risk× of risk in first-degree relatives to expected population rate)	Monozygotic twin concordance (%)	HLA association (relative risk)
Rheumatoid arthritis	1.7×	12 (population)	DR4 (3×)
Generalized osteoarthritis	2×	43	Inconsistent
Juvenile chronic arthritis	3–4×	40	DR5* (2.3–4.8*)
			DRw8* (10–25×)
Ankylosing spondylitis	15–25×	50	B27 (100×)
Systemic lupus erythematosus	9×	>25	DR2/3 (2–3×)
Systemic sclerosis	6–8×	No data	DR5 (2.5)

Data are based on pooled estimates from many sources. Source: Silman and Hochberg (1993).

Table 13 Genetic features of the major rheumatic diseases

Non-genetic host factors

This term is a slight misnomer but it is a convenient label for the non-environmental factors present in individuals that are not predominantly genetic in origin. A list of such factors examined in the rheumatic diseases is:

1. perinatal problems;
2. family size, position in family;
3. menstrual/menopausal status;
4. sex hormonal status;
5. stature and body form;
6. reproductive history;
7. organic comorbidity;
8. psychiatric comorbidity;
9. biochemical background;
10. height and weight.

Data in relation to some of the factors in the list are considered next.

Family size/position in family

In many instances this would be considered as a surrogate for overcrowding or a similar socioeconomic variable. For instance, in a study of rheumatoid arthritis, there was an increased risk of disease in older than younger siblings, suggesting that being first born carries an increased risk (Hazes *et al*. 1990b). This would be unlikely to have a simple socio-economic explanation. By contrast, a study of Behçet's disease suggested that there was a risk connected with large family size (Cooper *et al*. 1986).

Menstrual, hormonal and reproductive factors

It is appropriate to combine consideration of these variables as suggesting an influence of sex hormones. One of the most interesting aspects of the epidemiology of the major rheumatic diseases (see above) is the marked sex difference in occurrence, which is not easily explained by differences in lifestyle (such as occupation, smoking, or alcohol consumption), as is the case for other chronic disorders. It is thus reasonable to consider whether there are hormonal or reproductive effects that might explain these differences and there has been much recent work on the subject. A summary of some of the findings is shown in Table 14. Many of those factors listed might of course represent the sub- or preclinical effects of the disease rather than the cause, but such factors might be useful in explaining sex differences in occurrence.

Disease	Menstrual, hormonal, and reproductive risk factors
Rheumatoid arthritis	Early menarche, nulliparity, early post-partum period, possibly fetal loss in some groups, low testosterone in males
Osteoarthritis	Menopause, previous hysterectomy for menstrual irregularity, possible oestrogen excess
Systemic sclerosis	Infertility, possible fetal loss
Osteoporosis	Early menopause
Systemic lupus erythematosus	Pregnancy

Table 14 Menstrual, hormonal, and reproductive factors in various rheumatic diseases

Height and weight

There are a number of disorders where anthropometric variables are thought to be of relevance. Tallness may be a risk factor for low back pain. The greatest topic of interest has been the relationship between obesity and, particularly, non-inflammatory joint disease. Although obesity might also be seen as an environmental factor (i.e. excess calorie intake). The mechanical effect of obesity is to increase load on weight-bearing joints, such as the hip and knee, and it is thus of interest to note that obesity is more strongly linked to osteoarthritis of the knee than of the hip (Felson and Radin 1994). Methodologically, it is important to distinguish cause from effect. Thus in the presence of osteoarthritis there may be less physical activity with a greater tendency to obesity. Recent prospective studies have shown conclusively that obesity is a real risk factor not only for osteoarthritis of the knees (Hochberg *et al*. 1995), but also of the hands (Carman *et al*. 1994), suggesting perhaps a 'metabolic' effect.

The effect of comorbidity

Many of the diseases discussed in this volume will be classified as primary or secondary depending on whether there is another underlying pathology for the joint disease, e.g. polycythaemia and gout. The fact that this is true for a (normally small) proportion of clinical cases does not mean that such comorbidity is of relevance for the disease in general. Of greater relevance is an increased risk of joint disease in the presence of other illness, although the latter does not 'cause' the former. There are some data to support the increased coincidence of some disorders: for example, rheumatoid arthritis and autoimmune thyroid disease (Silman *et al*. 1989), scleroderma and cancer (Abu-Shakra *et al*. 1993), and neurosis and back pain (Leino and Magni 1993) are amongst a large list of such associations.

There are some interesting negative associations, i.e. the presence of one disorder 'protecting' against the development of another. Examples include the mutual exclusivity of schizophrenia and rheumatoid arthritis (Spector and Silman 1987), and osteoporosis and osteoarthritis (Dequeker 1986). The underlying explanation for these negative associations is, however, somewhat obscure.

Environmental factors

Infectious agents

The identification of *Borrelia burgdorferi* as the spirochaete responsible for Lyme disease, has acted as a stimulus to search for viral causes of other inflammatory joint diseases, such as rheumatoid arthritis for which a viral background seemed likely. It is of interest to review the epidemiological data suggesting a viral cause for rheumatoid arthritis as the lessons are applicable more widely.

Seroepidemiological studies

In this approach, antibody frequencies in a diseased and a disease-free population are compared. Numerous studies have confirmed the high titres of antibodies against a variety of Epstein–Barr virus (**EBV**)-related antigens in patients with rheumatoid arthritis. However, not all studies have been positive and, more importantly, the differences from a control population have not always been either biologically or statistically significant. Given the almost universal exposure to EBV in Western populations, it may be more relevant to look for a quantitative difference in response but this is methodologically more difficult. Epidemiologically, the geographical distribution of infectious mononucleosis and rheumatoid arthritis are similar, and infectious mononucleosis is apparently unknown in countries with a low prevalence of rheumatoid arthritis (Aho and Raunio 1982). One explanation for these observations in the face of the ubiquity of infection with EBV is the effect of age. In countries with a low prevalence of rheumatoid arthritis, infection with EBV is virtually universal by the age of 3 years and the infection is clinically silent; whereas in countries with a high prevalence, infection occurs at a later age and is more likely to be clinically apparent with, for example, infectious mononucleosis. The increased rate of antinuclear antibodies in rheumatoid arthritis is seen, however, in most populations including Mexican and American Indians and Afghans (Vaughan 1979). The evidence for EBV infection as a cause of rheumatoid arthritis is constrained by the lack of clinical evidence that EBV is arthritogenic, unlike, for example, rubella, hepatitis and mumps virus (Depper and Zvaifler 1981).

The other widely studied agent has been human parvovirus (**HPV**), given that arthritis can follow infection with this agent. A reasonable conclusion is that HPV probably has little relevance (Leading Article 1985) for rheumatoid arthritis, despite two reports from the United Kingdom, the first showing that 19 out of 153 patients with early synovitis had evidence of HPV infection (White *et al*. 1985) and the second describing joint problems in 17 patients after an HPV outbreak (Reid *et al*. 1985). Neither study had appropriate control groups and there were no patients with a persistent arthritis.

Retroviruses have also been investigated, owing to the similarity between rheumatoid arthritis and the arthritis produced by lentiviruses in animals, for example caprine arthritis encephalitis. However, attempts in man to show evidence of retrovirus infection in rheumatoid arthritis have been unsuccessful. There are also very good mycoplasma-induced animal models of rheumatoid arthritis and in these chronicity and severity, as in man, are related to genetic factors. Clinical and epidemiological studies in humans have, however, mainly failed to support a mycoplasma source for rheumatoid arthritis.

Lifestyle

In many chronic diseases there is a considerable wealth of epidemiological data linking aspects of lifestyle, such as diet, exercise, and cigarette and alcohol consumption, with the risk of disease. Studies of such variables in the rheumatic diseases have been mostly non-informative, for example, there have been studies supporting (Heliovaara *et al*. 1993) and refuting (Vessey *et al*. 1987) an increased risk of rheumatoid arthritis from cigarette smoking. Alcohol is well established to be associated with gout and possibly also osteoporosis. Diet is an aspect of lifestyle that is consistently considered by patients to be the explanation behind their disease, although scientific evidence is hard to find. Problems in studying diet include the accurate recall of diet at the appropriate time before disease onset (which might be many years in a disease with a long latency), and within-individual variation in dietary intake for many nutrients, which results in misclassification if an inappropriate dietary methodology is used, such as a food frequency interview or a 24-h recall.

Occupation

The investigation of occupational exposure as a cause of specific rheumatic syndromes is potentially of importance for those who are exposed, but of relatively minor importance at the population level. It is useful to distinguish the two epidemiological concepts of attributable risk and population attributable risk. Attributable risk, in this setting, estimates the proportion of an exposed individual's risk that is directly due to the exposure, whereas by contrast, the population attributable risk provides an estimate of the proportion of cases that arise in the population as a whole owing to that exposure. Thus there are well-established links between being a footballer (soccer) and the subsequent development of osteoarthrosis of the knee. The attributable risk is high for footballers, i.e. the occupation explained most of their increased risk, whereas in the population as a whole, being a footballer will explain only a small proportion of cases. The consequence of this fairly obvious point is that it is virtually impossible to identify most occupational exposures by undertaking retrospective case–control studies of random series of diagnosed cases, the approach frequently used for testing aetiological hypotheses. It is necessary to undertake prospective studies of occupationally derived cohorts.

Occupational exposure as far as the rheumatic diseases are concerned normally reflects either chemical or toxic exposure, or the outcome of mechanical trauma to joints and associated structures from the physical demands of the job. In practice, occupation is only rarely of interest in the inflammatory rheumatic disorders, although there have been suggestions that some cases of rheumatoid arthritis have an occupational cause (e.g. Klockars *et al*. 1987). By contrast there have been a number of toxic exposures linked to the development of scleroderma and indeed in this disease, which predominantly affects women, the development in a man might indicate a chemical exposure. Suggested exposures are:

1. silica dust (coal miners, gold miners, stonemasons);
2. organic chemicals:
    a. aromatic hydrocarbons (toluene, benzene, xylene, aromatic mixes—white spirit, dieselene);
    b. aliphatic hydrocarbons:
        i. chlorinated (vinyl chloride)
        ii. non-chlorinated (naphtha-n-hexane);
3. toxic oil;
4. epoxy resins;
5. biogenic amines—metaphenylenediamine;
6. urea–formaldehyde foam insulations;
7. drugs

It remains an unanswered (and possibly unanswerable) question as to whether silicone breast implants lead to this disease (Gabriel *et al*. 1994).

P>Osteoarthritis provides a useful example of mechanical causes, resulting from occupational exposure, that are linked with the disease; a list of such occupations is shown in Table 15. The scientifically difficult task is to try and combine the study of such occupations so as to achieve some more precise measure of joint stress. From this, overall risk of disease in relation to trauma might be determined, rather than the risk associated with specific occupations. Recent attempts at this exercise for osteoarthritis of the knee, have confirmed the increased risk from jobs with heavy demand and those that involve heavy bending, but the absolute increase in risk is small, less than twofold for the highest compared with the lowest stress group.

Exposure	Site
Sports	
Boxers	Hands
Baseball pitchers	Shoulders
Hurdlers	Hip
Runners	?Knees
Footballers (soccer)	?Knees, ?Hips
Footballers (American)	?Knees
Weight lifters	Knees
Other	
Parachutists	Knees
Jack-hammer operators	Wrists, hands
Cotton-mill workers	Hands
Coal miners	Knee
Dockers/shipyard workers	Knee
Farmers	Knee, hip

Table 15 Mechanical occupational exposures linked to osteoarthritis

Drugs

Pharmaceutical agents are a source of chemical exposure that have been linked to a number of rheumatic diseases. Many of these examples reflect an idiosyncratic response to the drug, or a genetically determined response (e.g. slow or fast acetylators in drug-induced systemic lupus) and are not a clear example of toxicity *per se*. Again, in public health terms, drugs are a relatively weak contributor to overall risk for most rheumatic diseases, systemic lupus being a notable exception. The chief epidemiological interest in relation to the aetiologic effects of drugs has been the hypothesis that the oral contraceptive pill reduces the risk of rheumatoid arthritis, to such an extent that there is a decline in incidence as a result (Vandenbroucke 1983). This has probably been the most investigated area in the epidemiology of rheumatic disease and a clear consensus has now emerged (Silman and Vandenbroucke 1989; Spector and Hochberg 1990). This is that the oral contraceptive pill probably either protects against or postpones the development of severe rheumatoid arthritis, although the mechanism for this is obscure. The studies themselves demonstrate the entire repertoire of investigational methods in epidemiology, and the various problems and biases involved in undertaking this area of research. Table 16 is instructive in so far as it illustrates the variety of approaches used to generate answers to the same question, although no single study is perfect on its own. This list is a fitting description of the current state of epidemiological research into the aetiology of the rheumatic diseases. The conclusions are that there is a lot of interest, that the studies are methodologically difficult but can be completed, that conflicting results can be expected, but that ultimately a useful answer for the basic scientists to follow up may emerge!

First author	Study design	Source of cases	Source of controls	Source of data	Odds ratio for ever used

5.1.2 Epidemiology of rheumatic diseases in selected non-European populations

Patricia A. Fraser

Epidemiology is the study of the distribution, transmission, and control of disease (Masi 1984). The primary focus of this chapter is the variation in frequencies of rheumatic diseases among several ethnic groups. Ethnicity-specific disease expression also provides clues to aetiological factors for rheumatic diseases. Comparative analysis of the frequencies of specific disease manifestations is a secondary focus of this chapter. The gaps in our knowledge of the causes and the mechanisms of transmission of rheumatic diseases preclude discussion about control and interventions. Observed variations in incidence, prevalence, and clinical and laboratory manifestations of systemic rheumatic diseases between ethnic groups may result from environmental factors. The correlation of exposure to *Mycoplasma pneumoniae* respiratory infections and cyclic variation in incidence of juvenile rheumatoid arthritis in one Canadian province (Oen *et al*. 1995) emphasizes the importance of region-specific microbial exposure. Inherited factors contribute to susceptibility to rheumatic diseases. These genetic factors may be linked to, or regulated by, multiple loci throughout the human genome. If the genes of interest are polymorphic, their allelic frequencies may vary between ethnic groups. Such genetic variation may be the basis for ethnic differences in susceptibility and disease expression. Survival is one important prognostic feature of disease expression. Ethnic differences in disease mortality may be multifactorial. Studies of the prognosis for systemic lupus erythematosus in African Americans emphasize the importance of socioeconomic factors (Karlson *et al*. 1995). Future epidemiological studies of the rheumatic diseases should be designed to obtain data on multiple variables such as genetic markers at multiple loci, climate, microbial exposure, cultural or behavioural factors (e.g. dietary habits, tobacco and alcohol use) (Adebajo 1995), and the conundrum of 'socioeconomic status'.

The occurrence and manifestations of juvenile arthritis, rheumatoid arthritis, systemic lupus erythematosus, and the seronegative spondylarthropathies in selected non-European populations are presented in this chapter. Limited data on Caucasians of European descent will be presented for the purpose of comparison. Similarly, features of arthritic disorders will be compared between Native Americans and Eskimos and between Native Americans and Mexicans because of the common origin of Native Americans and Eskimos and because of the significant contribution of Native Americans to the gene pool of Mexicans (Williams *et al*. 1985).

Interethnic comparisons of the epidemiology of rheumatic diseases are hampered by the lack of uniform sampling and disease definitions, and also by limited or missing data on many ethnic groups. Clinical case series have been included for several ethnic groups when formal epidemiological studies of prevalence or incidence are not available. These data are not equivalent in their scientific rigor to formal epidemiological studies. They are presented for the purpose of completeness of information on rheumatic diseases worldwide.

Juvenile arthritis

Definition

Descriptive terms and definitions of chronic inflammatory arthritis in childhood are numerous. North American diagnostic criteria for juvenile rheumatoid arthritis (Brewer *et al*. 1977) and European criteria for juvenile chronic arthritis (Ansell 1978) provide the foundation for an evolving worldwide nomenclature and classification of juvenile arthritis shown in Table 1 (Ansell 1990) and Table 2 (Fink and Fernandez-Vina 1995).

America [juvenile rheumatoid arthritis (JRA)]

Europe [juvenile chronic arthritis (JCA)]

Systemic JRA/JCA

Pauciarticular JRA/JCA:
Type I—ANA-positive (young girls)
Type II—HLA-B27-positive (older boys)

Polyarticular JRA/JCA:
Rheumatoid factor-negative (young children)
Rheumatoid factor-positive (older children)

[1]From Ansell (1990)
ANA, antinuclear antibody.

Table 1 Existing terminology/classification of childhood arthritis [1]

Systemic arthritis

Polyarthritis: rheumatoid factor-negative

Polyarthritis: rheumatoid factor-positive

Oligoarthritis

Extended oligoarthritis

Enthesitis-related arthritis

Psoriatic arthritis

Proposed classification from the Task Force of the Pediatric Standing Committee of the International League of Associations for Rheumatology (from Fink and Fernandez-Vina 1995)

Table 2 Idiopathic arthritides of childhood

Occurrence

Juvenile arthritis is the most common, childhood, chronic systemic rheumatic disease in the United States (Cassidy and Nelson 1988). This statistic reflects the frequency of juvenile arthritis in the largest ethnic group, Caucasians, and in Native Americans. Data on the occurrence of juvenile arthritis in Africa, Australia, and Asia are sparse.

Several survey methods have been used to estimate the occurrence of juvenile arthritis and other rheumatic diseases (Gewanter *et al*. 1983). The field population survey is the most accurate method because it includes actual physical examination of the population under study by trained observers. It is also the most costly. Estimates are also based on the number of cases presenting to a central clinic. The size of the source population must be known and it is assumed that all cases from this population base would present to this centre. The review of a medical records database for the diagnoses of interest has been used extensively. This approach also assumes the database captures virtually all of the source population. The practitioner survey interviews practitioners by questionnaire, which may be a preferable method in a population with a decentralized health-care system and has been used effectively to estimate frequencies for childhood rheumatic diseases in the United States (Gewanter *et al*. 1983).

Estimates of prevalence reveal an excess risk of juvenile arthritis among Native Americans when compared to Caucasians in various parts of North America. Juvenile arthritis is twice as common among Native Americans than among Caucasians in western Canada. Susceptibility to juvenile arthritis also varies between Native American tribal groups. In this analysis, data from Eskimo ethnic groups are compared to those from other Naive American tribal groups. The twofold difference in the prevalence of juvenile arthritis between Native Americans in Manitoba and British Columbia (Rosenberg *et al*. 1982) may be due to the high prevalence of juvenile-onset spondylarthropathy among the Native Americans of Manitoba (Hochberg 1984). Similarly designed studies reveal a variable prevalence for juvenile arthritis in several samples of Eskimos and Alaskan Native Americans (Oen *et al*. 1986; Boyer *et al*. 1988; Boyer *et al*. 1990; Boyer *et al*. 1991). The Inuit and Native Americans from the south-east coast of Alaska have the two highest reported prevalence rates for juvenile arthritis (126/100 000 and 83/100 000, respectively) (Oen *et al*. 1986; Boyer *et al*. 1991). Figure 1 includes estimates of the period prevalence of juvenile arthritis in Native Americans, Eskimos (Rosenberg *et al*. 1982; Oen *et al*. 1986; Boyer *et al*. 1988; Boyer *et al*. 1990; Boyer *et al*. 1991), and African Americans in Baltimore (Hochberg *et al*. 1983), and the frequency of juvenile arthritis in Caucasians in the United States (Lawrence *et al*. 1989) and Arabs in Kuwait, another Caucasian population (Khuffash and Majeed 1988).

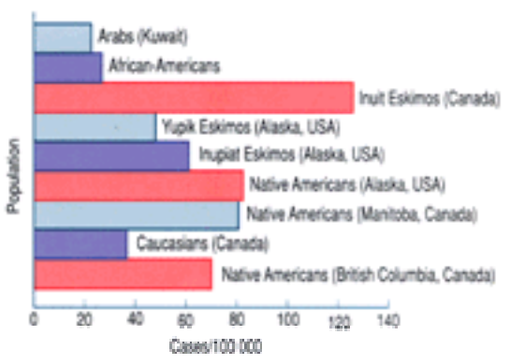

Fig. 1 Prevalence of juvenile arthritis.

Cases of juvenile arthritis have been observed in Chinese in Hawaii (Hicks 1977) and California (Hanson *et al*. 1977), but a formal estimate of the incidence of juvenile arthritis in British Columbia indicates that it is rare in North American Chinese (Hill 1976; Kelsey 1982). The incidence of juvenile arthritis in African Americans approximates that observed in Caucasians in the United States (Lawrence *et al*. 1989). Differences in method may account for the disparity in incidence estimates between United States and Canadian Caucasians. Incidence rates by race and ethnicity are listed in Table 3.

Population	Rate
Chinese (Canada)	0.00
Caucasian (British Columbia, Canada)	2.20
Native American (British Columbia)	7.20
Native Americans (S.E. Alaska, USA)	38.6
Inupiat Eskimo (Alaska, USA)	28.0
Yupik Eskimo (Alaska, USA)	42.5
Inuit Eskimos (Canada)	23.6
African American	6.20
Caucasian (USA)	9.20

Table 3 Annual incidence rate per 100 000 of juvenile arthritis

Gender differences and laboratory manifestations

The distribution of the different onset types of juvenile arthritis varies by race, ethnicity, and region. For example, onset types varied among three predominantly Caucasian samples in the United States (Hanson *et al*. 1977; Jacobs 1982; Aaron *et al*. 1985). In view of the strong genetic component in predisposition to juvenile arthritis and the known variation in the frequency of genetic markers within an ethnic group, the observed difference in the distribution of onset types in United States Caucasians may reflect the particular ethnic composition (e.g. ratio of individuals of northern versus southern European origin) in these samples. Smaller samples of individuals with juvenile arthritis in other ethnic groups also demonstrate variability in the distribution of onset types. Polyarticular-onset juvenile arthritis was twice as common among Canadian Native Americans as Canadian Caucasians (Rosenberg *et al*. 1982). Comparison of three samples of patients with juvenile arthritis among black Africans revealed different proportions of onset types and no evidence for a regional trend (Kanyerezi and Mbidde 1980; Gupta *et al*. 1981; Haffejee *et al*. 1984). The studies of juvenile arthritis among Kuwaiti Arabs (Khuffash and Majeed 1988), Ugandans (Kanyerezi and Mbidde 1980), Zambians (Gupta *et al*. 1981), Black and Indian South Africans (Haffejee *et al*. 1984), and Mexicans (Martinez-Cairo Cueto *et al*. 1978) are presented in Table 4.

Race/ethnicity/author and/or locale	Number	Systemic (%)	Polyarticular (%)	Pauciarticular (%)
Caucasians[a] (USA; Jacobs 1982)	200	9.0	16.0	75.0
Caucasians[a] (USA; Hanson *et al*. 1977)	500	43.0	23.0	34.0
Caucasians[a] (USA; Aaron *et al*. 1985)	327	15.0	27.0	58.0
Native Americans	34	11.8	58.8	29.4
Arabs (Kuwait)	41	39.0	39.0	22.0
Blacks (Uganda)	41	54.0	37.0	9.0
Blacks (Zambia)	8	37.5	37.5	25.0
Blacks (South Africa)	40	15.0	50.0	35.0
Indians (South Africa)	18	16.6	44.4	39.0
Mexicans	46	28.3	45.6	26.1

[a]Sample composition e.g. ~ 80% US Caucasian

Table 4 Juvenile arthritis onset types by author, race, or ethnicity

Equal sex ratios among Black and Indian South African (Haffejee *et al*. 1984) and Mexican individuals with juvenile arthritis (Martinez-Cairo Cueto *et al*. 1978) contrast with the female predominance in samples of Native American and North American Caucasians with juvenile arthritis (Rosenberg *et al*. 1982, Aaron *et al*. 1985) (Table 5). With the exception of two studies on sex ratios (Hanson *et al*. 1977; Aaron *et al*. 1985), data were not analysed to demonstrate the age dependence of sex ratios in pauciarticular juvenile arthritis (i.e. girls more often affected than boys in early onset, boys more than girls in late onset).

Race or ethnicity	Systemic	Polyarticular	Pauciarticular	All JA
Native Americans (British Columbia)				4.1:1
Caucasians (British Columbia)				5.8:1
Blacks/Indians (South Africa)	1.25:1	1.1:1	0.83:1	1:1
Mexicans	0.63:1	2:1	0.7:1	1.1:1
Arabs	2.2:1	33:1	8:1	1.3:1
US Caucasians (Hanson *et al*. 1977)	1.1:1	3.8:1	3.2:1	2:1
US Caucasians (Aaron *et al*. 1985)	1.6:1	5.3:1	2:1	2.4:1
Inuit				1:1

Table 5 Female:male ratio by onset type or all juvenile arthritis (JA)

The frequencies of antinuclear antibodies for individuals with juvenile arthritis in three racial groups in Table 6 are much lower than a recent report from the United States. Szer *et al*. (1991) noted antinuclear antibody positivity of 83, 42, and 39 per cent for patients with pauciarticular, polyarticular, and systemic juvenile arthritis, respectively. This discrepancy may be due to difficulty in comparing clinical case series and epidemiological studies, or to differences in laboratory methods, or both.

Race or ethnic group	Systemic	Polyarticular	Pauciarticular	JA
Native Americans (British Columbia)				53.3
Caucasians (British Columbia)				28.8
Blacks/Indian (South Africa)				6.8

Table 6 Frequency (per cent) of antinuclear antibody by race or ethnicity by onset type or juvenile arthritis (JA) unclassified

Case series must be utilized when we consider comparisons of rheumatoid factor positivity. With the exception of black Ugandans, rheumatoid factor-positive juvenile arthritis is threefold greater in the non-European populations included, although the proportion of polyarticular-onset juvenile arthritis is not significantly different among these populations. The disparity between the proportions of polyarticular-onset juvenile arthritis and seropositivity may indicate the presence of other stimuli for rheumatoid factor production such as malaria or other recurrent parasitic infections and tuberculosis (Haffejee *et al*. 1984). Estimates of the seroprevalence of rheumatoid factor in juvenile arthritis are presented in Table 7.

Race or ethnicity	Systemic	Polyarticular	Pauciarticular	JA
Native Americans (Alaska)				32.0
Native Americans (British Columbia)				36.0
Caucasians (British Columbia)				9.1
Black (South Africa)				36.0
Indian (South Africa)				33.0
Mexican	30.7	42.8	16.6	33.0
Black (Uganda)				10.0

Table 7 Frequency (per cent) of rheumatoid factor by race or ethnicity by onset subtype or unclassified juvenile arthritis (JA)

Juvenile spondylarthropathies

Juvenile-onset seronegative spondylarthropathies, which include ankylosing spondylitis, Reiter's syndrome, and seronegative enthesopathy and arthropathy syndrome (Rosenberg and Petty 1982), account for at least half of the arthritides of childhood in native North American populations. Specific criteria for childhood-onset ankylosing spondylitis are necessary since the application of adult criteria have limited value (Singsen 1990) and may result in underestimation of this condition. The demographic, clinical, and laboratory features of juvenile-onset spondylarthropathies (Rosenberg *et al*. 1982; Oen *et al*. 1986; Boyer *et al*. 1988; Boyer *et al*. 1990; Boyer *et al*. 1991) are summarized in Table 8.

Population	Diagnosis	Number of cases	Prevalence	Incidence	SPA:JA	HLA-B27

HLA-B27 (per cent)

Rheumatoid arthritis

Several variables affect comparisons of the prevalence estimates for rheumatoid arthritis.

Definition

The case definition of rheumatoid arthritis varies between studies. This non-uniform disease definition resulted from the evolution of disease criteria for rheumatoid arthritis over time—the Manchester grading system, the 1958 and 1962 American Rheumatism Association criteria, the New York criteria, 1987 revised, for rheumatoid arthritis [(Ropes *et al*. (1958), Lawrence (1961), Kellgren (1962), Lawrence and Wood (1963), and Arnett *et al*. (1988), respectively]. The earliest prevalence estimates to be presented in this section, from New Zealand Maoris (Rose and Prior 1963), rural Japan (Shichikawa *et al*. 1981), Jamaica (Lawrence *et al*. 1966), Puerto Rico (Mendez-Bryan *et al*. 1964), Liberia and Nigeria (Muller 1970), and among the South African Bantu (Solomon *et al*. 1975; Beighton *et al*. 1975), included probable and definite cases of rheumatoid arthritis. In later studies, prevalence rates were based on classical and definite cases of rheumatoid arthritis.

Occurrence

Rheumatoid arthritis does not occur at the same frequency at all ages. Its age distribution may vary between populations. Crude estimates of prevalence in populations with a younger age structure will be lower than age-adjusted prevalence rates since rheumatoid arthritis is a disease of middle age. This potential source of bias is one explanation offered for the very low prevalence of rheumatoid arthritis in several studies from different Asian and African, and African-derived population samples (Mijiyawa 1995).

Population sampling may also affect the comparability of data. Population-based epidemiological studies are preferred, when feasible.

Rheumatoid arthritis occurs in India, Pakistan, Oman, and Iraq at frequencies (0.75–1.98 per cent) similar to that observed in the United Kingdom and the United States (Al-Rawi *et al*. 1978; Pountain 1991; Malaviya *et al*. 1993; Hameed *et al*. 1995). The common methods used to estimate the occurrence of rheumatoid arthritis among samples of Native American facilitate the comparison of prevalence estimates among these groups. It is noteworthy that rheumatoid arthritis was confined to women in an Inuit sample, although records of both sexes were reviewed (Oen *et al*. 1986). In contrast, a field population survey among the Yakima was limited to women (Beasley *et al*. 1973). Variability between ethnic groups was observed between tribal groups and by locale. The majority (76 per cent) of those with rheumatoid arthritis among south-eastern Alaskan Native Americans were of Tlingit ancestry (Boyer *et al*. 1991). The prevalence of rheumatoid arthritis varied among the groups of Native Americans studied (Chippewa, Haida, Nootka and Pima, Yupik, and Inupiat Eskimos) from 0.6 to 7.1 per cent, with the highest rates among the Chippewa and the Pima (7.1 and 5.3 per cent, respectively) (Gofton *et al*. 1964; Harvey *et al*. 1983; Atkins *et al*. 1988; Del Puente *et al*. 1989; Boyer *et al*. 1990; Boyer *et al*. 1991).

Rheumatoid arthritis occurs at a lower frequency in populations of African ancestry when compared to Caucasians. This is best exemplified in a study in Manchester, England, where the age-adjusted prevalence of rheumatoid arthritis was significantly lower in Afro-Caribbeans (Afro-Caribbean: Caucasian 0.36:1) (MacGregor *et al*. 1994), and in a study that failed to detect any cases of rheumatoid arthritis among 2000 rural Nigerians (Silman *et al*. 1993).

Comparison of the prevalence rates of rheumatoid arthritis among populations of black African descent is more problematical and necessitates review of the raw data. This is necessary because several disease definitions were used in the studies of interest. Intercontinental differences in population age structure may also contribute to the observed differences in the prevalence of rheumatoid arthritis. For example, the age distribution in the United States is significantly older than that in most sub-Saharan African nations (Hall 1991). Since rheumatoid arthritis occurs most frequently in young and middle-aged adults, a country such as the United States may have a higher prevalence of rheumatoid arthritis on the basis of the age distribution of its population. The combined prevalence of definite and classical rheumatoid arthritis has been estimated for African Americans (Lawrence *et al*. 1989), while prevalence data for probable and definite rheumatoid arthritis are available from Jamaica and several black African samples. Variability is observed if the prevalence of definite rheumatoid arthritis among samples of black African descent is compared. Although the prevalence of definite rheumatoid arthritis is similar for African Americans, rural Jamaicans, and urban South African Bantu (Lawrence *et al*. 1966; Solomon *et al*. 1975; Lawrence *et al*. 1989), estimates from rural Africa are significantly lower (Beighton *et al*. 1975; Moolenburgh *et al*. 1984; Brighton *et al*. 1988). With the exception of the Jamaican sample, there is a striking difference between urban and rural black populations. This is best illustrated in southern Africa, where rural and urban estimates among the Tswana reveal a more than threefold difference in the prevalence of rheumatoid arthritis (Beighton *et al*. 1975; Solomon *et al*. 1975). It is difficult to draw any conclusions about ethnic differences in predisposition in black African populations. A study of 39 patients with rheumatoid arthritis admitted to a central hospital in Uganda did not show any ethnic predisposition among the Baganda, Banyarwanda, and Banyankole, the major tribal groups in that region (Kanyerezi 1969). A similar investigation in western Nigeria also failed to show heightened susceptibility in any ethnic group (Greenwood 1969).

The hypotheses that rheumatoid arthritis is a relatively new disease in Africa (Adebajo 1991) and that it is due to infection with a slow virus (Buchanan and Murdoch 1979) may explain the difference in urban and rural prevalence estimates for rheumatoid arthritis in Africa in populations of Bantu ancestry. Presumably, urban Bantu dwellers had greater exposure to the putative viral infection than did rural inhabitants. Similarly, the very low prevalence of the disease (0.2–0.5 per cent) among rural and urban Chinese in the People's Republic of China, Taiwan, Hong Kong, three Japanese samples, and Indonesia (Kato *et al*. 1971, Shichikawa *et al*. 1981; Beasley *et al*. 1983; Lau *et al*. 1993; Darmawan *et al*. 1993; Chou *et al*. 1994; Wigley *et al*. 1994) may indicate lack of exposure to the rheumatoid arthritis-associated virus. These hypotheses do not explain the very low prevalence of rheumatoid arthritis (0.1 per cent) in Chile, which is possibly due to the age distribution of the population (Gomez-Carpio *et al*. 1966). Such theories of differential susceptibility or aetiological agents can neither be confirmed nor refuted until standardized disease definitions are used to estimate the age-adjusted prevalence of rheumatoid arthritis in population-based studies. Table 9 lists 45 prevalence estimates for rheumatoid arthritis.

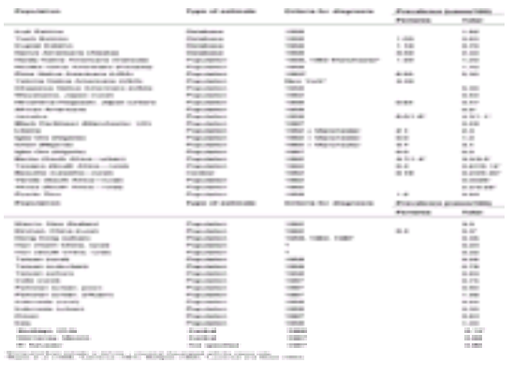

Table 9 Prevalence rates of rheumatoid arthritis

Comparative analyses of seropositivity in rheumatoid and non-rheumatoid arthritis show rates of seropositivity in non-rheumatoid from 2 to 20 per cent and between 9 to 94 per cent in rheumatoid (Table 10). It is interesting that two studies from Nigeria made more than 20 years apart provide very different estimates of the seroprevalence of rheumatoid factor (Greenwood 1969; Adebajo *et al*. 1993). A longitudinal study of rheumatoid factor and rheumatoid arthritis in the Pima indicated that the titre of rheumatoid factor predicts the risk of developing rheumatoid arthritis in this population (Del Puente *et al*. 1988). This observation may also explain the high prevalence rates of rheumatoid arthritis and of seropositive rheumatoid arthritis (78–94 per cent) among other Native American groups.

Population/locale	Type of sample	Total	Non-RA	RA
USA	Population		2.6	32.0
Uganda	Hospitalized			51.3[a]

Table 10 Frequency (per cent) of rheumatoid factor seropositivity in selected normal and rheumatoid arthritis (RA) samples

Systemic lupus erythematosus

Definition

The analysis of Jamaicans with systemic lupus erythematosus (Wilson and Hughes 1979) utilized 1971 criteria to define the disease (Cohen *et al*. 1971). The remainder of the studies used the 1982 revised criteria (Tan *et al*. 1982).

H4>*Occurrence*

Although there is little evidence for geographic clustering of systemic lupus erythematosus (Wallace and Quismorio 1995), there are abundant data to support the concept of differential susceptibility to lupus associated with ethnicity. The prevalence of systemic lupus erythematosus among African Americans is more than threefold greater than among Caucasians in the same regions (Siegel and Lee 1973; Fessel 1974). The available rates for systemic lupus in African Americans are stratified by sex and age, with peak prevalence between 15 and 64 years. United States incidence data are two- to threefold greater in African American than Caucasian women (McCarty *et al*. 1995). The same trends are seen in data from Afro-Caribbeans in Birmingham, UK (Johnson *et al*. 1995). The excess risk of systemic lupus erythematosus in populations of African ancestry residing outside continental Africa are unexplained. Genetic admixture of the lupus-prone individuals has been offered as a possible explanation for the excess susceptibility (Symmons 1995). The only study to address admixture in systemic lupus found no difference in its level (approx. 28 per cent) between African Americans patients in Baltimore and local controls (Bias *et al*. 1992). In several samples, age of onset in African-Americans and Afro-Caribbeans is significantly younger than locale-matched Caucasian lupus patients (Johnson *et al*. 1995; McCarty *et al*. 1995). Estimates of systemic lupus erythematosus occurrence in Curacao, a Caribbean island largely populated by descendants of enslaved Africans, differ slightly from other samples of African ancestry. Although the peak incidence occurs among women 45 to 65 years exceeds that for the 15 to 44 age group (186.6 versus 102.9/100 000) (Nossent 1992). The minor discordance between these two rates are not due to differences in mortality rates. Figure 2 summarizes age-specific population, prevalence, incidence, and mortality data for the Curacao sample.

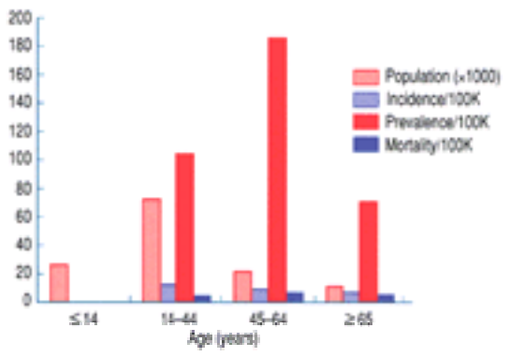

Fig. 2 Age-specific population, prevalence, incidence, and mortality in Curacao.

Among Native American women in Alaska aged 15 to 64 years, the prevalence of systemic lupus erythematosus is 280/100 000, which is intermediate between estimates for United States Caucasians and African Americans (140/100 000 and 410/100 000, respectively) (Boyer *et al*. 1991). The Nootka Native Americans in British Colombia have the highest reported prevalence of systemic lupus (500 cases/100 000 population) (Atkins *et al*. 1988), while the Sioux, Crow, and Arapaho exhibited the highest incidence rates of systemic lupus in a survey of 75 Native American peoples (Morton *et al*. 1976). The estimates for the Nootka, Crow, and Arapaho were derived from small populations (2000–3000) and it is likely that the incidence estimate for the Sioux is the most accurate (Hochberg 1990) because they were the most numerous group studied (population = 30 000).

Black South Africans were over-represented among inpatients with systemic lupus erythematosus in Cape Town (Jessop and Meyers 1973; Fessel 1988). Since admission to hospital with systemic lupus is highly correlated with disease severity, the disproportionate number of Blacks may reflect more severe disease rather than excess risk of lupus. This conclusion in supported by estimates from a central clinic in Johannesburg where the highest prevalence and incidence of systemic lupus was among Asian Indians, with decrements in the frequency among Coloured or mixed-race individuals and Caucasians, and the lowest frequencies in Blacks (Morrison *et al*. 1990).

Higher prevalence rates of systemic lupus erythematosus have been observed among Chinese, Japanese, and Filipinos in Hawaii, and Polynesians in New Zealand, when compared to Caucasians in either locale (Serdula and Rhoads 1979; Hart *et al*. 1983; Catalano and Hoffmeier 1989), but for several reasons we cannot determine whether so-called mongoloid ethnic groups originating in Asia are more susceptible to systemic lupus than are Caucasians. Estimates from China and Japan give rates similar to those computed in Hawaii but there were no local Caucasians available for comparison in those countries. Furthermore, comparisons of international rates among Caucasians also reveal significant variability (Hochberg 1990). The application of similar methods (Hochberg 1990) and an assessment of racial heterogeneity (Fessel 1988) are necessary to determine whether these ethnic groups exhibit a significant predisposition to systemic lupus. Prevalence and incidence estimates appear in Table 11.

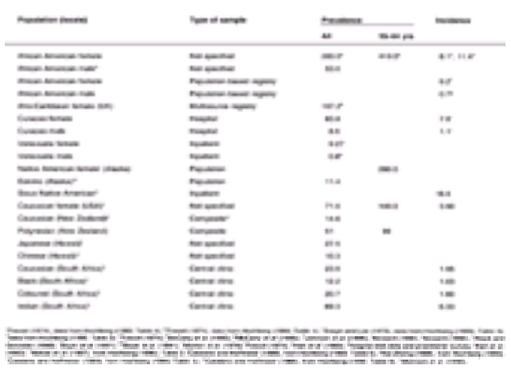

Table 11 Prevalence (cases/100 000) and incidence (new cases/100 000 per year) of systemic lupus

Clinical and laboratory manifestations

The ratio of females to males with systemic lupus erythematosus in the Unites States is 8–10:1 (Siegel and Lee 1973; Fessel 1974) and approaches 12:1 in Venezuela (Abadi and Gonzalez 1990). Case series in Latin America may indicate higher female to male ratios than among United States Caucasians (Alarcon 1986). Populations of black African descent in Jamaica and the United States demonstrate an earlier age of onset than Caucasians (Wilson and Hughes 1979; Ballou *et al*. 1982; Hochberg *et al*. 1985; Ward and Studenski 1990; Smikle *et al*. 1995), more frequent and more severe renal involvement, and greater mortalty (Harris *et al*. 1989; Williams *et al*. 1990; Smikle *et al*. 1995) Earlier age of onset is associated with HLA-DR8 in African Americans (Reveille *et al*. 1989). Among African Americans, discoid lupus (Hochberg *et al*. 1985; Ward and Studenski 1990), lupus pneumonitis, serositis, nephritis, hypocomplementaemia, hyperglobulinaemia (Ballou *et al*. 1982; Hochberg *et al*. 1985) and anti-Sm and antiribonucleoprotein (Ward and Studenski 1990) are significantly more common than among United States Caucasians, while photosensitivity is significantly less frequent (Hochberg *et al*. 1985; Ward and Studenski 1990). Photosensitivity occurs with a similar frequency among African Americans residing in a temperate climate and Jamaicans who are exposed to a subtropical climate. Interestingly, photosensitivity is twice as common in black South Africans who also reside in a temperate zone as among African Americans. The propensity for renal involvement in Afro-Caribbeans is best exemplified by the cohort analysis in Curacao. Lupus nephritis occurred at some time during the follow-up period in 78 per cent of patients (Figure 3) and was associated with greater mortality (Nossent 1993a). When multiple prognostic variables were examined, the SLEDAI score which incorporates data on active renal disease was more powerful than the variable for renal involvement alone as a predictor of mortality (Nossent 1993b). The frequencies of clinical and laboratory features of systemic lupus erythematosus in African American, Jamaican, and black South African and Zimbabwean samples are listed in Table 12 (Wilson and Hughes 1979; Hochberg *et al*. 1985; Taylor and Stein 1986; Dessein *et al*. 1988; Morrison *et al*. 1990; Ward and Studenski 1990; Nossent 1993b; Smikle *et al*. 1995).

Seronegative spondylarthropathies

Definition

The seronegative spondylarthropathies are a group of chronic rheumatic diseases characterized by variable combinations of asymmetrical peripheral arthritis, enthesopathy, involvement of the axial skeleton, mucocutaneous symptoms, higher than expected frequencies of the *HLA-B27* allele, and the absence of rheumatoid factor. Ankylosing spondylitis, Reiter's syndrome/'reactive arthritis', psoriatic arthritis/spondylitis, and inflammatory bowel disease-associated spondylitis are included within the spondylarthropathy category. Also to be included are syndromes that have several features of spondylarthropathies but do not meet the criteria for any one. The term undifferentiated spond(lyo)arthropathy has been designated for these conditions (Boyer *et al*. 1988).

The Rome criteria (Kellgren 1962) and the New York criteria (Bennett and Wood 1968) have been developed to assess the frequency of ankylosing spondylitis in populations. The Rome criteria are more suited to field studies since they do not require radiographs to make the diagnosis of definite ankylosing spondylitis. The criteria for Reiter's syndrome (Willkens *et al*. 1981) and the undifferentiated spondylarthropathies (Boyer *et al*. 1988) have not been used as extensively as those for ankylosing spondylitis. Also problematical is the relation of sacroiliitis to the groups of spondylarthropathy. Is asymptomatic sacroiliitis distinct from clinical spondylarthropathy or does it represent one end of the spectrum of spondylarthropathic disease expression?

Occurrence

Prevalence estimates for spondylarthropathies for several Native American and Eskimo groups and the Chinese (Morse *et al*. 1980; Beasley *et al*. 1983; Oen *et al*. 1986; Boyer *et al*. 1988; Boyer *et al*. 1990; Boyer *et al*. 1991) appear in Table 13. HLA-B27 and spondylarthropathies occur at higher frequencies in several Native American groups than in Caucasians, with the highest recorded rates among the Haida in Canada. The published criteria for Reiter's syndrome were not used in the Navajo (the study preceded the publication of the criteria) nor in one of the Inuit studies, so the accuracy and comparability of these estimates is uncertain.

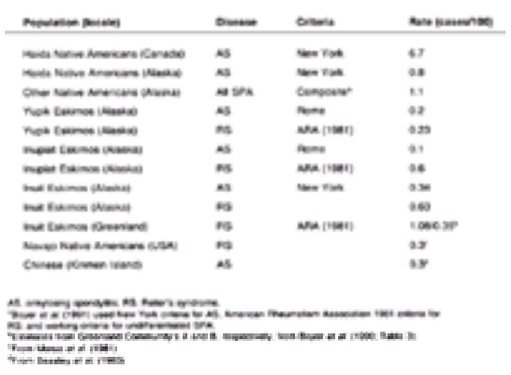

Table 13 Prevalence of seronegative spondylarthropathies (SPA)

In sharp contrast to the Native American groups, spondylarthropathy is diagnosed infrequently in African Americans and black Africans (Baum and Ziff 1971). The frequency of spondylarthropathies in African Americans is not known. The ratio of Caucasians to African Americans with ankylosing spondylitis (range 20:1–6.5:1) admitted to United States Veterans' hospitals serves as an indirect estimate of the prevalence of ankylosing spondylitis in African Americans (Baum and Ziff 1971). The rarity of spondylarthropathies in West Africans, who are racially heterogeneous and are one of the source populations for African Americans, has been attributed to the low frequency of HLA-B27. For example, the *HLA-B*2703* allele has been found in Gambians but ankylosing spondylitis has not been observed (Hill *et al*. 1991). Because of the low overall frequency of HLA-B27 (2.6 per cent) in Gambians, it is possible that one might not see cases of ankylosing spondylitis since only a proportion of HLA-B27-positive individuals develop ankylosing spondylitis. Alternatively, the absence of ankylosing spondylitis in a population with HLA-B27 may indicate the absence of environmental factors that interact with HLA-B27 to trigger spondylarthropathies, or that the HLA-B27 molecules in the population do not confer susceptibility to spondylarthropathies (Hill *et al*. 1991). In support of this latter theory, *HLA-B*2703* differs from other *B27* alleles at amino acid position 59 in the a_1-domain. This observation may explain the results of experiments with alloreactive T-cell clones with this allele (Calvo *et al*. 1990) and may indicate that peptide binding for *HLA-B*2703* is different from other B27 subtypes (Woodrow 1991). HLA-B27 frequencies in normal individuals and those with ankylosing spondylitis appear in Table 14.

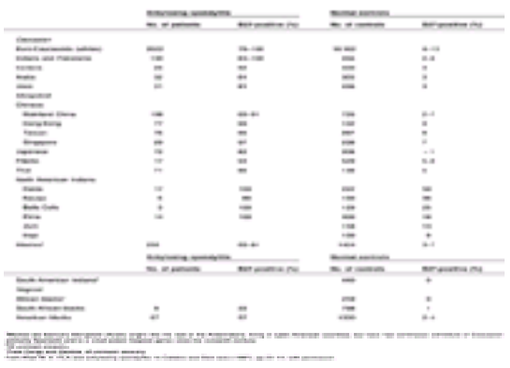

Table 14 HLA-B27 frequency in caucasoid, mongoloid, and negroid populations

Distribution of spondylarthropathy subsets and sex ratios

The relative frequencies of the spondylarthropathy subtypes vary within and between racial groups. As shown in Table 15, ankylosing spondylitis is the predominant spondylarthropathy in Caucasians of Northern European descent (Edmunds *et al*. 1991). Equal frequencies of ankylosing spondylitis and Reiter's syndrome are seen in Alaskan Native Americans and Eskimos (Boyer *et al*. 1990, 1991) and the Shona cultural group in Zimbabwe (Stein *et al*. 1990). Cases of ankylosing spondylitis comprise only 11 per cent of spondylarthropathies among the Alaskan Inuit, where the frequencies of Reiter's syndrome and undifferentiated spondylarthropathy are equal. With the exception of Native Americans in Alaska (Reiter's syndrome and undifferentiated spondylarthropathies are more common in females), males outnumber females with spondylarthropathies (Table 15).

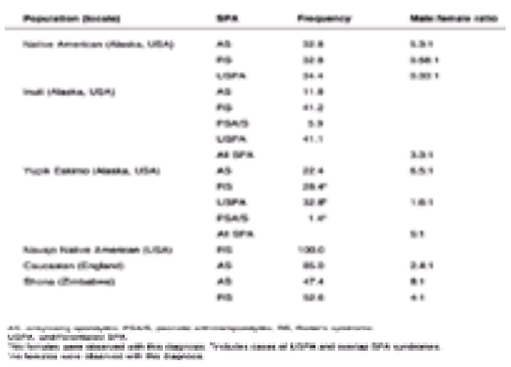

Table 15 Relative frequencies (per cent) of spondylarthropathy (SPA) subsets and sex ratios in several populations

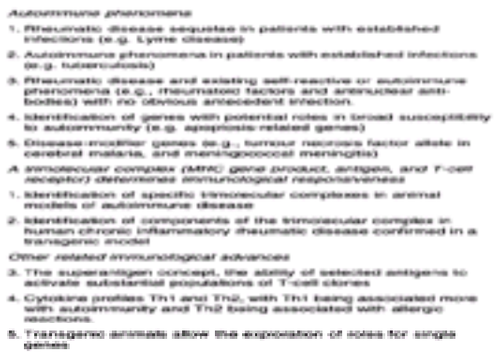
5.2 Nosology of the chronic inflammatory rheumatic diseases

Patricia Woo and David N. Glass

Because the causes and pathological mechanisms of the various chronic inflammatory rheumatic diseases are incompletely understood, their classification has traditionally relied on their clinical evolution. Synovitis, a feature of many rheumatic diseases, is not helpful in differentiating between them; it is so common a response to different stimuli that it does not necessarily signal the presence of any given disease. However, features such as the pattern of arthritis (symmetrical or asymmetrical), age at onset, and presence or absence of systemic features, including specific organ involvement, may be used for classification criteria. In juvenile chronic arthritis (juvenile rheumatoid arthritis in North America), for example, the number of joints involved during the first 3 months of illness is an important element in classification (Brewer *et al*. 1977). Aided by the development of a few supportive but generally non-specific laboratory tests, investigators have subdivided the chronic inflammatory rheumatic illnesses in a manner that has proved to be of practical help in patient management. This approach is not so useful in the planning of clinical and laboratory-based investigations, nor in the exchange of information between investigators and clinicians. It necessitates the considerable use of exclusions based on the absence of the development of other diseases. The proper classification of a group of patients can take many years to accomplish as their individual diseases evolve.

Advances in a variety of disciplines, both clinical and experimental, have greatly improved our understanding of the immune response and of relations between infection, inflammation, and autoimmunity (Table 1). This new information can be used to classify the chronic inflammatory rheumatic diseases using a mechanistic/pathological approach (Vaughan 1989).



Autoimmune phenomena

1. Rheumatic disease sequelae in patients with established infections (e.g. Lyme disease)
2. Autoimmune phenomena in patients with established infections (e.g. tuberculosis)
3. Rheumatic disease and existing self-reactive or autoimmune phenomena (e.g., rheumatoid factors and antinuclear antibodies) with no obvious antecedent infection
4. Identification of genes with potential roles in broad susceptibility to autoimmunity (e.g. apoptosis related genes)
5. Disease-modifier genes (e.g., tumour necrosis factor allele in cerebral malaria, and meningococcal meningitis)

A trimolecular complex (MHC gene product, antigen, and T-cell receptor) determines immunological responsiveness

1. Identification of specific trimolecular complexes in animal models of autoimmune disease
2. Identification of components of the trimolecular complex in human chronic inflammatory rheumatic disease confirmed in a transgenic model

Other related immunological advances

3. The superantigen concept, the ability of selected antigens to activate substantial populations of T-cell clones
4. Cytokine profiles Th1 and Th2, with Th1 being associated more with autoimmunity and Th2 being associated with allergic reactions.
5. Transgenic animals allow the exploration of roles for single genes.

Table 1 Advances in knowledge on which the hypothesis for infectious–immunological causes is based

Relating chronic inflammatory rheumatic diseases to infection, immune responses, and autoimmunity

It has become evident, especially within the last decade, that a few infections may lead directly to chronic rheumatic disease. Prominent examples include Lyme arthritis (an infection with the spirochaete *Borrelia burgdorferi*), rheumatic fever with group A b-haemolytic streptococcal infection, and Reiter's syndrome, which is associated with a range of gastrointestinal and urogenital infections that are primarily bacterial.

Immunological phenomena, long believed to be involved in most chronic inflammatory rheumatic diseases, are now better documented and understood. Immunologically competent cells such as lymphocytes and plasma cells are universally present in diseased tissues, and immune complexes are often formed locally and within the vascular compartment. The local release of cytokines involved in generating these immune responses is important, as is the profile of cytokines produced (Th1/Th2 from CD4 cells, and Tc1 and Tc2 from CD8 cells). This profile may well reflect the nature of the pathogen and the route of immunization, as well as host factors (Marrack and Kappler 1994; Simon *et al*. 1994; Mossman and Sad 1996). It is also noteworthy that the selective inhibition of cytokines can alter the manifestations of the disease: for example, treatment with antibody to tumour necrosis factor-a in rheumatoid arthritis (Elliott *et al*. 1993).

Many of the immunological changes are autoimmune (self-reactive) in nature. At about the same time as rheumatoid factors and antinuclear antibodies with a wide range of specificities were discovered in patients with chronic rheumatic diseases (e.g., rheumatoid arthritis and systemic lupus erythematosus), similar autoimmune phenomena were noted in individuals with established, non-rheumatic, infectious diseases (e.g., chronic forms of bacterial endocarditis and leprosy). This discovery supported the notion that the autoimmune phenomena in patients with chronic rheumatic diseases may have originated from an infectious process.

Meanwhile, understanding of the basic mechanisms of the immune response has greatly improved. Particularly important is the concept of a central role for a trimolecular complex consisting of a T-cell receptor responsive to antigen presentation by proteins of the major histocompatibility complex (**MHC**) genes, which determine the host's response (Davis and Bjorkman 1988). This finding implies that at least two immunological components, HLA and T-cell receptors, underlie susceptibility to many autoimmune rheumatic diseases.

Substantial progress has been made in evaluating this trimolecular complex in animal models of autoimmune disease, most notably the model of allergic encephalomyelitis in which the specific determinants (molecular binding sites) on the antigen (myelin basic protein), the MHC genes, and T-cell receptor have all been identified (Acha-Orbea *et al*. 1988). The component of the trimolecular complex most extensively studied in human disease is HLA (Todd *et al*. 1988; see also Chapter 3.3). The direct role of at least one MHC gene (*HLA-B27*) in the spondylarthropathies has been elegantly confirmed in a transgenic model using rats raised in germ-free environments (Hammer *et al*. 1990; Taurog *et al*. 1994). Because certain HLA genes are associated with specific rheumatic diseases, HLA typing of patients can be used to aid the classification of their disease.

The study of the T-cell receptor in human autoimmune disease is just beginning, and is likely to prove complex. A limited T-cell repertoire has been documented in rheumatoid arthritis and T-cell receptor genes have been associated with the disease (McDermott *et al*. 1995). The role of the thymus in regulating the T-cell repertoire (and hence the formation of trimolecular complexes) has also been recognized; further study of this process will clarify the roles that the components of the trimolecular complex have in autoimmune disease. Expansion of certain V_b-chains of the T-cell receptor can be induced peripherally by superantigens. These are thought to make external contacts with the MHC class II molecule and the V_b portion of a T-cell receptor, thereby stimulating entire families of T cells. Bacterial superantigens in man are heat-resistant enterotoxins, such as *Staphylococcus aureus* enterotoxin, causing toxic-shock syndromes and septic arthritis as a result of the production of large quantities of inflammatory cytokines (Bremell and Tarkowski 1995). Murine mycoplasma arthritides superantigen (MAM) can trigger and exacerbate murine collagen-induced arthritis, thus providing a model for autoimmunity (Cole and Griffiths 1993).

Another mechanism of 'disturbance' in the T-cell repertoire is the alteration in programmed death (apoptosis) of cells of the immune system. In three strains of lupus-prone mice there are spontaneous mutations of Fas apoptosis antigen, its receptor or its ligand, leading to persistence of autoreactive cells (reviewed in Mountz *et al*. 1994). Fas mutations have been described in human lymphoproliferative syndrome, which children also have features of autoimmune haemolytic anaemia (Fisher *et al*. 1995; Rieux-Laucat *et al*. 1995). In human systemic lupus erythematosus, expression of Fas antigen and Bcl-2 have been studied, but there is no consensus as yet as to their potential roles in immunopathogenesis.

These conceptual advances, discussed more fully in earlier chapters, suggest that many of the chronic rheumatic diseases have infectious causes with complicating immunological responses. In devising a classification that proposes or infers infectious causes complicated by a range of immune responses, several other factors need to be taken into account. While a substantial amount is known about the HLA genes and infectious agents in some arthritides, there is a paucity of knowledge concerning T-cell receptor genes and general autoimmune-predisposing genes. Any classification based on these variables must, therefore, be considered tentative. During the evolution of the disease, the immune response may be directed initially at antigen-recognition sites (epitopes) on the intact infecting organism. Later, antigenic fragments of the organism may persist, providing continuing immunopathological stimulation; the immune response may also become directed against self-antigens. Thus any classification must recognize that clinical stages of the disease may change as a result of changing immune response. Routes of inoculation as well as host genetic factors are responsible for determining whether the immune response will become chronic and the disease progressive. Because the evolution of disease, from a straightforward infection to a complex series of immune responses associated with a range of pathologies, has much to do with genetically defined host variables, genetic studies of patients can help the process of disease classification. The above considerations make it possible to devise classifications based on infectious/immunological causes, even when the likelihood of infectious processes can only be inferred from parallel circumstances in which the presence of infection is well established.

Classification of disease

For the purposes of this discussion, the chronic inflammatory rheumatic diseases can be divided into overlapping categories (see Table 2). The first category comprises the relatively rare diseases in which the products of infection-induced inflammation directly cause tissue damage. The harmful products of inflammation include proteolytic enzymes that are associated with the degradation of synovium and cartilage. Such diseases usually take an acute rather than a chronic course. Pyogenic arthritis, in which the products of the inflammatory process cause the destruction of substantial amounts of synovial and cartilaginous tissue, is an example. Other arthropathies caused by infectious agents include those of rubella and parvovirus, mycobacterial and mycoplasma infections.

Table 2 Categories in the classification of chronic inflammatory rheumatic diseases

Because pyogenic organisms do not normally seed to joints, unusual conditions conducive to rheumatic disease must be present. Local injury or disease may make individual joints especially vulnerable and systemic factors may affect the host's susceptibility to a given pathogen. Some form of mechanical problem in a joint, such as osteoarthritis, is common among these patients. Patients with rheumatoid arthritis, for example, have a greater risk of infection than those with osteoarthritis. Their disease, rheumatoid arthritis, is associated with impaired immune responses, which treatment may aggravate. In addition, arthroplasties carry a particular risk of infection, especially in immunocompromised patients. Therefore, in the patient with rheumatoid arthritis who undergoes an arthroplasty, both local and systemic factors may favour the development of bacterial arthritis (Goldenberg and Reed 1985). Systemic illnesses, for example diabetes mellitus, appear to confer a greater susceptibility (see Chapter 5.3.1). The majority of individuals with septic joints have at least one of these predisposing factors. Less common, but more specific, predisposing factors are host difficulties in handling infectious organisms, as in complement deficiency, hypogammaglobulinaemia, and deficiency of lymphocyte function antigen 1 (Atkinson 1995).

In the second category of rheumatic diseases an immune response directed primarily against a pathogenic organism or fragments of that organism causes inflammation that results in disease. Much of the tissue injury results from immune complexes. Cross-reactivity to self-antigens is not critical. Some rheumatic syndromes associated with streptococcal infection and with hepatitis B virus are typical of this category of illness. The intact infecting organism may sometimes be isolated from the involved joint and provide a source of initial tissue damage, as in category 1, but in other instances the organisms cannot be isolated. In these conditions an immune response directed specifically at antigenic fragments of the organism is likely to be responsible for some components of the pathology of the disease. Such organism-specific responses are well documented. For example, in post-streptococcal syndromes such as glomerulonephritis and vasculitis, immune responses in the form of immune-complex deposition contribute to the inflammatory process. Similarly, in hepatitis syndromes the increased amounts of immune complexes and reduced amounts of complement argue for their inclusion in the second category of diseases, as may the presence of hepatitis antigen in the immune complexes of some patients with vasculitis. Even if persistence of the intact organism is not essential, antigenic fragments may be important in generating a chronic immune response.

Characteristics of the host that affect his or her susceptibility to this category of disease are, at least as presently understood, not organism-specific, and have been identified in a small proportion of individuals at risk. They include some complement, immunoglobulin, and T-cell receptor deficiencies as well as defects of immune-complex clearance.

In a third category of disease, components of the first and second are present, that is, infection causes damage directly and results in an organism-specific immune response. In addition, autoimmunity develops in the form of reactivity with self-antigens including HLA. The best-documented example is probably rheumatic fever, in which the immune response to streptococcal infection becomes directed against host tissue antigens in cardiac muscle (see Chapter 5.3.12). Other diseases likely to be included are the spondylarthropathies, in which it is probable that initial infections with Gram-negative organisms and their plasmids are followed by an immune response directed against the self-antigen HLA-B27 in addition to components of the organisms involved; that is, molecular mimicry (Granfors *et al*. 1989) where the two antigens have common epitopes. We suggest that this theory of the development of HLA-B27-associated rheumatic disease will serve as a model for diseases in which infection is suspected as an initiating event but the organisms are as yet unknown (see below). Explanations other than cross-reactivity or molecular mimicry for the HLA-B27 association with spondylarthropathies are conceivable (Sieper and Braun 1995). Because certain class I or class II HLA genes are associated with each disease in the third category, people who do not carry the implicated gene are not susceptible to the diseases. The particular genes are necessary for the disease to develop but probably do not initiate the disease process.

In an extension of this category are diseases in which infectious agents have not been identified but a strong, autoimmune disease phenotype probably results from the infectious process. The more common chronic inflammatory rheumatic diseases, including rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis and polymyositis, fall into this category. The major laboratory findings in patients in this fourth category are immune responses, and most of the antigenic determinants identified to date are self-antigens. The earliest documented examples of these responses were rheumatoid factors found in rheumatoid arthritis and antinuclear antibodies found in systemic lupus erythematosus. The antibodies may contribute to the pathogenesis, as in congenital complete heart block in the new-born of some patients with systemic lupus erythematosus (Buyon and Winchester 1990). Their presence in these patients, given the overall hypothesis that many of these diseases are infections, has parallels with the presence of the same autoantibodies in patients with various chronic inflammatory infections such as tuberculosis, leprosy, and bacterial endocarditis (in which rheumatoid factors are particularly prominent).

Efforts to identify the infectious agents believed to precipitate these chronic rheumatic diseases have continued to be made. Candidate organisms include Epstein–Barr virus and *Proteus mirabilis* in rheumatoid arthritis, and coxsackie virus in dermatomyositis. It is likely, however, that several agents can precipitate the disease, given the same genetic susceptibility. The host's MHC gene products are important in pathogenesis. Certain HLA class I and class II genes are associated with these diseases, and MHC class III genes may be involved in systemic lupus erythematosus in some populations. Whether the HLA genes are themselves directly involved or serve as markers for MHC non-HLA genes involved in the pathogenesis is unknown. Additional MHC-region genes have been identified: these include those coding for tumour necrosis factors, heat-shock protein, and intracellular transporter genes, any of which may be critical to the disease (see Chapter 4.7).

The concept of a trimolecular complex, discussed above, indicates a role for T-cell receptor genes. T-cell receptors have been implicated in the collagen type-II model of an autoimmune-induced stimulus (Banerjee *et al*. 1988) and in other forms of autoimmunity induced in animals (Acha-Orbea *et al*. 1988). Currently, however, very few T-cell receptor genes have been associated with human disease, their analysis being more complex than that of HLA.

The identification of defects in apoptotic pathways and their association with autoimmunity in both experimental models and in man adds to the importance of the host element in determining the outcome of an infection in terms of subsequent autoimmunity (Watanabe-Fukunaga *et al*. 1992). It is also noteworthy that single cytokine genes in transgenic animals can create an *in vivo* environment in which arthritis develops (Keffer *et al*. 1991).

Some implications of an infection–immunological classification

Within these broad concepts, an infection would lead to the second and third categories of disease, that is, organism-specific, and then autoimmune responses could develop over time. The occurrence of these diseases in some individuals but not in others needs to be explained. Diseases in categories 2–3 can be regarded as failures of the hosts' initial defence mechanisms. Inherited susceptibility to disease has been suspected for a long time and some of the genetic influences on particular diseases are known, as is clear from the preceding discussion of HLA genes. The multiplicity of genes involved in addition to HLA suggests that autoimmunity is a complex genetic trait, as is the case in insulin-dependent diabetes mellitus (Davies *et al*. 1994). Microsatellite analysis of the human genome and immune models of diabetes mellitus illustrate the complexity of disease-susceptibility genes. It is clear that certain genes are necessary for disease to develop and that others act as 'modifiers,' responsible for the severity of disease, for example the tumour necrosis factor-a $_2$ allele in cerebral malaria (McGuire *et al*. 1994) and meningococcal meningitis (Girrourdin *et al*. 1992). Other unexplored factors are the virulence of the infecting organisms: for example, adhesive properties of bacteria can be involved in determining the outcome of bacterial infections. Exposure to infectious agents when the immune system is developing may be a cause for polyarthritis. For example, recent evidence suggests that an influenza A $_2$ epidemic caused an intrauterine infection that predisposed children to the development of a subtype of juvenile chronic arthritis (Pritchard *et al*. 1988). Such host/pathogen relations need to be investigated for their contributions to the chronic inflammatory rheumatic diseases.

The concept of a primary infectious origin for the chronic rheumatic diseases does not include discussion of other antigens known to generate disease (e.g., procainamide-induced systemic lupus erythematosus). Nevertheless, the infectious concept is applicable to many chronic rheumatic diseases, as well as other chronic (autoimmune) inflammatory diseases affecting other organs systems such as the gastrointestinal and renal tracts Further investigation should be promoted because it can be used to develop testable hypotheses aimed at identifying the types of immune responses, the infecting organisms, and genetic predisposing factors causing the disease. In addition, rationales for new therapeutic strategies are also provided (Table 3).

T-cell receptor immunization V_b17 in rheumatoid arthritis
Induction of oral tolerance (e.g., to collagen II in rheumatoid arthritis)
Use of antibiotics, sulphasalazine/tetracycline therapy in rheumatoid arthritis and spondylarthropathy

Table 3 New therapeutic strategies

5.3.1 Pyogenic arthritis in adults

Marc L. Miller

Septic arthritis caused by pyogenic bacteria is a true medical emergency. Prompt recognition of an infected joint and an immediate start to proper treatment are essential for a good outcome. Despite advances in antimicrobial therapy and in surgical approaches to pyogenic arthritis, the death rate in several large series has ranged up to 10 per cent (Rosenthal *et al*. 1980; Dubost *et al*. 1993), and up to one-third of cases are affected by residual functional impairment, persistent pain, or other complications (Goldenberg and Cohen 1976; Sharp *et al*. 1979; Cooper and Cawley 1986). Therefore, it is important to appreciate the clinical presentations of pyogenic arthritis, underlying risk factors and associated diseases, range of infectious agents, diagnostic techniques, and appropriate medical and surgical treatments.

This chapter will discuss pyogenic bacterial infections in adults only. Paediatric infections will be addressed in Chapter 5.3.2.

Pathophysiology

Bacteria can reach the joint by one of three routes:

1. by haematogenous spread from a distant infected site;
2. by direct penetration through the skin to the joint space;
3. by direct spread from a contiguous infected site.

Haematogenous seeding is by far the most common route for pyogenic joint infection. In the setting of bacteraemia, organisms leave the bloodstream and lodge in the synovium. The synovium is a highly vascular tissue without a limiting basement membrane to block bacterial access to the synovial fluid. However, factors other than the mere presence of bacteria in the bloodstream must be involved as most bacteraemic episodes do not result in septic arthritis and some bacteria that are frequent causes of bacteraemia are rare causes of joint infections. One of these factors is structural changes in the joint. Joints affected by a variety of chronic arthritides (including rheumatoid arthritis, osteoarthritis, Charcot's arthropathy, and gout or pseudogout) and prosthetic joints are at increased risk of pyogenic infections. The presence of synovitis, effusion, granulation tissue, or foreign material increase the likelihood of bacterial colonization (Goldenberg and Reed 1985; Youssef and York 1994).

Characteristics of the infecting organisms are also important. Those organisms that most commonly cause pyogenic arthritis, staphylococci and *Neisseria gonorrhoeae*, have an enhanced ability to adhere to synovial tissue or produce toxins that facilitate colonization (Switalski *et al*. 1993). These organisms are able to infect normal joints in normal hosts. Those organisms with low virulence for joint infection, such as Gram-negative bacilli, typically cause infections in the setting of a structurally abnormal joint or an alteration in host immune defences.

A third contributing factor is alteration in host immunity. This may be due to inherited or congenital immunodeficiency states involving granulocyte function, immunoglobulin production or complement deficiency, or to acquired immunodeficiency due to immunosuppressive therapy or to disease states such as cancer, diabetes, chronic liver disease, or human immunodeficiency virus infection (Rivera *et al*. 1992).

Direct entry of bacteria into the joint space can occur as the result of penetrating trauma, arthrocentesis, arthroscopy, or open surgical procedures such as arthroplasty. The incidence of infection following arthrocentesis is very low, less than 0.06 per cent in two large series (Hollander 1969; Gray *et al*. 1981). The risk of joint infection after arthrocentesis may be increased when an area of cellulitis overlies the joint or in the setting of bacteraemia, in which cases bacteria can be carried by the aspirating needle into the joint space. Persistent drainage from surgical portals should always raise the suspicion of postarthroscopic infection.

Direct spread from an adjacent focus of infection occurs in several clinical settings. Pyogenic arthritis may result from an adjacent osteomyelitis in adults, although this complication is rare, owing to the infrequency of untreated osteomyelitis in the antibiotic era. In adults, but not in children, there is an anastomosis between the metaphyseal and synovial vascular beds allowing direct entry of bacteria from an osseous focus of infection into the joint (Atcheson and Ward 1978). Direct extension of an enteric fistula in inflammatory bowel disease, of a psoas abscess, or of a gluteal abscess in a paraplegic can result in pyogenic arthritis of the hip.

Once infection is established bacteria multiply and spread throughout the synovium and eventually into the synovial fluid. Organisms are phagocytosed by polymorphonuclear leucocytes, resulting in the release of chemotactic factors and activation of complement. Additional phagocytic cells are recruited, resulting in a classic inflammatory reaction. Bacterial products and lysosomal proteolytic enzymes released from leucocytes stimulate the degradation of cartilage. In animal models, the proteoglycan content of cartilage is reduced by 40 per cent within 48 h of the induction of joint infection. Within 2 to 3 weeks, significant loss of collagen develops (Riegels-Nielsen *et al*. 1987). This rapid destruction underscores the importance of prompt detection and initiation of treatment, one aspect of which includes the removal of the products of bacterial and leucocyte degradation by draining the joint. Chronic inflammatory tissue, resembling rheumatoid pannus, that further erodes cartilage and subchondral bone may develop in untreated infections.

Non-gonococcal arthritis

Clinical manifestations

The clinical manifestations, epidemiology, and natural history of gonococcal and non-gonococcal arthritis are sufficiently distinct (Table 1) that infections due to *Neisseria* spp. will be discussed separately.

Gonococcal	Non-gonococcal
Most often affects healthy, sexually active, young adults	Most often affects the very young or very old. Underlying joint or other medical conditions
Females more often than males	Males more often than females
Hip uncommonly affected	Hips involved in 29%
Migratory polyarthralgias common	Polyarthralgias uncommon
Rash, tenosynovitis common	Extra-articular manifestations common
Synovial fluid:	Synovial fluid:
Gram's stain positive, 25%	Gram's stain positive, 50–60%
culture positive, 50%	culture positive, 90%
lactate not elevated	lactate elevated
Rapid response to therapy	Response often slow; may require surgical drainage
Full recovery in most cases	10% mortality; one-third with residual joint damage

Table 1 Distinguishing features of gonococcal and non-gonococcal arthritis

The typical patient with non-gonococcal bacterial arthritis presents with acute onset of pain, swelling, erythema, warmth, and tenderness of the infected joint (Baker and Schumacher 1993). There may be a tense effusion. The patient usually guards the joint against any movement. The severity of pain, tenderness, and swelling is generally greater than in other causes of joint inflammation and should immediately raise the suspicion of infection. Very rarely, patients present with a subacute or even chronic course and a paucity of inflammatory signs. This presentation is more commonly associated with less virulent organisms.

Localization of pain and tenderness may be difficult, and erythema, warmth, and swelling are not detectable in deep-seated joints. For instance, hip infections produce pain deep in the buttock, in the anterior thigh, or even in the knee, while pain from the sacroiliac joint may be referred to the buttock or posterior thigh and may mimic sciatica.

Systemic signs and symptoms of infection are common but not invariably present. In one large series, 90 per cent of patients with acute bacterial arthritis presented with a temperature of at least 37.8°C (Goldenberg and Cohen 1976); in another, fever was found in only 56 per cent (Rosenthal *et al*. 1980). Marked fever (greater than 39°C) was found in two series in 25 and 39 per cent, respectively (Newman 1976; Cooper and Cawley 1986). Therefore, while the presence of high fever in a patient with an acute arthritis should always raise the suspicion of a pyogenic infection, the absence of fever does not preclude the diagnosis.

The patient may also show signs and symptoms of an infection at a distant site from the joint, such as the skin, respiratory tract, or urinary tract.

While any joint is potentially susceptible to pyogenic infection, the knee is the site in more than half of cases and the hip in another 20 per cent. The remainder of cases is divided largely among the shoulder, wrist, elbow, and ankle (Manshady *et al*. 1980; Rosenthal *et al*. 1980; Cooper and Cawley 1986). Rarely the small joints of the fingers and toes or the axial joints (sacroiliac, sternoclavicular, sternomanubrial, or pubic symphysis) are involved. Typically, pyogenic infections cause monarticular arthritis, but in approximately 20 per cent of cases bacteraemia can lead to polyarticular involvement (Epstein *et al*. 1986; Dubost *et al*. 1993). Certainly a polyarticular presentation should not deter a search for infection in a patient with acute onset of illness, signs of toxicity, or a distant site of infection.

Laboratory studies

Patients with pyogenic arthritis commonly have non-specific laboratory signs of acute infection and inflammation. About half will have a peripheral leucocyte count greater than 10 000/mm^3. The erythrocyte sedimentation rate is generally elevated. In one series, the erythrocyte sedimentation rate was greater than 20 mm/h in 117 of 118 cases of pyogenic arthritis. In 76 of these, the rate was greater than 50 mm/h and in 30 cases greater than 100 mm/h (Newman 1976). Similarly, other acute phase reactants such as C-reactive protein may be elevated. The response of the acute phase reactants parallels the course of the infection and is a good indicator of response to therapy. Blood cultures are positive in about one-third of cases (Rosenthal *et al*. 1980).

The critical test in the evaluation of a patient with suspected pyogenic arthritis is the analysis of synovial fluid. The aspiration of frank pus immediately suggests bacterial infection, although joint fluid in chylous effusions associated with long-standing rheumatoid arthritis or subchondral fractures may have a similar appearance. Effusions due to gout or pseudogout can also at times appear grossly purulent.

The leucocyte count in synovial fluid is greater than 50 000/mm ^{3} in most cases and often exceeds 100 000/mm^3 (Krey and Bailen 1979). The differential count will show greater than 90 per cent polymorphonuclear leucocytes. When the count is less than 50 000/mm ^{3}, repeat aspiration in the next 24 to 48 h will show an increase to over that figure. Where the infection has been partially treated with antibiotics before aspiration, the count may never exceed 50 000/mm ^{3}. In about half of cases, the glucose in synovial fluid will be decreased to 20 to 40 per cent of that of the simultaneous serum glucose. However, similarly low levels are commonly found in rheumatoid effusions, which diminishes the differential diagnostic value of the synovial fluid glucose in rheumatoid patients (Goldenberg and Reed 1985). A markedly elevated level of lactic acid in the synovial fluid is associated with non-gonococcal pyogenic arthritis but not with non-infectious causes of inflammatory effusions (Riordan *et al*. 1982). The concentration of lactic acid may be of diagnostic help before cultures of synovial fluid are available or in cases of partially treated infections in which synovial fluid cultures remain negative.

Gram's stain of synovial fluid is positive in 50 to 65 per cent of all cases of non-gonococcal arthritis, approaching 75 per cent in staphylococcal infections but only about 50 per cent in infections caused by Gram-negative bacilli (Goldenberg and Cohen 1976; Newman 1976). Bacteria can be cultured from synovial fluid in nearly all cases of non-gonococcal arthritis. The occasional negative results can be attributed to preceding antibiotic therapy, poor handling of specimens, failure to culture for anaerobic organisms, or theoretically to the localization of organisms to the synovium rather than the fluid during the very early stage of infection. The yield from culture of synovial fluid may be improved by inoculating large volumes of it directly into bottles of blood culture media (Von Essen and Holtta 1986).

Imaging studies

Plain radiographs have limited value in evaluation of the suspected infected joint. Most commonly only periarticular soft-tissue swelling or a joint effusion will be present. The primary value of the radiograph is to demonstrate signs of other causes of acute pain and swelling, such as fracture, chondrocalcinosis, gouty erosions, or avascular necrosis, and to look for underlying chronic joint disease or accompanying osteomyelitis. Plain radiographs can be used to assess the extent of joint damage and cartilage loss in cases in which the diagnosis and treatment of infection have been delayed. The radiographic changes indicative of joint damage may lag behind the clinical signs of infection and may continue to appear even after there has been a response to therapy. Conventional tomography may better demonstrate early bone destruction, particularly in hard-to-visualize joints such as the sternoclavicular.

Except in a few clinical situations, radionuclide scanning also has limited value in the assessment of the suspected infected joint. While pyogenic arthritis of peripheral joints is readily detectable on physical examination, infections of the axial joints are often difficult to localize from the patient's description or by physical examination. In these cases, a technetium-99m bone scan can demonstrate increased activity that suggests involvement of a deep-seated joint (Gordon and Kabins 1980; Vyskocil *et al*. 1991). For example, in the evaluation of the patient with signs of infection and complaining of diffuse low back or buttock pain, the technetium scan may identify involvement of the sacroiliac joint. This may help to differentiate joint sepsis from intra-abdominal or retroperitoneal abscess, or from osteomyelitis of the pelvis. The technetium bone scan, however, does not differentiate between infectious and non-infectious inflammatory arthritis and therefore cannot distinguish an infected sacroiliac joint from sacroiliitis due to Reiter's syndrome, or an infected from an uninfected but actively inflamed peripheral joint in rheumatoid arthritis.

The accuracy of detecting joint infections with radionuclide scanning can be improved by scanning with either gallium-67- or indium-111-labelled leucocytes. Gallium scans used in sequence after a positive technetium scan may increase the specificity of technetium scanning. The gallium scan may become positive earlier than the technetium in poorly vascularized joints such as the sacroiliac or sternoclavicular, making it a useful test to consider even when the technetium scan is negative (Lopez-Longo *et al*. 1987). False-positive gallium scans have been reported in rheumatoid arthritis, thereby limiting the usefulness of this technique in evaluating the possibility of joint sepsis in that condition. Gallium and indium scans are of most value in suspected infection of a prosthetic joint, where they may distinguish an infected from an uninfected, painful, loose prosthesis. Although indium scanning does require the additional steps of removing, labelling, and then reinfusing the patient's leucocytes, it is more sensitive and specific than sequential technetium/gallium scanning and results are available at 24 h rather than 72 h as with gallium scanning (Merkel *et al*. 1985).

Conventional fluoroscopy or computed tomographic scanning can be of value in guiding diagnostic aspiration of deep-seated joints such as the hip or sacroiliac joint. While computed tomography and magnetic resonance imaging are seldom necessary in the evaluation of septic arthritis, these imaging techniques can be of great value when an infected joint fails to respond as expected to appropriate treatment because of adjacent osteomyelitis or a persistent collection of undrained pus. These techniques can also demonstrate soft tissue masses adjacent to axial joints, so indicating the need for abscess drainage (Wohlgethan *et al*. 1988).

Bacteriology

A wide variety of organisms has been cultured from infected joints (Table 2). *Staphylococcus aureus* is by far the most common cause of non-gonococcal arthritis, accounting for 40 to 50 per cent of cases in adults. *Staph. epidermis* is found in 10 to 15 per cent, various streptococcal species in 20 per cent, and various Gram-negative bacilli in 15 per cent of cases. The incidence of pneumococcal joint infections has been drastically reduced in the antibiotic era, reflecting the more effective treatment of pneumococcal infections of the respiratory tract and the decreased incidence of pneumococcal bacteraemia. *Haemophilus influenzae*, the organism most commonly found in pyogenic infections in children under the age of 2 years, accounts for only about 2 per cent of cases in adults (Goldenberg and Cohen 1976; Newman 1976; Sharp *et al*. 1979; Rosenthal *et al*. 1980; Goldenberg and Reed 1985; Cooper and Cawley 1986; Mikhail and Alarcon 1993; Youssef and York 1994). Anaerobic infections, often polymicrobial, occur in about 5 per cent of cases. Case reports have documented the unusual occurrence of arthritis due to *Listeria monocytogenes, Streptobacillus moniliformis*, and *Pasteurella multocida*. While *Staph. aureus* is the most common cause of both monarticular and polyarticular presentations, streptococci and *H. influenzae* are more frequently associated with polyarticular infections than would be expected by the overall incidence of joint infections with these organisms (Epstein *et al*. 1986; Dubost *et al*. 1993).

Organism	Percentage of cases
Staphylococcus	
aureus	40–50
epidermis	10–15
Streptococcal species	20
Gram-negative bacteria	15
S. pneumoniae	2
H. influenzae	2
Anaerobes	5

Table 2 Infecting organisms in non-gonococcal arthritis in adults

A variety of streptococcal species, most commonly group A b-haemolytic, but also group B, group C, group G, enterococcus, *Streptococcus milleri* and *Strep. viridans* have been found in infected joints. Group A streptococci are common inhabitants of the skin and respiratory tract and can seed the joints of normal hosts. Group B streptococci, usually associated with neonatal and puerperal sepsis, have been a cause of adult pyogenic arthritis, particularly in patients with prosthetic joints or predisposing medical conditions such as diabetes mellitus. About 40 per cent of reported cases have been diabetics, in whom the death rate was about 15 to 20 per cent. Group B streptococcal joint infections have been associated with significant complications in the form of residual damage and limited range of movement (Small *et al*. 1984; Pischel *et al*. 1985). Similarly, group C and G streptococcal infections appear to affect patients with underlying illnesses, and have been polyarticular in 30 per cent of reported cases (Ike 1990; Burhert and Watanakunakorn 1991). Enterococci are not usually reported as joint pathogens, despite their frequent association with infections of the biliary and urinary tracts, and with bacteraemia. Affected patients generally have either predisposing conditions or pre-existing joint disease.

H. influenzae is an encapsulated organism requiring opsonizing antibody and an effective reticuloendothelial system for optimal clearance. Patients with *H. influenzae* arthritis therefore often have predisposing conditions such as alcoholism, hypogammaglobulinaemia, multiple myeloma, systemic lupus erythematosus, or asplenia. Extra-articular *H. influenzae* infections are frequent, including sinusitis, pneumonia, meningitis, pharyngitis, or cellulitis. Almost half of reported cases have been polyarticular (Borenstein and Simon 1986).

Gram-negative bacilli have emerged as a more frequent cause of septic arthritis in the past two decades. This probably reflects the prolonged survival of patients with serious medical illnesses, the increased use of immunosuppressive drugs, and the increase in intravenous drug abuse. Gram-negative joint infections generally occur in two distinct clinical settings. The first involves elderly patients with underlying systemic illnesses or pre-existing joint disease. Here the presentation is usually abrupt, with frequent fevers and rigors. The most common organism is *Escherichia coli* (Newman *et al*. 1988). Also reported with some frequency are *Pseudomonas aeruginosa, Proteus mirabilis, Serratia marcesens*, and *Klebsiella* '*pneumoniae*'. Scattered case reports document rare joint infections with a number of Gram-negative organisms including *Aeromonas hydrophila, Acinetobacter* spp., *Arizona hinshawii, Eikenella corrodens, Enterobacter* spp., and *Kingella kingae*; these reports indicate the importance of bacteriological identification by culture in patients with suspected Gram-negative infections.

The second group consists of patients with a history of intravenous drug abuse. These patients tend to be younger and to have no pre-existing joint disease. Their presentation is often more insidious, with a longer duration of illness before diagnosis (Bayer *et al*. 1977; Chandrasekar and Narula 1986). There is a predilection for the axial joints and periarticular soft-tissue abscess or osteomyelitis are frequently encountered. *Ps. aeruginosa* and *Serr. 'marcesens*' have been reported in increased frequency in this group in some but not all series from large urban centres.

Salmonellal arthritis is a rare complication of salmonellosis. *Salmonella typhimurium* is the most common serotype cultured from joints, followed by *Sal. choleraesuis*. Patients with systemic lupus erythematosus or sickle-cell anaemia are at increased risk for salmonella arthritis because the chronic salmonella carrier state is more common in these conditions. This is the result of impaired clearance by the reticuloendothelial system, owing to inhibition of Fc receptors by circulating immune complexes in systemic lupus and to the functional hyposplenism that can accompany either condition. The presentation is usually monarticular but polyarticular cases have been reported. In many cases there is no history of a preceding diarrhoeal illness. The diagnosis of salmonellal arthritis may not be suspected after arthrocentesis because the synovial fluid is often non-purulent, and described as turbid, serosanguinous, or straw-coloured, despite a positive culture from it (Cohen *et al*. 1987; Medina *et al*. 1989).

Rat-bite fever caused by *Streptobacillus moniliformis*, a pleomorphic Gram-negative organism, presents as an acute illness with fever, rash, vomiting, and arthritis that is usually polyarticular. The infection is acquired from bites or close contact with infected rodents or from ingestion of contaminated food or beverages. When articular symptoms are prominent the clinical presentation may be confused with rheumatoid arthritis, adult Still's disease, systemic lupus, or gonococcaemia. Joint effusions can be either sterile and inflammatory or purulent with positive cultures of synovial fluid. Isolation and identification of the organism is difficult, owing to its variable staining characteristics and specific growth requirements (Holroyd *et al*. 1988).

Past. multocida is a small, Gram-negative coccobacillus that causes joint infections after animal bites, most commonly from cats or dogs. In approximately one-third of patients there is no history of a bite. Arthritis with this organism has been reported in both normal hosts and in patients with rheumatoid arthritis, chronic liver disease, or immunosuppression (Weber *et al*. 1984).

L. monocytogenes infections in general have been increasing in recent years, owing to the increased survival of immunocompromised patients. The few case reports of *L. monocytogenes* infections of the joints suggest that these occur in immunocompromised patients or in those with previous joint disease (Kurosh and Perednia 1989).

In recent years there has been increasing recognition of the role of anaerobic organisms in pyogenic arthritis, although the incidence of anaerobic bacterial arthritis is still quite low. Anaerobic joint infections typically occur after joint surgery, after penetrating trauma, or in patients with underlying diseases. In the setting of surgery or trauma, bacteria are introduced directly from the skin or from soil contaminated with faecal organisms. Peptococcal and clostridial species, and *Propionibacterium acnes* predominate. In the setting of underlying disease the anaerobic Gram-negative organisms, particularly *Bacteroides fragilis*, predominate. The route of infection can be haematogenous from a distant site such as the bowel or direct extension from an adjacent site such as a deep sacral decubitus. In about half of cases in all settings a single organism will be cultured, while half will be polymicrobial, usually mixed aerobic and anaerobic organisms (Fitzgerald *et al*. 1982; Brook and Frazier

1993).

Anaerobic joint infections are probably underdiagnosed. There are no specific diagnostic signs and therefore synovial fluid must be cultured for anaerobic organisms whenever the clinical setting suggests the possibility of anaerobic infection. Anaerobic cultures should also be obtained in any patient with suspected joint infection in whom initial aerobic cultures of synovial fluid are negative. Any anaerobic organisms isolated from synovial fluid should not be dismissed merely as contaminants if the clinical setting suggests infection.

Joint infections and rheumatoid arthritis

Patients with rheumatoid arthritis are at increased risk of pyogenic arthritis. While the precise prevalence of joint infections in rheumatoid arthritis is not known, in several large series approximately 10 per cent of all cases of non-gonococcal arthritis occurred in patients with that condition (Goldenberg and Cohen 1976; Rosenthal *et al*. 1980; Cooper and Cawley 1986).

Proliferative synovitis and structural changes in the rheumatoid joint may allow bacteria to become sequestered in the joint more readily and to escape normal host-defence mechanisms. The formation of pannus and damage to cartilage may more readily allow the spread of bacteria from the synovium to subchondral bone. There is some controversy about whether patients with rheumatoid arthritis have an increased risk for infections in general, but they are often treated with immunosuppressive medications, which put them at increased risk of infection. Rheumatoid patients with advanced disease may be significantly debilitated, may be bedridden with greater risk of infections of the respiratory or urinary tracts, and may develop skin ulcerations from vasculitis, all of which increase the risk of infection.

Staph. aureus is the infecting organism in 70 per cent of reported cases, followed by streptococci in 9 per cent, Gram-negative bacilli in 8 per cent, pneumococci in 7 per cent, and anaerobes in 3 per cent. Blood cultures are positive in 20 to 25 per cent of cases. The knee is involved in about half the cases. The hip, shoulder, elbow, wrist, and ankle are each involved in about 10 per cent of cases, while infections in the smaller joints of the hands and feet are unusual. Polyarticular infections are reported in about 30 per cent of cases. The source of infection can be identified in half of these patients. The skin is the most common site of distant infection, followed by the lungs, and the urinary and gastrointestinal tracts (Gardner and Weisman 1990).

Identifying joint infections in the patient with rheumatoid arthritis can be difficult clinically because joint inflammation is part of the underlying disease. Furthermore, fewer than one-half of rheumatoid patients with joint infections present with fever and even fewer develop a leucocytosis (Gardner and Weisman 1990). The erythrocyte sedimentation rate is of limited value in distinguishing infection from disease flare. Both infection and exacerbation of the rheumatoid condition can be monarticular or polyarticular. This difficulty in distinguishing between the two often leads to delay in diagnosis. Joint infection should be suspected in those patients whose disease activity changes abruptly from its normal pattern, particularly if only one or a few joints are involved; in those with systemic signs of toxicity; in those with a remote site of active or recent infection; or in patients on immunosuppressive therapy with long-standing, deforming disease or with accompanying, debilitating illnesses. Whenever one of these clinical states is present, synovial fluid should be obtained, Gram stained, and cultured before considering any treatment (such as an intra-articular steroid injection or systemic anti-inflammatory medication) for a flare-up of rheumatoid disease (Blackburn *et al*. 1986; Goldenberg 1989; Soria *et al*. 1992).

Distinguishing infection from disease exacerbation is further complicated by the occasional patient who develops a 'pseudoseptic' arthritis. In these cases there is an abrupt onset of usually monarticular joint pain and effusion, accompanied by fever. The synovial fluid is purulent, with the leucocyte count usually greater than 100 000/mm^3. Gram's stain and culture of the synovial fluid are negative, and the process quickly resolves within a few days without antibiotics (Call *et al*. 1985; Singleton *et al*. 1991). These episodes may be recurrent and identical in presentation in an individual patient, in which case antibiotics may be withheld pending the results of synovial fluid culture. In most instances, however, empirical antibiotic therapy should be started as soon as infection is suspected and cultures obtained. If adequate cultures are negative, then 'pseudoseptic' arthritis should be considered and antibiotics discontinued.

Owing mostly to the delay in establishing the diagnosis, joint infections in rheumatoid patients tend to have a poorer outcome than in other groups with pyogenic arthritis. The death rate in reported series is about 20 per cent, more than doubling in patients with polyarticular involvement (Gardner and Weisman 1990). Only about one-third will recover without any worsening of basic joint function. On occasion osteomyelitis or draining cutaneous fistulas will develop.

Prosthetic joint infections

While the risk of prosthetic joint infection has decreased significantly over the past three decades, infection remains a major cause of failure in arthroplasty. With evaluation and treatment of preoperative infections, improved surgical technique, and perioperative prophylactic antibiotics, infection after hip or knee arthroplasty has been reduced to less than 1 per cent of cases. The incidence of infection for revisions of prosthetic joints is about 5 to 10 times that of primary procedures (Poss *et al*. 1984; Wymenga *et al*. 1992).

A number of factors contribute to the risk of prosthetic joint infection. There is a risk of introducing bacteria whenever the joint space is entered. In addition the presence of foreign material in the joint promotes the growth of bacteria by sequestering organisms from the vascular supply and hence from the host immune-defence mechanisms and antibiotics. Methylmethacrylate cement may inhibit the phagocytic function of polymorphs and promote the production of glycocalyx, a fibrous collection of polysaccharides that enhance bacterial growth (Gristina and Kolkin 1983).

Prosthetic joint infections should be suspected whenever there are systemic or localized signs and symptoms of infection, or in cases of new or increasing prosthetic joint pain, even in the absence of clinical signs of infection. Over 90 per cent of all prosthetic joint infections present with joint pain; fever, and erythema and swelling of the joint occur in less than half of cases. Leucocytosis is unusual while an elevated erythrocyte sedimentation rate is almost always present.

About one-half of infections are detected in the first 12 months after surgery, with one-half of these occurring in the early postoperative period up to 3 months after surgery (Inman *et al*. 1984). Those cases that present in the early postoperative period are usually the result of bacteria introduced at the time of surgery or are due to wound infections. A large proportion of these patients will have or have had wounds complicated by haematoma, stitch abscess, dehiscence, or infection. These patients usually have an acute illness with fever, pain, and local signs of infection, including persistent drainage from the joint. However, infection should still be suspected in the patient with fever, leucocytosis, or elevated erythrocyte sedimentation rate that fails to drop with time, even in the absence of local signs of infection.

Infections occurring between 3 and 12 months postoperatively tend to have a more subacute presentation. Less than half will have local signs of joint infection. Most will present with either joint pain or failure to regain the expected functional level.

The prosthetic joint remains at risk for infection indefinitely. Infections diagnosed more than 1 year after surgery are usually the result of haematogenous seeding from a distant focus such as the urinary tract or skin, from dental work, or from surgical manipulation of the gastrointestinal or urinary tracts. The presentation is usually the insidious onset of pain in the absence of both systemic and local signs and symptoms of infection. There is often a delay of months from onset of pain to diagnosis. Occasionally, late infections present with draining sinus tracts.

Diagnosis of prosthetic joint infection is often difficult. In the early period, infection of the actual joint space must be distinguished from adjacent wound and soft tissue infection. In later infections presenting with only joint pain, the infected prosthesis must be distinguished from the uninfected but painful, loose prosthesis. Plain radiographs are usually normal in early infections. Loosening is defined as greater than 2 mm of lucency at the bone–cement or bone–metal (in cementless prostheses) interface, or any lucency at the metal–cement interface. Other findings in late infections include progressive cortical bone loss around the prosthesis, fractured cement, or a periosteal reaction when the infection has spread through the thickness of cortical bone. Radionuclide scans are useful in the evaluation of prosthetic joint loosening. A negative technetium-99m bone scan is strong evidence against infection and sequential technetium-99m and gallium-67 scanning can help to distinguish infected from non-infected loosening. Similarly, indium-111 uptake favours diagnosis of infection. Joint aspiration is necessary when infection is suspected on a clinical basis or if imaging studies are suggestive of infection or are equivocal. Culturing for anaerobic organisms is imperative. At times, bacteriological diagnosis can only be confirmed by bone biopsy or by culturing material obtained at surgery for removal of the prosthesis.

Staphylococcal species account for 50 to 60 per cent of prosthetic joint infections. *Staph. epidermis* is a more common cause of prosthetic than native joint infections. Various stretococcal species and Gram-negative bacilli each account for 15 to 20 per cent and anaerobes 5 to 10 per cent of cases. Mixed organisms are cultured in 10 to 20 per cent of cases, particularly those occurring in the early postoperative period (Inman *et al*. 1984). Organisms of low virulence that are seldom considered pathogens, such as diphtheroids, propionibacteria, and lactobacilli, are occasional causes of prosthetic joint infections and must not be dismissed as contaminants if

cultured from synovial fluid or biopsy material.

Neisserial arthritis

Gonococcal arthritis

N. gonorrhoeae can cause either localized mucosal infections of the genitourinary tract, rectum, pharynx, or conjunctiva, or disseminated infections of the skin, joints, and less commonly, heart and meninges. Disseminated gonococcal infection complicates approximately 0.1 to 0.3 per cent of localized infections. Seventy-five per cent of cases of disseminated gonococcal infection result from asymptomatic local infections (Eisenstein and Masi 1981). This makes effective preventive measures difficult.

Those strains of *N. gonorrhoeae* associated with disseminated disease differ biologically from those strains associated with symptomatic, localized disease (O'Brien *et al*. 1983). The strains that disseminate are more likely to be resistant to killing by normal human serum, have specific nutritional requirements when grown in culture, have specific cell-surface proteins, and tend to be more sensitive to antibiotics. These characteristics are also shared by those strains that cause asymptomatic localized infections. These strains do not provoke a local inflammatory reaction and thus the organism is not limited to the mucosa, allowing seeding of the bloodstream.

While the incidence of disseminated gonococcal infection has been decreasing in recent years due probably to a decrease in both the prevalence of those strains associated with disseminated disease and to a decline in the overall incidence of gonococcal infections, *N. gonorrhoeae* remains a common cause of bacterial arthritis in young, previously healthy, individuals particularly in urban centres where the largest reservoirs of localized gonococcal infection exist (Rompalo *et al*. 1987). Seventy-five per cent of cases occur between the ages of 15 and 30 years, in parallel with the years of peak incidence for localized gonococcal infections, although any sexually active individual is potentially at risk (Geelhoed-Duyvestijn *et al*. 1986). Women are affected three to five times more often than men. By contrast, non-gonococcal arthritis more commonly affects the very young or the very old, men, and individuals with underlying diseases or risk factors.

Individuals with inherited deficiencies of the terminal complement components, C5 to C9, have an increased risk of neisserial infection (Ross and Densen 1984). Complement deficiencies should be searched for in individuals with recurrent gonococcal or meningococcal infections.

Disseminated gonococcal infection has been classified according to the presence or absence of a purulent effusion (Holmes *et al*. 1971; Masi and Eisenstein 1981; O'Brien *et al*. 1983). About two-thirds of patients present with an acute illness of 3 to 4 days' duration, consisting of fever, rash, tenosynovitis, and migratory polyarthralgias or polyarthritis with non-purulent effusions (group I). The rash, present in 60 to 90 per cent of this group, is a diffuse, maculopapular eruption or a more limited number of vesiculopustular lesions on an erythematous base of approximately 5 mm. in diameter. Less commonly the lesions appear as haemorrhagic pustules or bullas. The rash generally spares the face and scalp but can appear anywhere on the trunk and extremities. The lesions may be painful. Tenosynovitis usually involves multiple sites, particularly at the wrist, fingers, ankles, and toes. It is present in 90 per cent of group I patients. Polyarthralgias and polyarthritis are migratory, with a predilection for upper extremity joints. When effusions are present they are small and cultures of synovial fluid are negative.

Group II patients present with a purulent arthritis that resembles the presentation of non-gonococcal arthritis. Typically, these patients present with an acute illness of 4 to 5 days' duration. Most have a monarticular arthritis, with the knee most commonly involved, followed by the ankle, wrist, and elbow. Involvement of the hip, shoulder, temporomandibular, and axial joints is rare, as is polyarticular involvement. About one-third of patients in this group will also have rash or tenosynovitis and about two-thirds will give a history of polyarthralgia preceding the development of monarthritis.

About 40 per cent of group I patients have positive blood cultures; this rarely if ever occurs in group II patients (O'Brien *et al*. 1983). This strongly negative correlation between positive blood cultures and the presence of purulent joint effusions suggests that group I patients present during the bacteraemic phase of the disseminated infection and group II patients during the phase of joint localization that can follow bacteraemia. Some series have reported progression from group I to II in individual patients (Holmes *et al*. 1971), although others believe that the groups are distinct (O'Brien *et al*. 1983; Koss 1985).

Leucocyte counts in synovial fluid in group II patients range from about 30 000/mm ^{3} to greater than 200 000/mm^3. This range overlaps with that in non-gonococcal arthritis, although counts tend to be slightly lower in gonococcal infections. The synovial fluid lactate is not increased in gonococcal arthritis. Gram's stain is positive in about one-quarter of cases, and *N. gonorrhoeae* can be successfully cultured from only about half of the purulent effusions (Scopelitis and Martinez-Osuna 1993). There are several explanations for this low rate of recovery of organisms even from purulent effusions. First, *N. gonorrhoeae* is difficult to culture, owing to its fastidious growth requirements. Second, organisms may be sequestered in the synovium and may not have entered the synovial fluid. Third, organisms may exist only transiently in the synovial fluid before they are phagocytosed and can no longer be cultured, but the synovitis persists in response to constituents of the gonococcal cell wall such as lipopolysaccharide. In animal studies, both killed gonococci and purified lipopolysaccharide can induce a purulent synovitis after injection into the joint space (Goldenberg *et al*. 1984). Finally, effusions may be caused or maintained by host immunological reactions to *N. gonorrhoeae*. Immune complexes have been demonstrated in both synovial fluid and the blood of patients with disseminated infection.

As positive cultures of synovial fluid are obtained in only a minority of patients, the diagnosis of disseminated gonococcal infection must often be presumed from a suggestive clinical presentation, together with isolation of *N. gonorrhoeae* from a site other than the joint. In patients with disseminated infection, positive cultures can be obtained from the cervix in 80 to 90 per cent of women, the urethra in 50 to 75 per cent of men, and the blood in 25 per cent. The pharynx and the rectum will be positive in a smaller number of cases (Scopelitis and Martinez-Osuna 1993). To culture *N. gonorrhoeae* from the joint, synovial fluid should be immediately spread on a prewarmed, chocolate-agar plate and incubated in a atmosphere enriched with carbon dioxide, or sent to the laboratory on transport media. Antibiotic-enriched culture media such as Thayer–Martin are used for isolating *N. gonorrhoeae* from sites that have a native bacterial flora, such as the pharynx, cervix, urethra, and rectum, but are not necessary and in fact may inhibit growth when culturing synovial fluid. Recently, the identification of *N. gonorrhoeae* DNA in culture-negative synovial fluid by the polymerase chain reaction has been reported. This technique potentially can improve diagnostic accuracy and hasten the time to diagnosis but is not yet readily available (Liebling *et al*. 1994)

The differential diagnosis of disseminated gonococcal infection is broad. Reiter's syndrome and disseminated gonococcal infection both commonly affect young, sexually active individuals. Urethritis, rashes, and inflammatory monarthritis or oligoarthritis can occur in both. The onset of illness in Reiter's syndrome tends to be more gradual than in disseminated gonococcal infection. Psoriasiform skin lesions, sacroiliitis, painless oral ulcers, conjunctivitis, and a recent history of a diarrhoeal illness favour the diagnosis of Reiter's syndrome. Analysis of synovial fluid does not distinguish between the two conditions unless a positive culture for *N. gonorrhoeae* is obtained. Not uncommonly the patient with disseminated gonococcal infection presenting with monarthritis must be distinguished from patients with non-gonococcal bacterial arthritis. Table 1 lists the distinguishing features. Other infectious illnesses may present with fever, rash, and polyarthralgias or polyarthritis, such as the prodrome of hepatitis B, subacute bacterial endocarditis, and bacterial arthritis due to *N. meningitidis*, Group A streptococcus, *H. influenzae*, or *Streptobac. moniliformis.* Acute rheumatic fever may present with fever and migratory arthritis distinguishable from disseminated gonococcal infection by evidence of a recent streptococcal infection, accompanying chorea or typical rash, and by rapid response to aspirin. Systemic lupus erythematosus, hypersensitivity vasculitis, and adult Still's disease may all present with fever, rash, and arthritis that at times might be confused with disseminated gonococcal infection, although the nature of the rash and the involvement of other organ systems should help to distinguish most cases.

The course of the disseminated infection is variable. In the preantibiotic era, some cases underwent spontaneous remission, while in others there was progression to destructive joint changes. In general the progression to irreversible damage in the cartilage and joint is not as rapid as with organisms such as staphylococci, streptococci, or Gram-negative bacilli. Rash, tenosynovitis, and polyarthralgias respond very promptly to antibiotics, while purulent effusions respond somewhat more slowly.

Meningococcal arthritis

Arthritis due to *N. meningitidis* follows one of several clinical patterns and may be confused with disseminated gonococcal infection (Fam *et al*. 1979; Schaad 1980). Joint manifestations complicate about 2 to 10 per cent of cases of acute meningococcaemia and may follow one of three clinical patterns. In the first, patients develop polyarthralgias, polyarthritis, or tenosynovitis during the acute phase of their meningococcal infection. They are acutely ill with fever, meningitis, and/or a diffuse, erythematous, macular rash or diffuse haemorrhagic skin lesions typical of acute meningococcaemia. When effusions occur in this group they are small and non-purulent. Synovial cultures are negative but *N. meningitidis* can be recovered from blood or cerebrospinal fluid. The articular manifestations respond rapidly to antibiotic therapy. When meningitis is absent, these patients resemble those in group I of disseminated gonococcal infection (see above) (Kidd *et al*. 1985).

The second group of patients, which resembles group II in disseminated gonococcal infection, develops purulent joint effusions that are most commonly monarticular or oligoarticular during the acute phase of meningococcaemia. Cultures of synovial fluid can be positive or negative. In some cases these effusions may be slow to resolve, even after appropriate antibiotics are given and the synovial fluid cultures are sterile.

A small number of patients with acute meningococcaemia will develop articular manifestations only after the acute stage of infection has responded to antibiotics and the patient is clearly improving (Jarrett *et al*. 1980). In these cases, monarticular, oligoarticular, or polyarticular effusions develop 1 to 2 weeks after the onset of the acute illness. Cultures of synovial fluid are negative but immune complexes are detectable in blood and synovial fluid, suggesting an immunological basis for the synovitis, which eventually resolves without further antibiotic therapy.

Patients with purulent arthritis, usually monarticular, but without signs of acute meningococcaemia are classified as primary meningococcal arthritis (Andersson and Krook 1987). The knee and ankle are most commonly involved. Cultures of synovial fluid are positive in 90 per cent of cases. Despite prompt and appropriate therapy these patients are at risk for joint damage and at times may require open drainage. Blood cultures are negative in this group.

Finally, joint manifestations may occur in the setting of chronic meningococcaemia, a condition marked by chronic rash and positive blood cultures. These patients generally present with polyarthralgias rather than frank arthritis. When effusions are present, cultures are negative, suggesting an immune-mediated mechanism.

Management

The three basic principles of management of pyogenic joint infections are: (i) prompt diagnosis and institution of therapy; (ii) appropriate antibiotics; and (iii) adequate drainage of the infected joint.

The most important factors in determining outcome are the length of time before beginning treatment and the length of time to sterilization of synovial fluid cultures (Ho and Su 1982). Therefore, the suspicion of joint infection should arise in any patient with an unexplained, painful or swollen joint, especially those with an acute presentation, with monarticular presentation, with systemic or local signs and symptoms of infection, with risk factors (such as underlying joint disease, recent joint trauma or surgery, diabetes, immunosuppression, or history of intravenous drug abuse), or with active or recent extra-articular infection.

In these settings there should be no delay in aspirating the involved joint or joints. The synovial fluid should be analysed for total and differential cell count, lactate, and crystals, and Gram stained and cultured to differentiate pyogenic infection from other causes of acute joint pain and swelling, including crystal-induced arthritis, exacerbation or presentation of an inflammatory arthritis, haemarthrosis, or trauma. The presence of urate or calcium pyrophosphate crystals, however, does not completely exclude the diagnosis of infection. In rare cases, crystals and infection have occurred in the same joint. The infectious process may 'leach' crystals out of the cartilage or synovium. Blood cultures should be obtained and a search for a distant focus of infection should be undertaken as appropriate for the individual patient.

If Gram's stain is positive or the analysis is otherwise suggestive of pyogenic infection, treatment should begin immediately. The patient should be admitted to hospital and given intravenous antibiotics as soon as all cultures have been obtained. Intra-articular antibiotics should be avoided because adequate concentrations in synovial fluid can be achieved via the parenteral route and because there is a risk of chemical synovitis with the intra-articular route. The concentration of antibiotics in synovial fluid parallels that in serum, and adequate levels can be achieved with standard parenteral doses. Penetration of the drug into the synovial fluid is greatest when the inflammation is most active at the start of therapy and falls off as the infection is controlled. Although they may achieve bactericidal levels in synovial fluid, aminoglycosides are sometimes less effective than other agents, possibly due to inhibition by the reduced pH of infected synovial fluid. Aminoglycosides are therefore inadequate for primary treatment of pyogenic arthritis. Erythromycin does not reach adequate levels in synovial fluid and therefore cannot be used as an alternative to penicillin (Esterhai and Gelb 1991).

Most often the initial choice of antibiotics is empirically guided by the results of Gram's stain, when positive, or by the clinical features when Gram's stain is negative. In choosing antibiotics, one must consider the age of the patient, any underlying disease, and the presence of extra-articular infection. Table 3 provides a guide to the empirical choice of antibiotics. When the results of antibiotic sensitivity testing become known, antibiotic coverage sould then be modified to provide a regimen that has the narrowest spectrum, is the least toxic, and is the least expensive.

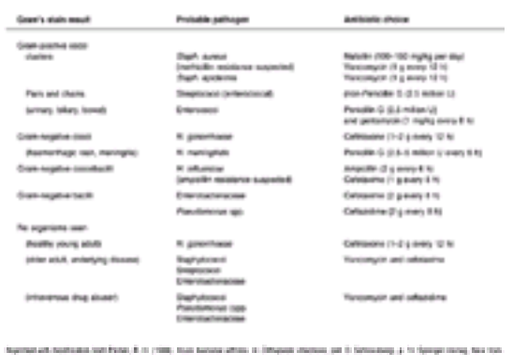

Table 3 Guidelines for initial antibiotic therapy of bacterial arthritis based on Gram's stain

In recent years, methicillin-resistant strains of *Staph. aureus* have become more prevalent in both hospital- and community-acquired infections (Ang-Fonte *et al*. 1985). Vancomycin should be the initial drug of choice for suspected *Staph. aureus* infection in those communities and hospitals where resistant strains exist.

Although those strains of *N. gonorrhoeae* that cause disseminated gonococcal infection are more likely to be antibiotic sensitive than those causing localized infections, strains that have chromosomally-mediated resistance to penicillin or are resistant because they produce plasmid-mediated penicillinase have become more common and widespread, and have been reported in disseminated infection (Wise *et al*. 1994). Therefore, in communities with resistant strains, a third-generation cephalosporin should replace penicillin G until antibiotic sensitivities are reported.

The duration of antibiotic therapy must be tailored to the individual presentation and response to therapy and to the infecting organism. In general, intravenous antibiotics should be continued until signs of joint inflammation have resolved, joint effusions have resolved or significantly decreased, and synovial cultures are sterile. Oral antibiotics can then be used to complete the course of treatment, which is usually about 2 weeks in uncomplicated cases but should be extended to 4 weeks or more where there was a significant delay in starting treatment, or a slow response, where infection was with virulent organisms such as *Staph. aureus* or Gram-negative bacilli, and in immunosuppressed patients (Syrogiannopoulos and Nelson 1988). The development of ambulatory intravenous antibiotic delivery systems has allowed earlier hospital discharge in appropriate patients (Williams *et al*. 1989).

The duration of parenteral antibiotic therapy for disseminated gonococcal infection is generally shorter than for non-gonococcal arthritis. In most patients with gonococcal arthritis with a good response to therapy, parenteral antibiotics can be substituted by oral after about 3 days of intravenous therapy to complete a 2-week course. Patients who have dermatitis/tenosynovitis only, without purulent arthritis, can be treated as outpatients, provided they are compliant and closely followed.

Occasional patients with purulent gonococcal effusions will develop a persistent inflammatory effusion, lasting weeks, after a good response to antibiotics and sterilization of synovial fluid. These effusions eventually resolve without further antibiotics. Recovery may be speeded by giving non-steroidal anti-inflammatory drugs.

Infected joints can be drained by closed needle aspiration, tidal irrigation (Ike 1993), arthroscopy, or arthrotomy. Each procedure has its appropriate place in the treatment of septic arthritis depending on the clinical situation. Which modality is chosen is probably not as critical to the ultimate outcome as the duration of time from

onset of infection to adequate drainage and sterilization of the joint fluid (Goldenberg *et al*. 1975; Lane *et al*. 1990; Ho 1993).

Initial treatment with serial, closed-needle aspiration avoids the expense and surgical morbidity and mortality of the more invasive procedures and is a satisfactory approach as long as the joint can be completely drained and there is clear evidence of improvement as indicated by resolution of systemic signs of toxicity, serial decrease in synovial fluid white blood-cell count and sterilization of the synovial fluid culture within 48 to 72 h (Broy and Schmid 1986).

The presence of risk factors for a poor outcome include delayed diagnosis, virulent organism, polyarticular involvement, or underlying disease, such as rheumatoid arthritis, and might prompt the early use of a more invasive procedure. Arthroscopy has the advantage of good visualization of the joint space and articular cartilage combined with effective drainage and irrigation, while avoiding the postoperative joint stiffness and slow functional improvement sometimes associated with arthrotomy (Thiery 1989). Arthroscopy is best suited for drainage of the knee joint, although, depending on the skill of the arthroscopist, it can be applied to other smaller joints.

Septic arthritis of the hip should be treated primarily by arthrotomy because of the difficulty and uncertainty of achieving adequate joint drainage by closed aspiration, and the increased risk of osteomyelitis and avascular necrosis in an incompletely drained and decompressed hip. Infection of the deep axial joints complicated by abscess formation requires open drainage.

Regardless of the mode of drainage, early mobilization of the infected joint is important in regaining maximal function. Most often the infected joint will be too painful to allow mobilization during the first few days of therapy. However, passive, range-of-motion exercises should be instituted as soon as pain permits. Both animal and human studies have demonstrated the advantages of a continuous, passive-motion device soon after surgical drainage of the knee. Isometric exercises to restore strength to the limb muscles and progressive ambulation to prevent the complications of prolonged bed rest should also be implemented (Esterhai and Gelb 1991; Mikhail and Alarcon 1993).

Management of the infected prosthetic joint involves the added complication of the presence of foreign material. In general, the prosthesis must be removed to treat the infection effectively. Exceptions include some very early postoperative infections in which the wound and joint can be effectively incised and drained, and where antibiotics are started without significant delay. Another exception is the patient who is not considered a candidate for surgery because of poor medical status and who is infected with an organism of low virulence. In this case, chronic suppression of infection by antibiotics has at times been successful in salvaging the prosthesis and preventing further infectious complications.

In nearly all other instances, the prosthesis, cement, and all necrotic bone and soft tissue should be removed as soon as infection is detected or strongly suspected. Appropriate antibiotics should be started, as outlined in Table 3, keeping in mind the increased frequency of *Staph. epidermis*, Gram-negative bacilli, and anaerobic infections. After 6 weeks of intravenous antibiotics a prosthesis can be reimplanted (Fig. 1) with a greater than 90 per cent chance of success and with a better functional outcome and greater patient satisfaction than with arthrodesis of the knee or excision arthroplasty (Girdlestone procedure) of the hip, which should be reserved for those patients unable or unwilling to tolerate a second surgical procedure (Insall *et al*. 1983). Others have reported success with a one-step procedure in which a new prosthesis is implanted at the time of removal of the infected prosthesis (Goksan and Freeman 1992).

Fig. 1 (a) Infected knee prosthesis. Note the radiolucent zone at the bone–cement interface of the tibial component indicating loosening (arrow); (b) the same knee after complete removal of the infected prosthesis and cement; and (c) the same knee 2 months later after reimplantation of a new prosthesis.

Septic bursitis

The many bursas found throughout the body are lined with a synovial membrane identical to that found in synovial joints. The bursas occupy superficial locations beneath the skin, cushioning the movements of tendons, muscles, and ligaments over bony structures. Bursitis may result from trauma, inflammatory conditions affecting synovial tissues (such as rheumatoid arthritis or gout), or from infection. Most cases of bursal infection are associated with recent trauma to the skin overlying the bursa or with an occupation causing repeated minor trauma to the bursa. Bacteria enter the bursa directly from the skin as a result of trauma, unlike septic arthritis in which the route of infection is most commonly haematogenous seeding. Underlying diseases affecting the bursa, including rheumatoid arthritis and gout, or previous episodes of non-infectious traumatic bursitis, increase the risk of septic bursitis. Immunosuppression, diabetes, and alcoholism may be additional predisposing factors (Canoso and Barza 1993).

Nearly all cases of septic bursitis involve the olecranon or prepatellar bursae. Both of these are closed structures that do not communicate with the adjacent joint. Presentation may be acute, with sudden onset of bursal pain, tenderness, swelling, and erythema leading to diagnosis within a few days of onset. Less commonly, presentation may be subacute or chronic with less dramatic local signs and symptoms present for weeks to months before the diagnosis is established. Involvement of the bursa is readily distinguishable from joint infection by the presence of very superficial, often tense, distension of the bursal sac and preservation of movement in the underlying joint, with little if any pain on motion. Fever is a common but not universal finding. Regional lymphadenopathy and adjacent cellulitis of the forearm or peripatellar skin are frequently present. Desquamation of the skin overlying the infected bursa and spontaneous drainage of the bursa through the skin may occur. Osteomyelitis of the underlying bone may occasionally complicate chronic cases.

The characteristics of synovial fluid from an infected bursa are variable. The gross appearance ranges from clear to frankly purulent. The leucocyte count may range from less than 2000 to several 100 000 cells/mm^3, with the proportion of polymorphs ranging from 50 to nearly 100 per cent. In contrast to pyogenic arthritis, the leucocyte count in synovial fluid is often less than 10 000/mm^3, so that relatively low counts should not deter one from pursuing the diagnosis of infection in the appropriate clinical setting (Ho *et al*. 1978; Canoso and Barza 1993).

In the absence of previous antibiotic therapy, culture of bursal synovial fluid will be positive in every case. Gram's stain is positive in about two-thirds of cases. *Staph. aureus* is the infecting organism in more than 90 per cent of cases. Sporadic cases are due to *Staph. epidermis* or group A streptococci.

Uncomplicated septic bursitis can be treated effectively with serial, closed-needle aspiration and oral antibiotics. Patients with underlying bursal disease, immunosuppressed patients, or those who fail to respond promptly to treatment as outpatients with oral antibiotics should be admitted to hospital and treated with intravenous antibiotics (Ho and Su 1981; Canoso and Barza 1993). Incision and drainage or excision of the infected bursa may be necessary in those cases with extensive involvement or failure to respond to closed drainage. Empirical antibiotic treatment should be with a semisynthetic, penicillinase-resistant penicillin or vancomycin, if methicillin-resistant *Staph. aureus* is a concern.

5.3.2 Pyogenic arthritis in children

Mary Anne Jackson and Komal B. Desai

Introduction

A successful outcome to suppurative arthritis in infancy and childhood is contingent upon early recognition and timely antimicrobial and surgical therapy. Despite the advent of newer antimicrobials that penetrate readily into infected joints, complications and permanent changes still arise in some cases of septic arthritis. This chapter reviews the epidemiology and pathogenesis of joint infection, and outlines the approach to diagnosis and management. Changes in the spectrum of childhood skeletal infection in the era of the *Haemophilus influenzae* type b (**Hib**) vaccine are highlighted.

Epidemiology

Acute septic arthritis is a relatively uncommon infection. One estimate suggests that two of every 1000 admissions to general hospitals are for septic arthritis (Smith 1974). Our institution serves a large, urban population in the American Midwest where approximately 6 000 children are admitted to the hospital each year. In the last fifteen years, an average of 10 admissions each year have been for septic arthritis. In a 30-year study of paediatric skeletal infection reported by Nelson, 682 cases of suppurative arthritis were described with an occurrence of 25 cases among 10 000 annual admissions (Nelson 1991).

Suppurative joint infection is an important disease of childhood. Among 138 cases treated at our institution since 1980, more than half were less than three years of age (Table 1). Although boys are reported to be affected twice as often as girls, in our series this predominance is seen most in the child older than 5 years; in the younger patient, the sex distribution tends to be more equal.

Age	Total	%
⩽2 months	11	8
3–23 months	58	42
2–5 years	36	26
6–11 years	19	14
>11 years	14	10

Table 1 Suppurative joint infection, The Children's Mercy Hospital Kansas City, Missouri 1980 to 1994

A history of non-penetrating trauma can be elicited in many children with septic arthritis; however, most investigators have questioned its role in the pathogenesis of the infection. In one study (Welkon *et al*. 1986), patients with septic arthritis and sterile cultures more frequently reported a history of trauma than those with culture-confirmed pyarthrosis.

An antecedent infection of the upper respiratory tract or otitis media occurs in 77 per cent of patients with septic arthritis due to *Haemophilus influenzae* type b compared with 18 per cent of those with pyarthrosis due to *Staphylococcus aureus* (Syriopolou and Smith 1987). This observation is consistent with findings in children with meningitis due to *H. influenzae* type b which suggests many have had an antecedent upper respiratory infection or otitis media (Harding *et al*. 1973).

Pathogenesis

In most cases, bacteria enter the joint space haematogenously. Less often, direct inoculation of bacteria into the joint space occurs during an episode of penetrating trauma. Contiguous extension of disease from infected soft tissues is felt to be rare in paediatric practice, and occurs most often in the adult diabetic (Argen *et al*. 1966).

Concomitant osteoarticular infection is a frequent occurrence in the neonate and happens occasionally in the older infant or child.

In neonates, osteoarthritis with destruction of the epiphysis and joint is common because metaphyseal and epiphyseal vessels communicate within the cartilaginous precursor of the ossific nucleus (Trueta 1957). As the ossific nucleus and epiphyseal plate form, separate vessels arise to supply the epiphysis and the communication with metaphyseal vessels disappears at approximately 1 year of age (Ogden 1979).

In children, there are four areas where the bony metaphysis is intracapsular: the proximal femur, proximal humerus, proximal radius, and distal lateral tibia (Morrissy 1989). If bacteria invade the joint from an adjacent osteomyelitis, the clinical presentation is similar to that of isolated joint infection and it is often difficult to differentiate between the two. Data from our institution suggest this type of skeletal infection may occur in up to 20 per cent of cases. In these cases, longer treatment with antibiotics is needed than in primary joint infection. More importantly, these patients have a greater frequency of permanent disability (Jackson *et al*. 1992).

Clinical manifestations

Monoarticular infection of weight-bearing joints is characteristic, with involvement of the knee, hip, or ankle accounting for 70 per cent of cases (Table 2). Usually the child with pyogenic joint infection presents acutely with fever and an exquisitely painful, swollen joint. In some cases, it may be difficult to localize the involved joint,

especially in a febrile, irritable infant. A careful examination after giving a short-acting sedative may be needed to locate the affected joint.

Joint	Total	%
Knee	46	33
Hip	38	28
Ankle	14	10
Elbow	9	7
Shoulder	8	6
Metatarsal	5	4
Sacroiliac	3	2
Wrist	3	2
Multiple	11	9
Interphalangeal	1	–

Table 2 Distribution of involved joints in suppurative joint infection, The Children's Mercy Hospital, Kansas City, Missouri 1980 to 1994

Diagnostic evaluation should be pursued promptly, especially in cases of septic arthritis of the hip where compromise of the vascular supply to the femoral head may result in destruction of the capital epiphysis and growth plate. A complete blood count, erythrocyte sedimentation rate (**ESR**), and radiographs of the joint involved should be obtained. In most cases, leucocytosis and elevation of the ESR in the range of 50 to 90 mm/h will be found; however, the diagnosis should not be excluded even if both of these are normal (Nelson and Koontz 1966). Radiographs may reveal periarticular, soft tissue swelling and joint effusion but also may be non-diagnostic (Morrey *et al*. 1975).

Radioisotope bone scanning is helpful in occasional cases where localization of the diseased joint is difficult. An increase or decrease in uptake on either side of the joint line with limitation to the joint capsule is seen in suppurative arthritis (Tuson *et al*. 1994). Magnetic resonance imaging has been shown to be a sensitive tool in the diagnosis of septic sacroiliitis (Sandrasegaran *et al*. 1994). In the child whose hip is painful on examination but plain radiographs are unrevealing, ultrasonography of the hip is useful in indentifying fluid and in guiding arthrocentesis (Dorr *et al*. 1988).

Aspiration of the joint is imperative to confirm the diagnosis. The fluid is usually frankly purulent and low glucose concentrations may be found. In most cases, the white blood cell count in the synovial fluid is greater than 50 000 and a differential count reveals more than 90 per cent polymorphonuclear leucocytes. A Gram-stained smear of the joint fluid will provide a presumptive identification of the causative agent in approximately one-third of cases. Culture of the joint fluid will reveal the precise organism in 50 to 60 per cent of cases. In 10 per cent blood culture will demonstrate the causative agent when cultures of the joint fluid are sterile. Despite careful culture of blood, joint fluid, and other appropriate sites, a microbiological diagnosis will not be obtained in 25 to 30 per cent of cases. If the clinical diagnosis is deemed to be septic arthritis, lack of a defined pathogen should not change the management of the patient.

General aetiology

The most commonly identified, causative bacteria of suppurative arthritis are presented in Table 3. Although *Haemophilus influenzae* type b has historically caused the majority of cases of suppurative arthritis in infants less than two years of age, we have seen no cases due to this pathogen since 1991 (Jackson, in press). Since the implementation of Hib vaccine in the United States in 1985, this organism has virtually disappeared as a cause of invasive disease. Currently, *Staphylococcus aureus* and streptococci account for close to 70 per cent of culture-confirmed cases of suppurative arthritis. Most streptococcal infections are caused by group A and B (neonates) or pneumococci, but, viridans streptococci and enterococci have also been reported (Fink and Nelson 1986). In teenagers with multiple joint involvement, gonococci are the most common pathogens (Keiser *et al*. 1968). Primary meningococcal arthritis is a rare form of meningococcal disease characterized by polyarticular infection, no involvement of other organs, and excellent prognosis (Schaad *et al*. 1981). *Pseudomonas aeruginosa* may cause infection in cases of puncture wound to the foot; other Gram-negative organisms cause infection infrequently (Fisher *et al*. 1985). Occasionally, salmonella arthritis occurs in the setting of salmonellosis or in the sickleaemic patient (Mallouh and Talab 1985). Anaerobes including *Bacteroides* spp., *Fusobacterium* spp. and *Eikenella corrodens* are most commonly involved in joint infection following a human bite (Resnick *et al*. 1985). *Kingella kingae* has been reported to be a possible aetiological agent in some septic arthritis cases and grew only when the initial synovial fluid specimen was inoculated into a blood culture bottle (Dagan 1993).

Age	Sterile	*S. aureus*	Hib[a]	Cocci[b]	GC[c]	Other[d]
<2 months	9	36	0	36	0	18
2–6 months	40	0	0	60	0	0
7–12 months	26	11	41	15	0	7
13–23 months	36	25	32	0	0	7
24–36 months	29	7	14	36	0	14
3–5 years	35	30	5	20	0	10

Table 3 Aetiology of suppurative joint infection (percentages) by age, The Children's Mercy Hospital, Kansas City, Missouri 1980 to 1994

Specific pathogens in septic arthritis

H. influenzae arthritis

With the advent of conjugate vaccine against *Haemophilus influenzae* type b, the prominence of the pathogen has diminished. Hib vaccine has been used in the United States since 1985, and the more efficacious, conjugate vaccine in infants from 2 months of age since 1990. Between 1986 and 1991, we noted a decline in the incidence of culture-confirmed, septic arthritis from 60 per cent to 20 per cent of infants less than 2 years of age. We have had no cases of Hib arthritis in our institution in the last three years. This changing trend was found in one other study before widespread use of the vaccine; thus the decline in this type of septic arthritis cannot be attributed solely to vaccine-induced immunity, but also to a reduction in nasopharyngeal colonization with this organism (Speiser *et al*. 1985).

Unimmunized infants of less than 2 years or incompletely immunized infants (those infants less than 12 to 15 months of age who have received the appropriate primary vaccine series but no booster) remain susceptible to Hib infection. In such instances, evaluation and management decisions should include Hib as a possible pathogen. As in other cases of disease from invasive *H. influenzae* type b, concomitant meningitis occurs in up to 30 per cent of affected children (Rotbart and Glode 1985). Examination of the cerebrospinal fluid is therefore an essential part of the initial evaluation of the young infant in whom septic arthritis due to *H. influenzae* type b is suspected.

A 1995 report notes the occurrence of the invasive, paediatric disease caused by *H. influenzae* type f, and suggests that reduction in nasopharyngeal Hib carriage may be associated with an increase in carriage of other non-type b strains (Nitta *et al*. 1995). A recent report of skeletal infection due to this organism highlights its ability to cause bone and joint infection (Chusid *et al*. 1992).

Gonococcal arthritis

Suppurative arthritis due to *Neisseria gonorrheae* is one of the manifestations of the disseminated gonococcaemia syndrome (Fig. 1). In more than one-half of cases,

polyarticular disease is found, with joints of the arm, especially wrists and fingers, most frequently involved (Bayer 1980). A history of migratory polyarthralgia in a febrile adolescent with arthritis of the wrist is so clinically distinct that a presumptive diagnosis can be made and appropriate therapy begun. Although analysis and culture of joint fluid is mandatory in all patients, the organism is found in joint fluid in less than one-half of cases. It is essential to culture from the pharynx, rectum and vagina/urethra in all patients with a suspected diagnosis of gonococcal arthritis (Angerine and Hall 1976).

Fig. 1 Typical skin lesions in a teenager with gonococcal arthritis

Septic arthritis of specific joints

Hip

When the hip is involved in septic arthritis, the child will assume a position of comfort with the hip flexed, externally rotated, and abducted. Asymmetry of the skin folds of the buttocks and thighs may be apparent, and significant limitation of passive hip abduction and extension is typical. Pathological subluxation of the hip may occur, and was found in 8 per cent of children with septic arthritis of the hip at our institution.

There is much potential for permanent disability in cases of septic arthritis of the hip. The femoral capital epiphysis is entirely intra-articular and capsular distension may interfere with the vascular supply to the femoral head. Therefore, in all cases where septic hip is suspected, the diagnosis should be promptly confirmed by aspiration of the joint under fluoroscopy. If purulent material is found, immediate drainage of the hip should be performed.

Sacroiliac joint

Infection of the sacroiliac joint is relatively unusual, accounting for 1 to 2 per cent of cases of septic arthritis. These children tend to be older (mean age, 10 years) and usually do not appear systemically ill. Most have acute onset of fever, with pain in the buttocks, groin, hip or abdomen. Often the patient has an antalgic gait but pain is poorly localized. The duration of symptoms before diagnosis averaged 7 days in one study (Patterson 1970), but chronic symptoms of up to 1 month have been reported (Schaad *et al*. 1980). The most common physical finding in patients with sacroiliac arthritis is a positive Fabere sign (pain with flexion, abduction and external rotation of the hip while stressing the sacroiliac joint by placing pressure on the flexed ipsilateral knee) (Hoppenfeld 1976).

As in many cases of septic arthritis, plain radiographs are often normal. A bone scan may localize the involved sacroiliac joint; however, a computed tomographic or magnetic resonance imaging scan is more sensitive and specific (Morgan *et al*. 1981).

Staphyloccocus aureus is the most commonly recognized pathogen and a positive blood culture is often found (Reilly *et al*. 1988). Antistaphylococcal therapy usually results in a prompt clinical response and drainage of the sacroiliac joint is usually unnecessary. *Brucella* spp. have a predilection for sacroiliac involvement and should be considered in individuals who were born or have travelled to endemic areas or have ingested raw milk. Diagnosis of brucella sacroiliitis may be confirmed by culture or serology and therapy should usually include trimethoprim sulphamethoxazole or doxycycline (for patients over 9 years of age) possibly with the addition of rifampicin.

Septic arthritis specific hosts

Neonates (Table 4)

Although suppurative skeletal infection in a newborn infant often reflects systemic infection with *Staphylococcus aureus, Candida albicans* or group B streptococci, systemic symptoms and signs are generally not apparent (Pittard *et al*. 1976). Non-specific symptoms such as irritability, lethargy or poor feeding may occur. However, a non-toxic appearance and absence of fever is found in more than one-half of cases, and a normal white cell count and ESR are generally found (Fox and Sprunt 1978). Local swelling of an extremity with overlying inflammation and/or flexion contracture are the most common clinical findings. Occasionally, a newborn with hip pyarthrosis may present with abdominal distension secondary to rupture into the abdomen of intra-articular pus (Freiberg and Perlman 1976).

Absence of systemic symptoms and signs
Multiple concomitant osteoarticular sites
Delayed diagnosis
Frequent permanent sequelae

Table 4 Characteristics of neonatal skeletal infection

A high index of suspicion is necessary and aspiration of all suspected joints is absolutely essential to confirm the diagnosis. Permanent sequelae are frequent in this age group. Hallel and Salvati (1975) found deformities of the femoral head in 70 per cent of neonates followed up for suppurative arthritis of the hip. Complications from skeletal infection in the neonate can be minimized by a high index of suspicion, detailed evaluation with a careful musculoskeletal examination in any baby with suspected sepsis, and early surgical drainage and antibiotic therapy.

Septic arthritis in chronic joint disease

The diagnosis of suppurative joint infection may be particularly difficult in the patient with underlying chronic disease of the joints, such as those with sickle haemoglobinopathy, haemophilia or systemic juvenile chronic arthritis. Although there is no hallmark for differentiating chronic, active disease from acute suppurative infection of the joint, most infected patients are febrile, have a more toxic appearance, and have marked local manifestations.

In haemophiliacs, septic arthritis has been considered a rare complication of haemarthrosis. Severe joint pain and systemic toxicity that persist despite giving

coagulation factors should be considered an indication for needle aspiration of the affected joint. Pneumococci (which have a predilection for diseased joints) and staphylococci are the most common pathogens of septic arthritis in haemophiliacs (Scott *et al*. 1985). Generally, a single joint, usually the knee, is involved and diagnosis may be delayed when a septic joint is superimposed on haemarthrosis. Recently, septic arthritis complicating pneumococcal, staphylococcal or salmonella bacteraemia has been reported in haemophiliacs infected with human immunodeficiency virus. Polyarticular disease with significant destruction occurred despite appropriate therapy (Ragni and Hawley 1989). However, a more favourable outcome has been reported in four recent cases where non-operative management with prompt antimicrobial therapy was advocated (Merchan *et al*. 1992).

Septic arthritis is uncommon in children with sickle haemoglobinopathy. Localized joint pain and fever are usually found, and symptoms and signs tend to persist for 4 days or longer (Syrogiannopoulos *et al*. 1986). Encapsulated bacteria typically cause infection in the patient with sickle haemoglobinopathy. Pneumococci are the most commonly recognized pathogens in such children with septic arthritis, although occasional disease secondary to *H. influenzae* type b is reported (Mallouh and Talab 1986). Salmonella have a predilection for bone in sicklaemic patients and may be found in cases of suppurative arthritis in association with an adjacent osteomyelitis (Seeler and Jacobs 1977).

Joint infection during rheumatoid arthritis is more common in adults than children. Usually, worsening of pain of an isolated joint occurs during a flare-up of the underlying disease; however, there is polyarticular involvement in almost 40 per cent of cases (Kaufman *et al*. 1976). As in other cases where septic arthritis complicates underlying chronic disease of the joint, a high index of suspicion is necessary to avoid a delay in diagnosis and poor subsequent outcome.

Penetrating injuries and arthritis

Suppurative arthritis following a penetrating injury to a joint is well described, although when first reported was most commonly associated with sewing-needle injury to the knee (Samilson *et al*. 1958). The knee is still the joint usually involved, but sewing needles have rarely been implicated as the agent of trauma in the last two decades. The clinical presentation is similar to other cases of pyarthrosis. In our series, 8 per cent of cases of suppurative arthritis followed a penetrating injury (Table 5). All cases were boys, with a mean age of 6 years. A wide variety of pathogens was found; however, *Pseudomonas aeruginosa* arthritis of the metatarsal joint following nail puncture occurred most frequently.

Age (years)	Sex	Joint	Trauma	Pathogen
2	M	Knee	Toothpick	Viridans streptococci
3	M	Knee	Plastic	Group A streptococci
3	M	Knee	Dog bite	Unknown
1	M	Knee	Human bite	Eikenella corrodens
4	M	Metatarsal	Nail	*Pseudomonas aeruginosa*
12	M	Knee	Nail	Gram-negative rods
4	M	Metatarsal	Nail	*Pseudomonas aeruginosa*
9	M	Metatarsal	Unknown	*Escherichia coli, Enterobacter cloacae*
7	M	Metatarsal	Nail	*Pseudomonas aeruginosa*
9	M	Metatarsal	Nail	*Pseudomonas aeruginosa*
10	M	Metatarsal	Nail	*Pseudomonas aeruginosa*

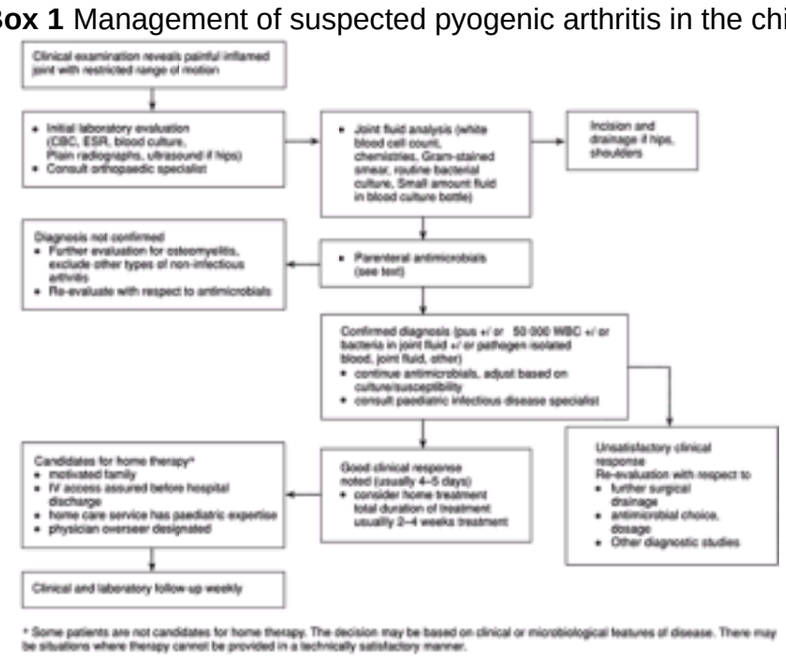
Table 5 Suppurative arthritis following puncture wound

Reactive or so-called traumatic arthritis follows an injury, usually a thorn or splinter puncture, and may be severe and difficult to distinguish from acute suppurative infection. In most cases, symptoms have been present for longer than a week and although there is pain on moving the joint, it is usually not as severe as that associated with a pyarthrosis (Green and Edwards 1987). Exploration of the joint to exclude a foreign body should be considered in cases where traumatic synovitis persists.

Management

The essentials of management of suppurative arthritis in childhood include the combination of an appropriately selected antimicrobial agent and adequate drainage of the pyarthrosis (see Box 1). Simple needle aspiration of the affected joint may be sufficient in some cases. However, emergency surgical drainage of the joint is mandatory in pyarthrosis of the hip and probably shoulder infection (Patterson 1978). Arthrotomy and drainage should also be considered in cases where the pus is thick, or when significant symptoms and signs persist despite initial needle aspiration of pus from the affected joint (Nade 1983).

Box 1 Management of suspected pyogenic arthritis in the child



When a presumptive diagnosis of septic arthritis is made, parenteral antibiotics should be begun promptly. In older children, an antistaphylococcal penicillin is the drug of choice. For infants who have not received a Hib booster vaccine (those less than 12 to 15 months of age), and for infants who have not received Hib vaccine and are less than 2 years old, I add coverage for *H. influenzae* type b in combination with the antistaphylococcal antibiotic. Cefuroxime is appropriate initial coverage as long as concomitant meningitis is not present. In that case, I prefer to combine an antistaphylococcal penicillin with a third-generation cephalosporin (usually cefotaxime or ceftriaxone) until the results of culture are known. Parenteral antimicrobial agents readily penetrate into infected joints, so intra-articular installation of antibiotics is not necessary.

The efficacy of a sequential intravenous–oral antimicrobial regimen has been demonstrated by numerous prospective studies (for example Feigin *et al*. (1975); Jackson and Nelson (1982)). Usually, intravenous therapy is given for 5 to 7 days. After all surgical procedures and when there is definite clinical improvement, a patient may be considered for an oral regimen if (i) an appropriate oral antimicrobial is available, (ii) the patient is able to take and retain oral medication, and (iii) there is a laboratory at hand to analyse the bactericidal activity of serum samples.

The oral dosage of the selected antibiotic is two to three times that used for otitis media or skin and soft tissue infection. A serum specimen for blood levels should be obtained 1 h after the oral dose is given (after the drug has reached steady-state concentrations) and adequate bactericidal activity should be confirmed. A serum bactericidal activity of at least 1:8 is considered adequate except in cases of streptococcal infection where a titre of 1:32 is needed. Adjustment of the antimicrobial dosage is usually required in 15 per cent of cases. In less than 5 per cent of cases, satisfactory bactericidal activity cannot be achieved and a total parenteral regimen must be used for the duration of therapy (Prober and Yeager 1979). Oral antibiotic regimens should not be used outside the hospital setting in a child unless you feel

compliance can be guaranteed.

The optimum duration of antimicrobial therapy for children with suppurative arthritis is dependent upon the duration of symptoms before diagnosis of the pathogen, the response to medical and surgical treatment, and whether or not there is concomitant bone infection. Generally, if the patient's clinical response is good and the ESR returns to normal, 3 weeks of therapy is adequate for staphylococcal and Gram-negative bacillary infection (Syrogiannopoulos and Nelson 1978). Shorter courses have been successful for streptococcal and haemophilus infection, in which a total of 10 to 14 days of therapy may be adequate. In all cases where an oral regimen is used, ESR and serum bactericidal activity should be monitored weekly until therapy is considered complete.

The risk of relapse or recurrent disease is quite small in cases of primary joint infection; however, for the child with pyarthrosis and concomitant bone infection, the potential for relapse or sequelae is significant. Therefore, if compliance cannot be guaranteed, an oral regimen is not appropriate for such patients. Delayed diagnosis, delay in surgical drainage, slow clinical response, and undocumented compliance are all risk factors for chronic disease (Badgley *et al*. 1936; Hallel and Salvati 1975).

Prognosis

In the child over 1 month of age, the prognosis for primary septic arthritis of the knee is good and more than 90 per cent have a satisfactory outcome (Howard *et al*. 1976). However, poor outcome has been estimated to occur in approximately 40 per cent of hip, 20 per cent of ankle and 30 per cent of shoulder infections, particularly if there is an adjacent osteomyelitis (Gillespie 1973; Welkon *et al*. 1986). There should be careful orthopaedic follow-up for at least 6 to 12 months in all children with supporative joint infection.

5.3.3 Osteomyelitis and associated conditions

Emilio Bouza and Patricia Muñoz

Introduction

The term osteomyelitis, although specifically applied to medullary infections involving trabecular bone, is used to describe any infection involving bone and marrow (Brause 1990; Laughlin *et al*. 1994; Laughlin *et al*. 1995).

The appearance of new groups of immunosuppressed patients at risk of osteomyelitis, and the emergence of new patterns of antimicrobial resistance in many micro-organisms responsible for bone and joint infections, is a cause of concern (Poiraudeau *et al*. 1993; Rogeaux *et al*. 1993). At the same time, recent and important changes in the field include the application of more precise diagnostic techniques and the use of aggressive surgery with implantation of new prosthetic devices. Finally, the development of non-toxic, highly efficacious, oral antimicrobial agents frequently permits a long-term approach to these difficult-to-treat infections during which the patient remains ambulatory.

First, general aspects of osteomyelitis, with special reference to chronic infections of the long bones, will be discussed. Other forms of osteomyelitis and arthritis will be considered at the end of the chapter.

Classification

The utility of a classification system depends on its ability to predict relevant prognostic, therapeutic, or aetiological data and to provide uniform criteria for comparative studies (Mader *et al*. 1992). A universally applied classification system for stratifying osteomyelitis and prosthetic joint infection would provide a framework to evaluate the efficacy of medical and surgical treatments in different institutions. To date, no attempt at this has been completely successful and there is no single classification system that is satisfactory. Osteomyelitis must, therefore, be classified on the basis of several characteristics. All of them are relevant to planning management and evaluating outcome. The most common criteria are detailed in Table 1.

Criteria	Classification
1. Age	Children — adults
2. Affected bone	Long — short
3. Host	Drug abusers — immunosuppressed — normal
4. Aetiology	Bacterial — non-bacterial
5. Pathogenesis	Haematogenous — contiguous
6. Existence of fracture	Consolidated — non-unions
7. Risk factors	With/without prosthetic material
8. Blood supply	Adequate — inadequate
9. Evolution	Acute — chronic

Table 1 Classification criteria for osteomyelitis

1. The age of the patient must always be considered, since pathogenesis and aetiology are usually different in neonates, children or adults. Haematogenous osteomyelitis is far more frequent in children. *Staphylococcus aureus, Enterobacteriaceae*, and group A and B b-haemolytic streptococci are the most common aetiological agents in neonates. In children under 4 years of age *Haemophilus influenzae* is the most important pathogen, followed by streptococci and *Staph. aureus*. In children older than 4 years *Staph. aureus*, streptococci, and *H. influenzae* predominate.
2. The affected bone is also an important factor. Long bones, particularly those of the lower limbs, are more susceptible to infection because their blood supply is poorer than in short bones. Also, they bear more weight and have worse venous return. Pelvic and cranial bones are infrequently involved (Sexton *et al*. 1993; Bernier *et al*. 1995; Lentz 1995).
3. The host is also very important and special risk groups must be considered. In intravenous drug abusers, atypical locations are more frequently encountered (pubic bones, clavicle or vertebra) and, besides staphylococci and streptococci, Gram-negative rods, mainly *Pseudomonas aeruginosa*, and yeasts must be considered as potential aetiological agents (Chandrasekar and Narula 1986). Patients with haemoglobinopathies, such as sickle-cell disease, have a higher incidence of infections caused by encapsulated bacteria such as *Strep. pneumoniae, H. influenzae*, or salmonella (Engh *et al*. 1971). Chronic haemodialysis is also a risk factor for osteomyelitis. The most common sites involved are the ribs and thoracic spine.
4. Most osteomyelitis is caused by Gram-positive bacteria, but practically any other micro-organisms may be responsible for bone infection. Gram-negative bacteria are frequently found in post-traumatic and postsurgical osteomyelitis, and anaerobic and mixed infections should also be considered in osteomyelitis associated with poor vascular supply such as in diabetics (Gerding 1995). Brook and Frazier (1993) isolated anaerobes in 33 per cent of cases of osteomyelitis diagnosed at a military institution. *Mycobacteria*, and particularly *Mycobacterium tuberculosis*, are still an important cause of osteomyelitis, and it is occasionally associated with other micro-organisms (*staphylococci*). Finally, fungal infections of the bone have been described in all agents responsible for systemic mycosis both in the normal and the immunocompromised host.
5. Taking into account the mechanism by which the infecting organisms reach the bone, osteomyelitis can be classified as haematogenous, secondary to a contiguous focus of infection, and caused by direct inoculation. Acute haematogenous osteomyelitis is more common in children and will be discussed later. In

adults, haematogenous osteomyelitis frequently involves the spine. This constitutes a diagnostic challenge since clinical and radiological manifestations may be non-specific and rapid evolution may produce significant neurological sequelae (Sapico and Montgomerie 1990; Heary *et al*. 1994). A recent review demonstrates a trend for haematogenous osteomyelitis to have shifted from its known incidence in early age to adulthood, from acute to insidious onset, and from infection by Gram-positive to Gram-negative organisms (Sharma *et al*. 1993).

6. The existence of an underlying fracture, above all with non-union (pseudoarthrosis), is of great importance, since it will influence the surgical approach.
7. The presence of any kind of prosthetic material near the infection site must be carefully sought, since it facilitates persistence of infection, increases the pathogenicity of micro-organisms such as *Staph. epidermidis*, and hinders the efficacy of antimicrobial treatment. Although the withdrawal of prosthetic materials is regularly recommended, it is not always necessary, or possible.
8. Waldvogel *et al*. (1970) classified contiguous osteomyelitis with respect to the integrity of the bone's vascular supply. The most characteristic example of osteomyelitis with poor vascular flow is that associated with infections of the diabetic foot. Neuropathic and vascular changes characteristic of diabetes mellitus put patients at risk for developing chronic foot damage after minor trauma and subsequent bone infection (Gerding 1995).
9. The disease activity in osteomyelitis is classified as acute or chronic. Osteomyelitis is considered acute when the appearance of symptoms is recent, and when there has been no previous therapy. On the other hand, osteomyelitis is chronic when symptoms have been present for 4 to 6 weeks or previous therapy has been given. This classification is important, since therapy and prognosis will be very different. At the present time, less than 6 per cent of haematogenous osteomyelitis becomes chronic but practically all post-traumatic infections are chronic.

Previous classifications have considered these important aspects, the most essential being the presence of vascular compromise, the presence of prosthetic material, and the rate of evolution.

Cierny and Mader (1984) proposed a commendable classification for adult chronic osteomyelitis that takes into account the anatomical status of the bone lesion, the involvement of soft tissues, and the expected host response to infection (Table 2). Accordingly, each case of adult chronic osteomyelitis must be classified with a number and a letter. Nevertheless, the system is imprecise and has not been broadly accepted or generally incorporated into clinical practice. Details of the classification are as follows.

Anatomical	Type I	Medullary
	Type II	Superficial
	Type III	Localized
	Type IV	Diffuse
Physiological	Class A	Normal host
	Class B	Compromised patient
	Class C	Poor-risk candidate

Table 2 Cierny/Mader classification for adult chronic osteomyelitis

Anatomical classification

Type I Intramedullary infection or infected (but consolidated) fractures with an intramedullary rod. Surgical treatment is simple and will not result in bone instability.

Type II Cortical bone infection (pressure sore). Bone excision is easy, although soft-tissue coverage may be more complicated.

Type III Osteomyelitis affecting cortical bone and marrow, but not including the whole bone circumference (sequestrum). Surgical debridement is complicated, although does not necessarily result in instability.

Type IV Osteomyelitis affecting the whole bone circumference. The surgical approach usually requires ablation of a bone segment and may result in bone instability. Type IV includes infected non-unions and infected articular prostheses.

Physiological classification

Class A Patients and tissues with normal response to infection and surgery.

Class B Patients with local or systemic immune deficiencies, that may predispose to infection (Table 3).

Systemic	Local
Malnutrition	Chronic lymphoedema
Renal or hepatic failure	Venous stasis
Immunodeficiency	Large- or small-vessel disease
Neoplasm	Arteritis
Diabetes mellitus	Scars
Extremes of age	Postradiation fibrosis
Smoking (tobacco)	Loss of local sensation
Chronic hypoxia	
Parenteral drug abuse	

Table 3 Local and systemic factors that affect the immunological, metabolic, and vascular response to osteomyelitis (Cierny/Mader)

Class C Patients not considered to be suitable surgical candidates, for whom the morbidity of treatment is greater than the risk of disease or exceeds the expected benefit.

Negative aspects of this classification are that it does not consider the aetiology or the bone involved. Surprisingly, the originators obtained relatively uniform results in all the stages, although compromised patients had a statistically inferior prognosis compared with patients who had apparently normal defence mechanisms (Cierny and Mader 1989).

Risk factors for osteomyelitis

Major risk factors for bone infections are contaminated open fractures, previous surgery, insertion of prosthetic material, delayed postoperative wound healing, and previous infections (Gillespie 1990). In one of the most important series of osteomyelitis, 29 per cent of patients had previous trauma with fracture, 4 per cent trauma without fracture, 42 per cent had recently undergone surgery involving bone, and 11 per cent had a prior open fracture (Guerrero 1989). Pressure sores are closely linked to underlying osteomyelitis, particularly diabetic foot ulcers (Newman *et al*. 1991). The demonstration of underlying bone involvement frequently requires MRI

and indium-111 scintigraphy (Newman *et al*. 1992).

Aetiology

Gram-positive micro-organisms remain the most common causative agents of osteomyelitis at all ages, although there is a trend towards greater involvement of Gram-negative organisms (Gentry and Rodríguez 1990) (Table 4). Gram-negative organisms should particularly be suspected in patients subject to prolonged stays in hospital or previous surgery, or those admitted to intensive care units or with open fractures (Gentry 1990). In contrast to haematogenous osteomyelitis, which is usually caused by a single pathogen, contiguous chronic osteomyelitis may involve multiple organisms.

Micro-organism	1970 (%)	1988 (%)
Staph. aureus	45	27
Other Gram-positive	5	5
Pseudomonas aeruginosa	5	15
Other Gram-negative	8	20
Polymicrobial	37	33

Table 4 Changing profile of micro-organisms isolated from osteomyelitis during the last two decades (per cent) (Gentry 1990)

Staphylococcus aureus is, undoubtedly, the most common aetiological agent of osteomyelitis of any kind (Guerrero 1987). In recent years, the emergence of methicillin-resistant strains (**MRSA**) (strains resistant to all b-lactam drugs) has been described by many hospitals throughout the world (Ish-Horowicz *et al*. 1992). Nevertheless, osteomyelitis caused by MRSA is less common than might be expected.

Staphylococcus epidermidis is one of the most common agents of bone and joint infection in patients with prosthetic materials, and a high proportion of these infections (more than 50 per cent at our institution) are resistant to methicillin. The aetiological role of *Staph. epidermidis* should only be fully accepted when the isolate is obtained from a usually sterile body fluid or tissue, and skin contamination can be reasonably ruled out. *Staphylococcus epidermidis* infection is extremely rare without the presence of underlying prosthetic material (De Wit et al.1993). It is frequently implicated in postsurgical sternal osteomyelitis (Miholic *et al*. 1985).

Although streptococci are of great importance in skin and soft tissue infections, their participation in osteomyelitis is rare (Burkert and Watanakunakorn 1991).

The group B b-haemolytic streptococcus (*Strep. agalactiae*) is exceptional as a cause of osteomyelitis. It is most commonly described in children (Ammari *et al*. 1992; Muñoz *et al*. 1992), or in elderly or immunosuppressed patients (McCarthy and Haber 1987; Elhanan and Raz 1993). Associated bacteraemia may cause high morbidity and mortality (Mateo *et al*. 1993; Farley 1995; Ganapathy and Rissing 1995).

Streptococcus pneumoniae osteomyelitis is also extremely uncommon in adults. It is occasionally described as a single focus of infection in normal children (Jacobs 1991). Cases caused by penicillin-resistant strains have also been reported (Gelfand and Cleveland 1992).

Enterococcus is very rarely implicated in osteomyelitis, and its significance when isolated should be questioned, especially if the biopsy or surgical specimen is not obtained aseptically. The authors have seen two patients with prosthesis-related infections caused by *Enterococcus*, and other cases have been published. In a well-designed study of biopsy confirmed, non-prosthetic osteomyelitis, *Enterococcus* accounted for 3 per cent of the cases (Gentry and Rodríguez-Gomez 1991). Other Gram-positive micro-organisms such as *Listeria* (Housang 1976) or *Bacillus* (Sliman *et al*. 1987; Drobniewski 1993) have only rarely been implicated in osteoarticular infections.

Among the Gram-negative organisms, *Pseudomonas* is one of the most commonly involved in bone infections. It is usually found in osteomyelitis following open fractures or surgical procedures. It is the most frequent cause of calcaneus osteomyelitis following infected puncture wounds of the foot (Dixon and Sydnor 1993; Lavery *et al*. 1994). *Salmonella* osteomyelitis occurs either as a complication of typhoid fever or in patients with various underlying diseases, including immunosuppressed patients and those with sickle-cell disease (Anand and Glatt 1994). Other Enterobacteriaceae have also been described, particularly in infections following open fractures or as a consequence of haematogenous bone involvement in patients with bacteraemia of another origin (Lacour *et al*. 1991; Voss *et al*. 1992).

Conditions predisposing to anaerobic bone infections are vascular disease, bites, a contiguous focus of infection, peripheral neuropathy, haematogenous spread, and trauma. Anaerobes are more frequently detected in osteomyelitis under pressure sores, or in bone infections of the diabetic foot (Hudson 1993). Pigmented *Prevotella* and *Porphyromonas* spp. were mostly isolated in infections of the skull and following bites. Members of the *Bacteroides fragilis* group have been detected in cases of hand and foot infection, and *Fusobacterium* spp. in skull, bite wounds, and haematogenous long-bone infections (Brook and Frazier 1993).

Fungal or nocardial osteomyelitis is found in both normal and immunocompromised hosts (Novak *et al*. 1988; Laurin *et al*. 1991; Pruitt *et al*. 1993; Young 1993; Assaad *et al*. 1994; Straus *et al*. 1994). *Mycobacterium tuberculosis* and, rarely, non-tuberculous mycobacteria, should also be considered as a cause of chronic bone infection (both in normal and immunocompromised hosts) (Cohen and Squires 1992; Jamil *et al*. 1992; Mahan and Jolles 1995 ; Yao and Sartoris 1995). Viruses are only rarely the cause of bone infections (Berman and Jensen 1990; Kain *et al*. 1990).

Diagnostic procedures

The diagnosis of osteomyelitis and prosthetic joint infections is usually made on the basis of clinical, laboratory, and imaging techniques. Although the problem is usually localized, a complete clinical history and examination must be performed (Levine *et al*. 1993). Information on the presence of any kind of prosthetic material, previous surgical and medical therapy, duration of previous antimicrobial courses, and the response must be carefully recorded.

Physical examination should focus on the integrity of involved bone and surrounding tissues, and on evidence of inflammatory signs, pain, bone instability, sinus tracts or neurovascular changes. The nutritional status of the patient should also be considered. The detection of a sinus tract with suppurative drainage will establish the diagnosis in an appropriate clinical setting. Further diagnostic techniques will be required to confirm the diagnosis, if necessary, and to establish the aetiology.

Laboratory investigations

Laboratory data are not essential for the diagnosis of osteoarticular infections. The erythrocyte sedimentation rate is usually high with active infections (92 per cent) and tends to fall after effective therapy. Its accuracy in infected prostheses is variable. In our experience, the erythrocyte sedimentation rate is not useful as an index of either activity or resolution in osteomyelitis.

C-reactive protein is also usually increased, although its measurement is less widely used (Unkila-Kallio *et al*. 1994). Only 35 per cent of patients have leucocytosis at the time of admission.

In summary, no single laboratory measure is reliable enough to be used routinely for the diagnosis of osteomyelitis.

Imaging techniques

Imaging plays an important part in establishing the diagnosis and directing the treatment of osteomyelitis. A variety of imaging methods may be used, including plain radiography, radionuclide imaging, computerized tomography (**CT**), and magnetic resonance imaging (**MRI**). Decisions on the best method can be challenging and should reflect the location of the suspected infection and associated underlying systemic or bone disorder. A brief review of the pathogenesis of osteomyelitis is necessary to help understand when each of imaging techniques is of value (Schauwecker *et al*. 1990; Wegener and Alavi 1991 ; Crim and Seeger 1994).

Once the micro-organism reaches the bone, a suppurative reaction is produced, followed by a marrow oedema, which can only be readily detected by MRI. The next step consists of vascular congestion, thrombosis, and ischaemia. At this time, soft tissue changes may be detected by CT but not by plain radiology. Finally (after at least 2 to 3 weeks), bone reaction begins, with the production of new periosteal bone, sequestrum, decalcification, and new bone formation, which can be detected even with plain films.

Plain films

The detection of acute osteomyelitis on a plain film requires at least a 35 per cent loss of calcium content in the bone lesion. This usually takes a minimum of 15 days. This is not the issue in chronic osteomyelitis, in which the dilemma is to establish whether radiological changes correspond to active infection, surgical sequelae or just trauma.

The detection of a sequestrum (a clearly defined, isolated necrotic area of bone surrounded by a osteopenic zone) or an involucrum (a hyperdense zone of bone under an elevated periosteum) is considered pathognomonic of osteomyelitis. Other signs that should suggest the presence of active infection are the detection of poorly delineated osteolytic areas, periosteal hyperplasia, or irregular periosteal bone extending into adjacent soft tissue (Gómez 1987).

The presence of periprosthetic bone reabsorption or new periosteal bone formation is highly suggestive of infection in the appropriate clinical setting. Considering their simplicity and low price, conventional radiographs should always be obtained if osteoarticular infection is suspected.

Isotope bone scanning

In most cases of chronic osteomyelitis, clinical and radiological data permit an easy diagnosis (Fig. 1, Fig. 2, and Fig. 3). However, sometimes bone changes from other causes and soft tissue infection make laboratory and radiographic signs unreliable as indicators of osteomyelitis. This happens regularly in acute haematogenous osteomyelitis. In this situation, scintigraphic methods can be helpful. Since it provides physiological data, scintigraphy is also useful in the evaluating therapeutic response. However, anatomical definition is inferior to that of CT or MRI. The following is a description of the widely used techniques, although more sophisticated methods are being developed (Fox and Zeiger 1993).

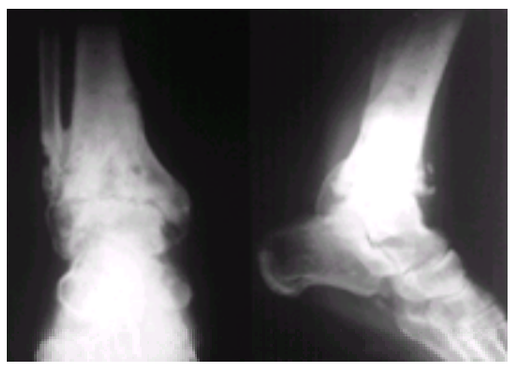

Fig. 1 Plain radiograph: post-traumatic osteomyelitis of the distal tibia.

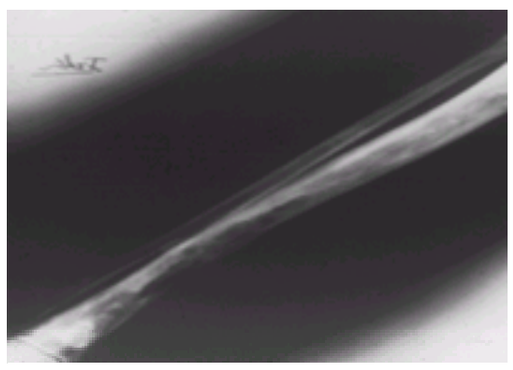

Fig. 2 Haematogenous osteomyelitis of the tibia in an adult with sickle-cell disease.

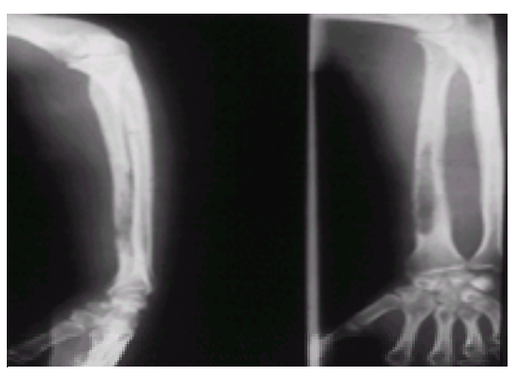

Fig. 3 Haematogenous involvement of bone in a patient with typhoid fever: *Salmonella typhi* osteomyelitis.

Technetium-99m methylene diphosphonate

Technetium-99m methylene diphosphonate (**MDP**) is taken up in areas of increased blood flow or osteoblastic activity. A three-phase bone MDP scan (vascular, pool, and late or bone phase) increases specificity, and is the first-line diagnostic imaging technique after a plain radiograph in evaluating suspected osteomyelitis.

Image quality is fairly good, the dose of irradiation is small, the cost is reasonable, and the technique is available in most centres. Preparation is simple, and the technique provides an earlier and more sensitive diagnosis than plain radiography.

However, specificity is poor and the negative predictive value of this technique is more reliable than positive prediction. False positives may be due to neoplasm,

fractures, heterotopic ossification, arthritis, neuropathic osteopathy, trauma or arthrosis. It is not very useful in children or following recent surgery to bone.

Gallium-67 citrate

Gallium-67 is taken up in areas where leucocytes or bacteria accumulate and provides quantitative information about inflammatory activity. A comparison with the MDP scan is of great value.

Gallium scans become positive earlier than MDP and are sensitive in detecting active bone/joint lesions. A normal gallium scan virtually excludes the presence of an inflammatory process.

False-positive gallium scans in ununited fractures or after recent surgery are common. Images are less precise than MDP scans.

Adult patients with previous bone disorders and possible osteomyelitis or patients with dubious results from MDP scanning should have a gallium scan. Gallium may also be the preferred technique for following response to therapy (Alazraki 1993).

Indium-111 or technetium-99 autologous leucocyte scintigraphy

If the other bone scans are inconclusive, ^{111}In-labelled leucocyte scintigraphy is the next line to take, particularly in adults with other bone disorders.

Patient's leucocytes are obtained and labelled. Afterwards, they are re-infused into the patient and accumulate in the focus of infection where they can be detected.

Indium scans have higher specificity than the previous techniques for the diagnosis of infection, particularly in previously traumatized bone. They provide very good results in osteomyelitis of the diabetic foot, infections associated with delayed or non-union, and prosthetic infections.

Indium scans have higher sensitivity in acute osteomyelitis than in chronic cases (100 per cent vs 60 per cent), probably due to the massive presence of leucocytes in the former (Schauwecker *et al*. 1984). False-positives may occur after trauma, tumours, and other osseous disorders (Nepola *et al*. 1993; Seabold *et al*. 1993). The quality of the image is inferior to that of Tc scintigraphy and it is not very accurate for the axial skeleton. Preparation is complex and long, and the major concerns about this technique are the hazards associated with the handling of blood, and the need to delay imaging for 18 to 24 h, which precludes a rapid result. Potential alternative agents for ^{111}In-labelled leucocytes include labelled immunoglobulin and labelled antigranulocyte antibody reagents.

Indium scans should be reserved for patients with a suspicion of osteomyelitis of the lower extremities not diagnosed with the previous techniques.

None of the types of scintigraphy permits differentiation between septic and non-septic inflammatory processes with sufficient accuracy. For this reason, other techniques are sometimes required.

Computed tomography

This technique accurately detects increased medullary density (typical of the early stages of osteomyelitis), as well as subsequent changes in soft tissues and cortical bone. Its principal advantage is excellent definition of cortical bone, including zones of necrosis, sclerosis, demineralization, periosteal changes, and adjacent soft-tissue swelling. CT does not provide information about the activity of the process and there may be image interference caused by the presence of prosthetic material. Radiation exposure is rather high and it is an expensive technique. CT is especially recommended in chronic osteomyelitis before surgery. It may help to delineate the presence of abscesses, a sinus tract or sequestrum (Maurer *et al*. 1992). It may also be useful for evaluation of infected joint prostheses and osteomyelitis of the spine, pelvis and sternum (Gostishchev *et al*. 1992).

Magnetic resonance tomography (MRI)

Magnetic resonance tomography readily detects the oedema of bone marrow that characterizes the earlier phases of bone infection. Typical features of osteomyelitis on MRI include a low-intensity area in T_1 (less fat) and a hyperintense area in T_2. Bone reaction to fracture or surgery would appear as low marrow intensity in T_1 and normal signal in T_2. Sinus tract and cellulitis would appear as hyperintense areas in T_2.

MRI has proved to be as sensitive as bone scintigraphy in the early detection of osteomyelitis, and, with its superior spatial resolution, it is often more specific than planar scintigraphy in differentiating bone from soft-tissue infection and in separating arthritis, cellulitis, and soft-tissue abscesses from osteomyelitis. In several comparative studies, MRI has been more accurate in detecting the presence and determining the extent of osteomyelitis than scintigraphy, CT scan, and conventional radiography. MRI may facilitate differentiation of acute from chronic osteomyelitis and may help to detect foci of active infection in the presence of chronic inflammation or post-traumatic lesions (Unger *et al*. 1988; Spaeth *et al*. 1991). The patient is not irradiated and newer techniques such as fat-suppressed, contrast-enhanced MRI are significantly more sensitive than scintigraphy, and more specific than non-enhanced MRI or scintigraphy (Morrison *et al*. 1993; Hopkins *et al*. 1995).

MRI also has some drawbacks. It does not provide very precise images of cortical bone and its usefulness decreases in the presence of metallic materials. False-positive results may be obtained in the presence of neoplasm, or intra-/extramedullary inflammation. Experience with MRI is as yet limited and the cost is high. A major indication for MRI is in osteomyelitis of the vertebrae and the foot (Meyers and Wiener 1991), and when diagnosis is still not established after using the previously described techniques.

Microbiological diagnosis

Blood cultures are usually negative in patients with chronic osteomyelitis, and the aetiological diagnosis usually relies on local samples. In acute haematogenous osteomyelitis, blood cultures and/or locally obtained aspirates are the procedures of choice.

It is important to note that only in a small proportion of cases do micro-organisms recovered from sinus tracts reflect the real causative agent present in the bone; *Staph. aureus* is the agent showing the best correlation (Gentry and Rodríguez 1990; Patzakis *et al*. 1994). The overall sensitivity and specificity of sinus-tract cultures for different micro-organisms are summarized in Table 5. Consequently, bone biopsy culture is now the standard method for determining specific antimicrobial therapy (sensitivity and specificity of 87 per cent and 93 per cent, respectively) (Perry *et al*. 1991; Howard *et al*. 1994). Bone biopsy should be taken, using local anaesthesia and imaging control, from the most painful site (Stratton 1989). The specimen must be transported to the laboratory immediately, and stained and cultured for most common pathogens, including aerobes, anaerobes, fungi, and mycobacteria. Quantitative bone cultures have not been effective in differentiating osteomyelitis from infection or colonization of adjacent soft tissue (Darouiche *et al*. 1994).

	Sensitivity (%)	Specificity (%)
Bone biopsy	100	100
Sinus tract:	76	86
Staph. aureus	70	90
Other Gram-positive	65	69
Pseudomonas aeruginosa	82	75
Other Gram-negative	88	96

Table 5 Correlation between cultures from the sinus tract and bone biopsy (Gentry and Rodríguez 1990)

The nature of the infection of a joint prosthesis may be particularly difficult to establish. In these cases, joint aspiration with a fine needle is recommended (sensitivity and specificity of 87 per cent and 95, respectively) (Roberts *et al*. 1992).

Finally, mention must be made of the serum bactericidal test, which is considered to be a predictor of therapeutic efficacy in acute and chronic osteomyelitis. This test is based on determining the ability of progressive dilutions of patient's serum to kill the infecting micro-organism. A multicentre study has shown that, in chronic osteomyelitis, peak and trough levels above 1:16 and 1:4, respectively, are desirable (Weinstein *et al*. 1987).

Histological diagnosis

Histological diagnosis of osteomyelitis is useful in all situations but particularly necessary in cases where there is reasonable doubt about the reliability of cultures. It is required in patients already receiving antimicrobial drugs, in osteomyelitis potentially caused by pathogens that are difficult to grow, and in patients where bone samples have to be taken from infected or colonized soft-tissue structures, which may lead to a false-positive result (McGuire 1989).

Bone histopathology also provides more precise information on the anatomical limits of the infected tissue and reassurance that surgical resection has reached healthy, viable bone.

Treatment

The issue of treatment for osteomyelitis has not been completely resolved. Recent research has provided additional insights into the pathogenesis of bone infection. Advances in pharmacology and in surgical techniques have improved our ability to treat such infections. Despite these advances, successful treatment of post-traumatic chronic tibial osteomyelitis depends on adherence to several basic principles: complete debridement of necrotic and infected tissue, obtaining bone stability, the elimination of dead space, and the provision of durable soft-tissue coverage (Dirschl and Almekinders 1993; Meadows *et al*. 1993). Therapy for osteomyelitis requires a multidisciplinary approach, which ideally should include the collaboration of surgeons, infectious disease physicians, rheumatologists, plastic surgeons, radiologists, and many other specialists. The adequate debridement of necrotic tissue is frequently necessary, and the combined orthopaedic and plastic surgical approach has permitted successful salvage of otherwise severely injured lower limbs.

Acute haematogenous osteomyelitis usually responds to antimicrobial therapy. The presence of an abscess, a metaphyseal cavity in haematogenous osteomyelitis, and evidence of spinal-cord compression in vertebral osteomyelitis require surgical treatment.

Chronic osteomyelitis usually implies that dead bone is present, which requires surgical debridement. Because of the chronic nature of the infection and the various presentations and surgical approaches, antibiotic treatment must be individualized. In general, however, at least 4 weeks of therapy is required (Bamberger 1993).

Systemic antimicrobials

The selection of antimicrobial drugs depends on their *in vitro* activity against the responsible pathogens, their penetration into bone tissue, their pharmacological characteristics, toxicity and cost. Table 6 summarizes some of the characteristics of an 'ideal' antimicrobial agent for the treatment of osteomyelitis. The following is a description of some of the antimicrobial agents most frequently used for the therapy of bone and joint infections.

1. Wide spectrum of antimicrobial activity
2. Bactericidal capacity
3. Good oral absorption
4. Long half-life
5. Good penetration in normal and necrotic bone
6. Good activity at low pH and in anaerobic conditions
7. Low toxicity
8. High resistance to bacterial inactivation mechanisms
9. Good clinical efficacy in animal models and humans
10. Low cost

Table 6 Ideal characteristics of antimicrobial agents for the treatment of osteomyelitis

Quinolones

Quinolones are well suited to the treatment of osteomyelitis, since most of them, including ciprofloxacin, ofloxacin and pefloxacin, reach satisfactory levels in bone tissue and their broad spectrum of activity covers most potential pathogens (Overbeck *et al*. 1995; Suh and Lorber 1995). Activity after oral administration is similar to that with parenteral administration. Combined with rifampin they now constitute a frequently used regimen for the treatment of osteomyelitis (Neu 1993). Several trials have shown that the new oral fluoroquinolones are as effective as parenteral cephalosporins and other broad-spectrum agents in treating osteoarticular infections. Tolerance is excellent and permits prolonged courses in ambulatory patients. Ofloxacin has more predictable absorption, although its activity against *Pseudomonas* is less than that of ciprofloxacin. None of them must be used to treat infections caused by MRSA. The widespread overuse of quinolones (1/44 Americans have received ciprofloxacin) has recently raised an alarm (Guay 1992; Greenfield 1993). However, in our opinion, osteoarticular infections can still be considered one of the most clear indications for these drugs.

Co-trimoxazole

Co-trimoxazole is usually active against *Staph. aureus* (including many methicillin-resistant strains) and against some Gram-negative organisms. The authors have treated 17 patients with complicated chronic osteomyelitis, achieving a satisfactory response in 82 per cent after a follow-up of more than two years (Bouza *et al*. 1992). Co-trimoxazole is, on many occasions, the only oral alternative for the therapy of bone and joint infections caused by MRSA.

Vancomycin

Vancomycin is almost uniformly effective against Gram-positive micro-organisms, but has the drawbacks of toxicity and the need for intravenous administration (Ish-Horowicz *et al*. 1992). It may be administered to patients who require parenteral therapy and in osteomyelitis caused by multiresistant Gram-positive micro-organisms (MRSA, *Staph. epidermidis*, etc.) (Refsahl and Andersen 1991). Bone penetration is poor (14 per cent of the serum concentration) and so simultaneous administration of rifampin is recommended.

Teicoplanin

Teicoplanin is a glycopeptide antibiotic with an antimicrobial spectrum of activity similar to that of vancomycin (Wilson and Gruneberg 1994). Nevertheless, it has a longer half-life that permits once-a-day dosing, which is particularly convenient for patients attending day-care hospitals or having antibacterial therapy at home. It can be administered both by intravenous and intramuscular routes, and it is better tolerated than vancomycin. Its efficacy in Gram-positive osteoarticular infections has recently been assessed. Microbiological eradication was achieved in 86 per cent of patients and clinical cure in more than 80 per cent; toxicity precluded termination of therapeutic courses in 12/60 patients. (LeFrock *et al*. 1992; Weinberg 1993).

Rifampin

Rifampin is a bactericidal antimicrobial agent with excellent activity against many Gram-positive micro-organisms. It is considered the most powerful antistaphylococcal agent. It achieves very good bone tissue concentrations (O'Reilly *et al*. 1992), and we feel that, whenever possible, it should be included in the therapeutic regimen of osteoarticular infections. However, it must never be used alone, since resistance develops rapidly if used as a single agent. Patients musts be warned that rifampin may turn body fluids a reddish colour.

Clindamycin

Clindamycin shows good activity against Gram-positive micro-organisms and some anaerobes, and its penetration into bone tissue is satisfactory (98 per cent of the serum concentration). A well-known side-effect of this antibiotic is *Clostridium difficile*-related colitis, especially in elderly patients.

b-Lactam drugs

Among b-lactam drugs, penicillins continue to have an important role. Penicillins are the drugs of choice in osteomyelitis caused by streptococci and staphylococci that are penicillin sensitive. Nevertheless, one should remember that more than 90 per cent of the staphylococci isolated nowadays are resistant to penicillin.

Amoxycillin is the drug of choice in the rare patients with enterococcal osteomyelitis and also in cases due to *Haemophilus* and *Salmonella*. The combination of amoxycillin and clavulanic acid has considerably increased the spectrum of antimicrobial activity of amoxycillin; it can be used in osteomyelitis caused by different *Enterobacteriaceae* and also in cases with anaerobic bacteria present in either mono- or polymicrobial infections.

Piperacillin and piperacillin with tazobactam are suitable agents for the treatment of osteomyelitis caused by *Pseudomonas*, anaerobic bacteria, and mixed infections.

The isoxazolil penicillins and other penicillins resistant to penicillinases are still the preferred drugs (in competition with first-generation cephalosporins) for treatment of most staphylococcal bone and joint infections.

Cephalosporins of all generations have been used in the treatment of osteomyelitis but those of the first generation remain among the drugs of choice for staphylococcal osteomyelitis. Second- and, more particularly, third- and fourth-generation cephalosporins are useful as substitutes for aminoglycosides in the lengthy treatment of Gram-negative osteomyelitis.

Finally, aztreonam is a useful drug for the treatment of Gram-negative osteomyelitis. Imipenem has a very broad spectrum of in vitro activity, including Gram-positive bacteria, *Enterobacteriaceae, Ps. aeruginosa* and anaerobes, but should be preserved for cases of osteomyelitis that are particularly difficult to treat or whose aetiology is polymicrobial (Jauregui *et al*. 1993).

Parenteral versus oral antimicrobial agents

Traditionally, parenteral agents were the drugs chosen for the treatment of osteomyelitis. Most still believe that at least the initial treatment of osteomyelitis should be with intravenous antibiotics. Others (us included), however, consider that in clinically stable patients with aetiologically well-documented osteomyelitis, some oral drugs are adequate from the very beginning. For maintenance therapy, intravenous antibiotics have been largely replaced by new, orally active, wide-spectrum agents that permit prolonged treatment in the ambulatory patient (Conrad and Marks 1989; Craig and Andes 1995). The drugs most frequently used for staphylococcal infections are combinations of rifampin with either oral fluoroquinolones or co-trimoxazole. Most Gram-negative infections in adults can be treated with an oral quinolone but for others there are no adequate oral drugs (Tice 1993).

Length of therapy

The use of new, orally active antimicrobials such as quinolones has modified the recommended length of therapy in chronic osteomyelitis. The 6-week benchmark, which was determined largely by experience with childhood haematogenous osteomyelitis, may not be applicable to contiguous-focus osteomyelitis after trauma in adults. At the present time, it is known that 6 weeks may not be sufficient for contiguous chronic osteomyelitis and the availability of oral antibiotics with a low toxicity profile permits a much longer duration of treatment and a higher rate of success. Unfortunately, to our knowledge, no well-designed prospective clinical trials have determined the precise duration of antimicrobial therapy for chronic osteomyelitis. We recommend a minimum of 3 months. This may be extended in certain circumstances, such as poor initial response, unsatisfactory coverage of soft tissues, presence of non-unions, and delayed withdrawal of prosthetic material.

Occasionally, patients not considered to be candidates for surgery require prolonged suppression rather than a curative approach.

Local delivery of antimicrobials

Several devices designed to deliver antimicrobials locally (cement, biodegradable microcapsules) have been developed, although the most widely used are gentamicin-impregnated polymethylmethacrylate beads, which are claimed to allow immediate filling of the bone defect and to provide high antibiotic concentrations. In some centres their use has become standard orthopaedic practice. Chains of beads are packed into the infected bone cavity after debridement, with the end projecting from the scar. During the following 4 to 6 weeks, the chain is progressively pulled out. The procedure is painful and sometimes adhesions prevent complete extraction of the beads.

A recent comparative study, involving 384 patients, suggests that local therapy with gentamicin-impregnated beads is as effective as standard systemic therapy for osteomyelitis. The conclusions may be biased by the fact that most patients received combined surgical and medical treatment (local and systemic antimicrobials). However, the data do suggest that both cost of treatment and toxicity are considerably lower in patients who are treated with local antibiotics alone (Blaha *et al*. 1993). Good results are reported in the treatment of infected non-union (Calhoun *et al*. 1993) and contaminated compound fractures (Ostermann *et al*. 1993). The main drawbacks are the potential danger of leaving foreign material in a septic space with connections to the exterior, and that gentamicin, the most commonly used antimicrobial in these devices, does not seem to be the most potent agent, considering that *Staph. aureus* is the major pathogen. New devices impregnated with more effective antimicrobials such as vancomycin, teicoplanin, or ciprofloxacin are being studied (Dacquet *et al*. 1992; Gerhart *et al*. 1993; DiMaio *et al*. 1994).

Surgical therapy

Antibiotic treatment is not a substitute for surgical debridement of infected, devitalized bone. Absence or inadequacy of surgical treatment is clearly associated with higher rates of initial failures or recurrences. We recommend early surgery whenever possible, before the administration of antimicrobial agents. The purpose of the surgical intervention is not only therapeutic but also may serve to establish the precise aetiological diagnosis.

On some occasions, the need for bone consolidation and stability precludes early surgical therapy and surgery has to be postponed until these occur. In this case, the administration of antimicrobials is 'palliative' until the definitive, and potentially curative, surgical procedure is possible.

The different surgical techniques for bone debridement will not be reviewed in detail in this chapter. However, the principle is that only viable bone should be left in place whenever possible.

Bone viability is of fundamental importance in the surgical management of osteomyelitis. The use of laser Doppler flowmetry as an adjunct to surgery, allowing quantitative evaluation of bone vascularity, has recently proved to be of great value (Duwelius and Schmidt 1992). When axial long bones are involved, aggressive debridement is not easy to perform since adequate wound coverage and mechanical stability may be difficult to achieve or maintain. Treatment of infected non-unions is especially difficult. Prognosis has become more optimistic with the development of new orthopaedic methods, such as the Ilizarov limb reconstruction method. This has proved to be cost-effective when compared with amputation (Cattaneo *et al*. 1992; Williams 1994). Occasionally, osteotomies, bone grafts and transports, or muscular flaps are also necessary (Mahan and Jolles 1995; Yajima *et al*. 1995).

Another situation that requires rapid functional reconstruction is osteomyelitis of the sternum associated with mediastinitis. For this, a wide debridement should be followed (at the same time or soon thereafter) by reconstruction of the chest wall by vascularized pectoral-muscle flaps (Banic *et al*. 1995).

A conservative, non-surgical approach is recommended for asymptomatic or mildly symptomatic osteomyelitis in elderly patients.

Finally, it is important to remember that amputation is sometimes the most functional therapeutic alternative in patients with refractory osteomyelitis of the feet or lower limbs (Lerner *et al*. 1993). We feel that early amputation in chronic and relapsing osteomyelitis of the foot, particularly when associated with poor vascular supply or neuropathic disease, is better for the patient than prolonged disability and antimicrobial therapy condemned to failure.

Administration of hyperbaric oxygen

Hyperbaric oxygen has been used successfully in the treatment of air embolism, in radio-osteonecrosis, in intoxication by carbon monoxide, in clostridial myonecrosis, in severely burned patients, and in other soft-tissue infections. Open, non-randomized studies suggest a potential value of hyperbaric oxygen in the treatment of refractory chronic osteomyelitis (Slack *et al*. 1965; Perrins *et al*. 1966; Depenbusch *et al*. 1972; Davis *et al*. 1986; Mader *et al*. 1990).

In an animal experimental model of chronic *Staph. aureus* osteomyelitis, hyperbaric oxygen was compared to treatment with parenteral cephalothin alone and with a combination of both for 4 weeks. Hyperbaric oxygen was as effective as parenteral cephalothin. At the end of treatment, the original *Staph. aureus* could be recovered from 91 per cent of control animals, 36 per cent of those treated with hyperbaric oxygen only, 47 per cent of those treated with cephalothin alone, and from 40 per cent of those treated with the combination.

Hyperbaric oxygen increases the bactericidal activity of phagocytic cells and the bactericidal effect of drugs as vancomycin and aminoglycosides. Collagen production by fibroblasts occurs more efficiently with oxygen tensions greater than 10 mmHg.

The role of hyperbaric oxygen in the treatment of human osteomyelitis requires definition by well-designed, prospective clinical studies.

Prognosis

Osteomyelitis-associated mortality is usually low, but the tendency for osteomyelitis to recur and become chronic is well known. Patients may experience unpredictable episodes of fistulous discharge. Recurrences are most common within a year of the initial episode, but extremely long intervals have been reported.

Malignant transformation arising from a fistula in patients with chronic osteomyelitis is extremely rare, although isolated cases have been described. This emphasizes the importance of histological examination (Mabit *et al*. 1993; Noonan *et al*. 1993).

Patients and doctors should realize that it is impossible to guarantee whether osteomyelitis can ever be 'cured,' since infections become manifest many years after injury or treatment.

Prophylaxis

Antimicrobial prophylaxis is recommended after open fractures, in which the infection rate is high.

For the implantation of articular prostheses both antimicrobial prophylaxis and environmental air cleaning are recommended. For hip, knee, and other major joint prostheses, the recommended antimicrobial prophylaxis is usually one to three doses of cefazolin starting at the induction of anaesthesia and over the next 24 to 48 h. In addition, antimicrobial prophylaxis is specially important, and widely used, when internal fixation of fractures or joint replacements are performed.

As most osteoarticular infections are proved to be acquired in the operating theatre, highly sophisticated, centrifugal laminar-flow systems have been installed, achieving a 10^4-fold reduction in the concentration of environmental micro-organisms and 10-fold reduction in the incidence of infection. At the present time, the incidence of infection has been reduced to 0.5 per cent in hip prostheses (Lidwell 1986; Schutzer and Harris 1988), while knee and shoulder prostheses are associated with a higher incidence of septic complications (1–4 per cent and 4–7 per cent, respectively) (Bengtsson 1993; Malchau *et al*. 1993).

Some orthopaedic surgeons recommend prophylactic antimicrobial agents for prevention of infection in patients with prosthetic joints undergoing certain invasive procedures. Particular attention should be paid to bacteriuria, the implantation of intravascular devices, drainage, and dental manipulations, for which a prophylactic approach similar to that for endocarditis is recommended.

Chronic post-traumatic osteomyelitis

Most information to date comes from experience with chronic post-traumatic osteomyelitis. The risk of infection after an open fracture varies widely with the site, size, and nature of an open fracture, as shown in Table 7, adapted from Gustilo *et al*. (1990).

Type	Wound	Fracture	Infection
Type I	< 1 cm Clean puncture Soft tissue damage +	Simple, transverse Comminution +	0–2%
Type II	> 1 cm Moderate contamination Soft tissue damage ++	Moderate contamination Comminution ++	2–7%
Type III:	Soft tissue damage +++	Instability Comminution +++	
Type III A	Soft tissue coverage: adequate	Contamination ++	7%
Type III B	Loss of soft tissue Exposure of bone or periosteal stripping	Contamination +++	10–50%
Type III C	Arterial injury		25–50%

Table 7 Risk of infection in open fractures (adapted from Gustilo *et al*. 1990)

Chronic osteomyelitis is usually a local disease that only rarely produces systemic manifestations. The most common symptoms are pain and suppurative discharge. As mentioned previously, the infection is characteristically recurrent and resistant to short courses of therapy. Fever is more common in acute infections or in the presence of soft-tissue abscesses.

The presence of an open draining fistula is always a marker of clinical activity of osteomyelitis.

The main principle of management of infection in non-consolidated bone fractures is to retain fracture fixation whenever possible. When infection becomes apparent, ultrasonography may determine the presence or absence of collections requiring drainage. In the absence of a collection or a wound discharge, only antimicrobial treatment should be provided. If discharge or collections are present, surgical drainage and debridement are necessary, the organisms present must be identified, and antimicrobial treatment prescribed.

Implants should be retained unless fracture has occurred, in which case repeated debridement with removal of all devitalized bone and soft tissue is required. After

this, either exchange implants or external fixation are undertaken.

Osteomyelitis in decubitus ulcers

The incidence of osteomyelitis under decubitus ulcers ranges from 28 to 70 per cent (Bohm *et al*. 1988; Bruck *et al*. 1991). Most patients with osteomyelitis have radiological changes but to confirm its activity and aetiology requires needle or surgical bone sampling. Antibiotics are indicated only if osteomyelitis is present. After surgical debridement, soft-tissue coverage is essential. Myocutaneous flaps are superior to skin flaps in securing skin cover.

Acute haematogenous osteomyelitis in children

Haematogenous osteomyelitis may appear as an acute onset of bone pain or limited motion of an extremity, regardless of the presence or absence of signs of infection such as fever, local tenderness, redness, swelling or heat.

Acute haematogenous osteomyelitis in children is becoming infrequent. Nelson (1990) reports that this diagnosis is made only approx. 15 times per year in a large referral unit for paediatric infectious diseases in the United States. Approximately one-third of the cases occur in children under 2 years of age, another one-third between 2 and 5 years, and the remaining one-third in children more than 5 years old (Nelson 1990).

In most children with acute haematogenous osteomyelitis no predisposing factors are apparent but it is well known that sickle-cell anaemia is associated with a higher risk of haematogenous osteomyelitis, particularly due to *Salmonella* (Adeyokunnu and Hendrickse 1980; Syrogiannopoulos *et al*. 1986). and *Staphylococcus* (Sadat-Ali *et al*. 1985).

Pain, pseudoparalysis (voluntary limitation of movement of one extremity), and fever are the most common clinical manifestations. Initially, local inflammatory signs are rarely present. As mentioned earlier, plain radiographs are frequently negative and isotope bone scanning is required (Herndon *et al*. 1985; Demopulos *et al*. 1988). The disease is almost always monostotic and long-bone metaphyses are the sites most frequently involved. Diagnostic confirmation requires needle aspiration or surgical debridement. Blood cultures are, in contrast to chronic osteomyelitis, frequently positive (in at least one-third of the episodes). Both blood and local samples should be always be obtained because, not uncommonly, only one of the samples is positive. *Staphylococcus aureus* is responsible for at least 50 per cent of the cases. The remaining cases are caused by different micro-organisms, among them *Streptococcus* and *Haemophilus* (Nelson 1990).

When pain is severe, needle or surgical decompression should be undertaken. If the infection opens into the synovial cavity, repeated needle aspiration may be sufficient.

When no pain or large collection of pus is present, antimicrobial treatment alone may be enough. Sequential treatment (intravenous drugs followed by oral antimicrobial agents) has proved adequate (Nelson 1982). A total of 10 to 14 days of intravenous antibiotics is followed by 2 to 6 additional weeks of oral agents. These should have an acceptable flavour, good oral absorption, low toxicity profile and be active against Gram-positives and *Haemophilus*. The indication for measuring serum bactericidal concentrations during follow-up still needs to be defined but trough or peak levels greater than 1/8 or 1/32 have been recommended (Prober and Yeager 1979; Nelson 1990).

Nowadays the prognosis of acute haematogenous osteomyelitis in childhood is much better than in the past. Death from this cause is almost non-existent and evolution to chronicity occurs in less than 5 per cent of cases (Dunkle and Brock 1982; Nelson 1990).

Vertebral osteomyelitis

The spinal column is the most common site of haematogenous osteomyelitis in adults, probably due to vertebrae having abundant red marrow and a slow and tortuous blood flow. Bacteria reach the vertebral bodies preferentially by the arteries but occasionally also through the venous plexus (Wiley and Trueta 1959; Waldvogel *et al*. 1970; Adatepe *et al*. 1986; Sapico and Montgomerie 1990).

More than 50 per cent of the episodes of vertebral osteomyelitis are due to *Staph. aureus*, approx. 30 per cent to *Enterobacteriaceae*, and the remaining 10 to 20 per cent to other micro-organisms such as *Brucella* spp, *M. tuberculosis*, and fungi (Sapico and Montgomerie 1979; Sapico and Montgomerie 1980; Sapico and Montgomerie 1990).

Vertebral osteomyelitis is generally monomicrobial but the association of *M. tuberculosis* with other pathogens, particularly *Staph. aureus*, is more than casual.

Pain that increases with spinal movement is the most common clinical manifestation of vertebral osteomyelitis. Other symptoms depend on the site of involvement. In patients with cervical osteomyelitis and prevertebral abscesses, odinophagia and dysphagia may be present.

Fever and/or an increased white blood-cell count is absent in up to half of the cases. An increased erythrocyte sedimentation rate has traditionally been considered to be a very sensitive marker for the presence of active vertebral infection. In our experience this is not the case and the diagnosis of vertebral osteomyelitis should not be rejected in patients with a normal erythrocyte sedimentation rate.

Overall, the lumbar spine is the most frequent location and is involved in more than 50 per cent of episodes of vertebral osteomyelitis, followed by 35 per cent in the dorsal spine, and the remaining 15 per cent in the cervical spine.

Lumbar osteomyelitis occurs occasionally as a septic metastasis of infections of the pelvis and genitourinary tract (Sapico and Montgomerie 1979); cervical bone infection is frequently a complication of parenteral drug abuse and is seen in patients with other predisposing conditions (Sapico and Montgomerie 1986).

Most cases of vertebral osteomyelitis have abnormalities on plain radiographs when first seen but in very acute presentations, pain may be present but the plain film is normal. Erosive, irregular images in the vertebral bodies and the adjacent intervertebral disc are common. Pre- and paravertebral abscesses and vertebral collapse are common complications (Fig. 4 and Fig. 5).

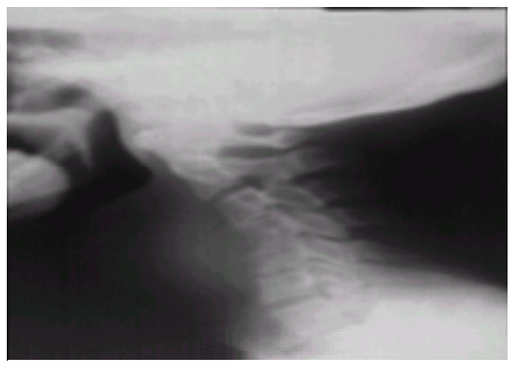

Fig. 4 Cervical vertebral osteomyelitis and prevertebral pyogenic abscess.

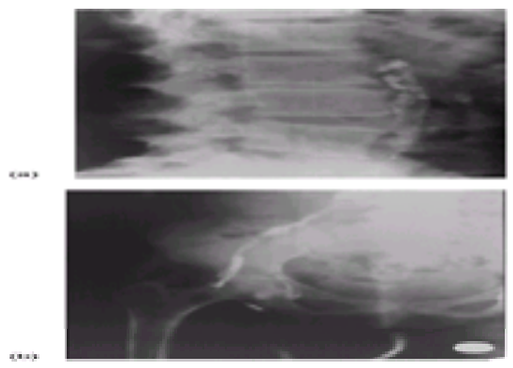

Fig. 5 Tuberculous vertebral osteomyelitis with a fistulous tract draining to the upper thigh.

Isotope imaging is diagnostically very sensitive in patients with normal or equivocal plain films. Both CT and MRI offer early and well-defined images that are very useful for directing aspiration or surgery (Boddicker *et al*. 1980; Modic *et al*. 1985; Sapico and Montgomerie 1990).

Microbiological confirmation requires either positive blood cultures, vertebral material or both. Only one-quarter of the episodes are documented with blood cultures and consequently bone aspiration should be undertaken whenever possible.

Most cases of vertebral osteomyelitis do not require surgical debridement. Surgery should be reserved for patients with spinal instability, neurological impairment, a large, progressive abscess impossible to drain by guided needle aspiration, or cases of unknown aetiology not responding rapidly to antimicrobial therapy.

Considerations governing antimicrobial therapy described previously also apply to vertebral involvement. Immobilization in bed is only required for patients with pain or vertebral instability and casts are not necessary in most cases.

Infected prosthesis (see Chapter 5.3.1)

Infections related to joint prostheses have been divided into those presenting in the first 3 months after surgery (type I), those presenting between 3 months and 1 year postoperatively (type II), and those occurring after 1 year postsurgery (type III) (Coventry 1975). Type I infections are almost exclusively acquired during surgery and may be divided into superficial (involving soft tissues but not the prosthesis), and deep (involving the prosthesis). In group II, most infections are surgically acquired and practically all of them involve the prosthesis. Finally, group III infections are of haematogenous origin and involve the prosthesis. At least 70 per cent of prosthetic joint infections are monomicrobial and the remaining 20 to 30 per cent are either polymicrobial or not documented (Buchholz *et al*. 1981; Buchholz *et al*. 1984). Among the responsible micro-organisms, *Staph. epidermidis* and *Staph. aureus* are far ahead of other bacteria, followed by Gram-negative rods and anaerobes.

Chronic infection of articular prostheses usually begins as continuous pain, frequently without obvious drainage through a sinus tract, prosthetic dysfunction or complete loosening (Fig. 6). Infections associated with prosthetic material are extremely difficult to treat and often require surgical removal of foreign bodies, which may be very radical when artificial joints are involved. Attempts to implant a new prosthesis are usually made after prolonged courses of antimicrobial therapy, leaving the patient with major incapacity for a long time. Recently, Drancourt *et al*. (1993) reported an acceptable rate of success (74 per cent) on treating osteoarticular prostheses infected with staphylococci with prolonged periods (9–12 months) of ofloxacin and replacing the prosthesis, when necessary, in a one-step procedure.

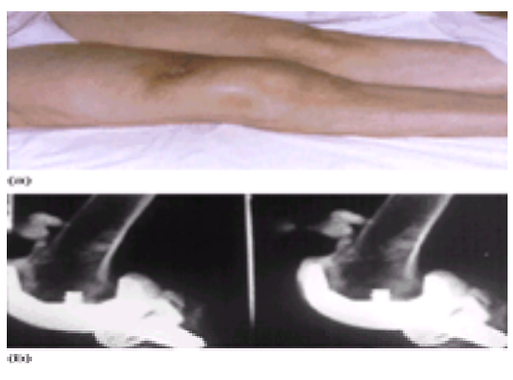

Fig. 6 Infected knee prosthesis: (a) fistulous tract; (b) fistulography.

Type I infections with superficial involvement and no evidence of prosthetic dysfunction should be treated with antimicrobial agents, removal of blood or collections, soft-tissue debridement, and irrigation. A high proportion of these cases (approx. 70 per cent) do not require future prosthetic replacement (Buchholz *et al*. 1984; Fitzgerald 1984; Fitzgerald and Jones 1985). Even in cases with deep infections, antimicrobial therapy and early debridement and irrigation save at least 50 per cent of the prostheses (Drancourt *et al*. 1993).

In patients with type II and III infections the final objective is to preserve a functional, pain-free prosthesis. In patients with no prosthetic dysfunction and with no or minimal pain, a trial of antimicrobial therapy without surgical replacement of the prosthesis can be attempted. We use, whenever possible, oral antimicrobial agents, usually including rifampin in a combination regimen. Treatment is continued for a 6- to 12-month period, provided an adequate response was rapidly obtained. In case of a late relapse, the treatment is individualized depending on many variables such as the age of the patient, functional status, and the risk for surgical replacement.

In patients with pain, prosthetic dysfunction or loosening, surgical replacement is necessary. It may be performed in two stages or in a single step, with a low rate of reinfection (Buchholz *et al*. 1984).

Infectious arthritis

Infectious arthritis must be considered as an emergency, since delays or inadequate treatment may result in great disability. The recognition, diagnosis, and treatment of this condition are therefore very important (Smith 1990).

Infectious arthritis should be suspected in any patient with a swollen joint but especially in children, debilitated patients, immunocompromised persons, those with infection elsewhere (even if on antibiotics), and those with other types of arthritis or a prosthetic joint (Fig. 7). Diagnosis depends on obtaining joint fluid for culture and Gram staining. Initial treatment with appropriate broad-spectrum antibiotics is later best narrowed to suit the individual organism. Treatment requires repeated needle aspiration or surgical drainage plus an antimicrobial course of 2 to 6 weeks (Middleton 1993).

Fig. 7 Right hip infection caused by *Staph. aureus* in an intravenous drug abuser.

This subject is described in more detail in Chapter 5.3.1. Some clinical and epidemiological features related to aetiological agents of infectious arthritis are shown in Table 8.

Risk factor	Micro-organisms
Infants	*Staph. aureus* Enterobacteria Group B streptococci
Children	*Staph. aureus* *H. influenzae* *Streptococcus* spp. Enterobacteria
Adults	*Staph. aureus* Group A streptococci Enterobacteriaceae *N. gonorrhoeae*
Rheumatoid arthritis	*Staph. aureus* *Streptococcus* spp. Enterobacteria
Prosthetic joint, postoperative, intra-articular injection	*Staph. epidermidis* *Staph. aureus* Enterobacteriaceae *Pseudomonas* spp.
Intravenous drug abuse	*Staph. aureus* or *Ps. aeruginosa*
Human bite	*Eikenella corrodens*, oral flora
Cat or dog bite	*Pasteurella multocida, anaerobes*
Rat bite	*Streptobacillus moniliformis*
Risk factor	**Micro-organisms**
Tick exposure	*Borrelia burgdorferi*
Unpasteurized dairy products	*Brucella* spp.
Trauma in aquatic environment	*Mycobacterium marinum*
Quarrelling injury	*Eikenella corrodens*
Abrasions or amputations	*N. gonorrhoeae*

Table 8 Epidemiological and clinical characteristics of aetiological agents of infectious arthritis

Most cases are caused by *Staph. aureus*, although many bacterial and viral pathogens may be involved. Among streptococci, group A b-haemolytic predominates, although group b have been described, mainly in immunosuppressed patients (Barberan *et al*. 1993). *Neisseria gonorrhoeae* is the predominant cause of bacterial arthritis in sexually active adults under 30 years of age with no other risk factor. Transient, disseminated, papular skin lesions precede the appearance of polyarticular symptoms and blood cultures are usually positive. In the rare event of monoarticular infection the micro-organism is only isolated from synovial fluid.

Gram-negative rods usually cause infectious arthritis in patients with underlying conditions, and *Pseudomonas* spp. have been associated sternoclavicular and sacroiliac joint infections in intravenous drug abusers.

Lyme arthritis should be suspected in patients with a history of tick exposure and erythema chronicum migrans. The diagnosis is usually serological.

Chronic monoarticular arthritis is usually caused by mycobacteria or fungus. Infectious arthritis caused by *M. tuberculosis* is infrequent, usually affecting the interphalangeal joints of the hand. *Mycobacterium kansasii* and *M. marinum* arthritis have also been described.

A number of fungi can cause infectious arthritis. *Sporothrix shenckii* infections are usually related to contact with soil and most commonly affect the knee. *Coccidioides immitis* arthritis can occur in endemic areas, in both immunocompetent and immunocompromised patients. Other fungi such as *Candida* (haematogenous spread), *Cryptococcus*, and *Aspergillus* are even rarer agents of infectious arthritis (Christensson *et al*. 1993; Cuende *et al*. 1993).

Many viral infections can produce joint symptoms. Among them, rubella (small joints of the hand), erythema infectiosum (parvovirus B19), and hepatitis B are the most common. Mycoplasmas and ureaplasmas are responsible for about two-fifths of cases of septic arthritis in patients with hypogammaglobulinaemia (Furr *et al*. 1994). Management is dealt with in other chapters.

Prognosis

Bad prognostic factors include: age exceeding 60 years, pre-existing arthritis, infection in hip and shoulder, symptoms for more than 7 days before treatment, involvement of more than four joints, and persistently positive cultures after 7 days of appropriate therapy.

Limitation of motion and persistence of pain are the most common sequel; although a mortality rate between 30 and 100 per cent has been described for polyarticular cases (Bould *et al*. 1993; Pitkin and Eykyn 1993).

5.3.4 Lyme disease

Daniel W. Rahn

Introduction

Lyme disease is a tick-borne infectious disorder caused by a spirochaete, *Borrelia burgdorferi*. The best clinical marker of disease onset is a characteristic expanding skin lesion, erythema migrans. Weeks to months later the nervous system, heart, and joints may be affected with rare involvement of other organ systems. Lyme disease responds to antibiotics throughout its course, but treatment of early disease is the most successful. Endemic foci of Lyme disease have been described in the United States, Europe, and Asia.

History

'Lyme arthritis' was recognized in November 1975 because of an epidemic of arthritis in children in the region of Lyme, Connecticut (Steere *et al*. 1977b). Prospective, community-based study demonstrated the illness to be a multisystem disorder (Lyme disease) (Steere *et al*. 1977b; Reik *et al*. 1979; Steere *et al*. 1979; Steere *et al*. 1980; Steere *et al*. 1983a), occurring at any age and in both sexes, usually beginning with a characteristic expanding skin lesion, erythema chronicum migrans (Afzelius 1910), now shortened by convention to erythema migrans. Erythema migrans had previously been associated with the bite of the sheep tick, *Ixodes ricinus* (Thone 1968), and with tick-borne meningopolyneuritis (Garin-Bujadoux 1922), but not with arthritis (Bannwarth 1944). Field studies in the Lyme region revealed the presence of a closely related tick, *I. scapularis*, which was subsequently implicated as the principal disease vector (Steere *et al*. 1978; Wallis *et al*. 1978; Steere and Malawista 1979).

In 1982, Burgdorfer and associates (Burgdorfer *et al*. 1982) isolated a spirochaete from *I. scapularis* ticks from Shelter Island, New York. Patients with Lyme disease were found to have an elevated serological response to this spirochaete and within months this organism had been cultured from blood, skin, and cerebrospinal fluid of patients with various manifestations of Lyme disease (Benach *et al*. 1983; Steere *et al*. 1983d).

Much has been learned about Lyme disease but many areas of uncertainty remain. There is no clear consensus among practising physicians regarding the geographic range, clinical spectrum, and optimal treatment of this complex disorder. Why some individuals develop chronic symptoms despite apparent elimination of infecting organisms also remains to be elucidated.

Causative agent: *Borrelia burgdorferi*

Lyme disease is caused by *B. burgdorferi*, a spirochaete 10 to 30 µm long and 0.2 to 0.25 µm wide. It can be grown only in a specialized medium (Barbour–Stoner–Kelly medium) that is not available routinely in clinical laboratories (Weber *et al*. 1993). *Borrelia burgdorferi* replicates slowly *in vitro*, with a generation time of around 12 to 20 h. The organism has an outer membrane that surrounds a periplasmic space, multiple flagella, and a protoplasmic cylinder. Its genetic material is contained on a single linear chromosome and both linear and circular plasmids. Immunodominant, species-specific, outer surface proteins are encoded on plasmids. Other non-species-specific antigens of importance are flagellin (41 kDa) and a high molecular-weight heat-shock protein.

Three different genospecies have been described to date: *B. burgdorferi* sensu stricto, *B. garinii*, and *B. afzelii* (Baranton *et al*. 1992; Canica *et al*. 1993). A serotyping system has been developed based on reactivity to different epitopes of OspA (Wilske *et al*. 1993). North American isolates have shown less variability with regard to OspA, than have European isolates. Genetic differences among isolates appear to explain the different virulence patterns seen in European and North American Lyme disease. *B. afzelii*, isolated predominantly in Europe, has a propensity to persist in the skin causing the chronic skin lesion acrodermatitis chronica atrophicans. The other species appear to have a greater tendency for haematogenous dissemination (van Dam *et al*. 1993; Wienecke *et al*. 1994).

Pathogenesis

Lyme disease develops after an infected tick transmits *B. burgdorferi* to a susceptible host. Following a period of latency, organisms spread outward in skin causing the characteristic skin lesion, erythema migrans. Organisms can be readily cultured from biopsy specimens of the primary skin lesion. Histological staining of lesions of erythema migrans may reveal occasional spirochaetes and there is an inflammatory infiltrate consisting of lymphocytes, histiocytes, and plasma cells. In addition to erythema migrans, *B. burgdorferi* causes another acute skin lesion, benign lymphocytoma (Weber *et al*. 1984), seen primarily in Europe. The infection subsequently disseminates to involve secondary skin sites (secondary annular lesions) and other organs (e.g., central nervous system, heart and joints).

Borrelia burgdorferi has been cultured from involved tissues during all stages of the illness. Positive cultures have been obtained from blood (early) (Benach *et al*. 1983; Steere *et al*. 1983d), secondary skin lesions (Åsbrink and Hovmark 1985), cerebrospinal fluid (Steere *et al*. 1983d), joint fluid (Snydman *et al*. 1986), iris, ligamentous tissue, and a long-standing lesion of acrodermatitis chronica atrophicans (Åsbrink and Hovmark 1985). As the disease progresses, however, it becomes progressively more difficult to isolate organisms by culture.

Chronic manifestations have primarily involved the nervous system (Reik *et al*. 1979; Pachner *et al*. 1985; Halperin *et al*. 1987; Halperin *et al*. 1989; Pachner *et al*. 1989; Logigian *et al*. 1990), joints (Steere *et al*. 1987; Steere *et al*. 1990), and skin (Åsbrink and Olsson 1985). There is mounting evidence to explain how *B. burgdorferi* might persist in antibiotic-treated patients. *In vitro* the organism was able to invade and survive within some human cells such as fibroblasts, macrophages and endothelial cells, and thereby evade the action of antibiotics (Comstock and Thomas 1989; Klempner et al.1993; Montgomery et al.1994). Also, *B. burgdorferi* can cross the blood–brain barrier early in the course of infection where routine oral antibiotic regimens do not produce bactericidal levels. Neurological dysfunction resulting from low-grade infection in the central nervous system may only become apparent clinically months to years later (Garcia-Monco *et al*. 1990; Pfister *et al*. 1990; Luft *et al*. 1992).

Other, parainfectious mechanisms may also contribute to the development of chronic neuropathy and arthritis, at least in some individuals. There is a sharp distinction between the response to antibiotics of individuals with early disease and the inconsistent response of those with chronic neurological involvement (see below). Similarly, the likelihood of Lyme arthritis responding to antibiotics is affected by duration of arthritis and immunogenetic factors, particularly HLA-DR4 (Steere *et al*. 1979; Steere *et al*. 1990). Joint inflammation in these individuals may persist after the joint fluid has become negative in the polymerase chain reaction (Nocton *et al*. 1994). Thus, initial infection may trigger persistent inflammation in immunogenetically susceptible individuals. Clinical heterogeneity and inconsistent antibiotic

responsiveness may be explained by differing mechanisms of inflammation at different stages of the illness.

Disabling fatigue has been a particularly troublesome symptom associated with late Lyme disease. Fatigue alone rarely, if ever, responds to antibiotic therapy. Proinflammatory cytokines have been implicated in the pathogenesis of both Lyme arthritis and chronic neurological manifestations, and may account for this pathological fatigue. It is not known whether either live *B. burgdorferi* or retained bacterial products are necessary to stimulate cytokine release, an issue with obvious implications for therapy.

Immune abnormalities are present in all stages of Lyme disease (Steere *et al*. 1977; Steere *et al*. 1979a; Hardin *et al*. 1979a; Hardin *et al*. 1979b). At disease onset, immune complexes are often detectable in serum (Hardin *et al*. 1979a; Hardin *et al*. 1979b) and the serum IgM is often elevated, both of which are associated with disease dissemination. When arthritis is present, immune complexes are uniformly elevated in joint fluid rather than serum (Hardin *et al*. 1979a; Hardin *et al*. 1984). The synovial lesion contains a mixed infiltrate of lymphocytes and plasma cells (Steere *et al*. 1979). Production of anti-*B. burgdorferi* antibody in the cerebrospinal fluid is a hallmark of chronic neurological involvement (Halperin *et al*. 1989; Logigian *et al*. 1990).

As infection spreads from a local (skin) site to involve other organs, an inflammatory response ensues, which includes immune elements and the release of cytokines. Variation in symptoms and clinical course reflects both direct effects of infection and immunological phenomena triggered by the infection. Systemic symptoms result from disseminated infection, immune-mediated inflammation, and release of cytokines. Organ-specific inflammation occurs when localized infection (e.g. joints and nervous system) stimulates a localized immune response. But in immunogenetically susceptible individuals the immunological response may be prolonged, and perhaps even self-perpetuating. Therapeutic advances will require a clearer understanding of the specific disease mechanisms, particularly regarding the question of persistence of spirochaetes or their antigens throughout the entire course of the illness.

Epidemiology

Cases of Lyme disease have been reported from most states in the United States as well as throughout Europe, the former Soviet Union, China, Japan, and (questionably) Australia (Dekonenko *et al*. 1988; Burgdorfer 1989). In the United States, endemic foci are clustered in the north-east from Massachusetts to Maryland, the mid-west in Wisconsin and Minnesota, and the west along the northern California coast (Steere *et al*. 1979; Craven and Dennis 1993). Although Lyme disease was first described only 20 years ago, *B. burgdorferi* has been identified by polymerase chain reaction in preserved mouse tissues collected along the southern New England coast in 1894 (Marshall et al.1994).

A national surveillance case definition was adopted in the United States in 1990 (Table 1). With the use of this case definition, the number of cases reported in the United States has been relatively stable over the past 4 years, with approx. 9000 new cases reported nationally in 1993 (Craven and Dennis 1993). This case count is not an accurate reflection of the true incidence of Lyme disease, however, because most cases are not reported.

Table 1 Lyme disease: United States national surveillance case definition

The highest incidence of Lyme disease is in children under the age of 15 years and middle-aged adults. Illness generally begins between May l and November 30, with the peak in June and July (Steere *et al*. 1983a). Limited studies have shown a significant prevalence of asymptomatic seropositivity in high-risk populations, the significance of which is unknown at present (Steere *et al*. 1986).

The primary vectors of Lyme disease are ixodid ticks. Endemic regions correspond to the distribution of *I. scapularis* (north-east and upper mid-west United States) (Steere *et al*. 1979), *I. pacificus* (California) (Steere *et al*. 1979), *I. ricinus* (Europe and Russia) (Dekonenko *et al*. 1988), and *I. persulcatus* (eastern Russia, China, and Japan) (Burgdorfer 1989). The vector in the north-east United States was previously thought to be a separate species, *I. dammini*, which has recently been shown to be onspecific with *I. scapularis*, its current designation (Oliver *et al*. 1993).

The epidemiology of Lyme disease is explained by the ecology of the tick vectors. The most thoroughly studied, *I. scapularis*, has a three-stage lifecycle (larva, nymph, and adult) spanning 2 years (Fig. 1). In the north-east United States, both the larval and nymphal stages feed on a variety of small mammals, especially the white-footed mouse (*Peromyscus leukopus*) (Wallis *et al*. 1978; Spielman *et al*. 1985; Mather *et al*. 1989). Infected nymphs transmit spirochaetes to mice, which in turn pass the infection on to larval ticks. Humans most often acquire infection from nymphs. Adult ticks feed primarily on larger mammals, especially deer. In endemic regions, 20 to 60 per cent of nymphal *I. scapularis* may be infected with *B. burgdorferi* (Burgdorfer *et al*. 1982; Steere *et al*. 1983d). In contrast the infection rate in *I. pacificus* in endemic areas of California has been found to be 2 per cent or less (Burgdorfer *et al*. 1985), where a complex, two-tick enzootic cycle maintains *B. burgdorferi* in nature (Brown and Lane 1992). An enzootic cycle involving *Neotoma mexicana* (a wood rat) and *I. spinipalpis* has recently been described in northern Colorado (Maupin *et al*. 1994).

Fig. 1 Larva, nymph, adult female and adult male *Ixodes scapularis* ticks (photo M. Fergione).

Birds may serve as hosts for larval and nymphal *Ixodes* ticks and provide a natural means of distributing ticks to new areas (Anderson *et al*. 1985; Anderson *et al*. 1986). Birds do not appear to be a reservoir for *B. burgdorferi*, however, and probably do not contribute significantly to the spread of infection.

Various public-health interventions have been designed to reduce the incidence of Lyme disease. Prompt removal of ticks prevents infection in the vast majority of exposed individuals (Shapiro *et al*. 1992). Eliminating deer can reduce the total tick population but is impractical. Distributing permethrine-impregnated (an acaricide) cotton balls in the nesting environment of mice has been shown to reduce the infestation of mice by ticks, which in turn can reduce the tick infection rate, but this too has obvious practical limitations (Ginsberg 1995). In some regions of the United States the perceived threat of Lyme disease is much greater than objective data can

support. The public-health approach in these regions must be focused on education of the public and health professionals rather than disease control. Adequate control of Lyme disease will require close collaboration between ecologists, epidemiologists, public-health officials, physicians, and an informed public.

Clinical features

Most cases of Lyme disease begin with a characteristic skin lesion (erythema migrans) (stage 1). Within days to weeks, the illness disseminates, with the development of secondary skin lesions, headache, and generalized musculoskeletal symptoms. Weeks later, carditis and acute neurological abnormalities may occur (stage 2). Months later, arthritis and chronic neurological abnormalities appear (stage 3). Chronic skin involvement (acrodermatitis chronica atrophicans) also occurs late in disease, predominantly in Europe. As a guide to therapy, it is best to characterize patients as having early localized (erythema migrans), acute disseminated (neurological or non-neurological), or chronic disease. Clinical stages may overlap or be skipped entirely (Hanrahan *et al*. 1984).

Early Lyme disease

Erythema migrans begins as a red macule or papule at the site of a tick bite (Steere *et al*. 1977c; Steere *et al*. 1983a). After an incubation period of a few days to a month, the lesion expands gradually (0.5–1 cm/day) to a mean diameter of l5 cm (range 3–68 cm). Lesions are flat and non-scaling with a red outer border and partial central clearing (Fig. 2). The centre may be flat, indurated, vesicular or necrotic. The posterior thigh, groin, popliteal fossa, and axilla are particularly common sites. Lesions are warm and minimally tender, and may go unnoticed.

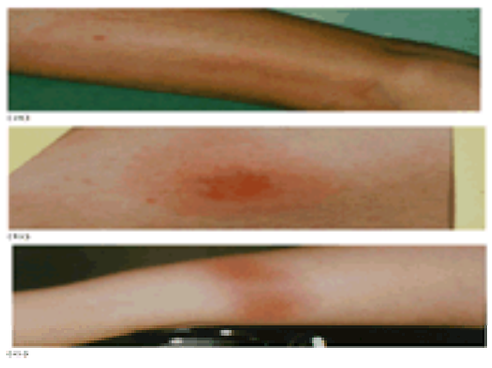

Fig. 2(a)–(c) Erythema migrans, various forms.

Half of patients in the United States develop multiple secondary lesions within days of onset of infection. Lymphocytoma cutis, a purplish nodule often on the nipple, has been reported as a manifestation of primary infection in Europe (Åsbrink and Olsson 1985). Erythema migrans and secondary lesions fade even without treatment in 3 to 4 weeks but may recur. Spirochaetes can be cultured from the skin of untreated patients even after lesions have resolved (Kuiper *et al*. 1994).

Malaise, fatigue, fever and chills, myalgia, arthralgia, headache, and paraesthesias often accompany erythema migrans (Steere *et al*. 1977c; Steere *et al*. 1983a). Recent studies have suggested that headache and paraesthesias may reflect early neurological dissemination (Reik *et al*. 1979; Garcia-Monco *et al*. 1990; Luft *et al*. 1992). Systemic signs and symptoms vary from day to day, and may appear before or after erythema migrans (or without it altogether). In untreated patients, symptoms may recur for months (especially fatigue and lethargy) after skin lesions have disappeared. European erythema migrans often has a prolonged, subacute course; secondary skin lesions, prominent systemic symptoms, laboratory abnormalities and subsequent arthritis are uncommon (Åsbrink and Olsson 1985).

Minor laboratory abnormalities associated with early Lyme disease are an increased erythrocyte sedimentation rate, total serum IgM, and serum glutamic oxaloacetic transaminase (Steere *et al*. 1977b; Steere *et al*. 1977c). Mild anaemia and leucocytosis also are common. Microscopic haematuria and low-grade proteinuria have been reported. Tests for rheumatoid factor or antinuclear antibodies are usually negative.

Disseminated and chronic Lyme disease

Neurological manifestations

Neurological abnormalities develop within several weeks of disease onset in a minority of patients (15 per cent in one series (Reik *et al*. 1979)). Cranial neuropathy (most commonly involving the facial nerve) (Clark *et al*. 1985), meningitis, and radiculoneuropathy alone or in combination (Reik *et al*. 1979; Pachner and Steere 1985; Halperin *et al*. 1987; Halperin *et al*. 1989; Pachner *et al*. 1989). Later in the disease, chorea, demyelinating encephalopathy or myelopathy, chronic encephalopathy, peripheral polyneuropathy, and transverse myelitis may occur (Reik *et al*. 1979; Ackerman *et al*. 1988; Halperin *et al*. 1987; Halperin *et al*. 1989; Logigian *et al*. 1990). Acute and chronic neurological Lyme disease differ in their natural history and response to therapy.

Radiculoneuropathy may affect any dermatome or even several contiguous dermatomes. Symptoms include paraesthesia, pain, sensory deficit and, often, motor weakness. Radiculoneuropathy is often accompanied by meningitis, a complex dubbed Bannwarth's syndrome.

The primary symptom of Lyme meningitis is headache, which may vary in intensity from hour to hour or day to day, and is often accompanied by a mild encephalopathy. Neck stiffness is common but meningismus is not. Spinal fluid contains a lymphocytic pleocytosis and mildly elevated protein, but glucose is normal. Studies with the polymerase chain reaction and rare positive cultures have shown that Lyme meningitis results from direct infection in the cerebrospinal fluid (Keller *et al*. 1992). Both radiculoneuropathy and meningitis eventually remit even without treatment but often only after waxing and waning for months (Reik *et al*. 1979).

Facial palsy, which may be bilateral, is the most common acute neurological manifestation of disseminated, early Lyme disease. Facial paralysis may occur when erythema migrans is present or within a few weeks after its resolution. Even in highly endemic areas, however, facial nerve palsy is usually idiopathic. The course of facial weakness is benign and not distinguishable from that of Bell's palsy; over 95 per cent of individuals experience complete or near complete resolution even without therapy. Fifty per cent of individuals with facial nerve palsy have an associated meningitis, so examination of the cerebrospinal fluid is indicated.

Chronic neurological manifestations emerge months to years after the onset of Lyme disease. Although symptoms vary, memory impairment, and peripheral, sensory polyneuropathy predominate (Reik *et al*. 1985; Halperin *et al*. 1987; Halperin *et al*. 1989; Logigian *et al*. 1990). The cerebrospinal fluid of individuals with chronic encephalopathy usually has a mildly elevated protein but no cells.

Carditis

Carditis develops in less than 5 per cent of cases, generally within several weeks of disease onset (Steere *et al*. 1978). Patients with carditis typically present with palpitations, light-headedness, or syncope due to varying degrees of atrioventricular block. Dilated cardiomyopathy, perhaps reflecting more diffuse myocardial involvement, has also been tentatively linked to Lyme disease (Steere *et al*. 1980; Stanek *et al*. 1990). Carditis remits spontaneously in days to a few weeks and, once resolved, does not recur. Although clinical manifestations are usually limited to the conduction system, subclinical myocardial involvement may be more extensive (McAlister *et al*. 1989). One fatal case involving concurrent *Babesia* infection has been reported (Marcus *et al*. 1985). Carditis should be suspected in individuals in endemic areas who develop heart block without other explanation.

Arthritis

Approximately 60 per cent of untreated individuals develop arthritis from weeks to years after the onset of illness (Steere *et al*. 1977; Steere *et al*. 1979). Frank arthritis may be preceded by months or even years of intermittent migratory myalgias, arthralgias, and periarticular pain. The typical attack begins suddenly with the rapid development of massive swelling of a single large joint, most often the knee. Individual attacks of arthritis usually last a few weeks to a few months and remit

spontaneously. Recurrences are common but attacks decrease in frequency by 10 to 20 per cent per year and eventually cease in most patients, even without antibiotic therapy (Steere *et al*. 1987).

Joint-fluid cell counts average about 25 000 cells/mm^3, with a predominance of polymorphonuclear leucocytes (Steere *et al*. 1977b). Protein is usually elevated; glucose usually normal. Attempts to culture *B. burgdorferi* from joint fluid have been almost invariably unsuccessful (Snydman *et al*. 1986) but the polymerase chain reaction has revealed *B. burgdorferi* DNA in most untreated patients (Bradley *et al*. 1994; Nocton *et al*. 1994). Arthritis in Lyme disease is almost certainly initiated by direct spirochaetal infection of the joint.

Arthritis becomes chronic in approximately 10 per cent of patients, especially individuals who are HLA-DR4 positive in whom pannus may form and erosions develop despite antibiotic therapy that is curative in other patients (Steere *et al*. 1979; Steere *et al*. 1987; Steere *et al*. 1990). The development of a serological immune response against outer surface proteins A and B has been linked to the development of chronic arthritis (Kalish *et al*. 1993). The synovium in chronic Lyme arthritis looks like that of rheumatoid arthritis (Steere *et al*. 1977b; Steere *et al*. 1979). In addition, there may be an obliterative endarteritis and spirochaetes have been seen using a variety of staining techniques. Thus, chronic Lyme arthritis is similar to rheumatoid arthritis, for which it may serve as a model.

Acrodermatitis chronica atrophicans

Acrodermatitis chronica atrophicans (Weber *et al*. 1984; Åsbrink *et al*. 1985) occurs relatively commonly in Europe but is rare in the United States (Kaufman *et al*. 1989). Lesions occur most often on distal extremities and begin as violaceous, infiltrated plaques or nodules that evolve into an atrophic stage. Acrodermatitis chronica atrophicans results from chronic persistence of infection in skin and has been associated with *B. afzelii* (Canica *et al*. 1993; van Dam et al.1993; Wienecke *et al*. 1994).

Diagnostic testing

Culture of *B. burgdorferi* from patients is necessary for definitive diagnosis, but has a significant yield only from affected (erythema migrans) skin (Steere *et al*. 1983; Åsbrink and Hovmark 1985; Berger *et al*. 1985). Spirochaetes are rarely visualized by tissue stains (Steere *et al*. 1983; Berger 1984; Johnston *et al*. 1985). Attempts should be made to isolate the organism by culture when erythema migrans is suspected in a patient from a region not previously known to be endemic; in endemic regions, this is not necessary for diagnosis.

Detection of specific anti-*B. burgdorferi* antibody is the most helpful diagnostic test for confirmation of the diagnosis of Lyme disease. Specific IgM antibody appears first after the onset of the disease and reaches a peak within 3 to 6 weeks. IgG antibody develops more slowly, often reaching a peak months later (Steere *et al*. 1983; Craft *et al*. 1984).

In the past, the performance of many commercially available immunofluorescence tests or enzyme-linked immunosorbent assays for *B. burgdorferi* antibodies has been poor, with unacceptably low sensitivity and/or specificity and lack of reproducibility (Schwartz *et al*. 1989; Luger and Krauss 1990; Magnarelli *et al*. 1990). The major problem at present, however, is not performance, which is comparable to that of many other serological tests, but rather that indiscriminate use of serological testing has set the stage for results with very low positive predictive value (Britton *et al*. 1993; Lightfoot *et al*. 1993). As an example, when the likelihood of Lyme disease is estimated to be 5 per cent before testing, a serological test with sensitivity and specificity of 95 per cent will have a positive predictive value of only 50 per cent. Patient selection has a profound effect on the predictive value of serological testing.

Serological tests may be falsely positive or negative for a variety of reasons. *Borrelia burgdorferi* contains epitopes that are cross-reactive with other spirochaetes, including *Treponema pallidum* and oral treponemes. Some patients with rheumatoid arthritis or systemic lupus erythematosus have low-titre, false-positive serological findings. Seronegative Lyme disease also occurs, but rarely, primarily following incomplete antibiotic therapy for early disease.

Western blotting is available as a confirming test (Dressler *et al*. 1993). This technique can distinguish between true seroreactivity against *B. burgdorferi* and false positivity. Both the technique for Western blotting and criteria for positivity must also be standardized, however. A workshop sponsored by the Centers for Disease Control in 1994 produced recommendations that Western blotting be used to confirm all positive enzyme immunoassay results (Table 2). The most cost-effective approach at present may be to reserve Western blotting for equivocal circumstances.

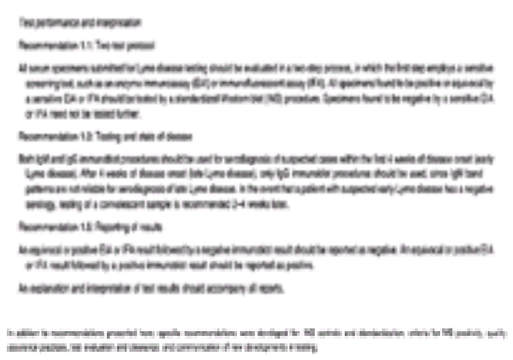

Table 2 Centers for Disease Control and Prevention Workgroup recommendations on laboratory testing for Lyme disease (draft)

Tests have been developed to measure cell-mediated immunity against *B. burgdorferi* but these have not added clinically useful information because of technical difficulties and the rarity with which the cell-mediated immune response differs from the serological response (Dattwyler *et al*. 1989; Zoschke *et al*. 1991).

Lyme disease of the central nervous system is associated with the production of specific antibody in cerebrospinal fluid. This locally driven immune response leads to a measurable increase in the concentration of specific antibody in the cerebrospinal fluid compared with that in serum. Measurement of antibody in cerebrospinal fluid is a useful adjunct in the diagnosis of neurological involvement in Lyme disease (Halperin *et al*. 1986; Halperin *et al*. 1989; Logigian *et al*. 1990). Positive tests for antibody in cerebrospinal fluid confirm *B. burgdorferi* infection of the central nervous system but negative tests do not rule it out, particularly late in the disease.

The polymerase chain reaction is being applied to the study of Lyme disease as a potential means of elucidating sites of active infection (Nocton *et al*. 1994; Keller *et al*. 1992). It has been validated as a sensitive and specific means of identifying *B. burgdorferi* in ticks (Persing *et al*. 1990). Study of both joint and cerebrospinal fluid of individuals has shown that the polymerase chain reaction has the potential to determine who harbours *B. burgdorferi* DNA. It is not clear whether the presence of DNA from the organism can be considered a surrogate for a positive culture, particularly since polymerase chain reaction-positive fluids are routinely culture-negative. A potential explanation for this observation can be based on the observation that the likelihood of a positive polymerase chain reaction seems to be higher if plasmid rather than genomic DNA targets are used (Persing *et al*. 1994). In culture, spirochaetes shed membrane blebs containing only plasmid DNA into the culture medium (Dorward and Garon 1990). It is plausible that *B. burgdorferi* may shed plasmid-rich DNA blebs into joint or cerebrospinal fluids in the virtual absence of intact organisms, which, in turn, could explain the disparate results for culture and the polymerase chain reaction.

The diagnosis of Lyme disease must be approached clinically. In a setting of risk by epidemiological criteria, an individual with clinical manifestations suggesting Lyme disease should undergo confirming serological testing. If negative, the diagnosis is unlikely. If positive, Lyme disease is likely. Serological status can be confirmed by Western blotting but the diagnosis must still be based on clinical criteria, even in individuals with definite seropositivity (Fig. 3).

Fig. 3 Algorithms for diagnosis of Lyme disease.

Differential diagnosis

Although erythema migrans is the most definitive clinical marker of Lyme disease, a cautionary note is warranted because an expanding erythema cannot be considered diagnostic of early Lyme disease in the absence of the right epidemiological setting. When present in its classical form following exposure in an endemic area, it is virtually diagnostic of Lyme disease, but skin lesions from other causes may mimic erythema migrans. Tick bites alone, without infection, may cause small annular areas of erythema. Efforts should be made to culture *B. burgdorferi* from skin lesions in questionable circumstances, particularly in regions not known to be endemic for Lyme disease.

Secondary lesions superficially resemble erythema multiforme. Several features help to distinguish between these entities: blistering, mucosal lesions, and involvement of the palms and soles are not typical of erythema migrans. Lyme disease has occasionally been associated with an urticarial rash, which must be distinguished from other causes of urticaria. Prominent musculoskeletal symptoms (arthralgias, myalgias and fever) may suggest a viral illness, especially when erythema migrans is absent or missed. Upper respiratory symptoms, which are very common with viral disease, are rare in early disseminated Lyme disease.

The headache, stiff neck, and pleocytosis of cerebrospinal fluid associated with Lyme meningitis are similar to the symptoms and signs associated with viral meningitis. Lyme meningitis has a more protracted course, however, often fluctuating in severity for weeks to months, which helps to distinguish it from viral meningitis. Isolated facial nerve palsy mimics idiopathic Bell's palsy; Lyme disease is one of the very few causes of bilateral facial palsy which is rare with idiopathic Bell's palsy. Generalized lymphadenopathy is occasionally seen in disseminated early Lyme disease. The fever and multiple skin lesions usually present at this stage of illness enable one to determine that the adenopathy is due to Lyme disease. Chronic fatigue may be a major and persistent complaint in Lyme disease but the non-specificity of fatigue is so low that it is not helpful diagnostically..

Disseminated and chronic Lyme disease shares clinical features with many other immune-mediated disorders. The pattern of joint inflammation is similar to that seen with reactive arthritis. The relatively brief duration of individual attacks of joint swelling in Lyme disease and absence of mucosal lesions are useful distinguishing features. In children, the attacks of arthritis, although generally shorter, are similar to those associated with the oligoarticular form of juvenile rheumatoid arthritis, but without iridocyclitis.

Late neurological involvement may mimic multiple sclerosis, Guillain–Barré syndrome, a dementing process, brain tumour, or an affective disorder. A history of previous features of Lyme disease helps, as does a complete neurological evaluation. A unique characteristic of neurological Lyme disease is that it may affect multiple levels of the nervous system: peripheral and cranial nerves, meninges, nerve roots, spinal cord and brain itself. Involvement of many different levels of the nervous system either simultaneously or sequentially is rarely seen in other diseases (Pachner and Steere 1985). In the evaluation of chronic fatigue, it is important to note that chronic fatigue alone is not a manifestation of active Lyme disease.

Diagnostic confusion has resulted from poor understanding of the how to distinguish fibromyalgia from Lyme disease. Fibromyalgia may occur as a sequela to Lyme disease, but there is no evidence that it results from persistent infection (Sigal 1990; Hsu *et al*. 1993; Steere *et al*. 1993). Lyme disease appears to be one of many triggers of this common syndrome. Fibromyalgia constitutes up to 25 per cent of presentations in rheumatology practice and affects up to 3 per cent of the normal population. Misdiagnosis of fibromyalgia as Lyme disease has led to extensive overdiagnosis of Lyme disease (Britton *et al*. 1993; Hsu *et al*. 1993; Lightfoot *et al*. 1993; Steere *et al*. 1993). The generalized pain, trigger points, debilitating fatigue, and sleep disturbance that characterize fibromyalgia are distinctly different from the joint and nervous system manifestations of Lyme disease. The treatment of fibromyalgia is not affected by a history of preceding Lyme disease.

Treatment

Antibiotic therapy of Lyme disease has advanced considerably over the past decade. Therapy must be tailored to the extent and duration of disease. The leading reason for antibiotic failure is incorrect diagnosis. Early disease responds readily to a variety of agents but the response of certain late manifestations, particularly neurological, is often incomplete. The appropriate endpoint of treatment for late disease may be difficult to determine because resolution may be slow and lag behind the completion of antibiotic therapy. Although the optimal duration of antibiotic therapy for the various stages of Lyme disease is still being determined, no clinical trials have evaluated treatment courses longer than 4 weeks for any stage of Lyme disease. Longer courses should only be administered in the context of a controlled clinical trial. Current recommendations are presented in Table 3.

Table 3 Treatment recommendations

Early Lyme disease

Early Lyme disease responds promptly to oral antibiotic therapy. Erythema migrans resolves in days and disease progression is halted (Steere *et al*. 1983b; Dattwyler *et al*. 1990; Luft *et al*. 1996). Secondary skin lesions, myalgias, arthralgias, fever, headache, stiff neck, and dysaesthesias indicate more severe infection and have a greater likelihood of incomplete response (Steere *et al*. 1983b; Dattwyler *et al*. 1990). Early treatment is important to prevent dissemination and maximize the likelihood of complete response. Because of the potential for early neurological spread, patients should be carefully evaluated for subtle involvement of the central nervous system. If headache or dys-/paraesthesias are present, formal evaluation with lumbar puncture and electrodiagnostic studies is indicated; if abnormal, intravenous antibiotic therapy should be chosen (Garcia-Monco *et al*. 1990; Pfister *et al*. 1990; Luft *et al*. 1992). If treated early, before any systemic immune challenge, patients may be susceptible to reinfection (Shrestha *et al*. 1985; Aguero-Rosenfeld *et al*. 1993).

Oral doxycycline, 100 mg twice daily, or amoxicillin, 500 mg three times a day (Dattwyler *et al*. 1990) (paediatric dose: 30 mg/kg a day), each for 21 days, are the

regimens of first choice for early disease. For penicillin-allergic individuals who should not take a tetracycline (pregnant or lactating women and children less than 9 years in age), cefuroxime axetil (500 mg twice daily) or erythromycin (250 mg four times a day) may be substituted (Nadelman *et al*. 1992). For individuals with a history of immediate hypersensitivity reactions to penicillin, cephalosporins should also be avoided. Outcomes with erythromycin or the newer macrolides, azithromycin and clarithromycin, have been less satisfactory than with the other choices (Steere *et al*. 1983b; Luft *et al*. 1996).

Maternal–fetal transmission of *B. burgdorferi* has been associated with stillbirth and neonatal death (Schlesinger *et al*. 1985; Weber *et al*. 1988). The direct role of *B. burgdorferi* in causing these adverse outcomes is unclear. Epidemiological surveys have demonstrated no congenital Lyme disease syndrome, however (Markowitz *et al*. 1986), and there is no evidence of fetal risk ascribable to maternal seropositivity alone (Strobino *et al*. 1993). There are no case reports of maternal fetal transmission associated with current recommended treatment. The available data favour aggressive treatment of Lyme disease in pregnancy.

About 10 per cent of patients experience a Jarisch–Herxheimer-like reaction shortly after the institution of therapy (Steere *et al*. 1983b). Regardless of which drug is selected and the duration of therapy, many patients have persistent symptoms particularly fatigue, for many weeks after its completion (Steere *et al*. 1983b; Dattwyler *et al*. 1990). These symptoms do not reflect continuing infection and do not respond to repeated courses of antibiotics, but eventually resolve in most patients. Persistent neurological complaints, however, should raise suspicion of inadequately treated nervous system infection which may progress over time even in seronegative individuals. The importance of careful neurological evaluation of all patients cannot be over emphasized.

Disseminated and chronic Lyme disease

Neurological disease

Optimal treatment of neurological involvement is still under investigation. Consensus has been slow to emerge because of the differences in the neurological features of European and North American Lyme disease and the slow, often incomplete, resolution of symptoms.

Acute neurological manifestations include meningitis, cranial neuropathy, and radiculoneuritis, and must be distinguished from the chronic manifestations described below. These respond to intravenous penicillin G, 20 million units a day for 10 days (Steere *et al*. 1983c); longer courses (14–21days) are recommended at present (Rahn and Malawista 1994). Ceftriaxone (Dattwyler *et al*. 1988) and cefotaxime (Pfister *et al*. 1989) have both been found effective when given intravenously for 14 days, and are superior to penicillin (Dattwyler *et al*. 1988). Headache usually begins to subside by the second day of therapy and disappears by 7 to 10 days. Radicular pain also resolves promptly but sensory and motor deficits frequently require 7 to 8 weeks for recovery (Steere *et al*. 1983c). Most experts currently recommend 4 weeks of therapy for all manifestations of central nervous Lyme disease.

Radiculopathy has been treated successfully in Europe with doxycycline, 100 mg twice daily for 14 days (Dotevall *et al*. 1988). This regimen has not been studied systematically in the United States. The recently recognized genetic differences between *B. burgdorferi* isolates (Baranton *et al*. 1992; Canica *et al*. 1993) suggest that future treatment should involve attempts to isolate and speciate the offending organism.

Chronic neurological manifestations, including encephalopathy and peripheral neuropathy, usually respond to antibiotic therapy, but response may be delayed or incomplete (Halperin *et al*. 1987; Halperin *et al*. 1989; Logigian *et al*. 1990). Some patients have persistent, non-progressive deficits after antibiotic therapy. Two to four weeks of treatment are generally recommended, with most authorities recommending 4 weeks.

Many individuals with ill-defined neurological complaints have been diagnosed to have neurological Lyme disease, without a history of exposure, serological confirmation, or even a clearly defined neurological lesion. The costs and risks attributable to misdiagnosis and inappropriate intravenous antibiotic therapy are considerable (Centers for Disease Control 1993; Lightfoot *et al*. 1993). It is best to withhold therapy until symptoms have been defined as precisely as possible. This may require neuropsychological testing for individuals with cognitive complaints, lumbar puncture for headache, and electrodiagnostic testing to evaluate sensorimotor complaints. Therapeutic trials should not be undertaken for treatment of vague symptoms without an objectively defined endpoint. The American College of Rheumatology has published a guideline recommending against intravenous therapy for seropositive individuals with non-specific symptoms within the spectrum of fibromyalgia (Britton *et al*. 1993).

Carditis

Carditis responds readily to intravenous antibiotic therapy with one of the above agents (Brown and Lane 1992) but it has also been treated successfully with oral antibiotics, salicylates or glucocorticoids (Steere *et al*. 1980). Carditis results from myocardial invasion by spirochaetes (de Koning *et al*. 1989), and should be treated with antibiotics. Prednisone, 40 to 60 mg a day in divided doses, rapidly reverses heart block (Steere *et al*. 1980) but may interfere with attempts to cure infection. For this reason, glucocorticoids should be given in short courses (fewer than 7 days) or avoided entirely. For patients with allergy to penicillin and cephalosporins, doxycycline (100 mg twice a day for 30 days) is a reasonable alternative choice. Cardiac pacing may be required temporarily (Steere *et al*. 1980; Clark *et al*. 1985).

Arthritis

Lyme arthritis responds to oral doxycycline (100 mg twice daily for 4 weeks) or amoxicillin/probenecid (500 mg each, four times daily). Either regimen cures most patients (Steere *et al*. 1994). Intravenous ceftriaxone is probably as effective when given for at least 2 weeks and offers the advantage of simultaneously treating neurological involvement but this must be balanced against the disadvantages of increased cost and increased risk of toxicity (antibiotic-associated colitis, line sepsis, acute cholecystitis, etc.) (Dattwyler *et al*. 1988; Steere *et al*. 1994). Parenteral penicillin is less effective for some patients than oral doxycycline or amoxicillin (Steere *et al*. 1985).

Treatment failures occur with all regimens, particularly in HLA-DR4 positive individuals (Steere *et al*. 1990). Longer courses of oral amoxicillin or tetracycline, or longer intravenous therapy with ceftriaxone or penicillin should be considered for those individuals who have not responded to an initial 4-week course, but this requires further study. In one study, there were no polymerase chain reaction-positive joint fluids after either 2 weeks of intravenous ceftriaxone or 8 weeks' oral therapy (Malawista *et al*. 1994). Antibiotic treatment failures may be treated successfully with synovectomy (Schoen *et al*. 1991). Recurrence after synovectomy has been rare.

Fibromyalgia

Fibromyalgia is the most common primary diagnosis for individuals coming to Lyme disease referral centres for treatment-resistant Lyme disease. In endemic areas in particular, fibromyalgia is often inappropriately treated with repeated, prolonged courses of antibiotics. Regardless of *B. burgdorferi* serological status, fibromyalgia should be treated in conventional ways.

Acrodermatitis chronica atrophicans

The infiltrative lesions of acrodermatitis chronica atrophicans are usually cured by 3 weeks of oral phenoxymethyl penicillin, 2 to 3 g daily in divided doses (Åsbrink *et al*. 1985).

Tick bite management

Ticks should be removed and the site observed for the appearance of erythema migrans. In one randomized, controlled trial in an endemic region in Connecticut, the risk of acquiring Lyme disease following a tick bite approximated the risk of adverse reaction to antibiotics administered prophylactically (Shapiro *et al*. 1992). In this trial, there were no instances of silent seroconversion and no individual developed disseminated disease, so the only risk associated with watchful waiting was a 1 per cent risk of developing erythema migrans. This low risk was much less than the tick infection rate, which was approx. 20 per cent. A cost-effectiveness analysis, based on the assumption that one-third of infected individuals would present with later disease and require intravenous therapy, concluded that prophylactic therapy was only indicated if the risk of acquiring Lyme disease following a tick bite exceeded 3 per cent (Magid *et al*. 1992). The current evidence favours an expectant, watchful, waiting approach, and not the prophylactic administration of antibiotics.

Vaccine development

Work in progress holds promise for the development of a Lyme vaccine. Vaccination with recombinant polypeptides from outer surface proteins (particularly OspA) have been shown to protect mice from infection and to provide at least limited cross-strain protection (Fikrig *et al*. 1992). Large-scale trials in humans are currently under way. The ability to induce immunity in humans, the range of cross-strain protection provided, and the durability of immunity must be determined (Lovrich *et al*. 1994). The trials currently in progress should define the potential for disease prevention through vaccination.

Summary of practical guidelines for management of Lyme disease

A pragmatic approach to the treatment of Lyme disease requires confirmation of the diagnosis, an assessment of the extent of disease (clinical staging), administration of antibiotic therapy appropriate to the extent of disease, and careful post-treatment follow-up. The choice of specific antibiotic, route of administration, and duration of therapy all are contingent upon an assessment of extent of disease. Generally, early disease (limited to primary and secondary skin sites) is treated with shorter-course antibiotic therapy administered orally, and more extensive disease requires longer oral and intravenous therapy.

My approach to management is summarized in Box 1.

Box 1 Management of Lyme disease

1. Early Lyme disease with clinical evidence limited to mild to moderate systemic symptoms, and one or multiple lesions of erythema migrans.

Always

(a) confirm diagnosis by observation of definite erythema migrans lesion(s) in individuals with a positive epidemiological history;
(b) search for evidence of neurological dissemination with a careful history and neurological examination;
(c) administer a 21-day course of oral antibiotic selected from the list in Table 3;
(d) follow up the patient at the end of the antibiotic course to ensure complete resolution of signs and symptoms of Lyme disease;
(e) counsel the patient about the possibility of relapse, especially neurological.

Often

(a) confirm the diagnosis serologically with enzyme immunoassay and Western blot, especially if the epidemiological history is questionable or skin lesions are atypical or absent;
(b) assess at the end of therapy for any persistent symptoms: delayed resolution may occur, especially of systemic symptoms such as fatigue and fibromyalgia-type complaints.

Sometimes

(a) perform a lumbar puncture if headache, paraesthesiae or facial nerve palsy are present at the time of diagnosis—abnormal spinal fluid should be considered evidence of neurological spread of infection and indicates the need for intravenous antibiotics;
(b) perform an electrocardiogram if the patient has had complaints possibly indicative of heart block;
(c) perform post-treatment serological tests if the initial diagnosis was questionable and initial serology was not positive.

2. Disseminated Lyme disease with clinical evidence of dissemination to joints, nervous system heart or other major organs.

Always

(a) confirm the diagnosis serologically (enzyme immunoassay and Western blot) and rule out alternative diagnoses to explain the clinical presentation;
(b) characterize the extent of disease before instituting antibiotics—perform a lumbar puncture if neurological signs or symptoms are present and aspirate joint fluid if joint swelling is present;
(c) administer antibiotic therapy as outlined in Table 3;
(d) follow up the patient serially until all symptoms are resolved.

Often

(a) observe the patient for continued resolution of signs and symptoms after completion of a course of antibiotic therapy if all signs of inflammation are not resolved;
(b) repeat initial studies to monitor for improvement and or progression after therapy (electromyography, nerve conduction studies, joint-fluid analysis, lumbar puncture).

Sometimes

(a) analyse spinal or joint fluid by polymerase chain reaction if the diagnosis is unclear by clinical and routine serological criteria;
(b) extend or repeat the course of antibiotic therapy if there is clinical evidence suggesting recurrence of inflammation after an initial response.

5.3.5 Viral arthritis

Stanley J. Naides

Viruses may affect the joints by a number of mechanisms. The mechanisms employed vary with the infecting virus and are based on mode of tissue entry, tissue tropism, mechanisms of replication, direct viral effects on cellular functions, the ability to establish persistent infection, local immune response, expression of host-like antigens, ability to alter host antigens, host age and genetic makeup, and the infection history of the host. Several viruses directly infect the cells of the synovium. The mechanism of injury may be through lysis of target cells. The target cells may die by one of three mechanisms:

1. Viral infection may result in classic cell necrosis with karyorrhexis.
2. The virus may initiate the cellular machinery for programmed cell death or apoptosis.
3. The virus may express virally encoded antigens on the cell surface which elicit an immune response which targets the killing of virally-infected cells.

Direct infection may also result in non-lytic mechanisms of viral arthritis pathogenesis. Immune activation may occur by transactivation of host genes by viral gene products. The infected cell elicits an immune response with itself as a target or recruits other cytokine-responsive cells. Viral infection may lead to expression of viral antigens on the cell surface. Such antigens may be seen as foreign and elicit an immune response. Alternatively, molecular mimicry of host autoantigens may break immune tolerance resulting in generation of an autoimmune response. Immune complex disease may result when the humoral response generates sufficient antibody to cause deposition of immune complexes either locally, at the site of viral infection, or systemically with deposition of circulating immune complex in synovium.

Parvovirus B19

Human parvovirus B19 was first discovered serendipitously in 1975 (Pattison 1988). It is a member of the family Parvoviridae, consisting of the smallest known DNA viruses, and the genus erythrovirus, autonomously replicating in erythroid precursors. Numerous autonomous parvoviruses are known to infect mammalian animal species. However, these viruses are extremely species specific and are not known to cross species barriers. B19 is a non-enveloped, single-stranded DNA virus measuring approximately 23 nm in diameter. Although infection of other tissue types may occur, reproduction is usually not as brisk in cells other than erythroid progenitors.

Epidemiology

B19 infection is common and geographically widespread. Seroepidemiological studies of community outbreaks of B19 infection demonstrate that a large proportion of B19 infections remain asymptomatic (Mosley 1994) or present as undiagnosed, non-specific viral illnesses. Up to 60 per cent of the general population has serological evidence for past B19 infection (Anderson *et al*. 1986). Outbreaks of B19 infection occur in late winter and spring, although epidemics have also been reported in summer and autumn. Within a community, B19 outbreaks tend to cycle every 3 to 5 years, representing the period of time for a fresh cohort of susceptible children to enter the school system. Since the seroprevalence of anti-B19 IgG antibodies is only approximately 50 per cent in adults, these periodic outbreaks often involve susceptible adults as well. The risk of infection in adults may be as high as 50 per cent with multiple exposures. Workers in occupations with increased exposure to children, such as school teachers, day-care workers, and hospital personnel, have increased risk of infection (Bell *et al*. 1989; Gillespie *et al*. 1990). Sporadic cases occur between outbreaks. Transmission is presumed to be via respiratory tract secretions.

The incubation period between infection and onset of symptoms is 7 to 18 days. In human volunteer studies, introduction of B19 nasally was followed in 7 days by a flu-like illness associated with viraemia, viral shedding in nasal secretions, and a reticulocytosis. At approximately 11 days postinfection, an incipient anti-B19 IgM antibody response was associated with clearing of viraemia, cessation of nasal shedding of virus, and a second phase of clinical illness with rash, arthralgia, and arthritis. Onset of the anti-B19 IgG antibody response occurred almost concurrently with the IgM response (Anderson *et al*. 1985). In natural infections, the temporal distinction between the two phases of clinical illness is often blurred.

Clinical features

Since 1981, well-defined, clinical syndromes have been attributed to B19 infection. B19 is the cause of transient aplastic crisis in the setting of chronic haemolytic anaemia, such as sickle cell disease, hereditary spherocytosis, a- and b-thalassaemias, pyruvate kinase deficiency, glucose-6-phosphate dehydrogenase deficiency, pyrimidine 5'-nucleotidase deficiency, hereditary stomatocytosis, autoimmune haemolytic anaemia, and HEMPAS (hereditary erythrocytic multinuclearity associated with a positive acidified—HAMS—test) (Naides 1992). B19 is the aetiological agent of erythema infectiosum, or fifth disease, a common rash illness of children characterized by bright red 'slapped cheeks' and a macular, maculopapular, and occasionally vesicular or haemorrhagic, eruption on the torso and extremities (Fig. 1).

Infection in children may be asymptomatic, and when symptoms do occur they tend to be mild and include sore throat, headache, fever, cough, anorexia, vomiting, diarrhoea, and arthralgia. Erythema infectiosum may also be seen in adults not previously infected. In adults, the rash tends to be more subtle and the bright red 'slapped cheeks' absent. A number of uncommon dermatological manifestations of B19 infection have been reported including a vesiculopustular eruption, purpura with or without thrombocytopenia, Henoch–Schönlein purpura, and a gloves and socks erythema (Mortimer *et al*. 1985; Feldmann *et al*. 1994).

Fig. 1 Classic 'slapped cheeks' of a child with erythema infectiosum, or fifth disease, caused by parvovirus B19. A lacy, macular erythematous eruption is also present on the trunk but is not in focus. (Reproduced from Feder (1994), with permission.)

B19 infection may be associated with paraesthesias in the fingers. Rarely, progressive arm weakness may occur as may numbness of the toes. In such instances, nerve conduction studies may show mild slowing of nerve conduction velocities and decreased amplitudes of motor and sensory potentials (Faden *et al*. 1990).

B19 may cross the placenta to infect the fetus. Clinically affected fetuses develop hydrops fetalis on the basis of a B19-induced aplastic crisis, resulting in a high output cardiac failure, or viral cardiomyopathy, both resulting in hydrops fetalis. B19 has been reported to cause less commonly pancytopenia, isolated anaemia, thrombocytopenia, leucopenia, myocarditis, neuropathy, or hepatitis (Naides 1992; Luban 1994). Recent reports have suggested that B19 may be associated with vasculitis in some cases (Corman and Dolson 1992). Patients with congenital or acquired immune deficiencies, including prior chemotherapy for lymphoproliferative disorders, immunosuppressive therapy for transplantation, or human acquired immune deficiency syndrome (**AIDS**), may fail to clear B19 infection. Such individuals may have chronic or recurrent anaemia, thrombocytopenia, or leucopenia. B19 infection is the leading cause of pure red cell aplasia in patients with AIDS (Frickhofen *et al*. 1990).

Among immune competent children with B19 infection, arthralgia may occur in about 5 per cent and joint swelling in only approximately 3 per cent of children under 10 years of age. In adolescents, joint pain and swelling occurrs in about 12 per cent and 5 per cent, respectively. However, joint pain occurs in about 77 per cent and joint swelling in 60 per cent of adults 20 years of age or older (Ager *et al*. 1966). In adults, B19 infection may be associated with a severe, flu-like illness in which polyarthralgia and joint swelling are prominent. The distribution of involved joints is rheumatoid like with prominent symmetrical involvement of the metacarpophalangeal, proximal interphalangeal, wrist, knee, and ankle joints. Patients usually experience sudden onset polyarthralgia or polyarthritis. Onset of joint symptoms may or may not be preceded by a viral prodrome consisting of fever, malaise, chills, and myalgias. Most present with acute, moderately severe, symmetrical polyarthritis that usually starts in the hands or knees and within 24 to 48 h spreads to include the wrists, ankles, feet, elbows, and shoulders. Spinal involvement is uncommon. Joint symptoms in adults are usually self limited but a minority of adults may have symptoms for prolonged periods of time. Chronic symptoms fall into one of two patterns. Approximately two-thirds of patients have continuous symptoms of morning stiffness and arthralgia with intermittent flares. The remaining one-third of patients will be symptom free between flares. Morning stiffness is prominent. About one-half of the patients meet diagnostic criteria for rheumatoid arthritis. Rheumatoid factor may be present in low to moderate titre during the acute phase of infection but usually resolves. Anti-DNA, antilymphocyte, antinuclear, and antiphospholipid antibodies may also be found acutely. Joint erosions and rheumatoid nodules have not been recorded. Chronic B19 arthropathy may last for up to 8 years, the longest follow-up to date. Several weeks after the initial infection, symptoms of acute synovitis tend to resolve. Pain remains a prominent feature in patients who continue to report morning stiffness. Approximately 12 per cent of patients presenting with 'early synovitis' have B19-induced, rheumatoid-like arthropathy, the majority of whom are women (Naides *et al*. 1990). Adults usually lack the classic 'slapped-cheek' rash seen in children.

The distribution of joint involvement in B19 arthropathy and its symmetry may suggest a diagnosis of a rheumatoid arthritis. About half of all patients with chronic B19 arthropathy meet the criteria of the American Rheumatism Association for a diagnosis of rheumatoid arthritis—morning stiffness which may last for more than an hour, symmetrical involvement, involvement of at least three joints, and involvement of the hand joints. Joint erosions and rheumatoid nodules are absent (Silman 1988). While an initial report suggested that chronic B19 arthropathy may be associated with HLA-DR4, as is seen in classic erosive rheumatoid arthritis, subsequent studies by the same group have demonstrated no increased association with DR4. The absence of rheumatoid nodules or joint destruction aids in the differential diagnosis of B19 arthropathy from classic, erosive rheumatoid arthritis (Naides *et al*. 1990).

Diagnosis

Diagnosis is based on laboratory confirmation in the appropriate clinical setting. A number of approaches and methodologies have been used in the laboratory to confirm B19 infection. Immune electron microscopy, detection of B19 DNA during viraemia, and detection of anti-B19 IgM antibody may be used. However, the most useful modality in the rheumatology clinic is the IgM serology because patients usually have anti-B19 IgM antibodies and have begun to clear viraemia at the time of presentation with polyarthralgia/polyarthritis. Both radioimmunoassays (RIA) and enzyme-linked immunoabsorbent assays (ELISA) have been used to detect B19 antigen and specific antibody to B19 capsid (Cohen *et al*. 1983; Anderson *et al*. 1986; Bell *et al*. 1989; Naides *et al*. 1990). A number of laboratories are developing recombinant B19 antigens for B19 diagnosis in response to the difficulty in obtaining B19 viraemic serum to use as an antigen source.

The anti-B19 IgM antibody response is usually positive for at least 2 months following onset of joint symptoms, but may wane shortly thereafter. However, the IgM antibody may be detectable in occasional patients for 6 months or longer. Because of the high seroprevalence of anti-B19 IgG in the adult population, detection of anti-B19 IgG antibody shortly after presentation of acute-onset joint symptoms in a patient in the absence of anti-B19 IgM suggests past B19 infection and other diagnoses should be pursued. Failure to obtain B19 serological testing at presentation may leave the diagnostic IgM antibody response undetected and result in failure to diagnose B19 arthropathy in those patients in whom joint symptoms persist.

Pathogenesis

Anti-B19 IgM antibody and acute phase IgG antibody (less than 1 week postinoculation) recognize determinants on the major capsid protein, VP2. In convalescent serum, anti-B19 IgG antibody recognizes determinants on the minor capsid protein, VP1 structural protein (Kurtzman *et al*. 1989). B19 VP1 and VP2 are products of alternate transcription of the same open reading frame and VP1 contains an additional 227 N-terminal amino acids not present in VP2. VP1 therefore contains unique determinants not present in the truncated form represented by VP2; these determinants may be in the unique non-overlapping N-terminal region or, alternatively, represent conformational differences in the sequences shared between the two proteins. Western blot analysis of serum from individuals with congenital immune deficiency, prior chemotherapy, or AIDS demonstrated the absence of convalescent anti-B19 IgG antibodies directed against VP1. These sera were unable to neutralize B19 virus in experimental bone marrow culture systems (Kurtzman *et al*. 1989; Sato *et al*. 1991). In the absence of neutralizing antibodies to B19, B19 persists in the bone marrow and may cause chronic or intermittent suppression of one or more haematopoietic lineages.

Management

There is no specific vaccine or treatment for B19 infection at this time. Neutralizing activity to B19 is found in commercially available pooled immunoglobulin since seroprevalence of anti-B19 IgG antibodies in the adult population is approximately 50 per cent (Anderson *et al*. 1986). Intravenous immunoglobulin has been successful in the treatment of bone marrow suppression and B19 persistence in immunocompromised patients. However, this may not be applicable to chronic arthropathy patients. Treatment is symptomatic with non-steroidal anti-inflammatory agents (Naides *et al*. 1990).

Rubella virus

Rubella virus is the sole member of the genus rubivirus in the Togaviridae family of enveloped RNA viruses. The spherical rubella virion measures 50 to 70 nm in diameter with a 30 nm dense core. An envelope is acquired by budding at vesicles or the cell surface. Spike-like projections on the envelope measuring 5 to 6 nm contain haemagglutinin activity that is detected by agglutination of erythrocytes from a variety of animal species (Frey 1994).

Epidemiology

Rubella host range is restricted to humans. Like B19 infection, transmission is by nasopharyngeal secretions with peak incidence in late winter and spring. Widespread rubella vaccination altered the epidemiology of rubella infection, which had occurred in 6 to 9 year cycles prior to vaccination. Most cases were in children. Now the age profile has shifted toward young adults whose risk of infection of 10 to 20 per cent is comparable to that during the prevaccine era. Recent rubella outbreaks in college students and in adults underscores the public health need for maintaining vaccination programmes.

Incubation time from infection to onset of the rash is 14 to 21 days. Viraemia occurs 6 to 7 days before eruption, peaks immediately prior to eruption, and clears within 48 h of the rash. Virus shedding in nasopharyngeal secretions may be detected from 7 days before and until 14 days after eruption, but is maximal just before onset of the rash until 5 to 6 days posteruption (Wolinsky 1990).

Clinical features

The spectrum of clinical disease in children and adults ranges from asymptomatic infection to a classic syndrome of low-grade fever, rash, coryza, malaise, and prominent posterior cervical, postauricular, and occipital lymphadenopathy. Constitutional symptoms may precede the skin eruption by 5 days. The eruption may vary during a brief 2 to 3 day period, starting as a morbilliform facial eruption before spreading to the torso and upper, then lower, extremities. The eruption may coalesce on the face and clear as the extremities become involved. Alternatively, the eruption may be limited to a transient blush.

Joint complaints are common in adult infection, especially in women. Joint symptoms may occur 1 week before or after onset of the rash. Joint involvement is usually symmetrical and may be migratory, resolving over a few days to 2 weeks. Arthralgias are more common than frank arthritis. Stiffness is prominent. The metacarpophalangeal and proximal interphalangeal joints of the hands, the knees, wrists, ankles, and elbows are most frequently involved. Periarthritis, tenosynovitis, and carpal tunnel syndrome may be seen. In some patients, symptoms may persist for several months or years (Smith *et al*. 1987; Ueno 1994).

Live attenuated vaccines have been employed in rubella vaccination with a high frequency of postvaccination arthralgia, myalgia, arthritis, and paraesthesias. The HPV77/DK12 strain is the most arthritogenic of the vaccine strains that have been available. The pattern of joint involvement is similar to natural infection. Arthritis usually occurs 2 weeks postinoculation and lasts less than a week. However, symptoms may persist in some patients for more than a year. The currently used vaccine RA27/3 may cause postvaccination joint symptoms in as many as 15 per cent or more of recipients (Howson and Fineberg 1992; Mitchell *et al*. 1993).

In children, two syndromes of rheumatological interest may occur. In the 'arm syndrome,' a brachial radiculoneuropathy causes arm and hand pain and dysaesthesias that are worse at night. The 'catcher's crouch' syndrome is a lumbar radiculoneuropathy characterized by popliteal fossa pain on arising in the morning. Those affected assume a 'catcher's crouch' position. The pain gradually decreases through the day. Both syndromes occur 1 to 2 months postvaccination. The initial episode may last up to 2 months but recurrences are usually shorter in duration. Episodes of 'arm syndrome' and 'catcher's crouch syndrome' may recur for up to 1 year but there is no permanent damage (Schaffner *et al*. 1974).

Diagnosis

Rubella is readily cultured from tissues and body fluids including throat swabs. Virus is detected in either direct assays of cytopathic effects in tissue culture or in an indirect assay of interference of enterovirus growth in primary African green monkey kidney cell culture. Detection of antirubella IgM antibody or anti-IgG antibody seroconversion is diagnostic of rubella infection. Antirubella IgM and IgG are usually present at the onset of joint symptoms. IgM antibody peaks 8 to 21 days after symptoms then decreases over the next 4 to 5 weeks to undetectable levels in most patients. Therefore, detection of antirubella IgM indicates recent infection, usually in the last 1 to 2 months. Since antirubella IgG rises rapidly over a period of 7 to 21 days after the onset of symptoms, a diagnosis of rubella infection based on IgG serology can only be made with paired acute and convalescent sera. The presence of IgG in a single serum sample only documents immunity (Meurman 1978).

Pathogenesis

Failure to mount an adequate immune response to specific epitopes may allow rubella virus to persist in patients with rubella arthritis. Virus may be detected in synovial fluid during arthritis flares and in lymphocytes years after symptom resolution. Onset of rash and arthritis is coincident with the appearance of antibodies, including neutralizing antibodies to whole virus suggesting a role for antibody or immune complexes in the synovitis (Wolinsky 1990).

Management

Non-steroidal anti-inflammatory agents may be used for symptom control. Low to moderate doses of steroids may be needed to control symptoms and viraemia (Mitchell *et al*. 1993).

Hepatitis B virus

Hepatitis B virus (**HBV**) is a member of the family Hepadnaviridae, genus orthohepadnavirus. HBV is an enveloped, double-stranded DNA, icosahedral virus measuring 42 nm in diameter (Hollinger 1990; Seeger 1994).

Epidemiology

HBV is transmitted by the parenteral and sexual routes. HBV infection occurs worldwide, but prevalence of hepatitis B surface antigen (Australian antigen) is higher in Asia, the Middle East, and sub-Sahara Africa. The prevalence in China may be as high as 10 per cent compared to 0.01 per cent in the United States. There is no known seasonality to primary HBV infections. Most acute infections in endemic regions occur at an early age with many acquired perinatally from infected mothers and it is usually asymptomatic. Incidence of infection in children may be as high as 5 per cent annually, with gradual decline of carriage rates and specific antibody with advanced age. In the west, most infections are acquired during adulthood during sexual or needle exposures. Adult infection is more often associated with acute hepatitis and 5 to 10 per cent of those with hepatitis develop persistent infection. In endemic regions, HBV is a common cause of chronic liver disease and a leading cause of hepatocellular carcinoma (Robinson 1994).

Clinical features

The incubation period from infection to hepatitis is usually 45 to 120 days. A preicteric prodromal period, lasting several days to a month, may be associated with fever, myalgia, malaise, anorexia, nausea, and vomiting. HBV infection may cause an immune-complex-mediated arthritis during this period. Significant viraemia occurs early in infection; soluble immune complexes with circulating hepatitis B virus surface antigen (**HBsAg**) are formed as antihepatitis B surface antigen antibodies (**HBsAb**) are produced. Arthritis onset is usually sudden and often severe. Joint involvement is usually symmetrical with simultaneous involvement of several joints at onset, but arthritis may be migratory or additive. The joints of the hands and knees are most often affected, but wrists, ankles, elbows, shoulders, and other large joints may be involved as well. Fusiform swelling may be seen in the small joints of the hand. Morning stiffness is common. Arthritis and urticaria may precede jaundice by days to weeks and may persist several weeks after jaundice. However, arthritis and rash usually subside soon after the onset of clinical jaundice. While arthritis is usually limited to the preicteric prodrome, those patients who develop chronic active hepatitis or chronic HBV viraemia may have recurrent arthralgias or arthritis. Polyarteritis nodosa is frequently associated with chronic hepatitis B viraemia (Guillevin *et al*. 1995).

Diagnosis

Urticaria in the presence of polyarthritis should raise the possibility of HBV infection. Acute hepatitis may be asymptomatic but elevated bilirubin and transaminases are usually present when the arthritis appears. Examination of joint fluid is not diagnostic. At the time of arthritis onset, peak levels of serum HBsAg are detectable. Virions, viral DNA, polymerase, and hepatitis Be antigen may be detectable in serum. Antihepatitis B core antigen IgM antibodies are present and indicate acute HBV infection as opposed to past or chronic infection (Hoofnagle 1981).

Pathogenesis

HBV arthritis is thought to be mediated by immune complex deposition in the synovium. Immune complexes containing HBsAg, antibody, and complement components may be detected.

Management

Management is limited to supportive measures including non-steroidal anti-inflammatory agents.

Hepatitis C virus

Hepatitis C virus (**HCV**) is a member of the family Flaviviridae. HCV is an enveloped, single-stranded RNA, spherical virus measuring 38 to 50 nm in diameter (Purcell 1994).

Epidemiology

HCV is distributed worldwide. Using current diagnostic tools, seroprevalence is less than 1 per cent in developed western countries but is higher in Africa and Asia where it may cause a quarter of acute and chronic hepatitis. In Japan, this figure may reach 50 per cent. HCV is transmitted by the parenteral and sexual routes, although the latter is uncommon. HCV is responsible for 95 per cent of post-transfusion hepatitis in countries routinely screening donated blood for HBV. More than half of all cases of non-A, non-B hepatitis are attributable to HCV infection (Bhandari and Wright 1995). HCV genotypic variants have been described and these differ in their pathogenicity, including severity of disease and response to a interferon. To date, 11 HCV subtypes have been delineated (Bhandari and Wright 1995).

Clinical features

Acute HCV infection is usually benign. Up to 80 per cent of post-transfusion infections are anicteric and asymptomatic. Liver enzyme elevations are usually minimal, when present. Community-acquired cases present because of more symptomatic illness in which significant enzyme elevations occur. However, fulminant HCV hepatitis is rare. HCV is strongly associated with HBV-negative hepatocellular carcinoma, especially in Africa and Japan.

Acute onset polyarthritis in a rheumatoid distribution, including the small joints of the hand, wrists, shoulders, knees, and hips, may occur in acute HCV infection (Siegel *et al*. 1993). Hepatitis C virus is often associated with type II cryoglobulinaemia. It may present as essential mixed cryoglobulinaemia—a triad of arthritis, palpable purpura, and cryoglobulinaemia. Indeed, a majority of patients with essential mixed cryoglobulinaemia have HCV infection. HCV infection is also seen in non-essential secondary cryoglobulinaemia, although less commonly. The presence of anti-HCV antibodies in essential mixed cryoglobulinaemia is associated with more severe cutaneous involvement, for example Raynaud's phenomena, purpura, livedo, distal ulcers, and gangrene. HCV RNA may be found in 75 per cent of cryoprecipitates from patients with essential mixed cryoglobulinaemia and anti-HCV antibodies (Munoz-Fernandez *et al*. 1994).

Diagnosis

Serological tests utilize an array of antigens in an enzyme immunoassay while a recombinant strip immunoblot assay (**RIBA**) is confirmatory. Second generation RIBA-2 tests for reactivity to four viral antigens; c33c, c22–3, c100–3, and 5–1–1. A positive RIBA-2, especially to c33c and c22–3, is a sensitive assay of HCV infection (Van der Poel 1994). C33c positivity is associated with viraemia. A minority of patients may have HCV RNA detectable by polymerase chain reaction amplification methods in the absence of a positive serology.

Pathogenesis

Chronic HCV infection leads to cirrhosis, end stage liver failure, and hepatocellular carcinoma but the frequency of these sequelae and the mechanisms by which they occur are not known. HCV infection persists despite vigorous antibody response to an array of viral epitopes. A high rate of mutation in the envelope protein is responsible for emergence of neutralization escape mutants and quasispecies (Shimizu *et al*. 1994). Why HCV elicits cryoglobulins remains to be determined.

Management

Interferon a has been shown to be efficacious in the treatment of chronic HCV hepatitis and HCV-associated cryoglobulinaemia. Interferon a2b at a dose of three million units thrice weekly for 6 months suppresses viral titres and ameliorates clinical disease in about half of patients (Jenkins *et al*. 1996). Those with cryoglobulinaemia failing interferon therapy require immunosuppressive therapy. Relapse after completion of the initial course of therapy is common. There is controversy as to whether interferon therapy precipitates autoimmune disease such as autoimmune thyroiditis.

Retroviruses

Human immunodeficiency virus (see Chapter 5.3.6)

Several musculoskeletal syndromes have been described in human immunodeficiency virus (**HIV**) infected patients (Calabrese 1993). Whether reactive arthritis, Reiter's syndrome, and psoriatic arthritis are more prevalent in HIV-infected populations remains somewhat controversial. The incidence and prevalence of these rheumatic diseases may vary between populations studied and may depend on geography, mode of HIV transmission, exposure to different infectious agents, racial and ethnic makeup, risk behaviours, and patient ascertainment (Berman *et al*. 1991). Reiter's syndrome may have a prevalence as high as 11 per cent in some HIV-infected populations. These patients differ from 'idiopathic' Reiter's syndrome patients in that they do not have sacroiliitis or anterior uveitis, nor do they present with the classic triad of arthritis, urethritis, and uveitis. The prevalence of HLA-B27 positivity appears to be lower in the HIV-infected patients as compared to non-HIV associated Reiter's syndrome. In Zimbabwe, where the route of HIV transmission is predominantly heterosexual, approximately 40 per cent of HIV patients with joint symptoms have Reiter's syndrome, and another 40 per cent have a pauciarticular presentation without extra-articular features characteristic of Reiter's syndrome (Davis and Stein 1991). In the United States, psoriatic arthritis limited to a pattern of asymmetric oligoarthritis may be seen in as many as a third of HIV-infected patients with psoriasis, but the overall incidence of psoriasis does not appear to be significantly increased. Whether the different patterns of rheumatic disease expression are attributable to HIV infection itself or coinfection with other agents remains controversial. The caprine arthritis–encephalitis virus, a goat retrovirus, causes an inflammatory destructive arthritis and lends support to the notion that HIV infection alone may have musculoskeletal manifestations.

Initial HIV infection may be associated with a transient flu-like illness with arthralgias. Later, three pain syndromes not associated with synovitis may be seen. The concurrence of rheumatoid arthritis and HIV is thought to be very rare. An acute symmetrical polyarthritis involving the small joints of the hands and the wrists has been described in four patients but three had periosteal new bone formation about the involved joints, a feature not seen in rheumatoid arthritis. A subacute oligoarticular arthritis, primarily of the knees and ankles, may cause severe arthralgia and disability but is transient, peaks in intensity within 1 to 6 weeks, and responds to non-steroidal anti-inflammatory agents. The synovial fluid is non-inflammatory. Mononuclear cell infiltrates may be seen in the synovium of the involved joints. As many as 10 per cent of HIV-infected patients may experience 'painful articular syndrome' characterized by intermittent severe joint pain predominantly of the shoulders, elbows, and knees which lasts about a day. The pain may be incapacitating and require short-term narcotic analgesics. Fibromyalgia has been reported in HIV-infected patients with a prevalence as high as 29 per cent in one series. The role of HIV and other potential agents in these pain syndromes remains to be clarified (Calabrese 1993).

Human T lymphocyte leukaemia virus 1

Human T lymphocyte leukaemia virus 1 (**HTLV**) is endemic in Japan where it has been observed to be associated with oligoarthritis and a nodular rash. The patients have positive serology for anti-HTLV antibodies. Type C viral particles are seen in skin lesions. The presence of atypical synovial cells with lobulated nuclei and T cell synovial infiltrates suggests direct involvement of the synovial tissue by the leukaemic process (Nishioka *et al*. 1993).

Alphaviruses

Chikungunya virus

Chikungunya virus was originally isolated during an epidemic of febrile arthritis in Tanzania in 1952 to 1953. The local tribal word, Chikungunya, 'that which twists or bends up', was applied to the virus and the disease. Retrospectively, it is likely that similar epidemics occurred in Indonesia, Africa, India, Asia, and possibly the southern United States from 1779 to 1828 (Ross 1956; Peters and Dalrymple 1990). Humans are the major reservoir for Chikungunya virus which is transmitted by *Aedes* mosquitoes. The reinfestation of *Aedes aegypti* and the introduction of *Aedes albopictus* into the western hemisphere raises the spectre of an expanded geographic distribution.

Epidemiology

It is transmitted from its reservoir hosts (baboons, monkeys, and, in Senegal, *Scotophilus* bat species) to man by *Aedes* mosquitoes in south and west central Africa, Thailand, Vietnam, and India. *Mansonia africana* and mosquitoes from other genera may also act as a vector (Jupp and McIntosh 1990). In a 1964 epidemic in Bangkok, Thailand, an estimated 40 000 patients out of an urban population of two million were infected (Halstead *et al*. 1969a). Thirty-one per cent of the prospectively studied cohort seroconverted to Chikungunya virus antibody positivity. Communities, particularly urban centres, that have not seen Chikungunya fever, either endemically or epidemically, in a long period of time and that have a number of school age children who have not experienced the virus are at risk for significant outbreaks.

Clinical features

Chikungunya fever has an explosive onset associated with fever and severe arthralgia (Tesh 1982). Constitutional symptoms and rash follow an illness that lasts from 1 to 7 days. The incubation period is usually 2 to 3 days but ranges from 1 to 12 days. Fever elevations occur quickly, reaching 39 to 40°C, and are accompanied by rigors. The acute illness may last 2 to 3 days with a range of 1 to 7 days. Following the acute illness, the fever may resolve for 1 to 2 days before recrudescence. Polyarthralgia is migratory and predominantly affects the small joints of the hands, wrists, feet, and ankles with less prominent involvement of the large joints. Previously injured joints may be more severely affected. Stiffness and swelling may occur but large effusions are uncommon. Severe cases may have persistence of symptoms for months before resolution. Approximately 10 per cent of patients will have joint symptoms at 1 year post infection. Generalized myalgia and back and shoulder pain are common. Skin eruption is characterized by facial and neck flushing followed by macular or maculopapular eruption beginning 1 to 10 days after illness onset. Typically, a rash occurs after 2 to 5 days and is associated with defervescence. The rash may last 1 to 5 days and may recur with fever. It is located on the torso, extremities, and occasionally the face, palms, and soles. It may be pruritic. In some patients, the affected skin desquamates (Halstead *et al*. 1969d; Peters and Dalrymple 1990).

Significant haemorrhage usually does not occur but isolated petechias and mucosal bleeding may occur. Suffusion of the conjunctiva is prominent. Sore throat, pharyngitis, headache, photophobia, retro-orbital pain, anorexia, nausea, vomiting, and abdominal pain may accompany the acute illness. Lymphadenopathy may be tender but is usually not massive. Symptoms in children tend to be milder (Halstead *et al*. 1969b; Halstead *et al*. 1969c). In symptomatic children, nausea and vomiting, pharyngitis, and facial flushing are prominent features but arthralgia, arthritis, and rash are uncommon. Children may present with a mild dengue-like haemorrhagic fever, headache, pharyngeal injection, vomiting, abdominal pain, constipation, diarrhoea, cough, or lymphadenopathy. Arthralgia and arthritis in children are milder and briefer in duration. A destructive arthropathy may occur in a few adult patients with chronic symptoms (Brighton and Simson 1984). Low titre rheumatoid factor may be found in those with long-standing symptoms.

This infection has not been studied intensively enough to allow conclusions regarding pathogenesis to be made. As noted above, few patients may go on to have chronic symptoms of arthralgia. Case reports would suggest that a few patients go on to have destructive lesions resulting from chronic disease manifestations.

Diagnosis

Chikungunya fever should be considered in any febrile patient resident in or returning from endemic areas. A history of epidemic occurrence should be sought. Mayaro virus, Ross River virus, rubella virus, parvovirus B19, and hepatitis B virus infections may present similarly. Synovial fluid shows decreased viscosity with poor mucin clot and 2000 to 5000 white cells/mm^3. Therefore the diagnosis depends on laboratory confirmation.

Virus may be isolated during days two to four. In some patients, viral antigen may be detected in acute sera by haemagglutination assay due to the intensity of the viraemia. Haemagglutination inhibition antibodies develop as viraemia is cleared. Complement fixation antibodies are positive by the third week and slowly decrease over the subsequent year. Neutralizing antibody production parallels haemagglutination inhibition activity. Chikungunya virus-specific IgM antibodies may be found for 6 months or longer (Nakitare *et al*. 1983).

Pathogenesis

Following mosquito bite, intense viraemia occurs within 48 h. Viraemia begins to wane around day three. The appearance of haemagglutination inhibition activity and neutralizing antibody is associated with clearing of the viraemia. Affected skin shows erythrocyte extravasation from superficial capillaries and perivascular cuffing. The virus absorbs to human platelets causing aggregation, suggesting a mechanism for bleeding. Synovitis in Chikungunya fever probably results from direct viral infection of synovium.

Management

Management for the patient is supportive. During the acute attack, range of motion exercises ameliorate stiffness. Non-steroidal anti-inflammatory agents are useful. However, chloroquine phosphate (250 mg/day) has been used when non-steroidal anti-inflammatory agents have failed (Brighton 1984).

O'nyong-nyong virus

O'nyong-nyong fever is closely related to Chikungunya virus. O'nyong-nyong virus was first described in the Acholi province of north-western Uganda in February, 1959. Within 2 years, it had spread through Uganda and the surrounding region, affecting two million people. Serologically determined attack rates ranged from 50 to 60 per cent with 9 to 78 per cent of infected individuals becoming symptomatic (Williams *et al*. 1962; Williams *et al*. 1965a; Williams *et al*. 1965b). Disease spread at a rate of 2 to 3 km daily. After the epidemic, the virus was not detected again until it was isolated from *Anopheles funestus* mosquitoes in Kenya in 1978. *Anopheles gambiae* also serves as a vector. Serological surveys indicate that O'nyong-nyong virus is endogenous. The non-human vertebrate reservoir for O'nyong-nyong virus is not known.

Clinical features

O'nyong-nyong fever is clinically similar to Chikungunya infections (Shore 1961). The name derives from the Acholi word meaning 'joint breaker'. The incubation period lasts at least 8 days and is followed by sudden-onset polyarthralgia/polyarthritis. Four days later, the appearance of skin eruptions is typically associated with improvement in joint symptoms. The eruption is uniform in nature and lasts 4 to 7 days before fading. The fever is less prominent but postcervical lymphadenopathy may be marked. Although residual joint pain often persists, there appears to be no long-term sequelae.

Diagnosis

Viral isolation by intracerebral injection into suckling mice produces runting, rash, and alopecia (Williams *et al*. 1962). Haemagglutination inhibition or complement

fixation tests identify the virus (Williams *et al*. 1962). The differential diagnosis is similar to that of Chikungunya fever. Mouse antisera raised against Chikungunya virus or O'nyong-nyong virus react equally well with O'nyong-nyong virus, but O'nyong-nyong antisera does not react well with Chikungunya virus. The mechanisms of O'nyong-nyong virus pathogenesis are unknown.

Management

Management is symptomatic. Patients recover without sequelae.

Igbo ora virus

Igbo ora virus is serologically similar to Chikungunya and O'nyong-nyong viruses (Moore *et al*. 1975). Infection was first observed in a single patient with fever, sore throat, and arthritis. In 1984, an epidemic of fever, myalgias, arthralgias, and skin eruption occurred in four villages in the Ivory Coast. Igbo ora was coined as 'the disease that breaks your wings'. The virus was isolated from *Anopheles funestus* and *Anopheles gambiae* mosquitoes and from affected individuals.

Ross River virus (epidemic polyarthritis)

Epidemics of fever and rash have been observed in Australia since 1928. Epidemics occurred among soldiers stationed in Australia during World War II. Isolation of Ross River virus from mosquitoes, its serological association with epidemic polyarthritis, and the isolation of the virus from epidemic polyarthritis patients in Australia confirmed Ross River virus is the aetiological agent of epidemic polyarthritis (Aaskov *et al*. 1985). Epidemic polyarthritis from Ross River virus has been seen in New South Wales. Antibodies to Ross River virus have been observed in the sera of endogenous populations in Papua New Guinea, West New Guinea, the Bismarck Archipelago, Rossel Island, and the Solomon Islands (Scrimgeour *et al*. 1987a; Scrimgeour *et al*. 1987b). From 1979 to 1980, a major epidemic of febrile polyarthritis occurred in the Fiji Islands, affecting over 40 000 individuals (Bennett *et al*. 1980). Serological surveys suggested that a low level of Ross River virus infection was present throughout the Fiji Islands before 1979 but that following the epidemic up to 90 per cent of the residents of some communities had antibody. A similar epidemic occurred in the Cook Islands early in 1980. Weber's line is a hypothetical line separating the Australian geographic zone from the Asiatic zone; west of Weber's line, antibodies to Ross River virus are not found (Peters and Dalrymple 1990).

In Australia, both endemic cases and epidemics occur in tropical and temperate regions. Significant numbers of cases are reported in Queensland and New South Wales, although cases and outbreaks are described in other regions as well. Seroprevalence may reach only 6 to 15 per cent in temperate coastal zones but it is 27 to 39 per cent in the plains of the Murray Valley river system (Boughton *et al*. 1984). High rain fall usually precedes epidemic periods, as this causes increased mosquito populations. Cases occur from the spring to the autumn.

Aedes vigilax is the major vector on the eastern coast of Australia where the mosquito breeds in salt marshes. *Aedes camptorhynchus* similarly breeds in salt marshes of southern Australia. *Culex annulirostris* is a fresh-water breeding vector. Other Australian *Aedes* species and *Mansonia uniformus* may also serve as vectors. Several mammalian species may serve as intermediate hosts, including domestic animals, rodents, and marsupials. In the Pacific islands outbreaks, *Aedes polynesiensis, Aedes aegypti, Aedes vigilax*, and *Culex annulirostris* may have contributed as well (Peters and Dalrymple 1990).

In Australia, infection rates range from 0.2 to 3.5 per cent per year. During epidemics in Fiji and New South Wales, the majority of those infected were symptomatic (Hawkes *et al*. 1985). While male and female infection rates were similar, there was a predominance of women in presenting cases. Children have a case to infection ratio lower than adults.

A newly described alphavirus in Australia, Barmah forest virus, may present in a fashion similar to epidemic febrile polyarthritis (Lindsay *et al*. 1995).

Clinical features

Arthralgias occur abruptly after a 7 to 11 day incubation period (Fraser 1986). A macular, papular, or maculopapular skin eruption, which may be pruritic, typically follows the onset of arthralgia by 1 to 2 days but in some patients may precede or follow joint symptoms by 11 days or 15 days, respectively. Occasionally, vesicles, papules, or petechias are seen. The trunk and extremities are typically involved although involvement of the palms, soles, and face may occur. The rash resolves by fading to a brownish discoloration or by desquamation. Despite its name, half of patients have no fever, and in those who do, modest fevers may last only 1 to 3 days. Headache, nausea, and myalgia are common. Mild photophobia, respiratory symptoms, and lymphadenopathy may occur.

A majority of patients have severe, incapacitating arthralgia. Joint distribution is often asymmetrical and migratory, with metacarpophalangeal and finger interphalangeal joints, wrists, knees, and ankles commonly involved. Shoulders, elbows, and toes may also be involved. Axial, hip, and temporomandibular involvement occasionally occurs. Arthralgias are worse in the morning and after periods of inactivity. Mild exercise tends to improve joint symptoms. One-third will have frank synovitis. Polyarticular swelling and tenosynovitis are common. As many as one-third have paraesthesias, palm, or sole pain. Some patients have classic carpal tunnel syndrome. Half of all patients are able to resume their activities of daily living within 4 weeks although residual polyarthralgia may be present. Joint symptoms recur but episodes of relapse gradually resolve. A few patients continue to have joint symptoms for up to 3 years (Fraser 1986; Peters and Dalrymple 1990).

Diagnosis

The diagnosis of Ross River virus infection should be considered in anyone with a febrile arthritis in the appropriate geographic setting. Acute rubella arthritis may present in a similar fashion although the signs and symptoms of an upper respiratory infection are more prominent in rubella. Patients may present without a rash. The differential diagnosis then would include early seronegative rheumatoid arthritis, systemic lupus erythematosus, parvovirus B19 infection, hepatitis B virus infection, hepatitis C virus infection, other alphavirus infections, Henoch–Schönlein purpura, and drug hypersensitivities. In those individuals who develop vesicles, differential from varicella or parvovirus B19 infection would need to be considered.

Synovial fluid cell counts range from 1500 to 13 800 cells/mm ^{3}. Monocytes and vacuolated macrophages dominate with few neutrophils. Virus has been isolated only from antibody negative sera. In the Australian epidemics prior to 1979, patients were antibody positive at the time of presentation. However, in the Pacific Island epidemics of 1979 to 1980, patients remained viraemic and serologically negative for up to a week following onset of the symptoms (Aaskov *et al*. 1981). Ross River virus antigen is detectable by fluorescent antibody staining of C6/36 cells inoculated with acute patient serum. Virus in serum is stable for up to a month at 0 to -10°C (Tesh *et al*. 1981).

Pathogenesis

Ross River viral antigen may be detected by specific immunofluorescence in monocytes and macrophages early but intact virus is not identifiable by electron microscopy or cell culture (Fraser *et al*. 1981). The dermis shows mild perivascular mononuclear cell, mostly T lymphocytic, infiltrate in both erythematous and purpuric eruptions. The purpuric form of eruption also shows extravasation of erythrocytes. Ross River virus antigen may be found in epithelial cells in the erythematous and purpuric lesions, and in the perivascular zone in the erythematous lesion. However, viral antigen was not found in the perivascular zone in the purpuric lesions (Fraser *et al*. 1983).

Management

Management of the acute infection is symptomatic. Aspirin or non-steroidal anti-inflammatory drugs provide relief for joint pain. Occasional patients may develop more persistent joint symptoms but full recovery is usual.

Sindbis virus

Sindbis virus is the prototype alphavirus used for molecular virology studies. It was isolated from *Culex* mosquitoes in the Egyptian village of the same name in 1952.

Epidemiology

Sindbis virus infection occurs in Sweden, Finland, and the neighbouring Karelian isthmus of Russia where it is known locally as Okelbo disease, Pogosta disease, or Karelian fever (Tesh 1982). *Aedes, Culex*, and *Culiseta* species transmit the virus to humans. Birds are an intermediate host (Niklasson 1988). Cases are confined to predominately forested areas and individuals involved in outdoor activities or occupations are at risk. Sindbis virus infection has also been reported from Uganda, South Africa, Zimbabwe, central Africa, and Australia, where sporadic cases and small outbreaks occur (Peters and Dalrymple 1990).

Clinical features

Skin eruption and arthralgia are the initial symptoms although one may precede the other by a few days. A fever may be present, although not high. Constitutional symptoms including headache, fatigue, malaise, nausea, vomiting, pharyngitis, and paraesthesias may be present but are usually not severe. The macular skin eruption typically begins on the torso, spreading to the arms and legs, palms, soles, and occasionally head. The eruption evolves to form papules which have a tendency to vesiculate. Vesiculation is particularly prominent on pressure points including the palms and soles. As the eruption fades, a brownish discoloration is left. Vesicles on the palms and soles may become haemorrhagic. The rash may recur during convalescence (Tesh 1982).

Arthralgia and arthritis may involve the small joints of the hands and feet, wrists, elbows, ankles, and knees. Occasionally, the axial skeleton becomes involved. Tendonitis is common, often involving the extensor tendons of the hand and the Achilles tendon. Non-erosive chronic arthropathy is common in both Swedish and Finnish reports, with up to one-third of patients having arthropathy two or more years after onset. A smaller number had symptoms for as long as 5 to 6 years (Niklasson *et al*. 1988).

Diagnosis

The diagnosis may be established by haemagglutination inhibition and complement fixation tests. Antibodies appear during the first week of illness.

Pathogenesis

Little is known about the pathogenesis of Sindbis virus disease. Virus has been isolated from a skin vesicle in the absence of viraemia. Skin lesions show perivascular oedema, haemorrhage, lymphocytic infiltrates, and areas of necrosis. Antiviral IgM may persist for years, raising the possibility that Sindbis virus arthritis is associated with viral persistence and direct viral effect on the synovium (Niklasson *et al*. 1988).

Management

Management is supportive.

Mayaro virus

Mayaro virus was first recognized in Trinidad in 1954 and has caused epidemics in Bolivia and Brazil. Mayaro virus has a monkey reservoir and is transmitted to man by *Haemogogus* mosquitoes feeding in the south American tropical rain forest. Mayaro virus was responsible for an outbreak in Belterra, Brazil in 1988, in which 800 out of 4000 exposed latex gatherers were infected with a clinical attack rate of 80 per cent. Illness was characterized by sudden onset of fever, headache, dizziness, chills, and arthralgias in the wrists, fingers, ankles, and toes. About 20 per cent had joint swelling. Unilateral, inguinal lymphadenopathy was seen in some patients. Leucopenia was common. Viraemia was present during the first 1 to 2 days of illness,. After 2 to 5 days, fever resolved but a maculopapular rash on the trunk and extremities appeared. The rash lasted about 3 days. Recovery was complete, although some patients had persistent arthralgias at 2 month follow-up (Hoch *et al*. 1981; LeDuc *et al*. 1981; Pinheiro *et al*. 1981). It is of interest that Mayaro virus has been isolated from a bird in Louisiana (Calisher *et al*. 1974).

Other viruses

Apart from specific viral infections noted above in which arthralgia and/or arthritis is typically a prominent feature, there are a host of commonly encountered viral syndromes in which joint involvement is occasionally seen. Children with varicella have been reported rarely to develop brief monoarticular or pauciatricular arthritis that is thought to be viral in origin. Adults who develop mumps occasionally have small or large joint synovitis lasting up to several weeks. Arthritis may precede or follow parotitis by up to 4 weeks.

Infection with adenovirus and coxsackieviruses A9, B2, B3, B4, and B6 have been associated with recurrent episodes of polyarthritis, pleuritis, myalgia, rash, pharyngitis, myocarditis, and leucocytosis. Epstein–Barr virus associated mononucleosis is frequently accompanied by polyarthralgia but occasional monoarticular knee arthritis occurs. Polyarthritis, fever, and myalgias due to echovirus 9 infection has been reported in a few cases. Arthritis associated with herpes simplex virus or cytomegalovirus infections are likewise rare. Herpes hominis occasionally causes arthritis of the knee known as herpes gladiatorum because it is seen in wrestlers. Vaccinia virus has been associated with postvaccination knee arthritis in only two reported cases.

5.3.6 Rheumatological aspects of HIV infection

Robert Winchester and Silviu Itescu

Introduction

The epidemic of human immunodeficiency virus (**HIV**) infection is giving rise to several novel rheumatic conditions, directing renewed attention to the problem of musculoskeletal infection and providing new approaches to the study of the disease mechanisms of certain classic rheumatic illnesses that occur with undiminished intensity and frequency in stages of advanced acquired immune deficiency. The rheumatological aspects of HIV infection vary according to the stage of HIV infection (Table 1). Infection with HIV-1 initiates a complex pattern of injury and host responses that mark distinct stages in the evolution of the disease. For a variable number of years the continuing infection appears to be confined largely to cells of the monocyte lineage. It appears reasonably controlled by a specific immune response, during which time there is a striking degree of viral mutation and consequent diversification. The clinical symptomatology of this phase of the retroviral infection largely reflects the ongoing immune response to what have now become endogenous antigens with the potential for cytotoxic cellular and immune complex mechanisms of injury. In some, this phase may be without apparent symptoms. During this phase of clinical—but not viral—latency, the virus evolves toward a form that can more efficiently infect and injure the CD4 T cell. Ultimately, in most individuals and through mechanisms that are poorly understood, progressive deterioration of the immune system develops largely as the result of impairment in the function and numbers of the CD4 lineage of T cells leading to development of an acquired immune deficiency syndrome (**AIDS**).

Events in HIV infection	Consequences on spectrum of rheumatic disease
Chronic immune response to HIV antigens: humoral and cell-mediated	B-cell hyperactivity, autoantibody production and non-specific symptoms of chronic immune stimulation
	Lymphocytic infiltrative syndromes, e.g. DILS and inflammatory myopathy
	Nephropathy
	Vasculitides
	Mikulicz syndrome from B-cell lymphoma
Activation of intact or disregulated residual immune and inflammatory response mechanisms	Highly prevalent Reiter's syndrome and psoriatic arthritis
Selective immune deficiency affecting CD4+'helper' T cells	Opportunistic infections of musculoskeletal system
	Amelioration of CD4-dependent rheumatic diseases, e.g. rheumatoid arthritis

DILS, diffuse infiltrative lymphocytosis syndrome.

Table 1 Rheumatological consequences of HIV infection

The rheumatological aspects of HIV infection may be placed in three broad categories (Table 1). The first includes the host response to the HIV infection and specific conditions that appear to arise as a direct result of this response. Because of the endogenous location of the stimulating antigen there is a potential for a sustained immune response characterized by cellular infiltration, the production of certain autoantibodies, and vasculopathic and nephropathic responses that are mediated by immune complexes. The diseases in this group include polymyositis, various vasculitides, and the diffuse infiltrative lymphocytosis syndrome that superficially resembles Sjögren's disease. This mimicking of the features of Sjögren's syndrome by the host response to HIV as well as the rheumatic disorders following infection with HTLV-1 have re-energized interest in the possibility of relationships between autoimmune disorders and retroviruses (Kalden and Gay 1994). The constitutional manifestations associated with chronic viral infection may also simulate non-specific features of conventional inflammatory rheumatic diseases, especially in view of the production of some autoantibodies. The second category of rheumatological diseases comprises joint infections and other musculoskeletal manifestations that arise as a direct consequence of a deficient helper arm of the immune response associated with CD4 T-cell depletion. This group includes infectious arthritis and osteomyelitis resulting from conventional and opportunistic pathogens. The third category of rheumatic illnesses consists of certain conventional rheumatic diseases with an immune pathogenesis, such as Reiter's disease, psoriatic arthritis, and various undifferentiated spondylarthropathy syndromes, which otherwise might not be expected to occur in an immunosuppressed individual, since they are effectively treated by therapeutic immunosuppression. The existence of these diseases in this setting presumably reflects pathogenic mechanisms that operate through residual components of the immune system that have not been impaired significantly by the acquired immune deficiency (Table 2).

Disease example	Reiter's syndrome	Rheumatoid arthritis
Polymorphic MHC element associated with susceptibility	Class I (e.g. HLA B27)	Class II (e.g. DR4)
Autoantibodies present?	No	Yes
Response to selective immunosuppression of advanced HIV infection	Unchanged to worsened	Ameliorated
T-cell lineage presumably recognizing antigen in context of MHC molecule	CD8 (cytotoxic)	CD4 (help)
Implication for immunopathogenesis	CD8-MHC Class I	CD4-MHC Class II
	T-cell drive	T- and B-cell drive

Table 2 A classification of autoimmune disease according to hypothetical critical immune recognition events

Biology of HIV-1 infection

Epidemiology

Approximately 10 million people are infected with HIV-1 (Quinn 1990). HIV is transmitted either sexually or by exchange of blood and other bodily fluids. Accordingly, promiscuity or needle sharing confer a risk for acquisition of HIV. The virus may also be transmitted vertically *in utero*, perinatally at the time of delivery, or postnatally through breast feeding, with approximately one in four children born to infected mothers becoming persistently infected (Friedland *et al*. 1986; Fischl *et al*. 1987). The predominant mode of transmission differs in various regions of the world and this influences the segment of the population at risk for the infection. In African and Asian countries, heterosexual transmission is the predominant mode of spread and the male:female ratio is approximately 1:1. There is now particularly rapid heterosexual spread of HIV in certain parts of India and South-East Asia. In North America and Europe where the primary modes of transmission have been intravenous drug use and male homosexual relationships, the predominance of cases occur in homosexual or bisexual men, approximately one-third in intravenous drug users, and the rapidly growing balance occurs through heterosexual contact. Although early in the epidemic contaminated blood products represented a major problem that resulted in the infection of a large proportion of haemophiliacs, only 2 per cent of the prevalent cases have resulted from administration of contaminated blood products (Quinn 1990).

Retroviral taxonomy

HIV-1 is a member of the family of retroviridae, defined as RNA viruses replicating via a DNA intermediate that is integrated in the genome of the host cell (Table 3). The family of retroviridae consists of three subfamilies: spumaviridae, oncornaviridae, and lentiviridae. Spumaviruses cause largely inapparent infections. Oncornaviruses, including the human T-cell leukaemia virus type 1 (**HTLV-1**), are transforming viruses that cause neoplasms in the infected host. HIV is a member of the non-transforming lentivirus subfamily that causes a slowly evolving infection characterized by virus–host interactions that include prolonged periods of clinical stability, weak neutralizing antibody responses, and ongoing, extensive, viral genetic mutation and antigenic drift. In tissue culture the lentiviruses cause cytopathic effects including fusion of selected haematopoietic cell lineages. Lentiviruses also include ovine visna maedi virus and caprine arthritis/encephalomyelitis virus that primarily infect monocyte lineage cells and result in illness in sheep and goats with virus–host interactions similar to those occurring in HIV infection.

Oncornaviridae
HTLV-1
Lentiviridae
Human, e.g. HIV-1, HIV-2
Animal, e.g. simian immunodeficiency virus, caprine arthritis/encephalomyelitis virus, visna maedi virus
Spumaviridae

Table 3 The retroviridae

Structure and organization

The lentiviruses have a distinctive oblong viral capsid seen on electron microscopy, with a protein core shell consisting of p24 molecules. The HIV virion consists of the retroviral genome, which is a double-stranded 7 to10-kb molecule of RNA associated with lower molecular weight RNA species, nucleoproteins, and several enzymes, including reverse transcriptase, ribonuclease, DNA endonuclease, and a protease (Fig. 1). The virion is encapsulated in an internal protein core shell, which is covered by an outer envelope composed of virally encoded glycoprotein and host cell lipid bilayer membrane containing host-derived proteins such as b_2-microglobulin, HLA molecules, actin, and ubiquitin (Arthur *et al*. 1992).

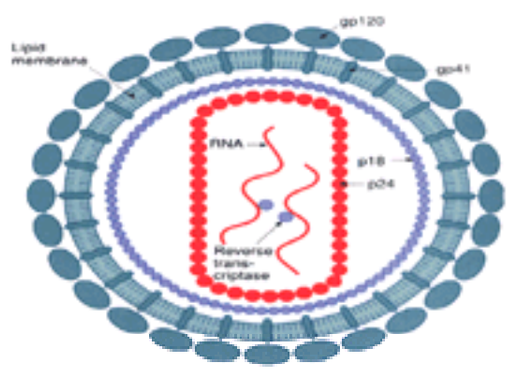

Fig. 1 Schematic representation of HIV-1 structure demonstrating location of various retroviral proteins.

The genomic RNA of all retroviruses contains three principal genes, *gag, pol*, and *env* (Fauci 1988; Greene 1991) that respectively encode structural proteins, reverse transcriptase, and envelope proteins. Each end of the genome contains the long terminal repeat sequence containing the viral promoter for RNA transcription, transcriptional stop signals, and polyadenylation sites (Fig. 2). The *gag* gene (group-associated antigen) encodes the virion structural proteins, including the protein core shell of p24 molecules. The *pol* gene encodes a precursor protein that is sequentially cleaved to produce the RNA-dependent DNA polymerase (reverse transcriptase) of the virus, a protease responsible for the cleavage, and an integrase. The *env* gene codes for two envelope-associated glycoproteins, a smaller transmembrane nchoring protein (gp41 in HIV) and a larger outer membrane protein (gp120 in HIV) which recognizes the target cell viral receptor and against which the host neutralizing antibodies are usually directed. In addition to the *gag, pol*, and *env* structural genes, the HIV-1 genome has at least six other accessory genes involved in regulation of viral replication (*tat, rev*, and *nef*), virion maturation (*vpr*) and morphogenesis (*vpu* and *vii*) (Fauci 1988; Greene 1991). The rev protein is of interest because it acts rather like the La/SSB molecule and is necessary for transportation of the large pool of unspliced or partially spliced viral mRNAs from the cell nucleus to the cytoplasm, where they are translated (Felber *et al*. 1989).

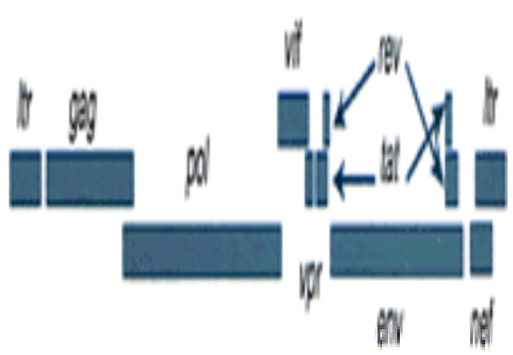

Fig. 2 Genomic organization of HIV-1. The genes encoding *tat* and *rev* exist as two non-contiguous elements, while the structural (*gag, pol, env*) and accessory genes (*vpr, vif, nef*) are shown as single elements.

Lifecycle and replication of HIV

Although the most striking clinical finding of HIV infection, AIDS, results from the infection of the CD4 T-cell lineage, infection of the monocyte plays a particularly central role in the biology of HIV-1 (Meltzer and Gendelman 1992). The monocyte/macrophage is usually the first cell that is infected. While the HIV infection progressively evolves towards a virus that has the ability to infect and injure T cells, this is not apparently a critical feature in the infectious cycle of the virus since often the virus is transmitted to another individual by an HIV-laden monocyte (Meltzer and Gendelman 1992). Macrophages are the major tissue reservoir of the virus at all stages of the infection (Meltzer and Gendelman 1992) with the virus evolving separately in different monocyte lineage compartments (Itescu *et al*. 1994a). As with the visna maedi virus, there is little or no cytopathic effect evident in the HIV-infected monocyte. To gain entry into a host cell (Fig. 3), the viral envelope gp120 molecule binds to the CD4 molecule on the surface of T-helper cells (Klatzmann *et al*. 1984), monocyte lineage cells (Koenig *et al*. 1986; Salahuddin *et al*. 1986), or skin Langerhans cells (Tschachler *et al*. 1987). Subsequently, fusion of cellular and viral membranes occurs, mediated by the HIV-1 gp41 protein. The change in HIV-1 tropism for macrophages or T cells correlates, in part, with structural differences within the HIV-1 gp120 envelope, most notably with the presence of particular residues in a 35-amino acid region within the highly variable principal neutralizing V3 domain (O'Brien *et al*. 1990; Cheng Mayer *et al*. 1991; Hwang *et al*. 1991; Shioda *et al*. 1991; Westervelt *et al*. 1992). Following internalization and uncoating of the virus particle, the viral RNA is reverse transcribed into DNA in the cytoplasm, transported to the nucleus, and integrated as provirus in the host genome.

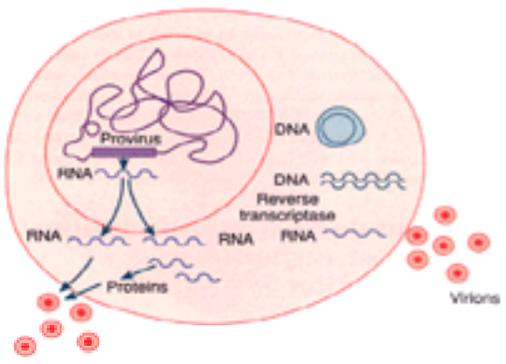

Fig. 3 HIV-1 lifecycle. Events depicted include cellular binding of HIV-1, virion internalization, reverse transcription of RNA genome, integration into host DNA as provirus, proviral transcription, virion transport and assembly, and budding of infectious particles.

The central features of HIV replication are depicted in Fig. 3. Regulation of HIV replication involves both host-regulated transcription initiation and virus-regulated post-transcriptional control. In T cells, HIV growth rates are closely linked to the growth state of the host's own T cell, with little or no virus production detected in non-proliferating T cells (Margolick *et al*. 1987). However, activation of these cells, which may occur during certain inflammatory disease states or following stimulation with antigens, mitogens such as phorbol myristate acetate or phytohaemagglutinin, and ytokines such as interleukin 2 (**IL-2**) or tumour necrosis factor-a (TNF-a), dramatically increases viral yields (Siekevitz *et al*. 1987). Coinfection with HTLV-1 also increases HIV-1 replication by a similar action of the transactivating protein of HTLV-1, tax (Siekevitz *et al*. 1987). All of these T-cell activators induce the intracellular production of various nuclear binding factors that mediate the programmes of T-cell activation, such as the NF_KB DNA transcription factor (Nabel *et al*. 1988) (Fig. 4). The presence of NF_KB, EBP-1, and Sp-1 binding sites in the long terminal repeat, promoter region of the virus (Nabel *et al*. 1988), accounts for the observed parallel activation of HIV replication and emphasizes how the virus has evolved to exploit normal immunological regulatory circuits of the host. For these reasons, the inflammation of rheumatic diseases arising in the HIV-infected individual may have an adverse impact on the host–viral balance, and it would appear reasonable to consider suppressing the inflammatory aspect of the rheumatic disease in an attempt to diminish the viral transactivation process that might initiate a period of accelerated immune decompensation. Similarly, the initiation of antiretroviral therapy should be considered in all HIV-infected persons developing inflammatory diseases. Indeed, the development of Reiter's syndrome has been rapidly followed by evidence of overt immune deficiency (Winchester *et al*. 1987).

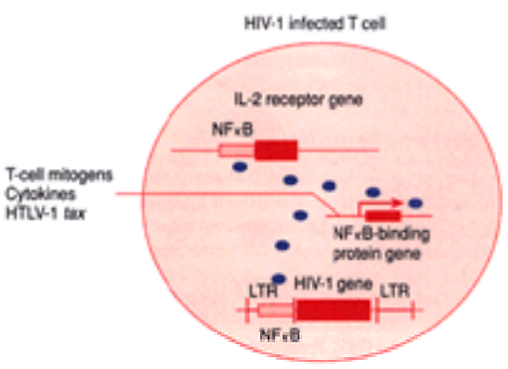

Fig. 4 HIV-1 transactivation. Schematic representation of NF_kB-binding protein induction by T-cell mitogens, cytokines, and HTLV-1, and initiation of both viral and host T-cell activation via NF_kB elements in the HIV-1 long terminal repeat (LTR) and the interleukin 2R (IL-2R) promoter.

The virus-specific post-transcriptional control of replication involves products of three viral genes: *tat, rev*, and *nef*. The tat protein is a powerful transactivator of the HIV genome. It requires specific transactivation responsive (TAR) regions in the viral mRNA transcripts (Muesing *et al*. 1987), leading to as much as a 1000-fold increase in viral mRNA expression. In addition to transactivation of HIV provirus, the tat protein is secreted extracellularly and taken up by uninfected cells (Viscidi *et al*. 1989). The nef protein is associated with cytoplasmic membranes by myristylation, and is a member of the G protein family, both binding GTP and displaying GTPase activity (Guy *et al*. 1987). It is thought to be critical for HIV pathogenesis since HIV strains with defective *nef* genes have been isolated from individuals with non-progressive disease (Kirchhoff *et al*. 1995).

Rheumatological manifestations of the host response to HIV-1 infection

General features

Following infection with HIV-1, specific antibodies develop that are directed against the major structural products of the viral genes *gag*, including p24, *pol* and *env*, including gp120 and gp41. IgM antibodies against gag or env proteins usually appear within 2 weeks of the acute clinical illness associated with primary HIV infection and by 3 months (Tindall *et al*. 1990) are replaced by IgG antibodies. The development of antibodies is occasionally delayed for several months or more. Viral infection can also be directly detected by p24 antigen capture assays, HIV culture, and viral RNA/DNA amplification using the polymerase chain reaction (PCR) (Piatak *et al*. 1993).

B-cell abnormalities

Involvement of the humoral (B-cell) arm of the immune system is reflected by the presence of polyclonal hypergammaglobulinaemia, circulating immune complexes, increased spontaneous B-cell proliferation and development of B-cell lymphomas (Solinger and Hess 1991). These features occur despite an inability to mount antigen-specific B-cell responses (Lane *et al*. 1983) and poor B-cell responsiveness to T-cell factors involved in proliferation and differentiation (Lane and Fauci 1985). Peripheral blood B cells from HIV-infected individuals are polyclonally activated and spontaneously secrete high levels of immunoglobulins (Lane *et al*. 1983). This may be a result of coinfection with known polyclonal B-cell activating viruses such as Epstein–Barr virus or cytomegalovirus (Lane and Fauci 1985), a direct consequence of effects on B cells by HIV-encoded proteins (Pahwa *et al*. 1985), or of B-cell stimulation by IL-6 which is induced in monocytes by HIV infection (Nakajima *et al*. 1989).

As anticipated because of the B-cell hyperreactivity in HIV infection there are a variety of autoantibodies; however, the well-characterized autoantibodies associated with classic rheumatic syndromes are not commonly observed. Rheumatoid factors are rarely detected (Solinger *et al*. 1988; Solinger and Hess 1991). Low titres of antinuclear antibodies are seen in a few patients, without being associated with analogous clinical syndromes in HIV-negative individuals (Solinger *et al*. 1988; Rynes 1990). Circulating immune complexes, measured by the Clq binding assay, are elevated in many HIV-infected individuals at all stages of disease, reflecting at least in part viral–antiviral complexes. However, C3 and C4 levels are not significantly decreased (Mayer-Siuta *et al*. 1988) nor is immune complex disease found in parallel. High titres of IgG anticardiolipin antibodies occur in 20 to 30 per cent of HIV-infected individuals (Bernard *et al*. 1990). While apparently not associated with the development of thrombotic events, these antibodies have been reported to be associated with thrombocytopenia (Canoso *et al*. 1987) and with cerebral perfusion defects (Rubbert *et al*. 1994). Autoantibodies against circulating lymphocytes have been reported in HIV-positive individuals at all stages of infection (Williams *et al*. 1984; Dorsett *et al*. 1990). These may be lymphocytotoxic, recognizing an extracellular domain of the CD4 molecule that is distinct from the HIV-1 gp120-binding region (Kowalski *et al*. 1989), or directed against the gp41 component of the HIV-1 envelope (Golding *et al*. 1988). In addition to these reactivities, antibodies directed to antineutrophil cytoplasmic antigens (**ANCA**) have been reported in up to 42 per cent of infected individuals (Klaassen *et al*. 1992; Savige *et al*. 1993). In these persons, ANCA antibodies are not associated with cutaneous or systemic vasculitis.

T-cell alterations

The host response to HIV includes an increase in the numbers of CD8+ T cells (Zolla-Pazner *et al*. 1987) that are either HIV-specific MHC class I restricted or unrestricted CD8 cytotoxic cells (Riviere *et al*. 1989). These are particularly prominent early in the course of HIV infection and tend to diminish with disease progression. Shortly after infection, the plasma viral load rises sharply and then decreases within weeks concomitantly with the development of host immune responses including HIV-specific cytotoxic T cells and neutralizing antibodies. At this initial stage the illness may assume a clinical form resembling infectious mononucleosis (De Wolf *et al*. 1988; Connor *et al*. 1993). Both neutralizing antibodies (Looney *et al*. 1988; Rusche *et al*. 1988; Javaherian *et al*. 1989; Koup *et al*. 1994) and cytotoxic T cells (Takahashi *et al*. 1990; Koup *et al*. 1994) elicited by natural infection recognize the immunodominant V3 loop of the envelope gp120 protein, and the high rates of sequence change in this region are thought to confer adaptive value to HIV-1 by allowing it to evade these host immune responses (Zwart *et al*. 1991). In addition, cytotoxic responses to various conserved viral proteins can be detected in most infected individuals throughout the disease course (Walker *et al*. 1987; Koenig *et al*. 1990; Phillips and McMichael 1993).

During this period the HIV envelope evolves to a T-cell tropic form associated with declining numbers of CD4 lymphocytes and increases in viral load. These events are predictive of progression from asymptomatic status to AIDS (Goedert *et al*. 1987; De Wolf *et al*. 1988; Moss *et al*. 1988; Connor *et al*. 1993; Weiss 1993). The median duration from initial infection to the development of frank immune deficiency is 7 to 10 years (Lui *et al*. 1988; Bacchetti and Moss 1989). The HLA genetics of the host appear to influence the course of the infection. Increased rates of progression to CD4 T-cell depletion and opportunistic infections have been reported in individuals with HLA B35 (Scorza-Smeraldi *et al*. 1986; Sheehy *et al*. 1989) and the HLA A1, B8, DR3 haplotype (Steel *et al*. 1988; Kaslow *et al*. 1990). In contrast, slower progression to immune incompetence occurs in infected individuals with the MHC class II alleles DRB1*1102 and DRB1*1301 (Itescu *et al*. 1994). These observations suggest that immunogenetic regulation of the host response to HIV infection may be critical in controlling HIV replication and limiting the progressive increase in viral burden.

Along with the progressive depletion of CD4+ T cells, HIV-infected individuals develop a qualitative helper cell defect, first evident as a deficient T-cell proliferative response to recall soluble antigens, and then to T-cell mitogens (Fahey 1986). These abnormalities are accompanied by diminished production of and response to IL-2 (Prince and John 1987), that results in a predominant T_{H1} pattern of immune deficit. These functional defects are simply demonstrated by cutaneous anergy to routine recall test antigens. They frequently precede the precipitous decline in CD4 cell numbers in late stages of the infection, may occur in the asymptomatic seropositive person with a CD4 count in the range of 400 to 500/mm^3, and lead to increased susceptibility to conventional and opportunistic infections. Because of the role of CD4 T cells in inducing CD8 T-cell maturation, the progressive loss of CD4-derived inductive signals ultimately leads to a functional deficiency of CD8 cell cytotoxicity against opportunistic pathogens, such as cytomegalovirus or perhaps HIV itself.

Rheumatic disorders related to T-cell proliferation

In a subset of individuals, the level of CD8 T cells remain high and may reach levels of greater than 2500/mm^3. Several distinctive syndromes occur in the setting of these elevated levels of CD8 T cells (Couderc *et al*. 1987; Itescu *et al*. 1989; Malbec *et al*. 1994) including the diffuse infiltrative lymphocytosis syndrome (**DILS**), generalized lymphadenopathy, and pseudotumoural splenomegaly. Each of these syndromes may be seen early in the course of HIV infection, while DILS is also found in long-term survivors.

Diffuse infiltrative lymphocytosis syndrome: a Sjögren's-like disease

The number of entities responsible for keratoconjunctivitis sicca and xerostomia have expanded over the past decade to include chronic graft-versus-host disease following bone marrow transplantation (Fox *et al*. 1986), infection with HTLV-1 (Vernant *et al*. 1988), and HIV-1 infection (Couderc *et al*. 1987; Itescu *et al*. 1989). The sicca syndrome occurring in HIV infection is a part of a syndrome designated 'diffuse infiltrative lymphocytosis', DILS, that differs from classic Sjögren's syndrome in a number of features. It appears to reflect a specific and seemingly beneficial host immune response to HIV (Itescu *et al*. 1994). DILS is encountered in a bimodal age distribution, being seen in children up to age 14 and in adults ranging in age from 22 to 62 years. DILS is not restricted to a particular risk group or ethnicity.

Clinical features

At presentation most patients with DILS meet criteria for AIDS-related complex, or stage 3B (Haverkos *et al*. 1985), with fevers, lymphadenopathy, and weight loss. In part reflecting ascertainment by a rheumatology service, bilateral parotid or submandibular gland enlargement is present in over 90 per cent of patients with DILS, being massive in two-thirds. Xerostomia occurs in 85 per cent, while xerophthalmia and keratoconjunctivitis sicca, diagnosed by Schirmer's test or rose bengal staining of the cornea, occur less frequently, in 40 per cent. Sicca symptoms are less evident in children with DILS. The decreased glandular secretions and associated lymphoid tissue enlargement predisposes to recurrent sinus and middle ear infections. Gallium scanning demonstrates bilateral isotope uptake in the involved tissue (Fig. 5). Computed tomography (CT) scans and magnetic resonance imaging (MRI) techniques show massive symmetrical and often cystic enlargement of major salivary glands (Itescu *et al*. 1993) (Fig. 6). The minor salivary gland tissues have focal lymphocytic infiltration indistinguishable from that of classic Sjögren's syndrome by conventional microscopy. There is a spectrum from complete preservation of glandular architecture to varying degrees of atrophic duct epithelium, canal dilatation, and interstitial fibrosis. Involved ductules usually express class II MHC molecules, suggesting local effects of cytokine release by infiltrating T cells (Fig. 7).

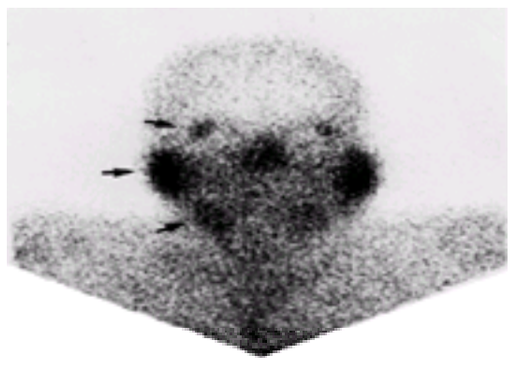

Fig. 5 Gallium scan demonstrating increased uptake bilaterally in the lacrimal, parotid, and submandibular glands (arrows) in an HIV-infected individual with diffuse infiltrative lymphocytosis syndrome.

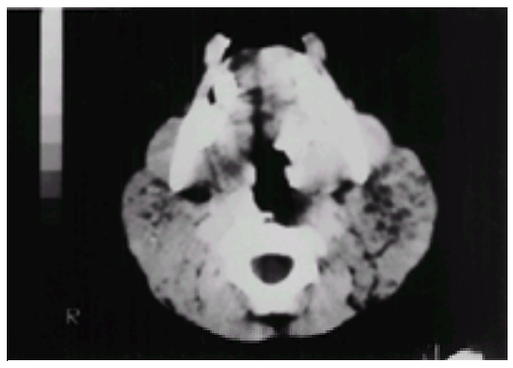

Fig. 6 CT scan of parotid glands in an HIV-infected child with DILS, demonstrating bilateral glandular enlargement with cystic changes.

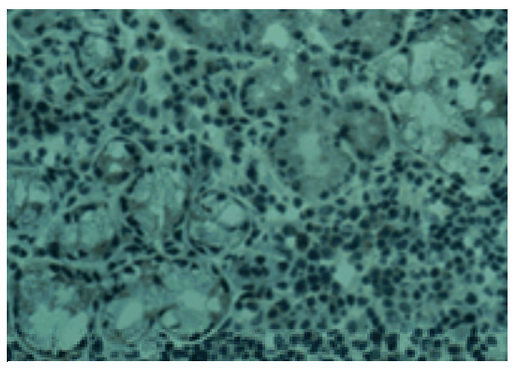

Fig. 7 Immunohistological study of minor salivary gland specimen from a patient with DILS demonstrating staining for HIV gp120 antigens expressed in the cytoplasm of several cells of the monocyte lineage. The positive cells are characterized by abundant cytoplasm and express CD14 lineage markers. They are in a periacinar location and adjacent to a focus of infiltrating lymphocytes.

Extraglandular involvement is particularly prominent. The development and extent of glandular and visceral lymphocytic infiltration in DILS is loosely correlated with the absolute numbers of circulating CD8 T cells, suggesting that lymphocytic infiltration is a direct consequence of the expanded population of circulating CD8 cells in these patients. Pulmonary involvement as a result of lymphocytic interstitial pneumonitis (**LIP**), which occurs in over 50 per cent of patients, appears to be the most serious complication of DILS and may be the initial manifestation of the syndrome. Affected patients may progress to frank respiratory insufficiency and endstage lung disease. Chest radiographs reveal bilateral interstitial infiltrates and gallium scanning often shows diffuse uptake throughout the lung fields. Diagnosis requires histological confirmation, and pulmonary infections, particularly *Pneumocystis pneumonia* or *Mycobacterium tuberculosis*, must be excluded. Superimposed bacterial pneumonias can complicate LIP. Enlargement of the tonsils, adenoids, and associated lymphoid tissue may be massive as can be seen in Fig. 6. Gastrointestinal manifestations include lymphocytic hepatitis, causing hepatomegaly and moderate elevations in transaminases and alkaline phosphatase, and gastric lymphocytic infiltration causing disorders in food intake resembling a linitis plastica. Lymphocytic interstitial nephritis, without glomerular involvement, may cause aseptic progressive renal insufficiency and a type IV renal tubular acidosis. Neurological involvement may cause lymphocytic meningitis, unilateral or bilateral palsy of the VIIth cranial nerve, and symmetric sensorimotor neuropathies. Other manifestations have included uveitis, lymphocytic thymoma, and of particular interest, lymphocytic mastitis which is illustrated in Fig. 8. Biopsy of the involved breast tissue revealed a massive CD8 T-cell infiltration, and the presence of HIV viral mRNA and viral proteins p24 and gp120 exclusively in infiltrating monocytes. The appearance of mastitis and LIP are the major features of visna maedi virus disease, suggesting that it may be a model of DILS.

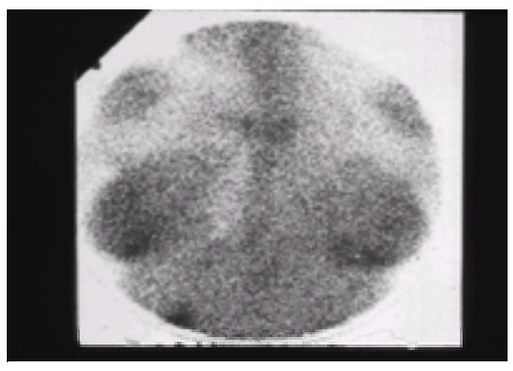

Fig. 8 Gallium scan of a female with DILS illustrating extensive bilateral uptake of the radionuclide in breast tissue. Biopsy of this tissue demonstrated CD8-predominant lymphocytic mastitis with the presence of HIV antigens evident in cells of the monocyte lineage. Analogous findings occur in ovine infection with the visna maedi agent.

HIV-infected individuals with DILS have a relatively low rate of progression to frank immune deficiency (Itescu *et al.* 1990), for durations of up to 10 years, CD4 T-cell levels decline by less than 10 per cent annually. Opportunistic infections and disseminated fungal or viral infections are rarely seen early in the course of DILS, but there is a considerably increased risk of developing high-grade B-cell salivary gland lymphomas. This complication should be suspected when there is a sudden, generalized increase in the size of the parotid glands, or when there is marked asymmetry. Biopsy is of great importance in making this diagnosis. Circulating cryoglobulins or monoclonal light chains may appear with lymphomatous transformation (Itescu 1991).

Pathogenesis

Immunophenotypic studies have demonstrated that the expanded circulating and infiltrative CD8 lymphocyte population in DILS has a memory phenotype (Itescu *et al*. 1993), expressing CD29 and CD11a/CD18 (LFA-1) molecules involved in effector functions including cell adhesion and cytotoxicity (Martz 1986; Springer *et al*. 1987; Springer 1990). The specific trafficking of CD8 lymphocytes to salivary gland and other tissues in DILS is probably regulated by the interaction between homing receptors on the lymphocytes and their ligands on postcapillary venule endothelial cells, including intercell adhesion molecule 1 (**ICAM-1**), a ligand for CD11a/CD18 (LFA-1) (Springer *et al*. 1987; Springer 1990), perhaps being induced by cytokines such as tumour necrosis factor-a (Springer *et al*. 1987; Springer 1990), produced in high quantities by HIV-infected monocytes (Roux Lombard *et al*. 1989). That the CD8 infiltration occurs in response to local replication of HIV is suggested by the marked diminution in salivary gland size frequently observed following treatment with antiretroviral agents, and by the demonstration of HIV-1 envelope proteins in salivary gland monocyte/macrophage lineage cells located in periacinar and perivascular areas adjacent to lymphoid aggregates and to postcapillary venule endothelial cells that selectively express ICAM-1 (Itescu *et al*. 1993). The T cells infiltrating the minor salivary glands in DILS are relatively oligoclonal, being drawn from a limited number of *V* and *J* gene segment subgroups but exhibiting extensive diversity in VDJ joining (Dwyer *et al*. 1993). The restricted repertoire of both the a- and b-chains of the T-cell receptor exemplified by common structural motifs, both germline and somatically encoded, constitutes compelling evidence that the infiltration of T cells into salivary tissue is the result of a subpopulation of lymphocytes that is responding in a very specific manner to structurally unique antigenic stimuli.

Predisposition to DILS is associated in black subjects with HLA DR5 (Itescu *et al*. 1989) and DR13 (Itescu *et al*. 1994). DNA sequence analysis demonstrates preferential association with the DRB1*1102 (JVM) allele of HLA DR5 (Itescu *et al*. 1994), which is extremely rare in white subjects (Johnson *et al*. 1989; Fernandez-Vina *et al*. 1990), but not with the HLA DR5 allele, DRB1*1101, which is predominant in white subjects. The DRB1*1301 subtype of HLA DRw6, found at the greatest increase in frequency, shares a b_1-chain diversity region motif with DRB1*1102, suggesting that this region may be of importance in predisposing a pattern of response to HIV.

HIV-1 is difficult to isolate and the predominant strains are tropic for monocyte lineage cells. However, viral isolates from individuals with longer disease duration are highly cytopathic and T-cell tropic. Analysis of the HIV-1 V3 domain in the T cells of persons with DILS revealed significantly lower nucleotide evolutionary divergence and amino acid heterogeneity than was observed in controls (Itescu *et al*. 1994).

Diagnosis

HIV infection should be considered in high-risk individuals presenting with the sicca syndrome, or in all individuals with the sicca syndrome that have atypical features, such as paediatric onset, male gender, prominent extraglandular manifestations, low or absent titres of autoantibodies, and reversed circulating CD4/CD8 T-cell ratio. Tentative criteria for the diagnosis of DILS are: (i) HIV-seropositivity shown by enzyme-linked immunosorbent assay (**ELISA**) and Western blot analysis, (ii) the presence of bilateral salivary gland enlargement or xerostomia persisting for more than 6 months, and (iii) histological confirmation of salivary or lacrimal gland lymphocytic infiltration, in the absence of granulomatous or neoplastic involvement. Typically, two or more foci of at least 50 lymphocytes/4 mm^2 of minor salivary gland tissue are seen, or grade 4 according to established criteria (Chisholm and Mason 1968). Rheumatoid factors are found in only 17 per cent of individuals with DILS and antinuclear antibodies with speckled pattern in 13 per cent, all at titres of less than 1:640. Antibodies against SSA/Ro and SSB/La, determined by ELISA using bovine and rabbit substrates as antigen sources (Buyon *et al*. 1989), are present in only 8 per cent of patients. LIP is an important element of DILS to delineate. After tissue confirmation of lymphocytic interstitial pneumonitis in adults, either by transbronchial or open lung biopsy, gallium scanning and pulmonary function studies are performed to assess the degree of pulmonary involvement. Appropriate biopsies are performed to measure the lymphocytic infiltration of other tissues because of the risk of other complications of HIV infection such as lymphoma or *Mycobacterium avium* infection that could masquerade as a feature of DILS.

Treatment

Treatment with zidovudine or other newer antiretroviral agents should be the first line of therapy. Zidovudine has often, but not uniformly, resulted in diminution of all of the manifestations of DILS including salivary gland enlargement. Discontinuation of zidovudine may result in striking re-enlargement of parotid glands. Circulating T-cell subsets are monitored regularly. Patients responding to zidovudine have demonstrated progressive diminution in CD8 cell numbers and either no change or a concomitant increase in CD4 cells. Symptomatic and progressive visceral involvement, not responsive to zidovudine, is very cautiously treated with 40 to 60 mg of prednisone daily, or other immunosuppressive agents such as chlorambucil, for a period not exceeding 8 to 12 weeks. Prior to commencing this therapy, the degree of circulating HIV antigen load is assessed usually by evaluating for the presence of p24 antigenaemia. Circulating p24 antigen is uncommon in DILS, but if elevated would constitute a relative contraindication to immunosuppressive therapy. More prolonged periods of steroid use and immunosuppression have resulted in the appearance of the development of opportunistic infections. Evidence of enhanced viral replication, ascertained by methods such as p24 antigen assays and cocultivation HIV reverse transcriptase levels, in patients who are being treated with prednisone would be an indication for immediate discontinuation of therapy. Treatment of the salivary gland lymphomas must be aggressive as these are high grade and associated with poor outcome.

Myopathy

Clinical features

HIV-infected individuals may develop a myopathy as a result of polymyositis-like inflammatory muscle disease, zidovudine therapy, or opportunistic infections (e.g. toxoplasmosis) (Snider *et al*. 1983; Dalakas *et al*. 1986; Dalakas *et al*. 1987; Baguley *et al*. 1988; Dalakas and Pezeshkpour 1988; Till and MacDonell 1990). Most patients with HIV-associated polymyositis present with an insidious onset of proximal muscle weakness and atrophy, as well as muscle pain and tenderness. Systemic features such as fever and weight loss may be present and typical skin lesions of dermatomyositis may be seen, such as heliotrope discoloration, periungual erythema, and erythematous plaques over the wrists and knuckles. In approximately 50 per cent of patients with myopathy, it is the initial manifestation of HIV infection, while in the remainder myopathy develops after the occurrence of opportunistic infections. Differential diagnosis includes vasculitic syndromes, which are usually associated with neuropathies and systemic organ involvement, and pyomyositis, which is usually a discrete unilateral process. Most patients with either inflammatory myopathy associated with HIV-1 or zidovudine-induced myopathy have elevations of muscle enzymes, as well as similar abnormalities on electromyography. Indeed, in one study, 16 per cent of all HIV-infected individuals taking zidovudine for more than 6 months developed abnormally elevated muscle enzymes, though only a few became symptomatic (Till and MacDonell 1990).

Diagnosis and pathogenesis

Muscle biopsy is the procedure of choice for determining the aetiology of HIV-associated myopathy. The entities are heterogeneous. In those with a polymyositis picture, classic myopathic changes are seen, including variation in fibre size, vacuolar change, and fibre destruction. In addition, type II atrophy and nemaline rod myopathy have been described (Dalakas *et al*. 1986; Dalakas *et al*. 1987; Panegyres *et al*. 1988). Most prominent, however, is the inflammatory perivascular and interstitial mononuclear cell infiltrate (Dalakas *et al*. 1986; Dalakas *et al*. 1987). In most, the infiltration consists predominantly of CD8+ lymphocytes, although CD4+ T cells and macrophages are also present (Espinoza *et al*. 1991), raising the possibility that the entity is related to the CD8 T-cell host response. HIV antigens have been demonstrated by immunofluorescence techniques in both muscle tissue and infiltrating mononuclear cells (Dalakas *et al*. 1986; Espinoza *et al*. 1991), however HIV-1 has not been cultured from muscle fibres in patients with polymyositis. The possible role of coinfection with HTLV-1, which is tropic for myocytes (Wiley *et al*. 1989) and may be associated clinically with a myositis (Mora *et al*. 1988), remains to be determined. In contrast, muscle biopsy in zidovudine-associated myopathy demonstrates similar myopathic changes but much less of an inflammatory infiltrate (Dalakas *et al*. 1990; Till and MacDonell 1990). In addition, ragged-red fibres suggestive of abnormal mitochondria are consistently observed. Electron microscopic studies confirm mitochondrial damage, with wide variation in size, swelling, degeneration, and laminar bodies present in these organelles (Dalakas *et al*. 1990; Till and MacDonell 1990). These mitochondrial abnormalities may be a result of inhibition by zidovudine of g-DNA polymerase (Mitsuya and Broder 1986), an enzyme required for mitochondrial DNA replication (Zimmerman *et al*. 1980). High blood lactate:pyruvate ratios, when determined repeatedly, may be a sensitive test for detecting the mitochondrial toxicity of zidovudine (Chariot *et al*. 1994).

Treatment

Therapy of zidovudine-induced myopathy requires discontinuation of the drug. In most cases, clinical improvement and decrease in creatine kinase values occur within 1 to 2 weeks. Careful reinstitution of lower-dose zidovudine may then be attempted. If no improvement occurs after zidovudine withdrawal, or if the affected individual was not taking the drug, muscle biopsy should be performed. Significant inflammatory infiltrates without evidence of mitochondrial changes or opportunistic pathogens indicate an immune-mediated myositis which usually responds to corticosteroid therapy. While these individuals appear to tolerate 40 to 60 mg of

prednisone daily, the fact that many patients with polymyositis are at advanced stages of HIV disease, as well as reports of Kaposi's sarcoma developing after treatment with prednisone and methotrexate (Espinoza *et al*. 1991), emphasize the need to taper steroids to the lowest dose effective in symptomatic control and to remain vigilant for possible infectious or malignant complications. Zidovudine therapy should be initiated or continued in polymyositis as it appears to be of benefit in the diminution of myopathic symptoms (Simpson 1988; Dalakas *et al*. 1990).

Vasculitis

Epidemiology

A number of vasculitic syndromes have been reported in HIV-infected individuals (Calabrese 1991; Gherardi *et al*. 1993). This is an area of considerable interest with the strong likelihood that some of these entities will be shown to be directly related to the host response to HIV infection. However, a direct causal relationship between infection with HIV and development of these syndromes remains to be established. Such determinations are complicated by the similarity in clinical manifestations between vasculitides and specific neurological, renal, pulmonary, or cardiac manifestations of HIV infection, and by the coexistence of pathogens such as Epstein–Barr virus, cytomegalovirus, and hepatitis B, which have also been causally related to various vasculitic syndromes (Sergent 1980; Marcellin *et al*. 1991; Louthrenoo 1993; Angulo *et al*. 1994). As with each of the other manifestations in the HIV-infected person, the rheumatologist is challenged by difficult and subtle differential diagnoses. The problems of distinguishing between the host response to hepatitis B and HIV infection has been informatively discussed (Angulo *et al*. 1994).

Clinical features

The reported vasculitic syndromes in HIV infection include involvement of small vessels in the hypersensitivity vasculitis group of either the neutrophilic or mononuclear cell type (Farthing *et al*. 1985; Chren *et al*. 1989; Potashner *et al*. 1990; Gherardi *et al*. 1993), lesions of medium-sized vessels in the polyarteritis nodosa group (Said *et al*. 1988; Gherardi *et al*. 1989; Valeriano *et al*. 1989; Angulo *et al*. 1994; Marks and Kuskov 1995), systemic granulomatous processes (Anders *et al*. 1989; Marks and Kuskov 1995), primary angiitis of the central nervous system (Yanker *et al*. 1986; Scaravalli *et al*. 1989), and involvement of the heart and great vessels (Marks and Kuskov 1995), with a fibroproliferative or aneurysmal process.

The most frequently encountered syndrome, hypersensitivity vasculitis, has been reported to occur either limited to the skin, presenting as palpable purpura, or in association with gut and renal involvement as part of Henoch–Schönlein purpura (Thompson *et al*. 1989; Gherardi *et al*. 1993). In some instances this could be attributed to a drug reaction. Polyarteritis nodosa-like forms of arteritides primarily involve muscles and nerves, and cause symmetric sensorimotor neuropathies, mononeuritis multiplex, muscle pain, and digital ischaemia and gangrene (Calabrese 1991; Jurgensen *et al*. 1995; Libman *et al*. 1995). Skin, gastrointestinal, and renal involvement are less common. Electromyographic studies help differentiate this condition from myopathy, demonstrating a pattern of axonal loss.

Churg–Strauss syndrome, characterized by purpuric skin lesions, bronchospasm, and eosinophilia, has been reported (Cooper and Patterson 1989). Other granulomatous processes, including lymphomatoid granulomatosis, have been reported in HIV-infected individuals, presenting chiefly with pulmonary and central nervous disease (Anders *et al*. 1989). Primary angiitis of the central nervous system may present either as a progressive loss of neurological function or as a fulminating encephalitic illness. Diagnosis is made by angiography or tissue biopsy. Positive serological findings or cultures for HIV in these cases may not be present in the periphery, and may be limited to the cerebrospinal fluid (Yanker *et al*. 1986).

Vasculitis resulting from cytomegalovirus, a major cause of morbidity among all immunocompromised patients because of infection of the endothelial cells by the virus, has been carefully reviewed (Golden *et al*. 1994). Virally induced proliferation and secondary ischaemia and host-mediated immune response to the virus contribute to the consequences of the vasculitis. Cutaneous and gastrointestinal involvement are prominent and must be diagnosed by biopsy.

Pathogenesis

Biopsy of involved skin in hypersensitivity angiitis demonstrates typical small vessel leucocytoclastic vasculitis with IgM and complement deposition within dermal capillaries. In Henoch–Schönlein purpura, the immune deposits in vessel walls contain IgA (Gherardi *et al*. 1993). Hypersensitivity to various drugs, particularly penicillins and sulphonamides, accounts for approximately 20 per cent of small vessel vasculitides (Gherardi *et al*. 1993). Productive infection with cytomegalovirus can be documented by the demonstration of viral inclusions in vascular endothelial cells (Gherardi *et al*. 1993; Golden *et al*. 1994). Polyarteritis nodosa-like disorders are associated with necrotizing vasculitic lesions in medium-sized vessels within muscle or epineurium. ANCA have been detected (Klaassen *et al*. 1992; Savige *et al*. 1993), however these antibodies are found at high prevalence in asymptomatic HIV-infected individuals. Although anticardiolipin antibodies occur in 20 to 30 per cent of HIV-infected individuals (Bernard *et al*. 1990), these antibodies have been reported to be associated with cerebral perfusion defects (Rubbert *et al*. 1994). In contrast, HIV p24 antigen has been reported within the vascular lesions (Bardin *et al*. 1987; Gherardi *et al*. 1993), and HIV RNA has been identified in perivascular cells of monocyte lineage (Gherardi *et al*. 1989; Gherardi *et al*. 1993), suggesting a possible direct role for HIV in the pathogenesis of the polyarteritis nodosa-like syndromes. HIV p24 antigen has also been detected within vascular endothelial cells in the midst of granulomatous inflammation associated with lymphomatoid granulomatosis or with primary central nervous angiitis (Anders *et al*. 1989; Calabrese 1991). The latter is further characterized by multinucleated giant cells within the internal elastic lamina on the surface of the cortex, brainstem, and associated leptomeninges. These findings may also be found in central nervous angiitis associated with herpes zoster infection (Eidelberg *et al*. 1986). The host response to bacterial infections, such as *Neisseria gonorrhoea*, have also been characterized by vasculitis (Ostlere *et al*. 1993).

Treatment

Any drugs possibly contributing to hypersensitivity vasculitis should be withdrawn. Life-threatening vasculitic complications involving the lungs, kidneys, or central nervous system require treatment with corticosteroids or other immunosuppressive agents. Additional treatment required may include antiretroviral agents and prophylactic therapy for herpes zoster and pneumocystis pneumonia. If cytomegalovirus inclusions are demonstrated within involved vascular endothelium, antiviral agents such as ganciclovir or foscarnet should be initiated promptly and immunosuppressive therapy concomitantly reduced (Golden *et al*. 1994).

HIV-associated nephropathy

HIV-associated nephropathy is another entity that is a component of the host response to HIV and which causes differential diagnostic problems for the rheumatologist, especially since, in concert with some of the autoantibodies that characterize the serum of patients with HIV, it may suggest the diagnosis of systemic lupus erythematosus. HIV-associated nephropathy is the most common finding among adult HIV-positive patients who present with nephrotic range proteinuria (D'Agati *et al*. 1989; Bourgoignie 1990). It is a clinicopathological complex characterized by varying degrees of focal segmental and global glomerulosclerosis with collapse of capillary tufts, mesangial cell proliferation, visceral epithelial cell hypertrophy and hyperplasia, microcystic tubular dilatation with tubular atrophy and degeneration, interstitial infiltration with mononuclear cells including a predominance of CD8 T cells, interstitial fibrosis, and endothelial tubuloreticular inclusions. Clinically, HIV-associated nephropathy differs from most idiopathic forms of focal segmental glomerulosclerosis in the greater severity of the renal pathology, the accelerated course to renal failure, and to a lesser degree, tubular damage.

Prevalence

The reported frequency of specific renal involvement in HIV varies to a certain degree according to whether ascertainment is by biopsy of those with symptomatic renal disease or at autopsy of all infected individuals (Bourgoignie 1990). In particular, diffuse mesangial cell hyperplasia and interstitial nephritis appear more frequent at autopsy, 31 and 12.5 per cent, respectively, compared with 5.7 and 1.7 per cent in patients undergoing biopsy, implying they did not give rise to findings that prompted biopsy (Bourgoignie 1990). In contrast, focal segmental glomerulosclerosis usually results in overt renal disease, accounting for 83 per cent of biopsy diagnoses of renal disease and from 1 to 15 per cent of diagnoses of renal pathology at autopsy according to population and criteria (Bourgoignie 1990). An overall prevalence of at least 7 per cent among HIV-infected adults is a reasonable estimate. The findings in children differ from those of adult series, with diffuse mesangial hyperplasia and focal segmental glomerulosclerosis found in approximately equal frequency (Strauss *et al*. 1989).

Epidemiology

The large majority of HIV-associated nephropathy in adults occurs in the stage of asymptomatic carrier or ARC and only 20 per cent occurs at the time when fully developed AIDS ensues (Haddoum *et al*. 1987; Pardo *et al*. 1987; Bourgoignie *et al*. 1988a; Carbone *et al*. 1989). In children, the average age at diagnosis of

HIV-associated nephropathy is approximately 3 years (range 6 months to 9 years) (Pardo *et al*. 1987; Connor *et al*. 1988; Strauss *et al*. 1989). Black subjects are far more likely to develop HIV-associated nephropathy than white subjects; this is apparent in all risk groups and in both adults and children, with a ratio of black to white patients approaching 11 to 1 (Bourgoignie *et al*. 1989; Strauss *et al*. 1989; Bourgoignie 1990; Ingulli *et al*. 1991). Because HIV-associated nephropathy develops at a stage of the infection where there is still a reasonably intact immune system which is responding to the virus with a specific immune response, it seems reasonable to hypothesize that this immune response may be the basis of the development of the nephropathy. In this sense HIV-associated nephropathy could be analogous to the development of diffuse infiltrative lymphocytosis syndrome, which is another, and possibly related, host response to HIV infection in which isolated renal tubular acidosis occurs.

Clinical features

Presenting manifestations of HIV-associated nephropathy, other than proteinuria and azotaemia, include nephrotic syndrome in 9 to 60 per cent (Pardo *et al*. 1987; Bourgoignie *et al*. 1988b), and hypertension in 39 per cent of individuals in one study (Carbone *et al*. 1989; D'Agati *et al*. 1989), although elsewhere this is less common (Chandler and Treser 1987; Rao *et al*. 1987; Bourgoignie *et al*. 1988b; Connor *et al*. 1988; Rao and Friedman 1989). Among adults, endstage renal disease ensues within 4 to 16 weeks (Rao *et al*. 1987; Carbone *et al*. 1989; D'Agati *et al*. 1989). A case of HIV-associated nephropathy with focal segmental membranous glomerulopathy that evolved to central nervous vasculitis and infarction, emphasizes that there may be a spectrum from HIV-associated nephropathy to some of the vasculitides (Bass *et al*. 1994). Cyclosporine and prednisone have been used in small numbers of patients and reported to control HIV-associated nephropathy in some, suggesting a role for participation of the immune response and cytokines in the mechanism of disease (Strauss *et al*. 1989; Ingulli *et al*. 1991; Ifudu *et al*. 1994). Other studies suggest that the progression to renal failure in HIV-associated nephropathy is slowed by zidovudine therapy (Ifudu *et al*. 1994), also directing attention to the importance of HIV replication in the pathogenesis of the syndrome.

Disorders occurring as a direct result of CD4 helper T-cell dysfunction

Musculoskeletal infections, including septic arthritis, osteomyelitis, and pyomyositis

Because of the central role played by the CD4 T cell in regulating both cellular and humoral immunity, the profound cell-mediated and humoral immunodeficiency in the later stages of HIV-1 infection predisposes individuals to a variety of infectious diseases. Infections may primarily develop in the musculoskeletal system as septic arthritis, osteomyelitis, and pyomyositis, or they may be systemic in nature and secondarily involve the musculoskeletal system, with either direct infection of bone joint and muscle or indirectly involving these structures with myalgias and arthralgias. In addition to these diagnostic challenges, the therapeutic approach to treating infection in the immunocompromised host must be altered to reflect the fact that there is an enhanced tendency for the microbial infections to persist after completion of conventional antibiotic therapy regimens, reflecting the failure of effective immune elimination of the residual organisms.

Septic arthritis and osteomyelitis are the two most common secondary infectious complications reported in HIV-infected individuals in case series studied in all parts of the world (Berman *et al*. 1991; Hughes *et al*. 1992; Ho 1993; Adebajo and Davis 1994; Goldenberg 1994). Septic arthritis may result from opportunistic or conventional infections that involve various joints, including those commonly affected by septic arthritis such as the hip, knee, wrist, metacarpophalangeal or interphalangeal joints, or those rarely involved such as the sacroiliac and sternomanubrial or sternoclavicular joints. The septic arthritis may be the first manifestation of AIDS, presenting the rheumatologist with the difficult diagnosis of both the septic process and the underlying HIV infection, or the arthritis may occur when an individual with known immune deficiency progresses into an advanced stage.

Organisms cultured from various joints have included, in addition to the anticipated organisms such as *Streptococcus pneumoniae* and *Staphylococcus aureus, Sporothrix schenckii* (Lipstein-Kresch *et al*. 1985), *Cryptococcus neoformans* (Ricciardi *et al*. 1986), *Histoplasma capsulatum* (Calabrese 1989), and *Mycobacterium avium intracellulare* species (Blumenthal *et al*. 1990). Other unusual pathogens cultured from septic joints in HIV-infected individuals include *Salmonella* spp. (Winchester *et al*. 1987; Gutierrez *et al*. 1993), *Haemophilus influenzae* type B (Lawrence *et al*. 1991), and *Campylobacter fetus* (Winchester *et al*. 1987).

Certain patterns of extra-articular involvement are the signatures of particular organisms such as the multifocal cutaneous cellulitis of *Campylobacter (Helicobacter) cinaedi* (Burman *et al*. 1995) associated with monoarticular or oligoarticular arthritis and an indolent febrile illness. Disseminated sporotrichosis infection may similarly present with diffuse skin lesions and oligo- or polyarthritis (Heller and Fuhrer 1991). Staphylococcal or streptococcal septic arthritis usually presents as an acutely swollen, painful, erythematous process in one or several joints, accompanied by systemic symptoms of bacteraemia. Staphylococcal infections may be widespread, causing septic bursitis (Jacobson *et al*. 1988; Buskila and Tenenbaum 1989), juxta-articular osteomyelitis (Masters and Lentino 1984), extensive periarticular soft-tissue involvement, and pyomyositis (Gaut *et al*. 1988).

Risk factor for HIV acquisition may influence the predominant infectious complications

In addition to the problem attributed to the effect of immune deficiency, the various high-risk behaviour patterns or underlying conditions associated with HIV infection may themselves independently predispose to infection with particular pathogens. *Staph. aureus, Pseudomonas aeruginosa*, or *Candida albicans* are usually the most frequently encountered organisms in the arthritis found in intravenous drug users regardless of whether HIV infection is present or absent (Rivera *et al*. 1992). If these infections, particularly *Pseudomonas*, occur in an individual, they should direct attention to the possibility of parenteral drug abuse (Munoz Fernandez *et al*. 1991), but some regions experience little Gram-negative disease among addicts (Munoz Fernandez *et al*. 1991). Among intravenous drug users infected with HIV, *Staph. aureus* infection, most commonly of the hip, accounts for about two-thirds of cases of non-gonococcal septic arthritis (Goldenberg 1991; Munoz Fernandez *et al*. 1991; Covelli *et al*. 1993). Pyogenic sacroiliitis or isolated sternoclavicular septic arthritis occurs predominantly among intravenous drug users and is usually caused by infection with *Staph. aureus* or Gram-negative organisms, including *Fusobacterium* as well as *P. aeruginosa* (Guyot *et al*. 1987).

Conversely, in Africa, where HIV is usually acquired by sexual promiscuity, gonococcal arthritis is the most common musculoskeletal infection and infection by *Staph. aureus, P. aeruginosa*, or *C. albicans* is uncommon (Blanche *et al*. 1993). Among HIV-infected haemophiliacs, the predominant cultured organisms are *Staph. aureus* and *Strep. pneumonia* (Pappo *et al*. 1989).

There is clear evidence that advanced infection of HIV by itself predisposes to a greatly increased risk of a variety of musculoskeletal infections (Blanche *et al*. 1993; Adebajo and Davis 1994). Similarly, an increased incidence of septic arthritis among HIV-infected haemophiliacs compared with those uninfected underlines the fact that immune deficiency of HIV infection itself predisposes to septic arthritis (Pappo *et al*. 1989). It has been argued that infections of the musculoskeletal system complicating HIV infection are rather more prevalent than the literature of reported cases might suggest (Ho 1993).

Osteomyelitis and pyomyositis

In addition to arthritis, osteomyelitis is a common problem. Juxta-articular osteomyelitis may be difficult to distinguish from arthritis, whereas other bony sites may be clinically more distinctive. Organisms reported to have caused osteomyelitis in HIV-infected individuals include *C. albicans* (Boix *et al*. 1990), *Mycobacterium kansasii* (Crawford and Baird 1987), and *Nocardia asteroides* (Masters and Lentino 1984). Staphylococcal juxta-articular osteomyelitis involving the olecranon process (Masters and Lentino 1984) or distal clavicle (Zimmermann *et al*. 1989) may present with subacute or chronic joint pain and swelling. Extensive periarticular infections, usually by *Staph. aureus*, can simulate multidigit dactylitis or arthritis.

Pyomyositis is a particular complication of staphylococcal infection and usually occurs in the more advanced stage of AIDS. Acute onset of unilateral thigh pain associated with soft-tissue swelling, erythema and woody induration of the distal thigh is characteristic of pyomyositis (Watts *et al*. 1987; Gaut *et al*. 1988; Goldenberg 1991). In the majority of cases, the cause is a single staphylococcal abscess; however, multiple collections may occur within the quadriceps muscle. Diagnosis is facilitated by imaging techniques, including ultrasound, CT, and MRI scans.

Clinical features and differential diagnosis

Several reviews deal with the changing pattern of musculoskeletal infection during this era and the general principles of diagnosis and therapy (Hughes *et al*. 1992; Ho 1993; Goldenberg 1994). Gram stain and culture of synovial fluid specimens in staphylococcal or streptococcal septic arthritis are diagnostic, and are frequently accompanied by positive blood cultures. Arthritis associated with *M. tuberculosis* may present its usual challenges in diagnosis. Septic arthritis caused by opportunistic organisms tends to be a more indolent and subtle process, often with minimal inflammation. In these patients, the underlying disorder may be suggested by the presence of associated extra-articular manifestations, such as necrotic, crusted skin lesions in sporotrichosis (Lipstein-Kresch *et al*. 1985). Synovial fluid aspirate often reveals low numbers of leucocytes with a relative increase in the proportion of monocytes. Culture of some of these organisms may require special

attention from the laboratory and the use of molecular biological methods. The radiological manifestations of musculoskeletal complications of HIV infection have been informatively summarized (Steinbach *et al*. 1993) and emphasize the extensive diagnostic evaluations that may be required to document the extent of structures involved with the infection.

A major problem in the diagnosis of infectious processes of the joints is distinguishing them from the inflammatory non-infectious entities that occur in HIV infection, in particular those of the spondylarthropathy group of illnesses. In addition, other entities that are part of HIV infection but not commonly encountered in rheumatology, such as B-cell lymphoma, Kaposi's sarcoma, and bacillary angiomatosis (an infection by an agent resembling that of trench fever, *Rochalimnaea quintana*) must be considered in the differential diagnosis (Steinbach *et al*. 1993). For example, in pyogenic sacroiliac joint infection, the pronounced pain, exquisite localized tenderness, asymmetry, and lack of involvement of other joints helps differentiate it from inflammatory sacroiliitis associated with the spondylarthropathies. Scintigraphy demonstrating unilateral involvement is also more suggestive of infection, especially when found in the absence of enthesopathy and other arthritis, however, diagnostic aspiration may be required (Guyot *et al*. 1987).

The fact that many patients present with atypical features of the infection because of the attenuated inflammatory response has been emphasized (Hughes *et al*. 1992). Systemic infections such as acute or subacute endocarditis occur with increased frequency in HIV and may present with arthralgias, arthritis, and back pain (Ho 1993). An instructive example of the diagnostic challenges that secondary infections present in the immunologically compromised host is the initial presentation of HIV infection as chronic syphilitic polyarthritis with an efflorescence of autoantibodies that suggested the presence of a rheumatic disease such as rheumatoid arthritis or systemic lupus erythematosus (Burgoyne *et al*. 1992). The rheumatologist has a particular problem in the approach to a patient who is not previously known to be infected with HIV. The general rule that is emerging in endemic areas of HIV infection is that the appearance of acute arthritis should prompt HIV testing (Blanche *et al*. 1993) and, by extension, in Europe and North America where HIV infection is more stratified, at least a strong suspicion of HIV infection should be entertained. Frequently the atypical manner of presentation directs attention to the probable presence of HIV infection, as for example the presentation of gonococcal arthritis involving a single hip and a sternoclavicular joint (Strongin *et al*. 1991). Atypical, invasive or extensive infection of the musculoskeletal system in a young individual should direct attention to the possibility of an underlying immune deficiency. For example, a report of sternoclavicular arthritis associated with *Strep. pneumoniae* as the presenting manifestation of AIDS illustrates that septic arthritis of a joint that is otherwise seldom involved by infectious processes should prompt a thorough search for predisposing conditions such as HIV infection (Leon *et al*. 1994).

Treatment

Septic arthritis or bursitis is initially treated with broad-spectrum coverage until culture results are available. Some organisms such as streptococcal and staphylococcal joint infections in HIV-positive individuals, or infection with organisms such as *Campylobacter (Helicobacter) cinaedi* (Burman *et al*. 1995), often respond as well to conventional antibiotic treatment as in HIV-negative intravenous drug users (Goldenberg 1991), yet streptococcal and staphylococcal bursitis is difficult to eradicate and requires prolonged therapy (Buskila and Tenenbaum 1989). Opportunistic infections are treated with appropriate antibiotic therapy, including intravenous amphotericin B for fungal infections. Sporotrichosis and allied infections will probably not be eradicated and require chronic maintenance therapy (Heller and Fuhrer 1991).

Some form of joint drainage is initiated soon after the diagnosis is reasonably established, although the precise method is still controversial (Ho 1993; Goldenberg 1994). Surgical drainage is required for appropriate treatment of osteomyelitis and pyomyositis in HIV infection in addition to antibiotics. Several less invasive procedures, such as 'tidal irrigation' or arthroscopic drainage appear to offer the promise of more rapidly controlling the sometimes strikingly rapid destructive consequences of septic arthritis in this group and have the advantage of avoiding the considerable morbidity of an arthrotomy (Ho 1993; Goldenberg 1994). The duration of antibiotic therapy must be given individual consideration in light of an assessment of the integrity of the residual immune function and with the knowledge that most infections in HIV-positive individuals require prolonged therapy and sometimes chronic suppressive therapy. Because most of these individuals are in an advanced stage of HIV infection, they require a comprehensive immunological staging evaluation and most probably appropriate retroviral therapy. Osteomyelitis may require permanent antimicrobial maintenance.

Immune-mediated arthritis occurring with the same or increased intensity and frequency in individuals with selective depletion of CD4 lineage T cells

The epidemiology of rheumatic disease is altered in the setting of HIV infection. The development of certain specific rheumatic disorders, and the absence of others, in individuals infected with HIV is consistent with a classification of immune-mediated rheumatic illnesses according to a hypothetical underlying immune recognition event (Table 2). Classic rheumatic disorders associated with prominent autoantibody and cellular responses, such as rheumatoid arthritis and systemic lupus erythematosus, are rarely found among HIV-infected individuals and, when seen, are often (Bijlsma *et al*. 1988; Amor 1989; Calabrese *et al*. 1989; Molina *et al*. 1995) but not always (Kerr and Spiera 1991), reported to improve with progression of HIV infection. This decrease emphasizes the probable importance of CD4 T cells in their immunopathogenesis.

Reiter's disease, reactive arthritis, psoriatic arthritis, and undifferentiated spondylarthropathy syndromes

Because advancing HIV infection is characterized by progressive immune deficiency, it came as a considerable surprise that certain of the seronegative spondylarthropathies occurred with undiminished, if not increased, frequency in the setting of frank AIDS, despite the fact that these rheumatic diseases respond to iatrogenic immunosuppression (Winchester *et al*. 1987). Both the musculoskeletal system, in the form of the spondylarthropathies (Winchester *et al*. 1987), and the skin, in the form of psoriasiform disease (Duvic 1995), are distinctive clinical markers for advanced HIV infection. The distinctions between the various seronegative spondylarthropathies are blurred in the HIV-infected individual. While HIV-infected patients presenting with classic Reiter's syndrome are at one end of the spectrum and those with classical psoriasis and psoriatic arthritis at the other, many develop features of an undifferentiated spondylarthropathy with or without cutaneous manifestations. Moreover, in the setting of HIV infection, a subset of individuals with Reiter's syndrome have a more distinctively fulminant and extensive disorder simulating psoriatic arthritis with unusually severe enthesopathy, upper limb joint manifestations, and cutaneous involvement which often becomes indistinguishable from pustular psoriasis (Winchester *et al*. 1987). The development of these disorders emphasizes their distinct mechanisms of immunological drive independent from the CD4 lineage as well as the broad spectrum of host–virus relationships that can occur in HIV infection, although psoriasis in isolated form is not associated with decreased survival (Obuch *et al*. 1992). Behçet's disease may fall into this category since its development has been attributed to antecedent HIV infection (Buskila *et al*. 1991). Curiously, ankylosing spondylitis has not been noted to occur at the expected frequency in this group.

Epidemiology

The precise frequency with which Reiter's syndrome, psoriatic arthritis, and the related spondylarthropathies occur in HIV-positive individuals continues to be the subject of inquiry, although there is universal agreement that their prevalence is not decreased and in a number of studies is variably increased (Berman *et al*. 1991; Calabrese *et al*. 1991; Monteagudo *et al*. 1991; Cuellar *et al*. 1994). Prevalence rates of spondylopathic disorders among HIV-infected individuals in the United States ranging up to nearly 5 per cent have been reported when ascertainment was performed by rheumatologists (Berman *et al*. 1988; Winchester *et al*. 1988). Calabrese and colleagues in a longitudinal study found psoriatic arthritis and Reiter's syndrome each at a frequency of 1.7 per cent and undifferentiated forms of oligo- or monoarticular rheumatism at a frequency of 11.1 per cent (Calabrese *et al*. 1991). For some of these patients, the standardized criteria for Reiter's syndrome or psoriatic arthritis are not proving adequate for classification. The uncommon clinical features of the spondylarthropathies that occur in these patients have been pointed out by a number of authors (Winchester *et al*. 1987; Altman *et al*. 1994; Kellner *et al*. 1994). Psoriasiform skin disease, sometimes occurring with spondylarthropathic disease, occurs at increased frequency among those infected with HIV (Cockerell 1991; Duvic 1991; Duvic 1995). It appears that both forms of Reiter's syndrome, the sexually transmitted venereal or endemic form preceded and apparently initiated by urethritis, and the epidemic or postdysenteric form following infection of the gastrointestinal tract, are seen in association with advanced HIV infection. Using strict criteria, the prevalence rates of 'complete' Reiter's syndrome among HIV-infected individuals in the United States were not found to be higher than those for HIV-negative groups matched demographically (Solinger and Hess 1993) and by high-risk behaviour (Clark *et al*. 1989; Hochberg *et al*. 1990). However, in these same studies, the frequency of psoriatic arthritis was over fivefold higher than expected in the HIV-positive cohort when compared with a demographically matched population (Solinger and Hess 1993). Studies from West and sub-Saharan Africa have reported between four- and sixfold higher HIV prevalence rates among patients with various spondylarthropathies than among the local populations (Blanche *et al*. 1993; Mijiyawa 1993). Together, these observations strongly suggest that there is a causal relationship between HIV infection and the development of various spondylarthropathy syndromes; however, their clinical expression may differ in comparison with analogous syndromes in the HIV-negative host.

Psoriasiform lesions, with or without arthritis, may be the first clinical manifestations of HIV infection. Alternatively, in individuals with pre-existent psoriasis, infection with HIV may significantly exacerbate the psoriatic condition, including the joint manifestations. In general, psoriasiform lesions in HIV infection are of greater severity

than in HIV-negative individuals and sometimes distinctive in distribution (Duvic *et al*. 1987; Duvic 1995). There is some divergence in studies on the prevalence of the psoriasiform disorders. Certain groups have found an increased prevalence of both psoriasiform lesions and musculoskeletal involvement plus psoriasiform skin lesions in HIV infection (Berman *et al*. 1988; Winchester *et al*. 1988; Solinger and Hess 1990; Calabrese *et al*. 1991). These studies have suggested that the prevalence of arthritis that resembles psoriatic arthritis in HIV infection is 1 to 3 per cent, compared with 0.05 to 0.14 per cent in HIV-negative individuals, and of psoriasiform lesions is 3 to 6 per cent, compared with 1 to 3 per cent in the HIV-negative population. Other studies have found similar prevalence rates of psoriasiform lesions but lower rates of arthritis, approximating those in the general population (Duvic *et al*. 1987; Kaplan *et al*. 1989). Possible explanations for these discrepancies may be differences in categorization of patients between centres, ethnic differences, variable use of diagnostic procedures such as confirmatory skin biopsies, and the high frequency of undifferentiated spondylarthropathy syndromes in HIV infection which do not meet criteria fully for either psoriatic arthritis or Reiter's syndrome.

Clinical features

The predominant finding in HIV-infected individuals with Reiter's syndrome is often relatively severe arthritis and enthesopathy, frequently accompanied by skin and nail disease (Fig. 9) (Winchester *et al*. 1987; Altman *et al*. 1994; Kellner *et al*. 1994). The course of the arthritis in HIV-associated Reiter's syndrome can take two general forms: an accumulative pattern evolving to full intensity over several weeks to months, or, more commonly, a milder intermittent pattern with recrudescences and remissions. The accumulative form is often associated with widespread polyarticular but asymmetric arthritis and is characterized by synovial thickening, erosions, and juxta-articular osteoporosis. The degree of upper extremity involvement and the accumulative pattern suggest features seen in psoriatic arthritis. The intermittent form usually has oligoarticular knee or ankle joint involvement and more closely resembles the clinical evolution of Reiter's syndrome in HIV-negative individuals. Enthesopathy is often unusually severe and profoundly disabling, while ocular involvement may be rather mild or absent. Cutaneous changes are usually striking in both intensity and extent. The distribution of cutaneous lesions is sometimes more like that found in pustular psoriasis.

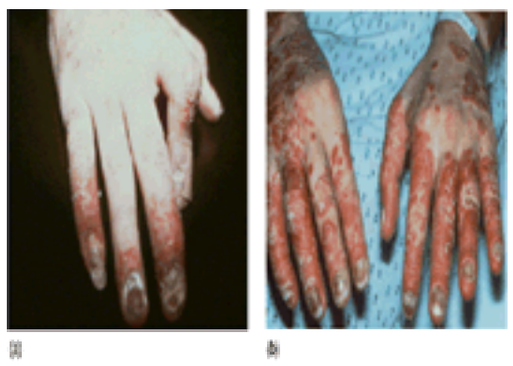

Fig. 9 Two patterns of HIV-associated spondylarthropathic hand involvement in HLA B27-positive persons; (a) illustrates findings typical of Reiter's syndrome, with onychodystrophy, subungual and acral hyperkeratosis, pseudoparonychia, fusiform swelling, and flexion contracture of the digits; (b) illustrates more extensive psoriasiform involvement of the skin of the hand and other parts of the body. Acral intensification and onychodystrophy are present.

The foot and ankle are the most commonly involved sites. Severe enthesopathy of the Achilles tendon, plantar fascia, and anterior or posterior tibial tendons may cause some patients to exhibit a characteristic broad-based 'AIDS' gait, walking with the feet in inversion and extension in an attempt to diminish pain by distributing weight on the lateral margins. New bone formation at the insertion of the Achilles tendon and/or plantar fascia may often be seen radiographically as typical fluffy periostitis. Multidigit dactylitis frequently occurs and, in combination with plantar fasciitis and extensor tenosynovitis, may simulate cellulitis or pedal oedema. While synovitis of the knee is prominent, hip disease and shoulder-girdle involvement are uncommon. The prevalence of axial involvement appears to be significantly less common than in the HIV-negative forms of the disease, with sacroiliitis only occasionally being seen, and spinal ankylosis very rarely. Synovitis at the elbow and wrist may result in early flexion contractures and fusion, while asymmetric involvement of the distal interphalangeal joints may cause progressive hand deformities (Fig. 9).

The cutaneous manifestations of HIV-associated Reiter's syndrome vary considerably from individual to individual, but are often very conspicuous and sustained, in contrast to HIV-negative Reiter's syndrome. The most prominent is keratoderma blenorrhagicum, a papulosquamous and pustular eruption that usually occurs on the palms and soles. In some instances (Fig. 10), the sole is involved with a uniform dyskeratosis. The rash may spread progressively over the body in a pattern indistinguishable from pustular psoriasis, except that there is a greater tendency for involvement of the groin and intertriginous regions (inverse or sebopsoriasis). A progressive intensification of changes in the distal digits is often very prominent. Acrokeratosis is common, often associated with erythema and periungual pseudoparonychia formation. Severe alterations in the nails of the hands and feet often accompanies involvement of the distal interphalangeal joints, and is manifested clinically as onychodystrophy with or without subungual hyperkeratoses and yellow discoloration of the nails (Fig. 9). Milder degrees of onychodystrophy are present without involvement of the distal interphalangeal joints. Conjunctivitis and iritis appear to be much less prominent than in HIV-negative Reiter's syndrome.

Fig. 10 Severe keratoderma blenorrhagica on the soles of an HIV-infected individual with lower limb arthritis and extensive psoriasiform skin lesions.

The cutaneous psoriasiform manifestations include lesions of psoriasis vulgaris, guttate psoriasis, keratoderma or pustular psoriasis, sebopsoriasis of the groin and axilla, and erythroderma (Fig. 11). Among the spectrum of psoriasiform skin diseases in HIV-positive patients, atypical features are present that are not seen in classic psoriasis, suggesting the existence of distinct disease mechanisms (Kaplan *et al*. 1987). The spondylarthropathy-like peripheral musculoskeletal involvement is equivalent to that described above in the section on Reiter's disease and oligoarthritis syndromes, but also includes individuals with preponderant distal interphalangeal joint disease including pencil-in-cup deformities. The severity of psoriatic arthritis in HIV-positive individuals has been emphasized (Bulbul *et al*. 1995). Enthesopathy and dactylitis, especially of the foot, are particularly prominent. Onychodystrophy is a common presenting symptom and is highly correlated with arthritis, especially in distal interphalangeal joints of the hands or feet. A significant number of patients with psoriatic skin manifestations or onychodystrophy only have limited musculoskeletal findings, such as dactylitis or enthesopathy, and do not meet the criteria for psoriatic arthritis (Berman *et al*. 1988; Espinoza *et al*. 1988; Winchester *et al*. 1988).

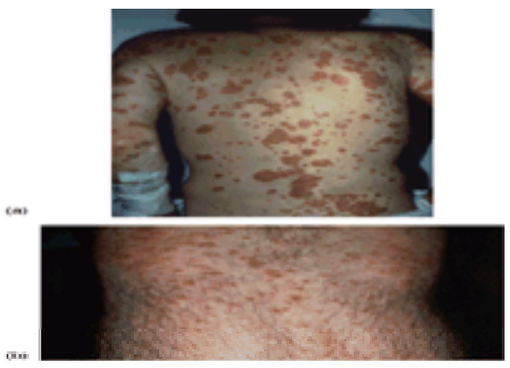

Fig. 11 Two patterns of psoriasiform skin involvement; (a) shows extensive psoriasiform involvement of the trunk in the HIV-infected patient shown in Fig. 9(a), initially presenting with features of Reiter's syndrome and progressing to severe multijoint arthritis with deformities. Extensive involvement of intertriginous areas (sebopsoriasis) was present; (b) illustrates psoriasis vulgaris in an HIV-positive person without significant arthritis.

Pathogenesis

The frequency of HLA B27 in HIV-positive Caucasian individuals with Reiter's syndrome approaches 80 per cent (Winchester *et al*. 1987; Berman *et al*. 1988; Forster *et al*. 1988), the same frequency observed in conventional Reiter's syndrome (Tiwari and Terasaki 1985). Over 30 per cent of cases are preceded by gastrointestinal infection with *Shigella flexneri, Salmonella* spp., *Yersinia enterocolitica* and *pseudotuberculosis*, and *Campylobacter jejuni* (Winchester *et al*. 1987; Forster *et al*. 1988). Temporal associations of Reiter's syndrome with infection by other organisms, including *Giardia lamblia* and atypical *Mycobacteria* spp., have also been observed but are of unknown significance (Winchester *et al*. 1987). High titres of antichlamydial antibodies have been reported in 33 per cent of HIV-positive individuals not necessarily afflicted with Reiter's syndrome, compared with 1.7 per cent in normal subjects (Gutierrez *et al*. 1990).

Whereas psoriasis vulgaris and psoriatic arthritis in the general population are associated with increased frequencies of HLA class I alleles Cw6, B13, B17, and B38 (White *et al*. 1972; Arnett 1985), no HLA associations have been detected with these disorders in HIV-infected individuals in two independent studies (Duvic *et al*. 1987; Winchester *et al*. 1988), suggesting differences in underlying pathogenesis and further arguing against a necessity for these conditions to occur at similar frequencies. In contrast, the presence of pustular psoriasis, and the arthritis that may accompany it, is associated with an increased frequency of HLA B27 in both HIV-negative and HIV-positive individuals (Arnett 1985; Winchester *et al*. 1988). It is this subgroup that most resembles Reiter's syndrome.

Progressive depletion of CD4 cells in HIV infection may be a permissive factor for greater severity, and possibly increased prevalence, of Reiter's syndrome by allowing the establishment of persistent infection with, or greater invasiveness of, gut micro-organisms such as *C. jejuni* (Perlman *et al*. 1988), or by diminishing help for B-cell dependent bacterial clearance mechanisms, which have been shown to be important in attenuating experimental chlamydial arthritis (Rank *et al*. 1988). In addition to quantitative depletion of CD4 cells, infection with HIV also leads to qualitative defects reflected by diminished interleukin 2 production following antigenic challenge (Antonen and Krohn 1986). Such defects have been observed in HLA B27-positive individuals developing Reiter's syndrome after a salmonella epidemic (Inman *et al*. 1989), and may contribute to selective microbial persistence and the development of Reiter's syndrome in HIV-infected individuals.

Biopsy of involved tissue in HIV-associated psoriasis is superficially similar to that in the idiopathic variety, demonstrating epidermal proliferation, dermal inflammatory cell infiltrate, tortuous dermal capillaries, and decreased numbers of epidermal Langerhans cells. Similar blood vessel changes, inflammatory cell infiltrate, and proliferative tissue are also present in psoriatic synovium (Espinoza *et al*. 1982). The depletion of epidermal Langerhans cells, which are CD4+ and readily infected by HIV *in vivo* (Belsito *et al*. 1984; Grelen *et al*. 1987), may be a permissive factor for the development of psoriatic lesions. In addition, products of the HIV proviral DNA may directly cause epidermal proliferation (Ensoli *et al*. 1990). In this regard, mice transgenic for the HIV *tat* gene preferentially express the tat protein in the skin and develop epidermal hyperkeratosis and acanthosis (Vogel *et al*. 1988). There is growing evidence for the participation of CD8 T cells in the pathogenesis of psoriasis and in the effect of cytokines (Duvic 1991; Winchester 1994).

The occurrence of these entities in the setting of HIV-induced immunosuppression and CD4 T-cell depletion suggests that the critical cells involved in disease pathogenesis may be residual components of the immune system, such as CD8 T lymphocytes or cells of the monocyte lineage. Indeed, immunopathological studies of synovium from HIV-infected patients with Reiter's syndrome demonstrate a lymphocytic infiltrate that is predominantly CD8+ (Espinoza *et al*. 1990). As the natural ligand for the CD8 structure on the surface of cytotoxic/suppressor cells is an MHC class I molecule such as HLA B27, we have postulated that, in Reiter's syndrome, cells of the CD8 lineage may be critically involved in an immune recognition event interacting with a particular antigen presented by HLA B27 molecules on the surface of cells of the monocyte/macrophage lineage (Meiser *et al*. 1982; Swain 1983) (Table 2). Two mechanistic hypotheses appear likely. In one, the pathogenesis of the spondylarthropathy is the same as when it occurs in a person not infected with HIV, while in the other, HIV-encoded peptides play an aetiological role in the rheumatic disease. HIV has been cultured from synovial fluid (Withington *et al*. 1987), abundant p24 antigen can be demonstrated in synovial tissue (Forster *et al*. 1988; Espinoza *et al*. 1990), and HIV DNA has been detected in synovial dendritic cells (Hughes *et al*. 1990), suggesting that the cellular infiltrate may, at least in part, be reactive to retroviral peptides. Parallel transactivation of HIV in this inflammatory milieu (Siekevitz *et al*. 1987) may act to increase HIV replication within these activated monocytes and T cells and lead to more rapid progression to AIDS. In support of this possibility is the fact that the appearance of Reiter's syndrome is an unfavourable prognostic sign, with many patients developing their first opportunistic infection within several months after the initial manifestations of Reiter's syndrome (Winchester *et al*. 1988).

Infectious agents thought to trigger psoriasis in the general population include streptococci in guttate psoriasis (Whyte and Baughman 1964) and staphylococci in pustular psoriasis (McFayden and Lyell 1971). Both organisms have also been implicated in psoriatic arthropathy (Mustakellio and Lassus 1964; Vasey *et al*. 1982). In HIV infection, the presence of psoriasis or psoriatic arthritis has been reported to be exacerbated by staphylococcal infections in almost 50 per cent of individuals (Duvic *et al*. 1987).

Treatment

The management of these entities is a difficult challenge (Duvic *et al*. 1987; Kaplan *et al*. 1989). Joint erosions, ankylosis, and osteolysis, together with chronic or recurrent enthesopathy, can rapidly lead to fibrosis, deformity, and functional disability. These are frequently compounded by generalized weakness, resulting from progressive muscle loss, and cachexia. Physical and rehabilitative therapy to maintain joint range of motion, prevent contractures, and strengthen muscle function is a central component in the comprehensive care of these patients. Optimal management involves a team-oriented approach including rheumatologists, physical and occupational therapists, and mental health care experts for management of the reactive depression that frequently accompanies the severe physical disability.

While the musculoskeletal pain and inflammation in mild cases may respond to conventional non-steroidal anti-inflammatory agents, severe manifestations of the spondylarthropathy syndromes in HIV infection are more effectively treated with phenylbutazone, given in 100 mg doses twice to three times daily. Monitoring of haematological parameters is recommended during this therapy, although no untoward cytopenias have been observed. Sulphasalazine, at doses of 0.5 to 1.5 g twice daily, may be administered together with phenylbutazone in severe cases. While controlled studies have not been performed, at least one-third of patients respond to this slow-acting drug. Maintenance sulphasalazine therapy is continued while phenylbutazone is gradually withdrawn. Intra-articular corticosteroid injection may sometimes be beneficial, and has not been associated with deleterious effects, in contrast to systemic corticosteroids which may cause extensive candidiasis and opportunistic infections in these patients (Duvic *et al*. 1987; Winchester *et al*. 1987). Prolonged and aggressive antibiotic therapy may, in theory, be of benefit in diminishing microbial persistence. Etretinate has been reported to be particularly efficacious in the treatment of both the joint and cutaneous manifestations of severe Reiter's syndrome previously unresponsive to non-steroidal anti-inflammatory drugs and topical corticosteroids, and in psoriasis (Belz *et al*. 1989; Louthrenoo 1993).

Zidovudine has been reported to improve skin disease (Ruzicka *et al*. 1987; Kaplan *et al*. 1989). In an unblinded study, 90 per cent of HIV-infected persons had either partial or complete improvement of their psoriatic skin disease following zidovudine treatment at a dosage of 1200 mg/day (Duvic *et al*. 1994). The associated arthritis in these individuals, however, did not improve with zidovudine. While zidovudine has no documented beneficial effect on the arthritic symptoms *per se*, therapy with this agent should be considered in all patients with Reiter's syndrome, whether presenting at advanced stages of immunosuppression or as the initial manifestation of HIV infection, in order to prevent the enhanced HIV replication that may secondarily occur as a result of CD4 cell activation. Zidovudine-induced myopathy may

become a confounding variable.

Methotrexate and other immunosuppressive agents are capable of strikingly ameliorating the skin and joint disease (Winchester *et al*. 1987; Maurer *et al*. 1994), but they should be used only with great caution because their use has been followed by the development of frank AIDS and death from opportunistic infection (Winchester *et al*. 1987). However, methotrexate administered to three individuals with HIV-associated psoriatic arthritis did not worsen the underlying immune deficiency in two of the three (Maurer *et al*. 1994), suggesting that it may have a limited place when used cautiously. Phototherapy has been asserted to be helpful and without evident problems (Ranki *et al*. 1991; Meola *et al*. 1993), but has also been associated with the appearance or exacerbation of Kaposi's sarcoma (Duvic *et al*. 1987) and the possibility of HIV activation has been emphasized (Duvic 1995). Studies in mice transgenic for HIV have shown that HIV may be activated by ultraviolet radiation, raising concerns for the use of phototherapy in humans (Morrey *et al*. 1991; Vogel *et al*. 1992). These mainstays of therapy in the HIV-negative patient with psoriasis or psoriatic arthritis are probably best reserved for very difficult situations that have failed to respond to all other approaches, because their mode of action parallels the consequences of HIV infection, although continued experimental experience with these therapies may define a risk–benefit balance that is acceptable in certain situations.

5.3.7 Mycobacterial diseases

Sanjiv N. Amin

Tuberculosis and leprosy are infectious diseases characterized by chronic inflammation. Tuberculosis is caused chiefly by the organism *Mycobacterium tuberculosis* and much less commonly by *M. bovis* and atypical mycobacteria (*M. avium, intercellulare, scrofulaceum, gordonae, marium*, etc.). Leprosy is caused by *M. leprae*. Most of these infections are readily amenable to modern medical and surgical treatment, which almost always cures the infection.

Tuberculosis

Epidemiology and pathogenesis

Tuberculosis was rapidly declining in the United States, Europe, and Australia until 1985, after which the trend was interrupted by the appearance of acquired immune deficiency disease (Modilevsky *et al*. 1989). Tuberculosis in persons infected by human immunodeficiency virus is characterized by extrapulmonary disease in as many as 70 per cent. At present, one-third of the world's population, estimated at 1.7 billion persons, is infected with *M. tuberculosis*. This reservoir of infection affects around 8 million new patients and results in 19 million deaths annually (Arachi 1991). Fewer than one-tenth of all patients with tuberculosis residing in developed nations suffer from infection of the bones and joints (Davies *et al*. 1994), but the proportion in other populations is much higher.

In the majority of instances, *M. tuberculosis* is transmitted from person to person via the respiratory route. A patient with infectious pulmonary tuberculosis (sputum smear-positive) coughs and produces an aerosol of small droplets, 1 to 5 µm in size, containing bacilli. The small droplets evaporate within a short distance from the mouth, and the desiccated bacilli remain airborne for long periods. Infection of a host occurs when a few bacilli are inhaled. These are sufficiently small to reach the pulmonary alveoli and are phagocytosed by alveolar macrophages.

The *M. tuberculosis* grows slowly, dividing approximately every 10 to 24 h. It has no known endotoxins or exotoxins, and there is no immediate host response to infection. Growth and multiplication of the organism are essentially unimpeded, until a specific cell-mediated immune response develops after 4 to 8 weeks, and only if a threshold number of *M. tuberculosis* organisms is reached. The collection of activated T cells and macrophages forms granulomas that undergo central coagulative necrosis (caseation). Healing then occurs, often with calcification.

Tuberculosis as a clinically manifested disease develops in a minority of the patients who fail to contain the primary infection. In some individuals the disease may appear within a few weeks of primary infection, and in others the bacilli may remain dormant within the macrophages for many years before entering a phase of exponential multiplication to cause the disease. The bacilli reach the bloodstream either by being carried in the lymph to the draining lymph nodes and thence to the thoracic duct, or by erosion of blood vessels in the walls of developing tuberculous lesions in the lungs. The bacilli that enter the bloodstream disseminate throughout the body, and some are deposited in bones or joints.

Immunology

There appears to be variation between individuals in their immune response to mycobacteria, which perhaps is genetically determined. The ability of the host to control infection with *M. tuberculosis* resides in its ability to mount an effective cellular immune response. Cell-mediated immunity develops when T lymphocytes become sensitized after recognizing their specific antigen and then release mediators that modulate macrophage function.

Delayed cellular hypersensitivity is the associated immunological response in the majority of patients with tuberculosis (Stanford 1983; Lucas 1988). Cell-mediated immunity and delayed hypersensitivity are closely related phenomena that occur in the host as a result of T cells becoming specifically activated by *M. tuberculosis*. Both result from the same immunological mechanism and alter the response of the host to subsequent exposure to antigen. Delayed hypersensitivity is responsible for the tuberculin skin-test reaction. There is no single dominant antigen, and the infected (or artificially sensitized) host develops an immune response to an array of mycobacterial proteins. Many of the observed effects of tuberculosis are considered to be due to delayed hypersensitivity (Sifford and Bates 1991) and it has been implicated in caseation and cavitation. Caseation follows the early exudative lesions in the soft tissues and results when blood vessels adjacent to the areas of inflammation thrombose causing tissue necrosis. Delayed hypersensitivity is also involved in the liquefaction of caseous lesions, probably as a result of lymphokine production, which attracts and activates macrophages. Macrophages then release hydrolytic enzymes that digest the necrotic debris.

Mycobacterial infections also stimulate humoral antibody responses, and production of antibodies to polysaccharide and protein antigens has been demonstrated. However, there is no evidence that these antibodies play a part in immunity, hypersensitivity, or the pathogenesis of tuberculosis (Dutt 1989; Ellner *et al*. 1989). Attempts to link HLA phenotype and susceptibility to tuberculous infection have not yielded a significant correlation (Shoemaker 1986).

Clinical manifestations

Primary tuberculous infection is usually asymptomatic and typically occurs in lower or mid zones of the lung as a pneumonitis with enlargement of hilar lymph nodes (primary complex). It may either undergo remission spontaneously or progress at once to clinical disease. After remission, there may be reactivation many months or years later, resulting in a chronic wasting disease. The lungs and respiratory tracts are most frequently affected, followed by lymph nodes, skeleton, pericardium, brain and meninges, abdomen, and skin.

Tuberculosis of a bone or joint is usually a low-grade and slowly progressive infection with a variable degree of local and systemic manifestations (Wolfgang 1978; Butorac *et al*. 1987; Martini *et al*. 1988), depending on the virulence of the organism and the defensive response mounted by the host. The onset of symptoms is insidious; involvement is monoarticular or mono-osseous in the majority of patients. Simultaneous involvement of other viscera (lungs, lymph nodes) is common. There are associated constitutional symptoms (fever, fatigue, weight loss, poor appetite, night sweats). Pre-existing arthritis or old trauma, alcoholism, prolonged use of corticosteroids, and immunodeficiency diseases are significant predisposing factors.

Tuberculosis can affect any part of the spine, although up to about two decades ago the thoracolumbar junction was more commonly affected (Davidson and Horowitz 1970). The infection may begin in and remain confined to a vertebral body, eventually leading to collapse, or it may affect the end-plate of the vertebral body with early involvement of the adjacent disc and the next vertebral end-plate. The formation of a paravertebral abscess is usual, and progressive necrosis of bone and disc

with sequestration leads to kyphotic deformity or gibbus at that site. The abscess may remain localized at the same site or track along tissue planes and neurovascular bundles to cause symptoms at a remote site. In the lumbar spine, the abscess may track along the psoas muscle to present as a swelling in groin or thigh; from thoracic vertebrae it may follow the course of a rib and present anteriorly on the chest wall. The local symptoms are pain, muscle spasm, and limited movement. The pain is characteristically worse during sleep, which perhaps is due to relaxation of the protective muscle spasm. In the occasional patient, pain may not be the predominant symptom, and kyphosis or a cold abscess is the first manifestation.

Primary involvement of the posterior elements of vertebrae appears less common. Haematogenous spread of infection to the pedicle is usually the initial event. Destruction of the neural arch and vertebral body posteriorly characterize the disease progression. Later in the course of disease, the medial ends of ribs are eroded, followed by the transverse processes of affected vertebrae. In the majority of cases only a single vertebra is involved (Kumar 1985). Disc spaces remain preserved until late in the disease and paraspinal masses are prominent. Clinical presentation in these patients is often with early paraplegia.

Tuberculosis involving the first and second cervical vertebrae may begin in the retropharyngeal space with secondary involvement of the bone, or more rarely in the bone itself (Lifeso 1987) (Fig. 1). With progression there is increasing ligamentous involvement, with minimal osteolytic erosions, into the odontoid or the arch of the first cervical vertebra. This would allow anterior subluxation of C1 on C2, increasing rotatory subluxation, and proximal translocation of the odontoid. In a final stage of the disease, bone destruction increases, with complete loss of the C1 arch or fracture through the base of the odontoid, leading to a grossly unstable articulation between the occiput and C2. The diagnosis is suspected if an individual with prolonged neck pain has restriction in all ranges of movement. The most serious complication of spinal tuberculosis is involvement of the spinal cord causing a neurological deficit. This may occur incompletely and slowly, with the patient complaining of difficulty in walking, or it can appear more dramatically, with complete spastic paraplegia or quadriplegia and loss of sphincter control. The neurological deficit may be secondary to medullary and radicular inflammation or cord compression by an abscess, tuberculoma, or subluxation of a vertebral body.

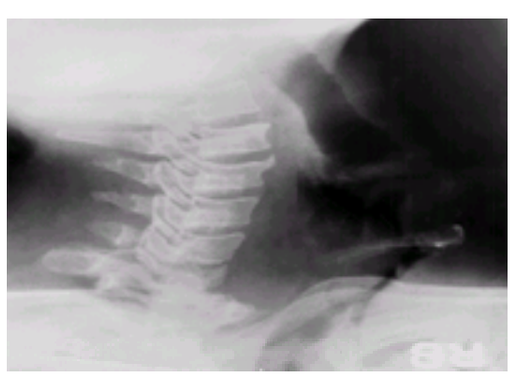

Fig. 1 Tuberculosis of C1 and C2 with a large retropharyngeal abscess.

Skeletal tuberculosis other than in the spine in adults more commonly occurs in the joints of the lower extremities (Fig. 2 and Fig. 3). It usually is monoarticular. Weight-bearing joints are more frequently affected, and microtrauma to cartilage is thought to predispose to the infection. The joints commonly involved are the hip, knee, ankle, sacroiliac, wrist, and shoulder in that order (Garrido *et al*. 1988; Pouchot *et al*. 1988). The infected individual usually has a long history of mild or moderate joint or bone pain along with a swelling or large effusion. On examination, there is synovial thickening and mild warmth. There is always significant muscle atrophy around the joint. If a sinus track has formed, there may be signs of superimposed pyogenic infection. Even in the early stages, there is limitation in the range of motion by effusion and synovial thickening. As infection progresses, flexion contractures and joint deformity develop. The end-result may be fibrous or bony ankylosis.

Fig. 2 The base of the right great toe was painful and swollen for 5 years in a 40-year-old premenopausal female; this was an indolent and slowly progressive lesion of tuberculosis.

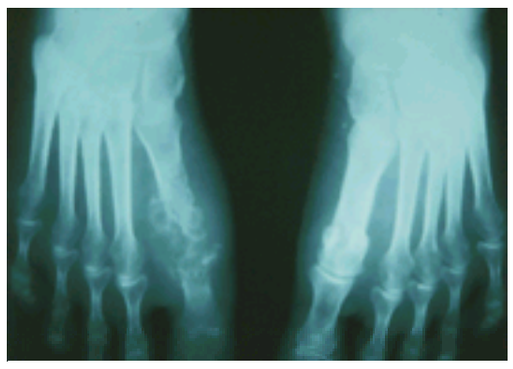

Fig. 3 Radiograph of the feet of the patient in Fig. 2 at 5 years after the onset of pain, revealing remarkable destruction of the bones and joints by tuberculous infection.

Tuberculous osteomyelitis may affect any long bone (Martini *et al*. 1986). The patient presents with local pain and sometimes a diffuse swelling may be evident, with or without a sinus opening. Involvement of the short bones of the hands or feet is termed tuberculous dactylitis. Soft tissue swelling is usually the first manifestation and the pain appears a few days or weeks thereafter. One or several fingers or toes may be affected.

Cystic tuberculosis of bone is another type of tuberculous osteomyelitis. Lesions are of variable size and well circumscribed. Multifocal cystic tuberculosis of bone was more common five decades ago, but it seems that solitary lesions are now predominant (Kumar *et al*. 1988). In the adult the common sites are the skull, axial skeleton, and shoulder and pelvic girdles. In children the metaphyses of long bones are often the sites of infection. This predilection is probably due to the vascular structure of the long bones in this region (Edeikin *et al*. 1963). Tubercle bacilli probably lodge in the small terminal branches of the arteries of the metaphyses and grow, caseate, and produce a cystic lesion. A soft tissue swelling is externally visible if the skull bone is affected (LeRoux *et al*. 1990). Most commonly, a circumscribed, punched out lesion, approx. 2 cm in diameter, results. At presentation, most patients are systemically well and manifest a painless swelling, which is firm if the periosteum is intact

or soft if not. Headache is uncommon, but if present, it is usually localized to the site of infection. Occasionally, there is a discharging sinus.

Poncet's disease is another pattern of joint involvement (Dall *et al*. 1989). Patients who have active visceral tuberculosis complain of polyarthritis or tenosynovitis affecting peripheral joints (Fig. 4), a form of reactive arthropathy. In some patients the symptoms and signs are suggestive of enthesopathy at the ankle, knee, hip, or elbow. There may be mild stiffness after inactivity, and swelling. These symptoms regress within a few weeks after starting treatment. Physicians from the Indian subcontinent do not doubt its existence as a definite entity.

Fig. 4 Tuberculous inflammation of the right middle proximal interphalangeal joint and left abductor pollicis longus tendon sheath in a 36-year-old woman.

Other, less frequently seen clinical features of tuberculosis include necrotic skin ulcers of erythema nodosum, shoulder-hand syndrome, parotid gland swelling, and red eye caused by uveitis and chorioretinitis. Secondary amyloidosis may appear many years after the tuberculous infection.

Investigations and diagnosis

Tuberculosis is diagnosed if the clinical pattern is suggestive and acid-fast bacilli are demonstrated in the lesions. However, the latter is often not possible and other criteria have to be sought as additional evidence.

To culture tubercle bacilli on the Lowenstein–Jensen medium requires 4 to 8 weeks to detect growth. Nowadays, radiometric techniques using highly selective media allow cultivation in 1 or 2 weeks, but confirmation of the identity of an isolated organism may require more time. Advances in molecular genetics have resulted in impressive DNA hybridization probes that are non-radioactive and easily utilized in a clinical microbiology laboratory. However, these probes require growth of the organism in culture because they are unreliable in detecting the relatively small numbers of organisms in clinical specimens such as tuberculous synovitis.

A smear from the infected site such as a paraspinal abscess usually provides the required evidence because the staining characteristics of *M. tuberculosis* are typical. A slender, curved, often polychromatically beaded rod is seen singly, in pairs, or in clumps of a few organisms, lying side by side. If stained with fluorescent auramine-rhodamine, the bacilli are visualized under the usual high-dry (100 ×) magnification. A more specific stain consists of carbol fuchsin and this requires careful scanning with oil-immersion (1000 ×) microscopy.

A simple smear from clinical specimens such as synovial fluid or infected bone scrapings seldom demonstrates the organism. The technique of polymerase chain reaction holds remarkable promise for this purpose. The key technological element of this procedure is a DNA polymerase that is heat-stable. The function of a DNA polymerase is to generate a complementary strand of DNA using a single strand of DNA as a template. A short segment of complementary DNA annealed to the template (which equates with the a short segment of double-stranded DNA) serves as a primer region. The DNA polymerase can add nucleotides to the primer in a sequential fashion based on the template sequence and result in a longer sequence of double-stranded DNA. The nucleotides are always added in the same direction from any given primer site. If a short primer sequence is added to the double-stranded DNA (chromosomal, plasmid) and the temperature is raised above the melting point of the double strands and then lowered, a number of the primers will anneal to their complementary segments on the chromosome or plasmid. Once annealed, the primer region is elongated by the addition of an appropriate DNA polymerase and deoxyribonucleotide triphosphates. Two primers from opposite ends and strands can anneal and result in a duplication of the target segment. Once the elongation is complete, the temperature is raised so that both the old and newly synthesized strands fall apart. By lowering the temperature, the target region of DNA is logarithmically amplified. Although the reaction mixture goes above 90 °C during each cycle, the heat-stable DNA polymerase is not completely inactivated and can result in millionfold amplifications of the target DNA sequence after 30 to 40 cycles. The temperatures for denaturing, annealing, and elongation steps are easily programmed into automated heat blocks that can reproducibly change temperatures with great precision. Thus, the polymerase chain reaction can amplify minute quantities of DNA to levels that are easily seen on routine agarose gel electrophoresis. However, the major limitation is that minute quantity of contaminating DNA also gets amplified and is seen on the agarose gel as a false-positive result. Present research is seeking to overcome this limitation. Also, the polymerase chain reaction does not differentiate dead from living organisms because it simply amplifies DNA. Thus, identifying a portion of the genome of an organism in a clinical specimen provides the ability to state that the organism was present, and it cannot distinguish between active and treated or inactive tuberculosis (Schluger *et al*. 1994). The correlation of clinical information with the greater sensitivity of the polymerase chain reaction is currently under study.

The typical histological feature is a tuberculous granuloma with partial or complete caseation necrosis. The epithelioid cells are surrounded by a wall of mononuclear cells, which is a lymphocyte mantle comprised mainly of T-suppressor cells. Such typical granulomas are not always seen (particularly in the synovium) and only a tuberculoid infiltrate may be visible. In this infiltrate are seen irregular accumulations of epithelioid cells among mononuclear cells, with or without necrosis and giant cells (Levy *et al*. 1986).

Serological tests for the diagnosis of tuberculosis (Daniel 1989) remain experimental and are not satisfactorily established for routine clinical use. Advances in the definition of species-specific antigenic determinants of *M. tuberculosis* had created a firm basis for the production of standardized serological immunoassays (Brisson-Noel *et al*. 1989). However, in the majority of patients, musculoskeletal tuberculosis is a paucibacillary disease in which the desired sensitivity of these tests is not achievable (Ivanyi 1988). This is attributed to the lack of sufficient antibody formation rather than to limitations in the techniques of detection. A raised erythrocyte sedimentation rate is a non-specific serological measure of inflammation and occasionally is in the normal range though the patient has active tuberculosis.

The likelihood of infection with *M. tuberculosis* can be assessed by intradermal injection of 5 tuberculin units of purified protein derivative (American Thoracic Society 1990). The diameter of any induration is recorded 48 to 72 h later. Reactivity to tuberculin (³5 mm induration) is found if the person has been exposed to mycobacteria and has intact cell-mediated immunity. A history of vaccination with bacille Calmette-Guérin is ignored in interpreting the results of tuberculin skin testing in adults, because skin-test reactivity from bacille Calmette-Guérin usually declines by adulthood. If skin testing is done periodically, as in hospital employees, the boosting phenomenon must be considered. In some tuberculin reactors, although the sensitivity to tuberculin declines with time to become a negative skin test, administration of the skin test boosts immunological memory so that a second tuberculin skin test up to 2 years later will be positive. If the person is being tested annually, the positive second response and negative first response are erroneously thought to represent recent infection requiring treatment. Another shortcoming of the test is cross-reactivity between mycobacterial antigens, and a positive test may result from exposure to environmental non-tuberculous mycobacteria. Tuberculin test sensitivity falls with age, early treatment, and in all conditions that diminish delayed hypersensitivity. In addition, for as yet unknown reasons, about one-tenth of individuals with tuberculosis do not respond to the ordinary intermediate strength of tuberculin (anergy).

Plain radiographs of the skeleton will have features suggestive of tuberculous infection. Osteoporosis is the first sign of active infection. The reactive hyperaemia, which is intense in an exudative lesion, stimulates osteolysis. If long bones are affected (osteomyelitis), small zones of clearly defined radiolucency indicate granular foci. Diffuse demineralization surrounds these osteolytic areas. As caseation takes place, the osteolytic foci become more evident. When the healing process begins, the perifocal bone becomes sclerotic. If the central demineralized area is merely exudative, healing results in reossification with eventual return of the normal trabecular pattern. If central caseation occurs during the active phase of infection, with calcium deposition, then the dense image of a sequestrum is surrounded by an osteolytic ring representing the fibrous wall beyond which the bone is demineralized. In tuberculous dactylitis the soft tissue swelling is obvious and there may be mild or exuberant periostitis of phalanges, metacarpals, or metatarsals (Bush and Schneider 1984). Expansion of the bone accompanied by cystic change is termed spina

ventosa. In involvement of a peripheral joint the synovial shadow may be clearly visible in a slightly underexposed radiograph. If the arthritis is destructive, then the joint space narrows due to erosion of cartilage, and the subchondral cortex of bone becomes ragged and osteoporotic. Vague, irregular densities seen in the surrounding soft tissues may signify abscess formation.

The radiographic appearance of spinal tuberculosis depends on the extent of infection (Chang *et al*. 1989). Destructive changes occasionally confined to a vertebral body or part of two posterior elements of the vertebral complex such as the lamina or pars, but these are uncommon and easily confused with malignant disease. More typically seen is reduction of the disc space, with irregularity of adjacent end-plates, surrounded by a soft tissue swelling due to a paravertebral abscess. Later, more extensive destruction and increased abscess formation are evident. Kyphotic or scoliotic deformity develops as vertebral destruction progresses. In children, secondary changes, such as an increase in vertebral height, may develop in uninvolved adjacent vertebrae to produce a compensatory lordosis above and below the kyphotic deformity. A severe kyphotic deformity may increase with time, even after healing has occurred, because of the gravitational effect on the deformed spine.

Radiological evidence of healing after successful drug treatment is usually observed late on routine radiographs, both in limb bones or joints (Fig. 5) and the spine. Bone destruction or loss of vertebral height can progress for up to 14 months and recovery of vertebral height is often not seen earlier than 15 months after beginning chemotherapy (Boxer *et al*. 1992). Thus the progression of bone destruction whilst on treatment is not always an adverse feature. Sclerosis is a feature of healing, and appears variably from onset to within 5 months of starting drug treatment. The change from sclerosis to normal bone density takes 5 years or much longer. Paravertebral soft-tissue masses may also take as long as 15 months to resolve. Involvement of adjacent vertebrae is often associated with the reduction in disc space, fusion of the vertebrae, and the formation of syndesmophyte-like bone bridges (Fig. 6).

Fig. 5 Progressive radiological destruction in tuberculous infection of the left elbow during the first 5 months of adequate treatment.

Fig. 6 Erosion of the left transverse process at the L2 vertebra with calcification along the track of caseous fluid to the above and below vertebrae.

Computed tomography (**CT**) is provenly superior to conventional radiographs in detecting and monitoring paravertebral abscesses, particularly those situated in the lumbar region (LaBerge and Brant-Zawadski 1984). The CT findings indicative of an abscess include an abnormal mass of low attenuation number, displacement of surrounding structures, obliteration of normal fascial planes, and a 'rind sign' consisting of a rim of increased tissue attenuation. However, none of these features is specific for tuberculosis, with the differential diagnoses being haematoma or neoplasia (Whelan *et al*. 1985), brucellosis, and other pyogenic infections. Tuberculous abscesses are often characterized by macroscopic calcifications. These 'rice bodies', occasionally seen on CT, are diagnostic of tuberculosis infection.

Magnetic resonance imaging (**MRI**) features of vertebral osteomyelitis are characteristic (Smith *et al*. 1989). The T_1-weighted images show a confluent decreased signal intensity at the involved vertebral bodies and intervening disc, whereas the T_2-weighted images demonstrate increased signal intensity. In addition, the normal biconcave configuration of the disc changes and the normal intranuclear cleft is lost. Abscesses can cause an abnormal area of low signal intensity on a T_1-weighted image and a relatively increased signal intensity on T_2-weighted images because of increased fluid content. The MRI can clearly delineate abscesses as distinct from the adjacent spinal cord, psoas muscle, and other surrounding paravertebral soft tissues. To differentiate tuberculous from other pyogenic infections, the clinical features, plain radiographs and CT have to be considered.

Treatment

The cornerstone of the treatment of musculoskeletal tuberculosis is a good regimen of antituberculous drugs, with surgical intervention in selected cases (Cooke 1985; Goldberger 1988; Davidson 1989). Because of increasing drug resistance, drug susceptibility testing is recommended on all *M. tuberculosis* isolates. The available drugs are listed in Table 1. In the treatment of newly diagnosed patients, the regimens should include, whenever possible, the main sterilizing drugs and those most effective in preventing the emergence of resistance. Patients in whom drug resistance is unlikely are prescribed isoniazid, rifampicin, and pyrazinamide. Some of the currently prescribed regimens for adults are:

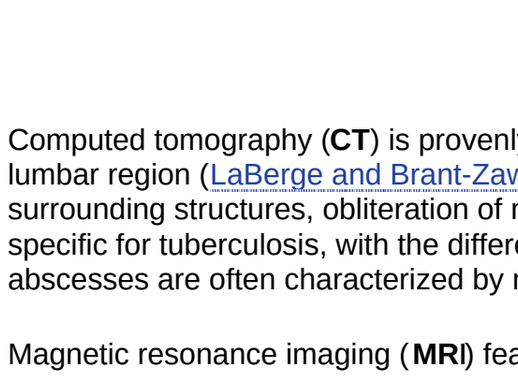

Table 1 Drugs for tuberculosis

1. rifampicin 450–600 mg, isoniazid 300 mg, pyrazinamide 1000–1500 mg, daily for 2 months, followed by rifampicin and isoniazid daily for 6 months;
2. rifampicin 450–600 mg, streptomycin 0.5–1.0 g, isoniazid 300 mg, pyrazinamide 1000–1500 mg or ethambutol 800 mg for the first 2 months, followed by

   a. rifampicin 450–600 mg and isoniazid 300 mg daily for 4 months,
   b. isoniazid 300 mg and ethambutol 800 mg daily for 6 months,
   c. isoniazid 300 mg, rifampicin 600 mg, and streptomycin 1 g twice weekly for 6 months;
3. rifampicin 450–600 mg, isoniazid 300 mg daily for 1 month, followed by rifampicin 600 mg and isoniazid 900 mg twice weekly for 8 months;
4. streptomycin 0.5 g, isoniazid 300 mg, ethambutol 800 mg daily for 3 months, followed by isoniazid and ethambutol for 12 to 18 months.

The duration of treatment is extended if there is no convincing evidence of improvement in clinical features. Surveillance is kept for 12 months after completion of treatment, as most relapses are likely to occur within this period. The introduction of short-course chemotherapy is a major step forward in the treatment of tuberculosis (Hannachi 1988). The twice-weekly drug regimens were developed with the intention to improve patient compliance.

Patients at increased risk for drug resistance should receive isoniazid, rifampicin, pyrazinamide, and ethambutol until susceptibility results are available. Ofloxacin and ciprofloxacin are bactericidal quinolones with low toxicity profiles and penetrate most tissues. They have been used for the treatment of drug-resistant tuberculosis, but reports of prospective controlled trials are not yet available. For adults, ofloxacin 600 mg/day or ciprofloxacin 1000 mg/day may be prescribed in combination with the other drugs.

The surgical treatment of skeletal tuberculosis depends on the tissue involved, whether it is bone, bursa or joint, and the severity of infection. Surgical treatment of bone tuberculosis without joint involvement consists of debridement of the abscess (if it is present) after starting the antituberculous drugs. Suction–irrigation systems are not necessary in tuberculous osteomyelitis. In an occasional patient, if structural instability is anticipated, grafting with cancellous bone chips is done at the time of initial debridement. The treatment of tuberculous arthritis depends on the extent of involvement at the time of detection. Surgery is not indicated if the infection is limited to the synovium (or bursa), with little or no radiographic involvement of the adjacent bone. If the synovium is affected and adjacent bone and cartilage are partially eroded but without gross instability of the joint, there is an argument for synovectomy together with antituberculous drugs to reduce the time needed for convalescence and reduce limitation in the range of joint movement. For advanced joint destruction (complete loss of cartilage and disorganization of the bones), the appropriate surgery is synovectomy, debridement, and fusion of the involved joint. Total arthroplasty is contraindicated in the presence of active tuberculosis. After the infection has been controlled, arthroplasty may be planned for weight-bearing joints (Kim 1988).

All adult patients with spinal tuberculosis are treated with the standardized drug regimen described above (ICMR/BMRC 1989; Medical Research Council 1993). Neurological complications are more frequent when the disease involves the upper and mid-thoracic spine (Omari *et al*. 1989). Surgical intervention is often necessary, especially to obtain adequate specimens for diagnostic purposes. In difficult cases, operative exploration of the lesion is often necessary for the management of complications such as abscesses and sinuses or myelopathy.

Summary of management

The diagnosis of tuberculosis is suspected from the clinical features and appropriate imaging. The final diagnosis is by smear of the aspirate for acid-fast bacilli or from histopathological examination of excised tissue. Appropriate specimens must be obtained before treatment is begun. The material is cultured whenever possible, chiefly to ascertain sensitivity to antituberculous drugs.

The initial drug treatment is with rifampicin, isoniazid, and pyrazinamide for the first 2 months, followed by rifampicin, isoniazid, and ethambutol for 7 or more months. Drug resistance is suspected if there is worsening of clinical signs and symptoms after the first 3 or 4 months of treatment and imaging reveals increased tissue destruction. If reports on culture and antituberculous drug sensitivity are available, then at least four of the appropriate drugs are selected, of which two or three must be bactericidal. In the absence of drug sensitivity reports the treatment must be changed to kanamycin, isoniazid, ethionamide, cycloserine, and ofloxacin or ciprofloxacin. The duration of treatment is then extended by 18 or 24 months.

Surgical intervention is most often necessary to obtain a specimen for diagnosis. In limb bones and vertebrae, necrotic tissue is debrided during the first operation and stabilization, if needed, is done at another operation after 6 or 8 months of drug treatment. Immobilization of the affected region is essential, and for spinal tuberculosis the plaster or acrylic cast must be worn for at least the first 3 months. If spinal instability is demonstrable clinically and on plain radiographs taken in the appropriate postures, then immobilization is prolonged to 6 months or more. Joint infection seldom necessitates synovectomy, except for the occasional patient in whom the diagnosis was delayed and there is a discharging sinus. Most patients not requiring synovectomy can remain ambulatory; if a leg joint is affected, partial weight bearing is recommended for the first 3 or 4 months. This is followed by physiotherapy to build lost muscle mass and tone. Surveillance for 1 year after the end of drug treatment is recommended.

Leprosy

Epidemiology and pathogenesis

The earliest written records describing leprosy come from China and India and date from 600 BC. The true scientific era began when Hensen published his tentative conclusion that the rod-shaped organisms consistently observed in material taken from patients with leprosy were probably responsible for the disease. The World Health Organization estimates that there are over 11 million cases in the world today; that number has not changed much in recent decades, with the majority of patients residing in the poorer nations (Shepard 1982). Leprosy can affect an individual at any age, but cases in infants of less than 1 year old are extremely rare.

Mycobacterium leprae is virtually non-toxic and may infest the human body in large numbers without causing symptoms. Most symptoms of the disease are due to immune reactions against the bacilli. The course after infection in individual patients is variable and determined by the ability of the host to mount an immune response that will limit the bacillary multiplication. There are patients with subclinical infection whose immunological reactivity after exposure to *M. leprae* changes and they do not develop clinical signs. Another group of patients develops skin lesions, which sometimes heal spontaneously, and this is termed the indeterminate form. The third group (estimated as around 10 per cent of all infected) are patients who have the chronic disease, and they chiefly develop dermal and neural involvement. The Ridley and Jopling (1966) classification is accepted widely and provides a good description of variations in clinical course as a basis of accurate clinical diagnosis. It comprises a continuous spectrum with the immunologically stable tuberculoid (**TT**), in which there are a few lesions containing few bacilli, at one pole, and the lepromatous (**LL**) at the other pole, which is a multibacillary disease with fulminant lesions. These poles are bridged by borderline borderline (**BB**), and borderline lepromatous (**BL**).

Leprosy is acquired by direct person-to-person transmission (Reich 1987). Spread within family members and others coming into physical contact with patients is facilitated by the indolence of clinical symptoms and the long incubation period, which varies from 6 months to several decades.

Intense bacillaemia is very common in patients with lepromatous leprosy and the organisms can be seen in stained smears of peripheral blood or buffy coats, but signs of toxaemia, including high fever, are absent. Even in the advanced stages of the disease, the lesions are restricted to the skin, peripheral nerves, anterior portion of eyes, upper respiratory tract, and testes. In lepromatous leprosy, collections of bacilli are also found in bone marrow liver, and spleen.

Although the usual course of leprosy is indolent, occasional interruption by the two types of 'reactional states' is observed in patients who are either untreated or already receiving antileprosy drugs. The type 1 lepra reaction can complicate all the three borderline conditions (BT, BB, and BL) and chiefly consists of a change in the course of the disease towards either the lepromatous or tuberculoid pole. The type 2 reaction (or erythema nodosum leprosum) occurs in patients with lepromatous or borderline leprosy, most frequently in the second half of the first year of treatment. Tender subcutaneous nodules develop and the associated features are low-grade fever, lymphadenopathy, and arthritis. Arthritis in this situation is a classical example of an immune-complex deposition disease.

Immunology and histopathology

Although both cell-mediated and humoral immunities occur simultaneously in leprosy, it is the cell-mediated component that assumes significance (Harboe 1985). Individuals capable of developing cell-mediated immunity localize the disease in the form of tuberculoid in the form of tuberculoid leprosy, while those with depleted cell-mediated immunity express it in the lepromatous form.

The ratio of CD4/CD8 lymphocytes is normal in patients with tuberculoid leprosy and it may be decreased or normal in patients with lepromatous leprosy, depending on the bacterial load. At the site of actual inflammation, CD4 cells constitute about 95 per cent of the lymphocyte population in tuberculoid granulomas and CD8 cells

dominate to the extent of 85 per cent in lepromatous lesions (Narayanan 1988).

There is speculation that macrophage function is defective in patients with lepromatous leprosy (Birdi *et al*. 1989). T cells from patients with lepromatous leprosy fail to produce interleukin 2 after exposure to *M. leprae*. The nature of the humoral immune response in leprosy is not clearly defined (Sehgal *et al*. 1989). As in other chronic infections, the concentrations of serum gammaglobulins increase in leprosy.

The earliest histopathological events in human leprosy are not known. Perhaps the majority of infections are overcome at the site of entry (possibly the mucosa of the respiratory tract) and the bacilli destroyed. The Schwann cells of the nerves in the upper respiratory tract may be the first to harbour the bacilli and haematogenous spread occurs thereafter. The skin is probably involved via the endothelial cells of small vessels. Bacilli are seen in superficial nerve plexuses and perivascular macrophages in the skin in early lesions, with mild local lymphocytic infiltration. In many cases (indeterminate leprosy) these lesions resolve spontaneously with eradication of bacilli. If the bacilli do persist and multiply in skin and/or nerves, the inflammatory reactions are amplified and lesions of leprosy appear. These lesions can be placed along an immunohistopathological spectrum that ranges from organized epithelioid-cell granulomas containing giant cells with few or no bacilli, through intermediate stages with less organized epithelioid cells containing more bacilli, to lepromatous leprosy with mainly macrophages and abundant bacilli. In the reactional state (type 1), there is increased inflammation in the lesions with activation of epithelioid cells and marked oedema. In type 2 states the classical lesions show oedema, polymorphonuclear leucocyte infiltration, and often a necrotizing vasculitis.

The intraosseous lesions of leprosy are characterized by granulomatous tissue reactions that lead to trabecular destruction. The lesions are evident in the epiphysis and metaphyses of tubular bones, and direct involvement of the medullary canal can also occur.

Clinical manifestations

The first signs of leprosy are usually cutaneous. Single or multiple, hypopigmented macules or plaques may appear. Sometimes an anaesthetic patch is first noticed by the patient, but often sensation remains preserved in early lesions, particularly on the face. In tuberculoid leprosy, the fully developed skin lesions are densely anaesthetic and have lost sweat glands and hair follicles. Their distribution is not symmetrical. Nerve involvement occurs early and the superficial nerve leading from lesion is enlarged. The supraorbital, facial, greater auricular, ulnar, median, radial cutaneous, common peroneal, sural, anterior, or posterior tibial nerves may be grossly enlarged and easily palpated. There may be severe paraesthesias initially, followed by muscle atrophy. If the disease progresses and the hands and feet are affected, then contractures develop (Paterson and Rad 1961). Repeated trauma in the absence of protective sensation results in ulcers that get secondarily infected (Fig. 7). In a more advanced stage, osteolysis of the terminal phalanges occurs. In lepromatous leprosy the skin lesions are macules, nodules, papules, or plaques with predilection for the face, wrists, elbows, buttocks, and knees. Involvement of major nerve trunks in common and leads to glove-and-stocking paraesthesias in the extremities.

Fig. 7 Trophic ulcers in a patient with tuberculoid leprosy.

The incidence of direct involvement of the skeleton in leprosy is probably under-reported. Symmetrical, peripheral, inflammatory polyarthritis of insidious onset with a pattern of exacerbation and remission is observed in some patients (Atkin *et al*. 1989), which is different from the joint involvement of erythema nodosum leprosum or lepra type 1 reaction. Affected joints can include the wrist, knees, and hands and feet. Morning stiffness is variable from 30 min to 1 h. Symptomatic improvement is observed within a few weeks of starting multidrug treatment.

A different pattern of involvement is with changes that are usually confined to the small bones of the face, the hands, and feet (Atkin *et al*. 1987). At the fingers and toes it may appear as a dactylitis. The osseous involvement is probably due to extension of infection from overlying dermal or mucosal areas. The periosteum is contaminated initially (leprous periostitis) and subsequently the cortex and marrow are infected (leprous osteitis and osteomyelitis). In an occasional patient, haematogenous spread of infection can occur, leading to other intramedullary foci in the tubular long bones and the ribs. Overall, the progression of the lesions is very slow.

Neuroarthropathy is a progressive, degenerative joint change due to lesions of peripheral nerves and is observed more frequently in patients admitted to hospital. The skeletal changes may follow the involvement of nerves by two or three decades. The bones of the hands and feet are most susceptible. In the feet the changes usually start in the medial arch and later involve the lateral arch, talus, and calcaneus (Horibe *et al*. 1988). In extreme cases, dissolution of the mid-foot results in separation of the forefoot and the hind foot, and the tibia is driven downwards to become weight-bearing. Infection and bone injury, which can occur separately as sequelae to neuropathy and trophic ulcers, tend to accelerate the skeletal changes, leading to disintegration of the affected bones and joints.

The acute and chronic arthritis associated with the reactional state of erythema nodosum leprosum is common (Karat *et al*. 1966). The development of synovitis and/or dactylitis coincides closely with the appearance of fulminant skin lesions (Fig. 8), and the patient is febrile and toxic.

Fig. 8 Erythema nodosum lesions in the lepra reaction.

Investigations and diagnosis

The principal criteria for the diagnosis of leprosy are:

1. a hypopigmented patch of skin with sensory impairment;
2. thickening of the peripheral nerves;

3. the presence of *M. leprae* in slit-skin smears—graded on the Ridley Jopling bacteriological index (**BI**) as 1+ to 6+;
4. the characteristic histopathological changes in a biopsy specimen of a skin lesion or a peripheral nerve;
5. positive serological tests.

Patients with lepromatous leprosy frequently have mild anaemia, an elevated erythrocyte sedimentation rate, and hypergammaglobulinaemia; 10 to 20 per cent of patients show a false-positive reaction in serological tests for syphilis, and also antinuclear antibodies.

Myocobacterium leprae is an acid-fast bacillus morphologically and biochemically similar to *M. tuberculosis*. It does not grow in artificial media or tissue cultures but is propagated consistently in the footpads of mice and nine-banded armadillos for the purpose of epidemiological studies and drug evaluation. The bacillus is slow to multiply and the doubling time is around 12 days in optimal conditions in murine footpads. The technique is expensive and time-consuming, and it takes at least 10 months for the organism to grow.

An enzyme-linked immunosorbent assay to detect antibodies to the *M. leprae* specific surface antigen has been developed (Burgess *et al*. 1988). The antigen used in the assay is a phenolic glycolipid 1 and the antibodies detected are predominantly IgM. Titres increase from the tuberculoid to the lepromatous pole of the leprosy spectrum. The early estimates of the sensitivity of this test were 95 per cent for the lepromatous pole and 30 per cent for the tuberculoid pole. This test is not yet available for use in clinical practice. In research laboratories, the polymerase chain-reaction assay is used to detect *M. leprae* DNA in skin biopsy samples (Jamil *et al*. 1993). Owing to its ability to detect small numbers of organisms, the polymerase chain reaction may prove to be a useful tool in paucibacillary disease.

The radiographic features of leprous osteitis are enlarged nutrient foramina, osteoporosis, endosteal thinning, and cyst-like lesions that are best appreciated in the phalanges. Bone sclerosis, which signifies the healing process, may also be seen. In the face, nasal destruction is characteristic. Destruction of the alveolar process and the anterior nasal spine of the maxilla appear to be related to primary involvement of the bone as well as to secondary infection. In patients with neuroarthropathy the typical changes begin with erosion of the terminal tufts of the phalanges and in the more advanced cases the entire length of terminal group of phalanges may be resorbed (MacMoran *et al*. 1987). A rare but specific radiographic finding is calcification of a large peripheral nerve such as the radial or ulnar.

Treatment

Multidrug therapy is the mainstay of treatment for leprosy (Ellard 1988; Hasting *et al*. 1988; Ye 1988). Rifampicin is by far the most potent bactericidal antileprosy drug. Dapsone is well tolerated, and until two decades ago it was the only drug used (monotherapy) in treatment of all forms of leprosy. Clofazimine is the third drug; it has the additional property of contributing to the control of erythema nodosum leprosum through its anti-inflammatory action. The main drawback of clofazimine is that it causes a deep-brown pigmentation of skin, more evident in light-skinned persons, which is slow to regress after cessation of treatment.

The current multidrug therapy recommended by the World Health Organization for leprosy in adults is, for multibacillary disease (BI>2+), rifampicin, 600 mg orally once monthly, dapsone 100 mg orally daily, and clofazimine, 300 mg orally once monthly and additionally 50 mg daily. The duration of treatment is at least 2 years and until negative skin tests are obtained, which occasionally extends to beyond 5 years. For paucibacillary disease (BI, 2+) the regimen is rifampicin, 600 mg orally once monthly, and dapsone, 100 mg orally daily. The duration of treatment is 6 months. All drugs are prescribed in full doses from the beginning of treatment and continued without interruption, even during the reactional states.

Evidence of clinical improvement should appear after 8 to 12 weeks from the beginning of treatment. The clinical response to adequate therapy may be confused by reactional states. Mild lepra reactions are controlled by non-steroidal anti-inflammatory drugs such as aspirin or indomethacin. In severe cares, prednisolone (60-100 mg/daily) may be required. For the reactional state of erythema nodosum leprosum, clofazimine 100 mg orally three times a day for 2 or 3 weeks followed by tapering off to a lower dose may be helpful. An alternative, effective drug is thalidomide, especially for those patients who later take a chronic course with erythema nodosum leprosum. The usual dose of thalidomide is 200 mg orally twice daily, which is then gradually tapered off to a maintenance dose of 50 to 100 mg daily. Thalidomide is absolutely contraindicated in pregnancy.

Non-steroidal anti-inflammatory drugs usually fail to alleviate the symptoms of the polyarthritis, and they regress within a few weeks after starting antibiotic treatment. Those who present with neuroarthropathy are far more difficult to treat, particularly when the feet are involved (Warren 1973). Absolute rest for the affected limbs and control of superimposed infection are mainstays of treatment. Immobilization in plaster until all ulcerative lesions of the skin have healed may be necessary. Regular exercises are required to maintain the flexibility of the other joints until the ulcers heal. Thereafter, graded weight bearing is permitted. Amputation may be indicated if advanced disintegration of bones and joints has occurred, as the patient would be better off with a prosthesis. Advanced deformities of the hands, associated with tendon rupture, can be functionally improved by appropriate tendon-transfer surgery.

Much effort in research is being directed to control of leprosy. Trials with bacille Calmette–Guérin have so far yielded conflicting results, with some revealing only modest efficacy. Two new vaccines (Antia *et al*. 1988), one named the ICRC and the other containing viable bacille Calmette–Guérin with heat-killed *M. leprae*, are currently in field trials.

Summary of management

The diagnosis is usually evident from the clinical examination of the skin, and tender nerves are palpable at the elbows, wrists, and near the head of the fibula. Polyarthritis and enthesitis are sometimes observed in all stages of the disease. Multidrug treatment is the mainstay of therapy, and the duration largely depends on the extent of dermal involvement. Ideally the bacillary count on the slit-skin smear enables one to judge if the patient has pauci- or multibacillary disease. Dapsone and rifampicin are given for 6 or 12 months to patients with paucibacillary disease. Those with multibacillary disease are given dapsone, rifampicin, and clofazimine for 2 years, and if the slit-skin smears remain positive the treatment may be extended to 5 years. The symptoms of arthritis and enthesitis regress within 3 or 4 months of the start of treatment. In late stages, some patients develop a neuropathic foot and subluxation of joints that require surgical rehabilitation. Reactive states are occasionally observed in the first year of treatment and the patient is then given aspirin or low-dose prednisolone for 6 to 8 weeks to alleviate the symptoms, while the multidrug therapy is continued.

5.3.8 Brucellar arthritis

E. Pascual

Introduction

Infection of the joints is the most frequent, localized complication of brucellosis, and a common cause of infectious arthritis in the countries where the disease is endemic.

Epidemiology

Brucellosis occurs naturally in domesticated animals. It constitutes an important economic problem and a serious heath hazard in many countries, especially in the Mediterranean region, Arabian peninsula, Indian subcontinent, Mexico, and parts of Central and South America. Of the six recognized species of brucella, only four are known to be human pathogens (Young 1995); *Brucella melitensis*, the most virulent, causes disease in goats, sheep, and camels, *B. abortus* in cattle, *B. suis* in pigs, and *B. canis* in dogs. Multiple viobars have been identified in *B. melitensis*. Localization of brucellae in the male and female reproductive organs accounts for the major clinical manifestation, that is abortion. Human infection is contracted from infected animals and is closely linked to poor methods of animal husbandry, feeding habits, and hygiene standards. The disease is common in some professions due to handling of infected animals or viscera, where the organism is acquired either through breaches in the skin or by infectious aerosol reaching the conjunctiva or the airways. Ingestion of unpasteurized dairy products is the most common cause of infection due to *B. melitensis*. Because of their high infectiveness, brucellae are a common cause of accidental infection in laboratory workers (Miller *et al*. 1987; Young 1995).

Infection acquired during foreign travel, often through consumption of infected, illegally marketed dairy products, is the cause of imported disease (Arnow *et al*. 1984; Revak *et al*. 1989). The possibility of illegal import of such products should be borne in mind (Thapar and Young 1986).

General characteristics of the organism

Brucellae are small, aerobic, non-motile, gram-negative coccobacilli which grow well at 37°C in any high quality peptone-based medium enriched with blood or serum. Their growth requires a much longer incubation period than pyogenic organisms and many strains of *B. abortus* and *B. suis* require supplementary CO_2, as described below (Young 1995).

The host defence

Experiments in rats have shown that after entering the blood stream, brucellae are phagocytosed by polymorphonuclear leucocytes. Within hours, phagocytosed organisms can be seen in the mononuclear phagocytic cells of the liver sinusoids, lymph nodes, spleen, and bone marrow—and probably in other organs rich in mononuclear phagocytic cells— where they reproduce (Spink 1964; Smith and Ficht 1990). The frequent isolation of brucellae from bone marrow cultures in diseased humans (Gotuzzo *et al*. 1986) as well as from liver biopsies (Spink 1964) indicates a similar distribution in humans. The permanence and reproduction of the organisms inside the cells may be important in understanding some of the characteristics of the disease.

The tissue response in established disease is a non-specific granulomatous lesion, very similar to sarcoidosis (Hunt and Bothwell 1967). Brucellae cannot be identified in these tissues but can be cultured from them (Spink 1964). Localized areas of suppuration or caseation may occur, most frequently in *B. suis* (Spink 1964) but also in *B. melitensis*.

General characteristics of the disease

The manifestations of brucellosis are non-specific and no combination of signs or symptoms can be considered to be characteristic. *B. melitensis* causes more severe disease than *B. abortus* and *B. suis*, probably because of its greater ability to avoid the host's defences (Smith and Ficht 1990). *B. suis* has a higher tendency to suppurative complications. The large, published series have focused on patients infected by *B. melitensis*, and generalization of this data to disease caused by the other brucellae may be inaccurate. Reference to the other infections will be indicated in the text, as appropriate.

Brucellosis is more common in men than in women both in the Middle East and Mediterranean countries (Colmenero *et al*. 1985; Andonopoulos *et al*. 1986; Mousa *et al*. 1987; Lulu *et al*. 1988; Ariza 1988; Batlle *et al*. 1989). In the same areas, the disease occurs with equal frequency in children of both sexes (Feiz *et al*. 1978; Lubani *et al*. 1986; Gómez -Reino *et al*. 1986; Al-Eissa *et al*. 1990), as happens with adults in Peru (Gotuzzo *et al*. 1987). It may be that where brucellosis is contracted as a professional hazard, more males are affected. Ingestion of milk, which is the usual cause of the disease in children and Peruvian adults (Gotuzzo *et al*. 1987), would result in equal incidence in both sexes.

The incubation period may be as short as 1 week but usually lasts from 2 to 8 weeks (Young 1995). The disease usually presents with fever, often without an undulant pattern, sweats, which may be drenching, and a general feeling of malaise. Weakness, anorexia, myalgia, and arthralgia are common. Patients often recall contact with possibly infected animals or their unpasteurized products but this evidence may be absent. Physical examination may show lymphadenopathies and enlargement of liver or spleen. Localized infections, especially in the skeleton, are common. Other possible causes, such as neurobrucellosis, endocarditis, hepatitis, and epididimo-orchitis, should be considered.

Subclinical disease occurs and may heal spontaneously. Patients may present with relapses following previous subclinical disease or with late, localized complications, simulating a very long incubation period.

The concept of chronic brucellosis was coined before the antibiotic era, to refer to a group of patients who complained of ill health after having suffered from brucellosis, generally due to *B. abortus*. A careful study (Spink 1951) showed that some of these patients had a bacteriologically proven relapse, or localized disease; in others, no explanation was found for the symptoms and it was felt that they were related to an unstable emotional state. It is unclear whether chronic brucellosis in the absence of infection exists and such diagnosis must be handled with care.

Brucellar arthritis

Arthralgia is more common in brucellosis than in other febrile illnesses. It has been recorded in 88 per cent (Thapar and Young 1986), 65 per cent (Colmenero *et al*. 1986), 65 per cent (Ariza 1988), and 58 per cent (Lulu *et al*. 1988) of adult patients studied prospectively, and in 87 per cent (Feiz *et al*. 1978) and 74 per cent (Al-Eissa *et al*. 1990) of the children thus studied; its presence may be a clue to the disease. Bone scans of patients with brucellosis and musculoskeletal symptoms

are very frequently abnormal, often in multiple sites (El Desouki 1991). Perhaps some of the minor musculoskeletal symptoms of these patients are due to localized infection. Since the treatment of brucellar arthritis and that of uncomplicated brucellosis is the same, once the diagnosis of brucellosis has been reached, it is not worthwhile conducting a search for arthritis to explain minor or unclear musculoskeletal symptoms.

Infection in the joints is the most common form of localized disease in brucellosis. It appears in 25 per cent (Colmenero *et al*. 1991), 29 per cent (Ariza 1988), 26 per cent (Lulu *et al*. 1988), 24 per cent (Gotuzzo *et al*. 1987), and 22 per cent (Andonopoulos *et al*. 1986) of adult patients studied prospectively, and in 38 per cent (Al-Eissa *et al*. 1990), 28 per cent (Llorens-Terol and Busquets 1980), and 19 per cent (Feiz *et al*. 1978) of children. In areas where brucellosis is endemic, brucellar arthritis may outnumber tuberculous arthritis (Rajapakse 1987). All the above series refer to *B. melitensis*.

The general clinical characteristics of brucellar arthritis are similar to those of infectious arthritis due to other organisms. The disease is generally monoarticular, but in 18 per cent of our patients more than one joint was affected (Batlle *et al*. 1989). The large peripheral joints, sacroiliacs, and the spine are the usual sites of articular involvement. Bursitis and osteomyelitis may occur. Some patients have simultaneous infection in more than one joint. The possibility of reactive arthritis has been considered.

Clinical and radiological characteristics

Arthritis of peripheral joints

Large peripheral joints are a common site of localized infection, ranging from 20 to 73 per cent of all arthritides in different adult series (Serre *et al*. 1981; Andonopoulos *et al*. 1986; Gotuzzo *et al*. 1987; Ariza 1988; Al-Rawi *et al*. 1989; Batlle *et al*. 1989) (Table 1). It is of interest that children nearly always show peripheral joint involvement, either with *B. melitensis* (Lubani *et al*. 1986; Gómez-Reino *et al*. 1986; Gotuzzo and Carrillo 1988; Benjamin *et al*. 1992) or *B. abortus* infections (Adam *et al*. 1967). *B. canis* knee arthritis in a child has been reported (Young 1983). In all age groups, the hip followed by the knee are the most common locations. Ankles, shoulders, elbows, wrists, and sternoclavicular joints (Berrocal *et al*. 1993) contribute a small percentage of cases. The smaller hand and feet joints seem to be rarely affected. A 'rheumatoid like' distribution may occur (Gotuzzo *et al*. 1982).

	Peripheral joints*	Sacroiliacs	Spine
Adults	Frequent	Frequent	Frequent
Children	Frequent	Infrequent (older children)	Exceptional

*In order of frequency: hip, knee, ankle, shoulder, elbow, wrist, and sternoclavicular joint.

Table 1 Distribution of joint involvement

Peripheral joint arthritis often, but not always, predominates over other disease manifestations, and the patient's main complaint is centred on the joint. Usually it occurs during the acute phase of the disease or during a relapse (Gotuzzo *et al*. 1982); fever, or other general symptoms of the disease, frequently accompany the arthritis, which tends to be symptomatic from the start and so patients tend to seek prompt medical attention. The joints are swollen and painful and an effusion is generally seen. Joint inflammation is not as intense as it is in some septic arthritides due to pyogenic organisms, and there is seldom obvious redness or unusual warmth in the skin. Local complications, such as popliteal cyst rupture, may occur (Laajam 1985).

If there is delay in the diagnosis or treatment, the structure of the joint is damaged resulting in radiological abnormalities, such as joint space narrowing (Fig. 1) and damage to the joint surfaces, similar to those of other infectious arthritides. The interval between the initiation of the infection and the appearance of structural damage in the joint tends to be longer than in pyogenic arthritides, but probably shorter than in tuberculosis. The sequelae left after appropriate treatment depends on the damage present when treatment was started. If this is started early enough, no sequelae will remain. In children with arthritis of the hip, dislocation and aseptic necrosis have been observed (Benjamin and Khan 1994). Brucellae may infect prosthetic joints (Agarwal *et al*. 1991). Bursitis and tenosynovitis due to *B. melitensis* (Mousa *et al*. 1987), *B. abortus*, and *B. suis* also may occur (Kelly *et al*. 1960).

Fig. 1 Radiograph of the hips showing diminished radiological joint space in a patient with brucellar arthritis of his right hip.

Sacroiliitis

Involvement of the sacroiliac joint comprises a large percentage of brucellar arthritides. Higher frequencies have been reported in the west Mediterranean countries—43 per cent in men and 20 per cent in women (Rotés-Querol 1957); 34 per cent (Serre *et al*. 1981); 51 per cent (Ariza 1988); and 36 per cent (Batlle *et al*. 1989)—as compared to countries further east—11 per cent in Greece (Andonopoulos *et al*. 1986) and 13 per cent and 5 per cent in the Middle East (Mousa *et al*. 1987; Al-Rawi *et al*. 1989). An incidence of 50 per cent was found in Peru (Gotuzzo *et al*. 1982). The reasons for these differences are unclear. Sacroiliitis seems to be an unusual complication of *B. abortus* and *B. suis* (Kelly *et al*. 1960). Sacroiliitis is uncommon in children (Lubani *et al*. 1986; Gómez-Reino *et al*. 1986) but young adults have a clearly increased risk for arthritis in this particular joint (Rotés-Querol 1957; Gotuzzo *et al*. 1982).

Sacroiliitis tends to occur in the acute, febrile phase of the disease, is usually unilateral, and clearly symptomatic from its start. The pain in some of the patients becomes so intense in 2 or 3 days that they can hardly move from the bed (Mousa *et al*. 1987). Radiation of the pain to the buttock, posterior thigh, and even below, is not unusual. In these patients, any movement of the leg is very painful and tests for hip manoeuvres or straight leg elevation may seem positive. In this setting, clinical differentiation of sacroiliitis from hip disease or sciatica may be difficult (Mousa *et al*. 1987; Gotuzzo and Carrillo 1988); gently tapping on the lower surface of the heel while the patient keeps the leg extended, clearly localizes the pain to the sacroiliac area. Other sacroiliac manoeuvres may produce too much pain, and may be difficult to interpret in this group. Standard manoeuvres provide appropriate information in patients with less intense symptoms.

Due to the acute nature of the sacroiliitis, the presenting radiographs do not aid the diagnosis; some blurring of the articular margins and widening of the sacroiliac space (Fig. 2) may occur when the disease is of longer duration (Ariza *et al*. 1993). Computed tomography (**CT**) scan generally allows earlier demonstration of joint infection. A bone scan provides early evidence of sacroiliitis on most occasions (Mousa *et al*. 1987; Bahar *et al*. 1988; Madkour *et al*. 1988; Cordero Sánchez *et al*.

1990). Brucellar sacroiliitis is a mild disease associated with a good outcome similar to that observed for patients with uncomplicated brucellosis (Ariza *et al*. 1993).

Fig. 2 Radiograph of the sacroiliac joints, showing widening and erosions of the right joint in a patient with long-standing right brucellar sacroiliitis.

Spondylitis

Infection in the spine is the cause of between 7 and 53 per cent of localized skeletal infection (Rotés-Querol 1957; Serre *et al*. 1981; Gotuzzo *et al*. 1982; Gotuzzo and Carrillo 1988; Ariza 1988; Al-Rawi *et al*. 1989; Batlle *et al*. 1989). Referral patterns to hospitals may account for some of the discrepancies. It is generally seen in older patients (Rotés-Querol 1957; Serre *et al*. 1981; Gotuzzo *et al*. 1982; Lifeso *et al*. 1985; Ariza *et al*. 1985a; Gotuzzo and Carrillo 1988 ; Colmenero *et al*. 1991) but not in children, neither with *B. melitensis* (Lubani *et al*. 1986; Gómez-Reino *et al*. 1986; Gotuzzo and Carrillo 1988) nor with *B. abortus* (Adam *et al*. 1967). The majority of patients from the United Kingdom or United States described as suffering from skeletal brucellosis are isolated cases or small series and are due to *B. abortus*, or *B. suis* (Kelly *et al*. 1960; Torres-Rojas *et al*. 1979; Manaster 1988); their clinical characteristics are similar to those caused by *B. melitensis*.

The lumbar spine is the most commonly affected segment, followed by the dorsal spine. The cervical spine accounts for a small percentage of the cases. Involvement of more than one disc space is not infrequent (Rotés-Querol 1957; Kelly *et al*. 1960; Serre *et al*. 1981; Ariza *et al*. 1985a; Lifeso *et al*. 1985; Gotuzzo and Carrillo 1988; Sharif *et al*. 1989). In contrast to peripheral arthritis or sacroiliitis, spondylitis is generally a late feature, often occurring in patients with only vague symptoms of a general infectious disorder, and not infrequently afebrile (Serre *et al*. 1981; Lifeso *et al*. 1985; Gotuzzo and Carrillo 1988), although careful register of the temperature may show a low grade fever and patients may complain of some malaise. In other series, 17 out of 20 patients had systemic symptoms, but these patients presented with the spine infection shortly after the start of the disease (Ariza *et al*. 1985a).

Onset of the disease is often insidious, and its hallmark is local pain of variable intensity, often moderate, frequently allowing the patient to maintain a fairly normal life. Pressure or percussion of the spinous processes of the vertebrae corresponding to the affected level often reproduces the pain, and some tenderness may also occur in the paravertebral muscles. Deformities are uncommon (Rotés-Querol 1957). Paravertebral abscesses appear in about 16 per cent of the patients (Ariza *et al*. 1985a) but are generally smaller than those of tuberculosis. In the cervical spine, abscesses may produce retropharyngeal swelling (Lifeso *et al*. 1985). Material obtained from the abscesses is usually sterile (Rotés-Querol 1957; Ariza *et al*. 1985a). Similar abscesses may occur with *B. abortus* (Torres-Rojas *et al*. 1979). Some patients may develop epidural abscesses from the infected disc space and develop a paraplegia. Compression of the medulla or nerve roots is found more frequently in cervical spondylitis, which should be considered a severe manifestation of the disease (Colmenero *et al*. 1992). In this case myelography shows extradural compression and these patients may need surgical decompression (Lifeso *et al*. 1985); despite surgery, severe sequelae may occur (Colmenero *et al*. 1991).

In the very early phases, radiographs of the affected segments are normal. After 2 months, nearly all patients show some radiographic alterations (Ariza *et al*. 1985a; Lifeso *et al*. 1985). The first sign seen is narrowing of the disc (Fig. 3), without bone abnormalities. Later, two different alterations are seen in the limiting vertebral end-plates: a limited form with an erosion, generally in the anterosuperior vertebral angle, with sclerotic base, which is considered as characteristic of brucellar spondylitis (Pedro Pons' sign) (Fig. 4); and a diffuse form, in which the corresponding vertebral end-plates show erosions, accompanied by disc-space narrowing (Fig. 5). Early signs of repair, with the appearance of osteophytes, occur (Rotés-Querol 1957; Serre *et al*. 1981; Gotuzzo *et al*. 1982; Ariza *et al*. 1985a; Lifeso *et al*. 1985; Gotuzzo and Carrillo 1988 ; Sharif *et al*. 1989). Both pathological (Rotés-Querol 1957) and radiological (Sharif *et al*. 1989) data suggest that the infection begins in the vertebra and then spreads to the disc. CT scans may show either localized epiphyseal changes (Sharif *et al*. 1989) or diffuse irregularities and erosions in the vertebral end-plates (Fig. 6). Paravertebral abscess formation (Lifeso *et al*. 1985; Manaster *et al*. 1988, Sharif *et al*. 1989) and epidural extension (Manaster *et al*. 1988) are also demonstrated. Experience with magnetic resonance imaging is limited, and has shown lesions of both localized epiphyseal changes and of diffuse disc-space infections; epidural extension was seen in all four patients studied in the absence of neurological damage (Sharif *et al*. 1990).

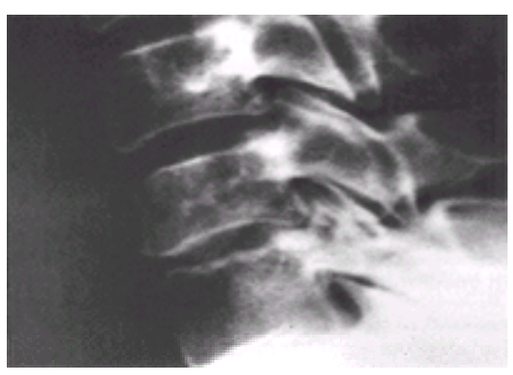

Fig. 3 Lateral radiograph of the lower cervical spine, showing diminished height of the disc space, in a patient with brucellar spondylitis

Fig. 4 Lateral radiograph of lumbar vertebrae, showing an upper corner lesion, with sclerotic base (Pedro Pons' sign), considered characteristic of brucellar spondylitis. Diminution in the height of the disc space is also seen.

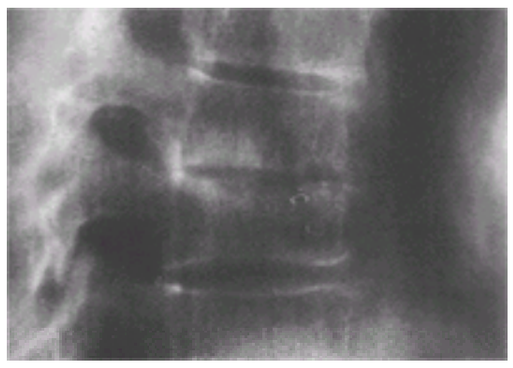

Fig. 5 Lateral tomography of the dorsal spine, showing diminished disc space height and vertebral end-plates erosions in a patient with brucellar spondylitis.

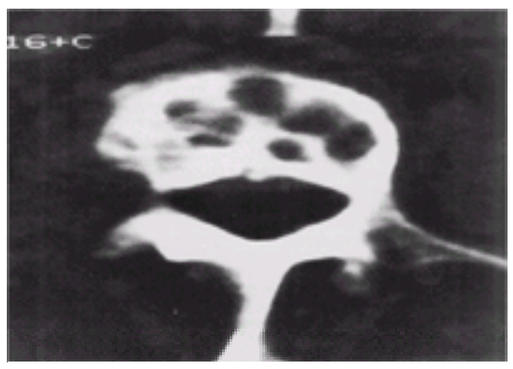

Fig. 6 CT scan through the vertebral end plate of a patient with brucellar spondylitis, showing erosive lesions.

Bone scans frequently show increased uptake at the level of the affected disc space, even when radiologically normal (Bahar *et al*. 1988; Madkour *et al*. 1988; Sharif *et al*. 1989) (Fig. 7). On the other hand, in a prospective study of brucellar spondylitis, bone scans were normal in some patients during the first 3 months of the disease, and later, at times, only slightly abnormal (Ariza *et al*. 1985a).

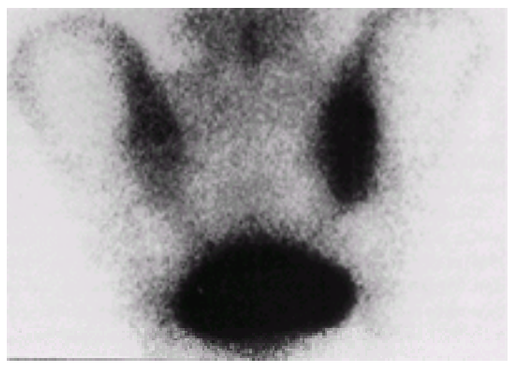

Fig. 7 Bone scan of the posterior pelvis of a patient with left brucellar sacroiliitis of short duration and normal radiograph.

Osteomyelitis

Osteomyelitis is an unusual feature of brucellosis, which may present as local pain and tenderness. *B. melitensis* has a predilection for the ribs and epiphyses of long bones, but may occur in other locations (Rotés-Querol 1957; Serre *et al*. 1981; Mousa *et al*. 1987). *B. suis* seems to prefer the long bones (Kelly *et al*. 1960; Keenan and Guttmann 1982; Bonfiglio *et al*. 1983).

Reactive arthritis

A report (Hodinka *et al*. 1978) of higher frequency of HLA-B27 in patients with brucellar spondylitis raised the possibility of brucellar reactive arthritis. Three HLA-B27-positive patients described as having reactive arthritis after brucellosis were subsequently reported (Dawes and Ghosh 1985). Other studies have failed to find such an association (Alarcón *et al*. 1981; Alarcón *et al*. 1985; Al-Rawi *et al*. 1987). My own experience with 86 prospectively followed patients with brucellar arthritis, is that none of them had any type of chronic arthritis remaining after antimicrobial treatment. As a rule, the symptoms improve clearly after appropriate treatment, both in peripheral and axial arthritides. It is of interest that brucella can be grown from erythema nodosum-like lesions (thought to be a hypersensitivity reaction) occurring in patients with brucellosis (Ariza *et al*. 1989).

The possibility of reactive brucellar arthritis is an open question; such diagnosis should be handled with care and only entertained in those patients in whom unexplained arthritis persists after successful antimicrobial treatment of proven brucellosis.

Other musculoskeletal manifestations

Acute brucellosis may present as a leucocytoclastic vasculitis (Vazquez Doval *et al*. 1991). Patients with brucellosis may also show lesions resembling panniculitis from which brucella can be grown (Ariza *et al*. 1989; Zuckerman *et al*. 1994). Soft tissue abscesses have been reported (Tovar *et al*. 1990)

General laboratory features

With the exception of serological and bacteriological data, the laboratory features of brucellosis are non-specific. The erythrocyte sedimentation rate generally shows some elevation—it was below 44 mm in 70 per cent of the patients with brucellar arthritis (Mousa *et al*. 1987), and normal in 16 per cent in another series (Rotés-Querol 1957). Frequent slight elevations or normal values have been found by others, both in adults (Colmenero *et al*. 1986; Al-Rawi *et al*. 1987; Lulu *et al*. 1988) and children (Gómez-Reino *et al*. 1986; Al-Eissa *et al*. 1990). A similar pattern is seen with *B. abortus* and *B. suis* (Kelly *et al*. 1960). Normal values are not unusual in late, localized forms, as in spondylitis (Serre *et al*. 1981). A normal or low leucocyte count, associated with lymphocytosis is usual (Crosby *et al*. 1984; Colmenero *et al*. 1986; Thapar and Young 1986; Mousa *et al*. 1987). Lymphopenia may be associated with more severe clinical manifestations (Crosby *et al*. 1984). Leucocytosis is unusual but may occur. Thrombocytopenia, anaemia, and pancytopenia may all occur (Crosby *et al*. 1984; Lulu *et al*. 1988).

Abnormality of liver function tests is a common feature of the disease (Colmenero *et al*. 1985; Thapar and Young 1986; Lulu *et al*. 1988), and occurs more frequently in the early phases.

Synovial fluid analysis

Published data of synovial fluid analysis in brucellar arthritis are scarce. Cell counts have been found to be below 50 000/mm ^{3}, (Gotuzzo and Carrillo 1988) or even lower—4460 to 8800/mm^3 (Andonopoulos *et al*. 1986); 6000 to 18 000/mm^3 (Mousa *et al*. 1987); and 8600 to 11 600/mm^3 (Mavridis *et al*. 1987). Glucose levels were within normal limits in the above series. Lactic acid levels have also been found to be normal (Mavridis *et al*. 1984). *B. melitensis* has been isolated from some of the synovial fluids in these studies. Our own unpublished data of the analysis of synovial fluids from 18 prospectively studied brucellar arthritides differ from the above results. The cell counts were 3200 to 90 000/mm^3; glucose was low in some of the fluids (0–100 mg/dl, mean 47 ± 33 SD), and lactic acid was also high in some samples (13–138 mg/dl, mean 74 ± 36 SD). *B. melitensis* was recovered from 73 per cent of these fluids, many of them with characteristics suggestive of non-infectious, inflammatory synovial fluid.

Diagnostic investigations

Importance of the clinical features

The clinical features of brucellosis are not specific. The manifestations of brucellar joint disease are similar to those of other infectious peripheral or axial arthritides, and may also resemble some inflammatory arthritides. Nevertheless, in the following circumstances, appropriate testing for brucellosis should always be done:

1. in all undiagnosed arthritides, with features fitting those of brucellosis, occurring in areas where the disease is endemic or in patients with a history of possible exposure to the disease;
2. in all cases of undiagnosed acute unilateral sacroiliitis;
3. in all cases of undiagnosed disc-space infection, especially those with radiological evidence of localized vertebral angle infection or infection of multiple levels.

About one-quarter of the patients do not recall exposure to possibly infected animals or unpasteurized diary products.

Bacteriological diagnosis

Isolation of brucellae from blood, synovial fluid, or other sources should always be attempted when the disease is suspected. It provides a definitive diagnosis and the possibility of differentiating *B. melitensis, B. abortus*, and *B. suis*, which cannot be done with the usual serological tests. When brucellosis is suspected, the laboratory should always be warned, since:

1. Brucellae are slow growing organisms and most cultures will be negative if not kept long enough—ideally up to 6 weeks (Rodríguez Torres 1988). In a series of 262 positive blood cultures, the growth was apparent in 8 per cent of the samples during the first week, 36 per cent during the second, 31 per cent during the third, 17 per cent during the fourth, 6 per cent during the fifth, and 2 per cent during the sixth week; the culture was not pursued further (Ariza 1988). More delayed growth was found in a smaller series, with a mean of 37 days (range 20 to 51 days) (Thapar and Young 1986).
2. Brucellae are a common cause of acquired infection in the laboratory and personnel should take special precautions (Miller *et al*. 1987).

Any high quality, peptone-based medium enriched with blood or serum is suitable for growing brucellae (Young 1995); a 10 per cent CO_2 atmosphere increases the yield and is necessary for most strains of *B. abortus*; culture systems with a solid phase are easier and less risky to handle in the laboratory (Rodríguez Torres 1988). Of practical importance, brucellae were isolated from seven blood cultures in a mean time of 2.1 days when processed by the lysis–centrifugation system; simultaneous standard blood cultures of the same samples were positive in only six cases, and the mean detection time was 20.6 days (Navas *et al*. 1993).

Blood cultures are often positive in disease due to *B. melitensis*. Table 2 shows the isolation rate of the organism from blood cultures obtained in different series of unselected patients and in patients with arthritis. Patients with relapsing disease have the same rate of positive blood cultures as new patients (Ariza 1988).

Unselected adults	
73 (Thapar and Young 1986)	
62 (Colmenero *et al*. 1986)	
78 (Ariza 1988)	
30 (Lulu *et al*. 1988)	
72 (Colmenero *et al*. 1991)	
Unselected children	
32 (Feiz *et al*. 1978)	
75 (Al-Eissa *et al*. 1990)	
Brucellar arthritis (adults)	
58 (Rotés-Querol 1957)	
41 (Batlle *et al*. 1969)	
41 (Al-Rawi *et al*. 1989)	
Brucellar arthritis (children)	
33 (Gómez-Reino *et al*. 1986)	
70 (Lubani *et al*. 1988)	

Table 2 Percentage of isolation of *Brucella melitensis* in blood cultures

Although blood cultures should be obtained when patients are febrile, in 30 per cent (Ariza 1988) and 31 per cent (Rodríguez Torres 1988) of afebrile patients the organism grew. Isolation of *B. melitensis* from blood cultures is less frequent in late, localized disease, and in spondylitis (Serre *et al*. 1981; Gotuzzo and Carrillo 1988; Colmenero *et al*. 1991). In these cases, bone marrow culture may be advantageous (Gotuzzo *et al*. 1986). Differences in disease characteristics, or laboratory procedures, probably account for the wide differences found between series; a 7 per cent positive rate was found in a large series in which blood cultures were frequently kept less than 10 days (Mousa *et al*. 1987). The isolation rate of *B. abortus* and *B. suis* is lower than that of *B. melitensis*.

Synovial fluid should always be cultured. *B. melitensis* grew in 73 per cent of the synovial fluids inoculated in blood culture flasks (Carro *et al*. 1988). Other series have obtained a 62 per cent (Gotuzzo and Carrillo 1988), 60 per cent (Andonopoulos *et al*. 1986), and 27 per cent (Gotuzzo *et al*. 1982) growth in the cultured samples. *B. abortus* has been cultured from synovial fluid (Al-Rawi *et al*. 1989) as well as *B. canis* (Young 1983). Material obtained by needle puncture from infected disc spaces (Seignon *et al*. 1980) or surgically from the sacroiliac joint (Porat and Shapiro 1984) may also grow brucellae. *B. abortus* or *B. suis* may grow in samples obtained from bone, bursa, tendons, and joints (Kelly *et al*. 1960).

Serological diagnosis

The attempts to isolate brucellae from blood or other sources are not always successful; moreover, a long incubation period is required. Under these circumstances, the possibility of serological diagnosis offers great advantages. Serological tests allow the detection of antibodies produced against the lipopolysaccharide of the bacterial cell wall (Diaz *et al*. 1968), which is common to *B. melitensis, B. abortus* and *B. suis*, but not *B. canis* which needs a specific antigenic suspension (Polt *et al*. 1982; Devi *et al*. 1987).

The standard tube agglutination test (**STA**) is the most widely used test. The test antigen is generally obtained from *B. abortus*; it reacts against *B. abortus, B. melitensis*, and *B. suis* and does not allow differentiation between them (Rodríguez Torres 1988; Young 1995). A positive STA is indicative of contact with brucellae. Although high titres are indicative of current infection, the presence of any positive titre, if the clinical features are compatible, must be investigated further. As in other serological investigations, the individual response, antigen preparations, and laboratory procedures influence the final titre (Rodríguez Torres 1988).

Blocking antibodies may result in a negative STA test at low dilutions, while a positive test is obtained with further serum dilution. This phenomenon occurs mainly in late, localized brucellosis (Rodríguez Torres 1988). The brucellar Coombs' test detects these blocking antibodies and allows the diagnosis to be made (Hall and Manion 1953). The brucellar Coombs' test always gives higher titres than the STA test (Rodríguez Torres 1988). A combination of the STA test and the brucellar Coombs' test allows detection of the large majority of infections, and appears adequate for routine clinical practice (Ariza 1988; Rodríguez Torres 1988). If simple

agglutination methods (Moyer *et al*. 1987) or the rose bengal slide agglutination test (Altwegg and Bohl 1985; Rodríguez Torres 1988) are used for screening, standard tests must be performed in the positive sera for definite serological diagnosis.

The pattern of the antigenic response may be measured with an enzyme-linked immunosorbent assay. IgM antibodies appear first and may disappear within a mean time of 9 months. IgG peaks at about 2 months but significant titres persist after 18 months or more (Ariza 1988; Gazapo *et al*. 1989). In a large group of serially followed patients, STA and IgM antibodies had a parallel decline, as did the Coombs' test and IgG antibodies (Ariza 1988; Ariza *et al*. 1992a). The measurement of specific antibodies allows the detection of occasional patients not discovered by other serological tests (Sippel *et al*. 1982; Gazapo *et al*. 1989; Ariza *et al*. 1992a). Detection of an elevation in the IgG antibody during the follow-up is a very useful serological sign for the diagnosis of relapses (Pellicer *et al*. 1988; Gazapo *et al*. 1989; Ariza I>et al. 1992a). The definitive diagnosis of a relapse requires either bacteriological or clinical evidence of the disease.

Occupationally exposed workers may have low, abnormal serological test results in the absence of disease. Due to similarities in the cell wall components, serological test for brucellosis may be positive in infections due to *F. tularensis, Yersinia enterocolitica* 0<9, vibriocholerae, and *Escherichia coli* 0<157 (Corbel *et al*. 1983); when a positive result is due to cross-reaction, titres tend to be lower against the cross-reacting antigenic suspension.

Treatment

The treatment of brucellar arthritis is similar to that of uncomplicated brucellosis (Box 1). The regimen recommended at present by the World Health Organization (Joint FAO/WHO expert committee on brucellosis 1986) includes a combination of rifampicin 900 mg combined with doxycycline at 200 mg, both given once a day for 6 weeks. The relapse rate of this regimen (5 per cent), is similar to that of doxycycline 200 mg/day for 45 days, combined with streptomycin 1 g/day for 14 days (4 per cent relapse rate) (Acocella *et al*. 1989). A study conducted after treatment for only 30 days, showed that the combination of rifampicin 15 mg/kg per day with doxycycline 100 mg every 12 h had a 38 per cent relapse rate, while a combination of tetracycline 0.5 g every 6 h and streptomycin 1 g/day (for only 21 days) had a 7.1 per cent relapse rate (Ariza *et al*. 1985b). In another trial, doxycycline 100 mg every 12 h and rifampicin 15 mg/kg per day in a single morning dose, for 45 days, showed a similar efficacy than a combination of doxycycline for 45 days plus streptomycin 1 g/day for 15 days, although the doxycycline–rifampicin combination was less effective in patients with spondylitis (Ariza *et al*. 1992b). A recent meta-analysis of six published randomized trials comparing the relative efficacy of rifampicin and doxycycline versus streptomycin and doxycycline, or another tetracycline, concluded that treatment with rifampicin and doxycycline presents a greater number of recurrences and lower number of cures than the classical treatment with streptomycin and tetracycline (Solera *et al*. 1994). Probably a regimen including streptomycin and a tetracycline is to be preferred for patients with severe complications, such as spondylitis of the cervical spine.

Box 1 Management of brucellar arthritis

Antimicrobial therapy:
Is the same as that used for uncomplicated brucellosis, i.e. a combination of rifampicin 900 mg/day and doxycycline 200 mg/day over 45 days (relapse rate 5%: relapsing patients : organisms have the same sensitivities as the pre-treatment isolates (relapse is not due to drug resistance). Patients should receive a second course of treatment.

For children under 8:
Use a combination of trimethoprim–sulphamethoxazole, 10–50 mg/kg/day, given twice daily, for 3 weeks and gentamicin, 5 mg/kg/day twice daily, intramuscularly given the first 5 days

Local management:
- Peripheral joints: no local manoeuvres (e.g. daily drainage) are required.
- Sacroileitis or spine infection: only bed rest and analgesia until pain eases.
- Epidural abscesses:
  Medical treatment may be enough, but the need for surgery is an open question.
  An antimicrobial regimen including streptomycin and a tetracycline may offer advantages.

Brucellae isolated from patients with relapses show similar drug sensitivities to the pretreatment isolates from the same patients (Ariza *et al*. 1986), indicating that the relapses are not due to drug resistance. A second course of treatment is generally effective in these patients.

A therapeutic study conducted on 1100 children with early disease, showed that very few relapses were seen after oral monotherapy combined with either streptomycin or gentamicin. These combinations fared better than other regimens. It was concluded that children of 8 years or younger should receive trimethoprim–sulphamethoxazole 10 to 50 mg/kg per day, twice daily for 3 weeks, with intramuscular injections of gentamicin 5 mg/kg per day, twice daily for the first 5 days. Children of 9 years or older should receive doxycycline 5 mg/kg per day, twice daily for 3 weeks, combined with intramuscular injections of gentamicin 5 mg/kg per day, twice daily for the first 5 days (Lubani *et al*. 1989). Monotherapy with trimethoprim–sulphamethoxazole (Gómez-Reino *et al*. 1986; Lubani *et al*. 1989) or with rifampicin (Llorens-Terol and Busquets 1980 ; Lubani *et al*. 1989) results in a higher relapse rate. Treatment of 113 children with 10 to 12 mg/kg trimethoprim, 50 to 60 mg/kg sulphamethoxazole, and rifampicin 15 to 20 mg/kg in two divided doses for 6 weeks resulted in only four relapses and offers a convenient oral therapy for children (Khuri Bulos *et al*. 1993).

Apart from antibiotics, patients with peripheral arthritis do not require repeated evacuation of the joint, as is necessary in pyogenic arthritides. Rarely, large paravertebral abscesses may require drainage. Epidural abscesses with cord compression may need surgery, although it is not clearly established if this more aggressive approach offers advantages over medical treatment alone.

5.3.9 Parasitic involvement

Tomás S. Bocanegra

Improvements in living and sanitary conditions, and aggressive eradication programmes, have reduced the prevalence of most parasitic diseases in Third World countries; however, these conditions continue to be endemic in many areas of the world (Cairncross 1995). In industrialized nations, parasites cause sporadic outbreaks of disease in urban communities (McAmilty *et al*. 1994; MacKenzie *et al*. 1994; Millard *et al*. 1994; Huang *et al*. 1995) and occasionally serious illness in immigrants and travellers (Encarnación *et al*. 1994). More importantly, in the last decade, there are reports of an increasing number of life-threatening infections with parasites in immunosuppressed patients and individuals infected with the human immunodeficiency virus (Pape *et al*. 1994; Ognibene *et al*. 1995; Weiss 1995).

The clinical presentation of parasitic infection varies from localized symptoms to a multisystem disease that may include musculoskeletal manifestations. The incidence of rheumatic manifestations in the different parasitic diseases is not known, but there are reports of a variety of musculoskeletal syndromes. Recently, the importance of considering parasitic disease in the differential diagnosis of patients presenting with rheumatic manifestations was recognized by the description of these syndromes in two major textbooks of rheumatology (Bocanegra 1993; Bocanegra 1994). The diagnosis of parasite-associated musculoskeletal syndrome is established on clinical grounds when manifestations develop in residents or travellers to endemic areas, in patients who have a documented infection with an intestinal or tissue-invasive parasite, and in those whose symptoms do not respond to conventional anti-inflammatory therapy but resolve after the eradication of the parasite (Bocanegra 1994; Doury 1994) (Table 1).

Residence in, or travelling to, endemic areas	
Documented parasitic infection	
Poor response to conventional treatment	
Resolution following eradication of parasite	

Table 1 Clinical characteristics of parasite-associated musculoskeletal syndromes

This chapter will review the rheumatic syndromes that develop in humans as a consequence of parasitic infestation or of the treatment of parasitic diseases.

Protozoal infections

There are reports of rheumatic syndromes with a variety of pathogenic, tissue-invasive, as well as oportunistic protozoa (see Box 1).

Box 1 Musculoskeletal syndrome induced by protozoa

	Articular	Muscular	Vascular	Treatment of choice
Toxoplasma	Polyarthritis	Polymyositis-like	Polyarteritis nodosa-like	Pyrimethamine and sulphadiazine
Amoeba	Arthralgias	None	Focal vasculitis	Metronidazole
Giardia	Oligoarthritis	None	Small vessel vasculitis	Metronidazole or tinidazole
Cryptosporidium	Oligoarthritis	None	None	Paromomycin
Isospora	Oligoarthritis	Focal and generalized myositis	Polyarteritis nodosa-like	Trimethoprim-sulphamethoxazole
Microsporidia	None	Generalized myopathy	None	Albendazole
Trypanosoma	None	Generalized myopathy (*T. rhodesience*), Polymyositis-like (*T. cruzi*)	None	Suramin (*T. rhodesience*) Nifurtimox (*T. cruzi*)
Plasmodium	None	Myalgias	Small vessel vasculitis	Chloroquine

Articular syndromes

A symmetrical polyarthritis of the small joints of the hands, wrists, and knees in a rheumatoid pattern may develop in patients infected with *Toxoplasma gondii*. Rheumatoid factor may or may not be present in serum, but all patients have serological evidence of acute toxoplasma infection (IgG toxoplasma antibodies) (Antezana 1979; Gemou *et al*. 1983; Balleari *et al*. 1991).

Arthralgia, back pain, and arthritis occurred in young adults with intestinal amoebiasis (Yonis 1943; Rappaport *et al*. 1951; Doury *et al*. 1977). Patients presented with a polyarthritis of recent onset affecting the small, medium, and large joints of the upper and lower limbs, preceded by mild gastrointestinal symptoms. One patient had concomitant urticaria. Joint symptoms resolved on treatment of the intestinal amoebiasis.

Giardiasis may cause joint symptoms, most commonly in children and young adults. The largest series of patients with articular symptoms associated with *Giardia lamblia* infection was reported by Goobar (1977). The most common pattern was a mild and self-limiting oligoarthritis of the large and medium-sized joints of the upper and lower limbs. The erythrocyte sedimentation rate was elevated but rheumatoid factor was negative with few exceptions. All patients had concomitant gastrointestinal manifestations and most had urticaria. Recently, there have been several other case reports of a similar pattern of joint involvement. However, in a few instances the small joints of the hands and feet were affected (Farthing *et al*. 1983; Woo and Panayi 1984; Barton *et al*. 1986; Shaw and Stevens 1987; Brougui and Richard 1990). Articular symptoms did not respond to non-steroidal anti-inflammatory agents but resolved after treatment with metronidazole.

Reactive arthritis may also develop after cryptosporidial gastroenteritis in young adults and children (Hay *et al*. 1987; Sheperd *et al*. 1989). Small, medium, and large joints are affected, but symptoms are usually self-limiting. In addition, there are reports of infectious and reactive arthritis in association with opportunistic infections by *Blastocystis hominis* and *Isospora belli* (Lee *et al*. 1990; Lakhanpal *et al*. 1991; Gonzalez-Dominguez *et al*. 1994; Krüger *et al*. 1994). In one case, *Blastocystis* was recovered from synovial fluid in the knee, supporting the possibility of an infectious cause; in the others, the oligoarthritis was preceded by diarrhoea and resolved

after antiparasitic treatment, suggesting a 'reactive' mechanism.

Muscular syndromes

Focal and diffuse myositis may occur in patients infected with protozoa, mostly due to invasion of muscle tissue by the parasite. However, in some cases, an immune-mediated mechanism may play a part.

Isospora hominis (Jeffrey 1974; Bonciou *et al*. 1981) may cause both a localized and a generalized myositis with proximal and distal muscle weakness. Toxoplasmosis may produce an acute and a chronic myositis with clinical manifestations and muscle enzyme abnormalities similar to those seen in idiopathic polymyositis (McNicholl and Underhill 1970; Greenlee *et al*. 1975; Topi *et al*. 1979; Roig-Quilis and Damjanov 1982). Patients usually have a concomitant febrile systemic illness and serological evidence of acute toxoplasma infection. Toxoplasma may or may not be found in the striated muscle. It is possible that toxoplasma is involved in idiopathic polymyositis, based on the higher than expected frequency of antitoxoplasma antibodies in patients with polymyositis and dermatomyositis (Magid and Kagen 1983), the improvement in dermatomyositis on treatment of associated toxoplasmosis (Harland *et al*. 1991), and the expression of major histocompatibility complex class I and II antigens in the inflammatory cells around the muscle fibres (Matsubara *et al*. 1990). However, there is no convincing proof for this hypothesis.

Granulomatous myositis due to microsporidial infection with pleistophora was reported in a patient with severe immunodeficiency (Ledford *et al*. 1985); clusters of parasitic spores were present in the striated muscle fibres. Clinically, the patient presented with muscle wasting, contractures, and cachexia. Muscle wasting is relatively common in American trypanosomiasis (Chagas' disease) caused by *Trypanosoma cruzi* and African trypanosomiasis caused by *T. rhodesiense* and *T. gambiense*, but it is unclear if it is due to direct invasion of the striated muscle by the parasite, denervation, or malnutrition. A symmetrical proximal myositis, similar to idiopathic polymyositis, occurred in a patient with Chagas' disease (Cossermelli *et al*. 1978). Encysted trypanosomes were identified in the muscle biopsy. The muscle weakness improved but did not resolve after treatment of the underlying trypanosomiasis.

Myalgia, muscle necrosis, and elevations of creatine kinase can occur in malaria (DeSilva *et al*. 1988; Swash and Schwartz 1993), and have been attributed to microvascular changes in the striated muscle.

Vascular syndromes

A polyarteritis nodosa-like syndrome is described in patients infected with *Toxoplasma gondii* and *Isospora hominis* (McGill 1957; Carmeni *et al*. 1991). These patients presented with fever, myalgias, weakness, paraesthesias, and weight loss. Muscle biopsy showed necrotizing vasculitis of small and medium arteries.

Localized arteritis due to parasitic invasion of the vessel wall may occur in toxoplasmosis of the central nervous system and in amoebic colitis, and may be the underlying cause of the tissue necrosis frequently observed in these conditions (Huang and Chou 1988; De La Torre and Gorraez 1989; Desphande *et al*. 1992). A systemic, immune complex-mediated vasculitis may occur in infections with *Plasmodium falciparum* and *Giardia lamblia*, resulting in uveitis, urticaria, erythema nodosum, and glomerulonephritis.

Helminthic infections

Musculoskeletal manifestations are more frequently reported in patients infected by helminths than in those with protozoal infections (see Box 2).

Box 2 Musculoskeletal syndrome induced by helminthies

	Articular	Muscular	Vascular	Treatment of choice
Taeniasis (intestinal)	Oligoarthritis and polyarthritis	None	None	Praziquantel
Cysticercus	Arthralgias	Myalgias, nodular myopathy	Localized around cysticercus	Albendazole
Hydatid cyst	Bone pain, mono- and polyarthritis	Asymptomatic muscular cysts	Polyarteritis nodosa-like	Albendazole, surgical excision of cyst
Coeneurosis	None	Asymptomatic nodules	None	Surgical excision
Sparganosis	None	Nodular, occasionally migratory	None	Surgical excision
Onathostoma	None	Nodular myositis, occasionally migratory	None	Albendazole, surgical excision
Strongyloides	Arthralgias, oligo- and polyarthritis	None	Leucocytoclastic vasculitis	Thiabendazole
Ascaris	Oligoarthritis	None	Churg-Strauss syndrome	Mebendazole
Trichuris	Oligoarthritis	None	None	Mebendazole
Ancylostoma	Oligoarthritis	None	None	Mebendazole
Toxocara	Arthralgias, monoarthritis	Localized myositis of the calf	None	Diethylcarbamazine
Dracunculus	Arthralgias, monoarthritis	Myalgias	None	Metronidazole
Filariae	Arthralgias, mono- and oligoarthritis	Modular myositis (onchocerca)	Leucocytoclastic vasculitis (loa-loa)	Diethylcarbamazine, ivermectin (onchocerca)
Schistosoma	Arthralgias, oligo- and polyarthritis, enthesitis	Diffuse myopathy	None	Praziquantel
Dirofilaria	Oligoarthritis	None	None	Self-limited
Trichina	None	Myalgias, polymyositis-like	Polyarteritis nodosa-like	Mebendazole

Articular syndromes

Arthritis occurs in humans infected with cestodes as definite host (taeniasis) and as intermediate hosts (cysticercosis and hydatid cyst). A symmetrical, 'rheumatoid-like' polyarthritis and an oligoarthritis of the knees have been reported in patients infected with *Taenia saginata* (Bocanegra *et al*. 1981; Bussiere *et al*. 1981). The patient with polyarthritis had elevated amounts of circulating immune complexes and IgE in serum and deposits of IgG and C3 in the synovium. Parasites were not found in the synovial fluid or tissues. Treatment with indomethacin was unsuccessful, but symptoms resolved after treatment of the parasitic infection.

Arthralgias and bone pain may occur in cysticercosis (Surianu *et al*. 1967) and hydatid disease (Fyfe *et al*. 1990). Bone involvement is seen in 1 to 2 per cent of patients with hydatid disease; about half of bone lesions are cysts in the thoracic or lumbar spine (Rao *et al*. 1991). Although the infection is probably acquired in childhood, clinical manifestations do not develop until adulthood, owing to the slow growth of the cyst. Radiographically, bone hydatic cysts present as a lytic lesion without sclerosis and are commonly confused with metastatic malignancy or plasmacytoma. Most commonly, bone hydatid disease affects the body of the vertebra but occasionally may affect the pedicles. Spinal compression with paraplegia may occur and carries a poor prognosis (Argenson *et al*. 1989). The pelvis and femur are affected less frequently, but their involvement may result in pathological fractures (Hooper and McLean 1977; Duran *et al*. 1978). A chronic granulomatous synovitis may occur when a cyst in the para-articular bone or muscle opens into the joint (Vigliani and Campailla 1977; Voutsinas *et al*. 1987). Patients may present with urticaria and eosinophilia in addition to monoarthritis. In one patient (Campoy *et al*. 1995), synovial fluid had increased numbers of eosinophils; synovial biopsy showed granulomas and the remains of hydatid cysts (Fig. 1).

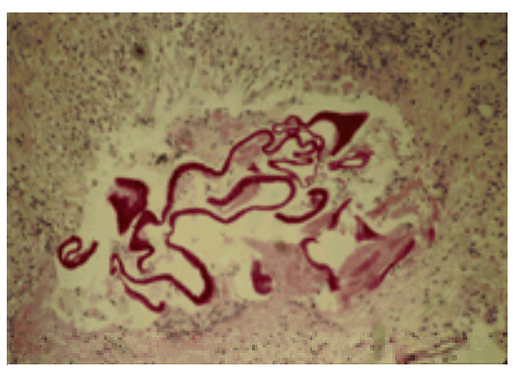

Fig. 1 Hydatid synovitis. Synovial biopsy of the knee showing inflammatory infiltrate, granulomas, and fragments of a hydatid cyst. Sections stained with periodic acid–Schiff. Original magnification ×10. (Reproduced from Campoy *et al*. 1995, with permission.).

There are reports of a seronegative polyarthritis of the small, medium, and large joints in a few patients with hydatid disease of the liver (Ballina-Garcia *et al*. 1987; Buskila *et al*. 1992). The arthritis did not respond to non-steroidal anti-inflammatory agents but resolved on removal of the hepatic hydatid cysts. The diagnosis of joint or bone involvement by hydatid disease is difficult and is often established accidentally by the finding of cysts during exploratory surgery. Needle biopsy of the cyst should not be performed, owing to the risk of disseminating the disease. The presence of eosinophilia in peripheral blood or synovial fluid, urticaria, and prior residence in an endemic area for hydatid disease in a patient presenting with arthritis or an unexplained cystic bone lesion should lead the physician to consider hydatid cyst in differential diagnosis. The treatment of bone and joint hydatid disease is of limited success because of the difficulty in removing the cyst and scoleces from the bone. In patients with arthritis associated with hepatic hydatid cysts, the symptoms resolve after the resection of the cyst. However, surgery carries a risk of anaphylactic shock due to the massive release of hydatid antigen in a patient already sensitized to it. Oral treatment with mebendazole may be beneficial in some patients but it has poor penetration of bone.

Joint pain and arthritis may develop in the course of invasive and intestinal infections with *Strongyloides stercoralis* (Bocanegra *et al*. 1981; Patey *et al*. 1990). Two articular syndromes have been reported: one characterized by symmetrical, polyarticular involvement similar to rheumatoid arthritis (Doury *et al*. 1975; Bocanegra *et al*. 1981; Amor *et al*. 1983; Forzy *et al*. 1988) and an oligoarthritis of the knees, ankles, hips, and sacroiliac joints (Amor *et al*. 1983; Akoglu *et al*. 1984; De Jonge-Bok *et al*. 1985; Menkes *et al*. 1987). Patients usually present with eosinophilia in peripheral blood and synovial fluid. Larvae of *Strongyloides* are found in stools and, in some patients, in the synovial fluid or in the synovium (Fig. 2). One patient with polyarthritis had immune complexes in serum and synovial fluid. HLA-B27 antigen was negative in all patients tested. Articular symptoms resolved in all patients on treatment with thiabendazole.

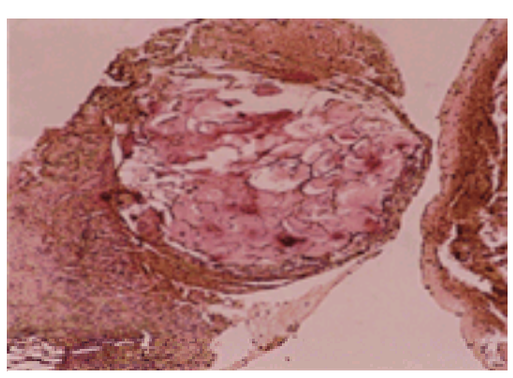

Fig. 2 *Strongyloides* synovitis: synovia from the ankle showing larvae of *Strongyloides stercoralis* surrounded by inflammatory infiltrate (reproduced from Akoglu *et al*. 1984, with permission,).

There are reports of arthralgia and monoarthritis of the knee in infections with *Toxocara canis* (canine ascarids) (William and Roy 1981; Le Luyer *et al*. 1990; Richardson de Corral *et al*. 1990; Van Linthoudt *et al*. 1990; Kraus *et al*. 1995). Some patients presented with panniculitis of the legs due to migration of the parasite through the subcutaneous tissues (Fig. 3). Diagnosis is confirmed by finding the parasite in the affected tissues or by a positive enzyme immunoassay for antitoxocara antibodies. The natural course of the disease is self-limiting, although albendazole has been used in some cases. Isolated cases of seronegative oligoarthritis of leg joints are reported in infections with *Ankylostoma duodenale, Ascaris lumbricoides*, and *Trichuris trichiura* (Treusch *et al*. 1981; Bissonnette and Beaudet 1983).

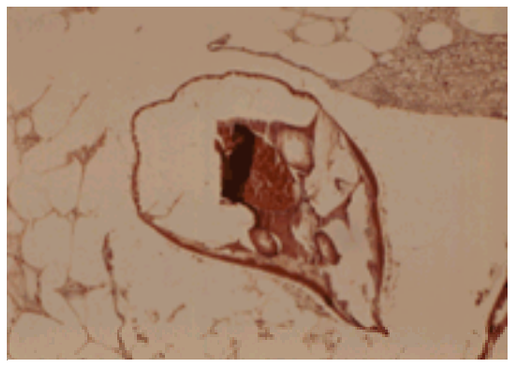

Fig. 3 *Toxocara* panniculitis: skin biopsy showing fragments of *Toxocara* and inflammatory cells in the subcutaneous tissue (reproduced from Kraus *et al*. 1995, with permission).

One-third to one-half of patients infected with *Dracunculus medinensis*, a tissue-dwelling nematode, develop arthralgias or myalgias in the legs (Garf 1985). Monoarthritis of the ankle or knee occurred in about 2 per cent of patients (Kothari *et al*. 1968) due to three possible mechanisms: (i) invasion of the joint by the parasite (Reddy and Sivaramappa 1968) with release of microfilariae into the joint—synovial fluid is inflammatory and contains microfilariae of the Guinea worm as well as increased eosinophils; (ii) a reactive arthritis due to the presence of adult worms in the neighbouring soft tissues (McLaughlin *et al*. 1984) —synovial fluid is inflammatory and may show eosinophilia but not microfilariae; (iii) infectious arthritis, most commonly due to staphylococci, which enter the joint through the skin ulcerations and sinus track created by the parasite (Greenwood 1968). Diagnosis is established by the presence of skin ulcerations and calcified parasites near the affected joints. Arthrocentesis and arthroscopy are helpful, particularly in cases of direct joint invasion and infectious arthritis. Non-steroidal anti-inflammatory agents are indicated in reactive arthritis. Antiparasitic treatment rarely results in parasite death and is not recommended. Surgical removal of Guinea worm from the soft tissue is difficult due to the length of the parasite and should not be attempted. However, arthroscopy or arthrotomy are indicated when Guinea worm is located in the joint. Intravenous antibiotics and arthrocentesis are the treatment of choice in infectious arthritis.

Joint pain and arthritis occur in filariasis caused by *Wuchereria bancrofti, Loa loa*, and *Onchocerca*. Intermittent polyarthralgias occur during the early phase of *W. bancrofti* filariasis. Arthritis occurs less often and then only in the late, obstructive phase of the infection (Alhadeff 1955). Among patients with arthritis, two-thirds have monoarticular involvement while the other one-third have oligoarthritis (less than four joints affected) (Ismail and Nagaratnam 1973). The joints most frequently affected are the knee, the ankle, and the hip (Salfield 1975). Involvement of the arms is rare, and when present is limited to large joints. The majority of patients do not have other manifestations of filariasis but may show eosinophilia, positive serology for filariasis, or microfilariae in peripheral blood or synovial fluid. Radiographs of the joints are unremarkable except for soft-tissue swelling. Synovial fluid is inflammatory with low cell counts. A few patients have a chylous effusion due to obstruction of the lymphatic vessels (Das and Sen 1968). Synovial biopsy may show mononuclear cell infiltrates and eosinophils or chronic fibrosis. The treatment of choice is ivermectin. Anti-inflammatory drugs alone are ineffective. Arthrocentesis is indicated only for diagnostic purposes but not for treatment. A similar articular syndrome has been noticed in loasis.

Polyarthralgias of large and medium joints of the limbs occurred in up to one-third of patients (Carme *et al*. 1989) and an oligoarthritis affecting the knees and ankles has been seen in a few cases (Bouvet *et al*. 1977). Radiographs of the joints show soft-tissue swelling and occasionally calcified filariae. Synovial fluid is inflammatory, with lymphomononuclear cells, eosinophilia, and occasionally polymorphonuclear cells and microfilariae (Doury *et al*. 1984; Roussel *et al*. 1989). Treatment is similar to that of *W. bancrofti* filariasis.

Infections with *Onchocerca volvulus* may occasionally produce back pain and arthritis of the hip, knee, or metatarsophalangeal joints (De Jou 1941; Commandre *et al*. 1976). Diagnosis is made by identification of microfilariae in skin-punch biopsy (skin-snip examination), in biopsies of subcutaneous nodules (onchocercomas), or in

the synovial fluid. The treatment of choice is ivermectin.

Dirofilaria immitis (dog heartworm) rarely infects humans. Most patients are asymptomatic, but a few develop respiratory symptoms including haemoptysis and pulmonary nodules. Arthritis of large leg joints was reported in patients infected with *D. immitis* and *D. tenuis* (Corman 1987; Langer *et al*. 1987). Synovial fluid has a low cell count with a predominance of mononuclear cells. Antiparasitic therapy is unnecessary since dirofilariae do not fully develop in man. Spontaneous death of the parasite leads to resolution of the symptoms.

Schistosomiasis in humans is caused by three species: *Schistosoma mansoni* and *S. japonicum* localized in the veins of the bowel, and *S. haematobium* in the veins of the genitourinary tract. Musculoskeletal manifestations may occur during the acute and chronic phases. Joint and muscle pain occur during the acute, serum sickness-like syndrome known as Katayama fever. Arthritis and enthesitis are seen in chronic schistosomiasis. Atkin *et al*. (1986) reported musculoskeletal manifestations in 80 per cent of patients. In general, these patients were older and had been infected with schistosomes for longer than those without rheumatic symptoms. The three syndromes identified were polyarthritis, in 60 per cent of patients, oligoarthritis in 30 per cent, and enthesitis in 10 per cent. However, enthesitis frequently occurred in patients with oligo- and polyarthritis and, all together, was the most common musculoskeletal syndrome. Polyarthritis affected the small joints of the hands and feet, knees and ankles in a symmetrical pattern, and was accompanied by morning stiffness. Oligoarthritis affected large joints of the legs. Enthesitis was not localized to any particular area. Synovial fluid was inflammatory, with cell counts of 7 000 to 30 000/ml and a clear predominance of polymorphonuclear leucocytes. An asymmetrical oligoarthritis of the large leg joints and unilateral sacroiliitis was the most common syndrome in another series of patients with schistosomiasis (Bassiouni and Kamel 1984). Many patients had enthesitis and/or calcaneal spurs. Synovia showed mononuclear cell infiltrates and, in some, ova of schistosomes (Bassiouni and Kamel 1984; Fachartz *et al*. 1993). Low-titre rheumatoid factor, higher levels of IgE and IgM antibodies, and circulating immune complexes were more common in patients with articular symptoms than in those without (Kamel *et al*. 1989; Bebars *et al*. 1992). The treatment of choice is a single oral dose of praziquantel.

Muscular syndromes

Cysticercosis develops in humans infected with *Taenia solium* as intermediate hosts. The most common locations of cysticerci are the central nervous system and the striated muscle. However, occasionally, the cysts may affect the extraocular muscles and the tongue (Stewart *et al*. 1993; Gupta *et al*. 1994). Among those with skeletal muscle involvement, a few develop symptoms consisting of muscle pain and nodules or generalized myopathy (Serre *et al*. 1970; Sawhney *et al*. 1976; Vilhena Lana-Peixoto *et al*. 1985). Deep-seated nodules can be palpated in the muscles of the pelvic and scapular girdles, mostly during muscle contraction. Occasionally, a diffuse, 'pseudohypertrophic' myopathy of the limb muscles is present. Despite an apparently impressive muscle development, many patients are weak. Commonly, patients have seizures or other symptoms indicative of involvement of the central nervous system. Muscle enzymes may be mildly elevated and the electromyogram may show a myopathic pattern. Diagnosis is made by demonstration of multiple muscle cysts by MRI or CT scan (Gupta *et al*. 1994), and muscle biopsy. Cysts contain non-viable larvae and are surrounded by an inflammatory infiltrate with mononuclear cells and eosinophils. Occasionally, cysts are calcified. The treatment of choice is albendazole. A short course of corticosteroids may be needed to prevent exacerbation of symptoms due to inflammation elicited by the dying larvae.

As in cysticercosis, man is an intermediate host of *Echinococcus granulosus* and *E. multilocularis*. Parasite larvae mainly encyst (hydatid cysts) in the liver and lungs. Muscular involvement is infrequent and may affect the chest wall, abdominal wall, pectoralis, sartorius, and proximal limb muscles (Schimrigk and Emser 1978; Menuier *et al*. 1983; Duncan and Tooke 1990; García-Picazo *et al*. 1995). The cysts are usually solitary and asymptomatic, presenting as a soft-tissue mass. CT scans or MRI show a well-defined cyst with a fluid-density signal. Diagnosis and treatment are achieved by complete excision of the cyst. Percutaneous needle biopsy is not recommended, as there is a risk of disseminating the scoleces along the needle tract and of precipitating anaphylactic shock from the release of large quantities of parasitic antigens. Intraoperative cyst aspiration and thorough irrigation of the cavity with hypertonic saline is recommended to inactivate the scoleces and reduce the risk of recurrence. A fibrous and inflammatory reaction with a mononuclear, neutrophilic, and eosinophilic cell infiltrate is seen on histological examination. Muscular manifestations may develop in infections caused by larvae of two other 'flat worms', *Taenia multiceps* (coenurosis) and *Spirometra* spp. (sparganosis). In coenurosis, larvae of *T. multiceps* encyst in the subcutaneous tissues and muscles of the neck, chest or abdomen causing painless nodules (Templeton 1968). In sparganosis acquired by the oral route, larvae of *Spirometra* are released in the intestine and migrate from there to different organs. During this process the larvae burrow through the subcutaneous tissue and muscles causing a slowly growing, occasionally migrating soft-tissue mass (Cho and Patel 1978; Nakamura *et al*. 1990). In both conditions, diagnosis and treatment are achieved by surgical excision of the mass.

Gnathostoma spinigerum (gnathostomiasis) may produce a localized soft-tissue abscess or a nodular, migratory, eosinophilic panniculitis due to migration of the larvae through the skin, subcutaneous tissues, and muscles (Rusnak and Lucey 1993; Stevens and Bryson 1994). Diagnosis is confirmed by positive serology. The treatment of choice is albendazole (Kraivichian *et al*. 1992).

An acute, transient myositis localized to the legs was reported in two children infected with *Toxocara canis* (visceral larva migrans) (Walsh *et al*. 1988). Both cases presented with eosinophilia and diffuse, non-tender swelling of the calf, which resolved spontaneously in 3 days. Diagnosis was established by positive serology (enzyme immunoassay) for *Toxocara*. *Onchocerca volvulus* may produce a nodular, localized, eosinophilic myositis of the abdominal wall (Neumann *et al*. 1985), and schistosomiasis has been associated with a diffuse myopathy of muscles of the shoulder and pelvic girdles (Mansour and Reese 1964).

Muscle involvement occurs during the invasive phase of trichinosis when larvae, released in the intestine by the adult female, migrate through the tissues and reach the striated muscle. The clinical presentation varies from asymptomatic infection to a severe, sometimes fatal, multisystem disease, depending on the immune status of the host and the parasite load; fewer than 10 larvae per gram of muscle rarely cause symptoms. Clinical manifestations characteristic of the invasive phase are: fever, chills, periorbital oedema, subconjunctival, retinal and subungual (splinter) haemorrhages, eosinophilia, myocarditis, and less frequently, encephalitis, nephritis and death. Myalgia and weakness affecting the proximal muscles of the arms and legs develop in two-thirds of patients infected by *T. nelsoni* (Ferraccioli *et al*. 1988). Occasionally, patients may present with manifestations indistinguishable from those of dermato- or polymyositis; that is, proximal muscle weakness, elevated creatine kinase, an electromyogram consistent with myositis, and extensive eosinophilic myositis on muscle biopsy (Herrera *et al*. 1985; MacLean *et al*. 1989; Durán-Ortiz *et al*. 1992; Louthrenoo *et al*. 1993). Larvae of trichinae are present in the muscle fibres (Fig. 4). Larvae of *Trichinella spiralis* are encapsulated while those of *T. pseudospiralis* are unencapsulated and mobile. The treatment of choice is with albendazole or mebendazole. Corticosteroids are indicated only in massive infections with severe myositis, myocarditis or central nervous involvement. Corticosteroids alone may aggravate muscle symptoms (Andrews *et al*. 1994).

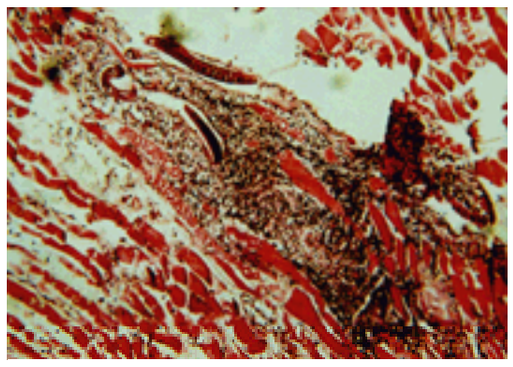

Fig. 4 Trichina myositis. Larvae of *Trichinella spiralis* and inflammatory cell infiltrate in a muscle biopsy of a child with trichinosis. Section stained with haematoxylin and eosin. Original magnification ×100. (Reproduced from Durán-Ortiz *et al*. 1992, with permission.).

Vascular syndromes

Vasculitis was induced in animals experimentally infected with larva migrans (Watzke *et al*. 1984) and is documented in a few patients infected with cestodes and nematodes. Vascular changes have been demonstrated in cysticercosis of the central nervous system and probably contribute to the basal arachnoiditis characteristic of racemous cysticercosis (Estañol *et al*. 1986). A case of histologically proven polyarteritis nodosa in a child with hepatic hydatidosis was reported recently (Bakkaloglu *et al*. 1994): treatment with prednisone and cyclophosphamide for 2 months was ineffective, but all symptoms resolved after treatment with mebendazole followed by surgical excision. Leucocytoclastic vasculitis characterized by palpable purpura, arthritis, eosinophilia, and immunoglobulin deposition in the vascular

walls has been reported in infections with *Strongyloides stercoralis* (Akoglu *et al*. 1984) and *Loa loa* (Portilla-Sogorb *et al*. 1991). As in other parasite-induced symptoms, all manifestations of vasculitis resolved after antiparasitic treatment. Nematode infections have been associated with more severe forms of necrotizing vasculitis. Reimann *et al*. (1943) and Frayha (1981) described cases of polyarteritis nodosa associated with trichinosis. More recently, Churg–Strauss vasculitis was reported in patients infected with ascarids (Chanham *et al*. 1990) and an *Angiostrongylus*-like nematode (Pirisi *et al*. 1995). In both cases the diagnosis was proven by histology. Grcevska (1993) reported recently a case of renal necrotizing vasculitis associated with glomerulonephritis in a patient infected with ascarids; the renal manifestations resolved completely after eradication of the parasite.

Musculoskeletal symptoms induced by antiparasitic treatment

Arthralgias and arthritis may develop during antiparasitic treatment, especially in patients infected with tissue-invasive parasites. In general, the frequency and severity of the symptoms vary according to the type of parasite, the parasite load, and the drug used. Mild joint and muscle pain occur in 2 to 3 per cent of patients with leishmaniasis treated with stibogluconate (Thakur and Kumar 1990), and in 10 to 15 per cent of patients with opisthochiasis treated with praziquantel (Viravan *et al*. 1986). More severe manifestations (Mazzotti reaction) develop in patients with filariasis treated with diethylcarbamazine or ivermectin (Ottesen 1987; Kumaraswami *et al*. 1988). Mazzotti reactions are seen more commonly in onchocerciasis and in lymphatic filariasis caused by *Bruggia* spp. The clinical manifestations of Mazzotti reaction vary from malaise and minor body aches to a severe, systemic, sometimes fatal reaction. Symptoms develop rapidly in the first few hours after the administration of diethylcarbamazine and consist of pruritus, rash, lymphadenopathy, fever, tachycardia, hypotension, and arthralgias. A second phase of the reaction is characterized by arthritis of the small and large joints, fever, and myalgia, developing in the first 3 to 5 days. Milder and less frequent symptoms have been reported with the use of ivermectin for the treatment of onchocerciasis and lymphatic filariasis.

The use of low initial doses of diethylcarbamazine often diminishes the severity of the early phase of the reaction. The treatment of the Mazzotti reaction is symptomatic; for patients with mild symptoms, analgesics and antipyretics are indicated. Corticosteroids, prednisone 60 mg/day, prevent the development of symptoms and are indicated in patients with heavy infections, although they may decrease the efficacy of diethylcarbamazine.

5.3.10 Fungal arthritis

Carol A. Kemper and Stanley C. Deresinski

Introduction

Fungal infection of joints is a challenging but uncommon clinical problem whose aetiology is often belatedly recognized. Fungal joint infection most often results from the haematogenous dissemination of the pathogen from a primary portal of infection (usually pulmonary) directly to the synovial tissue or may initially affect para-articular bone with subsequent rupture into a joint space. Less commonly, such infection occurs as the result of direct inoculation of the organism into the joint space or synovial tissue. An inflammatory aseptic arthritis may also occur in association with certain fungal infections (e.g. coccidioidomycosis or histoplasmosis) as a result of the immune response to the organism, rather than a result of infection of the joint itself.

Epidemiology

Only a handful of fungi, perhaps five or six species at most, are responsible for the majority of human mycotic musculoskeletal infections (Schwarz 1984; Bradsher 1988; Fader and McGinnis 1988; Silveira *et al*. 1991; Cuellar *et al*. 1992; Cueller *et al*. 1993) (Table 1), but virtually all of the approximately 100 fungi pathogenic in man have been reported to cause infection of bones and/or joints. The frequency with which arthritis occurs, its clinical presentation, and its outcome varies depending on the specific fungal agent as well as upon host variables. For example, fungal arthritis caused by the endemic dimorphic fungi, such as *Histoplasmosis capsulatum, Blastomycosis dermatiditis*, and *Coccidioides immitis*, is often seen in patients without overt immunodeficiency. In contrast, infection resulting from *Candida* spp. is usually found in association with intravascular infection in individuals with readily apparent host factors, such as those with indwelling central venous catheters (often in association with the administration of long-term antibiotic therapy and/or parenteral nutrition), or those undergoing haemodialysis, or intravenous drug users. Defects in cellular immunity are critical to the dissemination of certain fungi from their initial portal of infection and the secondary infection of joint spaces. Patients with haematological malignancy or the acquired immune deficiency syndrome (AIDS), organ transplants recipients receiving immunosuppressive agents, or those receiving chronic corticosteroids are especially at risk for fungal arthritis. HIV-infected individuals are especially vulnerable to disseminated infection with *Cryptococcus neoformans, C. immitis*, and *H. capsulatum*.

Table 1 Risk factors for infection and the clinical setting of fungal joint infection

Rarely, joint infection occurs secondary to direct inoculation of the organism into the joint during aspiration or injection, trauma, or surgical intervention. Human to human transmission of these mycoses does not, for all practical purposes, occur.

Exposure to *B. dermatiditis, C. immitis, H. capsulatum*, or *Paracoccidioides brasiliensis* ordinarily occurs within their respective endemic areas (see Table 1). *C. immitis* is limited to endemic zones in North, Central and South America, while *H. capsulatum* is found in areas of both hemispheres, often in association with avian and chiropteran habitats. *B. dermatiditis*, while most often acquired in the United States, has also been reported from Africa and the Middle East. *P. brasiliensis* is found in Central and South America, although rare cases have been described in North America. For each of these dimorphic fungi, inhalation of conidia or arthroconidia released by the mycelial phase of the organism results in a primary pulmonary infection which is either subacute or acute, and typically self-limited, or which, in some cases, becomes chronic. Secondary dissemination during the acute or chronic phase of pulmonary infection results in a varying incidence of clinical joint infection for each of these diseases. *C. neoformans* and *Sporothrix schenckii* have a worldwide distribution. In contrast to the other fungi, infection with candida is ordinarily the consequence of host invasion by endogenous colonizing organisms.

Clinical picture

The clinical presentation of joint infection is most often indolent, although the onset of some infections, such as those caused by *B. dermatiditis, Candida* spp., and, occasionally, other fungi, may be acute, with hot, erythematous and tender joints and accompanying fever. The presentation may thus resemble an acute bacterial septic arthritis. Most cases, however, present with the usual findings of arthritis with decreased range of motion, tenderness and swelling. There is often evidence of joint effusion, but in some cases of chronic infection resulting from *C. immitis*, joint swelling may be because of synovial proliferation rather than the accumulation of fluid. The initial list of differential diagnoses may therefore be quite broad, and includes septic arthritis, rheumatoid arthritis, mycobacterial infection, brucellosis, and pigmented villonodular synovitis. While fungal arthritis may present in the setting of widespread fungal infection, in many instances there is little clinical evidence of extra-articular infection. Large weight-bearing joints, particularly the knee, are the usual targets.

Radiographic examination generally reveals evidence of joint effusion. Other findings which may be seen with varied frequency, depending upon the aetiology, host factors, and the chronicity of the infection, include erosion of juxta-articular cortex, osteoporosis, and associated para-articular osteomyelitis. These radiographic findings are also common to those found in tuberculosis, rheumatoid arthritis, sarcoidosis, metastatic neoplasm, eosinophilic granuloma, and pigmented villonodular synovitis (MacKenzie *et al*. 1988).

Clinically important information about joint integrity and the presence of otherwise unapparent para-articular osteomyelitis may be provided by magnetic resonance imaging which has greater sensitivity and resolution than other conventional techniques (MacKenzie *et al*. 1988; Brown *et al*. 1990). However, the role of this

procedure in the clinical evaluation and management of fungal arthritis has not been critically evaluated. Nuclear medicine techniques, such as scanning after injection of technetium pyrophosphate, may serve to confirm clinical evidence of joint inflammation (Fig. 1).

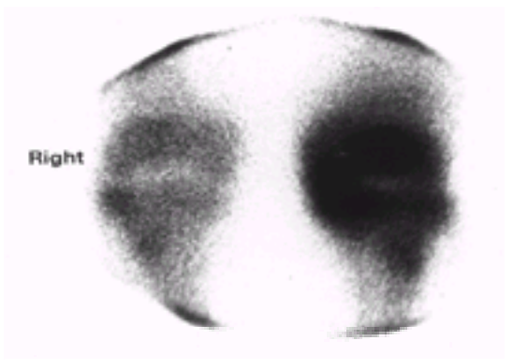

Fig. 1 Bone scintigraphy, using technetium-99m, demonstrating intense uptake of the radionuclide in the left knee of a patient with synovitis caused by *Sporothrix schenckii* (by courtesy of Jesse Hofflin MD).

Synovial fluid examination reveals an elevated white blood cell count. Although candidal and blastomycotic joint infections typically present with frankly purulent synovial fluid with a predominance of polymorphonuclear leucocytes, the other fungi often cause lesser degrees of inflammation with lower cell counts and variable predominance of either polymorphonuclear leucocytes or lymphocytes. The protein concentration is usually in excess of 3.0 g/dl while the glucose concentration is low to normal. Routine direct examination (e.g. Gram stain) usually does not reveal the organism, but cytological preparations are useful in the diagnosis of blastomycosis, cryptococcus, and, to a lesser degree, coccidioidomycosis. Culture of synovial fluid or synovial tissue usually yields the organism.

Synovial tissue histopathology is variable but often non-specific, such as in infection resulting from *S. schenckii* in which the organisms are few and difficult to visualize. Often a granulomatous reaction is observed and the differential diagnosis which must be considered includes fungal infection, brucellosis, mycobacterial infection, syphilis, protothecosis, rheumatoid arthritis, pigmented villonodular synovitis, sarcoidosis, Crohn's disease, foreign body reaction, gout, pseudogout, and oxalosis (Schwarz 1984).

The use of additional diagnostic procedures, such as blood cultures, bone marrow examination and culture, antibody tests, or tests for the detection of fungal antigen in serum or other body fluids, depend upon the clinical setting and the suspected aetiology. Tests of delayed dermal hypersensitivity to fungal antigens are generally not useful for diagnostic purposes.

Some infections may cause tenosynovitis in the absence of osteomyelitis or arthritis. Tenosynovitis may occur as the result of haematogenous dissemination or of direct inoculation, and is most often associated with *S. schenkii* infection, as well as, to lesser degrees, with infections caused by *C. immitis* and *C. neoformans*.

During the primary pulmonary infection with *C. immitis*, an acute self-limited arthritis or periarthritis, commonly referred to as 'desert rheumatism', may be seen in association with erythema nodosum, erythema multiforme, and occasionally hilar adenopathy. Thus the clinical picture may resemble sarcoidosis. An immunological process, probably immune complex deposition, is thought to be aetiologic. Acute aseptic inflammatory arthritis may also be seen in histoplasmosis, as well as in acute blastomycosis.

Management

Amphotericin B remains the therapeutic agent of choice for most serious fungal infections with the exception of those resulting from *Pseudoallescheria boydii* infection in which azole therapy (usually miconazole) is preferred. Several newer oral antifungal agents which may provide similar efficacy with less toxicity are undergoing active investigation.

Amphotericin B, administered intravenously, penetrates into synovial fluid to some extent (Farrell *et al*. 1978). While several authors have advocated directly injecting or irrigating the joint space with amphotericin B, the necessity for this mode of therapy is unproven, and there is concern that a chemical synovitis and articular damage may result. The toxicities of amphotericin are well known and include fever, chills, nausea, vomiting, hypotension, renal dysfunction, hypokalaemia and hypomagnesaemia. The renal toxicity may be dose limiting. Preliminary studies of lipid-associated amphotericin B indicate that higher doses of this drug may be administered with less toxicity than with standard preparations. Whether this is beneficial, however, remains unproven since such preparations also have reduced antifungal activity.

Fluorocytosine (5-FC) enters susceptible fungal cells through a specific permease system and is then converted to 5-fluorouracil. It has a narrow spectrum of activity which includes most *Candida* spp. as well as *C. neoformans*. In most instances, fluorocytosine is not administered as a single agent because of the possibility of the development of drug resistance during therapy. The drug penetrates well into all body fluids, including synovial fluid, and is renally excreted. The major toxicity, bone marrow suppression and resultant cytopenias, is directly related to serum concentrations in excess of 100 µg/ml. Serum concentrations of fluorocytosine should be closely monitored during administration, and dose adjustments must be made in the presence of changing renal function.

The azoles, such as miconazole, ketoconazole, fluconazole and itraconazole, inhibit the C-14 demethylation of lanosterol, thus impairing fungal cell membrane assembly. They have variable pharmacokinetic, toxicity, and antifungal profiles (Fromptling 1988). The intravenous form of miconazole has limited utility because of toxicity and unfavourable pharmacokinetics.

Ketoconazole was the first of the azoles available for oral administration. It has efficacy in a variety of fungal infections including those due to most *Candida* spp. (*Candida* (*Torulopsis*) *glabrata* is resistant), *H. capsulatum, B. dermatiditis, C. neoformans*, and *C. immitis*. Absorption is impaired in the absence of gastric acid. Ketoconazole penetrates into synovial fluid from the bloodstream. Elimination is non-renal with a terminal half-life of approximately 7.5 h. The most common adverse effect is gastrointestinal. Modest elevations in hepatic transaminases are not uncommon but significant hepatic toxicity rarely occurs. Depressed cortisol and testosterone levels may occur as a result of interference with sterol synthesis, but symptomatic hypocortisolism is very rare. Drug interactions occur with cyclosporin, phenytoin, warfarin, and rifampin (Hawkins Van Tyle 1984), as well as rifabutin; astemizole and terfenadine are contraindicated in patients receiving ketoconazole.

Fluconazole is a water-soluble bis-triazole with a high degree of bioavailability and the ability to penetrate into body fluids, including synovial fluid, and achieves concentrations similar to those in serum (O'Meeghan *et al*. 1990). Protein binding is low (approximately 10 per cent) and the elimination half-life is approximately 22 h. Clearance is predominantly renal. Drug–drug interactions occur with phenytoin, rifampicin, and rifabutin, as well as with astemizole and terfenadine. Hepatic toxicity is rare; steroid hormone synthesis is not affected. The spectrum of activity is similar to that of ketoconazole (Galgiani 1990).

Another bis-triazole, itraconazole, has a broader spectrum of activity than either ketoconazole or fluconazole. It has now been approved by the United States Food and Drug Administration for use in both blastomycosis and histoplasmosis, and is also very active against *S. schenkii* and most *Aspergillus* species (Tucker *et al*. 1988). Itraconazole is lipophilic, highly protein bound, well absorbed, and has an elimination half-life of approximately 24 h. Elimination is non-renal. Body fluid penetration is less than that of fluconazole. Cortisol synthesis is not impaired by itraconazole. Pharmacokinetic interaction with cyclosporin occurs (Kramer *et al*. 1990); the same precautions regarding drug–drug interactions should be observed with itraconazole as ketoconazole. Gastrointestinal side-effects are common (Tucker *et al*. 1990). Itraconazole, which requires stomach acid for absorption, is not recommended for patients who are receiving antacids, H_2 blockers, or those who have achlorhydria, unless adequate serum levels can be demonstrated.

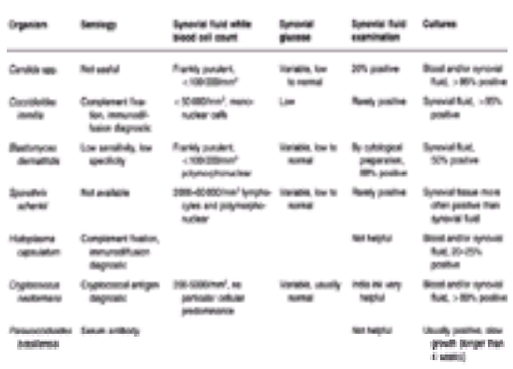
Individual mycoses

***Candida spp*.**

Candida albicans is a normal commensal of man and endogenous colonization is the source of most infections by *Candida* spp. Deep tissue infection generally occurs after amplification of colonization during an intervening immunodeficient state or during administration of broad-spectrum antibacterial therapy coupled with breaches in integumentary and mucosal barriers (Crislip and Edwards 1989). Candida infection of joints is typically the consequence of haematogenous dissemination (often from indwelling intravenous catheters in predisposed immunodeficient hosts or in intravenous drug users) (Marina *et al*. 1991). Joints previously afflicted by rheumatoid arthritis appear to be at increased risk of infection with candidal organisms (Campen *et al*. 1990). Less commonly, joint infection occurs secondary to direct inoculation of the organism into the joint during aspiration or injection of corticosteroids (Ginzler *et al*. 1979; Campen *et al*. 1990), trauma, or surgical intervention (including simple arthrotomy) (Arnold *et al*. 1981) (Table 1). Immunocompromise resulting from HIV infection does not appear to predispose to disseminated candidiasis or to candidal arthritis, except in those who use parenteral drugs (Edlestein and McCabe 1991; Munoz-Fernandez *et al*. 1991; Silveira *et al*. 1991). *Candida* spp. which have been implicated in septic arthritis include *C. albicans, Candida tropicalis, Candida parapsilosis, Candida guilliermondi, Candida krusei, Candida zeylanoides*, and *Torulopsis* (*Candida*) *glabrata*.

In contrast to many of the other fungal joint infections discussed here, the onset of disease caused by *Candida* spp. is acute in approximately two-thirds of cases (Bayer and Guze 1978). The remaining patients present with subacute disease. Instances of remarkably indolent presentations include those in which the arthritis was present for 9 months prior to diagnosis in a patient with acute myelocytic leukaemia (Gerster *et al*. 1980), and for 12 months in a patient receiving chronic haemodialysis (De Clerk *et al*. 1988). The large joints are most commonly affected.

Synovial fluid examination demonstrates a markedly elevated white blood-cell count (15 000 to 100 000 cells/mm ^{3}) with a predominance of polymorphonuclear leucocytes (Table 2) (Bayer and Guze 1978; Fainstein *et al*. 1982). The protein concentration is elevated while that of glucose is either low or normal. Histological examination of synovium reveals mononuclear cell infiltration but usually an absence of granulomata (Bayer and Guze 1978). The organism is visualized in only 20 per cent of cases on direct examination of synovial fluid by Gram stain or other methods. Synovial fluid or tissue consistently yield the organism in culture. Recovery of the organism from blood cultures may provide an important clue to the aetiology of the joint process.



Organism	Serology	Synovial fluid white blood cell count	Synovial glucose	Synovial fluid examination	Cultures
Candida spp.	Not useful	Frankly purulent, <100 000/mm^3	Variable, low to normal	20% positive	Blood and/or synovial fluid, >90% positive
Coccidioides immitis	Complement fixation, immunodiffusion diagnostic	<50 000/mm^3, mononuclear cells	Low	Rarely positive	Synovial fluid, <95% positive
Blastomyces dermatitidis	Low sensitivity, low specificity	Frankly purulent, <100 000/mm^3 polymorphonuclear	Variable, low to normal	By cytological preparation, 88% positive	Synovial fluid, 50% positive
Sporothrix schenkii	Not available	2000–50 000/mm^3 lymphocytes and polymorphonuclear	Variable, low to normal	Rarely positive	Synovial tissue more often positive than synovial fluid
Histoplasma capsulatum	Complement fixation, immunodiffusion diagnostic			Not helpful	Blood and/or synovial fluid, 20–25% positive
Cryptococcus neoformans	Cryptococcal antigen diagnostic	200–5000/mm^3, no particular cellular predominance	Variable, usually normal	India ink very helpful	Blood and/or synovial fluid, >80% positive
Paracoccidioides brasiliensis	Serum antibody			Not helpful	Usually positive, slow growth (longer than 4 weeks)

Table 2 Clinical and laboratory data helpful in the diagnosis of fungal joint infection

The cornerstone of management consists of systemic antifungal chemotherapy. Intravenously administered amphotericin B, with or without fluorocytosine, remains the standard treatment. However, based on limited data, the azoles (ketoconazole, fluconazole and itraconazole) appear to be as effective as amphotericin in the treatment of candidal infection caused by susceptible isolates, at least in non-neutropenic hosts. Several cases of candidal skeletal infection have been successfully managed with either ketoconazole (Gathe *et al*. 1987) or fluconazole alone (Sugar *et al*. 1990; Lafont *et al*. 1994). The potential role of lipopeptides, cilofungin, and lipid-associated amphotericin B is also unknown. Intra-articular amphotericin B has been utilized but the necessity or desirability of this method of treatment is questionable. Repeated joint aspiration is usually indicated. Surgical debridement may also be indicated (in addition to antifungal chemotherapy), particularly in cases of hip joint infection.

Candida spp. are causative in almost one-fifth of cases of nosocomial septic arthritis in neonates (Dan 1983; Ho *et al*. 1989), occurring exclusively in high-risk infants. Candida arthritis in neonates and in young infants is frequently associated with antibiotic therapy and parenteral administration of nutritional fluids (Yousefzadeh and Jackson 1980). Additional risk factors include prematurity, abdominal surgery, malnutrition, and immunosuppressive disease or therapy (Pope 1982).

In most neonatal cases, candida arthritis presents as just one facet of a systemic disease process and the organism may be recovered from a variety of extra-articular sites including blood, urine and spinal fluid. In the largest reported series (Dan 1983), joint aspirates yielded *C. albicans* in all but one instance. *C. tropicalis* was recovered from the remaining case. One or both knees were involved in 71 per cent of cases; polyarticular infection was seen in one-third of patients. The synovial fluid white blood-cell count was as high as 100 000/mm ^{3} with a predominance of polymorphonuclear leucocytes. The synovial membrane was hyperemic and purulent with erosion of cartilage. Radiographic evidence of adjacent osteomyelitis was seen in two-thirds of patients and in almost 90 per cent of joints, suggesting that in most cases, infection of the metaphysis was the original site of haematogenous dissemination with subsequent rupture into the articular cavity (Svirsky-Fein *et al*. 1979). Other radiographic findings included periarticular soft tissue swelling and joint effusion and, in the case of hip joint infection, subluxation of the femoral head. The mortality rate was 14 per cent. Major orthopaedic sequelas were seen in only one-tenth of survivors.

Fungal infection of prosthetic joints is exceedingly rare. In a series of reported cases, ten infections were identified in eight patients; all were caused by *Candida* spp. (Lambertus *et al*. 1988). One case was due each to *C. albicans* and *T. glabrata*, while three each were due to *C. tropicalis* and *C. parapsilosis*. Infection was probably the result of implantation of skin contaminants at the time of the original surgery. The infections were clinically low-grade, indolent, and presented 5 to 36 months after reconstructive arthroplasty. Pain and decreased range of motion were universally present and peri-articular swelling was common. Other signs of inflammation were absent. A sinus tract was seen in one patient. Radiographic examination revealed evidence of loosening and adjacent areas of osteolysis indicative of osteomyelitis. Technetium pyrophosphate and gallium nitrate scans are not useful in the setting of a loosened prosthesis (Fitzgerald and Kelly 1979). Synovial fluid white blood-cell counts were less inflammatory than that typically seen in native joint infections (4000 to 15 000/mm ^{3}); polymorphonuclear leucocytes were predominant.

Amphotericin B, with or without fluorocytosine, in combination with removal of the prosthesis and other foreign material, and debridement of affected tissue is the initial treatment of choice. Although no data are yet available, ketoconazole, fluconazole, and itraconazole may have a role in long-term 'maintenance' therapy of such cases. Reimplantation has been successfully reported in one patient 10 months after resection arthroplasty (Younkin *et al*. 1984).

Blastomycosis

Blastomycosis is an uncommonly encountered mycotic infection primarily endemic to parts of the midwestern, south-eastern, and Appalachian areas of the United States, but which is also seen in Africa and the Middle East (see Table 1). *B. dermatiditis* is a thermal dimorph whose mycelial phase is thought to reside in soil. Conversion to the yeast phase occurs after inhalation of spores. Primary pulmonary infection may be subclinical, acute, or subacute, but is usually self-limited; occasional cases may be chronic. Haematogenous dissemination is relatively frequent during the initial phase of the disease, leading to infection at almost any body site. While skin and bones are the most frequent sites of dissemination (25 to 60 per cent) in disseminated blastomycosis, only between 2.5 and 8 per cent of patients develop joint infection (Blastomycosis Cooperative Study of the Veterans Administration 1964; Witorsch and Utz 1968; George *et al*. 1985; McDonald *et al*. 1990). Those patients with particularly severe pulmonary disease, miliary involvement, or those who are immunocompromised are at the greatest risk for dissemination (Sarosi and Davies 1981; Recht *et al*. 1982). The risk of endogenous reactivation, which usually occurs during the first 2 to 3 years following the primary pulmonary infection, is small. Very rarely, joint infection is the result of direct inoculation secondary to trauma (Gnann *et al*. 1983).

While many patients with progressive or disseminated disease due to *B. dermatitidis* suffer from potentially predisposing conditions, such as diabetes, alcoholism, renal failure, and malignancy (Klein *et al*. 1986), this organism is not generally considered an opportunistic pathogen. Recht and colleagues described 78 patients with blastomycosis, 6 (13 per cent) of whom were immunocompromised, none, however, due to T-lymphocyte dysfunction (Recht *et al*. 1982). Those 6 patients had a similar clinical presentation and therapeutic response as the remaining patients who were not immunocompromised. Nevertheless, rapidly progressive and unusually

severe disease has been reported in patients with profoundly impaired immunity, such as patients who have had transplants and those with AIDS (Davies and Sarosi 1991).

Myalgias and arthralgias are common during the acute pulmonary phase of the disease, but erythema nodosum is not (Sarosi *et al*. 1974). A reactive arthritis, similar to that seen with coccidioidomycosis, has been reported (Berger and Kraman 1981).

The arthritis is monoarticular in 95 per cent of cases with the knee most commonly involved, followed by the ankle, elbow and wrist (see Table 2). Joint pain is often acute in onset and patients usually appear toxic. In contrast to coccidioidal arthritis, active pulmonary disease is present in more than 90 per cent of patients with joint involvement, and more than 70 per cent have evidence of additional dissemination to cutaneous or subcutaneous sites (Fountain 1973; Bayer *et al*. 1979b). In contrast to those with candidal or sporotrichal arthritis, less than one-third of patients have radiographic evidence of juxta-articular osteomyelitis (Bayer *et al*. 1979b).

Synovial fluid findings are similar to those seen in candida arthritis. The fluid is usually cloudy or frankly purulent with white blood-cell counts which may exceed 100 000/mm^3 and with a predominance of polymorphonuclear leucocytes. The concentration of protein in the synovial fluid exceeds 3.0 g/dl while the glucose is low to normal (Fountain 1973; Bayer *et al*. 1979b; Robert and Kauffman 1988). Cytological examination of synovial fluid may be more sensitive in detecting the organism than is culture. Bayer and colleagues described a series of nine patients who underwent joint fluid examination, eight (88 per cent) of whom had characteristic organisms detected by direct microscopy and seven (78 per cent) of whom had positive cultures of synovial fluid (Bayer *et al*. 1979b). In a study of five patients, cultures were positive in three (60 per cent) and KOH preparation were positive in two (40 per cent), but cytological examination of synovial fluid in four of the cases demonstrated the characteristic organisms in all (100 per cent) (George *et al*. 1985). The organism may also be recovered in culture or visualized on histopathology from synovial biopsy specimens. Histopathological examination of infected synovium reveals prominent polymorphonuclear leucocytes, often with microabscesses and occasional granulomata.

While most patients with acute self-limited pulmonary blastomycosis have demonstrable delayed dermal hypersensitivity to blastomycin, this reactivity wanes over time and is not of diagnostic value. Available serological tests have been disappointing with both false-negative and -positive results commonly seen.

Amphotericin B remains the drug of choice for many patients, particularly those who are critically ill, have evidence of progressive disease, or those who are immunosuppressed (Bradsher 1988). The total dose required is usually 1.0 to 2.0 g. In patients with joint infection and otherwise stable disease, itraconazole is very effective (approximate 90 per cent response rate) (Dismukes *et al*. 1992). The usual starting dose is 200 mg once daily, increasing to 400 mg daily as necessary. A loading dose of 200 mg three times daily can be given for the first 3 days. Therapy should be continued for approximately 6 months.

Ketoconazole also has some efficacy in patients without meningeal disease who are not severely immunocompromised (National Institute of Allergy and Infectious Disease Mycoses Study Group 1985; McManus and Jones 1986; Bradsher 1988). Ketoconazole should be initiated at a dose of 400 mg per day and continued for at least 6 months. The dose can be increased to 600 to 800 mg per day in those who are failing to respond to therapy or who develop a new focus of infection.

Fluconazole does not appear to be nearly as effective as itraconazole in the treatment of blastomycosis. There are, however, reported cases of its use in patients with pulmonary and meningeal disease (Pearson *et al*. 1992; Taillan *et al*. 1992).

Sporotrichosis

S. schenckii, a tissue dimorph, is commonly found on decaying vegetation and in soil in many areas of both hemispheres. Infections are both sporadic and epidemic. In contrast to the other soil fungi discussed here, cutaneous disease occurs secondary to inoculation of the organism as a result of trauma to the skin. The lymphocutaneous form, with the development of an ulcer at the site of cutaneous inoculation and proximal nodules in the area of lymphatic drainage, is the most common manifestation of infection (Belknap 1989). Persons at particular risk for this infection include rose cultivators and those who handle soil and spagnum moss (Kedes *et al*. 1964). Primary pulmonary infection may occur presumably as the result of inhalation of spores.

While arthralgias occur in approximately 2 per cent of those with acute cutaneous or lymphocutaneous disease, infection of the joint space with *S. schenckii* is rare, having occurred in only one of 3300 patients (0.03 per cent) in a large outbreak of sporotrichosis (Lurie 1963). Arthritis may occur in the presence of widespread dissemination to other sites, but is much more common as an isolated finding (Bayer *et al*. 1979a; Yao *et al*. 1986). Bayer and colleagues described 44 cases of sporotrichal joint infection, 20 per cent of which were associated with systemic and pulmonary disease (Bayer *et al*. 1979a). Most cases of sporotrichal arthritis are therefore believed to be caused by haematogenous dissemination of the organism, although some cases may be the result of articular extension of infection from an adjacent site of osteomyelitis or skin infection or, occasionally, from direct inoculation of the organism into the joint. More than 85 per cent of patients with systemic infection have predisposing underlying disease, including myeloproliferative disorders, malignancy, chronic corticosteroid use and alcoholism (Kedes *et al*. 1964; Bayer *et al*. 1979a).

Sporotrichal arthritis is an indolent and slowly progressive infectious process which predominantly affects the knee and other large weight-bearing joints, although the small joints of the hand and wrist are also commonly affected (Molstad and Strom 1978; Bayer *et al*. 1979a). Calhoun and colleagues described 11 cases of systemic sporotrichosis; 8 involved the skeletal system with a total of 12 joints being affected, including the wrist (63 per cent), knee (38 per cent), ankle (25 per cent), and elbow and phalanx (13 per cent each) (Calhoun *et al*. 1991). Monoarticular and polyarticular involvement occur with equal frequency. Most cases present as a slowly progressive synovitis or tenosynovitis with pain, warmth, swelling and restricted range of motion (Bayer *et al*. 1979a; Chang *et al*. 1984).

Radiographic abnormalities are seen in more than 90 per cent of cases, possibly reflecting the chronicity of infection prior to diagnosis. Osteoporosis of contiguous bone is the most common radiographic finding, followed by soft tissue swelling with effusion, 'punched out' osteolytic lesions, articular cartilage erosion and joint space narrowing (Bayer *et al*. 1979a) (see Fig. 2).

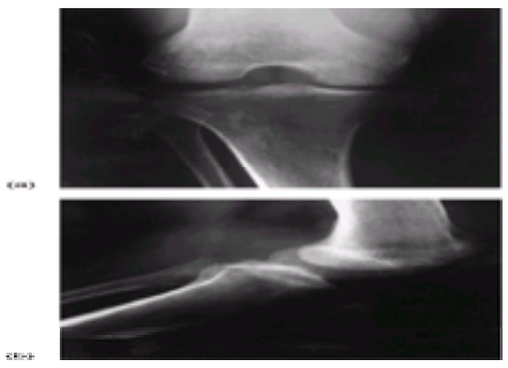


Fig. 2 (a) and (b). Radiographs of the left knee demonstrating only patchy osteopenia of the distal femur and proximal tibia from a patient with joint infection caused by *S. schenckii*. Bone scintigraphy of the same patient is shown in Fig. 1 (by courtesy of Jesse Hofflin MD).

Synovial fluid white blood-cell count is reported to range from 2800 to 60 000/mm^3. Both lymphocytes and polymorphonuclear leucocytes may be seen (see Table 2). The protein concentration is high while that of glucose is low to normal (Lesperance *et al*. 1988). The diagnosis may be delayed because of the isolated nature of the infection, the rarity of visualizing the organism on smears of synovial fluid, the often non-specific nature of synovial histopathology (which may resemble that of rheumatoid or tuberculous arthritis) (Stratton *et al*. 1981), and the paucity of organisms in tissue (Khan *et al*. 1983; Schwartz 1989) (Fig. 3). Asteroid bodies, often said to be pathognomonic of sporotrichosis, may, in fact, be seen in other infections. Isolation of the organism in culture is the cornerstone of diagnosis. Synovial tissue is more likely to yield the organism (usually within five days) than is synovial fluid. Skin tests are only useful for epidemiological surveys. A variety of serological tests have been utilized with varying results (Winn 1988).

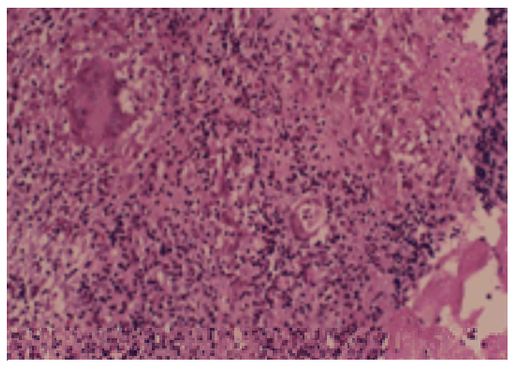

Fig. 3 Granulomatous reaction with typical giant cells in synovium obtained from the same patient described in Fig. 2. Organisms were not visualized with this stain or with Gomori–methanamine silver or periodic acid–Schiff stains, and the diagnosis was made by recovery of the organism in culture from the synovial tissue. Haematoxylin and eosin, original magnification × 200 (by courtesy of Jesse Hofflin MD).

While amphotericin B had been recommended for the treatment of skeletal sporotrichosis, newer data indicate that itraconazole is very effective in this infection. In a recent National Institute of Allergies and Infectious Diseases non-comparative clinical treatment trial of 30 patients with both lymphocutaneous and systemic sporotrichosis, one-half of whom had osseous or articular infection, itraconazole (100 to 600 mg daily for 3 to 18 months) was effective in 83 per cent (Sharkey-Mathis *et al*. 1993). However, 6 to 18 months after treatment was discontinued, 7 patients relapsed. Two of these patients have subsequently responded to a second course of therapy. Resolution of infection and normalization of joint mobility and function has been reported in 3 other patients who received itraconazole 200 mg daily (Winn *et al*. 1993).

Despite reasonably effective penetration by the drug into synovial fluid, ketoconazole has effected responses in only approximately two-thirds of patients with systemic sporotrichosis, including patients with joint infection (Dismukes *et al*. 1983; Graybill *et al*. 1983; Horsburgh *et al*. 1983; Pluss and Opal 1986; Calhoun *et al*. 1991). Fluconazole has been similarly disappointing in lymphocutaneous infection (Restrepo *et al*. 1986). Potassium iodide, which is effective in the lymphocutaneous form of the disease, has no role in the treatment of deep tissue infection, such as arthritis. Sporadic cases of skeletal disease have, however, reportedly responded to treatment with potassium iodide (Govender *et al*. 1989).

Intra-articular administration of amphotericin B has also been utilized, but this is unlikely to be necessary (Downs *et al*. 1989). Surgical debridement may also be necessary on occasion, but should be reserved for persistent culture positivity and in cases of tenosynovitis (Winn 1988).

Coccidioidomycosis

C. immitis is endemic to the soils of certain areas of the Lower Sonoran life zone of the Western hemisphere, with most cases resulting from exposure to airborne arthroconidia in Arizona and the the southern central valley of California (see Table 1). Upon reaching the alveoli of the infected host, the organism, a tissue dimorph, converts to the spherule–endospore phase. Approximately one-half of infected patients become symptomatic and, in the vast majority of these, the infection is self-limited with influenza-like symptoms. Transient arthralgias or aseptic inflammatory arthritis, which probably represents an immunologically mediated inflammatory process similar to erythema nodosum (which is also often seen), occur in 3 to 5 per cent of patients with primary pulmonary coccidioidomycosis (Fiese 1958). Treatment consists of giving non-steroidal anti-inflammatory agents.

Clinically important extrapulmonary dissemination occurs in fewer than 0.5 per cent of cases, although certain groups are at greater risk for dissemination. While many patients with disseminated disease have no impairment in immune function, approximately one-half are immunocompromised by corticosteroids, diabetes, renal failure, or other immunosuppresive therapy. HIV-infection increases both the risk of more frequent and more severe coccidioidomycosis (Galgiani and Ampel 1990).

Joint space infection occurs in up to 25 to 30 per cent of patients with disseminated disease, with occasional extension into adjacent bony areas (Fiese 1958; Deresinski 1980; Deresinski 1994). Monoarticular arthritis occurs in more that 90 per cent of cases, with large weight-bearing joints, particularly the knee and ankle, being most frequently affected (Deresinski 1980; Deresinski 1994). At the time of presentation with joint disease, occult sites of dissemination are present in up to 25 per cent of cases (Winter *et al*. 1975). Extrapulmonary sites of infection, including meningeal, bone, and joint infection, should therefore be avidly sought for in any patient with disseminated coccidioidomycosis.

While some patients may initially present with an acutely inflamed joint, most infections are indolent with progressive effusion and synovial thickening. The diagnosis of joint infection is often delayed, and chronic infection frequently results in significant articular and bony destruction with resultant loss of joint function (Fig. 4). Occasionally, chronic arthrocutaneous fistulas develop with drainage of synovial fluid (Fig. 5). Baker's cysts may occur as a consequence of knee involvement. Effusion and erosion of articular cortex and adjacent osteoporosis are commonly seen on radiographic examination (Carter 1934; Bayer and Guze 1979). Technetium pyrophosphate radioisotope scans usually localize to the affected joints.

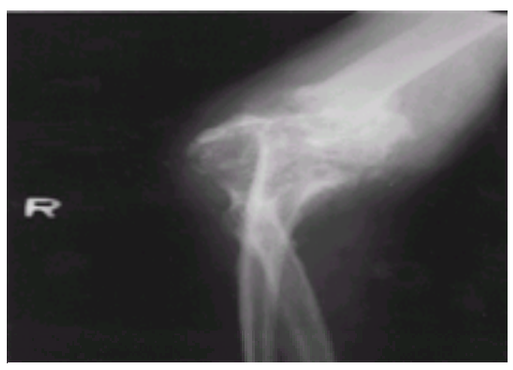

Fig. 4 Radiograph of the right elbow demonstrating destruction of the articular cortex and osteomyelitis of contiguous bone of an elderly women with chronic coccidioidal arthritis of many years duration despite multiple courses of antifungal therapy.

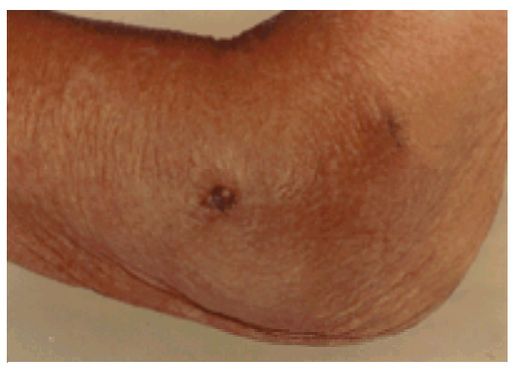

Fig. 5 Chronic coccidioidal arthritis of the same patient as in Fig. 4 demonstrating the right elbow joint fixed in flexion. The sinus tracts intermittently drain material from which *Coccidioides immitis* is recoverable in culture (by courtesy of John S. Hostetler MD).

Synovial fluid is inflammatory with total white blood-cell counts as high as 50 000/mm ^{3}(Table 2). Mononuclear cells usually, but not always, predominate. Protein is greater than 3.0 g/dl, glucose is low and mucin clot is poor (Aidem 1968; Deresinski and Stevens 1974). Culture of synovial fluid yields the organism in approximately 50 per cent of cases, usually within 3 to 6 days. Greater yield is seen with culture and histological examination of synovial tissue (Greenman *et al*. 1975). The affected proliferative synovium, which often invades cartilage and articular surfaces, exhibits granulomatous villonodular inflammatory changes with the characteristic endosporulating spherules visible on microscopic examination (Haug and Merrifield 1959). Most importantly, if coccidioidomycosis infection is suspected, the microbiology laboratory must be notified because of the significant biohazard represented by this organism in culture.

Serum complement-fixing antibody to coccidioidin is almost universally present, with the height of the titre reflecting the extent of dissemination, as in other manifestations of disseminated infection with this organism (Deresinski 1980). Delayed dermal hypersensitivity to coccidioidin may be absent.

Patient prognosis depends upon the extent of dissemination to other sites, particularly the central nervous system. Treatment consists of systemic administration of antifungal agents, and amphotericin B remains the treatment of choice in many cases. Patients with disseminated disease often receive a total of 1.0 to 2.5 g of amphotericin B. Continued therapy is indicated until remission has been achieved, as defined by objective clinical measures, and improvement in serological and radiographic data. Amphotericin B has also been administered intra-articularly, but the therapeutic necessity or advisability of this is uncertain. Arthrodesis is generally effective, but not desirable.

The need for synovectomy and debridement of infected bone and tissue remain controversial. Despite appropriate medical and surgical intervention, the joint infection often remains progressive and disabling (Lantz *et al*. 1988). In one study, 7 of 14 patients who received amphotericin alone failed therapy, whereas none of the 14 patients who were treated with a combination of medical and surgical approaches relapsed (Bried and Galgiani 1986). In another similar study, 7 of 9 patients who received amphotericin B and who underwent surgical debridement remained disease-free at least 4 years later (Bisla and Taber 1976). The two remaining patients developed recurrent disease, despite having received more than 3.0 g of amphotericin B each. Patients with complement fixation titres greater than or equal to 1:128 were most likely to fail in response to medical therapy alone (Bried and Galgiani 1986).

Ketoconazole (400 to 800 mg per day) has some efficacy, but the relapse rate is high (approximately 30 per cent) (Galgiani *et al*. 1988). Although both fluconazole and itraconazole have been used in cases of pulmonary disease and meningitis, relapses are frequent. The optimal dose and duration of therapy remain under study. An unusual case of prosthetic hip joint infection caused by *C. immitis* responsed to long-term therapy with fluconazole (Nomura nd Ruskin 1994).

Histoplasmosis

H. capsulatum is endemic to many areas within the temperate zones of the world, but is most heavily concentrated in the Ohio, Mississippi and Missouri River valleys of the United States (Table 1). The organism is a thermal dimorph with the mycelial phase existing in soil, generally in association with bird and bat guano. Large outbreaks occur in urban endemic areas. Speleologists throughout the world may be at risk.

Upon inhalation by the human or animal host, microconidia reach the alveoli where they convert to the yeast phase. While greater than 95 per cent of infections are subclinical, an influenza-like respiratory illness may result from infection. Haematogenous dissemination is rare and occurs most commonly in patients with impaired cellular immunity. Disseminated histoplasmosis is reported in approximately one-third of AIDS patients in Kansas City, Missouri (McKinsey *et al*. 1989). Persons with HIV infection who travel to or have previously lived in an endemic area are at risk for reactivation disease (Minamoto and Armstrong 1988; Salzman *et al*. 1988).

Immunologically mediated arthralgias and aseptic inflammatory arthritis, similar to that reported for coccidioidomycosis, are common in primary histoplasmosis (Class and Casio 1972; Rosenthal *et al*. 1983). Based on previously published reports, one review found that arthralgias occurred in 3 to 21 per cent, and erythema nodosum and erythema multiforme occurred in 1 to 42 per cent of patients with documented histoplasmosis (Schwarz 1984). During a single outbreak of acute histoplasmosis in 381 symptomatic patients, 16 (4.1 per cent) developed arthralgias and 6 (1.6 per cent) developed aseptic arthritis (Rosenthal *et al*. 1983). The knees, ankles, wrists, and small joints of the hands were the most common sites of involvement; approximately 50 per cent of the cases were polyarticular. The joint involvement may be additive or migratory, and is often symmetric. Synovial fluid is inflammatory. This clinical problem is self-limited and is treated with non-steroidal anti-inflammatory agents (Sellers *et al*. 1965).

In contrast to candida and coccidioidomycosis, infection of the synovium or joint space by *H. capsulatum* is exceedingly rare. It is usually monoarticular and has been reported in both apparently immunologically normal (Key and Large 1942; Omer *et al*. 1963; Van Der Schee *et al*. 1990) and compromised hosts (Jones 1985). Juxta-articular osteomyelitis may be present. The diagnosis of histoplasmosis can be made by culture of both blood and infected sites, including synovial fluid, and histological demonstration of the infecting organism. The organism is readily cultivated on a variety of media. The lysis–centrifugation technique hastens recovery from the blood of patients with active dissemination (Paya *et al*. 1987).

Detection of antigen in serum or urine has been utilized in the diagnosis of disseminated histoplasmosis (Wheat *et al*. 1986). Although both false-positive and -negative results occur, antibody tests are diagnostically useful. Detection of serum complement-fixing antibody to the yeast phase of the organism of 1:32 or greater should be regarded as presumptive evidence of histoplasmosis. Titres of 1:8 or greater to mycelial-phase antigens or the presence of 'M' or 'H' bands by immunodiffusion are also highly suggestive of histoplasmosis (Kaufmann 1971; Wheat *et al*. 1982). Histoplasmin skin testing is useful only for epidemiological purposes.

Amphotericin B remains the treatment of choice for severe, life-threatening forms of histoplasmosis. Inadequate information is available concerning the usefulness of the azoles in joint infection caused by *H. capsulatum*. However, both itraconazole (Sharkey-Mathis *et al*. 1993) and ketoconazole (National Institute of Allergy and Infectious Disease Mycoses Study Group 1985; Dismukes *et al*. 1992) have been effective in non-immunocompromised patients with other forms of this disease. In a recent non-comparative treatment trial, itraconazole (200 to 400 mg per day) was effective in 81 per cent of patients with histoplasmosis (Sharkey-Mathis *et al*. 1993). Patients with chronic pulmonary disease or less than 2 months of therapy were more likely to fail. In patients with AIDS, amphotericin B is often used to suppress the acute infection, but the majority of cases will recur without chronic suppressive therapy. For HIV-infected patients with milder disease, itraconazole alone is effective in approximately 80 per cent (Wheat *et al*. 1990)).

Cryptococcosis

C. neoformans is worldwide in distribution. Skin test surveys suggest that subclinical infection is quite common in normal hosts. Clinical disease occurs predominantly, but not exclusively, in individuals with defects in cellular immunity (Table 1). The incidence of cryptococcal disease has greatly increased because of the frequency with which patients with HIV are infected with this encapsulated yeast.

The primary pulmonary infection may be subclinical or acute, and haematogenous dissemination may result in diffuse organ involvement. Almost any organ can be involved, but the organism has a particular predilection for the brain and meninges (Perfect *et al*. 1983). Although osteomyelitis occurs in up to 10 per cent of patients with systemic disease, cryptococcal arthritis, frequently associated with areas of contiguous osteomyelitis, is rare with fewer than 25 cases reported in the literature (Bayer *et al*. 1980; Ricciardi *et al*. 1986; Stead *et al*. 1988). Most patients have severe deficits in cellular immunity, such as those with AIDS, sarcoidosis, diabetes, and renal allograft recipients (Bosch *et al*. 1994). Both gout and calcium pyrophosphate disease appear to increase the risk of cryptococcal infection in affected joints (Sinnott and Holt 1982; Ricciardi *et al*. 1986).

Although soft-tissue swelling, inflammation and frank cellulitis have been reported in cases of cryptococcal joint infection (Bunning and Barth 1984), most cases are indolent in presentation. The knee is involved in approximately 60 per cent of reported cases, followed by an equal number of cases in the sternoclavicular and acromial-clavicular joints, elbow, wrist and ankle (Table 2). Approximately one-third of the cases are polyarticular. Radiographs demonstrate an erosive arthritis and juxta-articular osteomyelitis, and computed tomographic scans often show evidence of parasynovial inflammation. Examination of the synovial fluid reveals a white blood-cell count of 200 to 20 000/mm^3, with a predominance of mononuclear cells. However, the peripheral white blood-cell count and erythrocyte sedimentation rate is often normal (Adams and McDonald 1984; Bunning and Barth 1984; Brand *et al*. 1985).

Amphotericin B should be administered as initial therapy in most cases of disseminated disease. Many experts advocate the concomitant administration of fluorocytosine for approximately 4 weeks. In order to avoid undue toxicity, serum concentrations of fluorocytosine can be monitored weekly and maintained within a

range of approximately 50 to 80 µg/ml. Once the systemic disease is under control and the joint disease is improving, consideration can be given to completing treatment with fluconazole (400 mg per day). Itraconazole may also be effective, but the data is limited. Patients with AIDS should remain on life-long suppressive maintenance therapy.

Paracoccidioidomycosis

Paracoccidioidomycosis is endemic only to areas of Central and South America where it is the most commonly encountered respiratory mycosis. *P. brasiliensis* is thermally dimorphic. As is true for the other dimorphic fungi, conidia released by the mycelial phase of the fungus are inhaled and convert to the yeast phase in the alveoli. Acute, self-limited pulmonary infection may occur, although most patients present with chronic pulmonary disease and evidence of chronic haematogenous dissemination, including painful granulomata of the skin, lymphadenopathy, and ulceration of mucous membranes (Sugar 1988). Skeletal disease occurs, but is rare (Table 1); no cases were identified in two reviews describing a total of 66 cases (Londero and Rambos 1972; Murray *et al*. 1974). A case of joint infection, with soft tissue swelling and cartilagenous destruction, has been described (Castaneda *et al*. 1985). Typical budding yeast forms were seen on examination of the synovial fluid and cultures were positive. The diagnosis is usually made on the basis of visualization of the organisms in synovial fluid or tissues, or by culture. Serological tests have been utilized with varying success. Skin tests are useful only for epidemiological surveys.

Although the disease is rarely encountered outside of endemic areas, the diagnosis should be suspected in any individual at epidemiological risk. Paracoccidioidomycosis primarily occurs in persons without evidence of immune dysfunction, but cases of severe disseminated disease have been recently described in immunosuppressed patients (Londero and Rambos 1972; Murray *et al*. 1974; Restrepo *et al*. 1976; Sugar *et al*. 1984; Sugar 1988).

Amphotericin B is effective in the treatment of disseminated paracoccidioidomycosis, although itraconazole and ketoconazole appear as effective in the treatment of milder cases (Stevens and Vo 1982; Sugar 1988; Kwon-Chung and Bennett 1992). Relapses after treatment are common, and chronic suppressive therapy with one of the azoles or a sulphonamide are therefore currently recommended.

Miscellaneous mycoses

A variety of additional fungi have been implicated in joint infections. Various species of *Aspergillus* have resulted in cases of joint infection, often associated with contiguous osteomyelitis (Tack *et al*. 1982; Denning and Stevens 1990; Cosgarea *et al*. 1993). While haematogenous dissemination of the organism was implicated in some cases, introduction of the organism into the joint space has occurred during surgical or arthroscopic procedures, or as a result of trauma.

Skeletal infections caused by *Alternaria* spp. and *Bipolaris hawaiiensis* (Sharkey *et al*. 1990), *Acremonium* spp. (Szombathy *et al*. 1988), *Cunninghamella bertholletiae* (Mostaza *et al*. 1989), *Exiophiala jeanselmei* (Roncoroni and Smayevsky 1988), *Exiophila spinifera* (Sharkey *et al*. 1990), *Fusarium solani* (Jakle *et al*. 1983), *Madurella mycetomi* (Yagi *et al*. 1983; McGinnis and Fader 1988), *Phialophora parasitica* (Kaell and Weitzman 1983), *Saccharomyces* spp. (Feld *et al*. 1982), *P. boydii* (Kemp *et al*. 1982; Ansara *et al*. 1987; Rippon 1988), and *Trichosporon beigelii* (Gardella *et al*. 1985) have also been reported.

5.3.11 Immunodeficiency

A. D. B. Webster

Introduction

Joint disease is a relatively common complication of immunodeficiency, and in the majority of cases it can be shown to be due to infection. Immunodeficiency is classified into 'primary' and 'secondary', most cases in the former category being due to inherited single or multiple gene defects, while the common forms of secondary immunodeficiency are associated with lymphoreticular neoplasia, particularly chronic lymphatic leukaemia and myeloma, or infection with the human immunodeficiency virus. It is useful to subclassify patients into those that have a predominantly antibody or cell-mediated immune deficiency, and those with severe combined immunodeficiency (see Table 1).

Table 1 Classification of immunodeficiency

Antibody deficiency

The principal diseases of the joint that may be associated with primary hypogammaglobulinaemia are shown in Table 2.

Disease	Comments
Mycoplasma arthritis	Mainly large joints but any joint can be affected
Monoarthritis of knee	Mainly in children, self-limiting
Tenosynovitis/arthralgia	Usually affects hands and feet; rapid response to immunoglobulin therapy
Echovirus disease	Flexion contractures of elbows and knees
Rheumatoid arthritis	Drugs used to treat rheumatoid arthritis may cause hypogammaglobulinaemia

Table 2 Joint disease in primary hypogammaglobulinaemia

Mycoplasma arthritis

Mycoplasmas are prokaryotic organisms which frequently infect mammals but which also occur in fish and reptiles (Taylor-Robinson 1990). There are many different types in humans, the majority colonizing mucosal surfaces and, in general, behaving as commensals. *Mycoplasma pneumoniae* is an exception, being a recognized pathogen that infects the respiratory tract causing pneumonia. Ureaplasmas, so called because they metabolize urea to ammonia, account for about a third of cases of 'non-specific' urethritis in otherwise healthy men, although the infection is usually self-limiting (Taylor-Robinson and McCormack 1980).

Mycoplasmas are normally found on mucosal surfaces and do not penetrate epithelial cells, although they may be taken up by phagocytes and remain viable within such cells (see below). When present in large numbers they do cause inflammation, possibly through direct activation of complement. Different strains have become adapted to different systems within the body: for instance ureaplasmas are mainly found in the urinary tract.

The first descriptions of mycoplasmas in the joints of patients with hypogammaglobulinaemia were published in 1978 (Stuckey *et al*. 1978; Webster *et al*. 1978), but even now there are some sceptics who suggest that the organisms may not cause the arthritis, but are merely 'passengers' in an immunocompromised host. This view stems from the early claim that patients with hypogammaglobulinaemia are prone to rheumatoid arthritis, as well as other autoimmune rheumatic disorders (Good *et al*. 1957). Most of the investigators involved in these early studies now concede that they were probably dealing with an infective arthritis. Surprisingly, mycoplasma arthritis has only been described so far in the primary hypogammaglobulinaemias (e.g. X-linked agammaglobulinaemia and 'common variable' immunodeficiency; see 'rheumatoid arthritis' below), and not in the secondary types associated with chronic lymphatic leukaemia and myeloma. Although cases may have been missed, the severity of the antibody deficiency may not be enough to predispose to systemic mycoplasma infection in the secondary immunodeficiencies. There are anecdotal reports of mycoplasma septicaemia and/or arthritis in patients on immunosuppressive drugs or following severe trauma, but, surprisingly, most of these patients were not investigated for immunoglobulin deficiency. Although there are claims that mycoplasmas may act as cofactors in the mechanism of the immune deficiency in acquired immune deficiency syndrome (**AIDS**), joint disease has not been described, although chronic mycoplasma infection of the kidneys may contribute to the characteristic nephropathy seen in AIDS (Bauer *et al*. 1991).

The evidence that mycoplasmas are a common cause of arthritis in hypogammaglobulinaemia can be summarized as follows. The organisms can consistently be

isolated in high titre from the joint during the active phase; the symptoms usually improve rapidly when antibiotics are given to which the organism is sensitive, and chronic arthritis with joint destruction occurs when antibiotic-resistant organisms are involved. Finally, some patients with severe, generalized infections develop discharging sinuses, often communicating with joints, from which mycoplasmas can be isolated (Taylor-Robinson *et al*. 1985).

Origin of infection

Ureaplasmas are commonly present in the vagina of pregnant women, and it is thought that most neonates become colonized in the respiratory tract shortly after birth, although the organisms then disappear through mechanisms that are not understood (Taylor-Robinson and McCormack 1980). In later life, colonization of the urinary tract may occur from sexual intercourse, and since about a third of healthy women are persistently colonized, most men are exposed to these organisms. Colonization is usually transient and asymptomatic, although a minority of men will develop urethritis. In contrast, there is a high incidence of symptomatic ureaplasma urethritis in both men and women with hypogammaglobulinaemia, which may progress to a chronic cystitis and occasionally pyelonephritis (Webster *et al*. 1981). Fibrosis of the bladder wall with contraction may be the end result of chronic infection. Many patients with hypogammaglobulinaemia who develop ureaplasma arthritis have previously suffered from an episode of urethritis, so it is likely that the origin of the infection is in the urinary tract. Trauma to a joint, which may be minor, often triggers the septic arthritis, suggesting that the organisms are present in small numbers in the circulation and become established at an inflammatory focus within the joint. Once one joint has been infected, there is a tendency for other joints to follow if the infection is not eliminated with appropriate antibiotics. Roifman *et al*. (1986) have suggested that ureaplasmas may cause chronic bronchitis in antibody deficient patients, and although this issue is controversial, the lungs may be a source of systemic infection.

Apart from *M. pneumoniae*, which is acquired by droplet inoculation from an infected person, two other mycoplasmas have been cultured from the inflamed joints of patients with hypogammaglobulinaemia. *M. hominis*, like ureaplasmas, is a commensal in the urinary tract, and is usually acquired through sexual contact. The 10 per cent of 'healthy' women with bacterial vaginosis have particularly heavy colonization of their vaginas with *M. hominis* (Hillier and Holmes 1990); antibody deficient women with this problem may have an increased risk of *M. hominis* arthritis. Women presenting with *M. hominis* arthritis should therefore be tested for bacterial vaginosis and if necessary be given metronidazole to eliminate the bacteria; this should reduce the risk of further systemic spread of the mycoplasma infection. We have seen dual infection in a joint with *M.hominis* and *Ureaplasma urealyticum* in one patient. *M. salivarium* has also been isolated from the joints of a few patients, presumably originating from the upper respiratory tract where it is found in the saliva of about 80 per cent of healthy individuals (So *et al*. 1982). This organism is unequivocally regarded as a commensal and is a good example of commensal overgrowth leading to disease in an immunocompromised host.

Clinical features

Large joints are usually affected, particularly the knees, although the ankles, hips, shoulders, and wrists (including carpal bones) are frequently involved in persistent infections. The fingers and toes are rarely affected, and when this does occur it usually involves a single interphalangeal joint. The initial symptoms are swelling and stiffness of the affected joint, usually with an obvious effusion when the knee is involved. Nodules may occur on the elbows that have the same histological features as classical rheumatoid nodules. Systemic symptoms are rare and there is usually no fever or blood leucocytosis. Joint pain increases over a few weeks or months, and if the infection persists the synovium will gradually deteriorate through chronic inflammation, leading eventually to fibrosis and fixation of the joint (Fig. 1). This sequence usually takes months, or sometimes years, to reach a conclusion if inappropriate or no treatment is offered.

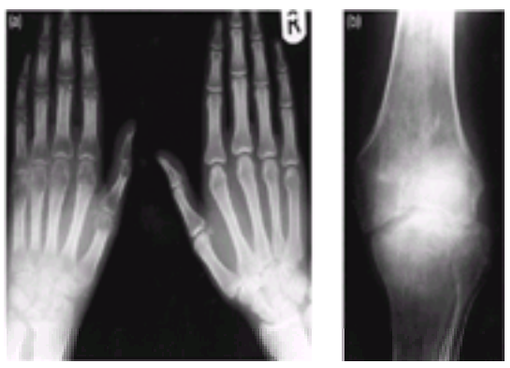

Fig. 1 (a) Chronic infection with *Ureaplasma urealyticum* of the wrist in a 30-year-old man with X-linked agammaglobulinaemia, showing destruction of the left distal ulna, the medial radius, and lunate, with osteoporosis of all joint levels related to disuse. (b) The left knee of the same patient showing destruction of the cartilage, obliteration of the joint space, and disorganization of the joint.

Some patients may enter a severe phase, presumably reflecting high levels of circulating organisms. Subcutaneous abscesses may then occur, sometimes at sites of minor trauma (e.g. injection sites), but more often adjacent to joints; the skin then breaks down leaving a chronically discharging sinus in communication with the joint space. Even at this relatively late stage, the patient may show no systemic effects of chronic infection, apart from being immobilized and in considerable pain.

Diagnosis

Organisms can be cultured from the synovial fluid, provided that appropriate techniques are used, although cultures may be negative if the patient has recently been treated with antibiotics, particularly erythromycin and tetracyclines. Unfortunately, there are only a few laboratories in the world that are in a position routinely to culture mycoplasmas, despite the fact that the techniques required are relatively straightforward. It should be be remembered that the diagnosis of *M. pneumoniae* infection in immunocompetent patients is usually made retrospectively by positive serology, which is obviously inappropriate in patients with hypogammaglobulinaemia. There are some routine laboratories that will culture for *M. pneumoniae*, although these organisms are slow growing and may take up to 2 weeks to show a positive result. Ureaplasmas, *M. hominis*, and *M. salivarium* need different media, and a positive result can be obtained in 48 h. Organisms can also be isolated from the pus of discharging sinuses, and from synovial tissue removed at biopsy.

Synovial fluid should always be sent for the routine culture of common pathogens, such as staphylococci and *Haemophilus influenzae*, which may rarely cause arthritis in patients with hyogammaglobulinaemia. Microscopic examination of the fluid is not very helpful unless it is clear with a predominant lymphocytosis, in which case mycoplasma arthritis is unlikely. The fluid is usually yellow and/or turbid, and contains many neutrophils. If the routine culture is negative, then the working diagnosis should be mycoplasma arthritis until proved otherwise. Occasionally, there may be confusion between mycoplasma arthritis and other types of arthropathy (see below) that have a raised incidence in patients with hypogammaglobulinaemia. In particular, rheumatoid arthritis in its early stages can be confused with mycoplasma infection, although multiple involvement of finger joints is very much against the latter.

Management

Patients should be given doxycycline as soon as synovial fluid has been aspirated. We use doxycycline intravenously (Pfizer) at a dose of 200 mg at once, followed by 100 mg/day until there is improvement in joint swelling and the level of serum C-reactive protein has become normal, which is a useful marker of disease activity. Treatment should then continue with oral doxycycline at 100 mg/day for at least 3 months. Fortunately, most mycoplasma strains are sensitive to doxycycline and there will be obvious improvement in the joint symptoms within a few days. However, it is useful to arrange sensitivity tests against a range of antibiotics as soon as possible, because occasionally the organism may be resistant. Sensitivity tests should include erythromycin, streptomycin, doxycycline, kanamycin, clindamycin, spectinomycin, netilmicin, ciprofloxacin, and azithromycin, the last being a new macrolide that accumulates in phagocytes, a property which may be of particular advantage in eradicating mycoplasmas. In our experience, patients who are infected with a doxycycline-resistant strain are very difficult to manage and usually progress to multi-joint involvement despite various combinations of other antibiotics. However, it is important to test regularly the antibiotic sensitivities of new isolates from joint aspirates in order to keep pace with any changes. Although this can be time consuming for the laboratory, there is a good chance that eventually the infection can be eradicated.

All antibiotics so far tested are static, and consequently long-term therapy is required (Escalante *et al*. 1985). Surgical interference of the joint should be kept to a minimum; arthroscopy and washing out the joint with saline is unhelpful, although drainage under vacuum of a very tense effusion for 24 h may rarely be necessary.

Trauma from surgical interference appears to increase the growth of mycoplasmas, as well as increasing the risk of sinus formation. The joints should be immobilized until there is no longer any swelling, and then if there is damage to the ligaments, the joint must be stabilized by splinting until there is full recovery. Provided the diagnosis is made early and the mycoplasmas are sensitive to tetracyclines, there is usually full recovery.

Patients who steadily deteriorate in spite of treatment with a wide range of antibiotics should be considered for therapy with hyperimmune serum. Unfortunately, regular treatment with intravenous human immunoglobulin has little effect on eradicating mycoplasma infection, because the specific antibody levels are so low in these preparations. However, intravenous human immunoglobulin may have some protective effect against infection. In our series of 18 patients with primary immunodeficiency and mycoplasma arthritis, most presented before treatment with intravenous human immunoglobulin, and in those who developed infection after treatment their trough levels of serum IgG were below 5 g/l (Franz *et al*. 1997). It is therefore reasonable to treat infected patients with high-dose, intravenous, human immunoglobulin (i.e. 400 mg/kg per week for 8 weeks), and as a prophylactic measure it is our policy to keep serum IgG levels above 7 g/l.

We have successfully treated two patients with goat serum taken from animals hyperimmunized with the patient's particular strain (Taylor-Robinson *et al*. 1985). Fortunately, serum sickness does not occur in patients with hypogammaglobulinaemia, who can tolerate repeated infusions of animal serum. The amount of serum given is somewhat arbitrary, and there are no standard immunization schedules for goats. We have raised titres in excess of 1:5000 by first subcutaneously injecting a mycoplasma concentrate in Freund's complete adjuvant, followed by intravenous injections of the concentrate alone at 4-week intervals. It may be better to immunize rabbits using published schedules that are known to produce very high titres of antisera (i.e. $1:10^{5}$), which might compensate for relatively small amounts of serum obtainable.

Monoclonal antibodies are not yet available, and anyway may have to be raised specifically against the infecting organism because of considerable strain variation in exposed antigenic epitopes. Nevertheless, this is worth considering early in a patient who is difficult to treat, as it will take many months to raise enough antibody.

Role of antibodies in protection against mycoplasmas

The clinical observations on patients with hypogammaglobulinaemia clearly demonstrate that antibodies are important in protection against mycoplasma arthritis. *In vitro* experiments have shown that the growth of mycoplasmas is readily inhibited by specific antibody, and that, even in the absence of antibody, mycoplasmas will activate the first component of complement. In turn this will activate the complement cascade and split C3, generating opsonic complement, which enables the organisms to be taken up by neutrophils (Webster *et al*. 1988). However, once within the neutrophil phagolysosome the organisms remain viable, and it is likely that neutrophils transport organisms from mucosae to the joints. The factors that encourage mycoplasma growth within the joints are unknown. It is likely, therefore, that the main function of specific antibodies against mycoplasmas is to control their growth on the mucosal surface. Massive overgrowth of organisms occurs in the absence of antibody. The result is inflammation, with influx of neutrophils and macrophages, followed by phagocytosis of large numbers of mycoplasmas which initiate chronic infection in a susceptible joint.

Bacterial septic arthritis

Patients with hypogammaglobulinaemia are prone to septicaemia and pneumonia due to pneumococci, non-typeable *H. influenzae*, and staphylococci, any of which can occasionally cause septic arthritis (Asherson and Webster 1980). However, in contrast to mycoplasma arthritis, bacterial arthritis is usually more acute and painful. Bacterial arthritis is extremely rare in patients already established on replacement immunoglobulin therapy, whereas mycoplasma infection still occurs.

Rheumatoid arthritis

Early reports suggested that there was a high incidence of rheumatoid arthritis in patients with hypogammaglobulinaemia, including those with X-linked agammaglobulinaemia (Good *et al*. 1957). However, it now seems likely that many of these patients suffered from mycoplasma arthritis. Nevertheless, rheumatoid arthritis does occur in patients with 'common variable' immunodeficiency, at a frequency of about 2 per cent in our series. It is often difficult to ascertain whether the arthritis precedes or follows the onset of hypogammaglobulinaemia, and there is the added complication that a number of drugs used to treat rheumatoid arthritis (see below) are known to 'cause' or 'trigger' hypogammaglobulinaemia (So *et al*. 1984). Nevertheless, there are patients whose hypogammaglobulinaemia clearly precedes the onset of classical rheumatoid arthritis, with the typical involvement of small joints of the hand, rheumatoid nodules, and gradual destruction of small and large joints. These patients are seronegative for rheumatoid factor and other relevant autoantibodies. This in itself is interesting, because it demonstrates that severe rheumatoid arthritis can occur and progress in the absence of autoantibodies, and supports the view that the disease is driven by cellular interactions.

Drug-associated hypogammaglobulinaemia

Gold, penicillamine, sulphasalazine, and phenytoin have been associated with hypogammaglobulinaemia, and partly explain the apparent raised incidence of rheumatoid arthritis and Still's disease in patients with selective IgA deficiency and other types of hypogammaglobulinaemia (Barclay *et al*. 1979). The immunoglobulin levels usually return to normal after withdrawal of the drug, although this may take many months or even years. The mechanism is unclear, and may be different for the four drugs. In the case of gold, there is evidence that the drug inhibits T-cell proliferation *in vitro* at concentrations likely to be found in tissues (Lipsky and Ziff 1977), but there is no evidence that it affects B-cell differentiation and immunoglobulin synthesis *in vitro*, even when cells are used from patients who have recovered from drug-associated hypogammaglobulinaemia (S. Sukram and A. D. B. Webster, unpublished). One possibility is that the drugs induce 'common variable' immunodeficiency in patients who have genetic predisposing factors for this disease. In this context, it is not yet known whether drug-associated hypogammaglobulinaemia is linked to the same susceptibility genes for common variable immunodeficiency which are located in the class II and III region on chromosome 6 (Schaffer *et al*. 1989; Howe *et al*. 1991).

Miscellaneous arthritides associated with hypogammaglobulinaemia

Chronic arthritis of the knee

Children with hypogammaglobulinaemia, particularly those with X-linked agammaglobulinaemia, are prone to a chronic insidious arthritis of the knee, which is usually unilateral. There is a chronic and relatively painless effusion, which may persist for many years, sometimes with hypertrophy of the epiphyseal cartilage (Fig. 2). The condition usually recovers spontaneously after a few months or years, leaving very little permanent damage apart from the unsightly appearance of enlarged condyles. Some damage to the cartilage may necessitate menisectomy in later years.

Fig. 2 Epiphyseal hypertrophy in the right knee of a 3-year-old boy with X-linked agammaglobulinaemia. There was a sterile effusion; the knee subsequently improved spontaneously.

The synovial fluid is colourless and contains mainly lymphocytes; it is sterile when cultured for bacteria, viruses, and mycoplasmas. Nevertheless, there is still a possibility that this is a low-grade mycoplasma infection, although antimycoplasma drugs such as doxycycline or erythromycin have no effect. Anti-inflammatory drugs

are often useful.

Our impression is that this complication is much less common since the introduction of intravenous immunoglobulin therapy in children with hypogammaglobulinaemia, and in one of our cases the arthritis improved after such therapy.

Chronic tenosynovitis/arthritis

This condition was relatively common in British patients with hypogammaglobulinaemia in the 1970s but is now very rare (Webster *et al*. 1976). It usually occurred in adult patients with 'common variable' immunodeficiency as one of the presenting features of the disease. The usual pattern was of a patient suffering from recurrent respiratory infections for many years, who then developed stiffness in the wrists, elbows, and ankles, with swelling of the tendon sheaths on the dorsal aspects of the wrist, hands, and feet. This sometimes led to tendon tethering with cystic swellings that required surgery. The arthritis was usually mild and fluctuating.

The condition was frequently confused with rheumatoid arthritis, but there were no bony erosions. Furthermore, the condition dramatically improved with intramuscular immunoglobulin therapy, suggesting an infectious cause, perhaps by a virus that was neutralized by antibodies in the immunoglobulin therapy. These cases are very rare nowadays in the United Kingdom, although some patients still suffer from mild, fluctuating arthropathy while on intramuscular or intravenous immunoglobulin therapy, which may represent a mild form of the same condition. One of our patients developed tenosynovitis and arthropathy while on intramuscular therapy, but rapidly improved when given intravenous therapy. Finally, it is possible that this condition is caused by low-level mycoplasma infection, as one of our patients initially responded to intravenous immunoglobulin and then relapsed with a confirmed mycoplasma infection which then responded to doxycycline.

Echovirus disease

Patients with severe primary antibody deficiency are prone to chronic echovirus infection of the central nervous system and muscles, and there are reports of arthritis in a few patients (McKinney *et al*. 1987). This is a 'slow' virus disease that mainly affects small vessels in the meninges, subcutaneous tissues, and muscles, leading in the muscles to fibrosis with a 'woody' sensation on palpation. The arms and legs are predominantly affected, and the muscle fibrosis can lead to flexion contractures at the knee and elbows, sometimes producing a characteristic stooped posture (Webster 1984). An erythematous rash may occur transiently, which, together with the subcutaneous oedema, was responsible for the early references to a 'dermatomyositis-like syndrome'. This was thought to provide further evidence that patients with hypogammaglobulinaemia had a predisposition to 'connective tissue disorders'.

The virus can usually be cultured from the cerebrospinal fluid, but occasionally cultures are repeatedly negative and molecular techniques are required to identify viral RNA (Webster *et al*. 1993). The treatment is unsatisfactory, although regular intravenous infusions with high titre, hyperimmune plasma can stabilize the disease, and in a few cases it may have eradicated the infection. Regular injection directly into the cerebrospinal fluid via an Omaya reservoir of pooled immunoglobulin, suitable for intravenous use and preferably with a reasonable titre to the relevant echovirus strain, has been associated with remission in a few patients (McKinney *et al*. 1987). However, most patients gradually deteriorate, sometimes with episodes of partial remission, and ultimately die from involvement of a critical centre in the brain.

Chronic echovirus disease is much less common in the United Kingdom than it was in the 1970s, probably reflecting the increased use of intravenous immunoglobulin during the 1980s. Because each batch of intravenous immunoglobulin is made from a pool of about 20 000 donors, it is likely that significant amounts of antibody to most enteroviral strains are present in these preparations. It is therefore important to maintain serum IgG levels above 7 g/l, particularly in young children with immunodeficiency who may be more susceptible to enteroviruses. This may be difficult to achieve in infants with poor venous access for regular intravenous immunoglobulin therapy. Regular subcutaneous infusions are becoming more popular in this age group but regular monitoring is needed to ensure an adequate serum level.

Defects in cellular immunity

There are a variety of primary defects in cellular immunity, ranging from highly selective T-cell defects to severe combined immunodeficiency. The survival of patients suffering from the latter depends on a successful bone marrow graft (Morgan *et al*. 1987). The best example of a secondary defect in cellular immunity is AIDS, which clinically closely resembles severe combined immunodeficiency. Although patients with selective T-cell defects are not prone to septic or other types of arthritis, those with severe combined immunodeficiency are prone to a wide range of infections, some leading to septic arthritis.

Complement deficiencies

Septic arthritis following pneumococcal, meningococcal, or gonococcal infection may occur in patients with genetically determined homozygous complement deficiencies (Rother 1986). Children with homozygous C2 deficiency, which occurs in about 1 in 10 000 of the population, are prone to pneumococcal and *H. influenzae* septicaemia, which may be associated with septic arthritis (see Chapter 5.3.2). However, some affected individuals are not prone to infection, presumably because they have other unknown host defence factors against these organisms. Once a patient has developed a septicaemia, it is usually appropriate to recommend regular, prophylactic, oral penicillin therapy, as well as advising the patient to take a broader-spectrum antibiotic (e.g. amoxicillin/clavulanic acid complex) in the event of illness. Patients with defects in other complement components, particularly the late components C7 and C8, are prone to neisserial septicaemia, and occasionally septic arthritis. Prophylactic penicillin may be appropriate for them.

Neutrophil defects

Chronic granulomatous disease (CGD) is one of the primary neutrophil defects described in which joints may be involved, although both primary and secondary neutropenia predisposes to septic arthritis and osteomyelitis, particularly due to staphylococci (White and Gallin 1986). In CGD affected patients are prone to chronic infection with catalase-positive organisms (e.g. salmonella, staphylococci, *Serratia marcescens*), usually causing chronic suppuration of lymph glands with draining sinuses. Staphylococcal and salmonellal osteomyelitis may sometimes occur, although involvement of the joints is very rare.

5.3.12 Rheumatic fever

Allan Gibofsky and John B. Zabriskie

Introduction

Acute rheumatic fever is a delayed, non-suppurative sequel to a pharyngeal infection with the group A streptococcus. Following the initial streptococcal pharyngitis, there is a latent period of 2 to 3 weeks. The onset of disease is usually characterized by an acute febrile illness, which may show itself in one of three classical ways: (i) the patient may present with migratory arthritis predominantly involving the large joints; (ii) there may be concomitant clinical and laboratory signs of carditis and valvulitis; (iii) there may be involvement of the central nervous system, manifesting itself as Sydenham's chorea. The clinical episodes are self-limiting but damage to the valves may be chronic and progressive, resulting in cardiac decompensation and death.

Although there has been a dramatic decline in both the severity and fatality of the disease since the turn of the century, there are recent reports of its resurgence in the United States (Veasy *et al*. 1987) and in many military installations in the world, reminding us that it remains a public health problem even in developed countries. In addition, the disease continues essentially unabated in many of the developing countries: estimates suggest there will be 10 to 20 million new cases per year in those countries where two-thirds of the world population lives.

Epidemiology

The incidence of rheumatic fever actually began to decline long before the introduction of antibiotics into clinical practice, decreasing, for example, from 250 to 100 patients/100 000 population from 1862 to 1962 in Denmark (Gordis 1985). The introduction of antibiotics in 1950 caused a rapid acceleration of this decline, until in 1980 the incidence ranged from 0.23 to 1.88 patients per 100 000, primarily children and teenagers. A notable exception has been in the Hawaii and Maori populations (both of Polynesian ancestry), where the rate continues to be 13.4/100 000 children admitted to hospital per year (Pope 1989).

As reviewed by Markowitz (1987), only a few M-streptococcal serotypes (types 5, 14, 18, 24) have been implicated in outbreaks of rheumatic fever, suggesting there could be a particular 'rheumatogenic' potential of certain strains of group A streptococci. However, in Trinidad, types 41 and 11 have been the most common strains isolated from rheumatics. In our own series, gathered over 20 years (see Table 1), a large number of different M serotypes were isolated, including six strains that were not typable. Kaplan *et al*. (1989) found that several different M types were isolated from the patients seen during an outbreak of rheumatic fever, and that these strains were both mucoid and non-mucoid in character. Whether or not certain strains are more 'rheumatogenic' than others remains unresolved. What is true, however, is that a streptococcal strain capable of causing a well-documented pharyngitis is almost always potentially capable of causing rheumatic fever, although some notable exceptions have been recorded (reviewed by Whitnack and Bisno 1980).

M type	RHD	No RHD	Total
Non-typable	1	5	6
1	1	1	2
2	0	1	1
5	1	1	2
6	1	1	2
12	0	2	2
18	2	2	4
19	2	1	3
28	1	0	1
TOTAL	9	11	23

RHD, patients with rheumatic heart disease; no RHD, patients without rheumatic heart disease.

Table 1 Positive throat cultures—group A b-haemolytic streptococci (Rockefeller University Hospital, rheumatic fever patients; *n* = 87)

Pathogenesis

There is little evidence for the direct involvement of group A streptococci in the affected tissues of patients with acute rheumatic fever, but there is a large body of epidemiological and immunological evidence indirectly implicating the group A streptococcus in the initiation of the disease process. For example, (i) it is well known that outbreaks of rheumatic fever closely follow epidemics of either streptococcal sore throats or scarlet fever (Whitnack and Bisno 1980), (ii) adequate treatment of a documented streptococcal pharyngitis markedly reduces the incidence of subsequent rheumatic fever (Denny *et al*. 1950), (iii) approximate antimicrobial prophylaxis prevents recurrences of the disease in patients known to have had acute rheumatic fever (Markowitz and Gordis 1972), and (iv), if one tests the serum of the majority of patients with acute rheumatic fever for three antistreptococcal antibodies (streptolysin O, hyaluronidase, and streptokinase), the vast majority of samples (whether or not the patients recall an antecedent streptococcal sore throat) will have elevated antibody titres to these antigens (Stollerman *et al*. 1956).

A note of caution is necessary concerning the documentation (either clinical or microbiological) of an antecedent streptococcal infection. The rate of isolation of group A streptococci from the oropharynx is extremely low, even in populations who generally do not have access to microbial antibiotics. Further, there appears to be an age-related discrepancy in the clinical documentation of an antecedent sore throat. In older children and young adults, the recollection of a streptococcal sore throat approaches 70 per cent; in younger children, it approaches only 20 per cent (Veasy *et al*. 1987). Thus, it is important to have a high index of suspicion of acute rheumatic fever in children or young adults presenting with signs of arthritis and/or carditis, even in the absence of a clinically documented sore throat.

Another intriguing, and as yet unexplained, observation has been the invariable association of rheumatic fever only with streptococcal pharyngitis rather than other streptococcal lesions. While there have been many outbreaks of impetigo, rheumatic fever almost never follows infection with these impetigo strains. Furthermore, as Potter *et al*. (1978) have pointed out, in Trinidad, where both impetigo and rheumatic fever are concomitant infections, the strains colonizing the skin are different from those associated with rheumatic fever, and did not influence the incidence of acute rheumatic fever.

These observations remain inexplicable. It is clear that group A streptococci fall into two main classes based on differences in the C-repeat regions of the M protein (Bessen *et al*. 1989). One class is clearly associated with streptococcal pharyngeal infection, the other (with some exceptions) belongs to strains commonly associated with impetigo. Thus, the particular strain of streptococcus may be crucial in initiating the disease process. The pharyngeal site of infection, with its large repository of lymphoid tissue, may also be important in the initiation of the abnormal humoral response by the host to those antigens cross-reactive with target organs (see below). Finally, while impetigo strains do colonize the pharynx, they do not appear to elicit as strong an immunological response to the M-protein moiety as do the pharyngeal strains (Kaplan *et al*. 1970; Bisno and Nelson 1975). This may prove to be an important factor, especially in light of the known cross-reactions between various streptococcal structures and mammalian proteins.

Group A streptococcus

Figure 1 is a schematic cross-section of the group A streptococcus. The capsule is composed of equimolar concentrations of *N*-acetyl glucosamine and glucuronic acid, and is structurally identical to hyaluronic acid of mammalian tissues (Kendall *et al*. 1937).

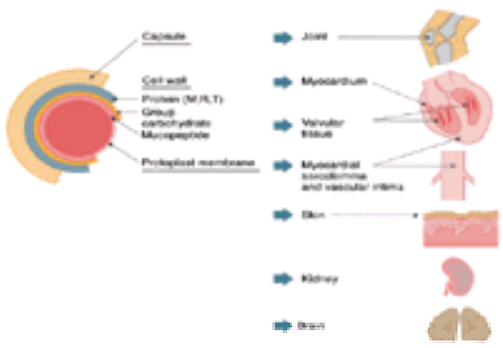

Fig. 1 Schematic representation of the various structures of the group A streptococcus. Note the wide variety of cross-reactions between its antigens and mammalian tissues.

Numerous past attempts to demonstrate antibodies to this capsule were unsuccessful (Seastone 1939; Quinn and Singh 1957). More recently, Fillit *et al*. (1986) successfully demonstrated high titres to hyaluronic acid, using techniques designed to detect non-precipitating antibodies in the serum of animals. Similar antibodies have been found in man (Faarber *et al*. 1984). Almost no published data implicate this capsule as important in human infections, although Stollerman (1975) commented on the presence of a large mucoid capsule as one of the more important characteristics of certain 'rheumatogenic' strains.

Investigations by Dr Rebecca Lancefield and others, spanning almost 70 years (reviewed by Fischetti 1989), have established that the M-protein molecule (at least 80 distinct serological types) is perhaps the most important virulence factor in human group A streptococcal infections. The protein is a helical, coiled-coil structure; it has striking structural homology with the cardiac cytoskeletal proteins tropomyosin and myosin, as well as with many other coil-coiled structures like keratin, DNA, lamin, and vimentin.

Once the amino acid sequence of a number of M proteins became known, it was possible to localize specifically those cross-reactive areas. The studies of Dale and Beachey (1985) showed that the part of the M protein involved in the opsonic reaction also cross-reacted with human sarcolemmal antigens. Sargent *et al*. (1987) more precisely localized this cross-reaction to the M-protein amino acid residues 164–197.

The evidence implicating these cross-reactions in the pathogenesis of acute rheumatic fever remains scant. Antibodies to myosin have been detected in the serum of patients with acute rheumatic fever, but they are also present in a large percentage of sera obtained from individuals who have had a streptococcal infection but did not subsequently develop acute rheumatic fever (Cunningham *et al*. 1988). The significance of this observation is unclear, since myosin is an internal protein of cardiac muscle cells and therefore not easily exposed to M-protein cross-reacting antibodies.

The group-specific carbohydrate of the streptococcus is a polysaccharide chain consisting of repeating units of rhamnose capped by *N*-acetyl glucosamine molecules. The *N*-acetyl glucosamine is immunodominant and gives rise to the serological group specificity of group A streptococci (McCarty 1970). The cross-reaction between group A carbohydrate and valvular glycoproteins was first described by Goldstein *et al*. (1968), and the reactivity was related to the *N*-acetyl glucosamine moiety present in both structures. Goldstein and Caravano (1967) noted that serum from patients with rheumatic fever reacted with the heart-valve glycoprotein. More recently, H. M. Fillit (personal communication) has observed strong reactivity of such sera with purified proteoglycan material. Thus, these cross-reactions could involve the sugar moiety present in both the proteoglycan portion of the glycoprotein and the carbohydrate.

It has always been assumed that group A anticarbohydrate antibodies did not play a part in the phagocytosis of group A streptococci. However, the studies of Salvadori *et al*. (1995) have demonstrated that human serum containing high titres of anti-group A carbohydrate antibody were opsonophagocytic for a number of different M-protein-specific strains, and that the opsonophagocytic properties were directed to the *N*-acetyl glucosamine moiety of the group A carbohydrate.

The mucopeptide portion of the cell wall is the 'backbone' of the organism and thus rather rigid in structure. It is composed of repeating units of muramic acid and *N*-acetyl glucosamine, cross-linked by peptide bridges (Chetty and Schwab 1984). It is particularly difficult to degrade and induces a wide variety of lesions when injected into various species, including arthritis in rats (Cromartie *et al*. 1977) and myocardial granulomas in mice that resemble (but are not identical to) lesions in rheumatic fever (Cromartie and Craddock 1966).

The connection between cell-wall mucopeptides and the pathogenesis of rheumatic fever remains obscure. Elevated titres of antimucopeptide antibody have been detected in the serum of patients with acute rheumatic fever, and also in the serum of patients with rheumatoid and juvenile rheumatoid arthritis (Heymer *et al*. 1976), but their pathogenetic relation to the clinical disease has been difficult to establish. There is no evidence that cell-wall antigens are present either in the Aschoff lesion or in the myocardial tissue obtained from patients with rheumatic fever.

Perhaps the most significant cross-reactions lie in the streptococcal membrane structure. We have shown (Zabriskie 1985) that immunization with membrane material elicited antibodies that bound to sections of heart in a pattern similar to that observed with serum from acute rheumatic fever (see Fig. 2).

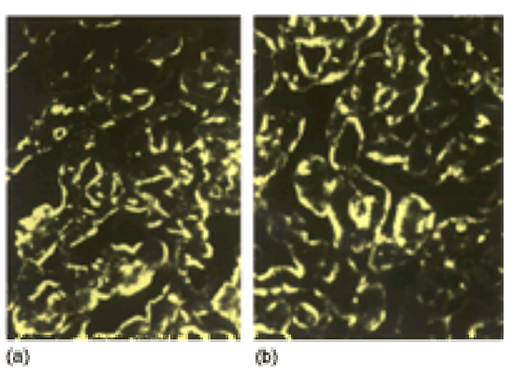

Fig. 2 Photomicrographs of immunofluorescent staining of heart sections with (a) rabbit serum immunized with group A streptococcal membranes and (b) serum obtained from a patient with acute rheumatic fever. Note the identical sarcolemmal staining patterns of both sera.

Kingston and Glynn (1971) were the first to show that animals immunized with streptococcal antigens develop serum antibodies that stain astrocytes. Husby *et al*. (1976) demonstrated that serum from patients with acute rheumatic fever with chorea contains antibodies that were specific for caudate cells. Absorption of the serum with streptococcal membrane antigens eliminated the reactivity with caudate cells.

Numerous other cross-reactions between streptococcal membranes and other organs have also been reported, for example renal basement membranes, basement membrane proteoglycans, and skin, particularly keratin. Here, space does not permit an exhaustive discussion of these cross-reactions, and the reader is referred to our recent review (Froude *et al*. 1989) for more detail. Whether or not these cross-reactions (especially those seen with basement membranes and skin) play a part in the disease awaits further study.

Genetics

The concept that rheumatic fever might be the result of a host genetic predisposition has intrigued investigators for over a century (Cheadle 1889). It has been variously suggested that the disease gene is transmitted in an autosomal-dominant fashion (Wilson *et al*. 1943), an autosomal-recessive fashion with limited penetrance (Taranta *et al*. 1959), or that it is possibly related to the genes conferring blood-group secretor status (Glynn and Holborow 1961).

Renewed interest in the genetics of rheumatic fever came with the recognition that gene products of the human major histocompatibility complex (**MHC**) were associated with certain clinical disease states. Using an alloserum from a multiparous donor, an increased frequency of a B-cell alloantigen was reported in several genetically distinct and ethnically diverse populations of individuals with rheumatic fever, and was not MHC-related (Patarroyo *et al*. 1979).

Most recently, studies were accomplished with a monoclonal antibody (D8/17) prepared by immunizing mice with B cells from a patient with rheumatic fever (Khanna *et al*. 1989). This B-cell antigen was expressed on increased numbers of B cells in 100 per cent of rheumatics of diverse ethnic origin, and only in 10 per cent of normal individuals. The antigen defined by this monoclonal antibody showed no association with, or linkage to, any of the known MHC haplotypes, nor did it appear to be related to B-cell activation antigens.

These findings are in contrast to reports of an increased frequency of HLA-DR4 and HLA-DR2 in white and black patients with rheumatic heart disease (Ayoub *et al*. 1986). Other studies have implicated HLA-DR1 and -DRW6 as susceptibility factors in Black South African patients with rheumatic heart disease (Maharaj *et al*. 1987). Most recently, Guilherme *et al*. (1991) have noted a close association of HLA-DR7 and -DW53 with rheumatic fever in Brazil. These apparently differing results concerning HLA antigens and susceptibility to rheumatic fever prompt speculation that the reported associations might involve genes close to, but not identical with, an unknown gene for that susceptibility. Alternatively, and more likely, susceptibility to acute rheumatic fever is polygenic, and the D8/17 antigen might be associated with only one of the genes (i.e., those of the MHC complex encoding for DR antigens) conferring susceptibility. While the explanation remains to be determined, it is none the less true that the presence of the D8/17 antigen appears to identify a population at special risk for contracting acute rheumatic fever.

Aetiological considerations

While a large body of evidence, both immunological and epidemiological, has implicated the group A streptococcus in the induction of the disease process, the exact pathological mechanisms involved still remain obscure. At least three main theories have been proposed.

The first is concerned with the question of whether persistence of the organism is important. Despite several controversial reports, no investigators have been able consistently to demonstrate live organisms in cardiac tissues or valves in rheumatic fever (Watson *et al*. 1961).

The second theory revolves around the question of whether the deposition of toxic products is required. Although an attractive hypothesis, little or no experimental evidence has been obtained in its support. For example, Halbert *et al*. (1961) suggested that streptolysin O (an extracellular product of group A streptococci) is cardiotoxic and might be carried to the site by circulating complexes containing streptolysin O and antibody. However, in spite of an intensive search for these products (J. B. Zabriskie, unpublished data), no such complexes have been identified *in situ* (Wagner 1960).

Renewed interest in these extracellular toxins has recently emerged with the observation by Schlievert *et al*. (1987) that certain streptococcal pyrogenic toxins (A and C) may act as superantigens. These antigens may stimulate large numbers of T cells through their unique interaction between MHC class II and T-cell receptors of specific V_b types. This interaction does not involve the usual concept of antigen presentation in the context of the MHC complex. Once activated, these cells induce the production of tumour necrosis factor, interferon-g, and a number of interleukin moieties, thereby contributing to the initiation of pathological damage. Furthermore, it has been suggested (Paliard *et al*. 1991) that in certain disease states such as rheumatoid arthritis, autoreactive cells of specific V_b lineage may 'home' to the target organ. Although an attractive hypothesis, no data on the role of these superantigens in rheumatic fever have as yet emerged.

Perhaps the best evidence to date favours the concept that, in the genetically susceptible individual, there is an abnormal host immune response (both humoral and cellular) to those streptococcal antigens cross-reactive with mammalian tissues. The evidence supporting this concept may be divided into three broad categories as follows.

1. Employing a wide variety of methods, numerous investigators have documented the presence of heart-reactive antibodies in serum from rheumatic fever. The incidence of these antibodies has varied from a low of 33 per cent to a high or 85 per cent in various series. While these antibodies are seen in other individuals (notably those with uncomplicated streptococcal infections and patients with post-streptococcal glomerulonephritis), the titres are always lower than in rheumatic fever and decrease with time during the convalescent period (Zabriskie 1985).
2. Serum in rheumatic fever also contains higher titres of antibodies to both myosin and tropomyosin than serum from patients with uncomplicated streptococcal infections. These myosin affinity-purified antibodies also cross-react with M-protein moieties, suggesting this molecule could be the antigenic stimulus for the production of myosin antibodies in these sera (Cunningham *et al*. 1988).
3. Finally, as indicated above, autoimmune antibodies are a prominent finding in another major clinical manifestation of acute rheumatic fever, chorea, and these antibodies are directed against the cells of the caudate nucleus. The titre of this antibody corresponds with clinical disease activity (Husby *et al*. 1976).

While not necessarily autoimmune in nature, the presence of elevated amounts of immune complexes has been well documented both in serum and joints in acute rheumatic fever (van de Rijn *et al*. 1978). These amounts, which may be as high as those seen in classical post-streptococcal glomerulonephritis, may be responsible for immune-complex vasculitis seen in acute rheumatic fever and may provide the initial impetus for vascular damage, followed by the secondary penetration of autoreactive antibodies. Support for the concept is found in the close clinical similarity of arthritis in rheumatic fever to experimentally induced serum sickness in animals or the arthritis secondary to drug hypersensitivity. Deposition of host immunoglobulin and complement is also seen in the cardiac tissues of patients with acute rheumatic fever, suggesting autoimmune deposition of immunoglobulins in or near the Aschoff lesions.

At a cellular level, there is now ample evidence for the presence of both lymphocytes and macrophages at the site of pathological damage in the heart in patients with acute rheumatic fever (Kemeny *et al*. 1989). The cells are predominantly CD4+ helper lymphocytes during acute stages of the disease (4:1). The ratio of CD4+/CD8+ lymphocytes (2:1) more closely approximates the normal ratio in valvular specimens in chronic rheumatics (see Table 2). A majority of these cells express Ia antigens. A potentially important finding has been the observation that macrophage-like fibroblasts present in the diseased valves express Ia antigens (Amoils *et al*. 1986) and might be the antigen-presenting cells for the CD4+ lymphocytes.

Patients	Type of valve	Type of valvulitis*	HLA-DR+	6003b-2	Leu 15+2	Leu 4+2	Leu 3a+2	Leu 8a+2	Leu 3a: Leu 4/5
Acute valvulitis									
1	Mitral	Acute	58.0	42.0	5.1	45.5	75.6	23.9	3.1
2	Mitral	Acute	49.8	43.1	8.9	43.1	58.7	34.3	1.9

8	Mitral	Chronic active	80.4	34.1	13.4	44.6	44.8	50.9	0.9
9	Mitral	Chronic active	48.1	29.6	6.8	65.8	61.8	33.3	1.8

*Determined in the frozen-section samples studied.
1, mononuclear macrophages; 2, B cells; 3, pan-T cells; 4, helper cells; 5, suppressor cells.

Table 2 Composition of mononuclear cellular infiltrates in acute and chronic active rheumatic valvulitis

There was greater reactivity to streptococcal antigens in preparations of mononuclear cells from peripheral blood of patients with acute rheumatic fever than in these cells isolated from patients with nephritis (Read *et al*. 1986). This abnormal reactivity peaked at 6 months after the attack but could persist for as long as 2 years after the initial episode. Once again the reactivity was specific only for those strains associated with acute rheumatic fever, suggesting an abnormal humoral and cellular response to streptococcal antigens unique to rheumatic fever-associated streptococci.

Support for the potential pathological importance of these T cells is further strengthened by the observation that lymphocytes obtained from experimental animals sensitized to cell membranes but not cell walls are specifically cytotoxic for syngeneic embryonic cardiac myofibrils in vitro (Yang *et al*. 1977). In humans, normal mononuclear cells primed in vitro by M-protein molecules from a rheumatic fever-associated strain were also cytotoxic for myofibrils but specificity solely for cardiac cells was lacking (Dale and Beachey 1987). Similar studies have not yet been done with lymphocytes from patients with active acute rheumatic fever.

Clinical features of acute rheumatic fever

The clinical presentation of acute rheumatic fever is rather variable, and the lack of a single pathognomonic feature has resulted in the development of the revised Jones criteria, as illustrated in Table 3 (Jones Criteria Update 1992), which are used to establish a diagnosis. It should be noted that these criteria were established only as guidelines for the diagnosis and were never intended to be 'etched in stone'. Thus, depending on the age, geographical location, and ethnic population, emphasis on one or the other criterion for the diagnosis of acute rheumatic fever may be more or less important. Manifestations of rheumatic fever that are not clearly expressed pose a dilemma because of the importance of clearly identifying a first rheumatic attack in order to establish the need for prophylaxis (see below). Some of the isolated manifestations, particularly polyarthritis, may be difficult or impossible to distinguish from other diseases, especially at their onset. The diagnosis can be made, however, when 'pure' chorea is the sole manifestation, because of the rarity with which this syndrome is due to any other cause.

Major manifestations	Minor manifestations
Carditis	Fever
Polyarthritis	Arthralgia
Chorea	Previous rheumatic fever or rheumatic heart disease
Erythema marginatum	
Subcutaneous nodules	
Laboratory findings	
(1) Elevated acute-phase reactants:	
(a) C-reactive protein	
(b) erythrocyte sedimentation rate	
(2) Prolonged P–R interval rate	
Supporting evidence of preceding streptococcal infection	
(a) Increased ASO or other streptococcal antibodies	
(b) Positive throat culture for group A haemolytic streptococci	
(c) Recent scarlet fever	

Jones Criteria Update (1992)
ASO, antistreptolysin O.

Table 3 Revised Jones criteria for diagnosis of acute rheumatic fever

Arthritis

In the classic, untreated case the arthritis of rheumatic fever affects several joints in quick succession, each for a short time. The legs are usually affected first and later the arms. The terms 'migrating' or 'migratory' are often used to describe the polyarthritis of rheumatic fever, but these designations are not meant to signify that the inflammation necessarily disappears in one joint when it appears in another. Rather, the various localizations usually overlap in time, and the onset, as opposed to the full course of the arthritis, 'migrates' from joint to joint.

Joint involvement is more common, and also more severe, in teenagers and young adults than in children. It occurs early in the rheumatic illness, and is usually the earliest symptomatic manifestation of the disease, although asymptomatic carditis may precede it. Rheumatic polyarthritis may be excruciatingly painful, but is almost always transient. The pain is usually more prominent than the objective signs of inflammation.

When the disease was allowed to express itself fully, unchecked by anti-inflammatory treatment, over half of patients studied show a true polyarthritis, with inflammation in any of from 6 to 16 joints. Classically, each joint is maximally inflamed for only a few days, or a week at the most: the inflammation decreases, perhaps lingering for another week or so, and then disappears completely. Radiographs taken at this point may show a slight effusion but most probably will be unremarkable.

In routine practice, however, many patients with arthritis and/or arthralgias are treated empirically with salicylates or other non-steroidal anti-inflammatory drugs. Accordingly, arthritis subsides quickly in the joint(s) already affected and does not 'migrate' to new joints. Thus, therapy may deprive the diagnostician of a useful sign. In a large series of patients with rheumatic fever and associated arthritis, most of whom had been treated, involvement of only a single large joint was common (25 per cent). One or both knees were affected in 76 per cent, and one or both ankles in 50 per cent. Elbows, wrists, hips, or small joints of the feet were involved in 12 to 15 per cent of patients, and shoulder or small joints of the head were affected in 7 to 8 per cent. Joints rarely affected were the lumbosacral (2 per cent), cervical (1 per cent), sternoclavicular (0.5 per cent), and temporomandibular (0.5 per cent). Involvement of the small joints of the hands or feet alone occurred in only 1 per cent of these patients (Feinstein and Spagnulo 1962).

Analysis of the synovial fluid in well-documented cases of rheumatic fever with arthritis generally reveals a sterile inflammatory fluid. There may be a decrease of the complement components C1q, C3 and C4, indicating their consumption by immune complexes in the joint fluid (Svartman *et al*. 1975).

Post-streptococcal reactive arthritis

A number of investigators (Goldsmith and Long 1982; Arnold and Tyndall 1989; Fink 1991) have raised the question of whether post-streptococcal migratory arthritis, in the absence of carditis both in adults and children, is really acute rheumatic fever, for the following reasons.

1. The latent period between the antecedent streptococcal infection and the onset of acute rheumatic fever is shorter (1–2 weeks) than the 3 to 4 weeks usually seen in classical acute rheumatic fever.
2. The response of the arthritis to aspirin and other non-steroidal medications is poor in comparison to the dramatic response seen in classical acute rheumatic fever.
3. Evidence of carditis is not usually seen in these patients and the arthritis is rather severe.

4. Extra-articular manifestations such as tenosynovitis and renal abnormalities are often seen in these patients.

While these cases (admittedly rare) do exist, migratory arthritis without evidence of other major Jones criteria, if supported by two minor manifestations (see Table 3), must still be considered acute rheumatic fever, especially in children. Variations in the response to aspirin in these children often are not recorded with serum salicylate concentrations, and an unusual clinical course is not sufficient to exclude the diagnosis of acute rheumatic fever; appropriate prophylactic measures should be therefore taken (reviewed by Gibofsky and Zabriskie 1994). Support for this concept may be found in the work of Crea and Mortimer (1959), in which 50 per cent of the children with signs of migratory arthritis alone went on to develop significant valvular damage after a long follow-up.

Rheumatic fever also occurs in adults. Although migratory arthritis is a common presenting symptom, a recent outbreak in San Diego Naval Training Camp (Wallace *et al*. 1989) revealed a 30 per cent incidence of valvular damage in these patients.

The importance of clearly defining this reactive arthritis as a variant of rheumatic fever has obvious implications for secondary prophylactic treatment. As suggested by some investigators, post-streptococcal reactive arthritis is a benign condition without need for prophylaxis. Yet as these patients by and large do fulfil the Jones criteria (one major, two minor), they should be considered as having rheumatic fever and treated as such.

Carditis

Cardiac valvular and muscle damage can manifest in a variety of signs or symptoms, including organic heart murmurs, cardiomegaly, congestive heart failure or pericarditis. Mild to moderate chest discomfort, pleuritic chest pain or a pericardial friction rub are indications of pericarditis. On clinical examination, the patient can have new or changing organic murmurs, most commonly mitral regurgitant murmurs, and occasionally aortic regurgitant murmurs and/or systolic ejection murmurs, caused by acute valvular inflammation and deformity. Rarely, a Carey Coombs mid-diastolic murmur caused by rapid flow over the mitral valve is heard. If the valvular damage is severe enough, together with concurrent cardiac dysfunction, congestive heart failure can ensue, which is the most life-threatening clinical syndrome of acute rheumatic fever. Congestive heart failure needs to be treated intensively and quickly with a combination of anti-inflammatory drugs, diuretics and, occasionally, steroids to acutely decrease the cardiac inflammation. Electrocardiographic abnormalities include all degrees of heart block, including atrioventricular dissociation, but first-degree heart block is not associated with a poor prognosis. Second- or third-degree heart block can occasionally be symptomatic. If heart block is associated with congestive heart failure, a temporary pacemaker can be placed if indicated. The most common manifestation of carditis is cardiomegaly, as seen on radiographs.

In the population of patients recently reviewed from our institution, The Rockefeller University Hospital, who were diagnosed with acute rheumatic fever between 1950 and 1970, with an average of 20 years of follow-up, 90 per cent had evidence of carditis at diagnosis (Table 4). In a classic review of 1000 patients (Bland and Jones 1951), only 65 per cent were diagnosed with carditis. The addition of Doppler sonography to the clinical evaluation of patients during the recent Utah outbreak increased the proportion diagnosed with carditis from 72 to 91 per cent (Veasy *et al*. 1987), indicating that, with more sensitive measurements of cardiac dysfunction, almost all patients with acute rheumatic fever have signs of acute carditis.

	RHD (*n*=60) %	No RHD (*n*=47) %	Total (*n*=87) %	Bland and Jones %
Carditis	100	83.0	90.1	65.3
Arthritis	67.5	68.1	67.8	41.0
Epistaxis	0.0	10.6	5.7	27.4
Chorea	5.0	2.1	3.4	51.8
Pericarditis	2.5	4.3	3.4	13.0
Nodules	7.5	0.0	3.4	8.8
Erythema marginatum	0.0	4.3	2.3	7.1

Table 4 Physical signs and symptoms of acute rheumatic fever, Rockefeller University Hospital 1950–1970

Rheumatic heart disease

Rheumatic heart disease is the most severe outcome of acute rheumatic fever. Usually occurring 10 to 20 years after the original attack, it is the major cause of acquired valvular disease in the world. The mitral valve is mainly involved and the aortic valve less often. Mitral stenosis is a classic finding in rheumatic heart disease and can manifest as a combination of mitral insufficiency and stenosis, secondary to severe calcification of the mitral valve. When symptoms of left atrial enlargement are present, mitral valve replacement may become necessary.

In various studies, the incidence of rheumatic heart disease in patients with a history of acute rheumatic fever has varied. In the classic study of Bland and Jones (1951), after 20 years, one-third of patients had no murmur, another one-third had died, and the remaining one-third was alive with rheumatic heart disease. A majority of the patients who died had rheumatic heart disease. While the dogma is that patients with rheumatic heart disease invariably have had more than one attack of acute rheumatic fever, recent analysis of our patients at the Rockefeller University Hospital disproves this. The population studied was 87 patients who had had only one documented attack of acute rheumatic fever, without any evidence (clinical or laboratory) of a recurrence during a 20-year follow-up under close supervision. Over 80 per cent had carditis at admission and approx. 50 per cent now have organic murmurs (Table 4). Thus, valvular damage manifesting as organic murmurs later in life is still likely to occur in 50 per cent of the patients if they presented with evidence of carditis at initial diagnosis. All of the patients in our population who ended up with rheumatic heart disease had carditis at diagnosis.

Chorea

Sydenham's chorea, chorea minor, or 'St. Vitus dance' is a neurological disorder consisting of abrupt, purposeless, non-rhythmic involuntary movements, muscular weakness, and emotional disturbances. They disappear during sleep, but may occur at rest and may interfere with voluntary activity. Initially, it may be possible to suppress these movements, which may affect all voluntary muscles, with the hands and face usually the most obvious. Grimaces and inappropriate smiles are common. Handwriting usually becomes clumsy and provides a convenient way of following the patient's course. Speech is often slurred. The movements are commonly more marked on one side and are occasionally completely unilateral (hemichorea).

The muscular weakness is best revealed by asking the patient to squeeze the examiner's hands: the pressure of the patient's grip increases and decreases continuously and capriciously, a phenomenon known as relapsing grip, or milking sign.

The emotional changes manifest themselves in outbursts of inappropriate behaviour, including crying and restlessness. In rare cases, the psychological manifestations may be severe and may result in transient psychosis.

The neurological examination fails to reveal sensory losses or involvement of the pyramidal tract. Diffuse hypotonia may be present.

Chorea may follow streptococcal infections after a latent period, which is longer, on the average, than the latent period of other rheumatic manifestations. Some patients with chorea have no other symptoms, but other patients develop chorea weeks or months after arthritis. In both cases, examination of the heart may reveal murmurs.

Skin lesions

Subcutaneous nodules

The subcutaneous nodules of rheumatic fever are firm and painless. The overlying skin is not inflamed and can usually be moved over the nodules. The diameter of these round lesions varies from a few millimetres to 1 or even 2 cm. They are located over bony surface or prominences, or near tendons; their number varies from a single nodule to a few dozen and averages three or four; when numerous, they are usually symmetrical. These nodules are present for one or more weeks, rarely for more than a month. They are smaller and more short-lived than the nodules of rheumatoid arthritis. Although in both diseases the elbows are most frequently involved, the rheumatic nodules are more common on the olecranon, and the rheumatoid nodules are usually found 3 or 4 cm distal to it. Rheumatic subcutaneous nodules generally appear only after the first few weeks of illness, usually only in patients with carditis.

Erythema marginatum

Erythema marginatum is an evanescent, non-pruritic skin rash, pink or faintly red, usually affecting the trunk, sometimes the proximal parts or the limbs, but not the face. The lesion extends centrifugally while the skin in the centre returns gradually to normal; hence, the name 'erythema marginatum'. The outer edge of the lesion is sharp, whereas the inner edge is diffuse. Because the margin of the lesion is usually continuous, making a ring, it is also known as 'erythema annulare'.

The individual lesions may appear and disappear in a matter of hours, usually to return. A hot bath or shower may make them more evident or may even reveal them for the first time.

Erythema marginatum usually occurs in the early phase of the disease. It often persists or recurs, even when all other manifestations of disease have disappeared. Occasionally, the lesions appear for the first time or, more probably, are noticed for the first time, late in the course of the illness or even during convalescence. This disorder usually occurs only in patients with carditis.

The minor manifestations of rheumatic fever

Temperature is increased in almost all rheumatic attacks and ranges from 38.4 to 40°C. Usually fever decreases in about a week without antipyretic treatment, and may become low grade for another week or two. Fever rarely lasts for more than 3 to 4 weeks.

Abdominal pain

The abdominal pain of rheumatic fever resembles that of other conditions associated with acute microvascular mesenteric inflammation and is non-specific. It usually occurs at or near the onset of the rheumatic attack, so that other manifestations may not yet be present to clarify the diagnosis. In many cases, it may mimic acute appendicitis.

Epistaxis

In the past, epistaxis occurred most prominently and severely in patients with severe and protracted rheumatic carditis. Early clinical studies reported a frequency as high as 48 per cent, but it probably occurs even less frequently now (see Table 3). Although epistaxis has been correlated in the past with the severity of rheumatic inflammation, it is difficult to assess retrospectively the possible thrombasthenic effect of large doses of salicylates administered for prolonged periods in protracted attacks.

Rheumatic pneumonia

Rheumatic pneumonia may appear during the course of severe rheumatic carditis. This inflammatory process is difficult or impossible to distinguish from pulmonary oedema or the alveolitis associated with respiratory distress syndrome due to a variety of pathophysiological states.

Laboratory findings

The diagnosis of rheumatic fever cannot readily be established by laboratory tests. Nevertheless, tests may be helpful in two ways: first in demonstrating that an antecedent streptococcal infection has occurred and second in documenting the presence or persistence of an inflammatory process. Serial chest radiographs may be helpful in following the course of carditis and the electrocardiogram may reflect the inflammatory process on the conduction system.

Throat cultures are usually negative by the time rheumatic fever appears but an attempt should be made to isolate the organism. It is our practice to take three throat cultures during the first 24 h, before giving antibiotics. Streptococcal antibodies are more useful because (i) they reach a peak titre at about the time of onset of rheumatic fever, (ii) they indicate true infection rather than transient carriage, and (ii) by performing several tests for different antibodies, any significant recent streptococcal infection can be detected. To demonstrate a rising titre, it is useful to take a serum specimen when the patient is first seen and another one 2 weeks later for comparison.

The specific antibody tests most frequently used to diagnosis streptococcal infections are those directed against extracellular products. They include antistreptolysin O, anti-DNAse B, antihyaluronidase, anti-NADase (anti-DPNase), and antistreptokinase. Antistreptolysin O has been the most widely used test and is generally available in hospitals in the United States.

Titres of antistreptolysin O vary with age, season, and geographical region. They reach peak levels in the young, school-age population. Titres of 200 to 300 Todd units/ml are common, therefore, in healthy children of elementary-school age. After a streptococcal pharyngitis, the antibody response peaks at about 4 to 5 weeks, which is usually during the second or third week of rheumatic fever (depending on how early it is detected). Thereafter, antibody titres fall off rapidly in the next several months, and, after 6 months, they decline more slowly. Since only 80 per cent of documented rheumatics exhibit a rise in the titre of antistreptolysin O, it is recommended that other antistreptococcal antibody tests be performed in the absence of a positive titre. These include anti-DNAse B, hyaluronidase or streptozyme, which is a combination of various streptococcal antigens.

Streptococcal antibodies, when increased, support but do not prove the diagnosis of acute rheumatic fever, nor are they a measure of rheumatic activity. Even in the absence of intercurrent streptococcal infection, titres decline during the rheumatic attack despite the persistence or severity of rheumatic activity.

Acute-phase reactants

Acute-phase reactants are elevated during acute rheumatic fever, just as they are during other inflammatory conditions. Both the C-reactive protein and erythrocyte sedimentation rate are almost invariably abnormal during the active rheumatic process, if it is not suppressed by antirheumatic drugs. Pure chorea and persistent erythema marginatum are exceptions. Particularly when treatment has been discontinued or is being tapered off, the C-reactive protein or erythrocyte sedimentation rate are useful in monitoring 'rebounds' of rheumatic inflammation, which indicate that the rheumatic process is still active. If either remains normal a few weeks after discontinuing antirheumatic therapy, the attack may be considered ended unless chorea appears. Even then, usually, there will be no exacerbation of the systemic inflammation and chorea will be present as an isolated manifestation.

Anaemia

A mild normochromic normocytic anaemia of chronic infection or inflammation may be seen during acute rheumatic fever. Suppressing the inflammation usually improves the anaemia, thus iron therapy is usually not indicated.

Clinical course and treatment of acute rheumatic fever

The mainstay of treatment for acute rheumatic fever has always been anti-inflammatory agents, most commonly aspirin. Dramatic improvement in symptoms is usually seen after the start of therapy. Usually 80 to 100 mg/kg per day in children and 4 to 8 g/day in adults is required for an effect to be seen. Aspirin concentrations can be measured and 20 to 30 mg/dl is the therapeutic range. The duration of anti-inflammatory therapy can vary but the treatment should be maintained until all symptoms are absent and laboratory values are normal. If severe carditis is also present, as indicated by significant cardiomegaly, congestive heart failure or third-degree heart

block, steroid therapy can be instituted. The usual dosage is 2 mg/kg per day of oral prednisone during the first 1 to 2 weeks. Depending on clinical and laboratory improvement, the dosage is then tapered over the next 2 weeks and during the last week aspirin may be added in the dosage recommended above sufficient to achieve 20 to 30 mg/dl.

Whether or not signs of pharyngitis are present at the time of diagnosis, antibiotic therapy with penicillin should be started and maintained for at least 10 days, in doses recommended for the eradication of a streptococcal pharyngitis. In addition, all family contacts should be cultured and treated for streptococcal infection, if positive. If compliance is an issue, depot penicillins, such as benzathine penicillin G 600 000 units in children, 1.2 million units in adults, should be given. Recurrences of acute rheumatic fever are most common within 2 years of the original attack but can occur at any time. The risk of recurrence decreases with age. Recurrence rates have been decreasing, from 20 to 2 to 4 per cent in recent outbreaks. This might be due to better surveillance and treatment.

Prophylaxis

Antibiotic prophylaxis with penicillin should be started immediately after the resolution of the acute episode. The optimal regimen consists of oral penicillin VK 250 000 units twice a day, or depot intramuscular injection of 1.2 million units penicillin G every 4 weeks. Recent data suggest, however, that injections every 3 weeks are more effective than every 4 weeks in preventing recurrences of acute rheumatic fever (Lue *et al*. 1986). If the patient is allergic to penicillin, erythromycin 250 mg/day can be substituted.

The end-point of prophylaxis is unclear; most believe it should continue at least until the patient is a young adult, which is usually 10 years from an acute attack with no recurrence. In our opinion, individuals with documented evidence of rheumatic heart disease should be on continuous prophylaxis indefinitely since our experience has been that rheumatic fever can recur even in the fifth or sixth decades. Another potential problem for recurrences is the presence in the household of young children who could transmit new group A streptococcal infections to rheumatic-susceptible individuals.

Obviously the alternative to long-term prophylaxis in an individual with rheumatic fever will be the introduction of streptococcal vaccines designed not only to prevent recurrent infections in rheumatic-susceptible individuals but also to prevent streptococcal disease in general. While it is not within the scope of this chapter to discuss the prospects for these vaccines (see review by Fischetti 1989), at least a few words are appropriate. Immunization of mice with either C-repeat peptides of M protein or 'cloned' M protein in a vaccinia virus vector protected them against intranasal infection with homologous or heterologous strains of group A streptococci. Whether or not these antigens and/or vectors are protective in man is being investigated. One of the major problems will be to avoid using those parts of the molecule that are cross-reactive with mammalian tissues.

Conclusion

In spite of its disappearance in many areas, rheumatic fever continues to be a serious problem in those geographical areas where two-thirds of the world's population lives. Even in developed countries with full access to medical care, and better nutrition and housing, the recent resurgence of rheumatic fever emphasizes the need for continued vigilance by physicians and other health officials in both diagnosing and treating the disease. The importance of early diagnosis and therapy cannot be overemphasized. Although the joint manifestations are transient and self-limiting, the cardiac sequelae are chronic and life-threatening. Whether the resurgence represents a change in the virulence of the organism or failure to recognize the importance and need for adequate treatment of an antecedent streptococcal infection is an area of intense debate and will therefore require careful and controlled epidemiological surveillance.

Nevertheless, rheumatic fever remains one of the few autoimmune disorders known to occur as a result of infection with a specific organism. The confirmed observation of an increased frequency of a B-cell alloantigen in several populations of rheumatics suggests that it might be possible to identify rheumatic fever-susceptible individuals at birth. If so, then from a public health standpoint, (i) these individuals would be prime candidates for immunization with any streptococcal vaccine that might be developed in the future, (ii) careful monitoring of streptococcal disease in the susceptible population could lead to early and effective antibiotic strategies, resulting in disease prevention, and (iii), in individuals previously infected, who later present with subtle or non-specific manifestations of the disease, the presence or absence of the marker could be of value in arriving at a diagnosis.

The continued study of rheumatic fever as a prime example of microbial–host interactions also has important implications for the study of autoimmune diseases in general and rheumatic diseases in particular. Further insights into this intriguing host–parasite relation may shed additional light on those diseases where infection is assumed to have occurred but has not as yet been identified.

5.4.1 Immunopathogenesis of rheumatoid arthritis

Ravinder N. Maini and Marc Feldmann

Historical review

The delineation of rheumatoid arthritis as a disease entity in the contemporary medical literature began to emerge in the eighteenth century. Initially, clinical observations sought to distinguish the disorder from other prevalent joint diseases, such as gout and rheumatic fever, and emphasized distinctive features, for example, its chronicity, joint deformities, female sex distribution, and disability. Thus Sydenham (1676), Landry-Beauvais (1800), Brodie, and others were in all probability describing rheumatoid arthritis in their writings, but it was Alfred Baring Garrod (1859) who first used the term 'rheumatoid' arthritis (Garrod 1859; and for reviews see Short 1974 and Fraser 1982).

The definition of rheumatoid arthritis and its separation from other forms of chronic polyarthritis did not end with Garrod, and has continued to evolve since. A proportion of patients who might previously have been diagnosed as having rheumatoid arthritis would now be readily reclassified as having polyarthritis seen in the context of ankylosing spondylitis, Reiter's syndrome, psoriatic arthritis, or inflammatory bowel disease. The uniform lack of rheumatoid factor (seronegativity), spinal involvement, and HLA-B27 positivity has linked these disorders into the so-called seronegative spondylarthropathies. It is of special historical interest to note that until the late 1950s, despite striking differences in clinical features, ankylosing spondylitis was termed rheumatoid spondylitis by North American physicians in the belief that it was part of the disease spectrum of rheumatoid arthritis. This view was essentially based on the striking histopathological similarity to rheumatoid arthritis of the synovitis and erosive arthropathy of diarthrodial joints in ankylosing spondylitis. However, the inflammatory lesion at the point of tendon and ligamentous attachments to bone (enthesopathy) and the association with HLA B27 proved to be sufficiently distinctive to constitute a basis for differentiation from rheumatoid arthritis.

The possibility that rheumatoid arthritis may result from an infection has had its proponents since the early part of the century. In the early days of modern medicine, rheumatoid arthritis, like other diseases of unknown causes, was thought to result from foci of infection (Hunter 1901; Wilcox 1935). The belief that rheumatoid arthritis may result from infection with *Mycobacterium tuberculosis* is alleged to have motivated Forrestier in France (Forrestier 1935) to use gold salts, which have some antimicrobial activity, in its therapy. An alternative concept of the aetiology of rheumatoid arthritis arose from microscopical observations of 'fibrinoid' change in rheumatoid joints and nodules. Fibrinoid change in connective tissue in systemic lupus and systemic sclerosis had prompted Klemperer *et al*. (1942) to consider that these diseases might result from diffuse primary degeneration of collagen. This led to the inclusion of rheumatoid arthritis in the group of 'collagen diseases'; however, the development of this new theory was hampered by the observation that the hydroxyproline and collagen content of subcutaneous nodules in rheumatoid arthritis was normal (Ziff *et al*. 1953).

The discovery by Waaler half a century ago (Waaler 1940) of IgM rheumatoid factor in the blood of patients with rheumatoid arthritis was the first immunological marker of rheumatic disease to be recognized and served to distinguish it from other forms of arthritis. However, a proportion of patients with the features of rheumatoid arthritis are persistently seronegative for rheumatoid factor, and this has formed the basis for a subdivision of rheumatoid arthritis, from which the recognized entity of seronegative spondylarthropathies arose. The patients who still remain in the category 'seronegative rheumatoid arthritis' may eventually prove to be a distinct subgroup with a different aetiological basis.

The finding of other autoantibodies circulating in the blood of patients with chronic polyarthritis has provided a continuing impetus for recognition of distinct rheumatic disorders. Notable, and first among these, was the LE cell test described by Hargraves *et al*. (1948), dependent on the presence of antinuclear antibodies, which served to distinguish patients with the polyarthritis of systemic lupus from those with rheumatoid arthritis. The better definition of the antigens with which such autoantibodies react has led to greater confidence in their diagnostic specificity; thus, antibodies to double-stranded-DNA and Sm antigen will distinguish systemic lupus from rheumatoid arthritis with some certainty. Similarly, more contemporary laboratory tests have contributed to the serological basis of disease classification of a patient with polyarthritis superficially resembling rheumatoid arthritis. The presence of anti-La (anti-SS-B) antibodies raises the strong probability of a diagnosis of primary Sjögren's syndrome, the presence of anticentromere or anti-Scl-70 antibodies suggests a diagnosis of systemic sclerosis, of anti-nRNP and anti-Jo-1 a diagnosis of overlap or mixed connective tissue disease, and of antineutrophil cytoplasmic antibody a diagnosis of Wegener's granulomatosis.

The relatively recent historical description of rheumatoid arthritis has prompted the speculation that it is a disease of modern times. A great deal of interest has therefore focused on seeking evidence of the occurrence of rheumatoid arthritis in mediaeval and ancient times. Examination of ancient medical writings and mediaeval paintings has yielded evidence which has satisfied some researchers that rheumatoid arthritis was indeed prevalent in these periods (Short 1974; Dequeker 1987; Dieppe 1988). However, subjectivity of judgement is an obvious problem in assessing such evidence and there appears to be a dearth of convincing descriptions, given that nowadays rheumatoid arthritis is such a common and ubiquitous cause of disability and pain. Another approach in establishing the antiquity of rheumatoid arthritis has been an attempt to gauge its prevalence by using palaeontographic methods. Fossil remains of archaic Indian skeletons found in Alabama and Kentucky in the United States, dated as several thousand years old, have been described as exhibiting changes consistent with an erosive arthritis compatible with rheumatoid arthritis (Rothschild and Woods 1990). However, the basis of ascribing the changes to rheumatoid arthritis has been challenged and the lack of rheumatoid pathology in a study of 800 skeletons excavated in the West Country in England has been used as an argument highlighting the lack of this disorder in ancient times (Rogers and Dieppe 1990).

The implication of the claim that rheumatoid arthritis is a relatively modern disease is the possibility that it might have become widespread as a result of an environmental trigger factor which in itself was new. A report from South Africa purporting to demonstrate an increased prevalence of rheumatoid arthritis in Xhosa

tribesmen living in urban surroundings compared with their cousins in rural areas (Solomon *et al*. 1975) has been interpreted as a recapitulation in a contemporary setting of a global scenario unfolding over the past two centuries. The insight that the epidemiology of acquired immunodeficiency disease (**AIDS**) has provided into how new diseases of man become established has provided an arena for renewed interest in the possibility that the environmental factor responsible could be an infectious agent.

Aetiology

Rheumatoid arthritis is a disease of unknown cause, but current thinking favours the notion that interplay among genetic factors, sex hormones, and an infectious agent initiates an autoimmune disease mechanism that culminates in a disease with inflammatory and destructive features.

Genetic factors

Genetic factors were implicated by population studies that showed a slight increase in the frequency of rheumatoid arthritis in first-degree relatives of patients with rheumatoid arthritis, especially if seropositive for rheumatoid factor (Lawrence 1970). Concordance rates of disease in identical twins in hospital-based studies were estimated to be of the order of 30 per cent, compared with 5 per cent in non-identical twins (Lawrence 1970), although the figures are lower in community-based studies (Silman *et al*. 1989), again supporting the concept of a genetic contribution, but arguing against the proposition that rheumatoid arthritis results from a dominant single-gene disorder. The rates of prevalence in the general population, families, and twins have in fact led to the conclusion that rheumatoid arthritis is a polygenic disease, and that non-inherited factors are also of great importance.

Attempts at identifying the genes involved in predisposition to rheumatoid arthritis took a step forward when tissue typing for HLA class II antigen of Caucasian patients showed that 60 to 70 per cent of patients with rheumatoid arthritis were HLA-DR4 positive by cellular or serological techniques compared with 20 to 25 per cent of control populations (Statsny 1976; Statsny 1978; Panayi *et al*. 1979). The patients with more severe rheumatoid arthritis, especially those with systemic complications such as vasculitis and Felty's syndrome, were even more likely to have HLA DR4 than patients with less aggressive disease confined to joints (Ollier *et al*. 1984; Westedt *et al*. 1986).

The increased frequency of HLA DR4 has also been reported in American black subjects, Japanese, Asian North Indians, and Latin Americans. In Israeli Jews and an Indian immigrant community in the United Kingdom an increased frequency of HLA DR1 has been found. The increase of HLA DR4 or DRl cannot, however, be found in all races and ethnic groups, and a notable exception was a study of Greek patients in whom no HLA associations could be discovered, irrespective of disease severity or serological status (reviewed by Goldstein and Arnett 1987).

Typing by mixed leucocyte culture has defined several HLA-DR4 subtypes. It is of considerable interest that while the subtypes HLA Dw4 and Dw14 are associated with rheumatoid arthritis in several studies, Dw15 is only associated with rheumatoid arthritis in the Japanese, while Dw10 and Dw13 are not associated with rheumatoid arthritis in any ethnic group. A recent study has shown that in *DR4* homozygotes, *Dw4*/*Dw14* individuals were at greater risk of developing rheumatoid arthritis than *Dw4*/*Dw4* (Wordsworth *et al*. 1992). The significance of this is discussed below.

At the phenotypic level, the importance of HLA class II molecules lies in their participation in a trimolecular reaction involving the HLA antigen-binding cleft formed by the a and b chains of an antigen-presenting cell binding to a processed linear peptide antigen of at least nine amino acids, and the HLA–antigen complex in turn binding to the variable portion of the T-cell receptor. Several research techniques have been used in an attempt to define the similarity of HLA class II molecules common to all patients with rheumatoid arthritis, including patients who are not necessarily HLA-DR4 positive. These include, for example, genotyping of DNA and nucleotide sequencing, using the polymerase chain reaction and enzymatic digestion for restriction fragment length polymorphisms. At the level of expressed surface proteins, HLA epitopes have been sought by using monoclonal antibodies and alloreactive T-cell clones (see Goldstein and Arnett 1987). These studies have lent support to the concept that susceptibility to rheumatoid arthritis is related to a 'shared epitope' on the HLA molecules (Gregersen *et al*. 1987; Hammer *et al*. 1995).

Nucleotide sequencing of *HLA-DR* b_1 exons coding amino acid residues 70 to 74 has revealed that HLA DR4 subtypes Dw4, Dw14, and Dw15 share similarities with each other (with a conservative substitution of glutamine with lysine at position 71 in Dw4) and with HLA DRl (Table 1) (Winchester and Gregersen 1988). The sequence predicts susceptibility to rheumatoid arthritis and, for example, is associated with rheumatoid arthritis in 83 per cent of Caucasians in Britain (Wordsworth *et al*. 1989). In contrast, negative associations are observed in individuals who are DR4w10, in whom the charged basic amino acids glutamine and arginine in positions 70 and 71 are replaced by the acidic amino acids aspartic and glutamic acid. In Dw13 individuals, in whom a negative association is also observed, arginine is substituted for glutamic acid in position 74. Molecular modelling studies suggest that amino acid residues 70 to 74 are located in the a-helix forming the wall of the peptide-binding groove, and thus likely to be involved in antigen binding and subsequent interaction with T-cell receptors (Fig. 1). Acidic substitutions could profoundly alter protein structures and thereby alter affinity for peptide antigens. The predictions that protein structures on the HLA molecule are important in susceptibility to rheumatoid arthritis are supported by serotyping with alloantisera and monoclonal antibodies as well as reactivity with homozygous T cells and T-cell clones (Goronzy *et al*. 1986; Winchester and Gregersen 1988). However, whether the susceptibility to rheumatoid arthritis is due to permissive binding of specific peptides such as those on autoantigens or on environmental antigens, whether superantigens may initiate disease by binding specifically to the HLA molecules (Herman *et al*. 1991), or whether selection or tolerance of the T-cell repertoire are also involved, remains to be elucidated.

DR type	Sequence					Association
	70	71	72	73	74	
DR4–W4	Q	K	R	A	A	Positive
–W14	Q	R	R	A	A	Positive
–W15	Q	R	R	A	A	Positive
DR1	Q	R	R	A	A	Positive
DR4–W10	D	E	R	A	A	Negative
–W13	Q	R	R	A	E	Negative

Q, glutamine; K, lysine; R, arginine; A, alanine; D, aspartic acid; E, glutamic acid.

Table 1 HLA-DR associations with rheumatoid arthritis defined by DR b_1 sequence position 70 to 74

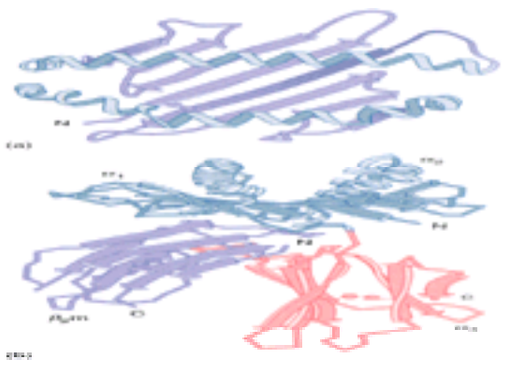

Fig. 1 Structure of HLA. (a) View of peptide-binding groove as seen by T-cell receptor. (b) From side.

The evidence that *Dw4*/*Dw14* heterozygotes are more likely to develop rheumatoid arthritis than are *Dw4* homozygotes (Wordsworth *et al*. 1992), and the evidence that individuals expressing DR4 (and not DR1) are more likely to have severe disease, challenges the concept that sequences 70 to 74 are the only HLA-D regions

that influence disease expression. This is despite the sequence identity of DR1 and DR4w4 in these positions, and a conservative substitution in Dw14 (Table 1). It has been hypothesized that the severity of disease and extra-articular complications are related to homozygosity and the density of disease-associated MHC molecules which critically influence the selection of the T-cell repertoire and tolerance to antigens (Weyand *et al*. 1992; Goronzy and Weyand 1993).

Although HLA genes are of obvious importance in rheumatoid arthritis, it has been calculated from studies of HLA in multicase families that they may only account for 37 per cent of the genetic factors involved (Deighton *et al*. 1989). However, a recent reanalysis has suggested that up to 60 per cent of susceptibility could be determined genetically (Macgregor and Silman 1994). Other susceptibility genes have been sought, and associations with T-cell receptors in gene polymorphisms and deletions of immunoglobulin genes have been observed (Olee *et al*. 1991). The picture is currently incomplete and their relative importance has not been documented.

Infectious agents

Population and twin studies strongly suggest that non-inherited, presumably environmental, factors such as infections may play a part in the aetiology of rheumatoid arthritis, although rearrangement of the a b genes on T-cell receptors may also contribute to the non-inherited component. As discussed above, although prevalence rates of rheumatoid arthritis from worldwide studies are similar, a population survey designed to seek effects of the environment showed that urbanized tribal South African black subjects suffered from rheumatoid arthritis more than their rural cousins. However, the classical clue of case clustering suggesting an infectious background has not been found for rheumatoid arthritis in any study, unlike Lyme disease. Attempts at demonstrating microbial organisms directly from joints have had a chequered history, since in all instances claims of positive findings—for example, of mycoplasma, diphtheroids, and viruses—have either been attributed to laboratory contamination or have been refuted on grounds of a lack of reproducibility.

Other studies have sought to implicate microbes in the aetiology of rheumatoid arthritis by seeking evidence of immune hyperreactivity to microbial antigens. Increased antibody titres to Epstein–Barr virus (**EBV**) antigens and an induced rheumatoid arthritis nuclear antigen have suggested that this ubiquitous virus, known to infect the majority of people by the late teens, may be of aetiological importance (Venables *et al*. 1981; Venables 1988). Its persistence in B lymphocytes of patients with rheumatoid arthritis in greater than normal amounts because of impaired cellular immunity could lead to the hyperreactivity of B cells, and autoantibody production typical of the disease. Sequence similarity of an EBV capsid antigen to the HLA-DR b susceptibility sequence QKRAA (Table 1) (Roudier *et al*. 1988) has suggested a possible explanation for the increased persistence of EBV in rheumatoid arthritis, while immunological cross-reactivity of EBV nuclear antigens to the autoantigens collagen, actin, and cytokeratin and to an antigen in the synovial membrane have suggested mechanisms for the induction of autoimmunity and for localization of immune cells to joints (Baboonian *et al*. 1991). However, these data fail to explain why only a small proportion of individuals infected with EBV might develop rheumatoid arthritis, and conversely, that there are well-documented patients with rheumatoid arthritis who have not been infected with EBV (Venables *et al*. 1981).

At least three bacteria have attracted attention in recent years as candidate agents in the aetiology of rheumatoid arthritis. The first, *M. tuberculosis*, gained current interest following the studies of Cohen *et al*. (1985) on an animal model of rheumatoid arthritis (see adjuvant arthritis in Animal models below). In these studies, mycobacterial protein showed immunological cross-reactivity and sequence similarity to a cartilage link protein, a finding which suggested a possible reason for the localization of the immune response to joints (van Eden *et al*. 1985). The link with human rheumatoid arthritis was suggested by the demonstration of reactivity of synovial T cells to mycobacterial antigens in rheumatoid arthritis (Holoshitz *et al*. 1986). The mycobacterial 65-kDa protein was subsequently shown to belong to the family of heat-shock proteins (**hsp65**) which are expressed in a variety of bacteria and also in the inflamed synovium of rheumatoid arthritis (van Eden *et al*. 1988; de Graeff-Meeder *et al*. 1990). Whether human hsp is a major target of T-cell autoreactivity in rheumatoid arthritis, however, is unproven, as there are significant differences in sequence and epitopes expressed by bacterial and human hsp (Gaston *et al*. 1989). Arguing against a role is the fact that identical responses to hsp65 are found in other inflammatory sites, for example, pleural effusion (Res *et al*. 1990). Attempts to suppress rheumatoid arthritis by vaccination with T cells derived from joints, in a protocol similar to that successfully used in adjuvant arthritis, could have provided support for the importance of mycobacterial immunity, but preliminary attempts have not been impressively successful (Van Laar *et al*. 1991).

In a further study seeking a mechanism dependent on molecular mimicry, antigens homologous to the amino acid sequence QKRAA (see Table 1) present in the hsp DNAj of *Escherichia coli* were reported to elicit T-cell responses only in patients with rheumatoid arthritis (Albani *et al*. 1995). It was suggested by these workers that activated T cells may cross-react with autologous DNAj heat-shock proteins that are expressed in the joints.

The third bacterium proposed as a candidate aetiological agent is *Proteus mirabilis*. Increased levels of IgG antibody to the organism have been detected in patients with rheumatoid arthritis but not ankylosing spondylitis or control subjects (Ebringer *et al*. 1989). It has been claimed that persistence of the organism in the urinary tracts, especially of women, may provide the nidus of infection that triggers a deleterious immune response culminating in rheumatoid arthritis.

The similarity of retrovirus-induced caprine arthritis to rheumatoid arthritis has attracted interest in the possibility that retroviruses may be of aetiological importance (Trabandt *et al*. 1992). Retroviral GAG proteins have been demonstrated immunohistochemically in the synovium of patients with rheumatoid arthritis (Ziegler *et al*. 1989), and a transgenic mouse carrying the human T-cell leukaemia virus type I that developed chronic arthritis with synovial inflammation and joint erosion similar to rheumatoid arthritis has been described (see Animal models).

Other aetiological factors

Apart from the possible role that infectious agents may play, the predominance of rheumatoid arthritis in females in the premenopausal period compared with males and the protective effect of the contraceptive pill, presumably because of its progesterone content, have suggested that sex hormones may accelerate or retard its onset (Lahita 1990). Other aetiological factors that have been considered include diet (Buchanan *et al*. 1991) and stress (Adler 1985), but their role in initiating disease is debatable, and may be more significant in altering disease expression and outcome.

Autoimmunity

Autoantibodies

The discovery of the autoantibody, IgM rheumatoid factor, in the blood of patients with rheumatoid arthritis was the principal reason for the inclusion in the group of autoimmune diseases. Although high-titre IgM rheumatoid factor is relatively specific for a diagnosis of rheumatoid arthritis in the context of chronic polyarthritis, its occurrence in many autoimmune rheumatic diseases without arthritis and in chronic infections has raised doubts about the role it might play in the pathogenesis of rheumatoid arthritis. However, rheumatoid factor-secreting plasma cells of IgG, IgA, and IgM class can be demonstrated in the rheumatoid synovium (reviewed by Maini *et al*. 1987), thus implicating them at the site of disease. Indeed, cells of the B-lymphocyte lineage constitute 10 to 15 per cent of the population of mononuclear cells in rheumatoid arthritis, produce autoantibodies, are a source of immune complexes that fix complement, and can act as efficient antigen-presenting cells. It seems likely that they contribute to perpetuation of the disease (Andrew *et al*. 1991).

IgG in patients with rheumatoid arthritis shows markedly reduced glycosylation, with a galactose 'pocket' in the Fc region (Parekh *et al*. 1985), in association with low levels of B-cell galactosyl transferase (Axford *et al*. 1987). It has been suggested that this glycosylation defect could result in conformational changes in the Fc region, rheumatoid factors more readily aggregating such molecules. Passive transfer of an acute synovitis in T-cell-primed mice has been shown to be enhanced using IgG containing autoantibodies to type II collagen when the antibodies are present as the agalactosyl glycoform. (Rademacher *et al*. 1994), demonstrating that agalactosyl IgG glycoforms are directly associated with pathogenicity in murine collagen-induced arthritis. However, the role of such glycosylation defects in the aetiology or pathogenesis of rheumatoid arthritis has yet to be established.

Other 'autoantibodies' that occur in rheumatoid arthritis include natural autoantibodies, antinuclear antibodies, anticollagen antibodies, antikeratin antibodies, and an IgG perinuclear factor. Of these, antibodies directed to two distinct epidermal antigens appear to show high diagnostic specificity for rheumatoid arthritis with a sensitivity of about 50 per cent. These are:

1. IgG antikeratin antibodies, which are present in 36 to 60 per cent of patients with rheumatoid arthritis, show a specificity of over 95 per cent in most studies. The antibody activity is directed against an antigen in the keratinized stratified epithelium of the rat oesophagus and is demonstrated by indirect immunofluorescence (Young *et al*. 1979). As a proportion of patients with rheumatoid arthritis without rheumatoid factor were positive in this test, it may be viewed as an additional serological marker of rheumatoid arthritis. Although it has been claimed that the antigen is an epidermal cytokeratin, the supporting data are poorly substantiated, and the identity of the antigen remains unknown.

2. An antibody directed against another epidermal antigen is known as antiperinuclear factor: this is demonstrated by an indirect immunofluorescence technique using buccal mucosal epithelial cells as substrate (Nienhuis and Mandema 1964). These IgG antibodies in rheumatoid arthritis are directed against spherical cytoplasmic granules and, when undiluted serum is used, show a diagnostic specificity of 98 per cent, with a sensitivity of 52 per cent (Westgeest *et al*. 1987). However, antiperinuclear factor has been found by some in a significant proportion of patients with Sjögren's syndrome, systemic lupus, systemic sclerosis, infectious mononucleosis, and metastatic lung cancer. It has been claimed that a positive test for antiperinuclear factor occurs in rheumatoid arthritis in the absence of IgM rheumatoid factor and therefore is of value in diagnosis. The biochemical and molecular properties of the antigen reactive with antibodies to antiperinuclear factor are also poorly characterized. Recent studies have shown colocalization of antiperinuclear factor and profilaggrin in human buccal cells, and evidence has accumulated suggesting that antibodies to antiperinuclear factor and stratified epithelial keratin recognize epitopes on profilaggrin (Berthelot *et al*. 1994; Sebbag *et al*. 1995).

Antinuclear antibodies detected by indirect immunofluorescence occur in up to 40 per cent of sera from patients with rheumatoid arthritis. Antibodies to histones, which also react as rheumatoid factors as a result of an epitope shared with IgG-Fc, have also been described in rheumatoid sera (Hannestad and Stollar 1978). Precipitating antibodies to soluble cellular antigen have been described in rheumatoid vasculitis (Venables *et al*. 1979). An antibody detected by Western blotting to a ribonucleoprotein termed RA33 has been found in 36 per cent of rheumatoid sera, including early in disease, but also occurs in sera from mixed connective tissue disease and systemic lupus. Partial sequencing of RA33 shows it to be identical to the A2 protein of the heterogeneous nuclear ribonucleoprotein (**hnRNP**) complex (Steiner *et al*. 1992; Hassfeld *et al*. 1995).

All the foregoing examples of antibodies appear to be associated specifically with rheumatoid arthritis, but react with antigens that are not restricted to the site of disease in joints. However, another set of antibodies in rheumatoid arthritis is directed against antigens present in cartilage only, such as collagen type II, IX, and XI, and chondrocyte-specific antigens. The published data on the frequency of these antibodies are variable in different series, possibly as a result of the differing derivation of collagen (both homologous and heterologous collagens are used and are not identical), lack of purity of antigens, interference from serum factors, and the wide variety of techniques for detection. In one study, antibodies to collagen II occurred in 29 per cent of patients with rheumatoid arthritis, while antibodies to type IX and XI were present in 40 per cent (Charriere *et al*. 1988). However, antibodies to collagen II and XI were also equally frequent in osteoporosis and Paget's disease, whereas anticollagen IX was relatively restricted to rheumatoid arthritis. Antibodies to collagen I and II are produced locally in rheumatoid joints (Tarkowski *et al*. 1989). Antibodies to chondrocyte membrane antigens occur in rheumatoid arthritis but have been poorly characterized so far (Mollenhauer *et al*. 1988), but a preliminary report suggests that a glycoprotein synthesized by chondrocytes is a specific T-cell autoantigen in rheumatoid arthritis (Rijnders *et al*. 1996).

Induction

In the context of autoimmune diseases in general, as in rheumatoid arthritis, environmental agents are seen as triggers rather than as being directly involved in the disease process. However, how environmental agents induce autoimmunity is not understood. Various hypotheses have been proposed of which the concept of 'antigenic mimicry' is the most popular.

'Antigenic mimicry' implies that an immune response to an extrinsic antigen (usually microbial), closely resembling an autoantigen, induces an immune response that cross-reacts with the autoantigen. If the response is to be long lasting, then the autoantigen must perpetuate it as the extrinsic antigen is eliminated. Despite the popularity of this concept, there are as yet no definite examples in human autoimmunity. Mimicry can occur in autoimmunity, it is the mechanism by which heterogeneous or chemically treated autoantigens can induce experimental autoimmune diseases, for example thyroiditis by using thyroglobulin, or collagen arthritis (see below).

Another concept, proposed by Bottazzo, Feldmann, and colleagues (reviewed by Feldmann 1987; Feldmann 1989), was that a local immune response, to any environmental agents, may release enough cytokines into the environment to upregulate local antigen-presenting capacity, so allowing autoantigens, otherwise 'hidden' from the immune system because of lack of HLA class II expression, to be presented to immunocompetent T cells that have escaped elimination or induction of tolerance. This was first proposed for endocrine autoimmune diseases, with the suggestion that the endocrine epithelium becomes the critical source of (atypical) antigen-presenting capacity and of autoantigen. Substantial evidence has since accumulated that this scheme may apply in both experimental models and human disease. Transgenic mice, producing interferon-g in their islets of Langerhans under the control of the insulin promoter, develop an immune, T-cell-dependent diabetes, with autoreactive T cells lysing islets and rejecting transplanted islets (Sarvetnick *et al*. 1990). In human Graves' thyroiditis, the antigen-presenting capacity of thyrocytes has been documented, as well as the presence of activated autoantigen-reactive T cells, and of local cytokines needed to maintain both antigen-presenting function and T-cell activation (reviewed Feldmann *et al*. 1991). In rheumatoid arthritis, abundant antigen-presenting function resides in macrophages, dendritic cells, B cells, endothelium, and possibly activated T cells, although which of these is most deeply involved in antigen presentation in rheumatoid arthritis is not known. The presence of CD5+ B lymphocytes and their descendants may contribute significantly to local antigen-presenting function by binding to autoantibody containing immune complexes in their immunoglobulin receptor (Andrew *et al*. 1991).

What are the important autoantigens in rheumatoid arthritis? In a local autoimmune disease the autoimmune response is localized by the restricted distribution of critical autoantigens. This can be shown in Graves' disease where antigens synthesized by thyroid epithelial cells—thyroglobulin, thyroid peroxidase, and thyroid-stimulating hormone receptor—are targets of both T- and B-cell recognition (Dayan *et al*. 1991). In rheumatoid arthritis, cartilage autoantigens such as collagen type II, type IX, and type XI recognized by T and B cells would fulfil this role. These antigens as well as other cartilage- or chondrocyte-specific antigens could be of importance in the initial localization to synovial joints. A report of benefit following daily intake of a preparation of purified chicken type II collagen, has excited interest in the possibility of induction of 'by-stander' T-cell tolerance by regulating T cells to joints from the gut lymphoid system (Trentham *et al*. 1993). T cells recognizing hsp65 or the antigen implicated in the autologous mixed lymphocyte reaction, which have been described in rheumatoid arthritis, could not have this role because the antigens are ubiquitous in cell types in most tissues, but may be of importance in maintaining the disease process, and in the extra-articular manifestations.

It is not clear whether rheumatoid arthritis should be considered as a single disease, with all cases having the same aetiology, or whether it should be viewed as a syndrome, with a range of aetiological factors initiating the same pathogenetic mechanism, and so producing a similar constellation of features.

Pathology

Introduction

The most pronounced and invariant pathology is in the synovial joints. There is a typical distribution, the small joints of the hands and feet, knees, and hips being most often implicated, symmetrically. In the different joints there are minor differences in pathology, but there is an overall pattern. There are also extra-articular manifestations, such as nodules and systemic disease.

Involvement of synovial joints

While attempts have been made to study the early events in rheumatoid arthritis, this is difficult, and so the pathology that is well known is from established cases. The involvement of synovial joints in rheumatoid arthritis is both of the synovial fluid and membrane (Zvaifler *et al*. 1994). Synovial fluid volumes are increased, and the cellularity increased; the predominant cell is the polymorph, which is only rarely seen in the lining layer of the synovial membrane. The other major cells in the synovial fluid and membrane are T cells and macrophages, with dendritic cells and cells of the B-lymphocyte lineage in small numbers. Typical numbers in acute cases are about 10^6/ml of polymorphs, and 1 to 3 × 10^5/ml of mononuclear cells. The exact relationship of the cells in the fluid to those in the membrane is not clear. Those in the fluid originate from the membrane, but how they reach the fluid is not clear. Whether they can re-enter the membrane or directly damage cartilage is also not known.

The involvement of synovial membrane is summarized in Fig. 2. There are several key features:

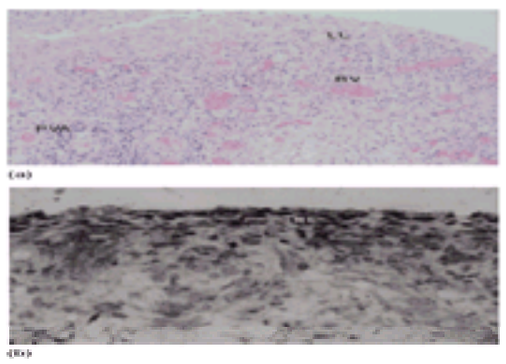

Fig. 2 Synovial membrane from a rheumatoid joint. (a) Haematoxylin–eosin staining of paraffin-embedded tissue (original magnification × 100) showing lining layer (LL) hypercellularity, prominent blood vessels (BV), and perivascular aggregates (PVA) of lymphocytes. The perivascular T lymphocytes are predominantly CD4+, CD45RO+, and CD29+ and a proportion bear activation markers HLA DR and IL-2 receptors. CD8+ T cells are distributed in interaggregate areas, as are plasma cells. (b) Tumour necrosis factor-a (TNF-a), IL-1a, b, and IL-6 are located in LL and in deeper layers: this cryostat section stained with $F(ab')_2$anti-TNF-a and developed with an immunoperoxidase method shows intracytoplasmic TNF-a.

1. The lining layer, normally two cells thick, is much thickened with increased numbers of both type A (macrophage-like) cells and type B (fibroblast-like) cells, both expressing activation markers.
2. The deeper layers are of increased cellularity, with perivascular accumulations and follicles. These are rich in T cells particularly CD4+ cells. CD8+ T cells are more frequently found in between perivascular accumulations, as are the abundant plasma cells and infrequent B cells. Macrophages are found in the follicles and in between. There are few polymorphs and dendritic cells in the membrane, the majority of which accumulate in fluid.
3. The rheumatoid synovium is particularly vascular. There are markedly increased numbers of vessels, and in some instances high-endothelial venules develop, as in lymph nodes.
4. Many of the cells, of all types, in the rheumatoid joint are activated. Thus HLA class II expression is found on nearly all the cell types, at an increased level, compared with that in normal or osteoarthritic joints. T cells are about 50 per cent class II positive, providing strong evidence of their activation status. B cells are positive, but typically plasma cells are not, as these lose the capacity to express class II. Macrophages express class II, as is often the case when activated, and class II-expressing fibroblasts and endothelial cells can also be seen.

Of interest is the HLA-DQ expression in rheumatoid arthritis, which is significantly greater than in other types of joint inflammation, for example Reiter's syndrome (Barkley *et al*. 1989a). The meaning of this difference is not clearly understood, as the relative roles of the commonest class II antigen, HLA DR, compared with the less common DQ and DP molecules are not known. Certain evidence allies HLA-DQ-restricted T cells to the suppressive immunoregulatory lineage (Sasazuki *et al*. 1986).

Other markers of activation abound. On the macrophage lineage, expression of CD11b (CR3) is increased, as is the related CD11c (p150/95). CD11a (lymphocyte function associated antigen-1) is increased on macrophages and many cell types. On T cells, expression of very late antigen (**VLA**) is increased, as is class II on a major proportion. In contrast interleukin (**IL**)-2 receptor is much less apparent. Endothelial cell expression of the adhesion molecules (**AMs**) **ICAM-1**(intercellular), VLA-1, and **ELAM-1** (endothelium–leucocyte) is increased. Tumour necrosis factor (**TNF**) receptors, also markers of activation, are upregulated in rheumatoid joints and are detectable on more than 80 per cent of T cells, on cells of the lining layer, and on cells at the cartilage–pannus junction (Deleuran *et al*. 1992; Brennan *et al*. 1995).

A common feature of activated cells is their increased production of cytokines and expression of cytokine receptors. This is the case in rheumatoid synovium, and the details will be discussed under pathogenesis.

Pannus

The junction between synovial tissue, cartilage, and bone is the site of early erosive damage in rheumatoid arthritis. This site becomes filled and overlaid by vascular tissue termed pannus. The lining layer of pannus is in continuity with the lining layer of hypercellular synovium and has been regarded as being derived from it. The cellular pannus forms a distinct junction with underlying cartilage (see Fig. 3), which shows many characteristics of degradation, including loss of matrix and water content, and chondrocyte depletion. The conventional view is that pannus has an invasive degradative effect on underlying cartilage, mediated by the secretions of enzymes such as metalloproteinases. This is associated with further loss of cartilage as a result of enzymatic destruction of matrix by chondrocytes themselves, coupled with a lack of synthesis of newly formed matrix. Pannus also appears to erode adjacent bone by a similar process involving degradation of bone matrix, but in addition involving active bone resorption by osteoclasts.

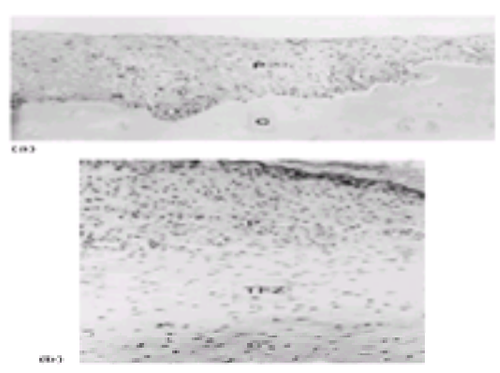

Fig. 3 Two types of cartilage–pannus junction seen in rheumatoid joints. (a) A distinct, well-defined margin can be seen between pannus (P) and cartilage (C). (b) A transitional fibroblastic zone (TFZ) separates a cellular, vascular pannus (P) from the underlying cartilage (C). Safranin O stain; original magnification × 46. (Reproduced with permission from Allard *et al*. 1987.)

A second type of pannus may also be observed, especially in the marginal cartilage area of weight-bearing joints. This consists of vascular pannus overlying cartilage with an indistinct, intervening, multilayered zone of fibroblast-like cells (Fig. 3). In contrast, the underlying cartilage of this pannus does not show degradative changes with loss of matrix. This type of pannus could represent a fibrotic healing phase, but has alternatively been termed a 'transitional' fibroblastic zone because the cytoplasm of these cells contains cartilage components such as keratan sulphate, chondroitin sulphate, and collagen type II (Allard *et al*. 1987; Allard *et al*. 1991). These cells may be derived from chondrocytes as a result of metaplastic change. However, the possibility has been raised that cells with the same phenotype resident in the subperiosteum, contiguous to synovium in normal joints, may give rise to the transitional fibroblastic zone in rheumatoid arthritis (Allard *et al*. 1990). The finding of proinflammatory cytokines capable of degrading cartilage (such as IL-l and TNF) in pannus cells contiguous with cartilage in the invasive type of erosion contrasts with absence of these cytokines in the transitional fibroblastic zone (Chu *et al*. 1991a; Chu *et al*. 1991b). Instead, the latter type of pannus shows the presence of only transforming growth factor-b (**TGF-b**), as this factor stimulates collagen and matrix production its presence is compatible with the proposal that the tissue is in an anabolic state of healing or differentiation.

Extra-articular manifestations

Local

These are more common in long-standing and severe cases. Rheumatoid nodules are the most common, and are found in areas susceptible to trauma, such as elbows. They consist of a palisade of macrophages surrounding fibrous tissue.

Systemic

There are disagreements about the extent and frequency of systemic manifestations, and whether rheumatoid arthritis is always manifest systemically. Elevated concentrations of acute-phase proteins such as C-reactive protein, serum amyloid A, or complement components are found in most cases, and these suggest that their production in liver is increased. IL-6 can activate the liver to produce many acute-phase proteins, and it is currently assumed that the increased production of IL-6 (and IL-1) in rheumatoid arthritis (reviewed Feldmann *et al*. 1996) is responsible.

In more severe cases there may be:

i. vasculitis;
ii. fibrosis of the lungs which may progress to significant fibrotic impairment of lung function;
iii. granuloma formation as characterized by nodule formation;
iv. serositis as characterized by pericarditis and pleurisy, commonly asymptomatic;
v. Felty's syndrome: enlargement of the spleen with lymphadenopathy, fever, leg ulcers, and susceptibility to bacterial infections.

Pathogenesis

Introduction

Describing the pathogenesis of a chronic disease, such as rheumatoid arthritis, for which there are no very accurate animal models, is difficult. It is possible to describe, on the basis of human studies, the events occurring when the disease is well established. Accurate description of early events is not possible, only informed speculation can be made. As the pathology—the morphological description of what has happened—has been discussed, consideration of the pathogenesis will be itemized in relation to how these changes may have evolved.

Cell recruitment

The vast majority of the increased number of cells in the rheumatoid joint are of lymphohaemopoietic origin, as shown by immunostaining techniques, and their presence in the rheumatoid joint implies that there are mechanisms for increasing cell input, and also for increasing retention. This increase in cellularity is accompanied by angiogenesis in the synovial membrane, thus increasing delivery of cells and molecules to areas of inflammation (Folkman 1995). Neovascularization involves angiogenic cytokines such as **VEGF** (vascular endothelial growth factor), an endothelial-specific mitogen which promotes the growth of new blood vessels (Colville-Nash and Scott 1992) and also renders the vasculature hyperpermeable *in vivo* (Ferrara *et al*. 1991). Much work has focused on the endothelium in rheumatoid arthritis, as blood-borne cells would first have to adhere and migrate through endothelium. Augmented expression of adhesion molecules capable of binding lymphocytes, polymorphs, and monocytes has been noted: ICAM-1, E-selectin, and **VCAM-1** (vascular cell adhesion molecule) are all increased at various pathological sites. Isolated rheumatoid synovial endothelial cells constitutively express ICAM-1 and E-selectin and this expression is upregulated by IL-1 and TNF (Abbot *et al*. 1992). Immunohistochemical techniques have shown that VCAM-1, ICAM-1, and E-selectin are highly expressed by rheumatoid synovial vascular endothelial cells and cells in the lining layer (Koch *et al*. 1992; Morales-Ducret *et al*. 1992; Wilkinson *et al*. 1993).

A local differentiation of T cells in rheumatoid arthritis synovial membrane has been suggested by the predominance of T cells with the phenotype of memory cells (CD45RO+, CD29). Increased expression of VLA-4 on CD45RO+ T cells could indicate selective migration of memory T cells into the inflamed synovial membrane. In fact CD45RO+ T cells have been shown to have a better adherence to endothelial cells than CD45RO- T cells (Pitzalis *et al*. 1987). In addition, synovial T cells in rheumatoid arthritis have a significantly greater capacity to migrate transendothelially compared with those from normal or rheumatoid arthritis peripheral blood (Cush *et al*. 1992).

Equally important in cell recruitment is the action of chemotactic factors, which promote the migration of cells into a site. Some of these mediators have been identified within rheumatoid joints including representatives of the two families of chemokines, the C-X-C(a) chemokines such as IL-8 (Brennan *et al*. 1990a), and the C-C(b) chemokines such as **RANTES** (regulated upon activation, T-cell expressed, and secreted) (Rathanaswami *et al*. 1993), **MCP-1** (monocyte chemoattractant protein 1) (Koch *et al*. 1992; Akahoshi *et al*. 1993), **MIP-1a**(macrophage inflammatory protein-a) (Koch *et al*. 1994), and MIP-1b (Villiger *et al*. 1992). As the majority of the cells in the rheumatoid arthritis synovium are macrophages and T lymphocytes, b-chemokines are likely to be important but neutrophil chemoattractants such as IL-8, **GROa** (melanoma growth-stimulating activity), and **ENA-78** (epithelial neutrophil activating peptide) are likely to play a role in neutrophil accumulation within the joint fluid. Split complement components C3a and C5a present in rheumatoid arthritis joints (Jose *et al*. 1990; Abbink *et al*. 1992) are also chemotactic for neutrophils.

T-cell activation in rheumatoid arthritis

The T lymphocyte is one of the most common cells in active rheumatoid arthritis, with an abundance ranging from 20 to 50 per cent of the cells extracted from synovial membrane. CD4+ cells are more abundant than CD8+ in the membrane, but not necessarily in the synovial fluid. The CD4+ cells tend to concentrate in perivascular nodules, whereas the CD8+ are more diffusely scattered. CD4+ cells have been subdivided into subsets, depending on their CD45 expression. In normal blood, about one-half are CD45RA+, indicating a 'virgin state'. Essentially all the cells in the rheumatoid joint lack CD45RA and express CD45RO/CD29, indicating a 'primed' or 'memory' state (Pitzalis *et al*. 1987). This is not surprising, as there is evidence for an ongoing immune response, as judged by the expression of T-cell activation markers, such as HLA class II (on 50 per cent), and IL-2 receptors on fewer cells (2 to 12 per cent) (Brennan *et al*. 1988a; Londei *et al*. 1989).

T lymphocytes may also be classified according to their T-cell receptor for antigen. In normal blood the great majority (more than 95 per cent) express a heterodimer of a and b chains, whereas a minority use g and d chains. Of interest was the observation (Brennan *et al*. 1988b) that there was selective enrichment of gd T cells in active rheumatoid joints. and that some of the gd T cells recognize mycobacterial antigens (Holoshitz *et al*. 1989). However, elevated gd cell numbers have not been confirmed in all studies. In patients who have augmented gd T cells in their blood there is a trend towards increased amounts of CD5+ B cells (Brennan *et al*. 1989c).

An important question is whether T cells have a critical role in rheumatoid arthritis. Firestein and Zvaifler (1990) , based on low or absent levels of T-cell cytokines in the rheumatoid synovial environment, have proposed that T cells may not be important in the chronic established phase of disease. Indeed, in controlled clinical trials of rheumatoid arthritis with anti-T-cell (for example anti-CD4, anti-CD5) monoclonal antibodies, no beneficial effects were observed (Olsen *et al*. 1994; Van der Lubbe *et al*. 1995). However, our opinion is that in a prolonged, chronic, asynchronous disease with profound immunoregulation, the quantity of cytokines detected need not reflect their importance. Various lines of evidence support this possibility. First is the abundance of T cells in rheumatoid joints. Virtually none are present in normal joints. Second is their partially activated status and proximity to antigen-presenting cells (see above). Third is the fact that the proportions of different types of T cells present in rheumatoid joints are not the same as in blood (as discussed above), indicating that it is not a reflection of passive trafficking in an inflammatory response. Fourth is the observation that antigen-specific T cells are present, are activated, and persist in rheumatoid joints. For example we found that collagen type II-specific T cells were present, and expressing IL-2 receptors, in three operative specimens in a patient with rheumatoid arthritis, over a period of more than 4 years (Fig. 4) (Londei *et al*. 1989). Finally, **Th1** cells (T-helper 1) appear to predominate in the joint and interferon-g and IL-2 are expressed, albeit at low levels, but with unexpectedly high IL-10 production (Buchan *et al*. 1988b; Simon *et al*. 1994; Cohen *et al*. 1995).

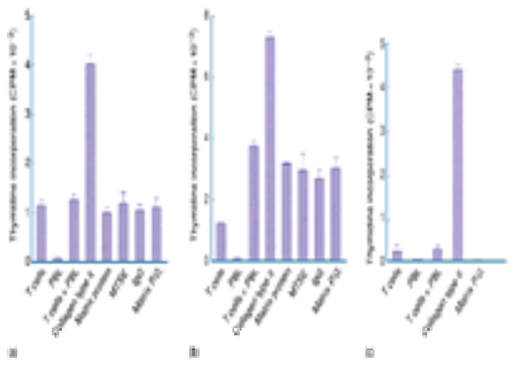

Fig. 4 Proliferative response of collagen type II-specific clones. (a) Clone 4 from the first synovial membrane. (b) Clone 55 with autologous mixed lymphocyte reactivity, from the first synovial membrane. (c) Clone B8 from the second synovial preparation. Results are the arithmetic means ± SEM of a representative experiment from each clone. In other experiments, collagen type I was also used, but there was no response from any of the clones. Cloned T cells (10^4), 2×10^4 irradiated, autologous, peripheral blood, mononuclear cells were cultured with or without the antigen indicated. Antigens were used at 100 µg/ml, except MTSE which was at 1 µg/ml. These were the optimal concentrations. PBL, peripheral blood lymphocytes; PG, proteoglycan; MTSE, mycobacterial tuberculosis soluble extract. (Reproduced with permission from Londei *et al*. 1989.)

A restricted pattern of V_b chains of the T-cell receptor was observed in rheumatoid joints by one group of workers, suggesting the possibility that activation of lymphocytes was mediated by superantigens (Paliard *et al*. 1991) However, other laboratories have not confirmed this observation. Thus, whereas Paliard *et al*. (1991) reported low V_b14 in blood of patients with rheumatoid arthritis compared with the level found in joints, Howell *et al*. (1991) reported that multiple *V*bgene families were transcribed in patients, although sequence similarities were found, in keeping with the hypothesis that superantigen may play a role in rheumatoid arthritis. Clearly much more work is needed in this area, but noting that all known autoimmune diseases and models are T-cell dependent, it is very likely that rheumatoid arthritis is T-cell dependent even in its later stages.

Whilst the function of T cells in rheumatoid arthritis is unresolved, much can be learned from investigations that define the role of T cells in induction and perpetuation of experimental models of arthritis. Collagen-induced arthritis is a CD4+ T-cell dependent disease as demonstrated by T-cell depletion (Ranges *et al*. 1985). However, unlike adjuvant arthritis, it is not readily transferred with T cells or T-cell clones. In the case of collagen-induced arthritis, transfer from histoincompatible DBA/1 mice to mice with subacute combined immunodeficiency has demonstrated that T and B cells act in synergy in the full expression of disease (Williams *et al*. 1992b; Taylor *et al*. 1995).

B-cell lineage

Plasma cells are abundant in rheumatoid arthritis. Some, but not all are involved in the production of rheumatoid factors. Rheumatoid factor immune complexes have been shown to induce the production of cytokines such as IL-1 and TNF (Fig. 5) (Chantry *et al*. 1989).

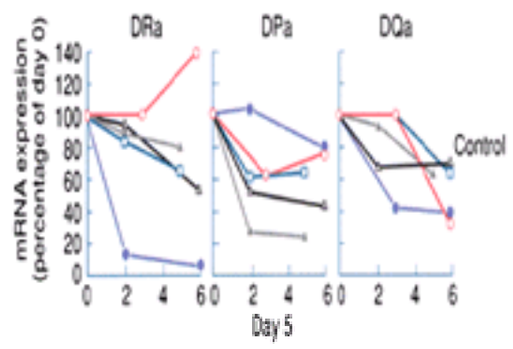

Fig. 5 Fresh isolated synovial membrane and synovial fluid cells obtained from five patients were placed in culture at 1×10^6/ml in the presence or absence of mediators (IFN-g and IL-2). Cells were harvested at the times indicated for the determination of cytoplasmic RNA. The results are expressed as percentages of the basal level. (●), Patient 1; (△), Patient 2; (▲), Patient 3; (□), Patient 4; (○), Patient 5. (Reproduced with permission from Kissonerghis *et al*. 1989.)

The specificity of the antibodies produced in rheumatoid joints has been investigated by the cell fusion technique using the human B-cell fusion partner, SPAZ4. Large numbers of hybridomas producing IgM and IgG were detected (Maini 1989). While a few of these were 'polyreactive', and some produced rheumatoid factors, the majority did not bind to a battery of autoantigens tested. However, it has been claimed that the majority of rheumatoid joints contain B cells producing antibody to collagen type II and IgG Fc (Tarkowski *et al*. 1989).

In examining the B-cell repertoire activated in rheumatoid joints, attempts are being made to ascertain whether there is any evidence of a restricted use of certain genes selected from among the multiple heavy-chain *V* genes available in the genome. In one such study, analysed by northern blotting, an overrepresentation of V_H4 was noted (Brown *et al*. 1992). Such overrepresentation may result from dominance of a B-cell subset in diseased tissues or from selection pressures created by specific antigens or superantigens. Alternatively, regulatory elements in flanking regions active in rheumatoid arthritis may favour recombination of particular individual gene elements and so skew the B-cell repertoire activated (Brown *et al*. 1995). As primed B cells recognizing antigen present antigen to T cells more efficiently than do macrophages (Lanzavecchia *et al*. 1985) and are probably important in the development and maintenance of the immune network in neonatal and adult life (reviewed by Plater-Zyberk *et al*. 1992), a greater understanding of the role of B cells should illuminate the pathogenesis of rheumatoid arthritis.

Antigen-presenting cells

There are abundant cells with antigen-presenting capacity in human rheumatoid joints. Which of these are of major importance in different stages of disease is a controversial question. Macrophages and monocytes represent some 30 to 50 per cent of the cell pool, and there is evidence for their activation, for example increased expression of HLA DQ, and diminished CD14. Dendritic cells are present in increased numbers. Regrettably, due to lack of specific markers for human dendritic cells, their numbers are not easy to quantify. However, cell separation studies by several groups have all demonstrated increased numbers of dendritic cells in rheumatoid synovial fluid, comprising up to 5 to 7 per cent of the mononuclear cells, whereas synovial tissue contained few dendritic cells (March 1987; Tsai *et al*. 1989). Dendritic cells from rheumatoid synovial fluid were potent antigen-presenting cells, but not more so than normal dendritic cells.

CD5+ B cells have Fc receptors and many produce rheumatoid factors. These may permit CD5 B cells to take up immune complexes and present the relevant antigens. The possible importance of CD5+ B cells in antigen presentation in rheumatoid arthritis has been discussed (Maini 1989). Chondrocytes can be activated to express HLA class II and may be critical in the early events of rheumatoid arthritis. ICAM-l expression in chondrocytes, which facilitates antigen-presenting cell function, has been reported (Davies *et al*. 1992).

Cell interaction

The importance of cell interactions in the rheumatoid joint can be inferred from the immunohistological studies, which show close apposition of T cells and antigen-presenting cells in nodules and in other sites throughout the synovial membrane. However, there are very few T cells in the pannus, suggesting that different

interactions may prevail in this specialized site.

Dissociated cells from rheumatoid joints, placed in tissue culture, in the absence of any extrinsic stimulus, rapidly reform into aggregates. This suggests that interactions are of critical importance in the disease process. Experimentally, one can demonstrate that these cell interactions are of importance *in vitro*. We have noted that rheumatoid synovial cells, placed in culture and in the absence of extrinsic stimulation, retain many features of active rheumatoid arthritis. Thus expression of HLA class II persists *in vitro*, at both the protein and mRNA levels, provided that the whole mixture of joint cells is cultured (Fig. 5). If only the adherent cells (chiefly fibroblasts) are cultured, class II expression apparently does not persist in culture (Teyton *et al*. 1987). Below, the persistence of cytokine production in cell cultures from rheumatoid joint not extrinsically stimulated is discussed.

The role of T cells in the persistence of class II expression has been studied by depleting T cells using a combination of lysis with antibody and complement, and antibody-coated magnetic beads. Even with an incomplete depletion of cells, a marked reduction in class II expression was noted after 6 days in culture (C.M. Hawrylowicz *et al*., unpublished observations). This emphasizes the importance of cell interactions, but does not clarify which T cells are of critical importance, nor which are the critical antigen-presenting cells.

Cytokine expression

As rheumatoid arthritis is mostly manifest in synovial joints, which are the sites of inflammation and destruction, cytokine production in the joints has been investigated by several groups. However, cytokines can also be detected in blood cells by immunostaining, for example IL-1a (Barkley *et al*. 1989b). Whether other cytokines can also be detected in the blood cells remains to be established. Elevated serum concentrations of cytokines have been reported, for example, IL-l b (Eastgate *et al*. 1988), but their reproducibility and significance remain to be established in view of the presence of serum cytokine inhibitors.

Rheumatoid joints contain a wide variety of activated cell types, and so it would be expected that many cytokines would be produced locally in the joint. When we began studies on the expression of cytokines in rheumatoid joints in 1985, slot blotting and cDNA hybridization were used to obtain maximum data on cytokine expression from a small number of cells. With these techniques 2×10^6 cells were used, and could provide data on about 6, or sometimes up to 10 cytokines. By densitometry, relative quantification was possible. Further advantages of this technique are its specificity for individual cytokines, ease of performance (same technique for all cytokines), and its resistance to artefacts caused by rheumatoid factors (a problem in binding assays), and to 'toxic' components of synovial fluid in bioassays (Buchan *et al*. 1988a; Buchan *et al*. 1988b). A disadvantage is that the amounts of cytokine mRNA being measured do not always correlate with the amounts of cytokine protein produced. This is especially a problem with cytokines known to be regulated post-transcriptionally, for example TNF-a. If this type of work was to be begun again, obviously the polymerase chain reaction (**PCR**) would be used, for its much greater sensitivity (Brenner *et al*. 1989). However, the use of PCR is not without problems; for example quantification is very difficult and contamination frequent. Using PCR to explore cytokine expression in rheumatoid arthritis has yielded the same results as slot blotting, that is, predominance of IL-1a and abundance of TNF-a (Brennan *et al*. 1989a). *In situ* hybridization has yielded analogous results (Firestein *et al*. 1990), and also provides information about localization, but quantification is difficult.

It is not surprising that virtually all the cytokines sought have been detected because of the wide variety of activated cells. Table 2 summarizes the cytokine expression in the rheumatoid joint. There are some interesting generalizations that can be made. For example, cytokines that are predominantly macrophage products are abundant, at both the mRNA and protein level, for example IL-1, IL-6, TNF, and IL-8. In contrast, cytokines produced by T cells are detectable at the mRNA level, but barely detectable at the protein level, for example interferon-g, lymphotoxin, and IL-2. The reasons for this discrepancy are not yet known, but TGF-b which inhibits cytokine production post-transcriptionally may be responsible. Local consumption of cytokines by cells with high-affinity receptors may also contribute, as, for example, there are free and cell-bound IL-2 receptors in rheumatoid joint cells (Symons *et al*. 1988).

Cytokine	mRNA	Protein
IL-1α	+	+
IL-1β	+	+
TNF-α	+	+
LT	+	–
IL-2	+	–
IL-3	–	–
IL-4	?	–
IFN-γ	+	–
GM-CSF	+	+
G-CSF	+	?
M-CSF	–	+
TGF-β	+	+
EGF	+	+
PDGF-A	+	+
PDGF-B	+	+

EGF, epidermal growth factor; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage CSF; IL, interleukin; LT, lymphotoxin; M-CSF, macrophage CSF; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TNF, tumour necrosis factor.
After Brennan *et al*. (1992).

Table 2 Summary of cytokines produced by rheumatoid synovial cells

Cytokines are essential for many processes in rheumatoid arthritis, such as cell growth and expression of HLA class II, reviewed in Feldmann *et al*. (1996). However, it is not clear which cytokines are of major importance in different processes. A critical step in the generation of an immune or inflammatory reaction is activation of macrophages and induction of HLA class II expression. Interferon-g is potentially the most effective cytokine at inducing such expression in the absence of other factors (Portillo *et al*. 1989). However, negligible amounts of interferon-g (or other T-cell lymphokines) are produced by rheumatoid synovial cells (Firestein and Zvaifler 1987; Brennan *et al*. 1989a) suggesting that other factors alone or in combination with this interferon-g are involved. One possible candidate is the haemopoietic growth factor **GM-CSF** (granulocyte–macrophage colony-stimulating factor) which induces HLA-DR expression on human monocytes (Chantry *et al*. 1990) and which could be an important macrophage activator and induce HLA class II expression in the rheumatoid joint (Alvaro-Garcia *et al*. 1989). However, the most significant inhibition of that expression which we observed in the rheumatoid synovial cultures was with anti-TNF antibody (unpublished observation) and was greater than that with antibodies to interferon-g or GM-CSF. This is unlikely to be a direct effect, as TNF by itself does not induce the expression of HLA class II (for example Pujol-Borell *et al*. 1987). This suggests that many different cytokines may work together to induce this expression (Sadeghi *et al*. 1992a; Sadeghi *et al*. 1992b) or that other, as yet undefined, molecules may be involved. Alternatively (or in addition) cell–cell interactions through cell adhesion molecules may be necessary to maintain this. Of interest is the observation that TNF-a is a potent inducer of many adhesion molecules including ICAM-1 and VCAM-1 (Pober *et al*. 1986; Rice and Bevilacqua 1989).

The activation and differentiation of B cells is also mediated by cytokines, of which IL-4 and IL-6 are the most important. IL-4 is a potent B-cell growth factor but is detected in negligible amounts in rheumatoid synovial cells (unpublished observation) or in synovial fluid. In contrast, high levels of IL-6 have been detected both in rheumatoid synovial fluid and in cells from rheumatoid synovial membrane (Hirano *et al*. 1988; Field *et al*. 1991). The presence of high levels of IL-6 in rheumatoid joints may explain the large numbers of plasma cells and few B cells in the synovium and the production of autoantibodies including rheumatoid factors. Lymphotoxin and TNF-a can also act as a B-cell growth factor (Kehrl *et al*. 1987). The presence of immune complexes containing rheumatoid factor may further contribute to the pathogenesis of rheumatoid arthritis by inducing the production of IL-1 as shown by Chantry *et al*. (1989) (Fig. 6). The 'cytokine synthesis inhibitor', IL-10, which inhibits T-cell production of interferon-g, is also a potent B-cell stimulator (Moore *et al*. 1990).

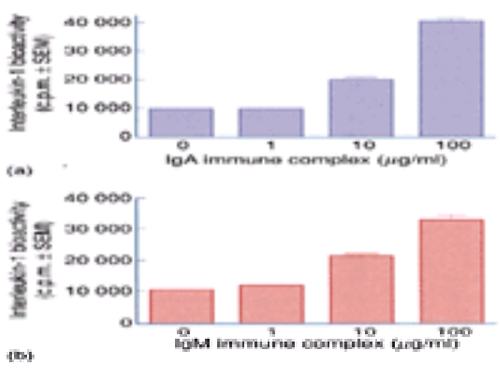

Fig. 6 Both IgA-containing immune complexes (a) and IgM-containing immune complexes (b) induce interleukin 1. Supernatants from monocytes cultured with various concentrations of immune complex for 24 h were assayed for interleukin1 bioactivity using the thymocyte comitogenic assay. Data is shown as [^{3}H]-thymidine incorporation (mean ± SEM of triplicate cultures). Proliferation due to phytohaemagglutinin antigen alone was 3486 ± 450 c.p.m. For both immune complexes significant (p<0.01) interleukin could be detected at concentrations as low as 10 µg/ml. (Reproduced with permission from Chantry *et al*. 1989.)

T-cell growth is controlled by cytokines. For many years, after the discovery of 'T-cell growth factor' and the purification, cloning, and expression of IL-2, it was thought that all T-cell growth was mediated by IL-2. Subsequent work has shown that the position is much more complex. IL-4, initially, described as a B-cell stimulating factor, is also a potent growth factor for many T cells, and IL-7, described as a pre-B growth factor, is also highly active (for example Londei *et al*. 1990). T-cell activation is found in rheumatoid arthritis, with many cells expressing HLA class II (20 to 50 per cent), and a few (2 to 12 per cent) expressing IL-2 receptors. However, the mechanism of T-cell growth is unclear, as while IL-2 mRNA is found (Buchan *et al*. 1988b), the protein is not readily detectable. This could be due to absorption by cell-bound receptors, to IL-2 inhibitors such as the soluble IL-2 receptor (Symons *et al*. 1991), or to post-transcriptional regulation. IL-4 is also not readily detectable, for possibly the same reasons. Currently it is unknown whether there is IL-7 in rheumatoid joints, but it is clearly an important candidate for T-cell growth regulation in rheumatoid arthritis. A synergy between all these cytokines could permit T-cell growth in the presence of low protein levels of each of these mediators. This possibility requires investigation using cells from rheumatoid joints in culture.

Fibrosis is an important component and complication of rheumatoid arthritis. It participates in deformation of joints, but pulmonary fibrosis can be a damaging systemic complication. Which cytokine drives the fibrosis in the rheumatoid joint (or other tissues) is not currently known. There are abundant candidates present in the rheumatoid joint, for example IL-1a and b, TNF-a, which may act indirectly via induction by platelet-derived growth factor (Raines *et al*. 1989), and TGF-a and -b. The presence in rheumatoid joints of members of the fibroblast growth family is not known, but is likely.

Cytokine regulation

Initial studies of the expression of IL-1 in rheumatoid joints revealed that all samples contained IL-1 mRNA. After the experimental activation of normal cells *in vitro*, that of IL-1 mRNA (and the expression of other cytokines) is brief (24 to 48 h), so the fact that all samples from rheumatoid arthritis were positive suggested that cytokine production in the rheumatoid joint may be relatively stable and persistent. In a chronic disease only persistent features can be relevant to the maintenance of the disease process, so the consistence and persistence of cytokine production suggested that it was of importance in the pathogenesis (Buchan *et al*. 1988a).

Cytokine persistence was directly tested *in vitro* by culturing dissociated cells from rheumatoid joints in the absence of extrinsic stimulation. The initial results showed that both IL-1a and IL-1b mRNA persisted for up to the 5-day culture period (Fig. 7) (Buchan *et al*. 1988a). This indicates that the signals necessary to regulate cytokine production are present in the culture, and so can be analysed.

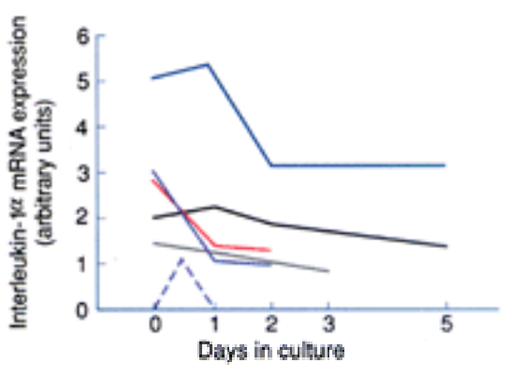

Fig. 7 Persistence of interleukin-1a mRNA production in rheumatoid joint cells in culture. Slot blot analysis of interleukin-1a production by rheumatoid arthritis synovial fluid mononuclear cells cultured in the absence of extrinsic antigen. SF and SM mononuclear cells were cultured for 0 to 5 days, the RNA extracted, blotted on to nitrocellulose, and probed with IL-1a. Integral values were calculated. Different symbols represent different patients. .....is interleukin 1a mRNA from mitogen-activated peripheral blood mononuclear cells. (Reproduced with modification from Buchan *et al*. 1988a.)

Neutralizing antibodies were chosen as the tool to investigate the signals involved in regulating the production of IL-1. The strongest non-microbial signals for the regulation of this production were the cytokines TNF-a and TNF-b (lymphotoxin), so neutralizing antibodies to these two cytokines were used. The results were clear cut; anti-TNF-a but not anti-TNF-b or control rabbit Ig inhibited IL-1 production after the first day of culture (Fig. 8(a)) (Brennan *et al*. 1989b). Assays at the mRNA level show more rapid kinetics, but the lack of an early effect on the amount of IL-1 protein indicates that already ongoing synthesis of IL-1 was not affected, but that subsequent activation was blocked. As a control, the same antibodies were used on cultures of cells from osteoarthritic joints. Despite the presence of immunoreactive TNF-a there was no effect of anti-TNF-a on the low levels of IL-1 in osteoarthritis (Fig. 8(b)). This is now known to be caused by the TNF in osteoarthritis not being biologically active.

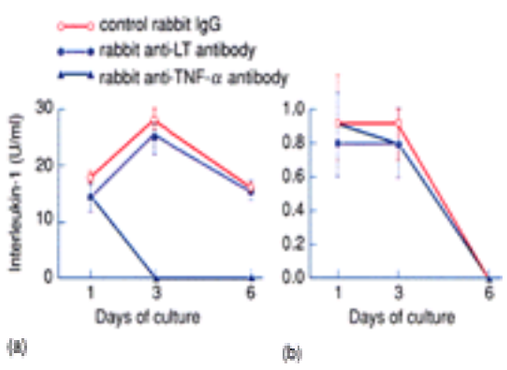

Fig. 8 (a) Effect of anti-TNF-a on rheumatoid arthritis joint cell culture. (b) Lack of effect of anti-TNF-a on osteoarthritis joint cell cultures. (Reproduced with modification from Brennan *et al*. 1989a.)

The finding that TNF-a was the single dominant signal regulating the production of IL-1 was surprising. It had been anticipated that multiple signals may be of importance, including immune complexes and perhaps other non-cytokine signals. However, samples from the first seven patients behaved in this way, regardless of their therapy. This led us to investigate what other effects of anti-TNF-a on the disease process may be. It has been postulated that GM-CSF is an important cytokine in rheumatoid arthritis, as it is an inducer of class II on monocytes, and induces cytokine production and macrophage activation (Alvaro-Garcia *et al*. 1989). It was therefore of interest to determine which cytokine regulates the production of GM-CSF in cell cultures from rheumatoid joints. Anti-TNF-a markedly inhibited the production of GM-CSF, but more slowly than inhibition of IL-1, being virtually complete only by day 5 (Haworth *et al*. 1991). We have also found that anti-TNF partially inhibits class II expression and also the aggregation normally found in these cultures. A summary of the effects of TNF in rheumatoid joints is shown in Fig. 9.

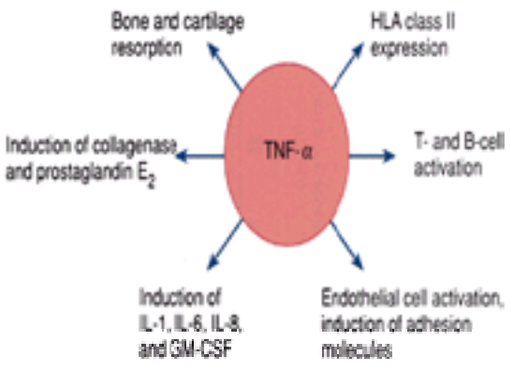

Fig. 9 Effects mediated by TNF-a in rheumatoid arthritis.

The results obtained in rheumatoid arthritis are analogous to those now described in the response of mice to systemic Gram-negative bacteria. Production of TNF-a, IL-1, and IL-6 was monitored; peaks of TNF-a preceded those of IL-1 then IL-6. Anti-TNF-a abrogated the production of IL-1 and IL-6 in this animal model (Fong *et al*. 1989). Thus it seems likely that in rheumatoid arthritis, the dominant position of TNF-a recapitulates the physiological situation.

Following the demonstration that anti-TNF can inhibit the production *in vitro* of IL-1 and other proinflammatory cytokines (IL-6, GM-CSF, IL-8) (Feldmann *et al*. 1996) and the successful amelioration of collagen-induced arthritis in DBA/1 mice by use of anti-TNF (Williams *et al*. 1992a), we formulated the hypothesis that TNF-a is at the apex of a cytokine cascade. This gave the rationale to blockade TNF in 20 patients with active rheumatoid arthritis in an open phase I/II trial lasting 8 weeks (Elliott *et al*. 1993).

The monoclonal antibody used was a chimeric (mouse Fv, human IgG1) neutralizing antibody produced by Centocor, Inc. The benefits of anti-TNF treatment were evident in all patients within a few days and lasted 8 to 26 weeks (median 12 weeks). Improvements in clinical parameters included reduction in pain and morning stiffness, falls in swollen and tender joint counts, increased erythrocyte sedimentation rate and reduced C-reactive protein and serum amyloid A. Following this initial success a randomized, double-blind, placebo-controlled, multicentre trial of anti-TNF in 73 patients was undertaken, the results of which confirmed the open study (Elliott *et al*. 1994) and supported the hypothesis that TNF is of major importance in the pathogenesis of rheumatoid arthritis (Fig. 10 and Fig. 11).

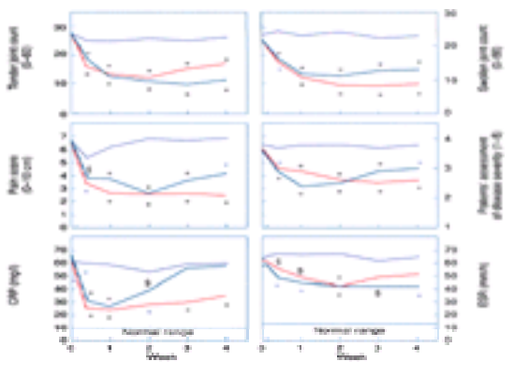

Fig. 10 Changes in clinical assessments in 73 patients treated with placebo (●), 1 mg/kg (▲), or 10 mg/kg (■) anti-TNF monoclonal antibody in a randomized, double-blind trial (*p* values represent significance versus placebo: + $p < 0.05$; § $p < 0.01$; * $p < 0.001$). Fig. 11 Overall clinical responses to placebo, 1 mg/kg, or 10 mg/kg anti-TNF monoclonal antibody in 73 patients, 4 weeks after treatment, in a randomized, double-blind trial (*p* values represent significance versus placebo). (Reproduced by kind permission from articles by Elliott *et al*. 1994, *Lancet*, **344**, 1105–10 and Maini *et al*. 1995, *Immunology Reviews*, **144**, 95–223.)

The mechanism of the anti-inflammatory action of anti-TNF-a antibody is under examination in current studies. A rapid decrease of serum IL-6 following anti-TNF demonstrates the effect of anti-TNF antibody on downregulation of other cytokines (Maini *et al*. 1995). A second, and possibly more important, effect of TNF blockade is in reducing the cellularity of the synovium (Maini *et al*. 1995). This is accompanied by an increase in peripheral blood lymphocyte count and a decrease in expression of adhesion molecules in synovial biopsies taken before and after therapy (Tak *et al*. 1996). There is an associated decrease in circulating levels of E-selectin and ICAM-1 (Paleolog *et al*. 1996). Viewed together, these data suggest that anti-TNF therapy reduces cell traffic into joints by reducing leucocyte–endothelium interactions, thereby reducing the mass of inflammatory tissue and its clinicopathological consequences.

Cytokine antagonists

In 1989, TNF-binding protein, capable of inhibiting the action of TNF, was discovered in the blood and urine of febrile patients (Englemann *et al*. 1989; Seckinger *et al*. 1989). This was subsequently found to be derived from the extracellular domain of the two TNF receptors, probably by proteolytic cleavage. On account of the proposed role of TNF-a in the pathogenesis of rheumatoid arthritis, the role of TNF inhibitor was explored, with the expectation that levels of soluble TNF receptors may be low.

Analysis of serum samples from a variety of arthritic patients has revealed that in rheumatoid arthritis the TNF inhibitor system is enhanced, and there are elevated levels of both soluble TNF receptors (p55 and p75) in serum and in the joint fluids, with an intermediate rise in levels in seronegative arthritis and osteoarthritis (Cope *et al*. 1992). However, these upregulated levels of soluble TNF receptors do not neutralize fully the TNF-a produced by cells from rheumatoid joints in culture, whereas they generally appear to be sufficient to neutralize TNF-a produced by cells from osteoarthritic joints in culture (Brennan *et al*. 1995). Thus, in arthritis there appears to be an attempt at homeostasis, which, however, is inadequate (Cope and Maini 1995). Other soluble cytokine receptors that in the fluid phase would act as cytokine antagonists have been described, for example, soluble IL-1 (Symons *et al*. 1991), –2 (p55), –4, –6, and –7 receptors and soluble interferon-g receptor, which may act as regulators of the cytokine network.

There is so far only one cytokine inhibitor described which acts as a receptor antagonist, i.e. the IL-1 receptor antagonist, which is produced in rheumatoid joints

(Arend 1991). This is a member of the IL-1 family, with 30 per cent homology to IL-1b. The physiological role of this molecule is unclear, as quantities greatly in excess of those of IL-1 are necessary to exert inhibitory effects, far larger than are physiologically present *in vivo*. Its role may be simply to localize the effects of IL-1 in the environment in which the cytokine is produced. Whatever the exact physiological roles of IL-1 receptor antagonist and soluble TNF receptor, these natural agents with the capacity to interfere with cytokine action are potential therapeutic agents in rheumatoid arthritis (Elliott and Maini 1996).

Immune suppression in rheumatoid arthritis

Despite the evidence for an ongoing autoimmune response at both the T- and B-cell level, there is also considerable evidence that the systemic immune response is suppressed in patients with rheumatoid arthritis. This has been demonstrated as a reduced response to tuberculin (purified protein derivative) testing (Kingsley *et al*. 1987), in IL-2 production, or in T-cell proliferative or cytokine production. Serial studies have shown that the degree of immune suppression is more severe as the patients are clinically more ill. The mechanisms of this suppression are not understood, but could lead eventually to new forms of therapy aimed at reinforcing the endogenous mechanisms of immune suppression.

A number of molecules found in the joints in rheumatoid arthritis may be important contributors to this process. These include prostaglandins and TGF-b. Other potential candidates not yet known to be present include oncostatin M, IL-10, and IL-4. Prostaglandins are produced in the inflammation of rheumatoid arthritis. However, most non-steroidal anti-inflammatory drugs interfere with the production of prostaglandins, and this does not overcome the endogenous suppression, which accordingly is mostly caused by other agents. TGF-b is found in large amounts in supernatants of synovial cell cultures (10 to 20 ng/ml) of which 1 to 2 ng/ml is bioactive (Brennan *et al*. 1990b). There is thus sufficient TGF-b to influence immune functions of T and B cells, and cytokine production. However, appropriate neutralizing experiments on synovial cell cultures remain to be done. Oncostatin M is growth inhibitory for a variety of cell types, is produced by activated T cells and macrophages, and so may be expected to be present. IL-10, a product of T cells and B cells, can interfere with antigen-presenting capacity and with the production of interferon-g. IL-10 has been demonstrated in rheumatoid joints and *in vitro* studies reveal that it is apparently exerting a suppressive effect on endogenous production of TNF-a and IL-1 (Katsikis *et al*. 1993). The beneficial effect of administration of recombinant IL-10 in established collagen-induced arthritis supports its possible therapeutic potential (Walmsley *et al*. 1996)

Animal models (see Chapter 3.4)

Research in unravelling the factors that initiate rheumatoid arthritis, understanding the perpetuation of disease, and devising new strategies for therapy or prevention has to some extent depended on concepts developed and validated in animal models. Recent clinical studies have raised questions that have increased, rather than diminished, the complementary value of the use of animal models. However, there is as yet no ideal animal model of rheumatoid arthritis that exhibits all key features, namely:

1. predictable and spontaneous development of an erosive, chronic, symmetrical arthritis punctuated by flares;
2. female preponderance;
3. association with the MHC homologue of HLA DR4 or DR1;
4. high frequency of circulating IgM rheumatoid factor;
5. synovitis with a cellular response, profile of local production of cytokines, proteases, and inflammatory mediators identical to that observed in rheumatoid arthritis;
6. cartilage and bone degeneration with pannus formation;
7. response to disease-modifying antirheumatoid drugs akin to that observed in rheumatoid arthritis.

Despite reservations, the ensuing section gives examples of existing and new models of rheumatoid arthritis, which have contributed to our understanding of this disease.

Collagen-induced arthritis

The distribution of collagen II is essentially restricted to cartilage and the vitreous humour of the eye. Intradermal injection of native collagen II in Freund's adjuvant (but not of collagen types I and III or denatured type II) induces a polyarthritis in rats (Trentham *et al*. 1977), mice (Courtenay *et al*. 1980), and monkeys (Cathcart *et al*. 1986). Heterologous or autologous type II collagens are effective but the former leads to a destructive yet self-limiting disorder, whereas the latter is characterized by a chronic remitting and exacerbating course of disease (Holmdahl *et al*. 1986). T- and B-cell responses to multiple epitopes on collagen II occur, and disease of a milder variety than in the immunized animals has been transferred into syngeneic animals by serum and/or T cells. Rheumatoid factor is detectable and villous synovitis with increased cellularity of the lining layer, infiltration of deeper layers with mononuclear cells (predominantly CD4+ T cells), and pannus formation echo the changes observed in rheumatoid arthritis. The best-documented susceptible mouse, the DBA/l, bears the *H-2q*haplotype; H-2^{r} mice are also susceptible, but H-2^{d} mice are resistant to collagen arthritis. Although a polygenic disease, it is of considerable interest that the HLA class II molecules mapping to I-A (the mouse homologue of human HLA DQ) appear to be the element controlling susceptibility and immune responses to type II collagen in DBA/1 (Holmdahl *et al*. 1989). The importance of non-MHC genes, for example, genes regulating complement synthesis and the expression of IgG subclass isotypes, has been deduced from other studies.

The collagen arthritis has significant similarities to rheumatoid arthritis and its importance lies in the ability of an immune response to a constituent of cartilage to induce disease. As B- and T-cell-specific responses to collagen II occur in a proportion of patients with rheumatoid arthritis, especially, and sometimes exclusively, when lymphocytes from the synovial membrane are studied, the model provides evidence that collagen immunity might perpetuate rheumatoid disease. The model has provided useful data on the arthritogenic epitopes on type II collagen and therapeutic manipulations have provided evidence that antibodies directed against CD4+ T cells (Ranges *et al*. 1985), B cells (Helfgott *et al*. 1984), and TNF-a (Williams *et al*. 1992a) are effective in ameliorating established disease.

Adjuvant arthritis

A single intradermal injection of Freund's complete adjuvant (containing *Mycobacterium tuberculosis*) in the footpad or tail of rats induces a severe arthropathy involving the wrists, ankles, paws, and caudal part of the spine and tail (Pearson 1956). The arthropathy in its developed stage consists of synovitis with villous formation, pannus eroding cartilage and bone, marked periostitis with new bone formation, and inflammation and fibrosis of periarticular tissues. After peaking, the inflammatory arthritis declines and is followed by fibrous and bony ankylosis of joints. Extra-articular features can be prominent and include balanitis, conjunctivitis, and cutaneous lesions resembling psoriasis. Although the disease in diarthrodial joints has some similarity to rheumatoid arthritis, the other features are reminiscent of the clinical spectrum of spondylarthropathies, especially Reiter's syndrome. This is further suggested by a consistent lack of IgM rheumatoid factor. Susceptibility is strain dependent; for example, Lewis rats are most susceptible, and Fisher rats are less so. Susceptibility is believed to involve multiple genes with no convincing role for the MHC genes.

The major interest in the model springs from the demonstration that the disease is mediated by T cells that recognize mycobacterial peptides (Cohen *et al*. 1985). Furthermore, there is evidence for molecular mimicry between a mycobacterial antigen and cartilage antigens (van Eden *et al*. 1985), and this is believed to be the key factor in localization of the disease to joints. The relevant antigen has been defined and is a mycobacterial nonapeptide present in a 65-kDa mycobacterial protein that belongs to the family of hsp65 (van Eden *et al*. 1988). The nonapeptide stimulates T-cell clones of the CD4 phenotype, termed A2b and A2c, derived from a parent line, A2, obtained from a rat with adjuvant arthritis. Following *in vivo* inoculation into irradiated syngeneic Lewis rats, A2b causes a severe arthritis, whereas A2c protects from disease induction and causes a rapid remission (Cohen *et al*. 1985). When hsp65 or the nonapeptide are given before Freund's adjuvant, the rats are protected from the disease.

The possibility that T cells equivalent to the suppressive clones isolated from adjuvant arthritis are present in the inflammatory exudate of rheumatoid arthritis has prompted optimism that T-cell vaccination may prove to be a promising therapy. Activated T cells, treated with hydrostatic pressure, or T-cell receptors cross-linked with glutaraldehyde are used as surrogate suppressor–inducers in vaccination protocols. However, preliminary trials have not shown any benefit in rheumatoid arthritis (Van Laar *et al*. 1991).

Streptococcal cell-wall arthritis

A single injection intraperitoneally of an aqueous suspension of group A streptococcal cell-wall fragments into rats induces a polyarthritis (Cromartie *et al*. 1977). The arthritis involves wrists, ankles, and other joints, spares the axial skeleton, and is biphasic with an early phase reaching its maximum at 3 days, followed by the onset

of a chronic arthritis 2 to 4 weeks later. Lewis (LEW/N) female rats are the most susceptible to this form of arthritis and exhibit many pathological features of rheumatoid arthritis—a villous synovial thickening with surface fibrin, thickening of the synovial lining layer, polymorph exudation into joint fluid, mononuclear cell infiltrates with a predominance of CD4+ T cells, angiogenesis, and fibroblast proliferation with pannus formation and associated erosion of underlying cartilage and bone. Low titres of IgM rheumatoid factor are detectable. The active proinflammatory constituent of streptococcal cell-wall is its peptidoglycan component, which has extensive pathophysiological effects involving many cell types; the smallest active subunit of peptidoglycan is muramyl dipeptide, which is itself an activator of macrophages and endothelial cells. Persistence of streptococcal cell-wall owing to its protective carbohydrate side chains, is believed to contribute to the initiation and perpetuation of disease.

The importance of T cells in the pathogenesis of the disease has been demonstrated by transfer of arthritis to nude, T-cell deficient, inbred Lewis rats. Like rheumatoid arthritis, the T-cell abnormalities include depressed responses to mitogen and defective production of IL-2. As hsp65 protects against arthritis induced by streptococcal cell wall (van den Broek *et al*. 1989), it has been suggested that this protein may be the host protein target for the T-cell response. However, the molecular basis of this has not been resolved. Although HLA class II molecules are rapidly induced in endothelial cells in inflamed tissues, the role of MHC antigen-associated susceptibility is ambiguous because a related strain of rats (the Fisher strain) with the same histocompatibility locus is relatively resistant to arthritis.

Of considerable interest are the observations on the hypothalamoadrenal axis in the arthritis induced by streptococcal cell wall. In susceptible female Lewis rats there is an abnormally low gene expression at the mRNA level of the corticotrophin-releasing hormone and encephalin, with a deficient response of adrenal corticotrophic hormone and adrenal corticosteroid (Sternberg *et al*. 1989a; Sternberg *et al*. 1989b). In contrast, Fisher rats, resistant to arthritis, show relatively rapid and efficient responses from the hypothalamoadrenal axis. That these neuroendocrine responses are important in the pathogenesis of disease is suggested by the observation that giving corticosteroid in small doses simultaneously administered with streptococcal cell wall improves the course of the induced arthritis and, conversely, blockade of the glucocorticoid receptor with RU 486 accelerates disease in resistant Fisher rats (Sternberg *et al*. 1989a).

Other models of arthritis

The transient inflammatory arthritis of serum sickness in rabbits induced by antigen and mediated by antigen–antibody complexes (Dixon *et al*. 1958) had antedated the description of chronic arthritis in the rabbit knee induced by intra-articular injection of protein antigens such as fibrin, heterologous gammaglobulin, and ovalbumin into previously sensitized animals that had received antigen in Freund's adjuvant (Dumonde and Glynn 1962). One aspect of interest in the latter model was the demonstration that the arthritis was dependent on antigen–antibody complexes sequestered in cartilaginous tissues (Jasin 1975) which could act as a depot of persistent immunogen and gave rise to a cellular immune response. The induction of arthritis by a similar protocol in neonatally thymectomized or bursectomized chickens demonstrated that arthritis was inducible by both thymus-dependent T and bursa-dependent B cells; however, the fully developed lesion required an intact thymus and bursa (Oates *et al*. 1972).

Infective agents as a cause of arthritis have attracted much interest; and mycoplasmas (Decker and Barden 1975) and erysipelotherix (Drew 1972) are both well-described causes of chronic arthritis in swine. In the former model, a chronic arthritis persisted long after viable organisms could be cultured from joints, blood, or lymph nodes and non-viable antigen persisted for longer periods, and it was suggested thst this might have been responsible for the destructive arthritis. In a model of swine arthritis resembling rheumatoid arthritis studied in Sweden, introduction of fish meal in the diet was causative of arthritis and evidence was obtained that this was associated with population of the gut by *Clostridium perfringens* (Mansson *et al*. 1971). Immune responses to the clostridium were demonstrable, but the organism could not be isolated from the joints and as such represented a form of reactive arthritis.

Caprine arthritis, mainly involving large joints, has generated interest in the arthritogenic potential of the causative lentivirus, which is a lentiform retrovirus, as is the human immunodeficiency virus (Crawford *et al*. 1980). In this disease, possibly acquired by ingestion of milk by goat kids, the virus is harboured by mononuclear phagocytes. Encephalitis also occurs and this feature makes it distinct from rheumatoid arthritis. Chronic destructive joint lesions are described, and these resemble rheumatoid arthritis, as does the mononuclear cell infiltrate in the synovium. However, the lentivirus cannot be isolated from joints. In contrast to rheumatoid arthritis, mononuclear cells rather than polymorphs are dominant in joint fluids and, also unlike rheumatoid arthritis, high levels of interferon activity are demonstrable. Studies of the tropism for joints and the pathogenesis of the inflammatory reaction provide insight into the pathways that might prove important in devising investigations of the possibility that retroviruses may cause rheumatoid arthritis.

The MRL/lpr mouse is generally regarded as a model of systemic lupus and develops a multisystem disease characterized by glomerulonephritis, vasculitis, and antibodies to double-stranded DNA and Sm antigen, associated with marked lymphoproliferation involving a T cell with an ab heterodime receptor, but lacking CD4 and CD8 antigens (Andrews *et al*. 1978). This mouse strain, however, also develops an arthritis of the hind limbs with invasion of cartilage by pannus, high levels of rheumatoid factor, and anticollagen type II antibodies; therefore in some respects it shows features of rheumatoid arthritis. Production of rheumatoid factor appears to be under the control of the lymphoproliferation gene. The early destruction of articular tissue is at the marginal junction of the synovium with cartilage and bone, in association with proliferation of fibroblastic cells, and antedates an inflammatory response (O'Sullivan *et al*. 1985). This spontaneous model of arthritis appears to be of importance in delineating the relationship between autoimmunity and non-immune cellular responses in the synovium and pannus invasion of cartilage and bone, as well as understanding the genetic regulation of rheumatoid factor.

Transgenic mice offer the possibility of assessing *in vivo* the effect of introduced genes on the development of disease. Two models have recently been published which may shed insight into the mechanism of arthritis. The simplest to evaluate is the introduction of a modified human TNF-a gene, under its own promoter, into fertilized ova. The modification of the gene was replacement of the TNF-a 3' untranslated region, which has been shown to confer mRNA instability, with the 3' untranslated region of b-globin, which has a very stable mRNA. With this deregulated TNF-a production, it was found that the mice developed a progressive arthritis by 4 weeks of age. The arthritis was preventable by the injection of antihuman TNF-a monoclonal antibody from birth onwards. The arthritis is characterized by subchondral erosions and frequent fibrosis, but further analysis is necessary to establish how closely this disease resembles rheumatoid arthritis (Keffer *et al*. 1991). This model, however, confirms the hypothesis that TNF-a is intimately involved in the arthritic process.

Transgenic mice carrying the human T-cell leukaemia virus-1 genome also develop a chronic erosive arthritis (Iwakura *et al*. 1991). In this model, approximately one-third of the mice highly expressing the transgene developed arthritis with synovial inflammation and cartilage erosion, closely resembling a pannus. Low levels of rheumatoid factor were occasionally detected. It was of interest that the mRNA of the *Tax* gene, a transacting transcriptional activator, was highly expressed in the joints. Thus it is likely that the arthritis is the result of increased cytokine expression in the joints. Supporting this is the preliminary observation, cited in Iwakura *et al*. (1991), that IL-1a mRNA is expressed in the joints of these mice, as it is in rheumatoid arthritis.

Conclusions

Our understanding of the pathogenesis of rheumatoid arthritis in molecular terms has progressed rapidly in the past few years. This has provided a number of molecular targets, and therapeutic trials based on these targets have been initiated. The first of these was CD4, and monoclonal anti-CD4 has been used by a number of groups, with beneficial though transient results in a proportion of patients.

Attempts are being made to devise peptide-based therapies which will selectively block the critical HLA peptide-presenting genomes. Neutralization of cytokines such as TNF-a and IL-1 with antibodies or soluble receptors has been successfully applied in clinical trials and has set the stage for an era of promising new therapeutic interventions.

These (and more) therapeutic trials will have an important benefit in helping to evaluate ideas concerning the pathogenesis of rheumatoid arthritis, and even if (as is likely) they are not totally successful, they will contribute to refining our concepts of the pathogenesis of the disease and to more effective therapies.

5.4.2 Rheumatoid arthritis–the clinical picture

Frank A. Wollheim

Introduction

Rheumatoid arthritis is a systemic disease with manifestations in many organs. However, in the majority of cases, involvement of the locomotor system dominates the clinical picture and forms the basis for diagnosis. In a classical textbook from 1957 it was stated that rheumatoid arthritis is 'a chronic systemic inflammatory disorder of unknown etiology characterized by the manner in which it involves the joints' (Short *et al*. 1957). There is no exact definition of rheumatoid arthritis, but several attempts to delineate criteria all are dominated by signs and symptoms from the locomotor system.

Criteria

Criteria are needed both in epidemiological work and in classification in the context of clinical trials. The original American Rheumatism Association (**ARA**) scheme of 1958 lists 11 criteria and no less than 20 exclusions (Ropes *et al*. 1958). With their help one could distinguish classical, definite, probable, and possible rheumatoid arthritis, characterized by decreasing number of criteria (Table 1). The main shortcoming of the ARA criteria is their complexity and low specificity (O'Sullivan and Cathcart 1972). Later, criteria 9, 10, and 11 were dropped to form the scheme of the Rome criteria (Kellgren 1962) (Table 2). The much simpler New York criteria were proposed in 1966 (Bennett and Burch 1967) (Table 3). These require a history of polyarthritis with clinical signs and either radiological erosions or presence of rheumatoid factor, and do not contain any exclusion criteria. The New York criteria performed better in the Sudbury study (O'Sullivan and Cathcart 1972) but they lack sensitivity for early and atypical cases. More recently the American College of Rheumatology (**ACR**) has developed criteria to replace the 1958 ARA criteria (Arnett *et al*. 1988). Rheumatoid arthritis is diagnosed if at least four of seven criteria are present. Only one category of rheumatoid arthritis is distinguished and exclusions are superfluous, owing to the detailed characterization of the criteria (Table 4). These criteria were developed by observing a number of 'typical' patients considered to be suffering from rheumatoid arthritis by experienced rheumatologists. The mean disease duration was 7.7 years. The performance of these criteria in epidemiological work has only recently been assessed but they may be best used in clinical trials aimed at patients with well-established disease.

Table 1 ARA criteria for rheumatoid arthritis (RA) of 1958 [a] (Ropes *et al*. 1958)

1. A past history of polyarthritis	
2. Symmetrical deformity of peripheral joints consisting of ankylosis or irreducible subluxation, especially of the lateral metatarsophalangeal or metacarpophalangeal joints; there must be some involvement of one hand or foot; involvement limited to large joints, such as the elbows or knees, does not satisfy this criterion	
3. Radiological changes of RA of grade 2 or more	
4. Positive serological test for rheumatoid factor	

[a] The diagnosis of definite RA requires 3 or 4 criteria fulfilled; one probable RA requires 2 criteria.

Table 2 The Rome criteria for the diagnosis of inactive rheumatoid arthritis (RA) [a]

1. History of an episode of three painful limb joints; each group of joints (e.g. proximal interphalangeal joints) is counted as one joint, scoring each side separately	
2. Swelling, limitation of motion, subluxation and/or ankylosis of three limb joints. Necessary inclusions: (1) at least one hand, wrist or foot; (2) symmetry of one joint pair. Exclusions: (1) distal interphalangeal joints; (2) fifth proximal interphalangeal joints; (3) first metatarsophalangeal joints; (4) hips	
3. Radiological changes (erosions)	
4. Serum positive for rheumatoid factor	

[a] RA is present if criterion 1 and 2, plus either 3 or 4, are met.

Table 3 The New York criteria for the diagnosis of rheumatoid arthritis (RA) [a]

Criterion	Comment
1. Morning stiffness	Duration > 1 h lasting >1 weeks
2. Arthritis of at least three areas[a]	Soft tissue swelling or exudation lasting >1 weeks
3. Arthritis of hand joints	Wrist, metacarpophalangeal joints or proximal interphalangeal joints lasting >1 weeks
4. Symmetrical arthritis	At least one area, lasting >1 weeks
5. Rheumatoid nodules	As observed by a physician
6. Serum rheumatoid factor	As assessed by a method positive in less than 5% of control subjects
7. Radiographic changes	As seen on anteroposterior films of wrists and hands

[a] Possible areas: proximal interphalangeal joints, metacarpophalangeal joints, wrist, elbow, knee, ankle, metatarsophalangeal joints. At least four criteria must be satisfied for inclusion.

Table 4 The revised criteria of 1987 (ARA/ACR)

Epidemiology

For lack of an obligate pathognomonic test, the diagnosis of rheumatoid arthritis rests on a composite of clinical and laboratory observations. In epidemiological work one has to rely on one of the criteria described above. Their limited precision was demonstrated in the Sudbury study, where only 12 of 40 cases of definite rheumatoid arthritis defined by the ARA criteria still fulfilled the criteria 4 years later. The New York criteria in the same study identified 15 patients with rheumatoid arthritis, and of these 11 were still positive at follow-up (O'Sullivan and Cathcart 1972). This uncertainty, if not evidence for transient disease, should be kept in mind when discussing the epidemiology of rheumatoid arthritis.

Worldwide prevalence

Rheumatoid arthritis has been identified in all populations that have been examined, and prevalence figures ranged between 0.2 and 5.3 per cent (Spector 1990) (Table 5). Nearly all studies indicate point prevalences of between 0.5 and 1 per cent. It is not known whether the high prevalence in Pima Indians is due to environment, genetics, or both and recent figures indicate a decreasing prevalence (Jacobsson *et al*. 1994). The age distribution is a confounding factor in developing countries, perhaps contributing to low figures in Africa.

Population	Reference	Size	Prevalence (%)
England	Lawrence (1961)	3000	0.9
Netherlands	Valkenburgh (1979)	6500	0.9
Sweden	Heligren (1970)	39 000	0.9
Bulgaria	Tzonchev (1966)	2695	0.8
Finland	Aho (1980)	8000	1.06
USA Tecumseh	Mikkelsen (1967)	6000	0.5
USA Sudbury	Cathcart (1970)	5552	0.9
USA Eskimos	Boyer (1968)	4600	1.0
USA Pima	del Puente (1989)	1449	5.3
USA Inuit	Oen (1986)	2055	0.6
Japan	Kato (1971)	11 393	0.6
South Africa	Myers (1978)	1601	0.7
	Bagshaw (1975)	1752	0.2
Liberia/Nigeria	Muller	1027	0.1
Israel	Adler (1957)	6769	0.3
Iraq	Al-Rawi (1976)	6998	1.0

Data from Spector (1990); where references may be found.

Table 5 Prevalence of rheumatoid arthritis in various adult populations

Incidence

Considering the difficulties involved in establishing early diagnosis of rheumatoid arthritis it is not surprising that only relatively few studies have addressed incidence. The Sudbury population study arrived at the high figure of 29 cases/10 000 per year based on only three observed cases (Table 6), whereas four other studies, using various methods, found annual figures between 9 and 2.9 cases/10 000. The 1987 ACR criteria were used in a prospective population-based registration of all new cases of arthritis in a population of 450 000 people in Norfolk, United Kingdom (Symmons *et al*. 1994), and showed an incidence of 3.4 in women and 1.4/10 000 in men. The incidence increased sharply with age in men from age 45. It increased in women until age 45, then plateaued and fell after age 75. No good longitudinal incidence data are available, although the study of Linos *et al*. (1980) indicated a decline from 9.2 to 4 in women but not men after the year 1964. This coincided with the advent of widespread use of contraceptive pills.

Population	Reference	Incidence	Method
Japan	Mirok [1967][1]	4.5/10 000	Population study
Holland	Dutcher [1968][2]	9/10 000	Hospital referrals
Sudbury USA	O'Sullivan [1968][3]	29/10 000	Population study
Finland	Isomäki [1978][4]	4.2/10 000	Health statistics
Olmsted USA	Linos [1980][5]	2.9/10 000	Hospital and physician records

Table 6 Annual incidence of rheumatoid arthritis in adults

Mortality

Evidence that mortality is increased in rheumatoid arthritis has accumulated since the 1950s, as shown in at least 16 studies (Spector and Scott 1988). Life expectancy is reduced by approximately 7 years in men and 3 years in women according to a Dutch study (Vandenbroucke *et al*. 1984). The increased mortality is mainly due to infections, renal disease, respiratory disease, and rheumatoid arthritis itself (Table 7). Two more recent reports from Japan and the United States confirm these data, and stress age, male sex, poor functional status, and low education as predictors of death (Suzuki *et al*. 1994; Wolfe *et al*. 1994).

Cause of death	RA (%)	Controls (%)
Cardiovascular	42.0	41.0
Cancer	14.0	20.0
Infection	9.5	1.0
Renal	8.0	1.0
Respiratory	7.0	4.0
RA	5.3	
Gastrointestinal	4.2	2.4

Data from Pincus and Callahan (1986)

Table 7 Mortality in rheumatoid arthritis (RA)

Clinical picture

Onset

The typical onset of insidious pain, stiffness, and symmetrical swelling of small joints in a middle-aged woman is but one of several presenting patterns. Up to one-third of patients have an acute or subacute onset. In some 10 per cent, palindromic rheumatism occurs for months or years before the onset of chronic disease. In several patients the first symptoms are not obviously located in the joints, but consist of fatigue, malaise, loss of weight, and subfebrility. Myalgia, morning stiffness, and depression in the absence of objective abnormalities may mimic functional, non-organic disease. This prodromal phase may last for weeks or months.

Triggering events such as infections, vaccinations, physical trauma, or psychological stress, although often suspected by lay persons, are not known to be involved. The onset of rheumatoid arthritis shows no seasonal variation (Eberhardt *et al*. 1990a).

The joints most commonly involved first were the finger (40 per cent), a shoulder (20 per cent), a foot joint (20 per cent), and a wrist (15 per cent). The knee joint was first involved in only 3 per cent of patients in our recent series (Eberhardt *et al*. 1990a). Asymmetrical onset is common.

The early events in rheumatoid arthritis are still largely unknown. A Finnish survey of the prevalence of both rheumatoid factor and antikeratin antibodies in the general population ('Minifinland') showed progressively increasing occurrences in the years preceding disease onset (Aho *et al*. 1989; Kurki *et al*. 1992), strongly indicating the existence of a presymptomatic phase of rheumatoid arthritis.

Articular involvement

Synovitis of the small joints of the hands and feet with symmetry and sparing of the distal interphalangeal joints may be the single most characteristic feature of rheumatoid arthritis, although the dominant side is often more severely affected (Owsianik *et al*. 1980). Lack of symmetry is seen in hemiparetic patients, in whom the paretic side is usually much less affected (Thompson and Bywaters 1961). The initial involvement may be confined to a few joints only. Spread occurs within months to years but the total number of affected joints tends to reach a plateau after the first years of illness. The number of joints involved in the early stages of rheumatoid arthritis is related to disease severity and functional outcome (Feigenbaum *et al*. 1979; Sherrer *et al*. 1986).

Although virtually any joint may be affected in rheumatoid arthritis, the dominating locations are the wrists, the metacarpophalangeal and proximal interphalangeal finger joints, the ankles and metatarsophalangeal joints, the knees, the shoulders, the hips, and the elbows (Fig. 1). The reason for involvement or sparing of joints in rheumatoid arthritis is poorly understood. Loading and overuse is related to severity and damage, but probably not to localization as such.

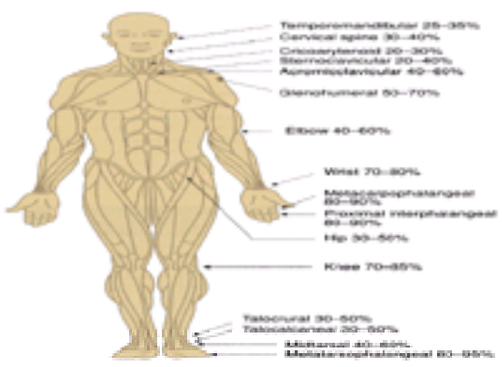

Fig. 1 Joint involvement in long-standing rheumatoid arthritis.

Hand

The hand joint affected by rheumatoid arthritis has many characteristic features which when present in combination may be almost pathognomonic. Boggy and tender swelling of proximal interphalangeal and metacarpophalangeal joints, wrists, and caput ulnae are common early signs. Tenosynovitis of extensors, and more often flexor, tendon sheets, with or without nodules are other features. Interosseal muscle atrophy is often seen early. Pain is prominent and may contribute to muscle atrophy. Limitation of motion, in particular dorsal flexion of wrist and finger flexion is very common. Compression of the median nerve in the carpal tunnel may be a presenting symptom of rheumatoid arthritis, and is frequent throughout the early development. Atrophy of the thenar muscle may be seen after long-standing compression of the median nerve.

As the disease progresses, signs of irreversible tissue damage appear: ulnar deviation of the fingers beginning with the index and fifth finger, volar subluxation of metacarpophalangeal joints, loosening of the distal radioulnar joint with dorsal protrusion of the ulnar head, as well as swan-neck and buttonhole deformities of the fingers occur in various combinations. Destruction of cartilage and bone as well as weakening and rupture of tendons and joint linings are contributing factors in the pathogenesis of hand deformities. Inability to make a fist, pinch thin objects, and loss of grip strength are important functional consequences of severe hand involvement in rheumatoid arthritis.

Elbow

Involvement of the elbow is present in half or more of the patients seen by specialists and it may become a major problem in 10 to 20 per cent. Extension defects usually develop, sometimes without the patients noticing anything abnormal. Active synovitis is readily palpated at the site of the groove normally present between the olecranon and the lateral epicondyle. Bulging, tenderness, and flexion contracture are typical findings, and all three may disappear after intra-articular injections of glucocorticoid. Epicondylitis and olecranon bursitis may be present in addition. Passive pronation and supination are painful in elbow synovitis. Destructive changes can be diagnosed by feeling crepitations when the radial head moves during this procedure.

Shoulder

The shoulder joints are involved in the majority of patients with rheumatoid arthritis, not least with increasing age. Synovitis of the glenohumoral joint causes tenderness on cranial palpation from below the axilla. It also results in pain with active and passive motion. Acromioclavicular synovitis is not uncommon giving local tenderness and a painful arch on abduction above 100°. Occasionally synovitis is present in the sternoclavicular joint. Rotator cuff tendinitis with varying degrees of supraspinatus injury is most common and causes considerable degrees of shoulder dysfunction, painful arch from 50° to 100° of abduction, and night pain. It may be difficult to distinguish inflammatory from degenerative abnormalities. Subacromial bursitis is also common, and may present with a palpable swelling.

Foot

Foot involvement is as common as hand involvement in rheumatoid arthritis, and 10 per cent of patients have the earliest erosions in the metatarsophalangeal joints (Eberhardt *et al*. 1990a). Pain in the forefoot elicited by walking is a well recognized presenting manifestation of rheumatoid arthritis (Luukkainen *et al*. 1983), and very often causes difficulties in ambulation. Synovitis is found in the metatarsophalangeal joints, giving rise to tenderness on direct palpation. Involvement is also seen in three more proximal foot joints. The joint between the distal tibia, fibula, and talus gives rise to tenderness on direct palpation distal to the malleoli. Talocalcaneal synovitis is diagnosed by causing pain on passive pronation or supination, and synovitis of the mid-tarsal joint gives rise to pain on rotating the foot while keeping the heel fixed. These joints may be involved individually. Foot deformities develop with time, e.g. lateral deviation of toes, hammer toes, cock-up toes, and valgus deformity of the ankle. Bursitis, corn formations, and tendinitis are also common.

Knee

The knee joint is the largest human joint. Although not often inflamed at the onset of rheumatoid arthritis, gonarthritis at some stage occurs in 80 per cent or more of all cases. Synovitis is usually easy to identify by tenderness and swelling below the patella. Other signs are exudation, which may be demonstrated by the patella click or the bulge sign. Gonarthritis often leads to quadriceps atrophy and flexion contracture, both of which should initiate prompt and vigilant therapy. The knee joint communicates with bursas in the fossa poplitea, which may become distended and merge into a large Baker's cyst. This may grow and dissect its way down into the calf muscle or rarely into the thigh and sometimes rupture, causing diffuse swelling and pain and may be mistaken for deep-vein thrombosis. Intra-articular pressure may increase to as much as 1100 mmHg in exudative knee joints (Geborek *et al*. 1989a). This will contribute to decreased muscular function, impede circulation through the synovial membrane, and lead to lactic acidosis and may be a pathogenic factor in the rupture of Baker's cysts. The natural course of long-standing knee involvement is often valgus instability, flexion contracture, and inability to walk. Increased intra-articular pressure may also contribute to bone erosion (Monsees *et al*. 1985).

Hip

Hip joint involvement is less common and was formerly considered as a late manifestation. However, once started the arthritis often leads to severe disability with pain on weight bearing and limitation of motion, in particular abduction and rotation. Functional limb shortening may sometimes be present secondary to adduction contracture. In a prospective study of recent-onset rheumatoid arthritis, hip involvement was found in 20 per cent. In 7 of 13 patients no symptoms were present despite abnormal swelling found on ultrasonography. Fifteen of 113 patients underwent total hip replacement after a median disease duration of 4 years (Eberhardt *et al*. 1995). Thus joint failure is more common in the hip than in the knee in early rheumatoid arthritis.

Involvement of the hip must be distinguished from periarticular bursitis or trochanteritis which is characterized by local tenderness, painful motion, and responsiveness to local infiltration with glucocorticoids (Raman and Haslock 1982).

Cervical spine

The cervical spine is involved in approximately 40 to 70 per cent of hospital patients with rheumatoid arthritis (Bland 1974). The dominating symptoms are occipital pain, sometimes worsened by motion, muscle spasm, and crepitation. Synovitis of the faceted joints is commonly present at C1 to C4. The symptoms in most patients improve with immobilization. However, in a small (but important) number of patients severe neurological complications develop secondary to subluxations. This may result in fatal outcome as shown in one study where 11 of 104 patients, dying in a geriatric hospital, had cervical cord compression at autopsy (Mikulowski *et al*. 1975). This complication will be dealt with below.

Temporomandibular joint

This is affected in one-quarter of patients, usually symmetrically and causing no major disability. In fact patients with unequivocal, palpable, synovial swelling or tenderness often do not report pain on chewing unless specifically asked. In severe destructive cases of rheumatoid arthritis, however, attrition of joint cartilage and bone causes malignment of the teeth with malocclusion (Chalmers and Blair 1973).

Synovitis of the cricoarytenoid joint

This is a well-recognized manifestation in rheumatoid arthritis, occurring in two-thirds of patients in a contemporary hospital-based study (Geterud 1991). The symptoms are sensation of a foreign body, hoarseness, and weak voice, as well as stridor, particularly at night. This may become severe and may eventually cause suffocation. The condition can be detected by palpating local tenderness and finding the vocal cords tender, red, swollen, and immovable on laryngoscopic examination. The laryngeal obstruction can be assessed by computed tomography. This condition is amenable to surgical correction (Geterud 1991).

Rheumatoid nodules

Rheumatoid nodules occur in 30 per cent or less of patients, and when present they are principally in extensor areas of the forearm and pressure areas throughout the skin. Although not specific for rheumatoid arthritis they constitute useful diagnostic and prognostic information, correlating strongly with seropositivity, somewhat with disease activity and progressive disease. Rarely they are the presenting symptom of rheumatoid arthritis, occasionally they are first detected in internal organs,

e.g. lungs, heart, and gallbladder.

The histological appearance is that of a central necrotic area surrounded by palisades of fibroblasts, histiocytes, and macrophages. Expression of HLA DR is present among these cells (Hedfors *et al*. 1983), and collagenase and proteinase production (Palmer *et al*. 1987) may explain the central necrosis.

Rheumatoid nodules develop in areas over spinal processes and over the neck in patients confined to bed, over the patellae in housewife's knee, and in the inside of the fingers in patients exposed to hand work, demonstrating pressure as an important pathogenetic factor.

It is of particular clinical significance to watch for skin ulcerations over rheumatoid nodules, as this indicates necrotizing vasculitis (Fig. 2).

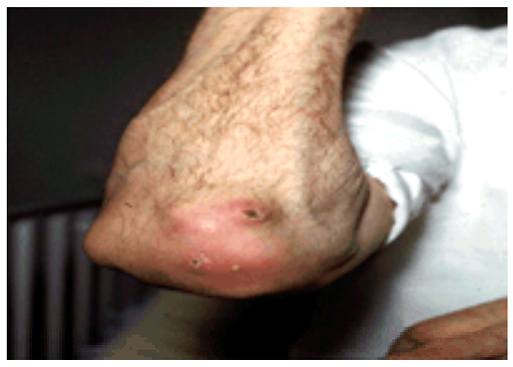

Fig. 2 Subcutaneous nodule over elbow with ulceration in a patient who developed necrotizing vasculitis and gangrene of toes.

Disease course

Rheumatoid arthritis is extremely heterogeneous with regard to severity and progression rate. Although early permanent remission may occur in some cases, this is rare once permanent joint damage has started. This does not rule out clinical improvement after initially severely impaired function (Eberhardt *et al*. 1990b). Long-term follow-up studies (Rasker and Cosh 1989), however, clearly indicate that functional deterioration occurs in most patients surviving 15 years or longer. It is suggested but not well documented that geographical differences may exist in this regard.

Some texts distinguish between cyclic types of disease with remissions and exacerbations and slow but relentless disease progression. In clinical practice, however, features of both types frequently are present in a majority of patients. A more useful distinction is that between widespread and more limited chronic joint involvement which can be assessed by careful joint examination (Feigenbaum *et al*. 1979).

Disease activity as manifested by number of swollen joints was low in half of patients with early rheumatoid arthritis followed for 6 years, whereas it was high in 17 per cent and fluctuating in the remainder (van Zeben *et al*. 1994). Disease activity can be monitored by simple measurements, such as joint swelling and tenderness. Erythrocyte sedimentation rate and C-reactive protein measured over time correlate with functional impairment (Hassell *et al*. 1993; Guillemin *et al*. 1994).

Non-articular manifestations

Rheumatoid arthritis is primarily a joint disease, but extra-articular manifestations can be detected in almost any organ system and may occasionally precede the onset of arthritis. Table 8 lists some of these. They are in general more prominent in seropositive and nodular disease.

Organ system	Manifestation	Cumulative frequency (%)
Lymph nodes	Enlargement, dysfunction	~ 50
Spleen	Splenomegaly	25
	Felty's syndrome	~ 1
Lungs	Pleuritis	~ 30
	Nodules	5
	Fibrosis	Rare
Heart	Pericarditis	~ 10
	Myopericarditis	~ 5
	Nodules	5
Muscles	Myositis	Common
	Atrophy	Common
Bone	Osteoporosis	Common
Skin	Nodules	~ 20
	Vasculitis	~ 1
Ophthalmic	Scleritis	1
	Nodules	~ 2
	Sjögren's syndrome	10
Neurological	Cord compression	~ 1
	Nerve entrapment	Common
	Polyneuropathy	Rare
	Mononeuritis multiplex	~ 1

Table 8 Some organ manifestations of rheumatoid arthritis

Lymph nodes

Lymph nodes are enlarged or of abnormal shape in the majority of patients but only rarely palpable. They show up on mammography and give rise to diagnostic concern (Andersson *et al*. 1980). However, in a few cases rheumatoid arthritis may start with widespread palpable lymphadenopathy and a histological picture mimicking Hodgkin's disease. It is of interest that total lymph-node irradiation has a transient suppressive effect on the synovitis in rheumatoid arthritis. Lymphopenia was seen in 15 per cent of cases in one study; it was related to severity but was not influenced by therapy (Symmons *et al*. 1989).

Pulmonary involvement

Pleuritis is most common but frequently asymptomatic. It may be associated with pericarditis and like other pulmonary and cardiac manifestations it is more common in older men. Rheumatoid nodules in the lungs are often asymptomatic and are only seen in seropositive cases. They may be single or multiple and can cause diagnostic problems. Smoking as well as exposure to, for example, silica are pathogenetic factors.

Diffuse interstitial fibrosis and fibrosing alveolitis are rare but serious manifestations, which individuals with HLA DR3 and carriers of the *PiZ* gene are more prone to develop (Geddes *et al*. 1977; Hyland *et al*. 1983). Smoking is also a contributing aetiological factor (Hyland *et al*. 1983).

Cardiac involvement

Pericarditis has been a common finding at autopsy, but causes symptoms in only a few patients. These may range from pain with friction rubs to severe exudative pericarditis with cardiac tamponade requiring surgical intervention (Hara *et al*. 1990). Most cases are, however, benign and self-limiting. Valvular insufficiency, conduction disturbances, and coronary occlusion may occasionally be due to endocarditis, nodulosis, or vasculitis.

Muscle involvement

Some degree of muscle atrophy is almost invariably present in rheumatoid arthritis, and there is electromyographic evidence of myositis (Moritz 1963). The type II or fast-twitch muscles are most affected (Halla *et al*. 1984). Focal necrosis is also seen. Creatine kinase levels are usually not elevated. Rheumatoid nodules may be

seen.

Bone

Generalized axial and appendicular bone loss is seen early in the course of rheumatoid arthritis and has been assessed by dual electron X-ray absorption (DEXA) measurements within 6 months from onset. Bone mineral loss is faster in postmenopausal women and in patients with active disease (Gough *et al*. 1994a). This is a strong argument for early disease suppressive therapy in severe rheumatoid arthritis. This bone loss should be distinguished from the juxta- and periarticular bone loss that probably is a consequence of local cytokine production. Increased bone resorption can also be measured indirectly by assaying the increased urinary excretion of pyridinoline crosslinks (Gough *et al*. 1994b).

Skin

Cold, clammy hands often accompany flaring rheumatoid arthritis. Palmar erythema is common and may reflect low androgen levels (Spector 1989). Various forms of arteritis manifestations are characteristic signs of systemic disease. Small splinter haemorrhages localize to the nailfolds and may disappear spontaneously. When larger arteries are affected, skin ulcerations develop, often on the lower extremities or where skin is exposed to pressure, e.g. the buttocks (Fig. 3). These ulcerations are very painful, may come in crops, and tend to grow and become chronic. Superinfection is a contributing factor. As mentioned, ulcerations may form over subcutaneous nodules in severe cases.

Fig. 3 Skin ulcers in the buttocks in a patient with rheumatoid vasculitis.

Leucocytoclastic vasculitis also occurs and is seen as a palpable purpura. This manifestation, as a rule, heals (Fig. 4).

Fig. 4 Palpable purpura in a case of rheumatoid arthritis, where healing occurred without immunosuppressive therapy.

Ocular involvement

Rheumatoid vasculitis gives rise to a severe form of scleritis (Tessler 1985) and rheumatoid arthritis is one of the common causes of scleritis. Scleritis is very painful, gives blurred vision and may last months to years. Episcleritis is a benign condition, resolving within weeks and not highly associated with rheumatoid arthritis. Rheumatoid nodules are not unusual in scleritis, and may cause scleral thinning, secondary glaucoma, and even perforation (scleromalacia). Uveitis and conjunctivitis are not manifestations of rheumatoid arthritis.

Secondary Sjögren's syndrome

Sjögren's syndrome is described in Chapter 5.10. Secondary Sjögren's syndrome in rheumatoid arthritis is not uncommon. It is distinct from primary Sjögren's syndrome (Table 9), and may start many years after onset of the joint disease. Artificial tears, careful oral hygiene to avoid an increase in caries, and bromhexin (*N*-cyklohexyl-*N*-methyl-E-l-2-amino-3.5-dibromobenzyl amine, or simpler Bisolvon, Boehringer Ingelheim) in doses of 24 mg thrice daily may help in management.

Primary	Secondary
Keratoconjunctivitis sicca	Milder
Xerostomia	Less pronounced
HLA association	HLA DR4; not HLA DR3
Extraglandular manifestations	Not common
Response to therapy	Bromhexin

Table 9 Secondary Sjögren's syndrome in rheumatoid arthritis compared with primary Sjögren's syndrome

Influence of age, sex, and pregnancy

Age

Several studies have compared the onset of rheumatoid arthritis at older age with that at younger age (Deal *et al*. 1985; Sherrer *et al*. 1986). More recently, van der Heijde (1991) analysed certain features in a prospective 2-year study in patients with recent onset of disease. The only features distinguishing the older patients were

a higher biochemical activity, more joint involvement, and persisting marked disease activity after 2 years. Some previous studies have claimed that rheumatoid arthritis with onset in old age is associated with a milder form of the disease, but conversely, Sherrer *et al*. (1986) as well as Sjöblom *et al*. (1984) found age to correlate with a poor prognosis. Van Schaardenburg (1993) compared cases with disease onset over and under 60 years. The only difference was a poorer functional outcome in older seropositive cases, who also had a higher mortality. This is largely due to comorbidity and not to the rheumatoid arthritis as such. However, no population-based data exist and the divergent data may reflect differences in patient selection.

Sex

Female preponderance is present in most series of elderly patients, although to a lesser extent than among younger patients (Silman 1989; Goemaere *et al*. 1990; Jonsson and Larsson 1990). In women, disease onset occurs on average 5 years earlier than in men, and clusters around the menopause. Concomitant health problems, such as osteoporosis and arteriosclerosis, are likely to influence disease course in a negative way. The rate of progression as assessed radiographically in established rheumatoid arthritis did not differ appreciably in relation to gender (Sjöblom *et al*. 1984). Men have a greater risk of developing serious vasculitis complications (Geirson *et al*. 1987).

Pregnancy

The pregnancy-induced amelioration in rheumatoid arthritis, first described by Hench (1938), has been the starting point of both clinical and basic research (Table 10). The relation between sex hormones, the immune system, and autoimmune disease in man and animals is still a much-discussed enigma (Parke 1990). Attempts to ascribe the pregnancy-related remission to a variety of circulating factors, such as a-fetoprotein, adrenal glucocorticoids, or pregnancy-associated immunosuppressive plasma proteins have failed (Klipple and Cecere 1989). The intriguing finding that some 73 per cent of pregnancies induce remission but the remainder do not (Persellin 1977), is elucidated by the recent report (Nelson *et al*. 1993) that improvement correlates with HLA-DQ disparity between mother and fetus. This observation, if confirmed, indicates that an anti-HLA immune response in the mother is implicated. Earlier work in Montpellier (Sany 1994) had used gammaglobulin eluted from human placenta for therapy in rheumatoid arthritis, based on the hypothesis that this contained anti-DR antibodies, which would suppress HLA-DR-expressing cells in the rheumatoid inflammatory tissue. Although such antibodies have indeed been found, this interesting form of therapy has not been pursued.

1938	Hench	Pregnancy-induced improvement of RA
1968	Engel	Marital status as a risk factor for RA
1978	Wingrave and Kay	Reduced incidence of RA in consumers of oral contraceptives
1980	Linos *et al*.	Decreasing incidence of RA in women, 1955–1974
1993	Nelson *et al*.	Maternal–fetal HLA-DQ disparity associated with pregnancy-induced remission

Table 10 Some historical developments relating to rheumatoid arthritis (RA) and pregnancy

Sex hormones

Another line of investigation has focused on the role of sex hormones, greatly stimulated by the report on the apparent protective action of oral contraceptives (Wingrave and Kay 1978) and a declining incidence of the disease in women (Linos *et al*. 1980). A number of conflicting results have been published. Whereas most European reports have found relative risks of around 0.5 for developing rheumatoid arthritis in women who currently or have ever used oral contraceptives, the studies from North America have not shown any protective effect. A recent meta-analysis concluded that there was a small but not statistically significant protective effect (Romieu *et al*. 1989).

More detailed analyses indicate that oral contraceptives mainly reduce the risk for developing severe rheumatoid arthritis (van Zeben *et al*. 1990) explaining why, in general, hospital-based studies showed protection, whereas population-based studies did not (Hazes and van Zeben 1991). Postmenopausal use of hormones does not confer protection, according to two recent studies. The reason for this is not known.

In a study from the United States, married women had an increased risk of developing rheumatoid arthritis (Engel 1968), whereas nulliparous women in the United Kingdom had a higher incidence of rheumatoid arthritis in several studies (Spector *et al*. 1990). In women who were both nulliparous and non-users of oral contraceptives, the risk of developing rheumatoid arthritis was even higher. Whereas the correlations are convincing, the mechanisms are unclear.

Attempts to use high-dose oral contraceptives therapeutically in 10 women with rheumatoid arthritis were not successful (Hazes *et al*. 1989). Two controlled trials in postmenopausal women have shown improvements in bone mineral density as well as improved well being and Ritchie index of joint tenderness, although no changes in erthrocyte sedimentation rate were observed (Hall *et al*. 1994; MacDonald *et al*. 1994). Furthermore, the treatment was well tolerated.

Analysis of androgenic sex hormones in the blood of patients with rheumatoid arthritis has not revealed any abnormalities in women whereas men consistently have low levels, although still within the normal range (Spector 1989). It is possible that this is related to HLA, as the gene for 21-hydroxylase, one of the enzymes involved in the synthesis of sex hormones, is located on the short arm of the sixth chromosome, close to the *HLA-B* locus.

Oestrogen may bind to chondrocytes through oestrogen receptors, or indirectly influence chondrocyte function by inducing cytokine release. In experimental systems, proteoglycan synthesis was inhibited by pharmacological concentrations. T-cell driven models of arthritis are suppressed by oestrogen. It is, however, not known whether these effects are of any relevance in rheumatoid arthritis (Chander and Spector 1991).

Complications

Rheumatoid arthritis is not only a systemic disease with a host of involved organs (see Table 8) but also it is associated with a number of potentially serious complications that contribute to illness and death.

Infections

Patients with rheumatoid arthritis are more afflicted by general infections (Nived *et al*. 1985) and there is anecdotal evidence that respiratory and other infections may trigger flares in rheumatoid arthritis (Wollheim *et al*. 1984). Importantly, rheumatoid arthritis joints are more susceptible to septic arthritis. This may be due to altered T-cell responsiveness and compromised granulocyte function. Local glucocorticoid injections add to the risk for the development of this complication (Östensson and Geborek 1991).

Septic arthritis occurs more often in patients with long-standing disease who are taking oral glucocorticoids. More than one joint may be involved. Usual signs of sepsis, such as fever and leucocytosis, may be absent, and the diagnostic delay may be weeks.

Septic arthritis may easily be overlooked in patients with marked disease activity. The most frequent infecting organism is *Staphylococcus aureus*. The diagnosis may be confirmed by aspiration and positive culture of synovial fluid. However, negative cultures of aspirated fluids are not unusual and cultures of the synovium are a more sensitive and reliable diagnostic method (Kamme and Lindberg 1981). The increased use of immunosuppressive agents probably increases the risk for septic arthritis as well as for other infectious complications. Patients treated with low-dose methotrexate have more respiratory tract and skin infections with relative risks of

1.5 to 2 (van der Veen *et al*. 1994). Furthermore, the introduction of a foreign body in prosthetic joint replacement increases susceptibility to haematogenous septic arthritis.

Neurological involvement

The most common neurological complication in rheumatoid arthritis is entrapment neuropathy secondary to proliferative synovitis. It is most prevalent in the carpal tunnel and in early disease. Rheumatoid arthritis is probably the most common single cause of median-nerve compression (Chamberlain and Bruckner 1970). Carpal tunnel syndrome may be the first symptom that brings the patient to see a doctor. The signs of sensory median-nerve compression are easy to identify as nocturnal paraesthesia of the middle fingers, and may be provoked by forced dorsiflexion of the wrist or percussion over the carpal tunnel. Electromyography shows delayed nerve conduction but is often not more informative than careful clinical examination with testing of motor function. Although median-nerve entrapment in the carpal tunnel is most prevalent, this nerve may also become compressed at the elbow level under the pronator teres muscle. It is important to arrive at a correct diagnosis in these cases, as decompression at the right level will result in prompt restoration of function.

Other entrapments are of the ulnar nerve and rarely the radial nerve at the elbow, as well as the anterior and posterior tibial nerves at the fibular head and in the tarsal tunnel, respectively. The latter gives rise to burning feet and intrinsic foot weakness (Goodgold *et al*. 1965).

An autonomic neuropathy has been defined in rheumatoid arthritis by means of orthostatic electrocardiography (Edmonds *et al*. 1979). It may reflect a microvasculopathy and be related to disturbed skin circulation.

The most alarming form of peripheral neuropathy is called mononeuritis multiplex. It is usually bilateral and most common in the legs. The sudden onset of motor neuropathy signals the presence of aggressive rheumatoid vasculitis and poor prognosis (Geirson *et al*. 1987). The relative incidence of this rare condition is higher in men.

Cervical spine dislocation

Cervical myelopathy associated with rheumatoid arthritis is a well-characterized entity (Marks and Sharp 1981). The symptoms include paraesthesia, numbness, weakness, spastic paralysis, paraplegia, tetraplegia, sensory loss, loss of bladder control, faecal incontinence, and syncope, often in connection with cough or vomiting. Sudden death is also a distinct outcome, particularly if the cervical instability is not recognized (Mikulowski *et al*. 1975).

Cervical subluxation at the atlantoaxial level is present in approximately one-third of patients with rheumatoid arthritis admitted to hospital, and is more prevalent in long-standing disease with pronounced destruction of peripheral joints. The majority of cases are asymptomatic, or suffer from pain without manifest neurological signs. The pain may be mild but is often unbearably intensive. It is usually localized to the neck. Although the atlantoaxial dislocation is augmented by active forward flexion of the head, this manoeuvre rarely precipitates pain.

Some patients suffer from disturbing cracking sensations without pain, when moving the head. Shortening of the neck occurs in extreme cases and an asymmetric posture may be seen.

These patients are particularly vulnerable while under anaesthesia or when involved in accidents and such events may be the starting point of progressive myelopathy.

The diagnosis of unstable subluxation is established by conventional sagittal radiography of the neck in neutral position and anterior flexion, measuring the distance between the anterior odontoid process and atlas (Fig. 5). Subluxation at lower levels between C3 and 4 is another less common complication. However, when present it is much more likely to cause pain and neurological symptoms than atlantoaxial subluxation.

Fig. 5 (a) A lateral film of the cervical spine in flexion in a 68-year-old woman with a long history of rheumatoid arthritis shows a marked increase in the distance between the anterior arch of the atlas and odontoid process, measuring 10.2 mm; normally, it should not exceed 3 mm. (b) Trispiral tomogram demonstrates atlantoaxial subluxation in detail.

Fractures

Several mechanisms contribute to bone loss in severe rheumatoid arthritis (Woolf 1991). Cytokines, such as interleukin 1 and tumour necrosis factor-a, are generated in the inflammatory process and are known to induce osteoclast activity. Inactivity and nutritional deficiency in combination with frequent administration of glucocorticoids constitute additional risk factors. Postmenopausal women with rheumatoid arthritis are thus at particular risk of developing fragility fractures in connection with minor trauma. Stress fractures, occurring without noticed trauma, are also common (Hooyman *et al*. 1984) and often overlooked, as pain is naturally assumed to be related to rheumatoid inflammation as such (Lakhanpal *et al*. 1986). Whereas bone loss is well documented already in early disease (Gough *et al*. 1994a), the role of glucocorticoids and their proper management are still not settled (Woolf 1991). Although a lower bone-mineral content is found in patients on low doses of glucocorticoids, it is not clear whether this is due to disease activity or drug use (Butler *et al*. 1991). Methotrexate inhibits osteoblast activity and may be yet another risk factor in some patients. Pre-existing osteoporosis is probably a risk factor in patients developing rheumatoid arthritis at a late age. There is no evidence to support the likelihood of impaired healing of fractures, not even in patients with marked disease activity.

Tendon and ligament damage

The destructive process in rheumatoid arthritis involves tendons and ligaments and may cause 'spontaneous' rupture. The most common sites of clinically significant involvement are the hands, wrists, shoulders, neck, knees, and feet.

The flexor tendons of the fingers are affected in more than half of patients by tenosynovitis and rheumatoid nodules, causing stenosis, pain, and occasionally rupture. The extensor tendons are likewise commonly detached and ruptures are frequent, starting with the fifth and spreading to the fourth, third, and second in that order. Reconstructive surgery should be performed at an early stage of this development.

Weakening of ligaments causes joint instability and subluxation of metacarpophalangeal joints, allowing ulnar drift and volar subluxation. Loosening of the distal radioulnar ligament likewise gives instability with piano-key sign and volar luxation of the radius and carpus, and prominence of the ulnar head. Rupture of the rotator cuff and supraspinate tendon is common, resulting in 'shrugging' of shoulders when abduction is attempted. At the knee, damage to the lateral and cruciate ligaments causes instability and pain, and in the ankles, valgus deformity is common. Atlantoaxial subluxation only occurs in the presence of weakening or rupture of transverse ligaments.

Amyloidosis

Rheumatoid arthritis remains the most common cause of secondary amyloidosis (amyloid A; **AA**) in Europe, occurring in some 2 to 5 per cent of hospital cases (Lender and Wolf 1972). Geographical differences in prevalence may exist. Amyloidosis was found in 17 out of 81 Japanese autopsies performed between 1960 and 1990 (Suzuki *et al*. 1994). No genetic predisposition has been identified in rheumatoid arthritis. Although related to active and widespread disease with prolonged high levels of C-reactive protein and AA in serum, the onset of clinical signs vary between years and decades. The most common type of organ failure in amyloidosis is uraemia, although the skin, liver, and gastrointestinal tract are microscopically involved in a majority of cases. Five-year survival was reduced to 50 per cent in earlier studies (Wegelius *et al*. 1980), but in more recent series, the use of intensive antirheumatic therapy gives a more favourable outlook of 70 to 93 per cent survivors (Ahlmén *et al*. 1987; Berglund *et al*. 1993). It is therefore important to be aware of the occurrence of amyloidosis and perform diagnostic procedures in suspected cases, usually presenting with proteinuria or decreased renal function (see Chapter 5.13.1).

Felty's syndrome

In 1924 Felty observed the occurrence of splenomegaly and neutropenia in five patients with rheumatoid arthritis (Felty 1924). This triad, although showed by Still in juvenile arthritis several decades earlier, has since been called Felty's syndrome. Felty's syndrome is seen in 1 per cent or less of hospital patients with rheumatoid arthritis, and has the same female/male ratio as rheumatoid arthritis itself (Goldberg and Pinals 1980; Campion *et al*. 1990). It has, with few exceptions, only been observed in Caucasians. The rheumatoid arthritis is typically rather destructive, but signs of ongoing synovitis are not prominent despite radiological progression of erosions. Systemic manifestations are common, with subcutaneous nodules, weight loss, and secondary Sjögren's syndrome in over half of the cases. Hepatomegaly and lymphadenopathy are common. Fever, skin pigmentation, and leg ulcers are other characteristics. The diagnosis is established when splenomegaly and a white cell count of less than $2 \times 10^9/mm^3$ are found on three consecutive occasions. Anaemia and thrombocytopenia are usually not pronounced, and in contrast to systemic lupus erythematosus, there is no lymphopenia. The mean disease duration at diagnosis was 20 years on average in one study, but asymptomatic Felty's syndrome may be present and thus undiagnosed for several years.

Skin ulceration and severe systemic infections constitute the main clinical problems in these patients. Repeated upper and lower respiratory infections also contribute to mortality, which is substantial. Eight of 32 patients died in one centre during 5 years' follow-up, and five of these succumbed with fulminant pneumonia. Although neutropenia is related to susceptibility, there is no quantitative correlation to the degree of leucopenia.

Serological abnormalities are present in most cases (Table 11). Of particular interest are antinuclear antibodies that are granulocyte specific (Faber and Elling 1966) and fix complement (Wiik and Munthe 1974). Plasma from patients with Felty's syndrome induced transient granulocytopenia, and failed to stimulate colony formation from bone marrow cells in culture, indicating the pathogenetic importance of circulating factors. A pathogenetic role for granulocyte– macrophage colony-stimulating factor is indicated by a recent observation, where administration of this factor corrected the neutropenia in a patient, but also elicited release of interleukin 6 and flare up of arthritis (Hazenberg *et al*. 1989).

Antinuclear antibody >80% with HEp-2 cells
Rheumatoid factor >90%, high titre IgG
Cryoglobulins—immune complexes with complement
Complement-fixing granulocyte-specific antinuclear antibodies
Relative hypocomplementaemia

Table 11 Serological markers of Felty's syndrome

The multiple occurrence of rheumatoid arthritis in relatives is more common than expected. HLA DR4 is present in close to 100 per cent and homozygosity of HLA DR4 was present in 14 of 28 tested cases in a recent report (Campion *et al*. 1990). The complement C4B null allele was also associated with Felty's syndrome in 17 of 30 patients. Thus genetic factors clearly distinguish rheumatoid arthritis in Felty's syndrome from other types (Thomson *et al*. 1988).

The management of Felty's syndrome is still controversial. The effect of splenectomy is not convincing and often transient at best. It confers no protection against sepsis. Anecdotal evidence claims responses to parenteral gold, penicillamine, and methotrexate (Campion *et al*. 1990). Two cases have apparently responded to cyclosporin A in combination with methylprednisolone (Camp *et al*. 1991). In view of potential risks with all these regimens a conservative approach to the management of Felty's syndrome is warranted in uncomplicated cases.

Laboratory abnormalities

Ideally, laboratory methods, to be clinically useful, should have one or more of the features listed in Table 12. There is presently a proliferation of new tests, many with promising novel features. However, it is not clear which, if any, of these will stand the test of time (di Giovine *et al*. 1990; Wollheim and Eberhardt 1992).

1. Diagnostic tool
2. Measure of general disease activity
3. Measure of organ-specific activity
4. Prognostic marker
5. Monitoring of therapeutic effectiveness

Table 12 Desirable features of laboratory tests in rheumatoid arthritis

The rheumatoid factor remains the most important aid in establishing the diagnosis of rheumatoid arthritis. The classical Waaler–Rose test, using sheep cells sensitized with rabbit gammaglobulin, combines relative specificity with reasonable sensitivity. Titres have been replaced by units and the use of World Health Organization standard serum should facilitate comparison between different laboratories.

Another development has been the introduction of enzyme-linked immunosorbent assays (**ELISA**) for the IgG, IgA, and IgM subclasses of rheumatoid factor. These can be made highly sensitive. Thus in one series of patients with early rheumatoid arthritis, 67 per cent were positive in the Waaler–Rose test compared with 85 per cent for IgM rheumatoid factor by ELISA (Eberhardt *et al*. 1990b). All three classes of rheumatoid factors are present in the majority of seropositive cases. A minority of cases may have only two and occasionally only one immunoglobulin class in the serum. Much attention has been focused on the putative clinical correlations with early selective occurrence of IgA rheumatoid factors, and some investigators find them predictive of erosive disease whereas others do not. It has not been ruled out

that technical differences, for instance whether human or rabbit IgG has been used for coating the ELISA plates, may explain the discrepancies. At present, however, ELISAs still should be considered research tools.

A large number of antinuclear antibodies are present in increased amounts in rheumatoid arthritis, but this is of more theoretical than practical interest. Granulocyte-specific antinuclear antibodies are present in two-thirds of patients. Another antibody reacting with a soluble nuclear antigen, called anti-RA 33, was present in one-third and seemed rather specific for this disease (Hassfeld *et al*. 1989). Other frequently found antibodies that are specific for histones, single-stranded DNA, or Epstein–Barr virus-related antigens are not specific for rheumatoid arthritis.

In the 1960s, reduced amounts of haemolytic complement in synovial fluid were found to distinguish seropositive rheumatoid arthritis from other forms of chronic arthritis (Zvaifler and Pekin 1963; Hedberg *et al*. 1964). The mechanism behind this characteristic finding is activation and accelerated catabolism of complement products.

Surprisingly, assays for complement in synovial fluid have not become widely used. Complement synthesis is high in rheumatoid inflammatory tissue, and plasma concentrations are often raised or normal. However, the relative concentrations of C3 and C4 are low when compared with other acute-phase reactants, and absolute values may be subnormal in the presence of active vasculitis. Detection of cleavage products, e.g. C2a and C3a, is direct evidence of complement activation, and may be useful for investigative purposes.

The acute-phase reaction in rheumatoid arthritis can be measured by a number of methods (Table 13). The erythrocyte sedimentation rate is most widely used and cheapest. Analysis of individual plasma proteins adds little essential information, although C-reactive protein is a more sensitive indicator of activity. It often remains elevated despite clinical remission, and has been found in some studies to correlate with destructive joint changes (Dawes *et al*. 1986; van Leeuwen *et al*. 1993). The erythrocyte sedimentation rate is influenced by anaemia and immunoglobulins, but this does not limit its usefulness in longitudinal monitoring of rheumatoid arthritis.

Analysis	Degree of change	Oestrogen influence	Glucocorticoids	Other comments
ESR	++++	+	−	Best and cheapest screen test
CRP	+++++		−	Highest amplitude of change
Orosomucoid	++++	−	+	
α_1 Antitrypsin	++	++	−	Liver ++, PiZ gene low levels
Haptoglobin	++++	+	−	Liver −, haemolysis + +
Fibrinogen	++++		−	Requires plasma
Caeruloplasmin	+	++	−	
Viscometry	++++			Expensive, not better than ESR
Complement (C3)	+, ↑, or −		Variable	
Complement (C4)	+, ↑, or −		Variable	C4 null gives low levels

ESR, erythrocyte sedimentation rate; CRP, C-reactive protein.

Table 13 Acute-phase reactants and rheumatoid arthritis

In recent years an increasing number of more or less tissue-specific markers have been identified and assays constructed for clinical use (Table 14). This field holds promise for better future monitoring of the disease process and response to therapy in rheumatoid arthritis (Wollheim and Eberhardt 1992).

Cell	Marker	Compartment
Granulocytes	Lactoferrin	Synovial fluid
	Cytidine deaminase	Serum, synovial fluid
	L1 calprotectin	Serum, synovial fluid
	Elastase	Synovial fluid, serum
Synovial membrane (fibroblasts)	Neopterin	Synovial fluid
	IL-1, TNF, IL-6	Serum, synovial fluid
Lymphocytes	IL-2 receptor	Synovial fluid, serum
	β_2-Microglobulin	Synovial fluid, serum
	$P_{III}NP$	Serum
	Hyaluronan	Serum
	IL-6	Serum, synovial fluid
Endothelial cells	von Willebrand factor	Serum
Cartilage	Proteoglycan fragments	Synovial fluid, serum
	COMP	Synovial fluid, serum
	CMP (148 kDa protein)	Serum
Bone	Deoxypyridinoline	Urine
	Osteocalcin	Serum
	Bone sialoprotein	Serum

CMP, cartilage matrix protein; COMP, cartilage oligomeric protein; IL, interleukin; $P_{III}NP$, type III collagen *N*-terminal propeptide; TNF, tumour necrosis factor.

Table 14 Tissue-specific markets of activity in rheumatoid arthritis

Cytidine deaminase, although not entirely granulocyte specific, has been claimed to be a better marker for inflammation in rheumatoid arthritis than C-reactive protein (Thompson 1987). Calprotectin (L1) may have a similar profile (Berntzen *et al*. 1989). Cytokines and cytokine receptors, although present in trace amounts only, are the subject of numerous studies due to their central position in the pathogenesis of rheumatoid arthritis (di Giovine *et al*. 1996). Increased interleukin 6 levels in synovial fluid but not plasma (Sack *et al*. 1993) and increased amounts of tumour necrosis factor-a and its soluble receptors, and interleukin-2 receptors have been found (Barrera *et al*. 1993).

The concentration of hyaluronate in serum has been correlated with disease activity and morning stiffness in rheumatoid arthritis (Engström-Laurent and Hällgren 1985). Hyaluronate is also a predictor of radiological damage in rheumatoid arthritis (Paimela *et al*. 1991). The type-III collagen *N*-terminal propeptide, $P_{III}NP$, has been used to monitor therapeutic response to disease suppressive therapy and claimed to differ from C-reactive protein (Hørslev-Petersen *et al*. 1988). Cartilage-specific markers have been used and found to vary independently of acute-phase reactants and to correlate with destruction and possibly to stage of disease in rheumatoid arthritis (Wollheim and Saxne 1992; Poole 1994).

Anaemia is common in rheumatoid arthritis and in part related to disease activity as so-called anaemia of chronic disease. This is not responsive to iron therapy, and may be due to hyporesponsiveness to erythropoietin (Means *et al*. 1989). In addition, iron deficiency is present in 30 to 50 per cent of patients with anaemia, as shown by low mean corpuscular volume (Vreugdenhil *et al*. 1990). This may be confirmed by negative iron stains of bone marrow aspirates. Analysis of synovial fluid has traditionally not been much used in evaluation of rheumatoid arthritis. However, it has now been shown that synovial fluid acidosis is related to destruction (Geborek *et al*. 1989b) and that higher concentrations of acid-phosphatase total protein predicted destructive disease (Luukkainen *et al*. 1989). Cytological testing of synovial fluid has been proposed for diagnostic work (Freemont 1991); however, it is not clear whether such observations will become clinically useful in prognostic work.

Lymphopenia was seen in 15 per cent of patients with rheumatoid arthritis. Both CD4 and CD8 cells were equally affected, and changes did not correlate with disease activity or drug therapy (Symmons *et al*. 1989).

Imaging (see also Section 4.9)

As radiography approaches its 100th birthday it remains a cornerstone in the diagnosis and assessment of rheumatoid arthritis. In the last decade, however, scintigraphy, ultrasonography, computed tomography, and magnetic resonance imaging (**MRI**) have emerged as important complementary techniques. Used in concert, they allow rather comprehensive objective documentation of the anatomic disease progression. However, judicious use, based on well-defined questions, will save patients unnecessary exposure to radiation and society unnecessary costs.

Important issues in early rheumatoid arthritis are concerned with presence or absence of erosive changes and with their quantification in the course of disease. Two

methods have emerged to meet the latter need. The Larsen–Dale index (Larsen *et al*. 1977) uses a set of standard radiographs for each joint and distinguishes five stages of involvement, starting with soft tissue swelling and juxta-articular osteoporosis and ending with complete cartilage and advanced bone destruction. This method has the advantage of relative simplicity and has been most used in Europe (Wollheim *et al*. 1988). The Sharp method involves assessing joint space narrowing and counting erosions (Sharp *et al*. 1971). Both are reproducible, but less sensitive to change than the human eye.

Functional impairment correlates with the Larsen index, but is not closely predictable from radiographic changes (Fig. 6). A most impressive example of discrepancy between severe radiographic erosions and preserved function is called 'typus robustus', seen in men, often those employed in heavy manual work.

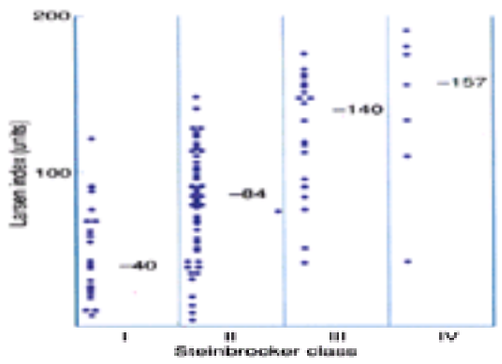

Fig. 6 Larsen index distribution in relation to functional classes according to Steinbrocker. Horizontal bars denote the median.

Scintigraphy with technetium pertechnetate is a simple and useful method to visualize synovial activity, and persistent activity predicts occurrence of radiographic erosions (Möttönen 1988). This promising technique needs to be tested as guide for therapy. Scintigraphy with bone-seeking technetium is useful in early detection of avascular necrosis. Other scintigraphic methods involve labelling of granulocytes with a radionuclide, using their localization after reinfusion to diagnose articular or extra-articular inflammation.

Ultrasonography is being used increasingly, as the technique improves. It has replaced arthrography in the diagnosis of Baker's cysts, and is useful for visualizing rotator-cuff lesions in the shoulder and hip joint effusion (Mitchell 1989).

MRI offers superior contrast resolution compared with other imaging techniques (Brahme 1991). It has been possible to visualize joint cartilage and MRI may be the most sensitive tool to detect early joint lesions. In the evaluation of instability of the neck, MRI allows visualization of granulation tissue around the odontoid process and its change after surgical fusion (Fig. 7). MRI also is a sensitive tool to detect effusion and tendon and ligament abnormality. The initial disadvantage of long exposure time has improved with newer, technically more sophisticated equipment.

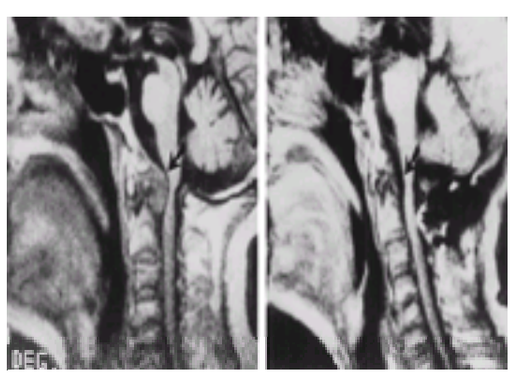

Fig. 7 Preoperative MRI (left) and 4 months postoperative MRI (right) after successful surgical fusion. Arrows indicate periodontoid pannus.

Treatment

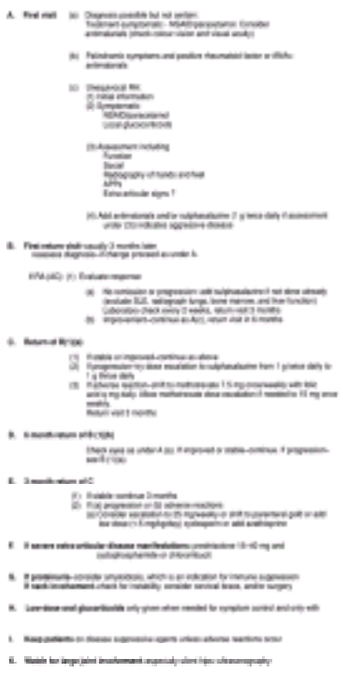
Assessment

Assessment of disease activity, joint damage, and change over time of these variables are essential tools to monitor intervention in rheumatoid arthritis. The traditional methodology of joint examination has been the subject of several evaluations and developments (Preevo *et al*. 1993). In essence, simple counts are better than weighted ones, swelling is a better indicator than tenderness, and a 28-joint count performs as well as more comprehensive 55- to 66-joint counts (Preevo *et al*. 1995). In December 1993 the European League Against Rheumatism published a handbook of standard methods for assessing disease activity. Simple self-assessment questionnaires are also available (Kazis *et al*. 1990). The radiological progression is still considered the gold standard to measure results of treatment. Based on average progression rates from different centres, it has been estimated that regardless of scoring system, due to great variability in progression rate, one would need patient groups of 150 to detect a 50 per cent slowing of radiological progression at a significance level of 0.05 per cent (Sharp *et al*. 1993). Obviously not many studies of disease suppressive agents meet such standards.

Individual goals

In addition to the physical and radiological assessment it is essential to identify and analyse individual disease-related problems and shortcomings, and list them in order of importance to the patient. This is often best accomplished in co-operation with the physiotherapist, occupational therapist, social worker, and metrologist or nurse, also called allied health professionals. Table 15 shows some of the main components of appropriate treatment of rheumatoid arthritis. Some or all of these therapeutic options may be indicated, according to variations in disease severity. It is, however, mandatory that the patient has easy access to a responsible physician with an overview of all the different aspects of management, and it is desirable that the health service provides the necessary organization. Box 1 has a schedule for management of drugs in rheumatoid arthritis.

Box 1 Management of rheumatoid arthritis (RA)



Patient education, adaption, and counselling

Physiotherapy—exercises, joint protection

Occupational therapy—adapt environment, personal aids, orthoses

Medication—pain control, disease suppression

Non-medical pain reduction—transcutaneous nerve stimulation, acupuncture, surgery

Rehabilitation—joint replacement, arthrodesis

Table 15 Main Components of Treatement for Rheumatoid Arthritis

Pharmacotherapy

The number of drugs used in the treatment of rheumatoid arthritis has increased steadily over the last decades, and there have been remarkable geographic differences in therapeutic traditions, often not scientifically based on proper trials. A new and more aggressive approach to early treatment of rheumatoid arthritis has yet to prove that it will change the long-term outcome. Originating in the feeling that most currently used drugs (Table 16) are only symptom modifying, a new terminology was proposed (Edmonds *et al*. 1993). It distinguishes between slow acting/disease modifying and 'disease controlling' drugs and requires sustained (2 year!) improvement of function and slowing or prevention of structural joint damage for the latter. The distinction obviously can only be made in retrospect and seems to be of little practical use at present.

Pain relief
Simple analgesics
Non-steroidal anti-inflammatory drugs

Disease suppression
Chloroquine—hydroxychloroquine
Gold—parenteral
D-Penicillamine
Sulphasalazine
Auranofin
Methotrexate
Azathioprine
Glucocorticoids
Cyclosporin A (now Neoral)

Disease complications
Anaemia: iron, erythropoietin
Osteoporosis: oestrogens, calcitonin, bisphosphonates
Vasculitis: glucocorticoids, chlorambucil, cyclophosphamide
Amyloidosis: chlorambucil, cyclophosphamide

Table 16 Pharmacology of rheumatoid arthritis

Non-steroidal anti-inflammatory drugs (NSAIDs)(see also Chapter 3.5.1)

NSAIDs are the dominating group of drugs and are prescribed periodically or continuously for the vast majority of patients. They offer reliable but limited symptomatic relief from pain and stiffness. Their mechanism of action is complex. NSAIDs inhibit constitutional Cox-1 and induced Cox-2 in varying proportions (Mitchell *et al*. 1994), which may have clinical implications. In addition to inhibition of cycloxygenase they also suppress neutrophil function and in vivo motility, and according to some investigators cause increase of suppressor lymphocyte function and reduced synthesis of rheumatoid factor (Brooks and Day 1991). They also inhibit platelet aggregation. In experimental systems high doses of NSAIDs have been found to inhibit chondrocyte synthesis of proteoglycans. This has caused speculation of potential harmful effects after long-term use in human disease. However, no convincing documentation of cartilage damage in rheumatoid arthritis has been produced.

It is hard to know with certainty if and how NSAID treatment affects long-term outcome in rheumatoid arthritis. There is, however, no doubt among most observers that they improve quality of life in an important way in most patients with rheumatoid arthritis for long periods.

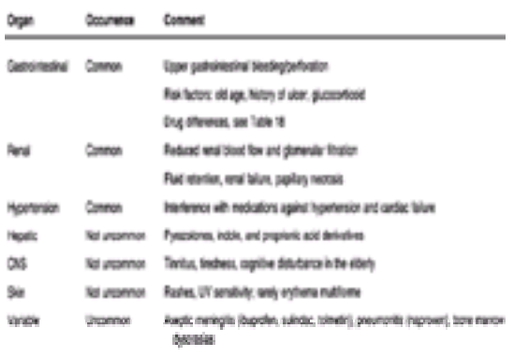
NSAIDs can be divided into two groups, those with a short and those with a long half-life. The former are often available in slow-release formulation, allowing them to be given once or twice daily, for which improved compliance is claimed. It is not possible to relate serum levels to effect, but a dose–response relationship has been established for some NSAIDs, e.g. naproxen and ibuprofen (Brooks and Day 1991).

NSAIDs contain an asymmetric carbon and inactive (*R*) and active (*S*) enantiomers. *In vivo* conversion occurs from (*R*) to (*S*) but not from (*S*) to (*R*). A variable rate of conversion perhaps contributes to variation in response and adverse effects. A large number of comparative short-term trials have on the whole failed to reveal relevant differences between NSAIDs, although individual patient preference has been suggested (Huskisson *et al*. 1976; Scott *et al*. 1982).

Aspirin was until recently the preferred first line NSAID, based on unsurpassed effectiveness and low price. However, a number of trials have shown it to be less well tolerated than other NSAIDs, and thus it is no longer considered a first choice. This does not apply to non-acetylated salicylates. If optimal dose of one NSAID has no satisfactory effect after 3 to 4 weeks, it is advisable to try another. Combined use of two or more NSAIDs is common practice but its rationale is not well founded; they should be prescribed one at a time. Indomethacin administration at night is popular, due to its combined analgesic and sedative effect.

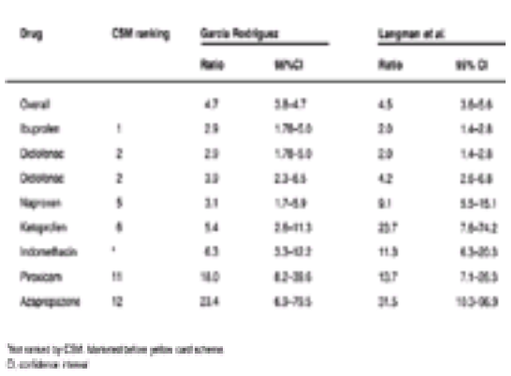
Adverse effects are very common, and may be life threatening (Fries *et al*. 1989; Langman 1989). Awareness and careful patient education are essential (Table 17). Gastric ulcer is more common that duodenal and may be asymptomatic. The overall risk factor is 3 to 4, which means that NSAIDs may be associated with one-quarter of all patients admitted to hospital with these conditions.. Patients at risk and requiring NSAIDs should receive prophylactic treatment with the prostaglandin E_1-analogue, misoprostol. Risk factors are old age, previous peptic ulcer, and concomitant use of glucocorticoids. There seems to be a hierarchy with

regard to upper gastointestinal toxicity among some NSAIDs (Bateman 1994; Table 18). Small bowel toxicity has also been suggested from biopsy studies, which show membranes and strictures as well as Crohn-like lesions (Bjarnason *et al*. 1988; Banerjee 1989). The practical importance of this is not known. Many patients also become constipated and develop nausea from NSAIDs.



Organ	Occurrence	Comment
Gastrointestinal	Common	Upper gastrointestinal bleeding/perforation
		Risk factors: old age, history of ulcer, glucocorticoid
		Drug differences, see Table 18
Renal	Common	Reduced renal blood flow and glomerular filtration
		Fluid retention, renal failure, papillary necrosis
Hypertension	Common	Interference with medications against hypertension and cardiac failure
Hepatic	Not uncommon	Pyrazolones, indole, and propionic acid derivatives
CNS	Not uncommon	Tinnitus, tiredness, cognitive disturbance in the elderly
Skin	Not uncommon	Rashes, UV sensitivity; rarely erythema multiforme
Variable	Uncommon	Aseptic meningitis (ibuprofen, sulindac, tolmetin); pneumonitis (naproxen); bone marrow dyscrasias

Table 17 Adverse reactions of non-steroidal anti-inflammatory drugs



Drug	CSM ranking	Garcia Rodriguez		Langman et al.	
		Ratio	95%CI	Ratio	95% CI
Overall		4.7	3.8–4.7	4.5	3.6–5.6
Ibuprofen	1	2.5	1.78–5.0	2.0	1.4–2.8
Diclofenac	2	2.3	1.78–5.0	2.0	1.4–2.8
Diclofenac	2	3.0	2.3–6.5	4.2	2.8–6.8
Naproxen	5	3.1	1.7–6.9	9.1	5.5–15.1
Ketoprofen	6	5.4	2.6–11.3	23.7	7.6–74.2
Indomethacin	*	6.3	3.3–12.2	11.3	6.3–20.3
Piroxicam	11	16.0	8.2–33.6	13.7	7.1–26.3
Azapropazone	12	23.4	6.3–75.5	31.5	10.3–96.9

*Rank reversed by CSM. Abbreviated before yellow card scheme
CI = confidence interval

Table 18 Odds ratio and 95 per cent CI for bleeding and perforation (Garcia Rodriguez) or acute gastrointestinal bleeding (Langman *et al.*), and CSM rank order of serious reports of gut toxicity expressed per million prescriptions in the first 5 years of marketing (after Bateman 1994)

Impaired renal blood flow is likely to occur in patients with pre-existing kidney diseases, and is thought to be related to the reduced presence of procirculatory prostaglandins. All NSAIDs have this effect, although two studies show sulindac to cause less impairment in short-term trials in patients with moderate renal failure (Eriksson *et al*. 1990; Whalton *et al*. 1990). It is important to avoid dehydration, which may precipitate severe renal failure in patients taking NSAIDs.

The effectiveness of thiazides and loop diuretics is reduced by NSAIDs with the possible exception of sulindac, and the same applies to b-blockers and angiotensin-converting enzyme inhibitors. A number of other pharmacokinetic as well as pharmacodynamic drug interactions have been identified (Brooks and Day 1991). Thus it is advisable to treat NSAIDs with respect, and only use them on strict indications of which rheumatoid arthritis, however, is one. Paracetamol (acetaminophen) in adequate dosage of 1 g three times a day is often a useful analgesic when NSAIDs are contraindicated.

Antimalarials

These are highly potent inhibitors of intracellular protein processing, and they accumulate in the cellular acid-vessel system for transport of macromolecules. They also inhibit monocyte production of interleukin1a and interleukin 6 in vitro (Sperber *et al*. 1993). They have a well-documented action of moderate disease suppression in rheumatoid arthritis, and cause, at an appropriate dosage, very few adverse reactions (Tett *et al*. 1990; Clark *et al*. 1993). Safety and little need for laboratory surveillance make them an inexpensive first choice among disease suppressing agents. Eye toxicity does not occur in patients without liver disease provided the dose of 4 mg/kg per day for chloroquine or 6 mg for hydroxychloroquine is not exceeded. It is also recommended to stop the drug for 4 to 6 weeks each year to check whether the disease may be in remission. Increased creatinine and 10 per cent lowered creatinine clearance may occur (Landewé *et al*. 1995). Antimalarials may diminish toxicity of methotrexate to the liver (Fries *et al*. 1991). Given in combination therapy with aureothiomalate, hydroxychloroqine improved efficacy without increasing adverse reactions (Scott *et al*. 1989). Antimalarials in combination with penicillamine, on the other hand, caused more adverse reactions and less therapeutic effect. Thus the antimalarials have a definite place in the management of rheumatoid arthritis of moderate severity, and may become of use in certain combination regimens.

Soluble gold salts

These have been given parenterally since the 1930s and are still considered among the most potent disease-suppressing agents in rheumatoid arthritis. The mechanism of action is unknown, but experimental data have shown inhibition of antigen presentation by macrophages, perhaps mediated by enzyme inhibition (Champion *et al*. 1990). This results in diminished lymphocyte function. It is remarkable that all clinically used preparations contain AuI and a sulphydryl ligand in an approximate ratio of 1:1. Aureothiomalate has been most studied, and proven superior to placebo and auranofin, an oral gold preparation, and equal to sulphasalazine in efficacy. Inefficacy, therapeutic escape, and not least, adverse reactions, however, seriously limit its use as a single drug (Sambrook *et al*. 1982). An impressive list of adverse reactions to parenteral gold compounds is shown in Table 19. Transient increase in joint pain, also called nitritoid reaction, rarely causes termination. A most serious, usually fatal complication, aplastic anaemia, may be treated successfully with bone marrow transplantation. Agranulocytosis and thrombocytopenia usually are reversible, but eliminate future use of the drug. Adverse reactions are interestingly not related to dose or circulating levels of gold. Aureothiomalate is administered once weekly in doses between 10 and 50 mg. When clinical remission is achieved, injection frequency is reduced to every 2 to 6 weeks. However, in practice, only half of the patients remain on therapy after 2 years and one-fifth after 4 years.

Table 19 Adverse reactions to parenteral gold

D-Penicillamine (dimethylcysteine)

In addition to its chelating effects on divalent metals, such as copper, D-penicillamine has a strongly reactive thiol group and forms mixed disulphides through oxidization. Thus free D-penicillamine has a very short half-life in vivo. It is excreted mainly in the form of penicillamine–cysteine mixed disulphide, but also forms disulphides with albumin and other proteins possessing reactive sulphydryl compounds. Oxidization and chelation occur readily in the gastrointestinal tract, which is why D-penicillamine should be administered without food or other drugs. Even then only half of the dose is absorbed.

The mechanism of action is not known, but D-penicillamine inhibits T-lymphocyte activation probably through a direct T-cell interaction (Lipsky and Ziff 1980). It also reduces the amount of circulating immune complexes and IgA–a_1-antitrypsin complexes as well as rheumatoid factor (Norberg *et al*. 1980). These effects are synchronous with the therapeutic response. Paradoxically, D-penicillamine causes a number of so-called autoimmune complications. An immune-complex glomerulonephritis, histologically identical with that of systemic lupus erythematosus, is accompanied by proteinuria which may last for a year. Occasionally full-blown systemic lupus develops with hypocomplementaemia and antinative DNA (Joyce 1990). Other autoimmune conditions occasionally induced by D-penicillamine are myasthenia, dermato-/polymyositis and Goodpasture's syndrome. After stopping D-penicillamine, these syndromes slowly remit although polymyositis may be fatal if not detected early.

Other side-effects are bone marrow suppression and various forms of skin lesions, including bullous pemphigoid eruptions. HLA DR3 is a risk factor for development of several of these complications. D-Penicillamine is contraindicated in pregnancy due to its teratogenic effect.

The use of D-penicillamine has diminished but it is still a useful drug in some patients. It is best used in doses from 125 to 750 mg/day, with slowly increasing dosage. Combination with sulphasalazine may be advantageous (Taggart *et al*. 1987).

Sulphasalazine

This was designed as a combined analgesic and antimicrobial agent against a putative intestinal pathogen causing rheumatoid arthritis (Svartz 1942). Although this mechanism of action is still hypothetical, its role as an effective disease-suppressing agent in rheumatoid arthritis is well documented (Porter and Capell 1990). The drug is largely but not completely split into 5-aminosalicylic acid and sulphapyridine by bacteria in the colon, and much of its adverse reactions are sulphapyridine related. However, the effect probably at least in part resides in the intact molecule. The onset of effect is 4 to 12 weeks. There is suggestive evidence for retardation of radiological progression if given in early rheumatoid arthritis (van der Heide *et al*. 1989; Hannonen *et al*. 1993).

The most common adverse reactions are nausea, abdominal pain, dizziness, and irritability, and this is only marginally improved by the use of enteric-coated tablets. An acute pneumonitis develops rarely, usually early. Thrombocytopenia occurs in 1:700 patients in the first 3 months of therapy (Keisu and Ekman 1992) but is rarer later on. Serious bone marrow toxicity is, however, uncommon. Spermiogenesis is affected, causing reversible subfertility (Birnie *et al*. 1981). Although some dose-related adverse reactions are more likely to occur in slow acetylators, fast acetylators are as likely to develop serious idiosyncratic reactions, and acetylator state does not influence response. Sulphasalazine is administered orally in doses starting with 0.5 g and increased to a maintenance dose of 1 g twice or three times daily.

Methotrexate

Methotrexate given once weekly, usually orally in doses of 5 to 15 mg, is widely used as a standard disease-suppressive agent, and placebo-controlled trials as well as follow-up studies of up to 90 month are favourable (Grosflam and Weinblatt 1991; Kremer and Phelps 1992), and superior to azathioprine (Jeurissen *et al*. 1991). Survival on the drug is also better than for parenteral gold, azathioprine, D-penicillamine, sulphasalazine, auranofin, and hydroxychloroquine (Morand *et al*. 1992).

The mechanism of action is not known. In addition to an antidihydrofolate reductase effect, methotrexate may have an immunosuppressive effect. Its toxicity may be reduced by administration of folate without loss of therapeutic effect (Morgan *et al*. 1994), indicating at least partly a folate-independent mode of action. The fast onset of clinical response suggests an anti-inflammatory mode of action.

The most common adverse reaction is gastrointestinal intolerance, which usually is not severe. Methotrexate may cause severe septic complications, both fungal and bacterial, and it may be advisable to stop the drug temporarily before arthroplastic surgery. Eosinophilia and pneumonitis arise in some 5 per cent of cases. Renal methotrexate clearance and creatinine clearance decreased by 10 per cent after 6 months (Kremer *et al*. 1995).

The question regarding long-term liver toxicity is still unsettled. Whereas biopsy studies reveal dose-dependent increased liver fibrosis, frank cirrhosis has not occurred with low-dose regimens. Routine liver biopsy is not recommended during initial years of therapy. While NSAIDs increase the toxicity from high-dose methotrexate, this is not reported with low-dose methotrexate, although patients with impaired renal function may be at higher risk.

Combination therapy of methotrexate with gold or azathioprine and hydroxychloroquine, or with hydroxychloroquine and sulphasalazine may be useful (Paulus 1990). A meta-analysis indicates the possibilities of a somewhat lower rate of radiologial progress than for other drugs except parenteral gold (Alarcón *et al*. 1992).

Auranofin

This is a lipophilic gold compound for oral use which is effective in rheumatoid arthritis, although weaker than parenteral gold (Champion *et al*. 1990). A 2-year placebo-controlled prospective study in early rheumatoid arthritis, indicated a retarding effect on radiological progression (Borg *et al*. 1988). The effective dose is 3 mg twice daily. The most common side-effects are diarrhoea and other mild gastrointestinal disturbances. Serious adverse reactions are unusual. The onset of effect is slow, which may be a disadvantage in short-term trials and explain its poor rating in a meta-analysis (Felson *et al*. 1990).

Azathioprine

The purine analogue azathioprine is an effective disease-suppressive drug in rheumatoid arthritis given in doses between 1.5 and 2.5 mg/kg per day, although onset of action is slow (Luqmani *et al*. 1990). Bone marrow toxicity and lymphoma induction are rare complications whereas nausea is common.

Cyclosporin (Neoral)

Cyclosporin is a fungal decapeptide with distinct actions on active T-lymphocytes and possibly antigen-presenting cells, lowering release of interleukin 2. It is an attractive candidate for immune modulation/suppression in rheumatoid arthritis. In doses of 2.5 to 5 mg it was better than placebo in several trials of active rheumatoid arthritis (van Rijthoven *et al*. 1986; Dougados *et al*. 1989; Tugwell *et al*. 1990) and not different from D-penicillamine, azathioprine, and hydroxychloroquine. Evidence for retardation of radiological progression is not convincing (Førre *et al*. 1994), but long-term trials in early rheumatoid arthritis to look into this crucial question are ongoing. A problem with this drug is that it induces hypertension and renal toxicity even in low doses. The long-term consequences of this are not known. Its effect on C-reactive protein is moderate or nil, and the erythrocyte sedimentation rate does not change. Disease activity increases rapidly after the drug is stopped. Cyclosporin A must, if used at all, be carefully monitored for adverse reactions, in particular hypertension and nephrotoxicity (Cash and Klippel 1994; Landewé *et al*. 1994).

Glucocorticoids

The introduction of glucocorticoid treatment of rheumatoid arthritis marks the beginning of modern rheumatology, in demonstrating reversibility of what was considered permanent disability (Hench *et al*. 1949). Glucocorticoids have a large number of effects on immune function and regulation, and cell traffic and adhesion. Inhibition of transcription of the interleukin 1b gene is one important effect (Lee *et al*. 1988). It is the most powerful and predictable remedy inducing immediate symptomatic relief in rheumatoid arthritis available to date, but its long-term effects are among the most controversial issues in the treatment of this disease (George and Kirwan 1990; McDougall *et al*. 1994).

High-dose systemic administration may prevent formation of erosions but adverse effects preclude its uninhibited use (Weiss 1989). The list of side-effects is long (George and Kirwan 1990) and diabetes, hypertension, excessive weight gain, cataract, arteriosclerosis, and not least osteoporosis are among them (Lukert and

Raisz 1990). New approaches to management of osteoporosis involving bisphosphonate, or oestrogen replacement in postmenopausal women are promising, and long-term trials involving low-dose glucocorticoids may become feasible. Patients with rheumatoid arthritis easily become addicted to oral glucocorticoids and it is therefore a serious decision to start such therapy.

Patients treated with NSAIDs have a low concentration of glucocorticoid receptors (Pelletier *et al*. 1994) as well as autoantibodies to lipocortin-1 with impaired responsiveness to glucocorticoids. Furthermore, the hypothalamic–hypophyseal–adrenal axis is hyporesponsive to, for example, surgical stress (Chikanza *et al*. 1992). Findings like these will have to be followed-up by formal clinical trials, before increased use of glucocorticoids can be advocated (Saag *et al*. 1994).

Pulsed intravenous megadoses of 1000 mg methyldprednisolone is no more effective than 100 mg, and this expensive form of administration may be overrated. Intra-articular use of crystalline preparations is, however, both effective and rational, since it delivers the disease-suppressive drug to the involved site. Triamcinolone hexacetonide has the longest lasting effect. If weight-bearing joints are injected a 24-h bed rest should be enforced in order to achieve better effect duration. Iatrogenic septic arthritis is no major problem when using a proper technique, but intra-articular glucocorticoids may predispose to later septic arthritis in the injected joint (Östensson and Geborek 1991).

Alkylating agents

Chlorambucil at 0.1 to 0.2 mg/kg per day and cyclophosphamide at 100 to 150 mg/day, are both active in the suppression of rheumatoid arthritis. No comparative studies have been published, but both drugs induce malignancies after prolonged use (Luqmani *et al*. 1994), and that limits their use in other than those with severe systemic disease (Table 16). Cyclophosphamide may be given in intravenous pulses of 15 mg/kg, which, however, may be no better than daily oral administration (Luqmani *et al*. 1994), except for lower risk of bladder toxicity. Both drugs may cause permanent gonadal failure in men and women. Bone marrow suppression is also a prominent feature, although cyclophosphamide may be slightly less toxic for megakaryocytes.

Combination therapy

This has been mentioned in connection with several drugs and is a matter of current interest (Paulus 1990; Brooks and Schwarzer 1991). Theoretically, benefits could be expected both from combining drugs with similar and different mechanisms of action, provided the adverse reactions differed and were dose related. Few controlled trials have been completed, however (Table 20). A promising combination was that of hydroxychloroquine, sulphasalazine, and methotrexate (O'Dell *et al*. 1994).

Table 20 Summary of studies using combination therapy in rheumatoid arthritis

Disease-suppressive strategies

Frustrated by lack of evidence for long-term disease modification by employment of established disease-suppressive drugs used according to the conventional 'pyramid', several authors have suggested alternative strategies. These include the early use of potent drug combinations, the inverted pyramid or step-down bridge treatment (Wilske and Healey 1990), the cyclic use of drug combinations (Schwarzer *et al*. 1990), and the successive use of various suppressive drugs according to monitored disability, the 'sawtooth strategy' (Fries 1990). The common feature is the aim for early, rapid control of disease activity and systemic glucocorticoid administration. Published data supporting these strategies are not available.

Experimental therapy

Limited success with established disease-suppressive agents in conjunction with increased knowledge of the rheumatoid disease process is stimulating active development of new therapies, targeting inflammatory mechanisms (Luqmani *et al*. 1994). Several lines of progress can be distinguished and an important breakthrough may be close (Table 21). It seems unlikely that one single substance will be able to stop the disease process; rather a multifaceted attack is more likely to be successful in the long term. Different targets depending on the stage and nature of the process may achieve the ultimate 'cure'. Escape mechanisms and redundancy are certainly very prevalent in the pathogenesis of rheumatoid arthritis, so the task is similar to that of Mr Sisyphus.

Target	Principle
The agent	Missing
Activated lymphocytes	Monoclonal antibodies Aphaeresis/photophoresis Oral tolerance induction/vaccination IL-2 fusion toxin, anti-CD5 ricin conjugate
Macrophage cytokine inhibition	Anti-IL-6 antibodies Anti-IL-1/sIL-1 receptor Anti-TNF/sTNF receptor
Cell adhesion molecules	Anti-ICAM-1
Proinflammation prostanoids	Fish- and plant-seed oil Selective Cox-2-inhibitors
Disease activity	Tetracycline Tenidap Bucillamine Podophyllotoxins Subneum Leflunomide Mycophenolic acid

IL, interleukin; TNF, tumour necrosis factor

Table 21 Experimental therapies in development for rheumatoid arthritis

Monoclonal anti-T-cell antibodies

A number of mouse antibodies which have been either chimeric or more recently humanized have been used in open as well as in a few placebo-controlled trials (Kalden 1994; Luqmani *et al*. 1994). The results have been equivocal or negative. Antibodies to CD7, although immunologically effective, have been uniformly ineffective did not influence disease symptoms, indicating that established disease is not dependent on CD7+ cells. Some of the anti-CD4 reagents have induced prolonged depletion from circulation of CD4+ helper cells but only transient clinical effects. Campath1H, a humanized antibody to CDw52, a cell surface structure on activated helper T cells, has induced depletion of CD4+ T cells lasting a year or longer, and a few patients died from infections that may have been drug related. In one study, clinical response correlated to diminished concentrations of tumour necrosis factor-a and interleukin 1. At present non-depleting anti-CD4 reagents are in trials with claims of more encouraging results.

Cytokine inhibition

Tissue destruction in rheumatoid arthritis is mediated by interleukin 6, tumour necrosis factor, and interleukin-1, and all three have been targets for immune therapy (Campion 1994). Interleukin-1 antagonism can be achieved by monoclonal antibodies, or by administering recombinant human interleukin-1 receptor. Trials are ongoing, the problem may be administering large enough doses, as the receptor is rapidly used up.

Remarkable short-term clinical remissions have been achieved with large doses of chimeric tumour necrosis factor-a antibody. This was originally developed for use in sepsis, where it, however, did not work. An open study on 20 patients was confirmed in a placebo-controlled trial. Response durations of 14 to 16 weeks were seen after administration of doses of 10 to 60 mg/kg but repeated treatment resulted in shorter periods of response, probably due to immune elimination of the antibody (Elliott *et al*. 1994a; Elliott *et al*. 1994b). Similar results are emerging using constructs of human Fc from IgG1 and two 55-kDa receptors for tumour necrosis factor. The striking observation has been made that the patients general well being improves within a day, indicating that this therapy really is affecting essential mechanisms. The effects are not lasting more than a few weeks, and immunization is a worry.

Diets and oral tolerance

Diets are of considerable interest and after many years of anecdotal accounts of carers, several controlled studies clearly show symptomatic effect of diets rich in unsaturated fish oil or plant-seed oil (Darlington 1994). One plausible mechanism behind the symptomatic effect seems to be reduced synthesis of inflammatory arachidonic acid products at the expense of eicosapentaenoic acid products. It has been hard to recruit patients for controlled trials and those entered have usually had relatively mild disease (Kjeldsen-Kragh *et al*. 1991). Elimination diets have also been attempted, usually with unconvincing effects (Darlington 1994).

Animal work has suggested oral tolerance induction in experimental autoimmune disease, such as experimental autoimmune encephalitis and adjuvant and collagen arthritis, by administering the antigen orally (Vischer and van Eden 1994). This principle, although claimed effective in initial open trials has not been confirmed in placebo-controlled trials. The suggested mechanism is that the antigen stimulates bystander suppressive pathways (Miller *et al*. 1992). Similar mechanisms may explain the effectiveness of Subreum (OM 8980), an orally administered Escherichia coli preparation (Vischer and van Eden 1994).

Other agents

Several substances are in phase III of clinical development or have actually been licensed in a few countries. Bucillamine is a disulphydryl amino acid similar to D-penicillamine and is much used in Japan. Tenidap is a cyclo-oxygenase inhibitor which also reduces C-reactive protein and is as effective as a NSAID–antimalarial combination (Littman *et al*. 1995). Minocyclin has shown moderate clinical efficacy in a double-blind study, where the interesting observation was a marked reduction in C-reactive protein combined with significant but less impressive clinical effects, indicating that the acute-phase response may not be directly linked to the rheumatoid process (Kloppenburg *et al*. 1994). Podophyllatoxin is a plant extract that in open studies induces prompt reduction in synovitis, acute-phase proteins, and rheumatoid factor concentration (Berglund *et al*. 1980). Unfortunately, it also causes severe abdominal pain or diarrhoea in most patients. A purified derivative called reumacon has weaker but significant clinical effects (Larsen *et al*. 1989). Intravenous immunoglobulin administration with or without apharesis, photophoresis, lymphapheresis, and infusion of retroplacental immunoglobulins have been tried as immunomodulating therapy. These interesting but extremely expensive procedures have yet to prove their efficacy (Sany 1994).

Surgical therapy

Surgery as a treatment in rheumatoid arthritis was made popular in the early 1960s when orthopaedic surgeons working at the Rheumatism Hospital in Heinola, Finland, showed that synovectomies were well tolerated even in active stages of the disease. Much of rheumatological endeavour since that period has been aimed at reducing the need for surgery. It need not be said that we are still far from this goal.

Synovectomy has become infrequent in most places, although pain relief may last for years. However, no retardation of radiological progression is achieved as was initially hoped (Gschwend *et al*. 1974; Doets *et al*. 1989). Tenosynovectomies have remained popular and the fastest and safest relief for nerve entrapment is still surgical decompression. The main indications for surgery are incapacitating pain and restoration or preservation of function. The state of surgical management was the subject of a recent publication (Kelly and Capell 1990).

The most frequent procedures are reconstructive arthroplasties of the hip. Approximately 10 per cent of a patient cohort with early rheumatoid arthritis were operated on within 5 years from onset in our unit (Eberhardt *et al*. 1995). Also common but much less frequently performed are total knee replacements. Shoulder arthroplasties have only recently become feasible and are still far from ideal (Bennett and Gerber 1994). Elbow reconstruction is also possible although loosening has been a major problem (Wadsworth 1993). Arthroplasty procedures of the wrist, fingers, and ankle joints have been devised but are at an experimental stage. Corrective arthrotomies of the metatarsal toe region are common and successful (Helal and Greiss 1984)

Surgical stabilization of the cervical spine to prevent or relieve compression of the medulla is an important task for highly specialized teams. With improved diagnostic and surgical techniques and results, the indications for this form of therapy can be widened (Zygmunt *et al*. 1988; Milbrink and Wingren 1989).

In order to achieve optimal results the rheumatologists and orthopaedic/hand surgeons must work together, preferably in joint clinics with the help of physiotherapists, occupational therapists, and other allied health professionals. Decisions should result from careful analysis of the problem(s) as seen by the patient and from weighing the possible gains and risks of the procedures. An operation always involves risks and is traumatic and tiresome for the patient. Psychological aspects also confound the issue; sometimes an operation is desired to demonstrate to the family how sick the patient is.

The majority of patients admitted to hospital are subjected to one or more operations with time. Two-thirds of these involve the lower limbs, with the often achieved goal of preserving ambulation. Patients with rheumatoid arthritis are at greater risk for acquiring infections, but less likely to have thromboembolic complications. Disease-suppressing therapy usually can be continued, but methotrexate may be an exception, owing to risk of infection. NSAIDs are given as required in most places, apparently with no important risk of bleeding. They have the added advantage of preventing postoperative calcifying myositis.

Surgical treatment is cost effective, since it reduces societies' costs for home service and may preserve productivity and independence (Goldie 1993).

Team rehabilitation

It should be emphasized that rheumatoid arthritis should never be managed without help of a professional team of allied health experts. Patient education is a neglected principle of adapting the individual to cope with a chronic incurable disease and may actually influence pain control and self-esteem favourably (Lindroth *et al*. 1995). Physical therapy may improve self-efficacy, physical capacity, and pain perception (Brighton *et al*. 1993; Stenström 1994). Proper use of technical aids for household and ambulation, adapted environment at home, at work, and in the car are other examples of important therapeutic measures that will reduce helplessness and improve quality of life for the patient. Thus, as mentioned, in most cases a team approach involving doctor(s), physiotherapist, occupational therapist, social worker, and nurse is best suited for the optimal management of rheumatoid arthritis.

Prognosis

There is a growing interest in developing early predictors of long-term outcome in rheumatoid arthritis, which would allow better patient selection for early intervention. Genetic markers and rheumatoid factors have a well-documented relation to disease susceptibility and development of erosions within a year (Gough *et al*. 1994b). The 'shared epitope' in double dose in particular, including DRB1*04 epitopes, also seems to predict a more destructive disease, but the correlation is far too weak to be of use for early therapeutic decisions (Wollheim *et al*. 1995). An in vitro test of Ig-synthesis induced by Epstein–Barr virus also can distinguish erosive from non-erosive cases (Jokinen *et al*. 1994). Early functional impairment is a crude but reliable indicator of poor prognosis (Rasker and Cosh 1989). Rheumatoid arthritis is still a severe disease in a large proportion of patients, although as mentioned (Heikkilä and Isomäki 1994) the proportion of milder cases may be increasing.

5.4.3 Juvenile rheumatoid arthritis (rheumatoid factor positive polyarthritis)

Barbara M. Ansell

This subset of juvenile chronic arthritis is clinically and genetically indistinguishable from rheumatoid arthritis in adults. The overall incidence is unknown; in a prospective study of 148 patients with juvenile chronic arthritis seen within 3 months of onset, 6 per cent persistently carried IgM rheumatoid factor in the first 3 months and two further patients became seropositive by the 5-year follow-up (Ansell *et al*. 1987). There was a female preponderance of 2:1 and the disease has been seen in patients as young as 3 or 4 years, although more commonly the illness starts in those aged 10 years or more (Ansell 1983). The frequency in this selected referral group may well be an over-estimate as of 1328 patients on the British Paediatric Rheumatology Group register only 2.1 per cent (28) fall into this category. In the British Paediatric Rheumatology Group register the female preponderance was even more marked at 13:1 and the median age of onset was 11.9 years, with the age range 1.9 to 15 years (Symmons *et al*. 1995, personal communication).

As early as 1969 Hanson and his colleagues, in a prospective study of 110 children, recorded the value of the IgM rheumatoid factor as a marker for this variant (Hanson *et al* 1969); patients whose disease started between the ages of 12 and 16 years accounted for more than 80 per cent of those with positive tests for rheumatoid factor; seropositivity also correlated closely with the presence of nodules. Similarly, in a cross-sectional review of 110 patients whose arthritis commenced under 14 years of age, Cassidy and Valkenberg noted a significant correlation between the serological reaction, age of onset, presence of nodules, and bone erosion (Cassidy and Valkenberg 1967).

Mode of presentation

The disease usually presents as a polyarthritis involving the small joints of the hands and feet. A combination of soft tissue swelling of the wrists and carpi with involvement of metacarpophalangeal and proximal interphalangeal and metatarsophalangeal joints was closely associated with the persistent presence of IgM rheumatoid factor (Ansell and Wood 1976). The large joints can also be involved early, particularly knees and ankles, usually in association with small joint involvement. Very occasionally the onset was palindromic (two in 138 patients), while a few had an insidious onset as 'wrist or foot strain' for a few weeks before the polyarthritis became obvious (Ansell 1983). Those with an onset under the age of 10 years tended to have wrists, ankles and hindfeet, and knees affected early with the small joints becoming affected later. Approximately a quarter of our patients ultimately had a family history of seropositive rheumatoid arthritis (parent, grandparent, or sib), which could post-date the child's illness.

Clinical manifestations

Although lassitude, loss of weight, and general malaise were recorded in about half our patients, fever (even low-grade) was rare. Generalized lymphadenopathy was occasionally present, particularly in those with a very acute onset of polyarthritis. Other systemic manifestations were uncommon, although pleural effusion and pericarditis have been seen, and pulmonary fibrosis in a boy and a girl as the presenting feature.

The pattern is one of a progressive arthritis with severe generalized stiffness; shoulders are often badly affected early, while hip involvement can occur at any time from a few months to several years. Neck, elbows, and hindfeet are gradually involved so that by 5 years a deforming arthritis with weight loss is usual.

Dorsal sheath effusions and severe extensor tenosynovitis are not uncommon and can be associated subsequently with rupture of the extensor tendons of the fourth or fifth fingers and the thumb. Flexor tenosynovitis is common and tends to be more nodular than grossly prolific, causing triggering of fingers. As in adults, carpal tunnel syndrome may complicate the picture as can entrapment neuropathy at knee and elbow. Nodules with typical rheumatoid histology have been seen along the forearm in 30 per cent of patients in the first year of disease (Ansell 1983). Cutaneous nodules were not seen until later and vasculitis is very rare early in the course of the disease.

Diagnosis

As low titres of rheumatoid factor can occur in other autoimmune rheumatic disorders (e.g. systemic lupus erythematosus and some types of vasculitis as well as in hypergammaglobulinaemia, as is seen in sarcoidosis), such causes must be excluded. Because transiently positive rheumatoid factor tests can occur in infections (particularly those of viral original but also bacterial infections e.g. subacute bacterial endocarditis), the European League Against Rheumatism (EULAR) criteria suggest that three consecutive positive tests over a 3-month period are required to classify this type of arthritis.

Using standard tests, IgM rheumatoid factor can be present within a few weeks of the first symptoms and in the majority by 3 months; titres tend to rise as the disease becomes established. It is exceptionally rare for the rheumatoid factor test to become positive after more than 1 year of illness (Ansell 1987); once present, unless long-term slow-acting drugs are used early, it tends to remain positive. The importance of positive test results as a hall-mark of a subgroup of children with polyarthritis who generally have a poor outcome has been stressed (Cassidy *et al*. 1989).

Radiological changes tend to be early in all sites and particularly in the hands and feet. Periostitis along the shafts of the metacarpals and metatarsals and at the bases of the proximal phalanges extending on to the epiphyses of the joints have been seen radiologically as early as 6 weeks, although this is more usual between 3 and 6 months (Ansell and Kent 1977) (Fig. 1). Radiological changes tend to progress rapidly with the development of erosions.

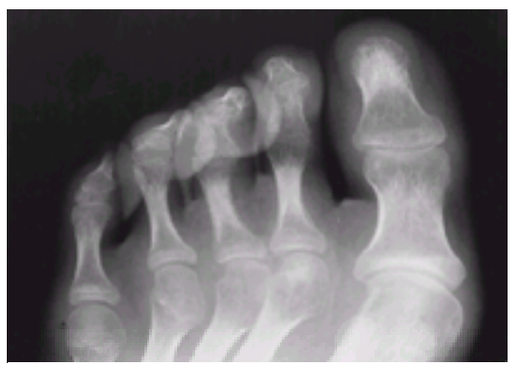

Fig. 1 Periostitis along the proximal phalanx of the second and third toe; note also the severity of the osteoporosis.

Course

In our early studies (Ansell and Wood 1976), the 15-year follow-up showed that a third of the patients had severe limitation of functional capacity (i.e. were unable to function independently) and the majority were still active. Slow-acting drugs, usually gold, had been introduced very late in treatment as previously the problems of this subgroup of seropositive juvenile arthritis had not been adequately recognized. Forty per cent had hip involvement, with destructive changes as early as 1 year; radiologically, protrusio, sometimes severe, had occurred within months from the first hip symptoms (Fig. 2).

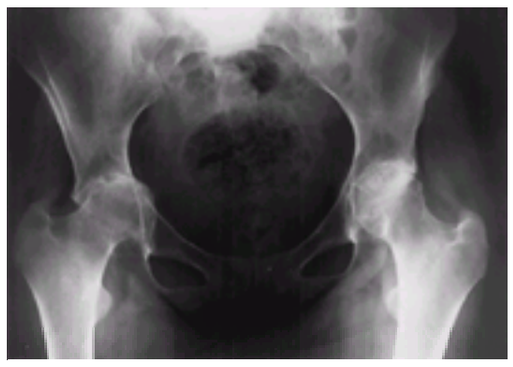

Fig. 2 Both hips were painful and limited in this 14-year-old girl with seropositive disease of 2 years duration. The right shows protrusio with marked narrowing of joint space and erosions; on the left the disease is less advanced.

A review of 138 patients, of whom two-thirds had been followed for at least 10 years, showed that death had occurred from renal failure due to amyloidosis in two, quadriplegia associated with both atlantoaxial and lower cervical subluxation in another, cardiac failure in a further patient, while infections of varying types caused death in the other three; non-fatal complications included vasculitis and peripheral neuropathy. No specific drug was noted to have been effective in suppressing disease activity, but the frequency of side-effects was a significant factor in preventing the maintenance of treatment schedules for long periods. In the minority where the disease was controlled, healing of erosions could occur (Fig. 3(a) and Fig. 3(b)). However, the overall review of 81 serial sets of radiographs (Williams and Ansell 1985), of whom two-thirds had received gold, penicillamine, or chloroquine and 13 per cent had received cytotoxic drugs, while confirming the association between wrist, carpus, and metacarpophalangeal joints in the hands and metatarsophalangeal joints in the feet, showed that lesions in these had progressed radiologically by 5 years (Fig. 4(a),Fig. 4(b) and Fig. 4(c)). In addition, a third of the patients showed erosive changes in large joints such as the hips, knees, or shoulders. Between 5 and 10 years from onset of disease, progression radiologically was evident in most patients with additional joints becoming involved in a further third. By this time, 17 per cent had had bilateral total hip replacement and 7 per cent knee replacement; atlantoaxial subluxation was common (Fig. 5). After 15 years or more, the radiological changes tended to stabilize, but various mechanical difficulties, often secondary to poor growth and degenerative change, as well as the primary destructive arthritis, were evident (Fig. 4(c)). The main differences between adults and children appeared to be a tendency to fusion of the carpal bones and distal interphalangeal joint erosion. Another problem in juveniles is alteration in growth in the presence of persistent disease activity.

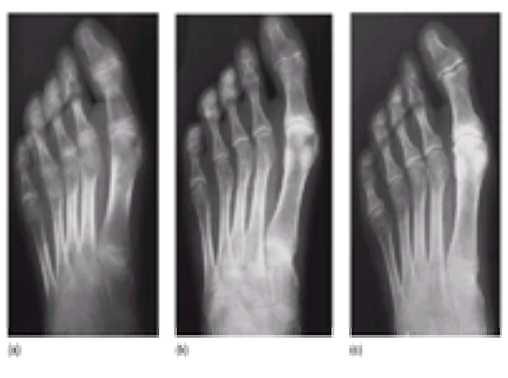

Fig. 3 (a) Radiograph of feet at presentation with disease duration of 3.5 months; note the erosions in the fifth metatarsals and periostitis along the fourth, third, and second proximal phalanges as well as irregularity in the shape of the first metatarsal head. Penicillamine therapy was commenced at this time and continued. (b) Eighteen months from the first picture there has been healing of the erosions in the fifth metatarsophalangeal joint and improvement in overall porosity with no new erosive changes. (c) This improvement has been maintained during the further 3-year treatment period.

Fig. 4 (a) At presentation this girl (aged 13.5 years) had crowding of the carpus and changes between the distal row of the carpus; the bases of the metacarpi and particularly the head of the second metacarpals on both sides are thinning. (b) Despite a prolonged course of gold, 5 years from onset there has been gross destructive arthritis affecting the carpus which is fusing, all metacarpophalangeal joints, and proximal and distal interphalangeal joints. (c) Twenty years from onset destruction has occurred, particularly in the metacarpophalangeal joints and at the wrists.

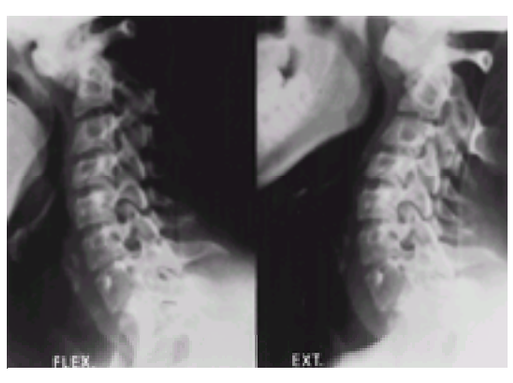

Fig. 5 Atlantoaxial subluxation causing compression on the cord but with relatively little change elsewhere in the cervical spine.

In addition to joint destruction, lone aortic regurgitation has been a serious complication. Reporting four cases in 1981, Leak *et al*. commented on the fact that this pursued a particularly aggressive course with sudden deterioration occurring in two patients, one of whom had an urgent aortic valve replacement, at which time pericarditis was also present, and the other died while awaiting assessment (Leak *et al*. 1981). The patient reported in full developed an aortic diastolic murmur, followed by bouts of chest pain associated with dyspnoea and a rapid deterioration in her clinical state. Histologically, the architecture of the aortic valve had been completely destroyed by multiple necrobiotic foci with the typical features of rheumatoid granulomata. There was active granulomatous tissue growing into the valve. These patients were young at onset (8–11 years) and aortic incompetence was seen to occur as early as 2 years from onset, but it has also been recorded as late as 15 years from onset. All had high titres of IgM rheumatoid factor and a severe destructive arthropathy requiring major joint replacement; three had subcutaneous nodules and one vasculitis. Further cases have been seen since this report; the valvular dysfunction can last only a short time before sudden deterioration (Fig. 6). In view of this, regular cardiac appraisal should be made part of the routine assessment in seropositive juvenile arthritis. Repeated non-invasive assessment can be made by echocardiography; measurement of the left ventricular diastolic dimension and fractional shortening are useful in predicting deterioration in function (O'Rourke *et al*. 1980). Development of the left ventricular dysfunction is an indication for urgent referral for consideration of surgery because the rapid deterioration with the development of angina in a young patient is associated with an increased risk of death (Reicheck *et al*. 1973). In addition to pericarditis and valvular lesions, a single case of endomyocardial fibrosis has been recorded in seropositive juvenile rheumatoid arthritis (Hughes *et al*. 1988). Whether this is indeed a complication of seropositive juvenile rheumatoid arthritis is not known; the patient had been on treatment with penicillamine at the time of her symptoms.

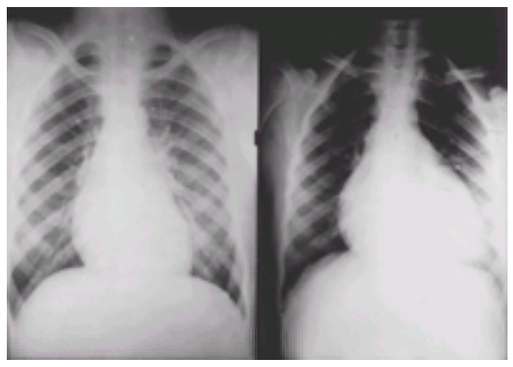

Fig. 6 Rapidly increasing cardiac silhouette over 4 months in a girl who had been noted to have a diastolic murmur 7 months before.

Pulmonary manifestations have been relatively uncommon in our long-term follow-up, although pleurisy with or without effusion has been seen as well as diffuse interstitial disease. Pulmonary arteritis has also been recorded (Gordon and Snyder 1964). The earliest account of rheumatoid lung disease in a child was that of Brinkman and Shaikoff who reported on a 13-year-old who had had progressive dyspnoea and cyanosis over 3 years (Brinkman and Shaikoff 1959). Nodules in the lungs appear excessively rarely, but pulmonary fibrosis is seen very occasionally (Fig. 7). Bronchiolitis obliterans has been reported in a 12-year-old girl with rheumatoid factor positive juvenile rheumatoid arthritis who was restarted on intramuscular gold about a month after mild side-effects had led to temporary withdrawal; this proved fatal despite intensive therapy (Pegg *et al*. 1994).

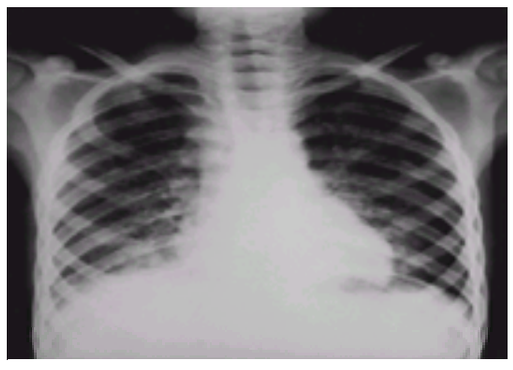

Fig. 7 This 15-year-old patient presented with increasing dyspnoea. Although seropositive, relatively mild juvenile rheumatoid arthritis of some 5-years duration was present affecting the hands and feet only. The duration of the chest symptoms could not be adequately assessed, but he had finger clubbing at presentation.

Genetic aspects

In a study of 52 Caucasian patients, all of whom had developed widespread erosions by 5 years from onset, 62 per cent were HLA DR4 (Clemens *et al*. 1983). Rheumatoid nodules were more frequent in the DR4 patients. There was no difference with respect to mean age of onset, family history of rheumatoid arthritis, or frequency of toxic reactions to long-acting drugs; the toxic reactions had occurred in 23 per cent and were more common in the DR4-negative patients. Although two patients in our group who were DR4 homozygous had required multiple arthroplasties (one had required replacement of the aortic valve within 5 years), the disease was of similar severity in both the DR4 heterozygotes and DR4-negative patients.

Nepom *et al*. found an association with HLA DW4 and HLA DW14 in seropositive polyarthritis juvenile rheumatoid arthritis subjects from the Pacific north-west United States (Nepom *et al*. 1984). Fraser *et al*. noted that late onset polyarticular juvenile rheumatoid arthritis, irrespective of seropositivity, was associated with one of the three common HLA DR4 extended haplotypes, notably HLA B44 SC30 DR4 (Fraser *et al*. 1990). The overall results are difficult to interpret, but there may be ethnic differences between the Caucasian subjects in different areas which would strongly influence the frequencies of the alleles and haplotypes under study.

Box 1 Summary

Seropositive juvenile rheumatoid arthritis is one of the rarer forms of arthritis of childhood. Affecting as it does older children and adolescents, it is important that as soon as the diagnosis is made, they come under a specialist clinic which has information and knowledge and at the same time is able to assess particular drug therapies. To date there has been no good prospective study and from our own personal experience it would seem that patients do better if they are introduced to a slow acting drug within 6 months of the disease, but only through long-term prospective studies, which should be co-ordinated through juvenile rheumatism centres, will this ever be established. In addition to the usual measures of joint protection, maintenance of function, and the use of non-steroidals, the question of local corticosteroid injections into a particularly troublesome joint will also need consideration. As genetically as well as clinically, they are similar to adult rheumatoid arthritis, it would seem that gold or methotrexate are probably the slow acting drugs of choice. There has been no work to date on cyclosporin. Should the onset of disease be under 10 years, it would appear that a proportion of these children will respond to hydrochloroquine; however, if after 6 months the joint count is increasing or the ESR is still very high, it is probably wise to switch to methotrexate or gold.

Management

Principles of management are the same as those for adults, namely maintenance of joint position and function and relief of pain by non-steroidal anti-inflammatory drugs. To date, those studied and accepted for children include ibuprofen, tolmetin, naprosyn, piroxicam, and diclofenac. These last three have been particularly valuable in appropriate dosage.

There have been no satisfactory prospective studies on the use of long-acting drugs, both because of the relative rarity of this subgroup of rheumatoid arthritis, and the problem of obtaining an overall picture. Children may attend paediatric clinics while adolescents become diverted to adult clinics; later the majority will attend adult clinics.

It is my impression that the introduction of a long acting drug within 6 months of the first symptoms will cause considerable improvement in some 70 per cent but nearly 30 per cent do not seem to respond satisfactorily to any present medication.

Chloroquine initially, and more recently hydroxychloroquine, in appropriate dosage has been used in some young patients as the sole long-acting drug. In a number, considerable improvement was seen in the first year of therapy (Hasson *et al*. 1993). Such patients were maintained on therapy for a further 2 years. If there was no benefit, another slow-acting drug was introduced.

At present, although there have been no studies of methotrexate in this subgroup, it would seem to be the slow-acting drug most frequently used. Its efficacy appears to be similar to that in adult rheumatoid arthritis and it is well tolerated. However, recurrence of activity has been seen occurring a year or two after control of the disease with no reduction in dosage. The effect on erosions is also not known, in that although no actual healing of erosions has as yet been demonstrated, certainly in some patients after 1 year no further erosions had developed. More work is required on this aspect.

A comparative study of gold and penicillamine early in the onset of disease was undertaken in 1980/81; this involved 24 patients (Ansell *et al*. 1981). At 1 year both gold and penicillamine were found to be effective; gold came into play more quickly. Three patients, two on gold and one on penicillamine, had stopped therapy by 1 year because of side-effects, but of those who were able to continue all had had a reduction in total active joint count and some fall in erythrocyte sedimentation rate. One in each group treated early in the disease became negative for IgM rheumatoid factor and both of these patients were in remission 3 years from commencement of therapy, with healing of erosions. However, even in this state, as in adults, relapses can occur on maintenance therapy. Overall, toxicity with gold and penicillamine is similar to that in adults but in an open study penicillamine appeared to have had the additional complication of myasthenia gravis, which occurred on several occasions, while one of our patients had myositis.

The role of sulphasalazine has not been adequately studied. Combination therapy in the form of gold and an antimalarial has been effective in a small group of patients; all of these had previously failed to respond adequately to gold or an antimalarial alone. In this group of patients with a relatively poor prognosis as regards persistence of disease activity and increasing erosions, multicentre studies are urgently needed.

For some patients, usually when they have become anaemic, have other complications such as weight loss and very severe arthritis, and at times poor growth, corticosteroids may be employed and whenever possible this should be on an alternate-day regimen. In general, cytotoxic therapy has been reserved for those patients whose disease is complicated by amyloidosis, but it has been used with apparent benefit for patients after aortic valve surgery who still had extremely active disease and two who had lung fibrosis and a further two with vasculitis.

In those few patients followed into adult life who have had children, a postpregnancy relapse of their disease has been seen in all but one, even though their disease was in a reasonable state at the commencement of pregnancy.

At the former Medical Research Coucil Rheumatism Unit at Taplow, some 10 per cent of all patients admitted underwent an orthopaedic surgical procedure. Approximately half of these were in patients suffering from seropositive juvenile rheumatoid arthritis, even though such patients accounted for only just over 10 per cent of admissions during that same period. Total replacement hip arthroplasty was one of the more common operations together with stabilization of the thumb and repair of extensor tendon ruptures; other surgery included fusion of the cervical spine and also of the hindfeet. Revision hip surgery has been required in many as the overall loosening rate has been 25 per cent with an average duration from initial surgery of 9.5 years (Witt *et al*. 1991). There has been a steady increase in the number of total replacement knee arthroplasties undertaken; long-term follow-up has not yet been reported. More recently, shoulder and elbow arthroplasty are under consideration in some special centres.

5.5.1 Spondylarthropathy, undifferentiated spondylarthritis, and overlap

Andrei Calin

Historical review

As discussed by Calin, in 1974 Moll and colleagues introduced the term 'spondarthritis'(Moll *et al* 1974; Calin 1984). The concept was further developed in 1976 by Wright and Moll in their text entitled *Seronegative polyarthritis* (Wright and Moll 1976). As pointed out by Wright in a chapter entitled 'Relationships between ankylosing spondylitis and other spondarthritides' in Moll's text on ankylosing spondylitis (Wright 1980), we misquoted their term as 'spondylarthritis' in our 1978 monograph on the subject (Calin and Fries 1978). Since then, common usage has resulted in the widespread acceptance of the terms 'spondylarthritis', 'spondylarthropathy', and 'spondyloarthropathy'. We still favour (Calin 1997) the perhaps best known and most commonly applied term 'spondylarthritis', with respect and apologies to Moll, Wright, Khan, and other colleagues who may still prefer one of the other terms (Moll 1980; Wright 1980; Khan 1990). Regardless of preference, all agree that the spondylarthropathies include an exciting and intriguing group of disorders that ranges from asymptomatic sacroiliitis to symptomatic sacroiliitis, widespread multisystem ankylosing spondylitis, enteropathic arthropathies, certain subsets of juvenile onset arthritis, the reactive arthritides, and other entities. These are summarized in Table 1 and Fig. 1. The latter shows how the conditions may overlap with, or develop into, ankylosing spondylitis.

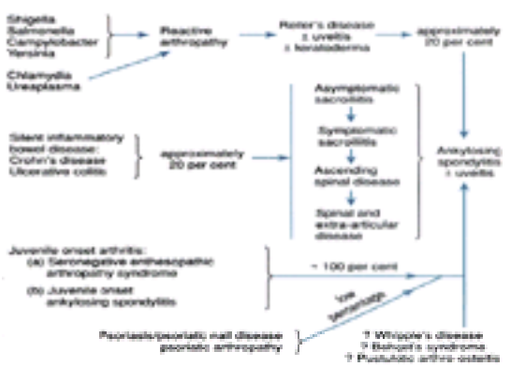

Fig. 1 The inter-related conditions making up the arthropathy group (well differentiated or undifferentiated); * = varying percentage.

Psoriatic arthropathy
Reiter's syndrome/reactive arthropathy (campylobacter, yersinia, shigella, salmonella)
Enteropathic spondylitis (Crohn's disease and ulcerative colitis)
Uveitis
Ankylosing spondylitis Juvenile ankylosing spondylitis Seronegative enthesopathic arthropathy syndrome
Pustulotic arthro-osteitis (considered by the Japanese to be part of spondylarthropathy spectrum (rare in USA and Europe))
Behçet's disease Whipple's disease (doubt exists as to whether these should be considered as part of the spectrum)
Undifferentiated spondylitis (i.e. subset of patients who have spondylarthropathic features but who fail to meet criteria for ankylosing spondylitis, Reiter's syndrome, or other condition, e.g. dactylitis, uveitis plus unilateral sacroiliitis)

Table 1 Individual conditions that overlap to form the spondylarthritides

Introduction

The seronegative spondylarthritides are characterized by involvement of the sacroiliac joints, by peripheral inflammatory arthropathy, insertional tendinitis (enthesopathy), and by the absence of rheumatoid factor (Calin 1989).

There are several other important features:

1. Pathological changes are concentrated at the site of insertion of ligaments or tendons into bone rather than the synovium. Further pathological changes may also develop in the eye, the aortic valve, lung parenchyma, and skin.
2. There is clinical evidence of overlap between the various spondylarthritides. Thus, a patient with psoriatic arthropathy may develop uveitis or sacroiliitis and a patient with inflammatory bowel disease may develop ankylosing spondylitis or mouth ulcers.
3. There is a tendency towards familial aggregation, with evidence that these disorders 'breed true' within families (Calin *et al*. 1984).
4. There is an association with HLA-B27, ranging from about 50 per cent (psoriatic and enteropathic spondylitis) to over 95 per cent (primary ankylosing spondylitis). The specific frequency depends on ethnic group and disease type (Table 2).

	HLA-B27 (%)
Healthy whites	6–14
(e.g. British)	8
(e.g. Northern Scandinavian)	14
Healthy blacks	~ 1–4
(e.g. African black)	~ 1
(e.g. USA black)	4
Indian Asians	2–6
Japanese	1–2
Chinese	5–10
Pakistanis	6–8
Haida Indians	50
Whites:	
Primary ankylosing spondylitis	95
Reactive arthropathy/Reiter's syndrome	80
Enteropathic spondylarthropathy	50
Uveitis	40–50
Psoriatic spondylitis	50–60
Blacks:	
Primary ankylosing spondylitis	50
Reactive arthropathy	50
Indonesian spondylarthropathy patients	8
Healthy Micronesians	9
Healthy Alaskan Eskimo	25–40

Table 2 Distribution of HLA-B27 among different healthy and diseased groups

Diagnostic criteria and classification

Classification or diagnostic criteria for several of the disorders belonging to the spondylarthropathy group already exist, for example the Rome (Kellgren *et al*. 1963), the New York (Bennet and Burch 1968), the Van der Linden *et al*. (Van der Linden *et al*. 1984), and other criteria for ankylosing spondylitis. Our group has long favoured the simple approach (i.e. that of symptomatic sacroiliitis) (Calin 1989a). Likewise, criteria exist for Reiter's syndrome (Willkens *et al*. 1981) and for psoriatic arthropathy (Vasey and Espinoza 1984).

There is a consensus that these criteria are too restricted, as there is a need to emphasize the existence of a much wider disease spectrum. For example radiographically detected sacroiliitis in the absence of symptoms would not be included in the existing classification. Moreover, patients with asymmetric sacroiliitis in addition to, for example, a dactylitis or uveitis, would be excluded from classification and yet clearly are part of the spondylarthropathy spectrum. Furthermore, patients with such limited or atypical forms of disease would be excluded from the typical clinical or epidemiological study. For this reason the European Spondylarthropathy Study Group (ESSG) has proposed criteria for the entire spondylarthropathy group of patients, which would encompass those with clearly defined entities such as Reiter's syndrome or ankylosing spondylitis on the one hand and those with an undifferentiated spondylarthropathy on the other (Dougados *et al*. 1991). In essence, patients with inflammatory spinal pain or asymmetric synovitis predominantly of the lower limb, together with at least one of the following: positive family history, psoriasis, inflammatory bowel disease, enthesopathic lesions, or asymmetric sacroiliitis, have 'undifferentiated spondylarthropathy', with an acceptable sensitivity and specificity. The proposed classification criteria known as the European Seronegative Study Group (ESSG) criteria for spondylarthropathy, will help broaden our acceptance and understanding of the entire spondylarthropathic disorders (Table 3(a)). Parallel to the ESSG criteria, Amor has developed an excellent point-scale that has good sensitivity and specificity in the assessment of patients with spondylarthritis (Table 3(b)). The two sets are compared in Table 3(c) (Amor *et al*. 1991). Reactive arthritis and enteropathic arthropathy are readily defined with Amor's criteria.

Table 3 Diagnostic criteria and classification (a) European Spondylarthropathy Study Group (ESSG) criteria (b) Criteria for diagnosing spondylarthropathies (Amor *et al*. 1991) (c) Comparison of the 12 items criteria (Amor *et al*. 1991) and ESSG criteria

Parallel to the awareness that patients may have a limited or atypical form of spondylarthropathy, there is an appreciation that first degree relatives of HLA-B27-positive probands with classical disease frequently have an inflammatory process that appears to be related in terms of pathology or clinical type to the probands disease and yet would not satisfy any of the above criteria. For this reason several of us have used the term 'undifferentiated spondylarthropathy' (Khan and Van der Linden 1990; Burns and Calin 1984) to describe such individuals. With the proposed new classification (Table 3(a)) all such individuals would be part of the diagnostic group.

Clinical subsets

The interrelated group of conditions constituting the spondylarthropathies have a variety of signs and symptoms (Fig. 2, Table 4). Edmunds *et al*. compared primary ankylosing spondylitis and psoriatic and enteropathic disease in a large controlled study (Edmunds *et al*. 1991). They are categorized according to the specific articular or extra-articular pattern. Depending on the associated clinical features (i.e. urethritis, eye disease, skin involvement) and the way the disease progresses (i.e. remission, relapse) a specific diagnostic label is given. However, as discussed above, clearly defined criteria are frequently absent and one often meets patients who have a spondylarthropathy but in whom the symptoms and signs are such that one is left with an undifferentiated picture. Family and epidemiological studies confirm this clinical finding. For example a patient may appear with unilateral sacroiliitis and little else, or chest wall symptoms due to intercostal muscle insertional tendinitis, and, for example, uveitis. Clearly, the specific phenotypic expression is the end product of a variety of interrelating genetic and environmental factors. Finally, the link between the skin and arthropathy should be stressed (Rosner *et al*. 1993).

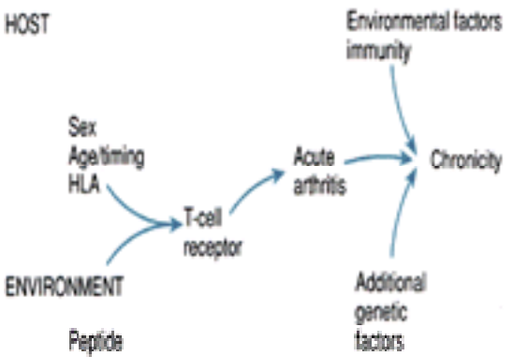

Fig. 2 The relationship between host, environmental, and other factors in determination of phenotypic expression.

	Ankylosing spondylitis	Reiter's syndrome	Psoriatic arthropathy	Enteropathic spondylitis	Juvenile arthropathy (juvenile ankylosing spondylitis subset)	Reactive arthropathy	Undifferentiated spondylo arthropathy
Sex	Male > female	Male=female	Female > male	Female=male	Male > female	Male=female	Male=female
Age of onset (years)	< 20	Any age	Any age	Any age	< 16	Any age	Any age
Uveitis	—	++	–	+	+	+	±
Conjunctivitis	–	+	–	–	–	+	+
Peripheral joints	Lower > upper	Lower usually	Upper > lower	Lower > upper	Lower > upper	Lower > upper	Lower > upper	Again lower
Sacroiliitis	Always	Often	Often	Often	Often	Often	±
HLA-B27(%)	90	80	20 (30 with sacroiliitis)	50	60	80	+
Enthesopathy	+	+	–	+	+	+	+
Aortic regurgitation	+	+	T_6	?	?	+	±
Familial aggregation	+	+	+	+	+	+	+
Risk for HLA-B27 positive individual (%)	1–20	20	?	?	?	20	?
Onset	Gradual	Sudden	Variable	Gradual	Variable	Sudden	Variable
Urethritis	–	+	–	–	–	?	?
Skin involvement	–	+	+/–	+	+	+	?
Mucous membrane involvement	–	+	–	+	–	–	±
Spinal involvement (spinal)	+	+	+	+	+	–	+
Self-limiting	–	?	?	–	?	?	?
Remission / relapses	–	?	?	–	?	?	?

Table 4 Comparison of seronegative spondylarthropathies

Pathogenesis

Even in the reactive arthropathies where the infective trigger is recognized (e.g. yersinia, shigella, salmonella, campylobacter, chlamydia) and the genetic background (HLA-B27) clearly defined, the precise pathogenesis is not well understood (Schur 1994; Inman and Scofield 1994; De Castro 1994; Khan 1996; Lopez-Larrea *et al*. 1996; Scofield 1996). The various steps may include:

1. low-grade inflammatory change in the bowel;
2. the absorption of micro-organisms or parts thereof;
3. endocytosis of the inciting fragments by antigen-presenting cells;
4. degrading of the material followed by linking of the putative antigenic peptide with the HLA molecule;
5. the expression on the cell surface of the combined HLA–peptide complex as a binary product;
6. finally, this HLA–antigenic peptide composite interacts with the T-cell receptor determinant, the three forming a tertiary product.

An acute arthropathy results and, perhaps, following further unknown environmental factors and poorly defined genetic characteristics (Fig. 2 and Fig. 3), the chronic disease state may develop (McClean *et al*. 1993; Scofield *et al*. 1993; Stieglitz and Lipsky 1993; Khan 1993; Rojo *et al*. 1993; Whelan and Archer 1993; De Vries *et al*. 1992; Hermann *et al*. 1993; Taurog *et al*. 1993a; Breban *et al*. 1993a; Skurnik *et al*. 1993; Madden *et al*. 1992). Why the sacroiliac joints are preferentially involved remains unknown (Braun and Sieper 1996).

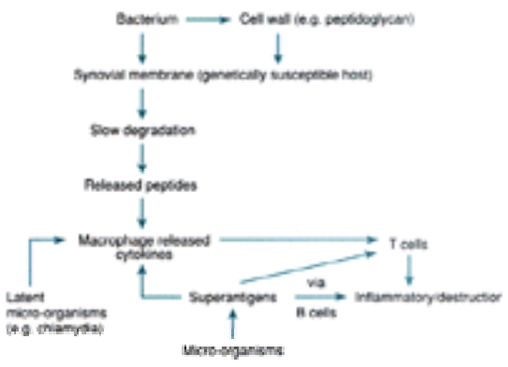

Fig. 3 The putative pathway between the infective trigger and disease pathogenesis.

HLA-B27

The HLA-B27 molecule is a two-chain structure that consists of a polymorphic glycoprotein, termed the heavy or a chain. The a chain is encoded by the HLA complex and is noncovalently linked to a non-HLA-encoded, non-polymorphic protein, b $_2$-microglobulin. The entire molecule is anchored to the cell membrane by the heavy chain. The extracellular portion of the heavy chain is divided into three domains, termed a $_1$, a_2, and a_3, each of which contains approximately 90 amino acids. The a_1 and a_2 domains are distal to the cell membrane and it is these that demonstrate the greatest HLA polymorphism. The a $_1$ and a_2 domains each consist of four b strands and an a helix. The eight b strands of these two domains form a b-pleated sheet or platform, which in turn supports the two a helices. These a helices create a groove which serves as the antigen-binding site for the putative peptide fragment which has been processed from the larger arthritogenic antigen. The two a helices with the bound antigen fragment comprise a ligand which is recognized by the T-cell receptor on a class 1-restricted, CD8-positive T cell.

There are several hypotheses explaining the HLA-B27 association with spondylarthropathy. In contrast to the situation with Reiter's disease, where clearly defined organisms are known to be operative (e.g. chlamydia, shigella, salmonella, campylobacter), the trigger for ankylosing spondylitis remains unclear and could either be one of the above organisms or viruses, or indeed other environmental phenomena (Ebringer 1991).

The first hypothesis suggests that a particular B27 molecule can act as a receptor for the aetiological agent. Support for such an hypothesis comes from observations that other cell surface molecules can act as receptors for viruses, such as CD4 for the human immunodeficiency virus. Individuals with B27 who contact the putative trigger will develop disease.

The second hypothesis suggests that the antigen-binding groove of only certain HLA molecules can accept the processed antigenic fragment that is ultimately responsible for causing disease. Thus, when the ankylosing spondylitis-causing organism enters the cell the antigens are degraded to peptides and only certain HLA molecules accept the antigen. The HLA molecule–antigenic peptide is then presented to the T cell and disease takes place.

The third hypothesis postulates that the T-cell antigen receptor which recognizes the HLA molecule-peptide complex is responsible for disease but because the T-cell recognition is restricted by an HLA molecule there is an association between the disease and B27.

Finally, there is an hypothesis related to the 'molecular mimicry' phenomenon. Here the peptide derived from the organism that causes disease is immunologically identical to HLA-B27. Therefore, the peptide is not recognized as foreign—no immune response is mounted and the disease process develops. Alternatively, the peptide is recognized as foreign and a vigorous immune response is mounted against the organism but the response cross reacts with self tissue causing disease. (For reviews see Khan 1993; Khan 1996; Schur 1994; Inman and Scofield 1994; De Castro 1994).

We still do not know which of these many possibilities—if any—is correct. Interestingly, certain strains of shigella which contain a plasmid (an extrachromosomal piece of DNA) are known to be arthritogenic, causing Reiter's syndrome. Recent data suggest that B27-positive individuals share structural and immunological homology with a sequence of five amino acids present in the plasmid (Stieglitz and Lipsky 1993).

At least 11 variants of the HLA-B27 molecule exist and until recently it was thought that disease predisposition did not appear to be restricted to a particular allele. However, Hill *et al*. have now described a rapid method of HLA Class 1 typing using the polymerase chain reaction and oligonucleotide hybridization that eliminates requirements for viable lymphocytes and, in addition, allows subtypes to be clearly defined (Hill *et al*. 1991). The authors studied black subjects in the Gambia, West Africa, and showed that the predominant subtype was HLA-B27.03. This is particularly rare or absent in other racial groups and interestingly the subtype is not recognized by cytotoxic T cells—perhaps explaining why spondylarthritis is rare in black Africa and when it does occur, may not be associated with HLA-B27.

HLA-B27.03 differs from the other common HLA-B27 subtypes by a single amino acid substitution of histidine for tyrosine at position 59 of the a $_1$ domain. This has been predicted by the 'arthritogenic peptide' model of HLA-B27 disease (Benjamin and Parham 1990). This model evokes a central role for cytotoxic T lymphocytes, which react with an HLA-B27-specific peptide carried by a foreign pathogen. It is proposed that HLA-B27-restricted lymphocytes cause disease when they recognize a similar or identical peptide normally expressed in joint tissue. This is in contrast to the 'altered self' and 'molecular mimicry' models where either the cysteine residue at position 67 or neighbouring residues are thought to be of paramount importance. (HLA-B27.03 shares this cysteine residue at position 67 with the other HLA-B27 subtypes.) Using monoclonal anti-HLA-B27 antibodies, several bacterial components have been recognized. The relevance of this cross-reaction remains unclear. Through a computerized search, a klebsiella protein has been identified that carries a stretch of six amino acids identical to residue 72 to 77 of two of the HLA-B27 variants. Moreover, a synthetic peptide carrying the six amino acids of the HLA-B27 protein is reactive with serum antibodies in some patients with disease. Another amino acid residue of interest is that of position 45, which has provided particular interest relating to the '45 pocket' hypothesis (Benjamin and Parham 1990). The effect of this pocket in peptide presentation is not known but it could have some functional role. The distribution of different HLA-B27 subtypes is given in Table 5.

Population	HLA-B27 subtype
Caucasoids	HLA-B*2704 HLA-B*2702
Native North Americans	HLA-B*2705
Siberian Chukchis	HLA-B*2704
Chinese	HLA-B*2705
Asian Indians	HLA-B*2705 HLA-B*2704 HLA-B*2702
West Africans	HLA-B*2703 HLA-B*2705

Table 5 Distribution of B27 subtypes in various population

The immune response to various triggers has been studied at length. For example during yersinia reactive arthropathy, high and persistent IgA anti-yersinia antibodies have been detected (Granfors and Toivanen 1986). This prolonged antibody response to yersinia, as well as the higher chlamydia antibody titres in synovial fluid as compared to that in serum in chlamydial reactive arthropathy (Hughes and Keat 1992), could indicate an antigenic persistence and impaired antigen elimination from the joint. In addition, proliferative responses specific to the organism which causes the infection preceding the arthropathy have been described (Gaston *et al*. 1989; Hermann *et al*. 1989). A response to a 65-kDa mycobacterial heat shock protein has been detected in patients with reactive arthropathy but its specificity is only minimal. The persistence of intrasynovial antigenic material is now recognized (Nikkari *et al*. 1992; Toivanen and Toivanen 1996).

Initial interest was created by Geczy *et al*. and Ebringer *et al*. with regard to klebsiella and ankylosing spondylitis (Geczy *et al*. 1985; Ebringer *et al*. 1985). The former group reported a specific modification of HLA-B27-positive lymphocytes in patients with ankylosing spondylitis—a phenomenon that has received little support elsewhere. The Ebringer data supported molecular mimicry with cross-reactivity between klebsiella and HLA-B27, a finding supported by other studies with different arthritogenic triggers (van Bohemen *et al*. 1984; Raybourne *et al*. 1988). Meanwhile, Schwimmbeck *et al*. described homology between the 72 to 77 amino acid sequence from HLA-B27.05 subtype and residues 188 to 193 of *Klebsiella pneumoniae* nitrogenase (Schwimmbeck *et al*. 1987). Likewise, Toivanen *et al*. have described a similar sequence between HLA-B27 and Yap 1, an outer membrane protein of yersinia (Toivanen *et al*. 1990). Relevance of the mimicry phenomenon to pathogenesis is complicated by the publication of several studies that fail to agree. Regardless of the putative klebsiella link, there is still no certainty that this organism is arthritogenic in ankylosing spondylitis. It may well be that numerous bacteria (and indeed viruses) can induce disease in genetically susceptible individuals (for review see Kingsley and Sieper 1993; Schoen 1996).

Transgenic rats have now been created that express HLA-B27 and this model will help clarify some of the above issues (Hammer *et al*. 1990). The HLA-B27-carrying rats spontaneously develop a disease characterized by involvement of the gastrointestinal tract, peripheral and axial joints, male genital tract, skin, nails, and heart. In Table 6 this disease is compared with the human spondylarthritides and adjuvant-induced arthritis in the rat (for review see Taurog 1997).

	Adjuvant disease	Transgenic rat	Ankylosing spondylitis	Reiter's syndrome/ reactive arthritis
Peripheral joints	+	+ (M>F)	+	+
Axial joints	+	+ (M>F)	++	±
Gastrointestinal tract	?	++ (M=F)	±	±
Male genital tract	+	+	−	±
Skin lesions	+	+	−	±
Nails	?	+	−	±
Heart	?	+	±	±
Eye lesions	+	− (?)	+	±
Enthesitis	+	+	+	+
Synovitis	+	+	+	+

Table 6 Comparison of adjuvant rat model, transgenic (HLA-B27+) rat, ankylosing spondylyitis, and reactive arthritis (Reiter's syndrome)

Disease susceptibility relates to the transgene product copy number in lymphoid cells, with the high expressing lines prone to disease. Differences in expression of the HLA-B27 gene product occur by disease onset, but differences in thymic and splenic messenger RNA levels are found *in utero*. HLA-B27 transgenic rats have been studied in cell transfer experiments (Breban *et al*. 1993b). The data reveal that disease can be transferred by engraftment of adult bone marrow cells from the diseased animals into irradiated non-transgenic rats. Bone marrow precursor cells are responsible for passage of disease. Moreover, the spondylarthropathy-like illness of rats has been found to be T-cell dependent (Breban *et al*. 1993b). These data argue for HLA-B27, itself, being involved in the pathogenesis of disease rather than there being a gene in linkage disequilibrium with HLA-B27 that is operative. When HLA-B27 positive b $_2$-microglobulin transgenic disease rats are raised in a germ-free environment, disease occurs but in a manner distinct from the regular situation. Specifically, the animals do not develop gut inflammation or arthropathy but they do develop more nail and skin changes as well as genital inflammation. These results suggest that gut flora are involved in some way in the development of spondylarthropathy (Taurog *et al*. 1993b).

Reactive arthropathy or intra-articular 'infection'?

Reactive arthropathy (Toivanen and Toivanen 1996) is defined as an inflammatory joint disease that relates to an infective organism that is distant in both time and place from the arthropathy. For example chlamydia induced urethritis may be followed 2 weeks later by uveitis, arthropathy, and other stigmata of Reiter's disease. A similar situation can follow dysenteric infection with campylobacter, yersinia, or other organism. However, there have been studies demonstrating chlamydia, yersinia, and most recently salmonella (Granfors *et al*. 1990) antigenic components within the synovial tissues. Whether the finding of intrasynovial micro-organism-related antigen represents an epiphenomenon or whether the material is central to disease pathogenesis remains unclear but at least at the moment it is not considered that viable organisms are found in the joint space (Highton and Poole 1993; Nikkari *et al*. 1992; Hughes and Keat 1992). Moreover, we have described postsalmonella vaccination arthropathy—a rheumatic condition related to the inoculation of dead organisms (Calin *et al*. 1987).

Interestingly, Lyme disease, which is known to be a multisystem disorder related to *Borrelia burgdorferi*, may produce a 'reactive' phenomenon in addition to the direct infective process (Weyand and Goronzy 1989).

Epidemiology and the spondylarthritides (see van der Linden and van der Heijde 1990)

Epidemiological studies tell us that reactive arthropathy is more common in the epidemic situation than where the organism is endemic. Adults are more at risk than are children in contradistinction to the situation with acute rheumatic fever. In postdysenteric arthropathy, patients frequently suffer only minimal gastrointestinal symptoms. As mentioned, postvaccination (salmonella) Reiter's disease can occur. Ankylosing spondylitis is seen in both the developing and developed world, with an higher age of onset in the latter. Other epidemiological studies demonstrate that ankylosing spondylitis occurs predominantly in the HLA-B27-positive Haida and Pima Indians and the HLA-B27-positive relatives of white patients with ankylosing spondylitis, while Reiter's syndrome occurs among the Navaho Indians and Inupiat Eskimo in addition to white family members of HLA-B27-positive probands with Reiter's disease. Presumably HLA-B27 is not sufficient in itself and, as stated above, an additional gene or genes modify the phenotypic expression (i.e. HLA-B27 plus appropriate environmental trigger, plus the ankylosing spondylitis gene results in ankylosing spondylitis while HLA-B27 plus environmental trigger plus the Reiter's gene leads to Reiter's syndrome) (Fig. 4).

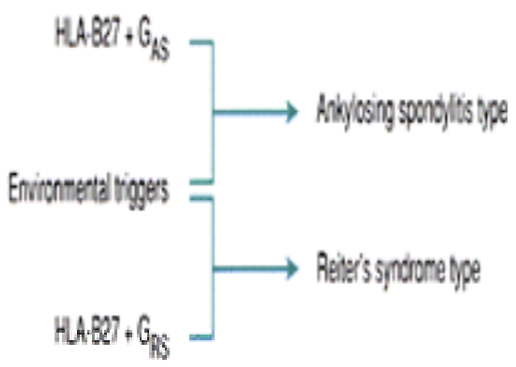

Fig. 4 Epidemiology and the spondylarthritides. G_{AS} = genes determining phenotypic expression of ankylosing spondylitis type. G_{RS} = genes determining phenotypic expression of Reiter's syndrome type.

The relationship between sex, phenotypic expression, mode of inheritance, and age at onset in the spondylarthropathies has recently been studied by Kennedy and colleagues (Kennedy *et al*. 1993b). Epidemiological studies have focused on the presence of spondylarthritis in Alaskan Eskimos (Boyer *et al*. 1994), the native population of Chukotka in Russia (Alexeeva *et al*. 1994), the Indonesian Chinese and native Indonesians (Nasution *et al*. 1993), and in Togo (Mijiyawa 1993). The varied prevalence rate is of great interest.

The risk for the HLA-B27-positive individual depends on the nature of that individual. For example if related to an HLA-B27-positive patient with ankylosing spondylitis, the chance of developing that same disease is approximately 1 in 3. HLA-B27-positive relatives of healthy HLA-B27-positive subjects are at much less risk of developing spondylarthropathy. Interplay between different chromosomes almost certainly occurs. Chromosome 6 is clearly important, with HLA-B27, -B60, and -CW6 all relevant. In addition, recent interest focuses on the tumour necrosis factor and class III genes (complement) on the same sixth chromosome. Other possible genetic factors relate to the T-cell receptor b gene (at a locus on the seventh chromosome) and the T-cell receptor a gene, the a_1-antitrypsin gene, and the IgG heavy-chain gene products related to loci on the fourteenth chromosome. Additional gene loci and products thereof include the IgG light g chain (chromosome 22). Studies using restriction fragment length polymorphisms have failed to confirm the presence of additional genetic material of relevance to disease pathogenesis. For example, no differences have been found between the frequencies of such polymorphisms for tumour necrosis factor between patients and controls (Verjans *et al*. 1991).

Intact antigen is taken up by the cell and partly digested by the so-called large multifunctional protease system, the product from a gene on the short arm of the 6th chromosome. This results in a nonapeptide (i.e. a nine amino acid peptide) reaching the endoplasmic reticulum via the transporter associated with peptide gene product. (The transporter associated with peptide genes are also found in the major histocompatibility complex.) The nonapeptide then becomes associated with the HLA-B27 Class 1 antigen and extrudes on the cell surface as a bimolecular product to face the T-cell receptor gene product. The resulting HLA-B27–antigen–T-cell receptor trimolecular complex releases cytokines and inflammatory mediators. This has been the focus for study (Maksymowych *et al*. 1994).

Reactive arthropathy appears to be mediated by HLA Class 1-restricted, CD8-positive T cells, given that both psoriatic arthropathy and Reiter's disease thrive in the presence of human immunodeficiency virus infection. This is in contrast to the CD4-positive, T-cell-maintained arthropathy of rheumatoid arthritis, which appears to remit in the presence of human immunodeficiency virus infection. Ankylosing spondylitis, itself, appears unaffected by the virus but few data exist.

The changing epidemiology of rheumatic diseases Calin *et al*. 1988; Will *et al*. 1990; Will *et al*. 1992)

The spondylarthropathies should perhaps be included in any discussion of changing epidemiological features. There are many reasons why the pattern (perceived or real) of a disease may change. Increased interest and recognition by the medical profession and greater concern and pressure from patients may lead to more emphasis on a particular disease. For example osteoporosis, until recently ignored by rheumatologists, has become a major focus of interest.

Chronic tophaceous gout, once the scourge of medical clinics, is an example of a rheumatic disorder which has all but disappeared, in part due to changing dietary habits and in part because of hypouricaemic agents. By contrast, a recent rise in prevalence of gout in older females relates to the greater use of diuretics.

Rheumatic fever, at least until recently, had become rare in the more affluent communities. The decline in fatal rheumatic carditis accelerated after 1945, perhaps due to an alteration in the pathogenicity of the streptococcal group A M antigen induced by penicillin. Altered streptococcal antigenicity may also be responsible for the recent recognition of a poststreptococcal arthropathy.

Recent studies also suggest that rheumatoid arthritis may be declining in frequency in the developed world, perhaps due to the advent of the contraceptive pill, but it is becoming more severe in the developing world. For example recent published data have demonstrated that as rural black Africans migrate to an urban environment, rheumatoid arthritis increases in frequency and becomes a more destructive disease. Hypothetical explanations for this phenomenon may include either exposure to new antigens present in an urban environment but uncommon in a less crowded rural setting or conversely a reduction in the antigenic load due to fewer parasitic infestations, which in turn could result in less immunosuppression.

There is increasing evidence accumulating from developing countries to suggest that the pattern of ankylosing spondylitis may be changing. This relates to both the age of onset of the disease and the pattern of joint involvement. Ankylosing spondylitis develops at an earlier age in countries with poor living conditions and as these improve the age of onset increases. We have recently suggested that the age of onset of the disease may also be increasing over time in Britain. The influence of potential left and right censoring biases on the United Kingdom data has been emphasized elsewhere, though the importance of this phenomenon is difficult to quantify. Can the conclusion of an increasing age of onset of ankylosing spondylitis in Britain be substantiated by data from other communities? The putative change may be due to a later age of exposure to the presumed 'infective trigger(s)' or altered pathogenicity of the trigger(s), perhaps due to a modifying factor such as the widespread use of antibiotics.

Amor *et al*. in France noted that the age of onset of ankylosing spondylitis was influenced by the geographic background of their patients (Amor *et al*. 1991). They observed that 25 per cent of patients from North Africa develop disease before the age of 15 years whereas only 10 per cent of patients in France did so. Moreover, 47 second generation North Africans with ankylosing spondylitis born and living in France (but whose parents were born in North Africa) were identified from a survey conducted by the French Society of Rheumatology in 1983. None of these 'Beur', as they are known, developed disease before the age of 15. Other studies have also noted a lower frequency of juvenile onset ankylosing spondylitis (at under age 16) in white Caucasian populations as compared to subjects in the developing world. In spite of the inevitable ascertainment biases, there is now a series of studies consistently demonstrating a greater frequency of patients with a lower age of disease onset from developing countries.

An entirely separate epidemiological route has been taken and the changing pattern of new patient referral to the London Hospital has been studied (Will *et al*. 1992). Of interest, patients with non-specific mechanical back pain have become progressively younger over the last three decades whereas new patients with ankylosing

spondylitis have become progressively older. These data, together with the French data of Amor, add further support for the changing pattern.

Family studies of sibling pairs with ankylosing spondylitis also suggest that the date of onset in each sib is similar while the age at onset is discordant suggesting exposure to the trigger at about the same time. This emphasises the importance of the environmental trigger determining the time of onset of disease in sibling pairs who have a similar genetic predisposition (Calin and Elswood 1989a).

The age of disease onset also influences the need for total hip replacement. Calin and Elswood have shown that 16 per cent of a juvenile cohort (10-15 years), 10 per cent of an early onset (18-20 years), and 1 per cent of a late onset cohort (30-40 years) had total hip replacements performed (Calin and Elswood 1989b). Amor *et al*. also observed that the frequency of total hip replacement in a spondylitic population correlates well with the mean age of disease onset (Amor *et al*. 1991). A study of total hip replacements performed in patients from four French hospitals between 1977 and 1983 was undertaken. Twenty-two of a total of 71 patients (30 per cent) who had total hip replacements were born in North Africa as compared with only 7.9 per cent of non-surgical patients treated in French hospitals during this same period. The explanation for more severe hip joint involvement in a juvenile cohort is unknown. The developing hip joint may be at greater risk of damage. Conversely, a more marked inflammatory response may result in greater joint destruction in juveniles compared with patients who develop the disease at an older age.

It is of interest that a changing pattern in inflammatory bowel disease is now also recognized and in many studies Crohn's disease, which became progressively more common until the mid-1970s, has now begun to be less prevalent. The intriguing interrelationship between the bowel and ankylosing spondylitis is, of course, well known (Mielants *et al*. 1993; Leirisalo-Repo *et al*. 1994; Mielants *et al*. 1995).

In conclusion, chronic rheumatic diseases should not be considered immutable processes. A changing pattern of disease is to be expected given the interaction of genes and the environment. Ankylosing spondylitis, and perhaps the other spondylarthropathies, should now be considered as another example of a rheumatic disorder whose characteristics may be altering as a result of a changing environment. We might expect a diminished need for total hip replacement among patients as a consequence of an increasing age of onset of patients in the West and perhaps in developing countries as the environment changes. Physicians will need to be increasingly aware that patients may present with symptoms of disease in their thirties or later. The epidemiological pattern among the other spondylarthropathies is less well defined.

The bowel and spondylarthritis (Mielants *et al*. 1993; Leirisalo-Repo 1994; Mielants *et al*. 1995)

The relationship between the bowel and arthritis is an intimate one. For example an active arthropathy may follow enteropathic infections such as those related to shigella, salmonella, yersinia, campylobacter, and other organisms. Moreover, patients with reactive arthropathy or Reiter's disease related to chlamydia may also develop enteric symptoms as a manifestation of the disease process.

It is well recognized that patients with inflammatory bowel disease (ulcerative colitis and Crohn's disease) may develop both peripheral and axial arthropathy. In general, the peripheral arthritis appears to be a complication of severe bowel involvement with a close relationship between the two components. By contrast, axial disease (sacroiliitis and ascending spinal disease) should be considered a manifestation of the same genetic background, in as much as there is no obvious link between the timing or disease severity of the two entities.

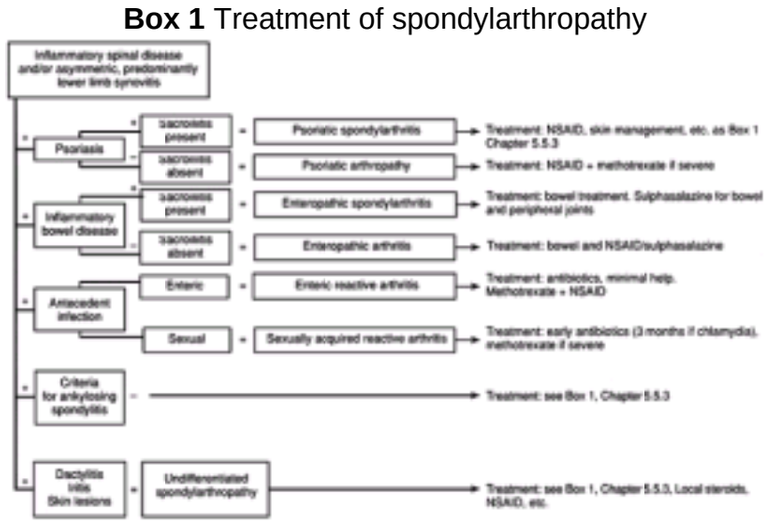
The story has been taken further by Mielants and Veys who performed ileocolonoscopy with biopsies of the gut and described clinical involvement of the terminal ileum as a common finding in the spondylarthropathy patients as a whole (Mielants and Veys 1990; Mielants *et al*. 1993; Mielants *et al*. 1995). Interestingly, the low grade bowel involvement that mimics mild Crohn's disease was often present as a silent phenomenon and appeared unrelated to the HLA-B27 marker. The authors concluded, from multiple studies, that a number of patients with undifferentiated spondylarthropathy could in fact be suffering from a form of subclinical Crohn's disease, of which arthritis is the only clinical manifestation (Leirisalo-Repo *et al*. 1994).

The putative relationship between the bowel, enteric micro-organisms, and arthropathy has been further addressed by way of therapy. Sulphasalazine has been used for years as a treatment for ulcerative colitis, colonic Crohn's disease, and, more recently, for rheumatoid arthropathy. It is metabolized to 5-aminosalicylic acid (active in inflammatory bowel disease) and sulphapyridine (active in rheumatoid disease). Work by Feratz *et al*. suggests efficacy also in ankylosing spondylitis and perhaps the other spondylarthropathies (Feratz *et al*. 1990). Whether this drug works by way of altering the bowel microflora or another mechanism remains unclear.

Titres of serum and secretory IgA (presumed to be of bowel mucosal origin) are raised in patients with ankylosing spondylitis and in patients with yersinia arthropathy, again arguing for a close link between events in the bowel wall and arthritis.

Finally, it is of note that the transgenic rat expressing human HLA-B27 develops a spontaneous arthropathy that mimics spondylarthritis. Strikingly, the main organ involvement is the bowel with marked diarrhoea (Hammer *et al*. 1990).

Box 1 Treatment of spondylarthropathy



Treatment (Box 1)

The management of the various components of spondylarthropathy are discussed in the separate chapters that follow. However, there are some general points that should be stressed. Drug therapy is often disappointing. For example for ankylosing spondylitis, itself, the major thrust of treatment relates to an exercise programme. In contrast to the situation in rheumatoid disease where rest is good for the joints, the patient with ankylosing spondylitis deteriorates with rest and improves with exercise. For those with reactive arthritis, the role of antibiotics has been considered but even the proponents of this approach would agree that outcome is only marginally improved (Leirisalo-Repo 1993; Bardin *et al*. 1992; Lauhio *et al*. 1991; Lauhio *et al*. 1992; Toivanen *et al*. 1993). One difficulty relates to the interpretation of the effect, if any, of an antibiotic. Does this relate to the antimicrobial action or, for example, the anticollagenolytic potential of the drug? There are theoretical reasons why sulphasalazine should be efficacious in the spondylarthropathies given the relationship between bowel inflammation and arthropathy. However, again, improvement is marginal and in large part beneficial only for peripheral joints rather than axial disease (Youssef *et al*. 1992; Kirwan *et al*. 1993; Job-Duslandre *et al*. 1993; Dougados *et al*. 1995).

Natural history and prognosis

Outcome in spondylarthropathy is notoriously difficult to define.

Since our early studies in the 1970s when we showed that Reiter's syndrome is typically not a self-limiting disorder (Calin and Fries 1976), there have been numerous studies showing that for many patients the outcome can be relentlessly progressive. For ankylosing spondylitis, itself, the natural history is varied although most believe that an intensive exercise programme has an excellent effect on disease progression. No longer is it believed that the disease 'burns out' for the majority (Kennedy *et al*. 1993a). Amor and colleagues have attempted to define predictive factors for the long-term outcome of spondylarthropathies and have suggested that those individuals with hip involvement, an erythrocyte sedimentation rate over 30, poor response to non-steroidal anti-inflammatory drugs, a decreased Schober's test, dactylitis, oligoarthropathy, and young age at onset have the worse prognosis (Amor *et al*. 1994). Although this study was not a formal prospective investigation, few

would disagree that these criteria relate to a less good outcome. Recently, we have defined outcome in terms of metrology, disease activity, function, global status, severity, and radiology (Calin 1995a; Calin 1995b; Mackay *et al*. 1996).

Finally, the influence of sex in arthritis and its relationship to cartilage damage cannot be ignored (Da Silva and Willoughby 1994).

Conclusion

During the next years we will understand why and how HLA-B27, other genes, the bowel, sex, and environmental triggers interact, resulting in the development of spondylarthropathy in its many guises. Once we understand this intricate, interrelated network we will know how to manage and perhaps cure our patients.

5.5.2 Spondylarthropathies in childhood

Taunton R. Southwood and Murray H. Passo

Synopsis

Juvenile spondylarthropathy is an umbrella term covering a relatively homogeneous group of diseases in children, usually beginning during the preadolescent or adolescent years. The diagnosis of spondylarthropathy is often more difficult in childhood than during the adult years because symptoms of back pain are uncommon in juvenile spondylarthropathy, particularly at the onset of the illness. Additionally, the radiographic features of spondylitis and sacroiliitis are often absent during childhood. The diagnosis usually rests on a combination of arthritis affecting large joints of the lower limbs and extra-articular inflammatory features including enthesitis, bowel pathology, acute uveitis, and psoriasis. The disease is reported more frequently in boys than girls, and more than 50 per cent of affected children eventually develop ankylosing spondylitis (Burgos-Vargas and Clark 1989; Cabral *et al*. 1992).

Because of the potentially lifelong implications of juvenile spondylarthropathy, every effort should be made to increase patients' and their families' knowledge about the disease and compliance with treatment. However, no published studies confirm that children with spondyarthropathy should be treated any differently from those with other forms of juvenile chronic arthritis. The principles of treatment are summarized as follows, but for further details, reference should be made to the chapters on juvenile chronic arthritis.

Education about the disease for the parents and the patient, presented in an age-appropriate form, is important. Physiotherapy, appropriate limb splinting, and hydrotherapy are aimed at maintaining back posture, flexibility and strength, as well as correcting any reduced range of peripheral joint movement. Orthotics, such as custom-moulded insoles, often alleviate the symptoms of plantar enthesitis. Pharmacotherapy is usually begun with a non-steroidal anti-inflammatory drug. Tolmetin sodium (30 mg/kg per day in three divided doses) and indomethacin (1.5–2.5 mg/kg per day in three divided doses, or as a daily dose if an appropriate slow-release preparation is available) appear to be the most effective. Intra-articular depot corticosteroids (e.g. triamcinolone hexacetonide: 1 mg/kg per joint for large joints, 0.5 mg/kg per joint for smaller joints) are used to control the peripheral arthritis of this condition, and should be considered early in the treatment programme. Sulphasalazine (commencing at a dose of 12.5 mg/kg per day and increasing weekly over a month to 50 mg/kg per day in divided doses) is the slow-acting antirheumatic drug of choice for uncontrolled spondylarthropathy, especially for significant axial involvement, polyarthritis, or severe, persistent oligoarthritis. Regular blood monitoring is required for bone marrow depression and hepatotoxicity, but skin rash and abdominal pain are the most common adverse effects. Methotrexate also may have a role in the long-term control of spondylarthropathy.

It is not uncommon for juvenile spondylarthropathy to run a fluctuating course, and occasionally the doses of non-steroidal anti-inflammatory drugs can be adjusted by the patients or their families to reflect these changes. In those children fortunate enough to experience prolonged remission, pharmacotherapy should be discontinued with caution, as relapse may occur after many symptom-free months or even years.

Aetiology

In considering the aetiology of juvenile spondylarthropathy, both inherited and environmental predisposing factors must be taken into account. Juvenile spondylarthropathy has a strong familial association with ankylosing spondylitis, and other inflammatory diseases such as acute uveitis, psoriasis or inflammatory bowel disease occur with increased frequency in family members (Petty 1990). The genetic predisposition to juvenile spondylarthropathy was first associated with the *HLA-B27* gene over 25 years ago (Ansell *et al*. 1969). Carriage of the gene confers an increased risk of developing ankylosing spondylitis; HLA-B27-positive children of a parent who has both HLA-B27 and ankylosing spondylitis are at least five times more likely to develop the disease than their HLA-B27-negative siblings (Van der Linden *et al*. 1984).

With the advent of molecular techniques, spondylarthropathies have been linked to several of the HLA-B27 subtypes B*2702, 04 and 05 (MacLean 1992), but only B*2705 has been associated with childhood disease. Compelling evidence in support of an aetiological role for HLA-B27 is found in animal models of the disease. Transgenic Lewis rats expressing a high cell-surface density of human B*2705 and b $_2$-microglobulin develop a spondylarthropathy during the first 6 weeks of life, characterized by peripheral arthritis, spinal inflammation, and inflammatory bowel disease. These features appear to be specific for the *HLA-B27* gene, as they are not seen in the rats expressing the *B*2705* gene in low copy number, or in rats transgenic for *HLA-B7* (Taurog *et al*. 1994). Genetic factors other than HLA-B27 are also likely to play an important part in humans. Jarvinen (1995) has demonstrated a disease concordance rate of 50 per cent for HLA-B27-positive monozygotic twins and only 20 per cent for HLA-B27-positive dizygotic twins.

Environmental factors, including enteric bacteria, are linked to the aetiology of juvenile spondylarthropathy by several intriguing strands of evidence. Enteric infections with salmonella, shigella, campylobacter or yersinia during childhood may be accompanied by peripheral arthritis, and occasionally by typical Reiter's syndrome (arthritis, urethritis, and conjunctivitis). Ninety per cent of children with Reiter's syndrome are HLA-B27 positive, and 80 per cent have had a preceding dysentery. Although the majority of these cases remit spontaneously, at least 1 in 5 develops radiographic evidence of sacroiliac arthritis (Cuttica *et al*. 1992) and there are anecdotal reports of progression to clinical spondylarthropathy (Southwood and Gaston 1993). The role of enteric bacteria in the arthritis associated with inflammatory bowel disease is less clear. There is no doubt that many children with inflammatory bowel disease develop arthritis (7–21 per cent). Successful treatment of the bowel inflammation with sulphasalazine may be accompanied by remission of peripheral arthritis, the benefit of remission appearing to depend on the antibiotic (sulpha-) component, which may alter enteric bacterial colonization. Patients with inflammatory bowel disease who are HLA-B27 positive are more likely to develop ankylosing spondylitis (Lindsley and Schaller 1974; Passo *et al*. 1986).

There are reports that subacute bowel inflammation (histological evidence of acute or chronic ileocolonic inflammation) is found in up to 80 per cent of patients with juvenile spondylarthropathy, and a similar proportion of patients with late-onset pauciarticular juvenile chronic arthritis (Mielants *et al*. 1987; Veys *et al*. 1992; Mielants *et al*. 1993). The finding of chronic mucosal inflammation appeared to predict evolution to ankylosing spondylitis in these patients. There is also evidence that immune responses to enteric bacteria are found in the synovial compartment of children with juvenile spondylarthropathy. Approximately 90 per cent of children who have HLA-B27 positive chronic arthritis have lymphocytes in synovial fluid responsive to enteric bacteria, compared with only 25 per cent of children with HLA-B27-negative disease (Life *et al*. 1993). However, the stimulus to accumulation of such lymphocytes within the joint space remains unclear. There have been no consistent reports of bacteria or foreign antigenic fragments in the synovial membrane or fluid. Potentially cross-reactive immune responses directed against both bacterial and human heat-shock proteins have been proposed, but there are several arguments against such a directly pathogenetic role. Cells recognizing specific pathogens account for only a tiny minority (1:500) of the synovial cell population (Kingsley, personal communication) and it is possible that the inflammatory milieu of the arthritic joint favours the relatively non-antigen-specific accumulation of memory T lymphocytes.

The importance of enteric colonization has been shown in the *HLA-B27* transgenic rat model. A group of *HLA-B27* transgenic rats maintained in a germ-free environment did not develop the spondylarthropathy or bowel inflammation seen in their littermates. The responsible enteric pathogen or pathogens have yet to be isolated (Taurog 1994). If this model is a true reflection of human disease, the *HLA-B27* gene may predispose an individual to spondylarthropathy by reducing immune resistance to enteric bacteria at the level of the antigen-presenting cell (Feltkamp *et al*. 1996).

Clinical features and outcome

It is frequently difficult to distinguish early or undifferentiated juvenile spondylarthropathy from juvenile chronic arthritis. The spondylarthropathies are dynamic diseases that may continue to evolve over several years before reaching full expression. A child with arthritis in a peripheral joint(s) may not be suspected of having a spondylarthropathy until classical signs of axial involvement develop during the adult years. This section will deal firstly with the clinical features of the undifferentiated spondylarthropathies, and then with recognizable spondylarthropathies of ankylosing spondylitis, inflammatory bowel disease, Reiter's syndrome, and psoriasis in childhood (Table 1).

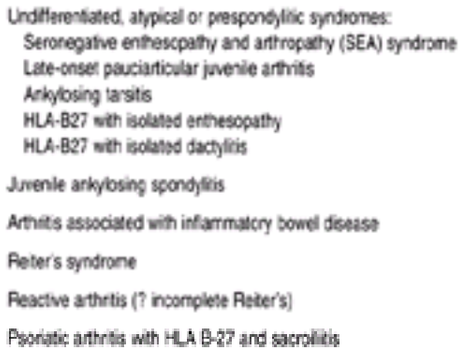

Table 1 Classification of spondylarthropathies in children

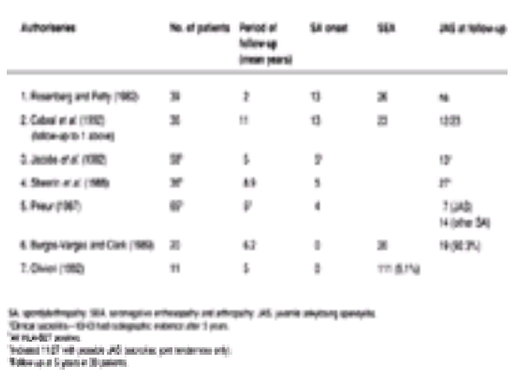
Undifferentiated or atypical spondylarthropathy

In a population-based study from Sweden, Andersson Gare *et al*. (1987) reported that 5 per cent of children with chronic arthritis were classified with a spondylarthropathy, but it has been estimated that between 10 and 15 per cent of children diagnosed as having juvenile chronic arthritis may eventually develop a spondylarthropathy. This poses a diagnostic challenge: to identify characteristic clinical features that predate the onset of back and sacroiliac symptoms, and therefore allow the prediction of outcome with some accuracy in this group of children with arthritis. Several descriptive, retrospective clinical studies of children who eventually developed an identifiable spondylarthropathy have provided useful information for this purpose (Schaller *et al*. 1976; Jacobs *et al*. 1982; Schaller 1983), and can be summarized as follows.

1. A family history of spondylarthropathy (defined as inflammatory low back disease) was described in up to 60 per cent of patients.
2. There was a strong male preponderance in patients; male:female ratios up to 10:1 have been reported.
3. Antecedent insults included febrile illnesses and musculoskeletal trauma.
4. The arthritis was of 'late onset'; only 40 per cent of the children were symptomatic by their ninth year. The earliest reported onset was at 12 months of age.
5. The arthritis was typically pauciarticular and asymmetrical, predominantly involving the large, weight-bearing joints of the lower limbs.
6. Extra-articular manifestations occurred in 42 per cent of patients, including urethritis, iritis, conjunctivitis, and keratoderma blennorrhagicum.
7. Enthesopathy was prominent in up to 75 per cent of patients.

Several sets of criteria have been proposed to differentiate childhood spondylarthropathy from other forms of juvenile arthritis. Most recently, the term 'late-onset pauci-articular juvenile chronic arthritis' has become fashionable, although there are no studies to indicate the validity of this designation (Table 2).



SA, spondyloarthropathy; SEA, seronegative enthesopathy and arthropathy; JAS, juvenile ankylosing spondylitis.
*Clinical sacroiliitis—10/43 had radiographic evidence after 5 years.
†All HLA-B27 positive.
‡Included 11/27 with juvenile JAS (sacroiliac joint tenderness only).
§Follow-up in 5 years in 39 patients.

Table 2 Unclassified or atypical spondylarthropathies in childhood

The SEA syndrome

Clinical features

Rosenberg and Petty (1982) described 39 children (35 boys and 4 girls) with a syndrome of seronegative enthesopathy and arthropathy (**SEA** syndrome). The mean age of onset of the first musculoskeletal symptom was 9.8 years (range 1–16 years). This group included 13 patients who fulfilled diagnostic criteria for the diagnosis of juvenile ankylosing spondylitis, inflammatory bowel disease, reactive arthritis, or Reiter's syndrome. The remaining 26 did not have one of these identifiable diseases, but did have the combination of enthesitis and arthritis or arthralgia. Enthesitis was demonstrated by discrete, localized tenderness at the bony insertions of ligaments, tendons or fascias. Principle sites of enthesitis included the calcaneal insertions of the plantar fascia and Achilles tendons, the metatarsal heads and base of the fifth metatarsal, the ischial tuberosities, iliac crests, and patellar tendon insertions. Low back pain and stiffness were present in only nine patients, but many had abnormal flattening of the lumbar curve on forward flexion. HLA typing of 32 children demonstrated that 23 (72 per cent), including the eight patients with juvenile ankylosing spondylitis and one with Reiter's syndrome, were HLA-B27 positive.

Juvenile ankylosing tarsitis has been described in up to 80 per cent of patients with SEA syndrome and 87 per cent of those with juvenile ankylosing spondylitis (Levi *et al*. 1990; Burgos-Vargas 1991). These patients develop inflammation of synovial sheaths and bursas, tendons, entheses and joints of the feet, leading to radiographic or MRI evidence of ankylosis. Additionally, non-traumatic atlantoaxial subluxation has been reported in two HLA-B27-positive children with SEA syndrome (Foster *et al*. 1995).

Outcome

There have been several longer-term follow-up studies of patients with SEA syndrome. Cabral *et al*. (1992) reported on 36 of the original 39 patients described by Rosenberg and Petty (1982), 2.5 to 23.5 years (mean 11 years) after the onset of their symptoms. Assessment of outcome in the patients who did not have ankylosing spondylitis, inflammatory bowel disease, reactive arthritis, or Reiter's syndrome in the original study revealed that the disease had progressed to definite or probable ankylosing spondylitis in half (12 patients). The presence of arthralgia was less specific than definite arthritis for predicting a spondylitic outcome. Burgos-Vargas and Clark (1989) reported 20 Mexican patients with SEA syndrome, and compared their outcome after at least 5 years of follow-up with 25 patients with polyarticular-onset juvenile chronic arthritis and 28 patients with definite ankylosing spondylitis of juvenile onset. Radiographic evidence of sacroiliitis of the ankylosing spondylitis type showed in four patients with SEA syndrome before the third year of follow-up. From the third to the fifth year of follow-up, back complaints and radiographically confirmed sacroiliitis fulfilling the diagnostic criteria for ankylosing spondylitis developed in an increasing proportion of the patients (47.1–75 per cent) and ultimately

affected 92.3 per cent. Other than the absence of back problems at the initial presentation, no significant differences in outcome were seen between the group with SEA syndrome and the group with juvenile ankylosing spondylitis.

Olivieri *et al*. (1992) reported that only 1 of 11 Caucasian HLA-B27-positive children (9.1 per cent) with SEA syndrome developed bilateral sacroiliitis after 5 years of disease. Ethnic and environmental factors were thought to have contributed to the discrepancy between these findings and those of the Mexican population reported by Burgos-Vargas and Clark (1989).

Atypical spondylarthropathy

Clinical features

Hussein *et al*. (1989) have proposed a set of diagnostic criteria for atypical spondylarthritis in a study of 26 children. Cases were classified according to criteria that were shown to be highly sensitive in differentiating atypical spondylarthropathies from other forms of juvenile chronic arthritis. The major criteria were (i) a family history of spondylarthropathy or oligoarthritis, (ii) enthesopathy, (iii) arthritis of digital joints including big toes, (iv) sacroiliitis, (v) presence of the *HLA-B27* gene, and (vi) recurrent arthralgia or arthritis. Minor criteria were (i) age of onset after 10 years of age, (ii) male sex, (iii) only the lower extremities affected, (iv) acute iritis or conjunctivitis, (v) arthritis of hips, and (vi) onset following an idiopathic enteritis. When four of the six major criteria were present, 96.1 per cent of the patients were correctly classified as having atypical spondylarthropathy, with a sensitivity of 84.6 per cent and a specificity of 100 per cent. The same diagnostic accuracy was achieved when three major and three minor criteria were present. Long-term follow-up studies of patients with atypical spondylarthropathy defined by the above criteria have not been reported.

HLA-B27-positive arthritis

Clinical features

The usefulness of HLA-B27 as a diagnostic marker of the juvenile spondylarthropathies has been discussed by many investigators, but interpretation of a positive HLA-B27 result is complicated by the occurrence of the gene in at least 8 per cent of the normal, non-arthritic childhood population. In addition, HLA-B27 has been associated with a number of different musculoskeletal diseases in children and it is unclear if these all form part of the spondylarthropathic spectrum. For example, there have been reports of children with isolated dactylitis (Siegel and Baum 1988), isolated peripheral enthesitis (Olivieri *et al*. 1990; Olivieri and Pasero 1992), and isolated hip flexion contractures (Bowyer 1995).

Outcome

A number of investigators have reported the outcome of children with arthritis who are HLA-B27 positive. Jacobs *et al*. (1982) described 58 such patients who were followed for a mean period of 5 years. The arthritis at the initiation of the illness was often transient and recurrent, pauciarticular and asymmetrical in distribution, and occurred primarily in the knees or ankles. Hip signs were noted in only seven of the patients at onset, but the hips were ultimately affected in 36 per cent. Radiographs of the sacroiliac joints were obtained for 43 of the patients, 10 of whom showed signs of sacroiliitis after a mean symptomatic period of 5 years (range 1–12 years). Other radiographic findings included periostitis, severe osteopenia, calcaneal erosions, or spurs. Rapid destruction of a single joint occurred in 3 of 58 patients.

Prieur (1987) reported a study of 65 children with HLA-B27-associated arthritis. There were 45 boys and 20 girls, with a mean age at onset of symptoms of 10 years (range 2.5–16 years). Just over a quarter of the patients (27 per cent) had arthritis in an upper limb during the first 6 months of disease. Enthesitis was present in 10 patients and 'sausage' digits in one-third. After 5 years' follow-up, 32 per cent had fulfilled criteria for the diagnosis of a defined spondylarthropathy: ankylosing spondylitis (7 patients), Reiter's syndrome (2 patients), psoriatic arthritis (9 patients), and Crohn's disease (3 patients).

Thirty-six HLA-B27-positive children with arthritis who had been followed for a mean period of 8.9 years were described by Sheerin *et al*. (1988). Five patients had an initial diagnosis of juvenile ankylosing spondylitis (14 per cent), and 24 (67 per cent) initially had peripheral arthritis without axial involvement. The most frequently involved joint was the knee (15 patients), followed by the ankle (8 patients), and the foot (5 patients). During the follow-up period, 22 patients had symptoms consistent with enthesitis, although it was demonstrable in only 16 patients (44 per cent). Eight patients (22 per cent) had extra-articular manifestations: acute iritis (4 patients), inflammatory bowel disease (1), psoriasis (2), and localized scleroderma (1). One of the patients with psoriasis had recurrent episodes of urethritis suggestive of incomplete Reiter's syndrome. Of the 28 patients in whom radiographs of sacroiliac region had been taken, 13 had normal results. A clinical course consistent with juvenile ankylosing spondylitis ultimately developed in 27 of the 36 patients.

Juvenile ankylosing spondylitis

The Rome and New York criteria for the diagnosis of ankylosing spondylitis (Kellgren *et al*. 1963; Bennett and Burch 1967) were derived for use in adults, and have not been validated in the paediatric population. However, there is a small proportion of children with arthritis who do fulfil the criteria for the diagnosis of the disease.

Epidemiology

Historical averages in populations of children with arthritis attending paediatric rheumatology clinics have suggested that 5 to 8 per cent have ankylosing spondylitis compared with 75 to 83 per cent with juvenile chronic arthritis (Ladd *et al*. 1971). The prevalence of juvenile ankylosing spondylitis can also be extrapolated from the numbers of adult patients who report that onset occurred before they were 16 years old. Lawrence *et al*. (1989) reported an estimated prevalence of ankylosing spondylitis in populations from the United States ranging from 129/100 000 (Carter *et al*. 1979) to 222/100 000 (Mikkelsen *et al*. 1967). Generally between 10 and 19 per cent of cases begin before the age of 16 years (Hart and Maclagan 1955). The prevalence depends on the population under study; for example, Burgos-Vargas *et al*. (1989), describing a Mexican Mestizo population in which ankylosing spondylitis was diagnosed between 1980 and 1987, reported that 54 per cent had onset of symptoms before the age of 16 years. Over 90 per cent of patients in published series of juvenile ankylosing spondylitis were HLA-B27 positive as is true in the adult population (Edmonds *et al*. 1974; Sturrock *et al*. 1974; Veys *et al*. 1976; Hafner 1987; Cassidy and Petty 1995). The sum of these data suggests that the prevalence of juvenile ankylosing spondylitis is approx. 12 to 18/100 000.

Clinical characteristics

Juvenile ankylosing spondylitis in children commonly presents as an arthritis affecting the large joints of the lower limbs, particularly the knees and ankles (Schaller *et al*. 1969; Ladd *et al*. 1971; Bywaters 1976; Kleinman *et al*. 1977; Schaller 1977; Ansell 1980; Garcia-Morteo *et al*. 1983; Hafner 1987; Burgos-Vargas *et al*. 1989; Burgos-Vargas and Vazquez-Mellado 1995). Although it is rare for the hips to be involved at presentation, there is a small group of children in whom recurrent, transient hip symptoms eventually develop into ankylosing spondylitis. The early course of the disease is frequently episodic, and other features of an undifferentiated spondylarthropathy may be present. Inflammation of the entheses may be prominent early in the disease course. The most common sites include Achilles tendon insertions, peripatellar insertions including the quadriceps and patellar tendons, and the insertions of the plantar fascia into calcaneum and metatarsal heads. Subtalar and mid-tarsal arthritis is not uncommon. Tarsometatarsal arthritis is sometimes associated with hindfoot involvement and results in a supination deformity. Indeed, spontaneous fusion and complete obliteration of the tarsometatarsal joints may occur (Levi *et al*. 1990; Burgos-Vargas 1991) (Fig. 1). Persistent hip involvement leading eventually to total hip arthroplasty is one of the most common peripheral articular complications of juvenile ankylosing spondylitis (Calin and Elswood 1988). Burgos-Vargas and Vazquez-Mellado (1995) assessed early clinical features that help to differentiate juvenile chronic arthritis from juvenile ankylosing spondylitis, using retrospective analysis of a group of patients at 6 months, 12 months, and 10 years after onset. Enthesitis and tarsal disease in children who have arthritis of the lower but not of the upper extremities appear to differentiate juvenile ankylosing spondylitis from juvenile chronic arthritis during the first year of symptoms.

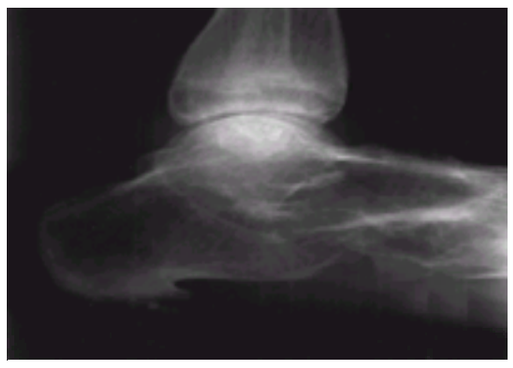


Fig. 1 Radiograph of ankle and hindfoot of the patient also illustrated in Fig. 2. The subtalar and talonavicular articulations are essentially ankylosed. A calcaneal spur is present from long-standing plantar fasciitis.

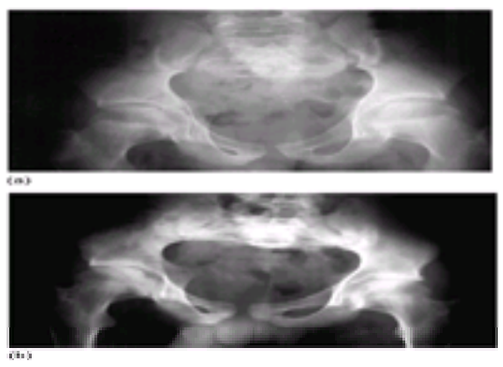

Fig. 2 (a) Radiograph of pelvis in a 14-year-old boy demonstrating normal sacroiliac joints. He was initially diagnosed as juvenile chronic arthritis. (b) Radiograph of the same patient after 4 years of disease activity. Note the sclerosis and erosion of the sacroiliac joints. The patient did not specifically complain of back pain but has limited lumbar flexion on Schober testing.

The joints of the arms are much less commonly affected, but occasionally the shoulders are involved. In contrast to adults with ankylosing spondylitis, most affected children do not report pain in the axial skeleton initially. Only 12.8 to 24 per cent have pain, stiffness or limitation of motion of the lumbosacral spine or sacroiliac within the first year of disease (Burgos-Vargas and Petty 1992). This may be due in part to the rather poorly localized symptoms of lumbosacral or sacroiliac joint disease, which may cause pain in the buttock, groin, or thigh. Evidence of sacroiliac involvement can be elicited by pressure over the sacroiliac joints or by compression of the joints using manoeuvres such as Patrick's test or Gaenslen's sign (Hoppenfeld 1976). Serial follow-up with Schober's measurements and measurement of chest expansion can reveal progressive restriction of the range of motion of the axial skeleton. Most patients develop axial involvement between 5 and 10 years after the onset of symptoms. Definite involvement of the spine and sacroiliitis in patients with juvenile ankylosing spondylitis occurred after a mean of 7.3 ± 2 years in a series of 35 patients (Burgos-Vargas and Vazquez-Mellado 1995). Serial plain radiographs of the sacroiliac joints may be helpful in monitoring the course of the disease (Fig. 2).

The systemic complications of juvenile ankylosing spondylitis include acute iritis (Ladd *et al*. 1971; Schaller 1977; Ansell 1980; Hafner 1987), aortic valve insufficiency (Stewart *et al*. 1978; Reid *et al*. 1979; Ansell 1980; Gore *et al*. 1981; Kean *et al*. 1980; Gerster *et al*. 1987; Stamato *et al*. 1995), C1–C2 subluxations (Reid and Hill 1978), and amyloidosis (Ansell 1980). The frequency of aortic valve insufficiency detected by imaging with colour Doppler ultrasound may be as high as 30 per cent of patients with a juvenile spondylarthropathy (Gerster *et al*. 1987), but others have reported figures of 8 per cent for aortic regurgitation and 5 per cent for mild mitral regurgitation (Stamato *et al*. 1995).

Several studies have compared juvenile with adult ankylosing spondylitis (Marks *et al*. 1982; Burgos-Vargas *et al*. 1989; Garcia-Morteo *et al*. 1983). Significant differences noted in the juvenile-onset type are the peripheral articular onset, precocious hip destruction, and the insidious, late development of axial involvement. Systemic complications are similar, apart from apical pulmonary disease, IgA nephropathy, and cauda equina syndrome, which have not been reported in children.

Outcome

The long-term outcome of juvenile ankylosing spondylitis is variable. Garcia-Morteo *et al*. (1983) found no juvenile-onset patients who retained full functional capacity after a mean disease duration of 15 years. Twelve patients (50 per cent) were in class II, seven in class III, and five in class IV using the Steinbocker classification. In contrast, the functional outcome of patients with the disease appears to be reasonably good, with a large proportion in employment (73 per cent) or continuing education (Marks *et al*. 1982). Most patients (95 per cent) require long-term anti-inflammatory therapy and have persistent peripheral arthritis. Calin and Elswood (1988) followed 135 patients with juvenile ankylosing spondylitis and reported that 74 per cent remained in full-time employment, a higher proportion than a comparable number of patients with adult-onset disease (54 per cent).

Inflammatory bowel disease-associated arthritis

Epidemiology

Peripheral arthritis and spondylitis are the most common extra-intestinal manifestations of chronic inflammatory bowel disease. Inflammatory bowel disease of unknown aetiology is divided into two major clinicopathological subtypes, ulcerative colitis and Crohn's disease; the common articular complications of each subtype are the same. In most series of adult patients, the prevalence of joint involvement is 4 to 22 per cent in ulcerative colitis and 2 to 22 per cent in Crohn's disease (Gavallese and Kantrowitz 1988). Two major reviews of arthritis associated with inflammatory bowel disease in children revealed similar prevalence: 9 to 21 per cent of patients with ulcerative colitis and 10 to 16 per cent of patients with Crohn's disease (Lindsley and Schaller 1974; Passo *et al*. 1986).

Clinical manifestations

The peripheral arthritis is pauciarticular, usually affecting the weight-bearing joints of the lower extremities, but occasionally involving joints of the upper extremities. The duration of attacks ranges from 2 days to 12 weeks, and averages about 1 month. These attacks occasionally precede the onset of bowel symptoms but usually coincide with or occur after the onset of bowel disease. After the initial attack, episodes of peripheral arthritis frequently occur during exacerbations or active periods of bowel disease. Passo *et al*. (1986) noted eight patients with Crohn's disease who had episodes of arthritis at times when they were free of bowel symptoms. These patients had anaemia and hypoalbuminaemia, however, suggesting that subclinical bowel inflammation may have been present. Importantly, most flares of bowel disease were not accompanied by arthritic manifestations. There was no correlation between the severity of the bowel inflammation and the occurrence of arthritis. Treatment of the bowel inflammation was usually associated with resolution of the peripheral arthritis.

Lindsley and Schaller (1974) describe five children with inflammatory bowel disease, all of whom had classical signs of ankylosing spondylitis (pain, loss of motion in the low back, and radiographic evidence of arthritis in the sacroiliac joints and lumbar spine). The symptoms were persistent and progressive, resulting in permanent impairment. Destructive hip disease was seen in four of these patients and all five suffered peripheral arthritis, including hip inflammation, at some time during follow-up. Joint symptoms preceded bowel symptoms in two of the five patients by 3 months and by 8 years; one had concurrent onset of bowel and joint symptoms. The activity of spondylitis and concurrent peripheral arthritis did not correlate with that of the bowel disease nor was treatment of the bowel disease effective in treatment of the spondylitis.

There are few reproducible data on HLA typing in children with spondylitis and inflammatory bowel disease. In adult patients, the prevalence of HLA-B27 positivity is 53 to 75 per cent, considerably lower than the 90 to 95 per cent prevalence seen in idiopathic ankylosing spondylitis (Gavallese and Kantrowitz 1988).

Reiter's syndrome

Prevalence

There are no estimates of the prevalence of Reiter's syndrome in the child population. Although fewer than 100 childhood cases have been described, reactive arthritis often goes unreported and probably many more cases have been encountered. There are several reviews of the literature and summaries of the data (Lockie and Hunder 1971; Iverson *et al*. 1975; Singsen *et al*. 1977; Rosenberg and Petty 1979; Cuttica *et al*. 1992). There is undoubtedly a considerable overlap between Reiter's syndrome and reactive arthritis.

Clinical manifestations

The clinical syndrome in children is similar to that described in adult patients. The individual features of arthritis, urethritis, conjunctivitis, keratoderma blennorrhagica, circinate balanitis, and oral mucosal ulcers may occur sequentially over a period of several weeks. Singsen *et al*. (1977) reported seven boys in a 2-year period who developed the triad of urethritis, arthritis, and conjunctivitis over a range of 4 to 24 days (mean 11 days). The evolution of signs and symptoms occurs asynchronously in many children. Whereas adult Reiter's syndrome often follows venereal infection, most cases of childhood Reiter's syndrome are preceded by enteric infection with species of salmonella, shigella, yersinia, or campylobacter. There are also individual reports of *Clostridium difficile* and parasitic infestation provoking Reiter's syndrome. A 14-year-old female was reported with Reiter's syndrome following an urinary-tract infection with *Escherichia coli* (Thomas and Roberton 1994). In 1992, Cuttica *et al*. (1992) reported the largest series of children with Reiter's syndrome and confirmed that diarrhoea antedated the onset of arthritis in 18/26 (69 per cent) patients; no patient reported venereal disease. The majority of patients (69 per cent) had pauciarticular involvement of lower extremities. Spine involvement was seen in six patients (23 per cent). The full triad of arthritis, conjunctivitis, and urethritis was seen in 9/16 (35 per cent). Reiter's syndrome in most children is a short-lived condition, characterized by complete resolution of the signs and symptoms; however, a protracted course and recurrent disease have been described (Iverson *et al*. 1975; Singsen *et al*. 1977). In Cuttica's series, mean duration of follow-up was 28.5 months (range 2–13.5 years); 15/26 (58 per cent) were in complete remission when last seen, seven (27 per cent) had a sustained course, three (11.5 per cent) had a fluctuating course, and only one child had a relapsing course. Functional outcome was grade I to II in 96 per cent. Radiographic erosions were noted in 4/26 (15 per cent) peripheral joints and sacroiliitis in 5/26 (21 per cent) (Cuttica *et al*. 1992). The long-term outcome of Reiter's syndrome in children is not well documented, although a proportion of cases undoubtedly progress to ankylosing spondylitis.

Juvenile psoriatic arthritis

Juvenile psoriatic arthritis has been traditionally grouped with the spondylarthropathies, but there is emerging evidence that the clinical and laboratory features of this disease have greater similarity to pauciarticular-onset juvenile chronic arthritis with an asymmetrical polyarticular course. Important dissimilarities to the spondylarthropathies are the lack of association with HLA-B27, and the relatively rare outcome of ankylosing spondylitis.

Prevalence

Most estimates of the prevalence of psoriasis in the general population range from 1 to 2 per cent (Baker 1966). In children, its estimated prevalence is approx. 0.3 per cent (Farber and Carsen 1966). The onset of psoriasis is frequently between 5 and 15 years of age, with one-third of all cases starting by the age of 15 years. Based on a population study by Hellgren (1969), Lawrence *et al*. (1989) calculated that approx 4.5 per cent of those with psoriasis have psoriatic arthritis. They further suggested that the prevalence of psoriatic arthritis in the United States is 0.67 per cent; accordingly, about 160 000 persons in the United States have psoriatic arthritis. Oriente *et al*. (1994) reported a similar prevalence of juvenile psoriatic arthritis of 1 per cent in a review of 425 patients with the onset of psoriasis before the age of 31 years. Cassidy and Petty (1995) estimate the prevalence of juvenile psoriatic arthritis at between 10 to 15 cases per 100 000 based on population studies reported by Espinoza (1985), making it approximately one-tenth as common as juvenile chronic arthritis, although fewer than 200 cases have been reported (Lambert *et al*. 1976; Calabro 1977; Sills 1980; Shore and Ansell 1982; Hamilton *et al*. 1990; Truckenbrodt and Hafner 1990).

Overall, juvenile psoriatic arthritis accounts for 2 to 8 per cent of chronic arthritic conditions in childhood (Lambert *et al*. 1976; Ansell 1977; Sills 1980). However, on using more liberal criteria for the diagnosis, Kuster and Quoss (1983) reported that it may account for as much as 40 per cent of juvenile chronic arthritis.

Clinical characteristics

Juvenile psoriatic arthropathy is a heterogeneous group of arthritic conditions that pose classificational problems. The majority of affected children resemble cases of juvenile chronic arthritis and a smaller fraction juvenile spondylarthropathy. In addition, there are probably children who have coincidental psoriasis and juvenile chronic arthritis (Petty 1994). Juvenile psoriatic arthritis has been defined by Lambert *et al*. (1976) as 'an inflammatory arthritis commencing prior to the age of 16 years, associated with psoriasis either preceding the onset of arthritis or occurring within the subsequent 15 years and usually with an absence of rheumatoid factor in the serum'. The psoriasis (nail and cutaneous manifestations) may lag behind the onset of arthritis by several months to years. In an effort to include patients who lack the typical cutaneous stigmata, Southwood *et al*. (1989) proposed a different set of criteria (the Vancouver criteria) for the definition of juvenile psoriatic arthritis (Table 3). Patients with conventionally defined psoriatic arthritis constituted 6 per cent of Southwood's patient population; indeed, according to the revised criteria, psoriatic arthritis constitutes approx. 19 per cent of the chronic arthritides of childhood. Shore and Ansell (1982) also described children without skin lesions but with probable juvenile psoriatic arthritis. Their 12 patients had asymmetrical arthritis of both upper and lower limbs, and a positive family history of psoriasis; 8 of the 12 had significant nail pitting. They suggested that such patients should be regarded as having 'probable juvenile psoriatic arthritis'. In the 5 years of follow-up, half of these patients developed overt psoriasis.

Definite psoriatic arthritis
Arthritis with typical psoriatic rash
Arthritis with three of the four following minor criteria:
Dactylitis
Nail pitting or onycholysis
Psoriasis-like rash
Family history of psoriasis (1st or 2nd degree relatives)
Probable psoriatic arthritis
Arthritis with 2 of the 4 minor criteria listed

[a]The clinical manifestations need not be present simultaneously. After Southwood *et al*. (1989) and Cassidy and Petty (1995).

Table 3 Vancouver criteria for the diagnosis of psoriatic arthritis in children [a]

Juvenile psoriatic arthritis differs from the other spondylarthropathies in that females are affected more often than males (1.5:1), but with marked variability among series (range 2:8 to 1:1.3, female:male) (Lambert *et al*. 1976; Shore and Ansell 1982; Southwood *et al*. 1989; Hamilton *et al*. 1990; Truckenbrodt and Hafner 1990; Koo *et al*. 1991). Simultaneous onset of arthritis and psoriasis is relatively uncommon. Most studies listed above show that the onset of arthritis is oligoarticular, but an asymmetrical polyarthritis evolves over the ensuing years. Sacroiliitis occurs in a significant number of cases (11–47 per cent), but is not inevitable (Southwood *et al*. 1989; Hamilton *et al*. 1990). The knee is the most commonly affected joint; dactylitis, tendinitis, and involvement of the distal interphalangeal joints are also extremely common. Dactylitis, distal interphalangeal inflammation, and the associated classical psoriatic nail changes are sometimes obvious (Fig. 3 and Fig. 4). The course of the disease tends to be more severe than that of pauciarticular juvenile arthritis; it is less severe, however, than the polyarticular course of juvenile chronic arthritis, especially in patients who are positive for rheumatoid factor. Overall, functional class I or II outcomes are common (Lambert *et al*. 1976; Calabro 1977). Fewer than 10 to 15 per cent of patients evolve into functional classes III or IV (Shore and Ansell 1982).

Fig. 3 The hands of an 8-year-old boy with severe psoriatic nail changes. They show arthritis of distal interphalangeal joints, dactylitis of the right fifth digit, and diffuse metacarpophalangeal involvement.

Fig. 4 The foot of the boy whose hands are depicted in Fig. 3, showing arthritis of the interphalangeal joint of the great toe and dactylitis of the third toe, as well as classical psoriatic nail changes.

Chronic iridocyclitis similar to that seen in juvenile arthritis developed in 8 to 17 per cent of reported patients with psoriatic arthritis (Sills 1980; Shore and Ansell 1982, Southwood *et al*. 1989; Truckenbrodt and Hafner 1990). Most patients with chronic iridocyclitis have also been positive for antinuclear antibody, which draws a closer association with juvenile chronic arthritis than the typical spondylarthropathies that manifest acute iritis.

No strong HLA association with juvenile psoriatic arthritis has been demonstrated. Hamilton *et al*. (1990) showed increased frequency of HLA-A2 and -B17, a possible increase in HLA-DR7, and no increase in HLA-B27. Southwood *et al*. (1989) found increased HLA-DR8 and decreased frequencies of HLA-DR4; HLA-B27 was found in eight patients (23 per cent), five of whom had clinical features of spondylarthropathy (back pain, limited range of motion in the back, and sacroiliitis). Ansell *et al*. (1993) confirmed the heterogeneity of 70 patients: HLA-B27 was increased in frequency, particularly in boys with older onset. HLA-A2, HLA-DR5, and HLA-DRw8 were found to be increased in early-onset cases. No correlation was found with the characteristic dactylitis with resultant 'sausage' toe or finger. It is likely that improvement in the classificational specificity of juvenile psoriatic arthritis as well as the spondylarthropathies in general will result in greater understanding of the aetiology, pathogenesis, and treatment of these diseases in the future.

5.5.3 Ankylosing spondylitis

Andrei Calin

Historical review

As summarized elsewhere (Calin 1988) Raymond, in 1912, provided convincing illustrations of mummies from Egypt who appeared to have ankylosing spondylitis. The paleopathologist, Sir Mark Ruffer, described a gentleman called Nefermaat who lived some 3000 years before Christ. His mummified remains demonstrated a rigid block of bone from the mid-cervical region to the sacrum. Short described 18 further instances of ankylosing spondylitis from Egyptian sources over the next 3 millennia and other examples exist from the Danish and French neolithic periods. More recent (AD 1200) remains of New Mexican Indians with ankylosing spondylitis have been described. There has, over the last decades, been some debate as to whether these individuals had diffuse idiopathic skeletal hyperostosis or ankylosing spondylitis; although there is no absolute certainty, the fused sacroiliac joints in many instances attest to such patients having ankylosing spondylitis.

In the nineteenth century Bechterew, Strumpell, and Marie promoted the general recognition of ankylosing spondylitis.

Diagnostic criteria

Criteria for the classification and diagnosis of different rheumatic diseases have been developed to help different clinicians in different locations use the same diagnostic labels for similar groups of patients. Originally, criteria were formulated in Rome in 1961 and later revised in New York in 1966 (Bennett and Burch 1968) (Table 1). The most frequent means of satisfying these is a radiographic demonstration of grade 3 or 4 bilateral sacroiliitis (Fig. 1), together with a history of back pain. In fact, few clinicians rely on these criteria and most would consider a patient as having ankylosing spondylitis if symptomatic and with sacroiliitis. Naturally, as discussed in Chapter 5.5.1, there are often exceptions to any list of criteria and, although of major concern to the epidemiologist, the clinician is often satisfied to use 'common sense' rather than rigid criteria. For example, we do recognize ankylosing spondylitis *sine* sacroiliitis on the one hand or atypical forms of disease on the other.

Fig. 1 Pelvic radiograph (anteroposterior view) revealing grade IV sacroiliitis. Note marked juxta-articular sclerosis and destruction of joint with fusion.

Rome criteria
Clinical criteria
1. Low back pain > 3 months, relieved by rest
2. Thoracic pain and stiffness
3. History of iritis
4. Limited motion of lumbar spine
5. Limited chest expansion
Radiological criteria
1. Bilateral sacroiliitis
Ankylosing spondylitis is diagnosed if bilateral sacroiliitis plus one clinical criterion, or four out of five clinical criteria, are present.

New York criteria
Clinical criteria
1. Limited movement of lumbar spine in three planes
2. Pain in lumbar spine or at dorsolumbar junction
3. Chest expansion = 2.5 cm
Radiological criteria
1. Bilateral sacroiliitis, grade 3–4
2. Unilateral sacroiliitis, grade 3–4, or bilateral sacroiliitis, grade 2

Table 1 Criteria for ankylosing spondylitis

The disease is considered primary if no other rheumatological disorder is present, or secondary if the sacroiliitis is related to psoriatic arthropathy, inflammatory bowel disease or Reiter's syndrome. One great difficulty lies in the prevalence of patients with clinical symptoms and radiological signs of disease but in whom the radiologist has failed to recognize sacroiliitis. Such individuals are often misdiagnosed as having mechanical back pain or other inappropriate labels. In essence, a single anteroposterior film of the pelvis is sufficient to define the radiological entity. More sophisticated investigations such as the use of magnetic resonance imaging are always expensive and may be inappropriate and unhelpful (Braun *et al*. 1994).

A review of the Rome Criteria reveals an obvious flaw: the limitation of spinal movement is not defined. The New York Criteria do define limitation of chest expansion as 2.5 cm or less but there is inevitably a major subjective component to chest expansion, and decreased movement typically occurs only late in the course of the disease. Pain, as such, is too sensitive and too non-specific to be used as a criterion and we have developed a simple analysis of the qualitative nature of pain in patients with inflammatory spinal disease (i.e. ankylosing spondylitis). Specifically, (Calin and Fries 1977) (i) patients are typically below 40 years of age at onset; (ii) the onset is insidious; (iii) duration has been at least 3 months at first attendance; (iv) there is an association with morning stiffness; and (v) improvement occurs with exercise. For those with three or more of these features a pelvic radiograph should elucidate whether there is evidence of sacroiliitis. HLA B27 typing has led to immense strides in the understanding of the spondylarthropathy group but should not be considered a diagnostic test or necessary for the diagnosis of ankylosing spondylitis. A patient with symptomatic sacroiliitis lacking HLA B27 still has ankylosing spondylitis and, moreover, the test is frequently negative in secondary forms of ankylosing spondylitis, where only some 50 per cent of those with enteropathic spondylitis or psoriatic spondylitis carry the antigen. Occasionally sacroiliitis is seen as a chance finding in the absence of pain. Presumably the precipitating trigger has been pulled in the susceptible individual, but for reasons not clearly understood, symptoms have never reached a threshold noticed by patient or physician. A review of Bayesian theory reminds us that HLA B27 typing can only be helpful when we are 50 per cent certain of the diagnosis.

By using Bayesian analysis it has been pointed out that if the clinician is 50 per cent certain of the diagnosis, then HLA B27 typing is helpful, whereas at the extremes of a priori probability such testing is of no use. Clearly, the physician is unlikely to know when he or she is 50 per cent confident! The clinician perhaps should simply treat with a non-steroidal anti-inflammatory drug if a diagnosis of ankylosing spondylitis appears possible, rather than relying on further testing such as computed tomography and other investigations (Calin 1980; Calin 1982).

In epidemiological and familial studies patients are sometimes found with unilateral sacroiliitis, dactylitis, syndesmophytes, and other stigmata of 'undifferentiated spondylarthropathy'(see Chapter 5.5.1).

Until the specific environmental trigger(s), gene(s), and biological mechanism(s) leading to disease pathogenesis are fully elucidated, the obsessional use of criteria for classification may be inappropriate.

Epidemiology

During the 1950s it was recognized that ankylosing spondylitis occurred in twins, brothers, fathers, mothers and other relatives of affected individuals. Indeed, Strecher (1957) found the disease to be 30 times more prevalent among relatives of spondylitics than among controls. The author suggested that the disease was inherited as a single autosomal dominant factor with '70 per cent penetrance in men and 10 per cent penetrance in women'. In 1967 Emery and Lawrence studied 188 available first-degree relatives of 76 probands with ankylosing spondylitis and appropriately matched controls. Sixteen per cent of the first-degree relatives of patients had sacroiliitis, with 20 per cent of the males affected and 8 per cent of the females—a ratio higher than the often quoted 10:1 (male:female) ratio claimed at that time.

The search for an explanation for this increased heritability took a dramatic step forward in 1973 with two reports of the association between ankylosing spondylitis and HLA B27. Indeed, the link between HLA B27 and ankylosing spondylitis could elucidate several observations:

1. The family clustering as discussed above. HLA B27 is inherited as an autosomal codominant characteristic, 50 per cent of first-degree relatives of probands with HLA B27 possessing the antigen.
2. Uveitis is a common accompaniment of ankylosing spondylitis. HLA B27 is found in some 40 per cent of individuals with acute unilateral self-limiting uveitis, even in the absence of underlying rheumatological disease.
3. Many patients with Reiter's disease develop sacroiliitis. Overall, some 80 per cent of patients with reactive arthropathy are HLA B27 positive, those developing sacroiliitis and ascending spinal disease being more closely linked to HLA B27. Whether the sacroiliitis in such patients should be considered a complication of Reiter's syndrome or a further manifestation of the HLA B27 status remains unclear.
4. Juvenile chronic arthropathy, psoriatic arthropathy, and inflammatory bowel disease can all be associated with sacroiliitis and ankylosing spondylitis and it is known that HLA B27 is increased in all three groups who have a spondylarthropathy picture.

For a further discussion of the link between HLA B27 and the spondylarthropathies, the reader is directed to Chapter 5.5.1 and elsewhere. Herein some further clinical aspects may be summarized:

1. Some 5 to 10 per cent of HLA B27 positive individuals develop ankylosing spondylitis after an unknown environmental event and 20 per cent of subjects with HLA B27 develop reactive arthropathy after contact with an arthritogenic agent (chlamydia, salmonella, etc.).
2. Up to 5 per cent of Caucasian patients with ankylosing spondylitis are not HLA B27 positive.
3. Only 50 per cent of those with psoriatic or enteropathic spondylitis are B27 positive.
4. The association between ankylosing spondylitis and HLA B27 in non-Caucasians (around 50 per cent) is much less than that seen in Caucasians.
5. Relatives of probands with both sacroiliitis and HLA B27, even when carrying an identical HLA haplotype, frequently remain disease free.
6. The Pima and Haida Indians, both with a high frequency of HLA B27, develop ankylosing spondylitis frequently but Reiter's syndrome rarely, if ever. By contrast, the Navaho Indians and Alaskan Inupiat Eskimos develop Reiter's syndrome more frequently than ankylosing spondylitis.
7. Ankylosing spondylitis and Reiter's syndrome tend to 'breed true' within families (Calin *et al*. 1984).
8. HLA B27 relatives of HLA B27-positive patients are 20 times more likely to develop ankylosing spondylitis than are HLA B27-positive relatives of healthy HLA B27 subjects. The distribution of HLA B27 among different healthy and disease groups is summarized in Chapter 5.5.2, Table 2, and discussed more fully elsewhere (Calin 1989; Calin and Elswood 1989a; De Castro 1994; Inman and Schfield 1994; Khan 1996; Toivanen and Toivanen 1996; Lopez-Larrea *et al*. 1996; Scofield 1996; Braun and Sieper 1996).

	Males	Females

Table 2 Major differences between ankylosing spondylitis in men and in women

9. Some 11 subtypes of HLA-B27 are now recognized.

Prevalence (see van der Linden and van der Heijde 1996)

With the increased awareness and interest in the disease, many patients who previously were thought to have mechanical back pain, 'seronegative rheumatoid arthritis', and other disorders are now recognized as having ankylosing spondylitis. The true prevalence of ankylosing spondylitis appears to be in the region of 0.25 to 1 per cent with a peak of 2 per cent in northern Norway. The figures contrast sharply with older data reporting a ratio of ankylosing spondylitis to rheumatoid disease of about 1:15.

Several studies of blood donor populations suggest that up to 20 per cent of HLA-B27-positive individuals develop symptomatic ankylosing spondylitis, the majority of whom did not carry a diagnosis. Of interest, some 20 per cent of HLA-B27-positive individuals develop reactive arthropathy/Reiter's syndrome following infection with an arthritogenic trigger. Other studies have suggested that some 10 per cent of individuals with HLA-B27 develop ankylosing spondylitis (Dawkins *et al*. 1981), while up to 20 per cent of Pima and Haida men with HLA-B27 have the condition.

The prevalence and nature of spondylarthropathy varies in different ethnic groups. For example, Boyer *et al*. (1994) identified 104 cases of spondylarthropathy in an Eskimo population, a prevalence of 2.5 per cent in adults aged 20 years and over. They found undifferentiated spondylarthropathy and reactive arthropathy to be more common than ankylosing spondylitis *per se*. Strikingly, they found the prevalence of spondylarthropathy to have an equal sex distribution. Of note, although the prevalence of HLA-B27 is in the range of 20 to 40 per cent, the number of cases of spondylarthropathy was not as high as that found among the Canadian Haida Indians (6 to 10 per cent) (Braun *et al*. 1994). Elsewhere, Alexeeva *et al*. (1994) studied the prevalence of spondylarthritis amongst the native population of Chukotaa in Russia. Among these circumpolar subjects, they found the prevalence of spondylarthropathy to be 2.5 per cent, with 1 per cent having ankylosing spondylitis. HLA-B27 occurred in 34 per cent of the population. Nasution *et al*. (1993) found intriguing data in Indonesia. Specifically, HLA-B27 was found in 62 per cent of the Chinese patients with ankylosing spondylitis compared with under 3 per cent among the healthy controls. In contrast, only 8 per cent of the native Indonesians with disease were HLA-B27 positive compared with 9 per cent of the healthy controls, indicating the lack of association between HLA-B27 and disease in native Indonesians. Finally, Mijiyawa (1993) found spondylarthritis in 31 of 2000 patients in Lomé, Togo. In this population eight patients were HIV carriers. They therefore concluded that spondylarthropathy would appear to be less rare in black Africans than hitherto considered. Moreover, the frequency is likely to rise with the increase in HIV prevalence.

Delay in diagnosis

Until recently delays of between 5 and 10 years were recorded between the onset of symptoms and the diagnosis at last being made. There are now preliminary data suggesting that this delay is decreasing (Calin *et al*. 1988).

Sex distribution

That ankylosing spondylitis may occur much more frequently in females than hitherto suggested has been confirmed by several studies. In our large series in Britain, the sex ratio is in the region of 2.5 to 1 in favour of men, a figure confirmed by other studies. Distinguishing features between men and women with disease are discussed below (and see Table 2) (Will *et al*. 1990a; Kennedy *et al*. 1993).

Racial distribution (see Khan 1990; Khan 1996)

It has long been recognized that ankylosing spondylitis occurs more frequently in Caucasian populations. In fact it appears that ankylosing spondylitis roughly follows the distribution of HLA-B27. For example, in the American Indian where HLA-B27 prevalences have been reported ranging from 18 to 50 per cent, ankylosing spondylitis is particularly frequent, whereas the condition is less common in the black American, where HLA-B27 has a prevalence of 3 to 4 per cent, and correspondingly rarer in black Africans, where HLA-B27 occurs in under 1 per cent. Strikingly, the association with HLA-B27 is less dominant in those races where this phenotype is less frequent (e.g. only 60 to 70 per cent of Japanese patients are HLA-B27 positive; the frequency of which in the general population is correspondingly low (1 to 2 per cent)).

Age distribution (see Kennedy et al. 1994)

Sacroiliac and spinal disease usually develop in the late teenage years or in the early twenties in primary ankylosing spondylitis, whereas in those with secondary forms of disease, older ages at onset are seen. Interestingly, in the developing world, ankylosing spondylitis occurs more frequently at a younger age, teenagers with onset of disease being frequently found. By contrast, in the developed world onset in the mid- to late twenties is relatively more common. As discussed in Chapter 5.5.1, there may well be a changing pattern in disease. Our studies (Will *et al*. 1990b; Will *et al*. 1992) have suggested that within France and Britain the age at onset of ankylosing spondylitis is increasing. The fact that different studies using different epidemiological techniques have produced these findings is of particular interest.

Pathological features

The unique pathology of ankylosing spondylitis and the spondylarthritides was clearly defined in 1971 by Ball and developed further by Bywaters (1984). In contrast to the situation in rheumatoid disease the primary pathological site is the enthesis (insertion of ligaments and capsules into bone) rather than the synovium. In addition, the enthesopathic change is characterized by fibrosis and ossification rather than joint destruction and instability. In the spine, enthesopathic changes at the site of insertion of the outer fibres of the anulus fibrosus result in squaring of vertebral bodies (Fig. 2), vertebral end-plate destruction, and syndesmophyte formation (Fig. 3). The enthesis is a metabolically active site, perhaps explaining why early changes in ankylosing spondylitis occur during growth in the teenage years. In spite of our understanding about HLA-B27 and the pathology we still do not understand why the enthesis preferentially becomes affected.

Fig. 2 Squaring of lumbar vertebral body in ankylosing spondylitis. Note sclerosis of bone at site of enthesopathic change at insertion of anterior fibres of the annulus fibrosis.

Fig. 3 Note syndesmorphytes between vertebral bodies. These are vertically directed new bone lesions associated with normal joint space.

In summary, ossification occurs in the region of the discs, the epiphyseal and sacroiliac joints and extraspinal sites, initiated by lesions at the site of ligamentous insertion. Synovitis itself does occur in peripheral joints and a proliferative synovitis can mimic that seen in rheumatoid disease. For reasons that we do not yet understand, soluble HLA Class II antigens are found in high levels in the synovial fluid in both rheumatoid arthritis and degenerative arthritis but in very low levels in spondylarthritis (Armas *et al*. 1990).

Clinical features

Ankylosing spondylitis will only be diagnosed when there is a high index of suspicion in a patient presenting with back pain of an inflammatory nature. In any such individual the differential diagnosis relates to mechanical dysfunction. The two conditions are contrasted in Table 3.

	Mechanical	Inflammatory
Pain history	+	++
Family history	–	+
Onset	Acute	Insidious
Age (years)	15–90	< 40
Sleep disturbance	+	++
Morning stiffness	+	+++
Involvement of other systems	–	+
Effect of exercise	Worse	Better
Effect of rest	Better	Worse
Radiation of pain	Anatomic (S1, L5)	Diffuse (thoracic, buttock)
Sensory symptoms	+	–
Motor symptoms	+	–
Scoliosis	+	–
Range of movement decreased	Asymmetrically	Symmetrically
Local tenderness	Local	Diffuse
Muscle spasm	Local	Diffuse
Straight-leg raising	Decreased	Normal
Sciatic nerve stretch	Positive	Absent
Hip involvement	–	+
Neurological	+	–
Other systems	–	+

Table 3 Differential findings in mechanical and inflammatory back pain

We have demonstrated a striking loss of bone mineral content in early disease (Will *et al*. 1990c). Juxta-articular and generalized osteoporosis are well recognized in rheumatoid disease but the relative role of hormonal factors, immobility, drug therapy, and the disease process is unclear. As discussed, ankylosing spondylitis is characterized by inflammation at the site of the enthesis which can lead to local bone erosion and juxtainsertional osteoporosis, followed by new bone formation. Although it has long been recognized that patients with severe ankylosing spondylitis may develop a dorsal kyphosis with some anterior wedging of the vertebrae, early osteoporosis has not until now been recognized. Whether the pattern of bone loss relates to tumour necrosis factor or other mediators remains unclear. HLA-B27-positive brothers of HLA-B27-positive patients have normal bone density. To what extent this early osteoporosis in patients who have normal spine mobility should be considered an early pathological marker, with changes at the enthesis being secondary in nature, is unknown.

Spinal symptoms

Late spinal complications

Few patients progress relentlessly to the classical late 'bamboo spine' (Fig. 4 and Fig. 5). The fused spine may fracture (Fig. 6) following trivial or even unrecognized injury and microfractures and clinical fractures are relatively common in severe ankylosing spondylitis. The spinal deformity may make it difficult to see a fracture site, particularly in the low neck, and special views may be required. The fracture may be clinically silent or a dramatic event which can be fatal in outcome. A sudden exacerbation of back pain, spontaneously or following mild trauma, may relate to a fracture or a localized defect of the vertebral end plate (destruction of the disc–bone border). Spondylodiscitis is the term given to this lesion and may require rest and analgesia, with pain decreasing over 2 or 3 weeks. This contrasts with the usual exercise programme required for patients. The nature of spondylodiscitis and its prevalence has recently been defined in a cross-sectional study of over 100 patients, some 12 per cent of whom had radiological evidence of discitis, though often asymptomatic in nature (Kabasakal *et al*. 1994).

Fig. 4 Cervical spine in severe ankylosing spondylitis. Note fusion of facetal joints and anterior fusion of bodies with squaring of vertebrae.

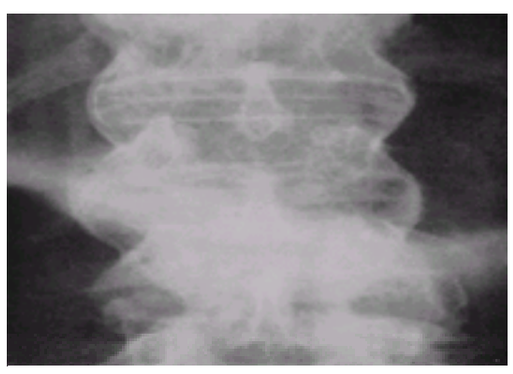

Fig. 5 Fused lumbar spine vertebrae with syndesmorphytes linking vertebrae.

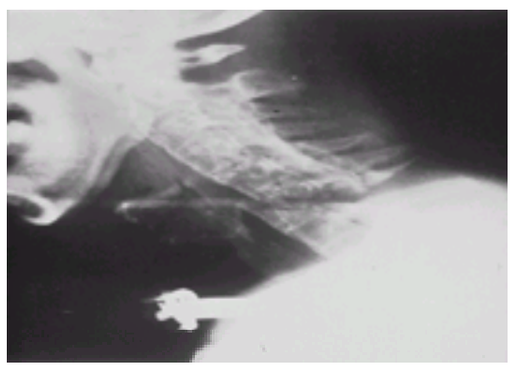

Fig. 6 Fracture of fused cervical spine in ankylosing spondylitis following minimal trauma—note defect in C6.

Extraspinal joint disease

Some 20 to 40 per cent of patients have peripheral joint disease at some stage during their illness. This may be asymmetric and often affects the lower limbs predominantly. Hip (Fig. 7) ankylosis and shoulder disease may provide major disability, with temporomandibular joint dysfunction occurring in up to 10 per cent of patients. HLA-DR4 may be associated with peripheral joint disease.

Fig. 7 Bilateral hip arthropathy in a female with ankylosing spondylitis. Note joint space reduction and erosive change in heads of femora.

We have recently shown that there is a striking inverse correlation between the age at onset of disease and hip involvement; the vast majority of individuals requiring a total hip replacement having onset of disease during the teenage years. Hip involvement in those with onset in the twenties or later is vanishingly rare. For those requiring hip replacement, bilateral surgery is frequent. The long-term outcome for those with total hip replacements is excellent, the majority doing well some 10 years after replacement (Calin and Elswood 1989b).

Enthesopathic lesions

In view of the pathological disorder it is not surprising that patients have insertional tendinitis at any site typified by involvement of the Achilles tendon, intercostal muscle insertions, plantar fasciitis, and dactylitis.

Apart from low back pain some patients have a 'pleuritic' type of chest pain that may cause sleep disturbance and anxiety. This pain is worse on inspiration and relates to an insertional tendinitis of the small costosternal and costovertebral muscles.

Extra-articular disease

Until recently ankylosing spondylitis was predominantly considered to be a spinal disease with little constitutional systemic involvement. It is now recognized that the disorder may affect all body systems and indeed may not be immunologically silent.

General symptoms

Constitutional features include fatigue, weight loss, low grade fever, hypochromic or normochromic anaemia, and increased erythrocyte sedimentation rate. For many patients, fatigue is the major component. We have shown (Calin *et al*. 1993a) that in a comparison of pain, stiffness, and fatigue, the three major features of ankylosing spondylitis, the last of these has been a major component for a large minority. The main difficulty relates to management. Exercise and anti-inflammatory drugs are good for both the pain and stiffness but, to date, fatigue remains a frustrating symptom to treat. Certain features such as an arthropathy and uveitis can occur at any time in the course of the disease; other problems are predominantly associated with severe chronic involvement. Examples of the latter include aortic regurgitation, cord compression, upper lobe pulmonary fibrosis, and amyloid deposition.

Eye disease

Iritis (Fig. 8) occurs in up to 40 per cent of patients with ankylosing spondylitis and, as mentioned, has little correlation with the disease activity in the spine. Although the visual episodes are often self-limiting, local steroid drops or systemic therapy may be required. In a recent study (Edmunds and Calin 1991) we have shown that there is no relationship between the inflammation of the uveal tract and spine. In addition we failed to define any obvious environmental trigger even in those with recurrent disease. For example, there is no seasonal pattern.

Fig. 8 An example of severe recurrent iritis with both active change and evidence of old damage.

Pulmonary involvement

Chronic infiltrative and fibrotic changes in the upper lobe of the lungs may occur. This upper lobe pulmonary fibrosis is now well recognized. Cough, sputum, and dyspnoea may develop with the sputum becoming profuse. Radiographs reveal usually bilateral upper lobe pulmonary fibrosis, sometimes with cyst formation and parenchial destruction. The lesions can be invaded by aspergillus with changes mimicking tuberculosis. Histology reveals patchy pneumonia with round cell and fibroblast infiltration progressing to interalveolar fibrosis. Dense pleural and pulmonary fibrosis can occur. Treatment is of no avail and death may follow massive haemoptysis.

A rigid chest wall may result from fusion of the thoracic joints but pulmonary ventilation is usually well maintained by the diaphragm. In an analysis of deaths in patients with ankylosing spondylitis Court-Brown and Doll (1965) noted deaths from respiratory causes to be some three times higher than in a control population.

Cardiovascular disease

Cardiovascular involvement is well recognized. The stated prevalence of this complication varies from 3.5 per cent of cases within 15 years to 10 per cent with up to 30 years duration. Although heart disease occurs more frequently in those with more severe spondylitis, cardiac conduction defects and other abnormalities may occur in those with minimal disease.

Aortic incompetence, cardiomegaly, and persistent defects in cardiac conduction are the most common findings with complete atrioventricular block occasionally occurring. Pericarditis has been described and cardiac involvement can range from being clinically silent to dominating the picture.

Aortic incompetence is the best studied complication. Up to 20 per cent of patients with ankylosing spondylitis may have anatomic evidence of involvement of the aortic valve but few of these have clinically detectable valvular dysfunction. Scar tissue and intimal fibrous proliferation may affect the aortic valve cusps and aorta behind and above the sinuses of Valsalva. Scar tissue may extend below the base of the aortic valve producing a subaortic fibrous ridge. Occasionally the aortitis is evident before any evidence of ankylosing spondylitis and the condition can thus be considered a *forme fruste*, similar to the occurrence of uveitis in a HLA-B27-positive individual without underlying rheumatological disease.

Amyloidosis

Amyloid is an occasional complication of ankylosing spondylitis. In one study, 3 of 35 patients were found to have amyloid on routine rectal biopsy. Although relatively common the event is rarely of clinical significance.

Renal disease

There appears to be no impairment of renal glomerular function in ankylosing spondylitis, in spite of the recognized pathological changes. In a study of 38 consecutive patients with severe ankylosing spondylitis, investigation of glomerular function failed to show any marked abnormality (Calin 1975). Nevertheless, immunoglobulin A (IgA) nephropathy is well recognized. However this appears to be of relatively little clinical significance.

Neurological syndromes

Involvement of the cauda equina may occur in the later stages of the disease. The syndrome presents with insidious onset of leg and buttock pain with sensory and motor impairment in association with bowel and bladder dysfunction. Lumbar diverticulae are found on myelographic examination. Unfortunately, treatment appears to be of no help, but a single case report suggests the value of a peritoneal shunt in one of our patients in whom the deterioration has been arrested.

Bowel disease (see Mielants et al. 1993a; Mielants et al. 1993b)

As discussed above and in Chapter 5.5.2 there is an intimate relationship between the bowel and ankylosing spondylitis. Low-grade bowel inflammation has been described (on ileocolonoscopy) in the absence of symptoms. The relevance of these findings remains unclear, although we know that the HLA-B27-positive transgenic rat develops a picture typical of spondylarthropathy with a major degree of bowel involvement. There is also a suggestion that there is increased gut permeability in patients and relatives, perhaps relating to disease pathogenesis (Martinez-Gonzalez *et al*. 1994).

Physical examination

Spinal mobility is symmetrically decreased but may still be normal in the earlier stages of disease. A variety of measurements have been described, although the modified Schober is the most useful. The distraction of a line drawn from the midpoint between the posterior iliac spines to an arbitrary site 10 cm above this point is measured and the distraction noted on forward flexion. In a normal individual this 10 cm line increases by some 50 to 100 per cent whereas a patient with active disease may only have a distraction of some 20 per cent or less. Lateral spinal flexion may be measured by noticing the distraction on contralateral flexion of a line drawn in the midaxillary plane. As mentioned above, chest expansion can be reduced, although this may only occur late in the disease. Moreover, in the female—for obvious reasons—chest expansion is difficult to measure precisely. Intermalleolar straddle on abducting the legs is a useful measurement of non-specific pelvic inflammation, and neck mobility can be measured. A formal approach to defining mobility in disease has now been validated (the Bath Ankylosing Spondylitis Radiology Index, BASRI) (Jenkinson *et al*. 1994).

There may be muscle spasm with loss of the normal lumbar lordosis, while some individuals may present with pain but no physical abnormality. Peripheral joints may be normal or grossly involved— particularly in women, who tend to have more peripheral joint disease than men.

Radiological evaluation

The five grades of sacroiliitis introduced by the New York Criteria range from 0 to 4. These are summarized in Table 4. Grade 0 refers to normal joints with clear sacroiliac margins and uniform joint space. There is no juxta-articular sclerosis. Grade 1 signifies suspicious change but no definite abnormality, while grades 2 and 3 relate to an increasing degree of sacroiliitis, as defined by blurring of the joint margin, juxta-articular sclerosis, decreased joint width, and erosive change. Grade 4 describes complete fusion or ankylosis of the joints with or without residual sclerosis.

Grade	
0 Normal	Grade depends on degree
1 Suspicious	of blurring of joint margins,
2 Minimal sacroiliitis	juxta-articular sclerosis,
3 Moderate sacroiliitis	erosive change, and
4 Ankylosis	narrowing

[a]According to New York criteria

Table 4 Sacroiliac changes in ankylosing spondylitis [a]

A single anteroposterior view radiograph of the pelvis is sufficient. Sacroiliitis does not occur as an age-related phenomenon although degenerative change of the sacroiliac joints may occur. Osteitis condensans ilii, a sclerotic condition of unknown cause producing dense bone in one or both iliacs but not the sacrum, may confuse the unwary. However, typically this iliac change allows the joint margin to be defined more clearly and therefore there should be no confusion between the two conditions. It is not unknown for an individual patient to have both sacroiliitis and osteitis condensans ilii.

Patients with bilateral, grade-4 sacroiliitis and no extrapelvic disease are frequently seen. Why some patients do not have progressive disease above the pelvic rim remains unclear.

In view of the enthesopathic nature of the disease it is not surprising that radiological changes occur elsewhere. Thus, vertebral squaring may occur, vertebral-end plate collapse may be seen, and varying degrees of ossification develop. The radiological changes may be contrasted with those seen in diffuse idiopathic hyperostosis (Table 6). Likewise syndesmophytes must be differentiated from osteophytes; the latter associated with disc-space narrowing. In essence, syndesmophytes move in a vertical direction whereas osteophytes are typically horizontal. McEwen *et al*. (1971) have defined the radiological differences between primary ankylosing spondylitis and the secondary spondylarthropathies, as summarized in Table 5. The BASRI allows for a simple and rapid assessment of entire spine and hips (Pande *et al*. 1995).

	Primary ankylosing spondylitis — and ankylosing spondylitis associated with inflammatory bowel disease	Ankylosing spondylitis associated with Reiter's syndrome and psoriatic arthropathy
Sacroiliac changes	Symmetrical	Asymmetrical
Osteitis pubis	++	+
Facetal joint involvement	+++	+
Squaring of vertebrae	++	+
Syndesmophytes	+++	+
Ossification	++	+
Spread	Ascending	Random

Table 5 Radiographic changes in primary and secondary forms of ankylosing spondylitis

	DISH	Ankylosing spondylitis
Usual age of onset (years)	> 50	< 40
Thoracolumbar kyphosis	±	++
Limitation of spinal mobility	±	++
Pain	±	++
Limitation of chest expansion	±	++
Radiography:		
Hyperostosis	+	+
SI joint erosion	–	++
SI joint synovial obliteration	±	++
SI joint ligamentous obliteration	+	++

ALL ossification	++	±
PLL ossification	+	0
Osteoporosis/lysis	–	++
Enthesopathies (whiskering) with erosions	–	++
Enthesopathies (whiskering) without erosions	++	+
HLA-B27 (white patients) (%)	6	95
HLA-B27 (black patients) (%)	2	50

[illegible] ALL, anterior longitudinal ligament; PLL, posterior longitudinal ligament.

Table 6 Differentiating features of diffuse idiopathic skeletal hyperostosis (DISH) and ankylosing spondylitis. Of note osteoporosis is an early and dramatic finding in ankylosing spondylitis (Will *et al*. 1989)

Radionuclide scanning may be more sensitive than radiography but the change is non-specific and is likely to confuse rather than help. Likewise computed tomography and MRI is expensive and usually unnecessary.

Ankylosing spondylitis and diffuse idiopathic skeletal hyperostosis are compared in Table 6. Osteoporosis is now well recognized as is the consequence (i.e. compression fractures) (Donnelly *et al*. 1994; Mullaji *et al*. 1994).

Laboratory abnormalities

Apart from the presence of HLA-B27 in over 95 per cent of white patients, the majority have no evidence of change in laboratory tests. In fact there is little correlation between erythrocyte sedimentation rate and other so-called mediators of inflammatory disease and disease activity as defined by clinical symptoms and findings. Serum alkaline phosphatase may be elevated and we and others have described elevated serum creatine phosphokinase levels. The explanation for this remains unclear. Circulating immune complexes may be found and one study suggested that psoriasis-associated retrovirus-like particles may be present. Likewise antibodies to proteoglycan occur and antibodies to heat shock protein are described. Interleukin 6 and acute phase reactants have recently been compared (Tutuncu *et al*. 1994). Interleukin 6 is more frequently raised in disease, compared to the situation with erythrocyte sedimentation rate, plasma viscosity or C-reactive protein (approximately 80 per cent compared with 50 per cent).

Ankylosing spondylitis in women

The disease is frequently missed in women unless a high degree of suspicion exists. Moreover certain features of the disease in women make definition of the disease more difficult. The major differences between the disease in men and women are summarized in Table 2. Women tend to have more peripheral joint involvement and the spinal disease progresses less rapidly. However, dramatic spinal involvement in women as in men is sometimes seen. Historically, the delay in diagnosis is greater in women than men but hopefully this difference is now decreasing. Interestingly, the sex distribution of primary ankylosing spondylitis favouring men in the ratio of 2.5 to 1 is even greater in psoriatic spondylitis (4 to 1), but for those with enteropathic disease the ratio is equal. Age is also a factor (Kennedy *et al*. 1993; Kennedy *et al*. 1994).

The sex ratio is said to favour males (about 6:1 in the early teenage years) but this ratio decreases with increasing age. By the late twenties the ratio is down to 2.3 to 1 with intermediate ratios in the ages between. However, our recent data suggest that even in teenagers, the ratio is approximately 3:1 in favour of boys.

Aetiology (see Khan 1993; Khan 1996; Rubin *et al*. 1994; Reveille *et al*. 1994 and further discussion in Chapter 5.5.1)

The cause of ankylosing spondylitis remains unknown. For the last decade interest has focused on a specific klebsiella serotype and the putative relationship between this organism and HLA-B27-positive lymphocytes of patients. However, it appears more likely that many different organisms can precipitate disease in susceptible individuals. The relationship between HLA-B27, other genes (Burney *et al*. 1994), and the environment is under intense scrutiny. As discussed more fully in Chapter 5.5.1 there are several recognized facts that must be taken into consideration:

1. Approximately 5 to 10 per cent of HLA-B27-positive individuals develop ankylosing spondylitis—a similar percentage to those who develop reactive arthropathy following infection with an arthritogenic organism.
2. Relatives of healthy HLA-B27-positive subjects only rarely develop disease while those of HLA-B27-positive patients are more likely to do so.
3. Both ankylosing spondylitis and Reiter's syndrome breed true within families.
4. The prevalence of ankylosing spondylitis follows the distribution of HLA-B27—where the latter is rare the association is less close.
5. Some 5 per cent of individuals with ankylosing spondylitis are HLA-B27 negative.
6. Certain ethnic groups such as the Haida and Pima are likely to develop ankylosing spondylitis while others such as the Navaho and Inupiat Eskimo develop Reiter's syndrome.
7. HLA-B27 is heterogeneic with some 11 subtypes recognized. To date few differences have been found between HLA-B27-positive patients and HLA-B27-positive controls. HLA*2706 and 09 may protect against disease in the Thai and Indonesians. and in Sardinia, respectively (Lopez-Larrea *et al*. 1996).
8. Serum IgA and secretory IgA are raised in spondylitics.
9. Iliocolonoscopic biopsy evaluation of the distal small bowel reveals some clinical inflammation in both HLA-B27-positive and -negative individuals, regardless of bowel symptoms.
10. Diet may modify arthritis in animals and perhaps in humans.
11. Silent carriage of certain microorganisms can precipitate disease in reactive arthritis.
12. There may be influence from genetic loci on chromosomes 2, 14, 19, and perhaps others.
13. There is apparent sharing of homologous amino-acid sequence by HLA-B27 (host antigen residue 72 to 77) and *Klebsiella pneumoniae* (residues 188 to 193). Moreover, there is cross-reactivity between plasmid and HLA-B27 and between HLA-B27 and heat shock protein.
14. The link between psoriasis, inflammatory bowel disease, and ankylosing spondylitis must not be forgotten.
15. Sulphasalazine, which is efficacious in the management of inflammatory bowel disease, has at least some effect in modifying the disease process in ankylosing spondylitis.
16. That ankylosing spondylitis is not immunologically silent is now recognized. Immunoglobulin allotypes are similar to those of controls.
17. Animal models are of major value. The adjuvant rat and the HLA-B27-positive transgenic rat and mice models will certainly further elucidate the situation. The latter suggests that HLA-B27 itself is of paramount importance.
18. Calin *et al*. (1993b) compared familial ankylosing spondylitis with sporadic diseases and determined that familial disease tended to be milder than the sporadic version, suggesting that the latter had fewer susceptibility but more severity genes in contrast to the former.

Prognosis

The outcome for an individual patient is difficult to define. Some patients have disease limited to the pelvis while others have progressive intractable inflammation of spine and elsewhere. HLA-B27 homogeneity is not associated with more severe disease. In an attempt to define entry variables leading to poor outcome we have recently shown that some 15 per cent of patients younger than 15 years of age at onset require one or more total hip replacements within 18 years compared with only 1 per cent of those in their late twenties. Clearly the developing hip is at particular risk.

Sib pairs concordant for disease (Calin and Elswood 1989a) have a similar disease process from the radiological standpoint but for the fact that the age at onset appears to be determined by environmental rather than genetic factors (i.e. the sib pairs share the same calendar date at onset rather than a similar age at onset). The younger sib is more likely to develop hip involvement as discussed above. By contrast, offspring concordant for disease with their parent develop a disorder that relates only little to the prior generation. Lehtinen (1993) has studied the nature of mortality and causes of death in 398 patients with ankylosing spondylitis. There are no major surprises. Patients died from cardiovascular causes, amyloidosis, and sometimes the effect of treatment.

In an attempt to define predictive factors in spondylarthropathy, Amor *et al*. (1994) suggested that early hip involvement, an erythrocyte sedimentation rate over 30, poor initial response to non-steroidal anti-inflammatory drug treatment, a decreased Schober, the presence of dactylitis or oligoarticular disease, and age at onset below 16 years were all associated with a worse prognosis. We would agree but also add lower social-educational background. In addition, sporadic disease (Calin *et al*. 1993b) would appear to have a worse prognosis than the familial disorder.

The story is further complicated because we have to develop an understanding not only of the natural history of ankylosing spondylitis but also of the effect of treatment. As recently discussed (Calin 1994), the situation in ankylosing spondylitis is infinitely more difficult than that for rheumatoid disease or systemic lupus erythematosus. In the study of outcome, in spondylitis, we do not have the advantage of valuable laboratory tests. We therefore need to rely much more on what the patient tells us. Happily, we know from data provided by Hidding *et al*. (1994) that there is an excellent correlation between the self-report of symptoms and observed status in patients with ankylosing spondylitis, in contrast to the situation in those with fibromyalgia and, to a lesser extent, rheumatoid arthritis.

Defining disease status in ankylosing spondylitis

We have recently developed and validated self-administered instruments that define disease status in ankylosing spondylitis (Garrett *et al*. 1994) and functional ability (Calin *et al*. 1994). The Bath Ankylosing Spondylitis Disease Activity Index and the Bath Ankylosing Spondylitis Functional Index, together, define with clarity and simplicity the clinical status of patients with this condition. These two self-administered instruments, in addition to an objective measurement (the Bath Ankylosing Spondylitis Metrology Index) will allow many more studies in terms of natural history and response to management. The Metrology Index (Jenkinson *et al*. 1994) consists of five simple measurements of cervical rotation, tragus to wall distance, lateral spinal flexion, modified Schober, and intermalleolar distance. Finally, we have produced the Bath Ankylosing Spondylitis Global Status, which allows the definition of the different components of clinical well-being, or otherwise, to be defined and compared (Pande *et al*. 1995), and the Bath Radiology Index (BASRI).

Management: general considerations (see Cuellar and Espinoza 1996)

The majority of patients with ankylosing spondylitis have good prognosis for a successful life pattern, despite chronic discomfort over many years. The disease progresses to severe and total ankylosis in relatively few patients. A summary of treatment is given in Box 1.

Box 1 Treatement of ankylosing spondylitis

The patients should stop smoking. The combination of chest and pulmonary disease is a tragic occurrence. Swimming is the best routine sport to pursue. For those few individuals with relentless disease, admission to an active rehabilitation unit is advisable. Hydrotherapy and aggressive remedial exercises provide benefit over the short term and our ongoing studies are addressing the long-term outcome in a controlled study.

Postural exercise

The patient must realize that the aim of therapy is to maintain normal posture and physical activity. A hard bed at night is more useful than a soft mattress. One pillow only should be used. Extension exercises should remind the patient that the natural tendency of the disease is towards flexion and loss of height. Thus, extension exercises must be performed at least twice daily. A hot shower provides decreased stiffness and allows the exercise regimen to be followed. During the day, adequate attention must be given to the position of work, the style of chairs, and the chance for mobility.

One major difficulty for the patient with ankylosing spondylitis is that of fatigue. Our recent study suggests that low-dose amitriptyline at night may ameliorate this phenomenon (Koh *et al*. 1996).

Therapy

There are few well-controlled studies comparing different agents. Phenylbutazone was for a long time the drug of choice but this agent has fallen into disrepute, although we still favour its use in those with severe disease who do not respond to indomethacin or other agents. Indomethacin is usually considered the drug of choice and we use the slow-release preparation of 75 mg given once at night or twice daily. Patients are advised to titrate the dosage downwards, some requiring one tablet every other night or simply one tablet once or twice weekly. Indeed, it is likely that although indomethacin has been available for some 30 years, there is no

newer non-steroidal anti-inflammatory drug with greater efficacy. For the majority of patients indomethacin is still the favoured agent (Calin and Elswood 1990).

Sulphasalazine has been shown in a meta-analysis to be efficacious when compared with placebo. The improvement is perhaps not dramatic and needs to be weighed against the relative cost and the inevitable need for blood testing. In a European-wide study of sulphasalazine in patients with ankylosing spondylitis, reactive arthropathy, and psoriatic spondylarthropathy, we have shown that sulphasalazine has a small role to play, particularly in those with peripheral stigmata (Dougados *et al*. 1995) We have recently focused on patients' perception of drug risks and preparedness to take this risk (O'Brien *et al*. 1990a; O'Brien *et al*. 1990b). Finally, we await with interest, outcome studies relating to a controlled evaluation of inpatient compared with outpatient management.

Other drug therapy includes auranofin, which appears to be only minimally efficacious if at all, and possibly azathioprine. Surgical treatment is indicated, particularly for hip replacements, but also vertebral wedge osteotomies may be done in order to correct deformity.

Radiotherapy

Radiotherapy may be of limited value but it has fallen into disrepute because of the risk of leukaemia. A retrospective case–controlled study comparing those who had received radiotherapy and those who had not (Calin and Elswood 1989c) showed that radiotherapy may have had little more than minimal effect in altering the course of the disease.

Genetic counselling

Family members of patients with ankylosing spondylitis and other HLA-B27-related arthropathies are advised against routine typing. It is important for the family and physician to have knowledge regarding the disease in order that this can be recognized early on in family members.

The National Ankylosing Spondylitis Society (NASS)

In Britain there is a flourishing patient association known as the National Ankylosing Spondylitis Society and this has now been followed in many other countries around the world. All patients should be directed to their national association where membership provides excellent educational material, newsletters, and advice about everyday and professional activities. For information regarding NASS or the international body contact: The Director, Mr Fergus Rogers, National Ankylosing Spondylitis Society, 5 Grosvenor Crescent, London, SW1X 7ER (Tel. 0171 235 9585; Fax 0171 235 5827).

Summary

Ankylosing spondylitis is a common disease. There are still many aspects of the disorder that remain poorly understood, both in terms of aetiology and natural history. For example, an epidemiological study suggested that even in the absence of specific and recognized complications, the death rate in patients with ankylosing spondylitis is greater than in matched controls (Radford *et al*. 1977). Nevertheless the physician and patient can usually remain optimistic about the long-term outlook. The vast majority of patients are following a satisfying professional, personal, and family life.

5.5.4 Psoriatic arthritis

Dafna D. Gladman

Introduction

Psoriatic arthritis is an inflammatory arthritis, associated with psoriasis (Wright and Moll 1976). Its original definition as seronegative for rheumatoid factor, has been replaced by 'usually seronegative' since as many as 15 per cent of the general population, particularly over age 60, may have a positive rheumatoid factor, and rheumatoid factor may be present in more than 10 per cent of patients with psoriasis who do not have arthritis (Gladman *et al*. 1986). The majority of patients with psoriatic arthritis run a benign course. However, in about a fifth of the patients a chronic, progressive, deforming arthritis may develop, resulting in significant joint destruction and limitation of daily activities.

Epidemiology

Psoriasis is a chronic skin condition which affects 1 to 3 per cent of the population (Farber and Scott 1979). The association between psoriasis and arthritis might be fortuitous. Since psoriasis is a common condition, and arthritis, particularly osteoarthritis, is quite prevalent, it is conceivable that psoriasis and some unrelated form of arthritis may occur in the same patient. Indeed, some patients with psoriasis do present with a coincidental rheumatoid arthritis, or osteoarthritis. Cats (1990) has argued that psoriasis is just a measure of disease expression in certain patients with peripheral arthritis and spondylarthropathy. However, epidemiological evidence described below supports the notion that psoriatic arthritis is a distinct form of arthritis associated with psoriasis.

Although the first description of arthritis associated with psoriasis was provided by Aliberti (Eccles and Wright 1985; O'Neill and Silman 1994), psoriatic arthritis was considered to be a variant of rheumatoid arthritis until forty years ago. Epidemiological studies over the past four decades have confirmed the association between psoriasis and arthritis. These studies have shown an increased frequency of arthritis among patients with psoriasis and an increased prevalence of psoriasis among patients with arthritis. Thus, 6 to 42 per cent of patients with psoriasis may have psoriatic arthritis (Table 1), while the prevalence of arthritis in the general population is about 3 per cent. Likewise, the prevalence of psoriasis among patients with seronegative arthritis is reported to be 20 per cent, while arthritis occurs in only 2 to 3 per cent of the general population (Eccles and Wright 1985; O'Neill and Silman 1994). Lawrence *et al*. (1989) recently estimated the prevalence of psoriatic arthritis in the United States to be 0.67 per cent, whereas the overall prevalence for rheumatoid arthritis was estimated at 1.2 per cent.

Authors (year)	Centre	Number of patients studied	Percentage with arthritis
Leczinsky (1948)	Sweden	534	7
Vilanova (1951)	Barcelona	214	25
Little *et al*. (1975)	Toronto	100	32
Leonard *et al*. (1978)	Rochester	77	39
Green *et al*. (1981)	Cape Town	61	42
Scarpa *et al*. (1984)	Naples	180	34

Table 1 The prevalence of psoriatic arthritis among patients with psoriasis

The discovery of the rheumatoid factor and its association with rheumatoid arthritis helped separate psoriatic arthritis as a distinct entity, since patients with arthritis and psoriasis tended to be seronegative. Radiographical features in psoriatic arthritis were found to be different from those of rheumatoid arthritis (Avila *et al*. 1960). A female preponderance was found in rheumatoid arthritis, whereas the gender ratio among patients with psoriatic arthritis was almost equal (Wright and Moll 1976; Eccles and Wright 1985; O'Neill and Silman 1994). Unlike patients with rheumatoid arthritis, patients with psoriatic arthritis may present with a spondylarthropathy. Psoriatic arthritis is therefore classified with the seronegative spondylarthropathies. The studies by Wright and Moll (1976) are notable for presenting the unique features of psoriatic arthritis, and paving the way for other clinical descriptions.

The frequency of psoriatic arthritis has been reported in 6 to 42 per cent of patients with psoriasis (Leczinsky 1948; Little *et al*. 1975; Leonard *et al*. 1978; Green *et al*. 1981; Scarpa *et al*. 1984; Stern 1985; Zanelli and Wilde 1992; Falk and Vandbakk 1993; Barii-Druko *et al*. 1994). The most quoted prevalence of 6.8 per cent (Leczinsky 1948), is based on a study of the prevalence of rheumatoid-type polyarthritis in a population of inpatients with psoriasis. This frequency does not include other patterns of psoriatic arthritis. More recently, Scarpa *et al*. (1984) and Stern (1985) identified 34 per cent and 20 per cent of their psoriatic patients, respectively, to have psoriatic arthritis, while Green *et al*. (1981) reported arthritis in 42 per cent of their outpatients with psoriasis. A recent study of the prevalence of psoriasis in the Lapp population (Falk and Vandakk 1993) identified 17 per cent of patients with psoriasis who had psoriatic arthritis, while a study from Croatia (Barii-Druko *et al*. 1994) found that 9.8 per cent of patients with psoriasis had psoriatic arthritis. Since psoriasis may affect 1 to 3 per cent of the population, and as many as 30 per cent of psoriatic patients may develop psoriatic arthritis, almost 1 per cent of the population may suffer from psoriatic arthritis, which is the expected prevalence of rheumatoid arthritis. This is indeed close to the estimated prevalence of 0.67 per cent reported for psoriatic arthritis in the United States (Lawrence *et al*. 1989). Little *et al*. (1975) and Leonard *et al*. (1978) suggested that psoriatic arthritis was more common in patients with severe psoriasis. Both groups of investigators reported frequencies of 30 per cent of psoriatic arthritis among patients whose psoriasis required admission to hospital. However, psoriatic arthritis may precede the diagnosis of psoriasis in about 15 per cent of the patients (Wright and Moll 1976; Kammer *et al*. 1979; Gladman *et al*. 1987; Jones *et al*. 1994) (Table 2). Moreover, the highest prevalence of psoriatic arthritis was recorded among patients attending an outpatient dermatology clinic in Cape Town (Green *et al*. 1981).

Table 2 Clinical features of psoriatic arthritis in large series

Clinical features

Psoriatic arthritis affects women and men almost equally, usually in their third or fourth decade (Wright 1956; Kammer *et al*. 1979; Green *et al*. 1981; Scarpa *et al*. 1984; Gladman *et al*. 1987). Nail lesions proved to be the only clinical feature which may identify patients with psoriasis destined to develop arthritis (Gladman *et al*. 1986). These lesions occur in close to 90 per cent of patients with psoriatic arthritis (Little *et al*. 1975; Wright and Moll 1976; Kammer *et al*. 1979; Green *et al*. 1981; Gladman *et al*. 1987) and in 46 per cent of patients with psoriasis uncomplicated by arthritis (Gladman *et al*. 1986).

The arthritis is inflammatory in nature. It may affect any peripheral joint, as well as the axial skeleton and the sacroiliac joints. Patients usually present with pain, associated with stiffness, which is more marked in the morning and improves with activity. More than half the patients complain of morning stiffness of more than 30-min duration (Gladman *et al*. 1987). Evidence of inflammation may be detected clinically by the presence of stress pain or tenderness, as well as effusions (Gladman *et al*. 1990a), although these signs may not be as easily detectable as they are in rheumatoid arthritis, since patients with psoriatic arthritis are less tender than patients with rheumatoid arthritis (Buskila *et al*. 1992). The inflamed joints in patients with psoriatic arthritis may have a purplish-red discoloration, a feature which is not often seen in rheumatoid arthritis. The effusions in psoriatic arthritis joints tend to be tense, and are often difficult to detect. There is no predilection to particular joints, with the exception of the distal interphalangeal joints. Roberts *et al*. (1976) suggested that the knees were more commonly involved, as well as the proximal interphalangeal and metacarpophalangeal joints in the three groups they described. Jones *et al*. (1994) found that women tended to have small joints and upper limb involvement, whereas men tended to have axial involvement. Features which appear to differentiate psoriatic arthritis from rheumatoid arthritis clinically are shown in Table 3.

	Psoriatic arthritis	Rheumatoid arthritis
Female preponderance	Uncommon	Common
Distal interphalangeal involvement	Common	Uncommon
Symmetry	Less common	Common
Erythema over affected joint	Common	Uncommon
Back involvement	Common	Uncommon
Enthesopathy	Common	Uncommon
Skin lesions	Common	Uncommon
Nail lesions	Common	Uncommon
Rheumatoid factor	Uncommon	Common
Osteopenia	Uncommon	Common
Osteolysis	Common	Uncommon
Ankylosis	Common	Uncommon

Table 3 Comparison between psoriatic arthritis and rheumatoid arthritis

The spondylarthropathy may present with an inflammatory type of back pain, which is associated with stiffness and improves with activity. Clinical evidence of sacroiliitis may be obtained by specific tests, including the Gaenzlen's manoeuvre, the FABER (flexion, abduction, external rotation of the hip) test, and direct pressure over the sacroiliac joints (Gladman *et al*. 1987; Hanly *et al*. 1988). In some patients restricted range of back movements may be documented, by a reduction of flexion–extension as well as lateral flexion and rotation (Gladman *et al*. 1987; Hanly *et al*. 1988). Unlike ankylosing spondylitis, many of the patients with psoriatic spondylarthropathy are asymptomatic, and demonstrate a full range of back movement (Gladman *et al*. 1987; Hanly *et al*. 1988; Gladman *et al*. 1992b; Gladman *et al*. 1993). In these patients the diagnosis of the spondylarthropathy is made radiographically.

Clinical spectrum of psoriatic arthritis

Wright and Moll (1976) presented the seminal work on the clinical patterns of psoriatic arthritis. They proposed that these include: distal arthritis, involving the distal interphalangeal joints (Fig. 1); an asymmetric oligoarthritis involving small or medium-sized joints in an asymmetric distribution (Fig. 2); a symmetric polyarthritis, indistinguishable from rheumatoid arthritis; arthritis mutilans, which is a deforming, destructive, and disabling form of arthritis (Fig. 3 and Fig. 4); and a spondylarthropathy (Fig. 5 and Fig. 6). Similar descriptions have been reported by others (Kammer *et al*. 1979; Scarpa *et al*. 1984; Gladman *et al*. 1987; Helliwell *et al*. 1991; Jones *et al*. 1994; Veale *et al*. 1994b). The frequency of the various patterns has varied in the literature (Table 2). Although in their initial description of the psoriatic arthritis patterns Wright and Moll (1976) suggested that the most common pattern was asymmetric oligoarthritis, more recent studies confirm that polyarthritis is most commonly seen among patients with psoriatic arthritis. Psoriatic arthritis is asymmetric in distribution in about half the cases, even when polyarticular distribution is noted. Thus, in comparison with rheumatoid arthritis, psoriatic arthritis tends to be characterized as an asymmetric form of arthritis. The exact prevalence of each of the psoriatic arthritis patterns has been difficult to establish, since investigators have not used the exact same definitions, particularly with regards to symmetry. Helliwell *et al*. (1991) suggested a method for defining symmetrical involvement in patients with psoriatic arthritis, such that for each level of joints if the ratio of the number of matched pairs to the total number of joints was more than 0.5 then the distribution was considered symmetrical. Jones *et al*. (1994) showed that using this method more patients were found to have a symmetrical arthritis. Although the distal pattern has been described as typical for psoriatic arthritis, its frequency has varied widely, and some investigators have not been able to identify patients with isolated distal joint involvement. It has also been recognized that the patterns themselves may change with time in individual patients (Gladman 1992). A patient may present initially with an oligoarthritis which later becomes polyarticular, or develop an initial polyarthritis, which persists in only a few joints. Indeed, Jones *et al*. (1994) recently documented these changes in pattern over time in over 60 per cent of their patients with psoriatic arthritis. Moreover, unless radiographs are performed on all patients, joints which had been previously involved may not be identified, and the spondylarthropathy may be missed (Little *et al*. 1975; Gladman *et al*. 1987; Hanly *et al*. 1988). While the patterns of psoriatic arthritis may facilitate the diagnosis, it is not clear whether they have a prognostic significance.

Fig. 2 An asymmetric oligoarthritis involving the third proximal interphalangeal joint on the right. Note the psoriatic lesions in the periungual areas of the left fourth and fifth fingers.

Fig. 3 Arthritis mutilans, which is a deforming, destructive, and disabling form of arthritis, showing the inability to use the hands fully.

Fig. 4 Telescoping of the third distal interphalangeal joint, seen in patients with psoriatic arthritis, which may be part of arthritis mutilans.

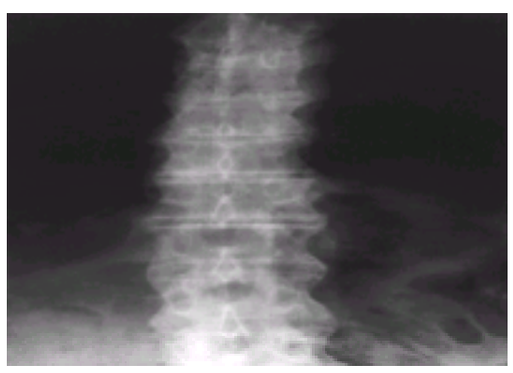

Fig. 5 Thoracolumbar spine in a patient with psoriatic spondylarthropathy, demonstrating syndesmophytes.

Fig. 6 Bilateral sacroiliitis in a patient with psoriatic spondylarthropathy.

A typical feature of psoriatic arthritis is the development of dactylitis, which presents as a swelling of a whole digit, with inflammation involving distal and proximal interphalangeal, and occasionally the metacarpophalangeal joints (Fig. 7). Dactylitis occurs in over a third of the patients (Gladman *et al*. 1987). The exact pathogenesis of the dactylitis is unclear. It may be related either to extensive inflammation and effusion in all the joints of a particular digit, with an associated tenosynovitis, or to soft tissue inflammation in the whole digit. The use of more advanced imaging techniques may help delineate the pathogenesis of 'sausage digits'.

Indeed, a recent scintigraphy study using human immunoglobulin labelled with technetium-99m demonstrates the inflammation in the digit which is missed by a bone scan (Stoeger *et al*. 1994). Tenosynovitis by itself is also a feature of psoriatic arthritis. Although inflammation of the extensor carpi ulnaris has been considered typical for rheumatoid arthritis, we have seen it quite often among the patients attending the psoriatic arthritis clinic. As in the other spondylarthropathies, such as Reiter's syndrome and ankylosing spondylitis, Achilles tendinitis, heel pain, and plantar fascitis are common among patients with psoriatic arthritis. Enthesitis, or inflammation at sites of tendon insertion, is frequent, particularly at the Achilles tendon, the insertion of the plantar fascia, and ligamentous insertions around the pelvic bones. These are commonly diagnosed radiographically as spurs (Fig. 8). A recent study from Finland (Lehtinen *et al*. 1994) offers an improved method, using ultrasound, to identify the presence of enthesitis in patients with spondylarthropathy.

Fig. 7 Dactylitis, which presents as swelling of a whole digit, with inflammation of the distal and proximal interphalangeal, and occasionally the metacarpophalangeal joints, involving the thumb and third finger. Note the psoriatic skin and nail lesions.

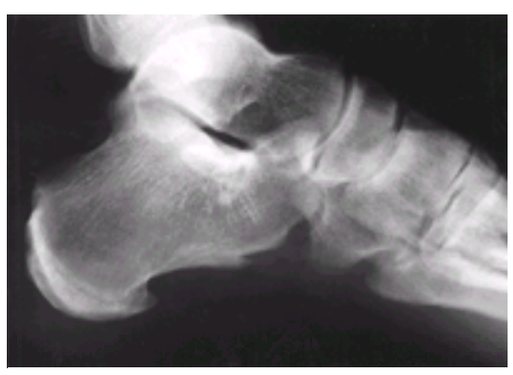

Fig. 8 Spur formation at the insertion of the plantar fascia, representing enthesitis.

The spondylarthropathy of psoriatic arthritis

The frequency of spinal involvement in psoriatic arthritis has varied from 2 per cent, as isolated back disease, to as high as 40 per cent, when associated with peripheral arthritis (Wright and Moll 1976; Lambert and Wright 1977; Kammer *et al*. 1979; Scarpa *et al*. 1984; Gladman *et al*. 1986; Gladman *et al*. 1987; Hanly *et al*. 1988; Moll 1994). Lambert and Wright (1977), found that 40 per cent of 130 patients with psoriatic arthritis had back involvement, based on back pain and reduced spinal mobility. Gladman *et al*. (1987), documented spinal involvement, based on both clinical and radiographical evidence, in 35 per cent of their patients at their first visit to the psoriatic arthritis clinic. This number increased to 51 per cent at follow-up (Gladman *et al*. 1992b). In both studies patients with spinal involvement tended to be male and older than patients without back involvement. Hanly *et al*. (1988) described 52 patients with psoriatic spondylarthropathy who had been followed for a minimum of 30 months, and for a mean of almost 5 years. Despite clinical and radiographical evidence of progression of sacroiliitis and spondylitis, patients' symptoms tended to improve with time, and their spinal mobility was generally good. They suggested that patients with psoriatic arthritis who have spinal involvement are not as symptomatic from their back disease as are patients with ankylosing spondylitis, and do not demonstrate the same degree of limitation of back movement that is noted in patients with ankylosing spondylitis (Hanly *et al*. 1988; Scarpa *et al*. 1988). The spondylarthropathy of patients with psoriatic arthritis was indeed found to be less severe than that seen in ankylosing spondylitis. This was evidenced by the lower frequency of symptomatic neck and back disease, as well as less limitation of movement and grade 4 sacroiliitis in patients with psoriatic arthritis compared with those with ankylosing spondylitis (Gladman *et al*. 1993). Moreover, among patients with psoriatic spondylarthropathy, there are gender-related differences in disease expression, with more advanced spondylarthropathy noted among men (Gladman *et al*. 1992b). The cervical spine in psoriatic arthritis received special attention in two recent studies. Salvarani *et al*. (1992a) studied 57 patients with psoriatic arthritis, of whom 70 per cent had radiographical evidence of cervical spine disease. They identified a high prevalence (23 per cent) of atlantoaxial subluxation. Jenkinson *et al*. (1994) detected cervical spine disease in 57 per cent of their patients with psoriatic arthritis, of whom only 3 had atlantoaxial subluxation. The majority of their patients had spondylitic type changes with apophysial joint narrowing or fusion and syndesmophytes. In both these studies neck involvement was related to prolonged disease duration. At the University of Toronto Psoriatic Arthritis Clinic, only 4 patients with atlantoaxial subluxation have been identified of a total of 450 patients followed over the past 17 years.

Extra-articular features

Skin psoriasis

The skin lesions of psoriasis consist of an erythematous scaly area that varies from a localized plaque on the elbows and knees to an incapacitating, generalized skin involvement with significant effect on the cardiovascular and heat regulating mechanism (Farber and Scott 1979; Goodfield 1994). The skin lesions are classified as: typical psoriasis vulgaris, with major involvement of the extensor surfaces; inverse psoriasis, affecting the flexural areas; pustular psoriasis, which may be localized to the palms and soles, or may be of the more generalized serious form called Von Zambush, and which may pose a threat to life; and the erythrodermic generalized group. The majority of patients with psoriatic arthritis demonstrate the classic psoriasis vulgaris pattern (Wright *et al*. 1979; Gladman *et al*. 1986; Gladman *et al*. 1987). Only 35 per cent of the patients describe a relationship between their skin and joint manifestations (Gladman *et al*. 1987). All areas of the skin may be affected, including the mucosa and the nails. Nail lesions include pitting, ridging, and onycholysis (Wright and Moll 1976). Two or all of these features in the same patient are in favour of a psoriatic origin for the nail dystrophy (Eastmond and Wright 1979). As already mentioned, nail lesions are particularly common among patients with psoriatic arthritis. Occasionally, distal interphalangeal joint disease may follow the development of onycholysis in a particular finger nail, but overall, there has not been a direct correlation between the presence of distal interphalangeal joint disease and nail lesions, since the former occurs in 35 per cent of the patients, whereas the latter occur in almost 90 per cent of the patients with psoriatic arthritis.

Other extra-articular features

The extradermal extra-articular features of psoriatic arthritis are similar to the features described in other seronegative spondylarthropathies and include iritis, which may occur in 7 per cent of the patients (Gladman *et al*. 1987), mouth ulcers, urethritis, colitis, and aortic valve disease (Wright and Moll 1976). A case of a patient with psoriatic arthritis with pyoderma gangrenosum was recently described (Smith and White 1994), and we have seen a case in our psoriatic arthritis clinic. The development of lymphoedema of the upper limb in patients with psoriatic arthritis was recently described in the literature (Mulherin *et al*. 1993). Similar cases have been seen at the University of Toronto Psoriatic Arthritis Clinic. The mechanism of this presentation is not entirely clear, but may represent a similar change to that occurring in dactylitis, with inflammation in both joints and tendons, leading to the clinical picture of 'lymphoedema'. Alternatively, in some of these cases it is possible that a ruptured capsule, as seen in a Baker's cyst in the knee, occurs in the wrist or elbow joint, leading to the soft tissue swelling noted in the distal portion of the upper limb.

Laboratory investigations in psoriatic arthritis

There are no specific laboratory tests which are diagnostic for psoriatic arthritis. Anaemia occurred in 14 per cent of the patients presenting to the psoriatic arthritis clinic (Gladman *et al*. 1987), perhaps reflecting the chronic disease, or an iron deficiency anaemia, secondary to therapy with non-steroidal anti-inflammatory drugs. Indeed, the much higher frequency of anaemia at follow-up (Gladman *et al*. 1990b), was thought to represent the untoward effect of these drugs. Elevated white-cell counts and other acute phase reactants may also be present (Gladman *et al*. 1987). This may reflect the acute phase inflammatory reaction, and may be seen in patients with psoriasis without arthritis. Elevated rythrocyte sedimentation rates may be seen in more than 40 per cent of patients with psoriatic arthritis, and probably reflect both joint and skin inflammation (Gladman *et al*. 1986; Gladman *et al*. 1987). Hyperuricaemia is not uncommon among patients with psoriasis and arthritis (Gladman *et al*. 1986; Gladman *et al*. 1987), and is probably related to the high turnover of skin cells. However, since both psoriasis and gout may occur in young males, one must rule out the possibility that the arthritis is crystal induced, before making the diagnosis of psoriatic arthritis in a patient with psoriasis. On the other hand, the presence of an acute monoarthritis, even in the first metatarsophalangeal joint in the presence of psoriasis does not mean the patient has gout. In both these situations a careful search for negatively birefringent, uric acid crystals should be carried out on the fluid obtained by joint aspiration.

Patients with psoriatic arthritis are usually seronegative for rheumatoid factor. However, in each series of patients with psoriatic arthritis there are about 10 to 15 per cent of the patients who have a positive rheumatoid factor, albeit in a low titre. It should be noted that patients with psoriasis uncomplicated by arthritis demonstrated the same frequency of a positive rheumatoid factor, despite the fact that they were younger on average than the patients with psoriatic arthritis (Gladman *et al*. 1986). Antinuclear factor has also been demonstrated in the sera of patients with uncomplicated psoriasis and patients with psoriatic arthritis, in the same frequency (Gladman *et al*. 1986). Whether this antinuclear antibody reflects the presence of antibodies to stratum corneum antigens is unclear (Gladman 1985). The demonstration of hypergammaglobulinaemia in patients with psoriatic arthritis provides further evidence for immunological abnormalities in patients with this condition (Gladman 1985).

Radiographical features of psoriatic arthritis

Radiographical abnormalities may be seen in both peripheral joints and the axial skeleton in patients with psoriatic arthritis (Resnick and Niwayama 1981). The features commonly associated with psoriatic arthritis and which help differentiate it from rheumatoid arthritis include: absence of juxta-articular osteoporosis; the predilection for distal interphalangeal joints; 'whittling' (lysis) of terminal phalanges (Fig. 9); lack of symmetry; gross destruction of isolated joint; 'pencil-in-cup' appearance (Fig. 10); ankylosis (Fig. 10); fluffy periostitis (Fig. 11); and both classical and atypical spondylitis (Wright and Moll 1971; Resnick and Niwayama 1981; Fig. 5a, Fig. 6 and Fig. 7).

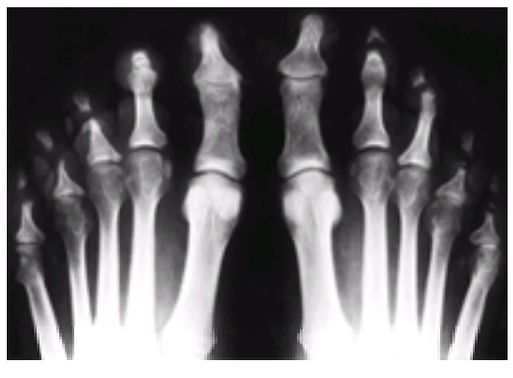

Fig. 9 'Whittling' (lysis) of terminal phalanges of the first and second toes bilaterally.

Fig. 10 'Pencil-in-cup' appearance seen in its early phase in the second right proximal, the fifth right distal, and the left fifth distal interphalangeal joints. Fully developed changes are seen in the left index distal and the left thumb interphalangeal joints. In addition, ankylosis is seen in the right distal interphalangeal joint

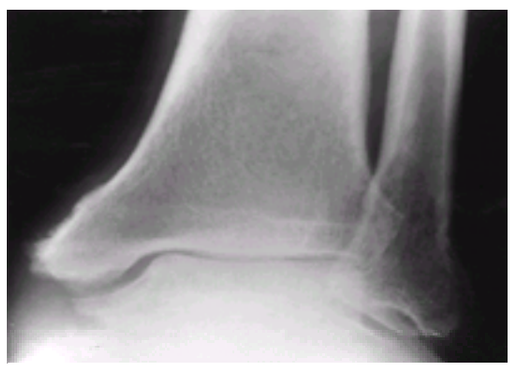

Fig. 11 Fluffy periostitis in the distal end of the tibia.

Diagnosis of psoriatic arthritis

There are no available diagnostic criteria for psoriatic arthritis (Gladman 1995). None the less, the diagnosis of psoriatic arthritis is generally based on the definition of the disease: an inflammatory arthritis in the presence of psoriatic skin lesions, usually seronegative for rheumatoid factor. In a patient with psoriasis, the development of an inflammatory arthritis makes the diagnosis easier. The clinical and radiographical features described above help identify the patient with psoriatic arthritis who had not previously demonstrated skin lesions. Thus, a patient who presents with an asymmetric oligoarthritis, or an inflammatory polyarthritis which includes distal interphalangeal joints, or peripheral arthritis with a spondylarthropathy, should be investigated for the presence of psoriasis, and psoriatic arthritis should clearly be considered in the differential diagnosis. The presence of dactylitis is certainly helpful, as is the presence of enthesitis. It should be noted that the skin lesions may be minimal, and indeed 'hidden'. One must therefore search for these lesions, particularly in the umbilical area, the anal cleft, the scalp, and the ears. Nail lesions are not always recognized by the patient, and should be looked for carefully. The common occurrence of distal joint involvement means that psoriatic arthritis needs to be differentiated from osteoarthritis. The distal interphalangeal lesions in patients with psoriatic arthritis are inflammatory in nature, and tend to be swollen, such that for

the most part they can be differentiated clinically as softer than the hard bony enlargement of Heberden's nodes. The presence of more proximal joint involvement, particularly the wrist and metacarpophalangeal joints, also helps distinguish psoriatic arthritis from osteoarthritis. However, osteoarthritis is a common condition, particularly with advancing age, and a patient may have Heberden's nodes complicating pre-existing psoriatic arthritis. Reiter's disease occasionally presents a diagnostic difficulty. The skin lesions in pustular psoriasis may be indistinguishable both clinically and pathologically from those of Reiter's syndrome, and the clinical features of the arthritis and the spondylarthropathy are similar. Psoriatic arthritis tends to be polyarticular, which may help. Iritis and mucous membrane lesions may be more common in Reiter's disease.

Pathogenesis of psoriatic arthritis

Understanding the pathogenetic mechanisms of disease is crucial for both the development of appropriate therapeutic approaches and the ultimate cure of a disease. It is likely that similar mechanisms would be operating in the development of both skin and joint disease in psoriatic arthritis. Although the exact pathogenetic mechanisms in psoriatic arthritis remain to be elucidated, factors thought to be important include genetic, immunological, and environmental (Gladman 1992; Abu-Shakra and Gladman 1994).

Genetic factors

More than 40 per cent of patients with psoriasis or psoriatic arthritis have a family history of the skin or joint disease in first-degree family members (Gladman *et al*. 1986; Gladman *et al*. 1987). Further support for genetic factors as possible aetiological mechanisms for psoriatic arthritis has come from the observations of high concordance for psoriasis in monozygotic twins and from clustering of both psoriasis and psoriatic arthritis within families (Espinoza 1985; Eastmond 1994). The discovery of the HLA system on chromosome 6 of humans, and the ability to detect HLA alloantigens of both class 1 and class 2, has allowed further elaboration of genetic mechanisms in psoriasis and psoriatic arthritis. Population studies in psoriasis revealed an increased frequency of HLA antigens B13, B17, B37, Cw6 and DR7 (Espinoza 1985; Gladman *et al*. 1986; Eastmond 1994). In psoriatic arthritis, increased frequencies of HLA-B13, -B17, -B27, -B38, -B39, -DR4, and -DR7 have been reported (Espinoza 1985; Gladman *et al*. 1986; Sakkas *et al*. 1990). Gladman *et al*. (1986) compared 158 patients with psoriatic arthritis to 101 patients with uncomplicated psoriasis. They found that the HLA-B7 or -B27 antigens were more common among patients with psoriatic arthritis, whereas B17, Cw6, and DR7 were more common among patients with uncomplicated psoriasis. HLA-B27 has clearly been associated with back disease in psoriatic arthritis, thus lending further credence to its grouping with the HLA-B27-associated spondylarthropathy. HLA-DR4 appears to be associated with the peripheral articular pattern of psoriatic arthritis (Gladman *et al*. 1986). A search for other genetic markers in psoriatic arthritis revealed that there were no specific T-cell receptor genes unique to the disease (Sakkas *et al*. 1990). However, Southern blot analysis using DNA probes for the immunoglobulin heavy chain gene (IgH) on chromosome 14q32 suggests that the gene may confer susceptibility to arthritis in patients with psoriasis (Sakkas *et al*. 1991). A recent identification of a gene for familial psoriasis on chromosome 17 is intriguing, but its relationship to psoriatic arthritis is unclear (Tomfohrde *et al*. 1994).

Immunological mechanisms

The clinical and pathological features of both psoriasis and psoriatic arthritis support the role of immunological factors in the pathogenesis of these conditions. The inflammatory nature of the disease, the cellular infiltrates seen both in skin and joint lesions, and the deposition of immunoglobulins in the epidermis as well as the synovial membrane, all support an immune mechanism (Gladman 1985; Panayi 1994). Autoantibodies, such as antinuclear antibodies, rheumatoid factor, and antibodies against skin antigens, as well as immune complexes, have been found in the sera of patients with psoriasis and psoriatic arthritis, supporting a hyperactive humoral immune mechanism (Gladman 1985). It has recently been hypothesized that antibodies against psoriasis-specific non-histone proteins found in patients with psoriasis, may facilitate displacement of the non-histone complex from DNA which may contain the psoriasis gene (Cormane and Asghar 1987), thus allowing for the development of the disease. This hypothesis is of particular interest since the identification of a psoriasis gene on chromosome 17.

On the cellular side, an imbalance of T-cell activity has been shown, which may result from either lack of T-cell suppression or excess of helper cell activity. Indeed, T-lymphocyte hyporeactivity to mitogens, impaired suppressor cell function, and a decrease in certain T-cell subpopulations have been demonstrated in psoriatic arthritis (Gladman 1985). The presence of activated T cells in psoriatic skin lesions was suggested by the demonstration of T lymphocytes bearing HLA-DR molecules as well as receptors for interleukin 2 in the lesions (Gottlieb 1988). In addition, keratinocytes bearing HLA-DR molecules were found in association with an increased frequency of psoriatic arthritis in patients with psoriasis. This prompted the proposal that these cells serve to present antigen to T cells, leading to mediator release and an inflammatory response (Gottlieb 1988). These T cells have indeed been found to express HLA-DR molecules, receptors for IL-2, and a variety of adhesion molecules, and to secrete proinflammatory cytokines, in particular IL-6 (Abu-Shakra and Gladman 1993). Fibroblasts from the skin and synovium of patients with psoriatic arthritis have an increased proliferative activity and the capability of secretion of increased amounts of IL-1b, IL-6 and platelet-derived growth factors. Activated T cells have been noted in the affected tissues (both skin and joints) in psoriatic arthritis by most investigators (Gladman 1993; Veale *et al*. 1993; Panayi 1994; Veale *et al*. 1994a). The results of several studies suggest that cytokines secreted from activated T cells and other mononuclear proinflammatory cells induce proliferation and activation of synovial and epidermal fibroblasts. It is of interest that both psoriasis and psoriatic arthritis, but not rheumatoid arthritis, have been reported to flare in the presence of the acquired immune deficiency virus (Buskila and Gladman 1990), suggesting that helper T (CD4) cells are not required for the disease process in psoriatic arthritis (Vasey *et al*. 1989). Indeed a decreased helper/suppressor T-cell ratio has been shown in patients with severe psoriasis (Rubins and Merson 1987). Moreover, deficient helper T-cell function in psoriatic patients was demonstrated using an antibody-specific induction system (Ventura *et al*. 1989). Panayi (1994) recently reviewed the immunological abnormalities seen in psoriatic arthritis. These include the presence of activated T lymphocytes in synovial membranes, an increase in macrophage numbers, and the presence of B cells. Although the presence of activated T cells in the affected tissues (both skin and joints) in psoriatic arthritis has been noted by most investigators (Gladman 1993; Veale *et al*. 1993; Panayi 1994; Veale *et al*. 1994a), the presence of an increased number of macrophages has not been uniformly described. This may be related to the stage in the disease at which the observations were made (Gladman 1993). It is still unclear whether the activated T cells are the cause of the arthritis, or the result of as yet unidentified factor.

Over the past 10 years the role of metabolites of arachidonic acid, such as prostaglandins and particularly leukotrienes, in the pathogenesis of both psoriasis and psoriatic arthritis has been evaluated (Voorhees 1983). Levels of leukotriene B4 have been shown to be increased in the psoriatic skin lesions, and injections of this compound has caused intraepidermal microabscesses. Drugs which lower the levels of leukotriene B4 are effective in controlling the skin lesions. However, the evidence is not conclusive. Greaves and Camp (1988) recently proposed an integrated approach to inflammation of human skin, considering the lipoxygenase system, platelet activating factor, and cytokines. This is an attractive proposal which allows for the integration of all the immunological abnormalities described. However, in a recent study, Veale *et al*. (1994c) demonstrated that Efamol marine was able to alter prostaglandin metabolism but did not produce a clinical improvement in either skin or joint manifestations in patients with psoriatic arthritis.

Environmental factors

Infection

Some investigators believe that guttate psoriasis is initiated by an infectious agent (Vasey 1985). Support for the role of bacterial antigens in the pathogenesis of psoriasis and psoriatic arthritis comes from indirect observations of enhanced humoral and cellular immunity to Gram-positive bacteria typically found in the psoriatic plaques. However, psoriatic plaques often become secondarily infected, thus the cause–effect relationship of bacteria and psoriasis is complicated. Moreover, Grinlinton *et al*. (1993) demonstrated that the response to streptococcal antigens by gd+ T cells from patients with psoriatic arthritis was also noted by cells from patients with rheumatoid arthritis, suggesting that this reaction may be a feature of inflammatory arthritis.

The exacerbation of psoriasis and psoriatic arthritis seen in the context of acquired immune deficiency virus infection is intriguing (Vasey *et al*. 1989). The possibility that psoriatic arthritis might be virus induced has recently been proposed by Luxembourg *et al*. (1987). However, an investigation of antigens related to the major internal protein p27 of a psoriasis-associated retrovirus-like particle failed to reveal specificity for psoriatic patients (Rødahl and Iversen 1985). Thus an exact viral aetiology for psoriasis or psoriatic arthritis has yet to be described.

Trauma

In almost all accounts of psoriatic arthritis there are reports of patients whose arthritis developed after trauma. However, the majority of these are anecdotal case reports (Langevitz *et al*. 1990). Scarpa *et al*. (1992) reviewed the records of 138 patients with psoriatic arthritis and compared the frequency of a traumatic event prior to the development of the arthritis to that recorded in 138 patients with rheumatoid arthritis. They found that trauma of some type preceded the diagnosis of psoriatic arthritis in 9 per cent of the cases, whereas in rheumatoid arthritis it was found in only 1 per cent of the patients, suggesting a role for trauma in some patients with

psoriatic arthritis.

Treatment of psoriatic arthritis

The treatment modalities employed in psoriatic arthritis are in part based on the pathogenetic mechanisms discussed above. They concentrate on control of inflammation, and an attempt to modify the immunological mechanisms thought to be operating in this disease (Gladman 1992).

The treatment of psoriasis

The treatment of psoriatic arthritis includes treatment for the skin condition as well as treatment for the joint disease. The skin lesions are treated by topical medications, aimed at controlling the inflammation and skin proliferation, including tar, anthralin, and corticosteroids (Marks 1980). In refractory cases, systemic medications such as methotrexate (Roenigk *et al*. 1969), **PUVA** (psoralen and ultraviolet A light) (Parish *et al*. 1974), retinoic acid derivatives (Klinkhoff *et al*. 1989), and more recently cyclosporin (Ellis *et al*. 1991) are used. The possible pathogenetic role of leukotrienes in the development of psoriatic arthritis has resulted in fish oil recently being introduced as a treatment for psoriasis (Gupta *et al*. 1989a).

The treatment of psoriatic arthritis

Non-steroidal anti-inflammatory therapy

The initial treatment for psoriatic arthritis consists of non-steroidal anti-inflammatory drugs (**NSAIDs**), including enteric-coated acetylsalicylic acid (**ECASA**), ibuprofen, naproxen, indomethacin, tolmetin, piroxicam, diclofenac sodium, and others (Abu-Shakra and Gladman 1993). In patients whose primary problem is that of peripheral arthritis, medications such as ECASA, ibuprofen, naproxen, or diclofenac sodium might be preferred. However, if there is evidence of a spondylarthropathy, it seems that indomethacin or tolmetin would be more appropriate. The latter two drugs would also be appropriate if morning stiffness is prolonged, and may be used in conjunction with other NSAIDs. Several of the NSAIDs have been incriminated in exacerbating the psoriasis (Abel *et al*. 1986), perhaps through the prostaglandin mechanism. It may therefore be necessary to change medications if an exacerbation of psoriasis occurs.

Disease-modifying drugs for psoriatic arthritis

If the arthritis persists despite the use of non-steroidal anti-inflammatory medications, then the next level of medications is embarked upon, that is, disease-modifying antirheumatic drugs.

Gold

Gold has been studied in a controlled fashion in psoriatic arthritis, using either intramuscular (Dowart *et al*. 1978) or oral (Carrett and Calin 1989) preparations. It has recently been shown that the intramuscular preparation is superior to the oral gold in patients with this condition (Palit *et al*. 1990). Moreover, although gold may control the inflammatory process in patients with psoriatic arthritis, it has not prevented progression of erosive disease over a 2-year period (Mader *et al*. 1995).

Penicillamine

Penicillamine has also been used successfully in psoriatic arthritis (Roux *et al*. 1979). Both gold and penicillamine are quite slow acting, however, requiring at least 6 months for a therapeutic effect. Therefore, other medications whose onset of action is faster have been tried.

Antimalarials

Although physicians have been reluctant to use antimalarials because of anecdotal reports of flares of psoriasis, and despite the lack of controlled trials, both chloroquine phosphate and hydroxychloroquine have been used (Kammer *et al*. 1979). Indeed, chloroquine has been shown to reduce disease activity in patients with psoriatic arthritis over a period of 6 months, and the frequency of psoriatic flares was no greater than that observed in the control group (Gladman *et al*. 1992a).

Methotrexate

Methotrexate, which has been found to be effective in controlling the skin psoriasis, has been used in psoriatic arthritis since 1964, when Black *et al*. (1964) performed a double-blind study of 21 patients using parenteral methotrexate. There have been two controlled trials of the use of low-dose weekly methotrexate in psoriatic arthritis. Willkens *et al*. (1984) demonstrated improvement in grip strength, morning stiffness, and joint count in patients with psoriatic arthritis, and physician global assessment was improved in the methotrexate group at 3 months, but only physician global assessment was significantly higher in the methotrexate group compared with the placebo. Zacharia and Zacharia (1987) found significant improvement in pain and functional scores as well as a decrease in the erthrocyte sedimentation rate during treatment with low-dose weekly methotrexate for psoriatic arthritis. Espinoza *et al*. (1992), in a retrospective uncontrolled study of 40 patients with psoriatic arthritis treated with a mean of dose of 11.2 mg/week of methotrexate during a mean period of 34 months, found that 37 per cent of the patients had an excellent response (no evidence of active synovitis) while 58 per cent had a good response (no more than four active joints and a decrease of at least 50 per cent in the number of those previously involved). Only two patients had discontinued the drug because of toxicity; one with leucopenia and the other stomatitis. Eleven patients developed liver test abnormalities. However, cirrhosis related to methotrexate was not noted. Abu-Shakra *et al*. (1995) found that while methotrexate reduced the actively inflamed joint count in patients with psoriatic arthritis, it did not prevent disease progression in these patients over a period of 2 years of treatment. None the less, methotrexate is used regularly for the treatment of psoriatic arthritis, particularly in the face of severe psoriasis. Methotrexate has an advantage over gold and penicillamine since it is effective within a few weeks. In addition, because it is given as an intermittent dose, once a week, patients prefer to take it rather than take other medications which are required daily, and often in repeated doses. Concerns about severe liver disease from methotrexate therapy, which resulted from reports in the late 1960s and early 1970s, seem to have been alleviated since more judicious use of intermittent dose has become commonplace.

Sulphasalazine

Sulphasalazine has been shown in two double-blind, placebo-controlled trials to be effective in psoriatic arthritis (Farr *et al*. 1990; Fraser *et al*. 1993). Rahman and Gladman (1995) recently demonstrated that sulphasalazine may not be tolerated by all patients with psoriatic arthritis, but in patients who are able to continue therapy the clinical response is impressive, and there is also improvement in the skin psoriasis.

Azathioprine

Azathioprine has also been used in psoriatic arthritis (Levy *et al*. 1972), but since its effect on psoriasis is not well recognized, it has not been as useful as it is in rheumatoid arthritis. We have recently used azathioprine in patients with psoriatic arthritis who had not responded to or were unable to tolerate methotrexate, with encouraging results.

Retinoids

Retinoids have only been studied in uncontrolled fashion, since it is difficult to blind both patients and observers to their side-effects (Klinkhoff *et al*. 1989). While these drugs may be effective against both skin and joint manifestations, their toxicity appears high. There is a new retinoid being tested at present which may prove less toxic.

Cyclosporin

Cyclosporin has recently been studied as a therapeutic option for both psoriasis and psoriatic arthritis (Gupta *et al*. 1989b; Salvarani *et al*. 1992b). Although it has been suggested that it is effective and safe, NSAIDs cannot be used concomitantly. Moreover, its adverse effects, particularly on the kidney, preclude its widespread use.

Steroids

Oral steroids are usually avoided in psoriatic arthritis, since on dose reduction they can cause significant flares of the skin psoriasis. However, intra-articular steroids may be used at any time, especially when there is a joint which is particularly inflamed. We tend to avoid injecting joints which are surrounded by psoriatic plaques because of fear of causing infections.

Dietary modification

Based on the pathogenetic mechanisms proposed for both psoriasis and psoriatic arthritis, there may be a role for fish oil preparations or specific immunomodulators in the treatment of both conditions. A pilot study of MaxEpa in psoriatic arthritis was promising (Peloso and Gladman 1992), but a more recent placebo-controlled trial of Efamol marine demonstrated no efficacy in psoriatic arthritis (Veale *et al*. 1994c). The use of oral vitamin D_3 for the treatment of psoriatic arthritis has recently been proposed (Huckins *et al*. 1990)

Other medications

Psoralen and ultraviolet A light has been used in psoriatic arthritis with some success (Perlman *et al*. 1979). More recently, the use of extracorporeal photochemotherapy has been proposed (de Misa *et al*. 1994). Buskila *et al*. (1991) described a woman with psoriatic arthritis, who experienced a remarkable improvement of her arthritis while she was taking bromocriptine for primary infertility due to hyperprolactinaemia. Others have also reported similar results (Abu-Shakra and Gladman 1993). Peptide T has also been advocated for the treatment of psoriatic arthritis, but information is currently available only from case reports (Abu-Shakra and Gladman 1993).

Physiotherapy and occupational therapeutic modalities should be used both for symptomatic relief and to avoid development of deformities. Patients may require splints and need to be instructed as to energy conservation and joint protection. In patients with spondylarthropathy, specific back exercises may be necessary.

The approach to the management of a patient with psoriatic arthritis should be to control the inflammatory process, in both the skin and the joints. If conservative measures such as topical medications and NSAIDs are not helpful, disease-suppressive medications should be used. In cases where both skin and joint disease are active, medications such as methotrexate and retinoids should be considered early. Sulphasalazine and azathioprine may also work in these situations. Where the arthritis is a problem, and skin lesions are well controlled with topical medications, then the other medications, including gold, chloroquine, penicillamine, and azathioprine might be used first. Newer modalities, such as cyclosporin, should be reserved for patients with particularly aggressive disease.

Monitoring disease activity during courses of NSAIDs and disease-modifying drugs should be based on the actively inflamed joint count and effusion count, which have been found to be reliable measures of disease activity (Gladman *et al*. 1990a) despite the fact that patients with psoriatic arthritis do not demonstrate the same degree of tenderness as do patients with rheumatoid arthritis (Buskila *et al*. 1992). It is important to emphasize that the pain scale has not been shown to correlate with measures of disease severity (Duffy *et al*. 1992; Blackmore *et al*. 1995).

Surgery

Surgery is reserved for patients whose joints have become deformed and damaged. There are no systematic studies of surgery in psoriatic arthritis. There is a concern that the joints do not recover function very well, and that there may be bone formation similar to what has been described in ankylosing spondylitis (Dwosh *et al*. 1976). Our own experience with knee and hip surgery has been good. However, surgical procedures performed on several of our patients in an attempt to correct flexion deformities of the fingers have not been rewarding. Patients developed recurrence or worsening of their deformities, and ended up with a less functional hand than prior to surgery.

Recently an approach to the treatment of temporomandibular joint disease in psoriatic arthritis has been described (Peterson and Shepherd 1992). Hicken *et al*. (1994) recently reviewed their experience with foot and ankle surgery in 17 patients with psoriatic arthritis collected over a 15-year period. There were 27 operations which included forefoot arthroplasty or arthrodesis and toe arthroplasty or arthrodesis. The operations were considered successful in 89 per cent of the cases. Complications occurred in a patient who had a local infection associated with a local flare of psoriasis and required corrective surgery, another patient who required an additional procedure, and a third patient who had delayed union.

The course and prognosis of psoriatic arthritis

The course of psoriatic arthritis is variable. There are patients who have few episodes and who recover completely, but in many the disease is persistent. A third of the patients relate the course of their skin disease and joint disease (Gladman *et al*. 1987). The lack of a systematic approach to disease assessment in psoriatic arthritis has hindered the performance of follow-up studies. Clinical measures of inflammatory activity as well as damage have only recently been validated in psoriatic arthritis (Gladman *et al*. 1990a). Roberts *et al*. (1976) concluded in their follow-up study that 'apart from the deforming group the arthritis was not notably progressive'. However, there was time lost from work in at least 60 per cent of all patients, and radiographical progression was recorded in about 15 per cent. Stern (1985) noted that more than 50 per cent of the patients with psoriatic arthritis had some limitation on their daily activities, and they were twice as likely to be unemployed as patients with other joint disease. Hanly *et al*. (1988) and Gladman *et al*. (1990b), suggested that the disease is progressive, based on the increased number of deformed and damaged joints observed in their patients, who were followed according to a standard protocol in the University of Toronto Psoriatic Arthritis Clinic. Coulton *et al*. (1989) reported on the outcome of 40 patients admitted to hospital for psoriatic arthritis who were followed for a mean of 8 years. At the end of that period, none of the patients died. However, 35 per cent of their patients were in Steinbrocker's classes III and IV, supporting the notion that a proportion of patients with psoriatic arthritis become disabled. Clear evidence of progression of deformities was demonstrable when patients were compared at presentation and at follow-up, based on duration of follow-up at the psoriatic arthritis clinic (Gladman 1994). None the less, the Health Assessment Questionnaire in patients with psoriatic arthritis does not give the same high scores seen in rheumatoid arthritis (Jones *et al*. 1994; Blackmore *et al*. 1995). This may very well be due to the fact that the questionnaire correlates highly with pain, which is less likely to be an issue for patients with psoriatic arthritis than for those with rheumatoid arthritis (Buskila *et al*. 1992).

It would be of benefit to be able to identify those patients who are destined to develop the more severe disease and treat them appropriately. In an attempt to identify such prognostic factors, Gladman *et al*. (1995) studied 305 patients who entered the psoriatic arthritis clinic with less than ten deformed joints, and identified clinical indicators for progression through four stages: no deformities, one to four deformities, five to nine deformities and ten or more deformities. Patients who had five or more effused joints at presentation to the clinic were more likely to progress, as were patients treated with disease-modifying drugs, while patients who had a low erythrocyte edimentation rate were less likely to develop more deformities during follow-up. There was no correlation with disease duration. Moreover, Gladman *et al*. (1995) recently demonstrated that the HLA antigens B27, B39, and DQw3 were more important than the clinical features in predicting such progression. Thus, prognostic factors for severe disease in psoriatic arthritis are identifiable and may serve as markers for specific therapeutic modalities.

Approach to the management of psoriatic arthritis

My overall approach to a patient with psoriatic arthritis includes confirming the diagnosis, assessing the extent of disease activity in terms of both joint and skin disease, and assessing the degree of damage that has occurred. This involves a careful history, physical examination, laboratory assessment, and radiographical evaluation. The goal of treatment is control of inflammation which will hopefully lead to control of symptoms, and prevention of deformities and damage, so that the patient may continue to lead an active and productive life.

Once the diagnosis has been made and the patient assessed, my approach to management begins with patient education. I explain to the patient that he/she suffers from an inflammatory arthritis, that the treatment is aimed at controlling inflammation, and therefore medications need to be taken regularly. The role of daily stresses on exacerbations of both skin and joint disease is reviewed. The need to treat both skin and joint manifestations of the disease is also discussed. These topics often need to be repeated during follow-up.

The actual therapeutic approach is then tailored to the individual patient (see Box 1). A patient who has mild disease, with minimal skin lesions and mild arthritis without deformities, is treated with topical ointments for the skin, and non-steroidal anti-inflammatory drugs for the joints. I tend to use enteric-coated acetylsalicylic

acid, ibuprofen, naproxen, or diclofenac for polyarticular disease, and those that complain of pain. In patients with oligoarticular disease, and those with spondylarthropathies, I tend to use indomethacin or tolmetin. While there is no scientific proof to support this approach, it seems to be empirically correct. However, since patients vary both in their response to and tolerance of different NSAIDs, this sequence is often changed. More for individuals who clearly express aversion to taking pills, I tend to choose those NSAIDs which can be given once daily.

I also use intra-articular corticosteroid injections for individual joints. I find that in psoriatic arthritis the inflammation is intense and deformity can ensue rapidly. My patients are educated to call immediately when a red, hot joint appears, and to present themselves for joint injections. Although some people feel that intra-articular steroids are not as effective in seronegative disease as they are in rheumatoid arthritis, this has not been my experience. We have been able to control severe inflammation and prevent damage in joints which we injected early (as judged by what happened to other joints in the same individual). This applies to both large and small joints in this disease. I use joint injections as an adjunct to systemic therapy as well, at any point in the disease, provided the joint is not completely destroyed.

In a patient with mild psoriasis but more active and severe arthritis, I tend to use second-line medications early. I use antimalarials, sulphasalazine, methotrexate, gold, and azathioprine, for this type of patient. If the patient demonstrates a spondylarthropathy, I would tend to choose sulphasalazine first, since it seems to control spinal disease as well as peripheral disease, whereas the other medications have not been shown to be as effective for spinal involvement.

In a patient who has severe psoriasis, even if the arthritis is not that severe, I tend to start with methrotrexate, since it has been shown to be effective for both components of the disease. If the methotrexate is not tolerated, then I switch to either sulphasalazine (unless there is sulpha allergy) or azathioprine. If the methotrexate is tolerated, but not completely effective, I add either an antimalarial or sulphasalazine. In patients with severe psoriasis and mild arthritis I have used PUVA, which works well for the skin and has worked well for the joints.

Box 1 Therapeutic approach to the management of psoriatic arthritis

Type of presentation	NSAIDs	Second line	Intra-articular
Mild skin Mild joint	Yes	No	As required
Mild skin Moderate joint	Yes	Sulphasalazine, methotrexate, antimalarials, gold, indomethacin	As required
Severe skin Mild joint	Yes	Methotrexate, sulphasalazine, cyclosporin, PUVA, retinoids	As required
Severe skin Severe joint	Yes	Methotrexate, sulphasalazine, indomethacin, PUVA, cyclosporin, retinoids	As required

I reserve the use of cyclosporin A and retinoids for patients with severe psoriasis and arthritis who either refuse to take methotrexate, or are unable to tolerate it. These drugs are more toxic than the others and need to be used with caution.

5.5.5 Reactive arthropathy, Reiter's syndrome, and enteric arthropathy in adults

Bernard P. Amor and Antoine A. Toubert

Historical considerations

A brief historical survey may help in understanding the different names for what is now called reactive arthritis. The occurrence of arthritis following acute diarrhoea or a urethral discharge was intriguing enough to be mentioned occasionally in the ancient medical literature. Hippocrates noted that 'a youth does not suffer from gout until after sexual intercourse', gout at that time meaning acute arthritis. He also mentioned that diarrhoea which stops suddenly may create deposits in the chest and the joints. The observations of Martiniere in 1664, Stoll in 1776, and Brodie in 1818 are also often cited, among many others (see Gounelle and Marche 1941). Clinical descriptions improved when microbiological techniques allowed differentiation of septic from aseptic arthritis. The first description of an identifiable infectious agent triggering aseptic arthritis was made during the First World War by Fiessinger and Leroy (1916), who reported an outbreak of *Shigella dysenteriae* and described four of the dysenteric patients as suffering from what they called an 'oculo-urethro-synovial' syndrome. Hans Reiter (1916) described the same oculo–urethro–synovial triad in a young officer and discussed the role of a treponema called 'treponema arthritidis'. During the Second World War and the period of confusion that followed, epidemics of dysentery (Bauer and Engelman 1942; Marche 1946; Paronen 1948; Masbernard 1959; Noer 1966) were associated with new cases of what was now called 'Reiter's syndrome'. Further observation of these cases showed an unsuspected frequency of relapses and chronic evolution, often unrelated to new infectious episodes (Csonka 1958).

During the same period, the curing of gonococcal infections with penicillin confirmed the identification of non-gonococcal urethritis and disrupted the old and mixed concept of chronic gonococcal arthritis. Among the different aetiological agents of non-gonococcal urethritis, *Chlamydia trachomatis* (Harkness 1950; Ford and Rasmussen 1964; Dunlop *et al*. 1965; Schachter *et al*. 1969; Keat *et al*. 1980; Amor 1985) has progressively become recognized as the one most closely associated with a triad similar to that described by Fiessinger, Leroy, and Reiter after diarrhoea. 'Post-dysenteric or epidemic Reiter' and 'postvenereal or endemic Reiter's syndrome' were defined, and a first set of criteria proposed (Willkens *et al*. 1981). Concurrently, the clinical overlap and genetic links between complete or incomplete Reiter's syndrome, ankylosing spondylitis, and psoriasis appeared more and more impressive as observation periods lengthened (Marche 1954; Khan and Hall 1965; Sairanen 1969).

The association between HLA-B27 antigen, ankylosing spondylitis (Brewerton *et al*. 1973a; Schlosstein *et al*. 1973), and Reiter's syndrome or reactive arthritis (Amor *et al*. 1974; Brewerton *et al*. 1973b) provided strong support to the clinical data.

In 1973 and 1974, Aho and colleagues reported aseptic arthritis following gut infection with *Yersinia enterocolitica*, mostly in HLA-B27-positive individuals, and proposed a new term, 'reactive arthritis', which was so successful that it has progressively replaced all the previous terms (Aho *et al*. 1973; Aho *et al*. 1974).

During the same period, the clinical overlap and genetic links between reactive arthritis, ankylosing spondylitis, and other apparent entities were growing stronger, and the introduction of the concept and the term 'spond(ylo)arthropathies' was welcomed (Moll *et al*. 1974).

Definition

Reactive arthritides are often defined as aseptic arthritis triggered by an infectious agent located outside the joint. This definition is unsatisfactory because in some cases non-viable agents can be identified in the joints, and, moreover, in many patients no triggering agent may be found despite identical clinical features.

Reactive arthritides are now considered as belonging to the spondylarthropathies. Therefore, as a first step, they can be defined as spondylarthropathy according to the criteria shown in Table 1 if the sum of the scores for the 12 items is 6 or more (Amor *et al*. 1990). They can then be defined as reactive arthritis if item 7 (urethritis or cervicitis less than 1 month before an arthritic episode) and/or item 8 (acute diarrhoea less than 1 month before an arthritic episode) are present. The validity of these criteria has been established in a study including 140 spondylarthropathies and 1829 control rheumatic patients (see Table 3(b) of Chapter 5.5.1). The serial recording of the disease pattern of one patient throughout its evolution (Fig. 1) explains this definition.

Criteria	Score
A. Clinical symptoms or past history of:	
1. Lumbar or dorsal pain during the night or morning stiffness of the lumbar or dorsal spine	1
2. Asymmetrical oligoarthritis	2
3. Buttock pain—if alternating alternately the right or the left buttock	1 or 2
4. Sausage-like toe or digit	2
5. Heel pain	2
6. Iritis	2
7. Non-gonococcal urethritis or cervicitus accompanying, or within 1 month before, the onset of arthritis	1
8. Acute diarrhoea accompanying, or within 1 month before, the onset of arthritis	1
9. Presence or history of psoriasis and/or balanitis and/or of inflammatory bowel disease (ulcerative colitis, Crohn's disease)	2
B. Radiological finding:	
10. Sacroiliitis (grade ≥ 2 if bilateral, grade ≥ 3 if unilateral)	3
C. Genetic background:	
11. Presence of HLA-B27 and/or familial history of ankylosing spondylitis, Reiter's syndrome, uveitis, psoriasis or chronic enteropathies	2
D. Response to treatment:	
12. Close-out improvement of rheumatic complaints with non-steroidal anti-inflammatory drugs (NSAIDs) in less than 48 h or relapse of the pain in less than 48 h if NSAIDs discontinued	2

Table 1 Criteria for diagnosing spondylarthropathies (Amor *et al*. 1990)

Factors observed during first 2 years of disease	Mild (n=80)	Severe (n=20)	Risk for severity		Proposed weighting
			Ratio	95% CI	
Hip arthritis	0	7	22.65	4.43–115.8	4
ESR > 30	10	16	7.88	4.84–9.15	3
Poor efficacy of NSAIDs	5	11	6.33	2.56–27.11	3
Limitation of lumbar axis	2	7	7.88	2–25	3
Sausage-like finger or toe	2	5	6.48	1.48–48	2
Oligarthritis	12	12		1.38–13.1	1
Onset < 16 years	12	10	3.47	1.059–12.75	1

A sum of 2 or more is predictive of a benign outcome (sensitivity 92.5%, specificity 78%). A sum of 7 or more indicates a risk of severe outcome (sensitivity 50%, specificity 97.5%).
ESR erythrocyte sedimentation rate, NSAID non-steroidal anti-inflammatory drug.

Table 3 Seven predictive factors of long-term outcome in spondylarthropathy (Amor *et al*. 1994)

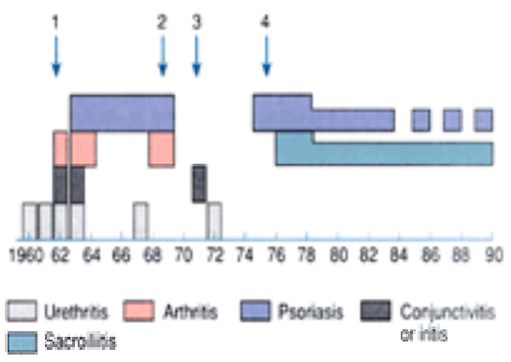

Fig. 1 Synoptic recording of disease pattern across 30 years of follow-up in a typical patient with Reiter's syndrome. 1. The diagnosis is sexually acquired reactive arthritis. 2. Psoriasis: the diagnosis could be psoriatic arthritis. 3. Isolated iritis. 4. Buttock and back pain/sacroiliitis: the diagnosis could be ankylosing spondylitis. It is clear that this patient does not have four different diseases but only one, a spondylarthropathy, which has taken the clinical aspect of reactive arthritis at onset. He is B27-positive and has enough items (see Table 1) to be defined as spondylarthropathy at all stages of his disease.

It may still be useful in clinical practice or for research purposes to subdivide reactive arthritis according to the triggering agent, when it can be identified.

Clinical features

Reactive arthritis, like other spondylarthropathies, combines four syndromes: a peripheral arthritis syndrome, an enthesopathic syndrome, a pelviaxial syndrome, and an extramusculoskeletal syndrome. The combination of these four may vary from one spondylarthropathy to another, in the subgroup of reactive arthritis from one patient to another, and in a given patient during the course of the disease. Nevertheless, the diagnosis of spondylarthropathy will remain unchanged.

General conditions

The onset of reactive arthritis is sometimes acute, with fever as high as 39°C, severe weight loss, and diffuse, polyarticular involvement. However, in most cases in which synovitis is limited to a few joints, low-grade fever or no fever at all is the rule.

The peripheral arthritis syndrome

The onset is acute and within a few days two to four joints (oligoarthritis), mainly knees and ankles, are painful and swollen with an asymmetrical distribution (item 1). Mono- and polyarthritis may be observed. They are not helpful for diagnosis, but they do not exclude it if the other items of the criteria of spondylarthropathies are present.

Diffuse swelling of an entire finger(s) or toe(s), commonly described as sausage digit or toe, is very specific (item 4).

The enthesopathic syndrome

Localized painful parts of bones at the level of the enthesis, in isolation or associated with arthritis, are described spontaneously or after questioning in 42 per cent of patients. Heel pain is the most frequently recognized enthesopathic pain because it is easier to differentiate from joint pain than enthesopathic pains localized around the knee or the hip.

The pelviaxial syndrome

Highly distinctive features are inflammatory dorsal or low back pain (item 1), or buttock pain (item 3), observed in 50 per cent of patients.

The extramusculoskeletal syndrome

Intestinal and genitourinary symptoms are not only of diagnostic but also of pathophysiological and therapeutic importance; they will be described and discussed in more detail at the end of this chapter.

Mucocutaneous lesions (Montgomery et al. 1959)

Balanitis circinata is a painless, erythematous lesion of the glans penis. The size of the lesion may vary but its boundaries with normal mucosa are always clearly

defined (Fig. 2). Similar painless, erythematous, well-defined lesions may be found on the oral mucosa (hard and soft palate, gingiva, tongue, cheeks) (Fig. 3).

Fig. 2 Balanitis.

Fig. 3 An erythematous, painless, palatal mucosal lesion.

Mucosal lesions are not frequent (9–40 per cent) but are very specific. Being painless, they may be ignored by the patient.

Lesions of pustular psoriasis, when localized on the palms and/or the soles of the feet, are called keratoderma blennorrhagica (Fig. 4) and are diagnostically very suggestive, as are hyperkeratosis and parakeratosis of the nails. These lesions are infrequent but are often associated with a severe outcome (Temine *et al*. 1972). Ordinary psoriatic lesions may also be seen.

Fig. 4 Keratoderma blennorrhagica.

Visceral involvement, very similar to that observed in other spondylarthropathies, is infrequent (1 per cent), and includes cardiac conduction abnormalities (prolongation of the PR interval, complete heart block) in early disease and aortic insufficiency in late disease. An association with transient neurological dysfunction such as peripheral or cranial nerve palsy, Parsonage–Turner syndrome, and hemiplegia has been described (Oates and Hancock 1959).

'Pleuritic' chest wall or pseudonephritic pains are probably unrecognized enthesopathic pains of the chest or due to involvement of the costovertebral joints (Benhamou *et al*. 1987).

Ocular lesions

Conjunctivitis is a part of the classical triad and is observed very early, before or at the onset of arthritis; the discharge is sterile and subsides in 1 to 4 weeks. Uveitis is less frequent in early disease but occurs in 15 per cent of patients with recurring disease, often as an incident separate from arthritis.

Intestinal symptoms

Acute diarrhoea may precede the musculoskeletal symptoms by 1 month or less (Table 1; item 8). This diarrhoea, resulting from an outbreak of enterobacterial infection, may affect many individuals, but only some of them will go on to suffer from what has been called epidemic reactive arthritis. Dysenteric symptoms are sometimes very mild in these patients and even milder than in non-arthritic patients. If no medical advice or treatment was required, the symptoms may be ignored if patients are not closely questioned. The provocative agent has commonly disappeared from the gut when the joint symptoms arise, and during an epidemic it is identified in diarrhoeal but not in arthritic patients. The isolation of a triggering agent from the stool of an arthritic patient is a rare event, except for salmonellae (Hannu and Leirisalo-Repo 1988). An agent is called arthritogenic if, during an outbreak, some cases of reactive arthritis are observed among a number with only dysentery. *Shigella flexneri* type 1 and 2, *Salmonella enteritidis* and *S. typhimurium, S. abony, S. blocley, S. schwarzengrund, S. heidelberg, S. haifa, S. manila, S. newport, Clostridium difficile* (Puterman and Rubinow 1993), *Vibrio parahaemoliticus* (Tamura *et al*. 1993), *Yersinia pseudotuberculosis*, and *Y. enterocolitica* fall within this definition. *Shigella sonnei, S. typhi*, and *Escherichia coli* dysenteric syndrome, in contrast, have so far not been complicated by reactive arthritis. *Yersinia enterocolitica* is often mentioned as the triggering agent in Northern Europe. Infection by *Y. enterocolitica* in Belgium, the country with the highest incidence of this infection, is strongly associated with eating raw pork (Tauxe *et al*. 1987).

Chronic diarrhoea or other gut symptoms are not associated with reactive arthritis; nevertheless, overlap with inflammatory bowel disease-associated arthropathies and the histological finding of silent inflammatory gut lesions in some cases of reactive arthritis make the demarcation blurred and the diagnosis of undifferentiated spondylarthropathies very helpful (see 'Enteric arthropathies in adults' below).

Urogenital symptoms

Non-specific urethritis is generally limited to a mild, painless, and non-purulent urethral discharge. It may be asymptomatic and detected by examination of the first

morning urine specimen. Occasionally, however, it is severe and accompanied by prostatitis. In women, cervicitis is usually marked by vaginal discharge but may be asymptomatic.

Urethritis can also be a postdysenteric phenomenon, apparently not sexually acquired, raising the possibility that inflammation may be due to mechanisms other than direct infection.

Non-gonococcal, sexually acquired urethritis was followed by a clinical picture of reactive arthritis in 16 out of 531 men followed prospectively (Keat *et al*. 1987). Agents associated with non-gonococcal urethritis, and particularly *Ch. trachomatis*, which is the most frequently isolated, have therefore been considered as candidates for triggering sexually acquired reactive arthritis. *Chlamydia pneumonia* infection and antibodies against *Ch. pneumoniae* are highly prevalent in the adult population These antibodies make the genus/species tests unhelpful as a means of screening for the serological diagnosis of *Ch. tracomatis* infections (Freidank *et al*. 1993). But is *Ch. pneumoniae* itself able to trigger a reactive arthritis (Braun *et al*. 1994)?

Mycoplasmas and even ureaplasmas that are pathogenic for the human genital tract still require rigorous investigation. It is now clear that sexually acquired reactive arthritis is not attributable to a single micro-organism. Recurrent or repeated infections do not always lead to recurrence of arthritis and may occur in the absence of further sexual intercourse.

In women, reports of reactive arthritis following acute urogenital symptoms are scarce. Of women reviewed 2 to 4 years after the onset of salpingitis, 72 per cent had radiological or scintiscan evidence of sacroiliitis and a substantial proportion of these also had low back pain (Szanto and Hagenfeldt 1979). However, these findings have not, to date, been correlated with any specific microbiological data and raise difficulties of interpretation that remain unresolved.

Genetic background

Family studies of first- and second-degree relatives may be helpful for diagnosis. Questions should not be limited to the history of reactive arthritis, even if multiple cases have been reported in some families (Wright 1978), but should also concern other rheumatological aspects of spondylarthropathies (ankylosing spondylitis, episodes of oligoarthritis) and their most common extra-articular manifestations or associations (iritis, psoriatic skin lesions, or inflammatory bowel disease). A well-defined family history (Table 1; item 11) may provide a reliable diagnosis in the absence of specific clinical symptoms when testing for HLA-B27 antigen is not desirable for technical or economical reasons, and in HLA-B27-negative individuals (Dougados *et al*. 1991).

Response to treatment

Response to treatment is not a common tool for diagnosis, except when it is dramatic or specific, such as with colchicine in gout, penicillin in gonococcal arthritis, and corticosteroids in polymyalgia rheumatica. Pain at night and morning stiffness in spondylarthropathies are very sensitive to non-steroidal anti-inflammatory drugs. Item 12 in the diagnostic criteria (Table 1) takes advantage of this response and defines its limits (dramatic improvement within 48 h with these drugs or relapse of pain in less than 48 h after their discontinuation).

Laboratory features

The inflammatory nature of the disease is biologically confirmed by an elevated erythrocyte sedimentation rate and an increased concentration of C-reactive protein. Analysis of synovial fluid shows more than 2000 cells/mm^3, with a majority of polymorphonuclear leucocytes; synovial biopsy shows inflammatory changes including vascular congestion and perivascular cell infiltration, mainly of neutrophils. Cultures of synovial tissue or fluid are negative. The synovial complement concentration is normal. HLA-B27 is present in 50 to 80 per cent of cases. In the absence of, or in addition to, a family history, the presence of the HLA-B27 antigen constitutes item 11 in the criteria.

For therapeutic decisions in some cases, but mainly for epidemiological or for research purposes, many biological tests can be performed: these include stool cultures, which might be positive during an outbreak of gastroenteritis but are often negative when arthritic symptoms occur. *Chlamydia trachomatis* may be detected by microimmunofluorescence with specific antisera on urethral or cervical scrapings. Tests for detecting specific antibodies or the stimulation of blood mononuclear cells by bacterial antigen have no significant predictive value for reactive arthritis in the general population or even in the rheumatology clinic (Sieper *et al*. 1993a); the proliferation of mononuclear cells from synovial fluid appears more specific and could give some information on the triggering agent when the preceding infection is asymptomatic (Ford *et al*. 1985; Sieper *et al*. 1993b). The search for the products of triggering agents using specific monoclonal antibodies, or DNA or RNA hybridization, is limited to research purposes (Granfors *et al*. 1989).

In the early stages, no radiographic signs are found except for changes in the sacroiliac joint in 4 per cent of patients, probably present before the onset of reactive arthritis.

Evolution

In the short term

The first oligoarticular episode subsides in 3 to 6 months, during which time symptomatic treatment is generally required. The first episode may be longer in severe polyarticular involvement, or very short and often wrongly attributed to trauma when only one joint is affected. Two sites, the metatarsophalangeal joints and the heels, may remain painful for months and in some cases for 1 to 4 years. Extramusculoskeletal symptoms also subside, but balanitis and psoriatic lesions may persist for longer. When all symptoms are taken into account, 75 per cent of patients are in complete remission at the end of the second year after onset (Fig. 5). One per cent of patients with reactive arthritis, particularly those with keratoderma blennorrhagica, may have a very severe and even fatal outcome (Temine *et al*. 1972).

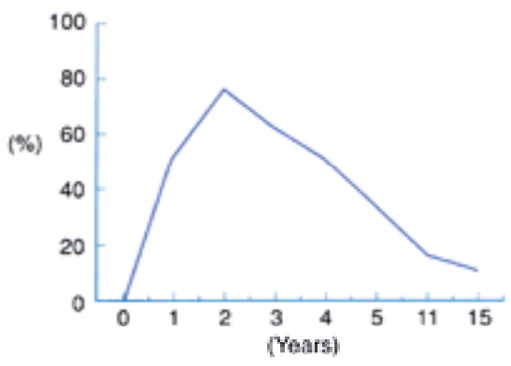

Fig. 5 Complete remission: incidence across 15 years.

In the long term and prognosis (Amor 1979; Amor et al. 1994)

Figure 6 is based on synoptic recording of the disease pattern, as shown in Fig. 1, applied to 140 patients with reactive arthritis across 15 years. It shows the percentage of relapses and clinical involvement in these patients over time. Relapses begin 3 to 4 years after the first episode and can consist of recurrence of peripheral arthritis or enthesopathic pain (Fig. 6a), of pelviaxial symptoms (Fig. 6b), or of iritis or other extra-articular symptoms (Fig. 6c); these symptoms can be isolated or associated. Radiographic changes may now be observed. Narrowing of joint spaces and erosions are very uncommon, except when reactive arthritis is associated with psoriatic lesions.

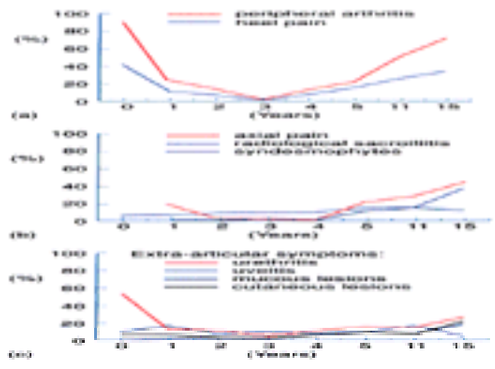

Fig. 6 Synoptic recording, as in Fig. 1, of the disease pattern in 140 patients with reactive arthritis across 15 years. (a) Recurrence of peripheral arthritis or enthesopathic pain; (b) recurrence of pelviaxial symptoms; (c) recurrence of iritis or other extra-articular symptoms.

Enthesopathic lesions can be visualized at an early stage by focal uptake of [$^{99}Tc^{m}$] methylene diphosphonate (**MDP**) (Fig. 7). Later radiographic changes, such as bone erosions (Fig. 8) and large and fluffy bone spurs, may develop along the metatarsals, the phalanges of the feet, the calcaneum (Fig. 9), and the pelvis.

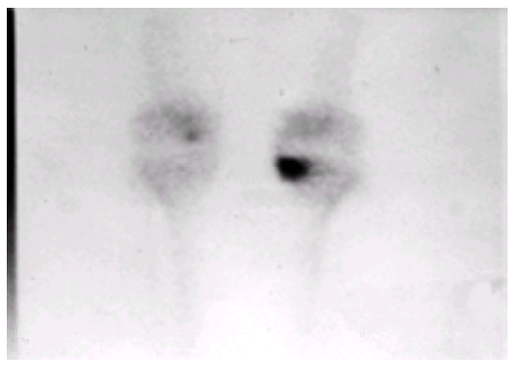

Fig. 7 Enthesopathic lesion visualized by focal uptake of [$^{99}Tc^{m}$]MDP.

Fig. 8 Advanced changes in enthesopathic lesions: erosion and calcaneal spur.

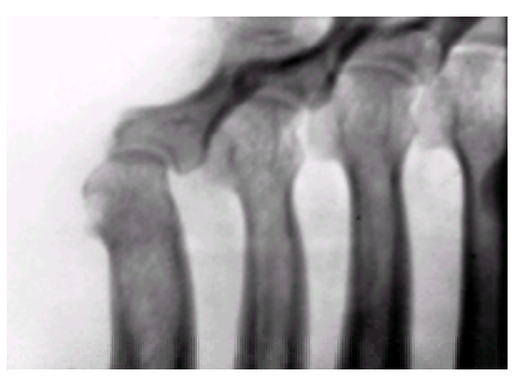

Fig. 9 Enthesopathic erosive lesion of the fifth metatarsal head.

Sacroiliitis, indistinguishable from that seen in ankylosing spondylitis, is observed in 4 per cent of patients at onset. Its frequency increases with time: it is observed in 37 per cent of patients followed for 15 years or more (see Fig. 6b) and is associated with axial lesions of ankylosing spondylitis in 15 per cent of cases. Over 25 per cent of patients were forced to change occupation or were unemployable. The percentage of remissions and the clinical nature of relapses over time are similar in HLA-B27-positive and -negative patients (Table 2). Seven predictive factors of long-term outcome have been selected and weighted (Table 3). If the sum of these factors at entry was 3 or less, a benign outcome could be predicted with a sensitivity of 92 per cent and a specificity of 78 per cent (Amor *et al*. 1994).

Duration of follow-up (years)	No. of patients	HLA-B27 (percentage remissions)		
		B27	B27+	B27 –
1	123	75	50	55
5–10	69	68	36	38.4
11–15	40	65	17.6	20

Table 2 Percentage of complete remissions according to HLA-B27 antigen status over time

Reactive arthritis according to sex, age, and triggering agents

Better knowledge of the disease and more accurate diagnostic criteria have allowed recognition of reactive arthritis in women and children. Nevertheless, the sex ratio (M:F) is still 3:1 and three-quarters of affected patients are young adults under 40 years of age.

As an example, more than 1000 cases of postdysenteric reactive arthritis were observed in Algeria between 1954 and 1960 among young French adults during their military service, whereas the local population, whatever its ethnic origin, remained unaffected. The local population has a frequency of HLA-B27 antigen of 6 per cent and ankylosing spondylitis is as common as in other caucasoid countries but more severe (Will *et al*. 1990). This observation suggests that some agents, especially those that are water-borne, do not trigger reactive arthritis in very young children.

In patients with yersinial arthritis who were HLA-B27-positive, inflammatory symptoms in the urinary tract, ocular inflammation, and back pain during acute disease were significantly more common than in HLA-B27-negative patients (Leirisalo *et al*. 1982). In contrast, erythema nodosum was more frequent in HLA-B27-negative patients with yersinial arthritis.

Differential diagnosis outside the spondylarthropathy group

Other sexually acquired arthritis

Gonococcal arthritis must be suspected in any cases of acute or subacute arthritis, usually in women. A search for *Neisseria gonorrhoea* in urethral and cervical discharges, and by culture of blood and synovial fluid, must be made concurrently with a search for agents that trigger reactive arthritis. During isolation procedures, if a gonococcal infection is suspected clinically, a therapeutic test using antibiotics exclusively is justified because arthritis will subside dramatically within 3 days and completely within 10 days.

Human immunodeficiency virus (HIV)-associated arthritis

Acute but transitory joint pains are described during the early stage of the disease; they differ from the synovitis of reactive arthritis, but reactive arthritis, like other spondylarthropathies, may be worsened by HIV (Winchester *et al*. 1987; Rowe and Keat 1989). The search for HIV infection is often recommended in even the typical case of reactive arthritis.

Behçet's syndrome

In Behçet's syndrome the painful aphthous ulcerations of oral or genital mucosa are different from the painless mucosal lesions of reactive arthritis. The total or posterior uveitis of Behçet's syndrome may be distinguished from the iritis or anterior uveitis of spondylarthropathies. Strictly oral but recurrent aphthous lesions are sometimes described by spondylarthropathic patients, leading to some confusion in their classification, which may explain some of the discrepancies concerning the frequency of sacroiliitis in Behçet's syndrome.

Parvovirus arthropathies

In parvovirus arthropathies, an acute arthritis associated with lumbar pain may mimic the onset of reactive arthritis. However, the transient erythematous skin lesions and the spontaneous recovery may help in the clinical identification of this disease (White *et al*. 1985).

Lyme disease

Oligoarthritis in Lyme disease (Steere *et al*. 1983) in young people may be confused with reactive arthritis if patients are not asked about a past history of erythema chronicum migrans or a stay in an endemic area. Enthesopathic pains are sometimes described in Lyme disease. When serological indications of Lyme disease are unclear, treatment with high doses of penicillin alone (or other antibiotics), which promptly relieves symptoms in Lyme disease but is ineffective in reactive arthritis, may be helpful.

Differential diagnosis inside the spondylarthropathy group: limits of this concept

Among patients identified as having reactive arthritis in the absence of the typical oculo–urethro–synovial triad, differential diagnosis from the other spondylarthropathies is often disputed because overlaps are numerous. From a practical point of view, these disputes are probably unimportant. However, questions as to the limits of the spondylarthropathy group do arise; they concern psoriatic arthropathies and **SAPHO** (see below).

According to the criteria for spondylarthropathies, patients with psoriatic arthritis are classified into those that meet these criteria and those that do not and in whom psoriasis appears to be associated with other rheumatic disorders such as rheumatoid arthritis.

SAPHO (synovitis, acne, palmoplantar pustulosis, hyperostosis, aseptic osteomyelitis) (Chamot et al. 1987)

The use of this grouping may help to classify patients with different clinical presentations, such as acute pseudoseptic arthritis associated with palmoplantar pustular lesions and multifocal aseptic osteomyelitis whether associated or not with the same skin lesions. The boundaries between palmoplantar pustulosis and psoriasis, the occurrence of bone lesions around the sacroiliac joints, and the presence of HLA-B27 antigen in some patients may make their classification difficult.

The boundaries of reactive arthritis

Postyersinial erythema nodosum may be used to introduce the issue of the boundaries of reactive arthritis. The highly statistical difference in the occurrence of erythema nodosum between HLA-B27-positive and -negative individuals may indicate that postyersinial erythema nodosum is not reactive arthritis but the result of the interaction of the same infectious agent on a different genetic background. Erythema nodosum is not otherwise described among the cutaneous manifestations observed in reactive arthritis triggered by infectious agents other than *Yersinia* spp.

The definition of reactive arthritis given earlier clarifies this issue because postyersinial erythema nodosum does not fit the diagnostic criteria for the spondylarthropathies.

The same can be said for diseases that have sometimes incorrectly been called reactive arthritis, such as rheumatic fever or parasitic arthritis. No relation exists at any level (clinical, pathological, genetic, or therapeutic) between rheumatic fever and reactive arthritis. It is nevertheless suggested that b-haemolytic streptococci may trigger reactive arthritis as well as rheumatic fever in genetically predisposed patients (Valtonen *et al*. 1993). The treatment of carcinoma of the bladder by intravesical injection of bacillus Calmette–Guérin may induce an arthritis which in some cases fits the diagnostic criteria for the spondylarthropathies. Anecdotal reports of arthritis associated with brucellae, *Mycobacterium phlei*, or parasitic infections cannot be classified as reactive arthritis because they are cured by a specific treatment, which is not the case in true reactive arthritis.

Pathogenesis of reactive arthritis

The precise disease mechanism for reactive arthritis is still unknown and research in this field has focused mainly on immunogenetics because of the association between this arthritis and HLA-B27, and on microbiology in view of the clinical data concerning the triggering of the disease by micro-organisms (Enterobacteriaciae and *Ch. trachomatis*). The interplay between these two areas of research has generated hypotheses that apply not only to reactive arthritis but also to the other forms of spondylarthropathies and even more generally to an HLA–disease association (for a full review of possible pathogenetic mechanisms, see Chapter 5.4.1.). Several controversial aspects of the links between HLA-B27 and reactive arthritis-triggering bacteria have been unravelled by some recent findings. They all point to an important role of the *in situ* antibacterial immune response. Concerning *Ch. trachomatis*, analysis by polymerase chain reaction has shown that the organism could be

present in the synovium of reactive arthritis (Rahman *et al*. 1992), albeit in a form lacking the expression of the lipopolysaccharide and major outer-membrane surface antigen (Beutler *et al*. 1994), so reflecting a state of latency and an inability of the host to clear the infection. This phenomenon could be caused by the local production of interferon-g, consistent with the predominant Th1 phenotype of the T-helper cells in synovial fluid (Simon *et al*. 1993). Another major advance has been the isolation from lymphocytes in the synovial fluid of reactive arthritis of HLA-B27-restricted, CD8 + and bacteria-specific, cytotoxic T lymphocytes (Herman *et al*. 1993). Finally, the absence of arthritis in HLA-B27 transgenic rats (Hammer *et al*. 1990) raised in a germ-free environment (Taurog *et al*. 1994) provides a strong argument for the direct effects of both HLA-B27 and bacterial antigens in the pathogenesis of reactive arthritis and provides a precious tool for future experimental studies.

Management (Box 1)

There is no cure for reactive arthritis, but symptomatic treatments may considerably reduce the discomfort resulting from its musculoskeletal and extra-articular features.

Non-steroidal anti-inflammatory drugs promptly relieve pelviaxial pain but do not always have such clear-cut efficacy for arthritis and enthesopathies. Local injections of corticosteroids are in this instance helpful while awaiting the usual remission, 3 to 6 months later. Arthritic metatarsophalangeal joints should receive local injections very early in the disease course, and should then be passively and actively mobilized to avoid permanent deformity from fibrous retraction. In a double-blind, placebo-controlled study of 3 months, lymecycline significantly decreased the duration of illness in patients with *Ch. trachomatis*-triggered reactive arthritis but not in those with other reactive arthritides (Lauhio *et al*. 1991). A 6-month follow-up of an outbreak of *S. enteritidis* enterocolitis found arthritic symptoms in 17 of 108 patients (15 per cent) that were not prevented by early antibiotic treatment; neither did antibiotics affect the duration of reactive arthritis (Locht *et al*. 1993).

Urethritis following dysentery subsides spontaneously in a few days. Postvenereal or apparently spontaneous urethritis may be aseptic and does not respond to antibiotics. Its chronicity or frequent relapses may disturb the patient and the family. A feeling of guilt and anxiety about sexual misconduct should be allayed and the patient enlightened. Intraurethral instillation of corticosteroid may stop the chronic urethral discharge.

Early conjunctivitis subsides spontaneously. Inflammation of the uveal tract requires steroid eye-drops or subconjunctival injections. However, systemic steroids have no proven, as opposed to anecdotal, role in the management of reactive arthritis. For those patients with relentless progression of the disease, second-line drugs may be given. The efficacy of sulphasalazine (2–3 g/24 h) in ankylosing spondylitis (Dougados *et al*. 1986) has been shown in a 6-month controlled study against placebo. The clinical benefit of this drug is more clear-cut in spondylarthropathies with peripheral involvement (Amor *et al*. 1984) such as reactive arthritis. Uncontrolled data suggest that methotrexate (7.5–15 mg/week) and gold salts given in a schedule similar to that used in rheumatoid arthritis may be suitable. In a placebo-controlled study (Calin 1986), azathioprine (1–2 mg/kg body wt daily) was shown to be helpful. However, immunosuppressive therapy should be avoided in young adults, unless other treatment has failed, and must be used as a last resort.

Prevention of reactive arthritis and of relapses

The diversity of agents that may trigger reactive arthritis and the significant number of cases in which no infectious agent at all is identified render preventive treatment, akin to the use of penicillin in rheumatic fever, impracticable.

Nevertheless, the number of patients with sexually acquired reactive arthritis has notably decreased in recent years and this may be due to early treatment of non-gonococcal urethritis. A study in Greenland, where epidemiological conditions are favourable (Bardin *et al*. 1990), seems to indicate that the treatment of non-gonococcal urethritis with tetracycline significantly reduces relapses of the arthritis.

Many workers have observed that in epidemic dysentery, patients with reactive arthritis have not required treatment during the dysenteric episode. This observation may also indicate that the genetic background of reactive arthritis has protects from severe diarrhoea.

Enteric arthropathies in adults

Connections between gut diseases and arthritis have been described for reactive arthritis, where only acute and time-limited dysenteric syndromes occurring within 1 month before the onset of the arthritis are considered as criteria for diagnosis (item 8; Table 1).

However, an association between gut disease and arthritis can be observed in other conditions:

1. arthritis associated with or complicating chronic inflammatory bowel diseases;
2. arthritis leading to the discovery of minor and previously not mentioned gut symptoms;
3. arthritis associated with purely histological gut lesions.

The whole of this puzzle is more or less included within the definition of spondylarthropathies, but a description of each entity, emphasizing the clinical differences, is nevertheless needed. Apparently unrelated to the spondylarthropathies are the arthritis of Whipple's disease, the bypass arthritis–dermatitis syndrome, collagenous colitis, and gluten-sensitive enteropathy.

Issues concerning the bowel flora, diet, and arthritis are mainly speculative and are discussed in Chapter 5.5.1.

Arthritis associated with inflammatory bowel disease

Ulcerative colitis

The association between colitis and arthritis was first described at the end of the nineteenth century (White 1895). It was dismissed as coincident rheumatoid arthritis until 1958, when closer studies showed it to be a seronegative arthritis with distinctive features (Bywaters and Ansell 1958). Different series have shown incidences of arthritis varying from 2.5 to 22 per cent. An incidence of 11.5 per cent in a large unselected series of 269 cases (Wright and Watkinson 1966) is typical. Ulcerative colitis itself occurs in 50/100 000 individuals in England and Scandinavia, but may be less prevalent in other geographical areas.

Crohn's disease

The prevalence of Crohn's disease now exceeds that of ulcerative colitis. The disease has become more frequent in the last 30 years, mainly in northern Europe (Moll 1985), and is making an appearance in southern Europe and in Africa. Arthritis occurs in 10 to 20 per cent in most series.

Arthritis in both ulcerative colitis and Crohn's disease shows many similarities, and both are considered as members of the spondylarthropathy group. Item 9 (present or past history of inflammatory bowel disease) of the criteria shown in Table 1 allows for their classification in this group.

A familial history of inflammatory bowel disease (item 11) associated with any of the other items (sum > 6), in the absence of such disease in the patient, allows only for the diagnosis of spondylarthropathy.

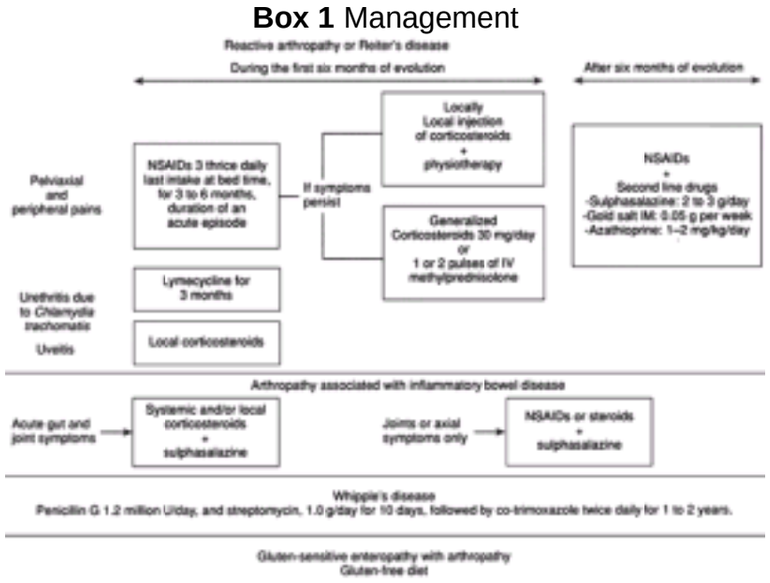
As in other spondylarthropathies, four clinical syndromes, more or less combined, may be described: a peripheral arthritis syndrome, an enthesopathic syndrome, a spinal or axial syndrome, and an extra-articular syndrome.

Peripheral arthritis

Mono- or asymmetrical oligoarthritis is coincident with the onset of inflammatory bowel disease or arises during the course of the disease. There is a close temporal association between exacerbations of the gut and joint disorders. Enteropathic arthritis remits after removal of the diseased bowel segment.

The knees are most commonly involved, closely followed by the ankles. Other joints may be affected, but less frequently. Individual attacks are self-limiting, 50 per cent lasting less than 6 months and only 20 per cent persisting longer than 1 year. Even when recurrent they do not lead to permanent joint damage or deformity (Haslock and Wright 1973). A few cases of erosive large-joint arthritis associated with granulomatous synovitis have been reported in Crohn's disease (Toubert *et al*. 1985). Otherwise the synovial tissue shows non-specific inflammatory changes as in synovial fluid (more than 4000 cells/mm ^{3}, the majority polymorphs).

Box 1 Management



Enthesopathic pain, particularly in the heel, may either be isolated or associated with peripheral arthritis or axial involvement.

Axial involvement

In contrast to peripheral arthritis, sacroiliitis and/or spondylitis are not clearly associated either with the onset of inflammatory bowel disease or with gut exacerbations. Spondylitis is often present years before the onset of colitis or ileitis.

The frequency of ankylosing spondylitis (5 per cent), and asymptomatic sacroiliitis (14 per cent) (Wright and Watkinson 1965) is similar in males and females. HLA-B27 antigen is present in 50 per cent of these patients. HLA-Bw62 is increased in Crohn's disease and in Crohn's arthritis (Mielants and Veys 1990).

Other osteoarticular manifestations

Clubbing of fingers has been reported (Kitis *et al*. 1979) but pulmonary osteoarthropathy may be only coincidental, as are many other more common musculoskeletal disorders.

In Crohn's disease, psoas or retroperitoneal abscess may be complicated by septic arthritis of the hip (Kyle 1971).

Extra-articular syndrome (Greenstein et al. 1976)

Uveitis is observed in 10 per cent of the cases and occurs more frequently in arthritic patients.

Erythema nodosum appears more frequently in Crohn's disease (6.6 per cent) than in ulcerative colitis (4 per cent), while pyoderma gangrenosum is more frequent in ulcerative colitis (5 per cent compared to 1.3 per cent) (Greenstein *et al*. 1976). In the same study, out of 160 patients with Crohn's disease, 17 had both cutaneous and joint lesions, 23 had only arthritis, and 13 only skin lesions. Psoriasis was observed in 1.5 per cent of the patients.

Aphthous stomatitis (4 per cent) is the oral lesion most frequently seen, often associated with erythema nodosum.

Gallstones, kidney stones, and liver disease are not associated with arthritis.

Arthritis with mild, previously unnoticed gut symptoms and asymptomatic gut lesions

When patients suffering from features of spondylarthropathy are asked about gastrointestinal symptoms, some previously unnoticed dysfunctions may be revealed, such as mild but recurrent episodes of diarrhoea, anal fistula, episodes of unexplained weight loss, or a low serum cholesterol. Ileocolonoscopy in those patients often shows Crohn's disease-like lesions (aphthoid ulceration, histiocytic microgranuloma, pyloric metaplasia, and sarcoid-like granuloma). These instances of subclinical inflammatory bowel disease, mainly Crohn's disease, are underestimated (Hogan *et al*. 1980).

Mielants and Veys (1990) have found similar lesions in patients with spondylarthropathies with a negative history for gut symptoms and in patients with ankylosing spondylitis whose next of kin suffered from proven Crohn's disease. In all patients with Crohn's disease-like lesions, the gut inflammation persisted together with the joint inflammation and was more severe in nature, whereas most acute lesions disappeared.

Systematic ileocolonoscopy has been performed in 30 patients suffering from spondylarthropathies without any gut symptoms and in 18 non-arthritic patients who required this examination. Macroscopic and microscopic lesions were classified according to the descriptions of Mielants and Veys (1990). Mild lesions suggestive of gut inflammation were observed in 10 of the 30 patients and in none of the reference group ($p < 0.02$). Microscopically, there were minimal signs of inflammation (lymphocyte and plasma-cell infiltration) at the ileum level in 18 out of 19 patients compared to 11 out of 18 in the reference group ($p < 0.05$), and at the rectum level in 15 out of 19 compared to 8 out of 17 ($p < 0.05$) (Dougados *et al*. 1987).

Whipple's disease

Whipple's disease is a rare, multisystem disorder first described in 1907. Most of 500 documented cases originate from Europe and the United States. Despite its rarity, some reports mention the occurrence of Whipple's disease among individuals living in close proximity to one another (Maizel *et al*. 1970). Three patients in the same village within a 10-year period and two patients who inhabited the same farmhouse, although several years apart, were reported by Capron *et al*. (1973) and Capron *et al*. (1975).

Clinical features

Clinical manifestations (Rubinow 1988) attributable to virtually every organ system may occur in Whipple's disease and frequently may appear years or sometimes decades before the onset of diarrhoea and malabsorption. Polyarthritis, prolonged fever, weight loss, lymphadenopathy, arterial hypotension, hyperpigmentation, polyserositis, and cardiac and pulmonary symptoms are seen with varying frequency. Central nervous abnormalities including personality changes, memory loss, ataxia, presenile dementia, myoclonus, spastic paresis, seizures, ophthalmoplegia, papilloedema, retrobulbar neuritis, and deafness may appear early in the course of the disease. Anaemia and leucopenia are common haematological manifestations. Only on rare occasions have these features been recognized as prodromes of Whipple's disease.

Polyarthritis is the most common prodromal feature: 60 to 90 per cent of patients have articular involvement, which is the sole initial manifestation of the disease in 50 per cent of them.

The attacks of arthritis are characteristically acute in onset, often transient, and intermittent. They last from a few hours only to a few days and usually remit

spontaneously. More rarely, the attacks may be of longer duration or even continue relentlessly for several years. Migratory oligoarthritis is more frequent than symmetrical polyarthritis or monoarthritis. Some patients complain only of recurrent arthralgia, whereas in others mild to florid synovitis may be observed. In order of frequency the joints affected are the knees, ankles, wrists, elbows, and small joints of the hands and shoulders. Residual joint deformity is usually absent or mild. The attacks of arthritis do not parallel the occurrence of diarrhoea, and the arthritis appears to subside several months to 2 years before the onset of diarrhoea and weight loss. The arthritis usually resolves within 2 months of instituting antibiotic therapy, and the reappearance of joint symptoms may herald a relapse due to premature discontinuation of that therapy. Subcutaneous nodules and clubbing are infrequent features.

Findings in synovial fluid vary with the clinical severity of the arthritis from more than 20 000 cells/mm ^{3}, mainly polymorphs, to lower white counts with a high percentage of mononuclear cells. The histopathological appearances of the synovial membrane parallel the inflammatory response found in the synovial fluid. Large, foamy, vacuolated cells containing periodic acid–Schiff (**PAS**)-positive granules and bacilli in various stages of degradation have been observed during acute episodes of arthritis in two patients, and non-caseating granulomatous lesions with histological features of sarcoidosis (Rouillon *et al*. 1993).

The involvement of axial joints is not as frequent as peripheral arthritis. When strict criteria were applied, only 4 of 95 patients could be classified as either definite ankylosing spondylitis or sacroiliitis. The spondylarthropathy criteria have not been tested on enough patients with Whipple's disease to know how many would be classified in this group of diseases. HLA-B27 antigen is present in over 30 per cent of patients according to Dobbins (1985) and in 1 out of 6 patients described by Khan (1982).

The ability to attribute early arthritic features to Whipple's disease requires a high index of suspicion and astute clinical acumen. Many patients are managed for many years as palindromic rheumatism, atypical rheumatoid arthritis, systemic lupus, or sarcoidosis. With the onset of abdominal pain, diarrhoea, steatorrhea, and weight loss the disease is more readily recognizable.

The diagnosis depends on the presence of PAS-positive macrophages in the jejunum or extraintestinal sites and eventually electron-microscopic demonstration of typical bacilli. Bacterial identification is made possible by applying the polymerase chain reaction to amplify the 16 *s* ribosomal RNA gene sequences in tissue samples (Relman *et al*. 1992).

Pathogenesis

Different organisms easily cultured by routine microbiological methods for the bowel flora have been proposed as Whipple's bacillus. None of them combines the size and the Gram-positive coloration of the intracellular bacilli. By applying the polymerase chain reaction to amplify 16- *s* ribosomal RNA gene sequences, a previously uncultured new bacterium, *Tropheryma whippelii*, was discovered. It has some homology with the actinomycetes. Other bacteria have also been described (Harmsen *et al*. 1994). A dysfunction of monocytes and macrophages was shown by Bjerknes *et al*. (1985): phagocytosis was normal but no intracellular degradation of *E. coli, Streptococcus pyogenes*, or zymogen particles was observed. Degradation was similarly impaired 3 and 9 months after therapy; intracellular binary fission could take place after phagocytosis. Conceivably, impaired degradation of killed or viable bacteria may lead to macrophage overload and impair their antigen-presenting functions.

Treatment

The efficacy of antibiotic therapy in Whipple's disease makes this condition, once universally fatal, totally distinct from arthritis associated with inflammatory bowel disease.

Tetracycline has been the mainstay of most treatment schedules but despite initial resolution in nearly all cases of gastrointestinal and extraintestinal features, within a week to a month after beginning tetracycline (1 g/day), some patients developed late, irreversible lesions of the central nervous system (Knox *et al*. 1976). The present recommendations for the treatment of newly diagnosed patients include parenteral penicillin G, 1.2 million units/day, and streptomycin, 1.0 g/day for 10 days, followed by co-trimoxazole twice daily for 1 to 2 years (Dobbins 1985).

Arthritis–dermatitis syndrome associated with bypass surgery (Utsinger et al. 1988)

Arthritis occurs in 8 to 36 per cent of patients (mostly females) after jejunocolonic bypass. The onset may be at any time in the first 3 years after bypass. The joints commonly affected include the metacarpophalangeal and proximal interphalangeal, wrists, knees, and ankles, sometimes with a symmetrical, rheumatoid-like presentation. The pattern of involvement is most often one of brief remissions. Chronic arthritis, juxta-articular erosions, and spondylitis are very rare. White-cell counts in synovial fluid have ranged from 500 to 39 000 cells/mm ^{3}, of which 10 to 98 per cent are polymorphonuclear leucocytes. Synovial biopsy demonstrates chronic synovitis with lymphocytic predominance but no lymphoid follicles.

Rheumatoid factor and antinuclear antibodies are absent, and the arthritis has no consistent histocompatibility association.

Dermatitis

Skin lesions accompany this arthritis in over 80 per cent of patients. The most common lesions are urticarial or papulovesicular. Lesions progress in 24 to 72 h from initially discrete macules of 2 to 12 mm diameter to pustulovesicles. Lesions are often at different stages of development. Other skin lesions include necrobiosis lipoidica, erythema nodosum, and various forms of cutaneous vasculitis. Jorizzo *et al*. (1983) suggest that the bowel bypass syndrome may occur without actual bypass.

This syndrome is associated with elevated levels of circulating immune complexes and cryoprotein precipitates (Utsinger *et al*. 1988). The antibodies in the complexes are more often to *E. coli* than to *Bacillus fragilis* or to group D streptococci.

Collagenous colitis

This condition was first described by Lindström (1976) and of some 40 patients to date, 10 per cent have had arthritis. Intestinal features consist of intermittent or persistent diarrhoea without bleeding. The majority of the patients are adult women, with a mean age of 56 years. The diagnostic finding is the linear deposition of hyaline material, 1 to 100 µm thick, consisting principally of collagen III, in the subepithelium of the colon. Lymphocytes, plasma cells, and a few eosinophils are also found, and sometimes an inflammatory exudate is present. The histological findings are distinct enough to differentiate the condition from other diseases of the colon (Rams *et al*. 1987). The aetiology is unknown. Treatment is symptomatic. Sulphasalazine and mepacrine have been recommended, with, in some cases, efficacy for both colitis and arthritis (Combe *et al*. 1988).

Gluten-sensitive enteropathy

There are some descriptions of arthropathy in cases of gluten-sensitive enteropathy (Adelizzi *et al*. 1982; Bourne *et al*. 1985; Pinals 1986). Occult coeliac disease in adults (Chakravarty and Scott 1992) and in children (Simoes and Amor 1992) is also associated with arthropathies. Effusive arthritis was present in knees and ankles, and responded promptly to a gluten-free diet. Arthralgia, sclerodactyly, and finger contracture have been described in a 60-year-old man, 10 years after the initial diagnosis of coeliac disease.

5.6.1 Pauciarticular-onset juvenile chronic arthritis

David D. Sherry and Elizabeth D. Mellins and Barbara S. Nepom

Pauciarticular-onset juvenile chronic arthritis is the most commonly encountered subset of the chronic childhood arthritides, accounting for 40 to 50 per cent of all patients with juvenile chronic arthritis. By definition its onset occurs before the age of 16 years, active synovitis of at least one joint is present continuously for a minimum of 6 weeks by American Rheumatism Association criteria (Brewer *et al*. 1977) or for 3 months by European League Against Rheumatism criteria (Wood 1978), and a total of four or fewer joints are involved during the first 6 months of disease. Some of the characteristics which make this disease entity quite distinct from other forms of juvenile or adult arthritis include its striking predilection for preschool-age girls, the tendency for involvement of large joints excluding the hip and shoulder, the frequent occurrence of chronic anterior uveitis, the presence of antinuclear antibodies, and unique immunogenetic associations.

In our discussion we do not include a group of patients sometimes called pauciarticular juvenile chronic arthritis type 2. This designation refers to a condition predominantly affecting older boys (over 8 years old), with lower extremity arthritis, in whom HLA B27 is frequently found. These children generally have enthesitis (Rosenberg and Petty 1982) and may have more than four joints involved. The pattern of disease in these children is more consistent with spondylarthropathy than pauciarticular-onset juvenile chronic arthritis (see Chapter 5.5.2).

Epidemiology

Pauciarticular-onset juvenile chronic arthritis is a rheumatic disease distinctly of childhood, and the vast majority of patients are female toddlers. Overall, the disease affects an estimated 20 to 30 per 100 000 children (Gare *et al*. 1987). The female to male ratio is 4:1 (Petty 1979), and may be as high as 7.5:1 among children with iridocyclitis and chronic arthritis (Spalter 1975). The age at onset peaks sharply between 1 and 3 years, but ranges from as young as a few months of age to the teenage years (see Fig. 1 and Cassidy and Petty 1995). Only a limited number of cases in adults have been reported (Chaouat *et al*. 1990; Kenesi-Laurent *et al*. 1991), and the absence of HLA DR5 and of eye involvement in patients in the latter series raises the possibility that pauciarticular arthritis in adults represents a distinct disease entity. No unique racial or geographic associations have been described for this type of arthritis.

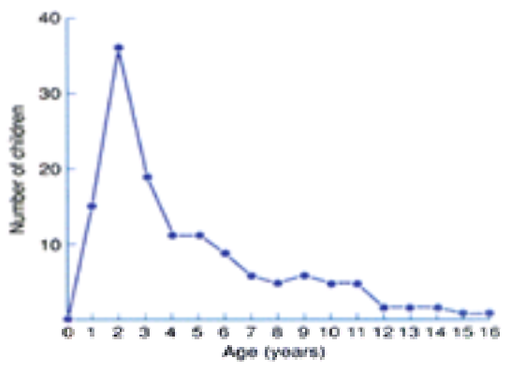

Fig. 1 Age at onset in 137 consecutive children with pauciarticular-onset juvenile chronic arthritis.

Clinical features

Juvenile chronic arthritis is always a diagnosis of exclusion, as there are no pathognomonic signs, symptoms, or laboratory investigations. Nevertheless, the classic clinical picture is quite recognizable: an otherwise healthy female toddler who has arthritis in only a few joints, such as one knee and one ankle (see Fig. 2(a)). Clinical features are usually mild compared with other forms of juvenile chronic arthritis, reactive arthritis, or joint infections (Morrissy 1990; Sherry 1990; Cassidy and Petty 1995). Non-articular inflammation is rare, except for chronic asymptomatic uveitis (discussed in detail below). Many children complain of little pain and are brought to the physician because joint swelling was noted by a parent. In one study, 26 per cent of patients presented without any pain whatsoever (Sherry *et al*. 1990). Those with symptoms usually complain of morning stiffness, gelling, or pain with use, but typically are not incapacitated and limit their activities only modestly. Constitutional signs and symptoms such as fever, malaise, anorexia, or organomegaly are not a part of pauciarticular-onset juvenile chronic arthritis and, if present, virtually exclude this diagnosis.

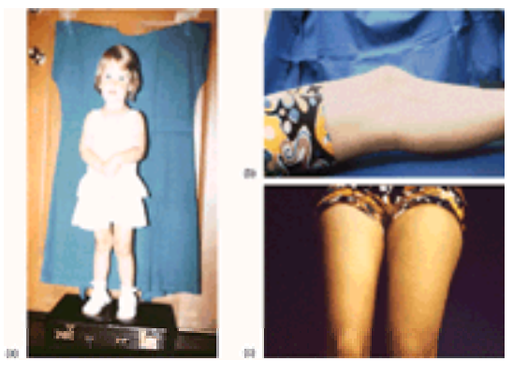

Fig. 2 Clinical features of pauciarticular-onset juvenile chronic arthritis. (a) Archetypical patient with pauciarticular-onset juvenile chronic arthritis. Note generally healthy young girl with involvement of a single knee. (b) Unilateral flexion contracture as seen frequently in pauciarticular-onset juvenile chronic arthritis. To evaluate

for subtle flexion contraction, especially in children with hypermobility, lift both heels equally high and observe for unequal knee height. (c) Thigh atrophy in unilateral disease. This may be a permanent sequela.

In 137 consecutive patients with this condition, we have found that almost half had involvement of the knee, with the ankle joint being the next most frequently affected (Table 1). In general, the joints most frequently involved are reported to be, in order, the knee, ankle, and elbow (Schaller and Wedgwood 1972; Ansell 1977). Involvement of other joints is less frequent, but not uncommon. Children with arthritis in just one or two small joints of the hand do not have the usual pattern of joint involvement, but in our experience, most do not progress to polyarticular changes. Involvement of the shoulder is exceedingly rare. Occasional patients with this pauciarticular-onset arthritis will eventually develop disease of the temporomandibular joint (Strabrun 1991) or cervical spine; the latter can produce torticollis. Arthritis of the hip is so rare in this condition that when that joint is involved at presentation, the diagnosis is suspect and should be made only after extensive evaluation for other causes. There will also be an occasional child who has five or six joints affected over the first 6 months, but whose disease never evolves into the typical polyarticular pattern with symmetrical involvement of many joints including the small joints of the hands. Although meeting criteria for polyarticular-onset juvenile arthritis, these children have a disease more like the pauciarticular-onset disease in terms of their risk for chronic uveitis and long-term prognosis.

	%
Single joint	62
Two joints	31
Three joints	4
Four joints	3
Knee	47
Ankle	21
Small hand joint	12
Wrist	5
Elbow	3
Hip	3

Table 1 Pattern of joint involvement at presentation in 137 consecutive cases of pauciarticular-onset juvenile chronic arthritis

Laboratory features

No particular laboratory abnormalities are diagnostic of pauciarticular-onset juvenile chronic arthritis. Acute-phase reactants are usually normal to slightly elevated. Occasionally one will see a child with synovitis of a few joints and a markedly elevated erythrocyte sedimentation rate. This should prompt an extensive search for infection or occult inflammation, such as inflammatory bowel disease or leukaemia. Reactive or viral arthritis may also produce high erythrocyte sedimentation rates. A rare condition, congenital hyperfibrinogenaemia, will cause a persistently elevated erythrocyte sedimentation rate without other laboratory features of inflammation.

Antinuclear antibodies (**ANA**) are present in 40 to 75 per cent of children with pauciarticular-onset chronic arthritis, depending on the analytical technique employed. These are directed to a heterogeneous mixture of nuclear antigens and usually give a homogeneous pattern, although a speckled pattern can also be observed. Antibodies to histones are relatively common; one report identified them in 42 per cent of patients with uveitis-negative, pauciarticular-onset disease (Malleson *et al*. 1992). ANA titres are usually low, less than or equal to three dilutions beyond the threshold of normal. Higher titres, especially in the older patient, should be investigated for specific autoantigens. For example, antibodies to DNA and extractable nuclear antigens would lead to the suspicion of systemic lupus erythematosus or mixed connective tissue disease. Antinuclear antibodies may develop over time; therefore, an initially negative ANA should be repeated within 1 year, owing to its critical importance in determining uveitis risk (see below). Most studies find no connection between the titre of ANA and disease activity. There is no evidence that ANA precede the development of pauciarticular-onset juvenile chronic arthritis; in fact, most healthy children with an isolated positive ANA will not develop any rheumatic disease when followed over several years (Cabral *et al*. 1992).

Rheumatoid factor is distinctly rare, occurring in less than 5 per cent of children with pauciarticular-onset disease. When it is present, it portends a polyarticular, prolonged course with a high risk of erosive arthritis. Non-classical rheumatoid factors (IgG and IgA) have been reported, but the significance of these is unknown.

Synovial fluid or a synovial biopsy are usually obtained only as an aid to excluding other diagnoses. Synovial fluid most often contains less than 25 000 white blood cells/mm^3, with most of these being polymorphonuclear. The glucose concentration in synovial fluid is within 10 per cent of the serum glucose concentration; protein concentration is elevated.

A synovial biopsy has features similar to those of adult rheumatoid arthritis, with hyperplasia and hypertrophy of the synovial lining, and vascular endothelial hyperplasia with lymphocytic and plasma cell infiltration. Progression of these inflammatory changes to pannus formation and cartilaginous and eventually bony erosion, although uncommon in pauciarticular-onset arthritis, can occur and is indistinguishable pathologically from other forms of juvenile or adult rheumatoid arthritis (Cassidy and Petty 1995).

Radiographs taken early in the disease process reveal joint effusion or soft tissue swelling. Over time, juxta-articular osteoporosis occurs, followed in more severe cases by joint space narrowing and ultimately erosions. However, many bones are cartilaginous in young children (such as the carpals) or have cartilaginous epiphyses. As these ossify, the articular surface may appear quite irregular or multiple ossification centres may occur, giving the appearance of an erosion. Bilateral views are necessary to assess joint space narrowing or growth abnormalities. The expertise of a paediatric radiologist familiar with the spectrum of normal variants in childhood musculoskeletal imaging should be sought.

Course

In most children with pauciarticular-onset arthritis, the disease remains pauciarticular. Although synovitis may develop in new joints over time, the total number of affected joints remains below five. A relatively short course of active arthritis, usually 2 to 5 years, is typical. Some of these children will have a subsequent episode of chronic arthritis, sometimes many years after the original episode. Each episode seems to mimic the first in terms of joints affected and duration of disease.

An important minority will eventually develop arthritis in many joints, yet only about 20 per cent of all children with disease of pauciarticular onset will later be classified as functional stage III or IV (Stoeber 1981; Cush and Fink 1987). There is a growing impression among paediatric rheumatologists that a larger number of children with pauciarticular-onset chronic arthritis may have long-term, active synovitis than was formerly appreciated (Cush and Fink 1987), and this number may not be reflected in the functional classification data. One North American study showed that patients with three or four arthritic joints at onset, or who had involvement of the ankle, wrist, or smaller joints, were more likely to develop a polyarticular course (Cush and Fink 1987; Wallace and Levinson 1991). However, in a European study, those with monoarticular disease developed polyarticular arthritis slightly more frequently than those with the oligoarticular type (Dequecker and Mardjuadi 1982). It is generally only those converting to a polyarticular course who develop marked joint destruction, similar to those with polyarticular-onset juvenile chronic arthritis. A patient whose disease remains pauciarticular for 5 years is unlikely to progress to polyarticular involvement.

Complications

Articular complications

Children with pauciarticular-onset chronic arthritis are at risk of developing juxta-articular muscle atrophy, bony enlargement of the joint, or leg length inequality (Fig. 2(b and c)). Muscle atrophy may be dramatic. When knee synovitis starts before the age of 3 years, quadriceps muscle atrophy may continue years after disease is past (Vostrejs and Hollister 1988). Bony overgrowth around the affected joint is primarily of cosmetic concern. In those children with unilateral knee involvement, bony

overgrowth may lead to a significant leg length discrepancy. When disease begins before 3 years of age, a longer leg develops on the affected side (Vostrejs and Hollister 1988), whereas when disease onset is after the age of 9 years, premature epiphyseal closure can occur, resulting in a shorter leg on the involved side (Simon *et al*. 1981). Mechanically, a longer leg on the involved side may be a problem, since the child will flex the arthritic knee to keep the pelvis level, thus exacerbating a flexion contracture. Rarely, a severe flexion contracture may progress to subluxation. Flexion contracture of the elbow can lead to an apparent foreshortening of the arm, causing a dwarf-like appearance. Effectively controlling joint inflammation can minimize, but not necessarily eliminate, these complications.

Synovial cysts, especially in the popliteal space, are not uncommon (Szer et al.1992). Intra-articular triamcinolone hexacetonide (1 mg/kg) is curative in most, because these cysts communicate with the adjacent joint. Acute onset of intense limb pain and swelling suggests a ruptured cyst.

Ocular complications

In addition to musculoskeletal complications, a chronic, insidious and potentially sight-threatening form of uveitis can occur in children with pauciarticular-onset chronic arthritis. Described first in a case report in 1910 (Ohm 1910), the association of chronic uveitis and juvenile arthritis is now firmly established and available data suggest it is observed worldwide (for historical review see Rosenberg 1987). The ocular inflammation of juvenile chronic arthritis characteristically affects the anterior uveal tract (the iris and ciliary body); involvement of the posterior uveal tract (the choroid) is infrequent (Key and Kimure 1975).

Prevalence studies of uveitis in patients with pauciarticular-onset juvenile chronic arthritis in the United States and Britain suggest that approximately 20 per cent develop chronic uveitis (reviewed in Sherry *et al*. 1991). Uveitis is also seen in a small fraction of patients with polyarticular onset (5 per cent) and more rarely in those with systemic-onset juvenile chronic arthritis (Key and Kimure 1975; Chylack 1977). The risk of uveitis is associated with the pauciarticular mode of onset of arthritis and not with the later extent of articular disease. In two independent studies, polyarticular disease developed in about 45 per cent of pauciarticular-onset patients with uveitis (Kanski and Shun-shin 1984; Wolf *et al*. 1987). Children with uveitis thus appear to contribute disproportionately to the group with pauciarticular-onset whose disease becomes polyarticular.

In addition to pauciarticular onset of arthritis, other risk factors for the uveitis associated with juvenile chronic arthritis have been identified (Table 2). Young girls who are seropositive for ANA and seronegative for rheumatoid factors are at highest risk. Indeed, the risk of developing uveitis for ANA-positive females whose pauciarticular-onset disease began before the age of 2 years is estimated at greater than 95 per cent (Chylack *et al*. 1979). It is not known why ANA are a serological marker of those at risk. Interestingly, these antibodies are not found in patients with chronic anterior uveitis without juvenile chronic arthritis, although this disease has otherwise similar characteristics, including a female preponderance (Rosenberg and Romanchuk 1990). In children with uveitis associated with chronic arthritis, the titre of the ANA is usually intermediate (less than 1:640) and does not correlate with the severity of ocular disease (Kanski 1977). No differences in reactivity to defined nuclear antigens are found in the ANA of children with and without uveitis (Malleson *et al*. 1989). One study of children with pauciarticular-onset chronic arthritis reported a correlation between antibodies to a novel 15-kDa nuclear antigen and uveitis, although some individuals with this antibody did not show ANA positivity in other tests (Neuteboom *et al*. 1992).

Female gender	
Female–male ratio	4.7–7.5 : 1[a]
Young onset age of arthritis	
Mean onset age (years)	4.6
Oligoarthritis	
Percentage with pauciarticular-onset arthritis	86.6
Percentage with polyarticular-onset arthritis	12.6
Percentage with systemic-onset arthritis	0.8
Antinuclear antibody positivity	
Percentage positive	80–90[b]

[a]Reviewed in Cassidy and Petty (1995).
[b]The percentage of uveitis patients with detectable antinuclear antibodies has risen to 90+ per cent since 1975 when sensitive assays became available (Wolf *et al*. 1987).
Table modified with permission from Rosenberg (1987).

Table 2 Risk factors associated with uveitis in juvenile chronic arthritis

The uveitis is commonly asymptomatic, even in the face of substantial damage to the eye. In reported series, pain and redness of the eye occur in up to 25 per cent of patients; visual disturbance, photophobia, and headache are less frequent (reviewed in Cassidy and Petty 1995). Detection of disease generally requires slit-lamp ophthalmological examination. Routine surveillance (slit lamp) of at-risk patients is thus essential, at a frequency determined by the presence of risk factors (Table 3). Biomicroscopic signs of active disease include the presence of inflammatory cells and protein flare in the anterior chamber of the eye and fresh keratitic precipitates. On the initial rheumatological evaluation, one should look carefully for evidence of earlier uveitis, such as pupillary irregularities and punctate corneal deposits (Fig. 3). If present, immediate ophthalmic evaluation is appropriate. If not, regular slit-lamp examinations should be arranged.

Systemic onset:	Yearly
Pauciarticular or polyarticular onset	
Under 7 years of age at onset:	
ANA positive:	Every 3–4 months for 4 years, then: Every 6 months for 3 years, then: Yearly
ANA negative:	Every 6 months for 7 years, then: Yearly
Seven years of age or older at onset:	Every 6 months for 4 years, then: Yearly

These guidelines are for patients who do not develop uveitis during this time. For those patients who develop uveitis, ophthalmological treatment and surveillance will be determined by the ophthalmologist; most patients will require more frequent long-term surveillance.
[a]Taken from the American Academy of Pediatrics Section on Rheumatology and Section of Ophthalmology (1993).

Table 3 Uveitis surveillance: recommended frequency of slit lamp examinations [a]

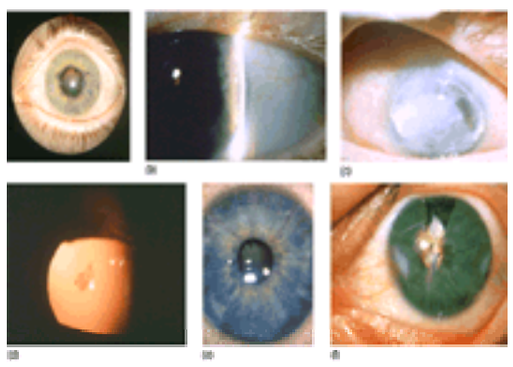

Fig. 3 Ocular involvement in juvenile chronic arthritis. (a) Signs of uveitis visible on clinical examination. This eye has developed pupillary irregularities from synechiae, which adhere the iris to the lens capsule. The dilation of the pupil reveals numerous areas of adhesion. The clouding of the pupillary reflex is caused by keratitic precipitates, which are clumps of inflammatory cells on the posterior surface of the cornea. (b) The white lacy area represents paralimbal band keratopathy, caused by deposition of calcium in Bowman's layer. (c) Extremely severe, untreated band keratopathy. (d) Small posterior subcapsular cataract, seen by retroillumination. Cataract formation may result from either steroid therapy or disease. (e) Chronic iritis with more advanced, complicated cataract. Posterior synechiae are also visible and can induce secondary glaucoma. (f) Ocular findings after surgical intervention for complicated cataract. The pupil has been secondarily scarred

down, after removal of cataract membrane. Ocular inflammation predisposes to this degree of scarring, which severely compromises vision. Current surgical techniques attempt to avoid these complications. Note the horseshoe iridectomy, performed for glaucoma, as well as the paralimbal band keratopathy at 3 and 9 o'clock.

In most children, uveitis and arthritis develop at different times. Uveitis is documented before onset of arthritis in 10 per cent of affected children (Rosenberg 1987), but asymptomatic (and undetected) uveitis may precede arthritis more often. Among routinely screened children with chronic arthritis, uveitis is usually detected within 7 years (median, 2 years) of the onset of arthritis (Kanski and Shun-shin 1984). However, uveitis has developed up to 34 years after joint symptoms (Cassidy *et al*. 1977).

This uveitis is a chronic condition, rarely lasting less than 2 years and often more than 15 years (Smiley 1976). In a study of 20 patients, the course was remitting and relapsing in 60 per cent, persistent in 20 per cent, and limited to a single episode in 20 per cent (Rosenberg 1987). Both eyes are involved in roughly two-thirds of patients (Rosenberg 1987), but both are not necessarily inflamed at the same time. Moreover, children with uveitis of one eye rarely develop involvement of the second eye after more than 1 year of unilateral disease (Kanski 1990). Eye and joint disease evolve independently, and the overall severity of each is likely to differ (Leak and Ansell 1987). In many cases, uveitis persists years after the arthritis has become inactive (Key and Kimure 1975).

A variety of ocular complications can occur in the uveitis associated with juvenile chronic arthritis (Fig. 3). Posterior synechiae, which are fibrous bands adhering the iris to the lens, give the pupil a star-burst or irregular appearance. Band keratopathy, a layer of calcium deposits in Bowman's membrane of the cornea, is another characteristic sequela. The pathogenesis of this condition is unknown and active iritis may persist for years without the development of keratopathy. Other complications include cataracts, glaucoma, and rarely, phthisis bulbi. Approximately 40 per cent of affected eyes progress to 20/200 visual acuity or below, and approximately 10 per cent of affected eyes will become blind (Rosenberg 1987).

Differential diagnosis

Conditions that may simulate pauciarticular-onset juvenile chronic arthritis can be classified into four major categories: monoarticular conditions, short-lived inflammatory conditions, spondylarthropathies, and complaints of pain without joint inflammation. A list of these conditions, along with some of the features distinguishing them from pauciarticular-onset arthritis, is given in Table 4 (see also related chapters in this text).

Table 4 Differential diagnosis of pauciarticular-onset juvenile chronic arthritis

Monoarticular conditions

Monoarticular conditions are the most difficult to sort out and include several requiring immediate intervention. However, it is not uncommon for careful examination of a child with monoarticular complaints to reveal involvement of other joints. When a single joint is involved, pauciarticular-onset juvenile chronic arthritis is a frequent cause, but the conditions described in Table 4 should also be considered.

Short-lived inflammatory conditions

These conditions cause inflammation in one or several joints which can simulate pauciarticular-onset juvenile chronic arthritis, and include inflammatory reactions to a number of viral and bacterial infections. However, the inflammation is relatively fleeting, usually lasting 1 to 4, but occasionally up to 8 weeks. When evaluating a child within the first weeks of disease, one need not withhold anti-inflammatory treatment in order to establish a diagnosis. Only rarely would juvenile chronic arthritis respond so well as to go into complete remission in such a short time.

Spondylarthropathies

These conditions are discussed at length in Chapter 5.5.2, and are contrasted with pauciarticular-onset juvenile chronic arthritis in Table 4. Briefly, unlike pauciarticular-onset disease, they occur predominantly in adolescents, boys are much more commonly affected than girls, the arthritis is usually limited to the lower extremity and involves both large and small joints, enthesitis is common, and HLA B27 is highly associated (Rosenberg and Petty 1982). Heel pain is often noted in spondylarthropathies but is uncommon in pauciarticular-onset arthritis. Furthermore, the iritis that occurs with the spondylarthropathies, in contrast to that of pauciarticular-onset disease, is typically acute and painful, leading to scleral injection and photophobia.

Pain complaints without joint inflammation

Many children present with musculoskeletal pain that does not emanate from the joint. Younger children in particular may not localize their pain accurately. These conditions can be persistent and underlying arthritis may be suspected, but true arthritis is never seen. The most common examples are listed in Table 4.

Treatment

As pauciarticular-onset juvenile chronic arthritis often affects the joints and eyes of very young children, a team approach which provides expertise in paediatric rheumatology, ophthalmology, physical therapy, and sometimes psychosocial issues is optimal. The overall guiding principle in treating these children is to keep the joint(s) as normal as possible while the disease is active so that once it becomes quiescent, the child is left with minimal complications. A corollary to this is to treat ocular inflammation early and thoroughly.

Control of intra-articular inflammation is paramount (Emery 1993). Initially non-steroidal anti-inflammatory drugs (**NSAIDs**) are given (see Table 5 and Ansell 1983; Silver 1988; Duffy *et al*. 1989; Hollingworth 1993). While a few studies have demonstrated the effectiveness of particular NSAIDs, such as aspirin, tolmetin, and naproxen (Levinson *et al*. 1977; Moran *et al*. 1979; Kvien *et al*. 1984), there are no consistent findings as to relative efficacy and tolerance. Therefore, the choice of non-steroidal drug is largely empirical, often dictated by the availability of liquid preparations for small children or by individual response. Twice-daily preparations enhance compliance.

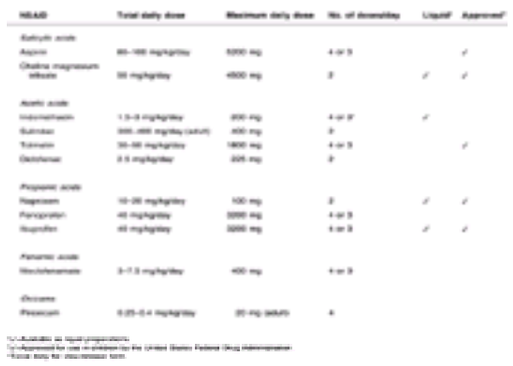

Table 5 Non-steroidal anti-inflammatory drug (NSAID) use in children with juvenile chronic arthritis

Most NSAIDs are tolerated well by children, with little clinical evidence of gastritis. Chemical hepatitis is their most common untoward effect, with aspirin the leading cause (Bernstein *et al*. 1977). We recommend close monitoring when liver function tests such as aspartate aminotransferase reach a level greater than three times normal, and we generally will stop the medication when the level rises to four times normal.

Pseudoporphyria, a skin disorder characterized by skin fragility, vesiculation, and scarring, has recently been reported as a side-effect of NSAIDs, particularly naproxen, among patients with juvenile chronic arthritis (Levy *et al*. 1990; Lang and Finlayson 1994). Both excessive sun exposure and fair complexion seem to increase risk for this complication. Scarring can also occur in the absence of blistering (Wallace *et al*. 1994).

The association of aspirin with Reye's syndrome, though controversial, is of concern, and it is prudent to interrupt aspirin therapy when influenza or varicella infection is suspected. It is not necessary or practical, however, to stop the drug during every viral syndrome in young children. It has been recommended that children treated with aspirin receive an annual influenza immunization (Committee on Infectious Diseases 1994).

Idiosyncratic reactions to all of the NSAIDs can occur. Neurological complications such as depression or personality changes are uncommon, and can be difficult to detect in very young children. Close attention to parental concerns is warranted.

While children often take NSAIDs for years without side-effects, potentially severe complications can occur, such as blood dyscrasias or renal papillary necrosis. Therefore we recommend careful monitoring during their use, including a complete blood count with platelet count, aspartate aminotransferase, alanine aminotransferase, blood urea nitrogen, creatinine, and urinalysis at least twice a year while on a stable dose.

Often an individual child will not respond, or not respond optimally, to a particular preparation. It can be difficult to determine when to move on to a different NSAID, and especially to a disease-modifying drug. Our guidelines are to try three NSAIDs, preferably from three different biochemical classes, at an optimal dose for 2 months each before moving on to other therapy (Lovell *et al*. 1984).

Intra-articular steroids are very useful and can be given in a number of different situations (Allen *et al*. 1986). These injections are warranted in some very young children who have great difficulty taking oral medications, especially those with only a few involved joints. If a single joint is affected, we are more likely to try intra-articular injection early. We will also consider steroid injection when the joint swelling is extreme and unlikely to respond rapidly to NSAID use. Injections can also be very useful if NSAID therapy is not possible owing to severe allergy or toxicity such as renal papillary necrosis.

In addition, we consider synovial cysts an indication for intra-articular injection. Synovial cysts usually completely resolve on injection of the adjacent joint with a steroid preparation (Allen *et al*. 1986). We will also consider intra-articular steroids if the arthritis is severe (intense symptoms or flexion contracture) or prolonged. Unacceptable duration of arthritis must be determined individually, but in our clinic we will inject a joint if it is markedly swollen over 3 months on optimum NSAID therapy. Finally, medical therapy will sometimes control inflammation successfully except for one recalcitrant joint; in that case, intra-articular injection may be a useful adjunct.

Some joints may not respond to an initial injection but respond well to a second attempt. If successful, joint injection can be repeated to a maximum of three injections per year per joint, or a total maximum of six injections per joint. If the arthritis continues beyond this time, more aggressive treatment is required. Intra-articular steroids may lead to localized cutaneous atrophy, hypopigmentation, or intra-articular calcifications, but these are rarely of clinical significance. We use triamcinalone hexacetonide up to 1 mg/kg for the larger joints. Triamcinalone acetonide may also be used.

Some children with prolonged or intense arthritis, or with evolution to a more severe polyarticular course, will require more aggressive medical treatment. In these cases, we frequently use sulphasalazine because of its ease of administration, relative safety, and effectiveness in chronic arthritis (Gedalia *et al*. 1993). Its use is especially attractive in those children whose disease is not erosive, but who have persistent and recalcitrant inflammation. Long-term sequelae such as degenerative joint disease are of concern in patients with persistent inflammation, even in the absence of radiographic changes.

For those children who develop destructive joint changes, more aggressive therapy may be indicated. As in children with polyarticular or systemic-onset chronic arthritis, early recognition and aggressive treatment of destructive disease is critical for optimal outcome. While pauciarticular-onset juvenile chronic arthritis most often carries a favourable prognosis, it is important to monitor patients closely to identify those who will progress to more severe disease. For example, radiographs of affected joints should be obtained yearly in patients with persistent arthritis. Unlike typical adult rheumatoid arthritis, radiographic signs of destructive joint disease may not become evident in juvenile chronic arthritis until many years into the disease course.

For those patients requiring further disease-modifying drugs, there are several options (Rosenberg 1989; Gabriel and Levinson 1990 ; Giannini *et al*. 1993), although few studies have been done in pauciarticular-onset juvenile chronic arthritis. There is some controversy as to the effectiveness of hydroxychloroquine, and one study found no difference between it and placebo (Van Kerckhove *et al*. 1988). Similarly, good data on the use of gold and penicillamine are scant. Methotrexate has been used in some pauciarticular-onset patients with good results (Truckenbrodt and Häfner 1986; Wallace *et al*. 1989; Giannini *et al*. 1992); its safety and efficacy make it an increasingly attractive option in this setting. We currently will often use methotrexate if NSAIDs and sulphasalazine have failed. Methotrexate is usually given at a dose between 0.3 and 0.6 mg/kg per week (usually leaning toward the higher dose) as a single oral, subcutaneous, or intramuscular dose. An occasional patient is given as much as 1 mg/kg per week. We monitor blood counts, liver enzymes, and renal function monthly. The role of liver biopsy in ascertaining toxicity is controversial and presently we do not recommend it (Walker *et al*. 1993).

In those patients whose arthritis completely resolves, the question of when to stop medication arises. The length of treatment depends on the severity and duration of the arthritis; in general, the more difficult it is to achieve remission, the longer the treatment will continue after remission. For example, if the disease lasts 6 to 12 months, we will discontinue medications 3 to 6 months after remission. If the disease lasts longer, medications should be continued for 6 to 12 months past remission. In pauciarticular-onset juvenile arthritis, remission must be a clinical diagnosis, as many children will never have morning stiffness, increased erythrocyte sedimentation rate, or even joint pain. We define remission as the complete clinical absence of active synovitis, in addition to the lack of the conventional signs and symptoms mentioned above. Thus we continue to treat children if they have joint swelling, even if they have no complaints and are fully functional.

Motor activity is so critical to all aspects of childhood, including growth, development, and social interactions, that we are very aggressive in the use of physical therapy to keep the range of motion and muscular strength as normal as possible. However, age-appropriate exercise programmes require experience and creativity. Young children may be particularly difficult to treat because they unconsciously substitute the use of unaffected muscle groups during exercise; for the same reason, normal play activities are not an acceptable alternative to directed physical therapy. Many of these children benefit from seeing a physical therapist experienced in the treatment of these diseases. This can also help decrease parent–child conflicts over exercising.

Although not usually needed, orthotic devices can be very useful in appropriate patients. A few children have tenacious flexion contractures that require serial night splinting or even serial casting to correct. Serial casting is usually carried out three times a week for up to a month. Casting under anaesthesia is done infrequently but can be of great help in difficult situations. Where there is length inequality, shoe lifts on the short side improve gait and encourage full knee extension on the long

side; this also helps keep the quadriceps muscle strong, especially the vastus medialis, which contracts only during the last 10° of knee extension.

Surgical intervention is rarely necessary. Synovectomy for chronic arthritis is controversial and long-term benefit is limited. In one well-designed study, synovectomy did not prevent progressive joint destruction in adult rheumatoid arthritis (Arthritis Foundation Committee on Evaluation of Synovectomy 1988). Although the complications of arthroscopic synovectomy are much lower than with the open procedure, the effort required in rehabilitation makes this procedure inappropriate for younger children. Chemical and irradiation synovectomies in children have not been adequately studied and we have no experience with these modalities. The rare child with subluxation of the knee may require surgical correction; long-term outcome is uncertain regardless of surgery. Leg length inequality can, rarely, persist into adolescence and is amenable to growth-stopping procedures on the long leg (Simon *et al*. 1981).

In some patients, eye involvement proves to be more of a therapeutic challenge than the joint disease. Corticosteroid eye drops and mydriatics to prevent synechiae are the typical initial regimen and are generally thought to be effective in preserving vision in eyes with minimal inflammation (Wolf *et al*. 1987). None the less, in one study, 42 per cent of children had not responded to topical steroids after 6 months, despite early detection and treatment of disease (Chylack 1977). Unresponsive disease is usually treated with subtenon injections of steroid or with oral prednisone; however, these increase the risk of cataract formation and glaucoma. Adjunctive use of NSAIDs may permit a reduction in steroid dose (Olson *et al*. 1988). Experience with immunosuppressive therapy such as azathioprine or chlorambucil is limited (reviewed in Kanski 1990); cyclosporin A has been used in severe, refractory uveitis. Band keratopathy may require chelation with EDTA or corneal scraping. Surgical intervention may also be necessary for cataracts and glaucoma. In the past, surgical treatment has been only marginally successful in these children, but results with microsurgical techniques and laser therapy are improving (Flynn *et al*. 1988; Kanski 1990).

The psychosocial aspects of pauciarticular-onset juvenile chronic arthritis bear some mention, especially as they may affect the ability to deliver therapy. The vast majority of patients are young and resilient and do quite well psychologically. They are not particularly limited and are able to carry out developmental tasks without difficulty. However, control issues may become a source of persistent strife between child and parent. This is especially true of the young child who may dislike taking medicine or exercising and the adolescent who is beginning to individuate from the family and deny imperfections. Moreover, even though pauciarticular-onset arthritis may be a mild condition in the spectrum of chronic childhood diseases, it can be a source of substantial distress in individual families. The degree of other stresses in the family, particularly parental dysfunction, may contribute more to the state of psychological health of children with juvenile chronic arthritis than the disease itself (Daltroy *et al*. 1992). Therefore, appropriate attention to these issues can potentially have a dramatic impact on the well-being of the child.

The child with pauciarticular-onset chronic arthritis is best cared for by an interdisciplinary team consisting of members who are experienced with the complications of this disease and intimately familiar with each other's roles (Brewer *et al*. 1989). This will enhance both family education and team communication. This team should include physicians (a paediatric rheumatologist, ophthalmologist, and orthopaedist), nurses, physical and occupational therapists, a social worker, and, as needed, other health professionals such as a nutritionist. It is with such a team that a uniform, consistent plan of therapy can be initiated and appropriately altered if complications arise. Preventive measures, especially those dealing with psychological or behaviour factors, can be instituted.

Prognosis

Over 80 per cent of children with pauciarticular-onset chronic arthritis suffer little or no musculoskeletal disability at 15-year follow-up (Ansell and Wood 1976; Stoeber 1981; Dequecker and Mardjuadi 1982). The small percentage of those who do poorly is exclusively made up of those children whose disease follows a polyarticular course (Cush and Fink 1987). The majority of the children who become polyarticular do so within the first 5 years of onset. It has been hoped that certain HLA genes might be associated with the subset of children who progress to a polyarticular course and thus predict those at high risk, but at this time there is no consensus that particular genes are helpful in predicting disease course in an individual child (see below).

The outcome in the associated uveitis varies from remission without residua to significant visual loss. A critical determinant affecting outcome is the extent of disease at initial examination (Wolf *et al*. 1987). Eyes which are normal or have mild uveitis at first evaluation do significantly better than those with posterior synechiae (Table 6). In addition, early onset of uveitis in relationship to arthritis correlates with poor outcome (Wolf *et al*. 1987). Ocular prognosis is of greatest concern if uveitis is documented before the onset of arthritis, as progression to symptomatic disease implies significant injury to the eye (Wolf *et al*. 1987). These results strongly suggest that early intervention beneficially influences outcome; indeed, if untreated, uveitis may cause irreversible injury and visual loss in as little as 2 years (Wolf *et al*. 1987). However, there may also be a subgroup of patients with a more benign form of the disease (Smiley 1976). Kanski (1977) reported that 8 out of 26 eyes with continuing active uveitis for more than 10 years remained free of complications or visual loss. Unfortunately, no particular features distinguish such a subset of children at disease onset. The overall prognosis for vision among patients with the uveitis associated with juvenile arthritis has apparently improved in recent years (Sherry *et al*. 1991; Cassidy and Petty 1995). This observed decrease in disease severity is probably due to more comprehensive detection of uveitis, including benign disease, and to more timely treatment.

Cumulative complications	Initial examination	
	Mild uveitis[a] (% of eyes)	Advanced uveitis[b] (% of eyes)
None	64	
Posterior synechiae	12	100
Cataract	28	81[c]
Band keratopathy	5	77[c]
Glaucoma	17	45[c]
Phthisis bulbi	0	13
Final visual acuity < 20/200	3	58[c]

[a]Normal, cells, flare, or keratitic precipitates (*n* = 58 eyes).

Table 6 Frequency of complications of chronic uveitis

Aetiology

The aetiology of pauciarticular-onset juvenile chronic arthritis is unknown. Any satisfactory model of pathogenesis must account for the two most striking features of this disease: the preponderance of young female patients and the frequent association of uveitis. The former suggests a possible contribution of an X-linked gene; the latter may reflect tropism of an infectious agent or involvement of an autoantigen common to the eye and the joint.

One attractive hypothesis is that dysregulation of the immune response is important in disease aetiology. This notion is supported by the observation that disease susceptibility is conferred by particular HLA haplotypes (see below). There is also some evidence of aberrant immune reactivity in these patients (reviewed in Miller 1990). Examples include the presence of ANA, elevated levels of circulating immune complexes, and altered *in vitro* immunoglobulin synthesis. Children with pauciarticular-onset chronic arthritis have been found to have an increased C3d/C3 ratio, suggesting activation of the alternate complement pathway. A correlation between C3d/C3 ratios and the titre of IgG antibodies to lipid A was also observed in pauciarticular-onset disease, suggesting these antibodies may play a role in disease pathology (Olds and Miller 1990). In addition, IgA deficiency and pauciarticular-onset disease have been associated. These findings may represent primary immune abnormalities that contribute to pathogenesis or may be secondary to the disease process. Other indices of immune function in these patients, such as lymphocyte subpopulation ratios and responses to mitogens, are usually normal.

The possibility that juvenile chronic arthritis represents a chronic infection or that it is initiated by an environmental trigger has prompted the search for candidate micro-organisms. No single pathogen has been consistently identified with the development of this disease (Phillips 1988). Rubella virus has been isolated from lymphoreticular cells of 7 of 19 children with chronic rheumatic disease, including 2 of 6 with pauciarticular-onset disease (Chantler *et al*. 1985). Persistence of rubella virus in these patients may reflect an aetiological role for the virus or a state of immunodeficiency in the patients. In two small series, antibody to peptidoglycan, a constituent of bacterial cell walls, was elevated in 25 to 50 per cent of pauciarticular patients with chronic uveitis (Burgos-Vargas *et al*. 1986; Moore *et al*. 1989). This finding may be relevant to disease aetiology because humoral immunity to streptococcal cell wall preparations has been implicated in the pathogenesis of chronic synovitis in animal models (Greenblat *et al*. 1980). Alternatively, these antibodies may reflect a state of altered immune reactivity in children with juvenile chronic arthritis. In this regard, it is of interest that defective antibody responses to immunization with bacteriophage were observed in a study of children with each type of

juvenile chronic arthritis (Ilowite *et al*. 1987).

The aetiology of the associated uveitis is likewise unknown, but appears to be immune mediated. Histopathological studies show non-granulomatous, inflammatory infiltration, including plasma cells and lymphocytes (Sabetes *et al*. 1979). Ocular fluids from affected eyes contain elevated immunoglobulin levels (Sabetes *et al*. 1979; Rahi *et al*. 1977) and ANA (Rahi *et al*. 1977). The antigenic stimulus that initiates or maintains this process has not been identified. Inflammation of both the joint and eye occur in several diseases (e.g. Kawasaki's disease, seronegative spondylarthropathies, inflammatory bowel disease). The possibility that collagen acts as an autoantigen at both sites has been investigated in patients with juvenile chronic arthritis, but studies have failed to demonstrate a heightened immune response to collagen in children with uveitis (Rosenberg 1987). In one study, 29 per cent of patients with pauciarticular-onset juvenile chronic arthritis and uveitis were found to have serum antibodies to a low-molecular-weight fraction of bovine iris proteins. However, the presence of these antibodies did not correlate with severity of uveal inflammation (Hunt *et al*. 1993). Paradoxically, 30 per cent of children with this chronic arthritis and uveitis manifest a humoral response to a retinal antigen, S (Petty *et al*. 1987). Immunization with this protein induces an acute uveitis in animal models, but its role in chronic uveitis is unclear, as there is at present no animal model of chronic uveitis.

Immunogenetics

Several lines of evidence indicate that genetic factors are involved in disease susceptibility (summarized in Maksymowych and Glass 1988; Cassidy and Petty 1995). Multiple cases of pauciarticular-onset juvenile chronic arthritis within one family are unusual, but some have been reported. In addition, concordance for disease is increased in twins; in many cases, clinical disease manifestations between twins are similar (Clemens *et al*. 1985). Most compelling, a large number of studies indicate that certain genes within the *HLA* complex contribute to disease susceptibility (the *HLA* association studies discussed below are reviewed in Nepom 1991; Nepom and Glass 1992; De Inocencio *et al*. 1993; Fernandez-Vina *et al*. 1994).

These reported *HLA* associations are quite complex, in contrast to those of many other rheumatic diseases where a single allele or family of alleles confers disease risk. In pauciarticular-onset juvenile chronic arthritis, not only are a number of different alleles associated with disease, but products of different loci are involved. The sometimes confusing results of these different studies are further confounded by variations in *HLA* typing methods, inclusion criteria, and ethnic and geographic populations. None the less, the reproducibility of many *HLA* associations by many different investigators substantiates their importance in susceptibility to pauciarticular-onset juvenile chronic arthritis.

Initial studies described *HLA* class I associations with pauciarticular disease, with *HLA A2*, the most consistently identified allele. The consensus of more recent studies using precise DNA-based HLA typing techniques is that alleles of the class II loci are most strongly associated. However, there is some evidence that the *HLA-A2 *0201* allele remains significantly associated with disease even after class II associations are taken into account (Fernandez-Vina *et al*. 1994).

Among *HLA* class II genes, several alleles of the *DRB1* locus are the most reproducibly associated with disease. *DR8* (primarily the *DRB1*0801* allele in many studies) shows the strongest correlation, with relative risks of approximately 4 to 12. In a number of different North American and northern and southern European populations, *DR8* accounts for approximately 25 to 50 per cent of patients. The *DR8* association is intriguing, since this allele is infrequent (3 to 10 per cent) in control Caucasian populations, and has not been associated with other autoimmune conditions. Among Caucasians, *DRB1*0801* is strongly linked to the *DQ* genes *DQA1*0401* and *DQB1*0402*, but the association in some studies is stronger with *DR* than *DQ*.

DR5 is also consistently associated with pauciarticular-onset juvenile chronic arthritis, with a relative risk of about 2 to 7 in most studies, slightly lower than that for *DR8*. Several *DR5*+ alleles are present among patients, but *DRB1*1104* alleles are most significantly increased (Melin-Aldana *et al*. 1992; Haas *et al*. 1994).

DR6 has been variably reported to be increased in some populations. The *DRB1*1301* allele appears primarily responsible for this association.

In contrast, *DR4*, which is the *HLA* type most highly associated with both adult and juvenile rheumatoid factor-positive rheumatoid arthritis, is almost never seen in pauciarticular-onset juvenile chronic arthritis. *DR7* also seems to provide protection for this disease.

Interestingly, pauciarticular-onset juvenile chronic arthritis was one of the first diseases shown to be associated with an allele of the *DPB1* locus. Several groups have shown that *DPB1*0201* contributes to disease susceptibility, an effect independent of the *DRB1* contribution and not due to linkage with a particular haplotype. Possessing *DPB1*0201* may not by itself provide enough susceptibility to lead to disease expression; instead, it adds to the risk conferred by the *DRB1* susceptibility alleles.

Gene dosage may play a role in determining the magnitude of risk for this disorder. In addition to the additive contribution of *DPB1* to *DRB1* alleles, some studies have reported increased frequencies of patients heterozygous for two *DRB1* susceptibility alleles. Possessing *A*0201* may also increase risk when added to *DR* and *DQ* susceptibility alleles. Thus, having more than one susceptibility allele may confer additional susceptibility or modulate disease.

Despite quite reproducible *HLA* associations with disease, one cannot rule out the possibility that they are due to involvement of genes linked to these alleles, rather than to the *HLA* genes themselves. Recent studies have examined possible associations with pauciarticular-juvenile chronic arthritis of candidate non- *HLA* genes known to reside near or within the major histocompatibility complex that may contribute to immune processes. So far neither *TAP* nor *LMP* alleles have been reproducibly associated with this disorder (reviewed in Ploski and Førre 1994), although some studies report positive correlations (Donn *et al*. 1994). Other candidate polymorphic genes in the MHC include the genes for tumour necrosis factor, heat-shock protein 70, certain complement components, and other antigen processing genes.

Genes linked to the MHC clearly do not account entirely for disease expression, so, in addition to a hypothesized role for environmental agents, contributing non-*HLA*-linked genes have been sought. The T-cell receptor (**TCR**) for antigen is a leading candidate, but so far no associations with germline TCR polymorphisms have been consistently recognized (Nepom *et al*. 1991). Skewed usage of TCR genes within synovial compartment T cells, however, has been reported (Sioud *et al*. 1992; Bernstein *et al*. 1993). Some groups have found an association of a particular subset of patients with a null allele of the TCR *V*b 6.1 gene (Maksymowych *et al*. 1992; Charmley *et al*. 1994), while others have not (Ploski *et al*. 1993). Another group has noted an increase of null alleles of several different TCR genes among patients (Barron *et al*. 1993). The relevance of these findings to disease susceptibility awaits further confirmation.

Finally, McDowell *et al*. reported an association of certain disease subsets with an allele of the interleukin-1a gene, a lymphokine encoded on chromosome 2, and not linked to the *HLA* region (McDowell *et al*. 1995). Interestingly, this polymorphism occurs in the promoter region of the gene, suggesting intriguing mechanistic possibilities.

Many investigators have hoped that disease-associated alleles will allow prediction of clinical manifestations of pauciarticular-onset juvenile chronic arthritis, such as which patients are at increased risk for uveitis or progression to polyarticular disease. While an association of iritis, ANA, and *DR5* has been observed by some groups, other studies have not consistently borne this out. *DR8* has also been variably linked to the occurrence of uveitis. Similarly, attempts to link *HLA* alleles to severity of joint disease have been confusing. *DR8, DR5*, and a *DR6* haplotype have all been reported to be increased among patients with mild or persistently pauciarticular arthritis. Some reports correlate genes on the *DQA1*0101*/*DRB1*0101* haplotype with severe arthritis. Another links an interleukin-1a allele with chronic iridocyclitis (McDowell *et al*. 1995). Although at present none of these associations is strong enough for use in predicting specific manifestations in an individual patient, it is hoped that further elucidation of immunogenetic associations with specific aspects of this disorder will ultimately lead to improved understanding of disease pathogenesis as well as clinical utility in the management of patients.

Summary

The typical child with pauciarticular-onset juvenile chronic arthritis is a female toddler with chronic arthritis in a couple of large joints. Up to 70 per cent have antinuclear antibodies present, which select out the 20 per cent who will develop chronic asymptomatic uveitis. Education, physical therapy, and non-steroidal agents are usually required, but complications or severe disease may necessitate further therapy. Ocular disease requires prompt, intensive therapy. Many children have joint disease that is active only a few years and 80 per cent suffer no major functional disability at 15 years after onset. The remaining 20 per cent can have widespread destructive arthritis.

Illustrative cases

Case 1

A 5-year-old girl presents with a 1-month history of a swollen, but not very painful, left knee. She is not stiff in the mornings or after prolonged sitting. There is no history of trauma, piercing injury, tick bite, rash, or travel to an area where Lyme disease is endemic. Family history is negative for arthritis, low back pain, enthesitis, acute iritis, inflammatory bowel disease, and psoriasis.

Physical examination is normal except for increased intra-articular fluid in the left knee. Her leg lengths are closely checked for inequality and they are equal. She does not have a knee flexion contracture. When lying supine with both legs elevated to 45°, the left leg is not as hyperextensible as the right. Her left thigh circumference is 1 cm less than the right when measured at a level 7 cm above the patella. All other joints are normal. Her pupils and corneas are closely observed in a darkened room and reveal no evidence of scarring from chronic uveitis.

> At this point we have a young girl who generally feels well, with an isolated swollen left knee. The lack of bony overgrowth indicates that this process has not been prolonged. Because she has no systemic signs, the diagnosis of pauciarticular-onset juvenile chronic arthritis is high on the list. However, a reactive arthritis cannot be ruled out because of the brevity of the episode to date. Lyme disease is unlikely in the absence of travel to an endemic area or a history of exposure.
>
> Laboratory evaluations that would be helpful at this point includes a complete blood count, platelet count, erythrocyte sedimentation rate, urinalysis, ANA, and rheumatoid factor. Had any abnormalities in her eyes been noted, she would have been sent that day to an ophthalmologist; since there were no gross changes, she is instructed to see an ophthalmologist within 2 weeks.

She is begun on an oral anti-inflammatory medication.

Laboratory test results from her first visit show normal blood counts, erythrocyte sedimentation rate, and urinalysis. Rheumatoid factor is absent; ANA are present at 1:80. Report of the slit-lamp examination from the ophthalmologist is normal. Over the next 2 months there is only slight improvement.

At this point the diagnosis of pauciarticular-onset juvenile chronic arthritis is more assured, owing to continuation of symptoms for more than 6 weeks and normal laboratory values except for the positive ANA, which is typical for this condition. In spite of some improvement and minimal functional impairment, however, the arthritis is still active, so other NSAIDs will be tried. Quarterly slit-lamp examinations are scheduled with her ophthalmologist.

After another 2 months on optimal NSAID doses, the patient returns with continued disease.

Persistent swelling in a single joint over this period of time encourages one to think of other diagnoses such as pigmented villonodular synovitis. In addition, if the diagnosis is pauciarticular-onset juvenile chronic arthritis, it would now be reasonable to treat the joint more specifically. Therefore, synovial fluid is removed from her knee and, since infection is not a consideration, intra-articular triamcinolone hexacetonide is given. Her NSAID is continued. Analysis of the fluid shows 12 000 white blood cells (90 per cent polymorphonuclear cells) and 2000 red blood cells.

Her knee becomes much less swollen over the next 2 months, but then fluid reaccumulates.

The relatively large number of red blood cells in the synovial fluid and the recurrent nature of the arthritis makes pigmented villonodular synovitis a concern. Therefore a synovial biopsy is taken. The biopsy shows acute and chronic inflammation, which rules out the diagnosis of pigmented villonodular synovitis. A second injection of intra-articular corticosteroid is given and she subsequently does well. She has no pain or limitation of range of motion. She has a slit-lamp examination of her eyes every 3 months to look for asymptomatic uveitis.

Case 2

At 2 years of age this girl develops arthritis in her knees and one thumb. Laboratory test results show a sedimentation rate of 25 mm/h and normal blood counts. She has a negative rheumatoid factor but does have ANA at a titre of 1:160. She is initially treated with an oral anti-inflammatory medication. An ophthalmologist evaluates her eyes every 3 months for signs of uveitis.

> This little girl shows a classic presentation for pauciarticular-onset juvenile chronic arthritis: involvement of fewer than five joints, primarily large joints, with an essentially normal laboratory evaluation except for the typical positive ANA.
>
> After initial improvement arthritis develops in a fourth joint, an elbow. In addition, about 1 year after presentation, evidence of uveitis is noted during routine ophthalmological surveillance; she is treated with local corticosteroids and mydriatics.
>
> Because of ongoing synovitis, she is placed on sulphasalazine. This is a useful choice when arthritis is clearly not under control and a disease-modifying medication is desired, but the situation does not seem to warrant a cytotoxic drug.
>
> This example also points out the critical importance of routine ophthalmological surveillance. Her uveitis is noted early, when simple local measures will usually bring it under control and prevent potentially devastating visual impairment. In this child's case the uveitis and progression of arthritis occurred concurrently, but more often the two do not occur simultaneously.
>
> Her arthritis is well controlled on sulphasalazine and a NSAID, and her uveitis is brought under control. However, at 5 years of age she develops recurrent synovitis. Over a 2-month period, she begins to complain of morning stiffness for the first time, and she develops arthritis in multiple small joints of her hands, feet, wrists, neck, hips, and ankles. Repeat blood samples and radiographs are obtained.
>
> Her laboratory tests remain unchanged, with continued positive ANA and negative rheumatoid factor. Radiographs of multiple joints show juxta-articular osteoporosis but no erosions. Now this child has moved into the category of pauciarticular-onset juvenile chronic arthritis with evolution to a polyarticular course. She is at great risk for progressive, erosive disease because of the widespread nature of her joint involvement, in spite of the lack of radiographically visible erosions. Children, in contrast to most adults, may not show erosions until many years into their disease. Typically, the ANA will remain positive and the rheumatoid factor negative throughout the course. She now requires the addition of methotrexate to her regimen to help control the arthritis, as well as formal physiotherapy two or three times a week to maintain strength, joint range of motion, and functional activities. As her prognosis is now significantly altered, it must be discussed again at length with her parents.
>
> Over the ensuing years, this girl continues to have occasional flares of synovitis, although her arthritis is generally kept under moderate control with methotrexate. She has developed erosions in a number of joints and will probably have permanent sequelae from her arthritis, such as the eventual need for joint replacement. She had two further episodes of uveitis, but both were noted early and treated aggressively and successfully. She continues to have ophthalmological screening every 3 months.

5.6.2 Systemic-onset juvenile chronic arthritis

Ronald M. Laxer and Rayfel Schneider

Introduction

While the earliest English language description of systemic-onset juvenile chronic arthritis dates back to 1897 (Still 1897), Espinel has argued eloquently that Caravaggio's 'Il amore dormiente', painted in the early 1600s, is really the first description of this fascinating entity (Espinel 1994). The painting depicts a young boy with jaundice, recessed jaw, distended abdomen, muscle atrophy, and multiple joint deformities. It was, however, Still's classic paper that highlighted the unique features of systemic-onset juvenile chronic arthritis and differentiated it from both rheumatoid arthritis in adults and other forms of chronic arthritis of childhood. Although a great deal has been written about the clinical aspects of systemic-onset juvenile chronic arthritis, there has been little investigation into the aetiology, pathogenesis, and treatment of this severe, and potentially fatal, form of juvenile chronic arthritis.

While arthritis is required to confirm the diagnosis of systemic-onset juvenile chronic arthritis, true joint inflammation may not be present at the onset of the disease. In fact, patients with otherwise classic features of systemic-onset juvenile chronic arthritis have developed arthritis as late as 9 years after the onset (Calabro *et al*. 1976). In addition to chronic arthritis, the American College of Rheumatology classification criteria require 2 weeks of intermittent fever spikes to at least 103°F (Brewer *et al*. 1977), while the European League Against Rheumatology criteria (Ansell 1978) require at least one other feature (rash, adenopathy, hepatosplenomegaly, pericarditis) in addition to fever and arthritis.

Epidemiology

Variations in classification criteria for juvenile chronic arthritis and the reports of both population-based studies and specialty clinic or hospital-based studies account for the wide prevalence range (8–220 cases/100 000) and wide incidence range (2.6–13.9 cases/100 000) reported for juvenile chronic arthritis (Hochberg 1981; Gewanter *et al*. 1983; Towner *et al*. 1983; Andersson Gare *et al*. 1987). Although difficult to determine, the prevalence probably approximates to 50 cases/100 000 and systemic-onset disease accounts for approximately 10 to 20 per cent of these patients with a reported range of 7 to 43 per cent (Hanson *et al*. 1977; Andersson Gare and Fasth 1992).

In contrast to the two to three fold female predominance for all juvenile chronic arthritis, there is an almost equal sex incidence in systemic-onset disease. However, females may be more commonly affected when the disease begins after age 10 years (Ansell and Wood 1976). Although systemic-onset disease may occur at any age from the neonatal period to adolescence, in two-thirds of patients the onset is under 5 years of age (Ansell 1977) and the mean age at onset is 4 to 6 years (Schaller 1977).

The non-articular features of systemic-onset juvenile chronic arthritis make a viral aetiology an attractive hypothesis, but there is little direct evidence to support this. Seasonal variation in disease onset, with a higher incidence in the late spring, summer, and autumn, has been reported (Lindsley 1987), but is not corroborated by others except for a similar variation in a specific geographic region in a Canadian study (Feldman *et al*. 1996).

HLA associations

HLA studies have demonstrated genetic heterogeneity in patients with systemic-onset disease (Maksymowych and Glass 1988; Nepom 1991). Inconsistent and weak associations have been reported for a variety of class I antigens. Stronger associations have been reported for class II antigens including DR5 (relative risk 4–7) and DR8 (relative risk 4–5), which have both been associated with pauciarticular juvenile chronic arthritis, and DR4 (relative risk 2–5), which has been associated with rheumatoid factor positive polyarticular disease (De Inocencio *et al*. 1993). Unlike rheumatoid factor positive arthritis, there has not been a striking association with DR4 homozygosity and there are conflicting reports regarding the prognostic significance of DR4 in systemic disease (Singh *et al*. 1989; Bedford *et al*. 1992). As with other HLA associations, the DR4 association with systemic disease does not appear to hold true for all systemic disease populations (Nepom and Glass 1992). An association with Dw7 has also been reported (Stasny and Fink 1979).

Clinical features (Table 1)

Very common
Spiking fever (with chills and sweats)
Evanescent rash
Myalgias
Arthralgias
Arthritis
Common
Generalized lymphadenopathy
Hepatosplenomegaly
Polyserositis
Anorexia
Weight loss
Rare
Myocarditis
Coagulopathy
Ocular involvement
Central nervous system involvement
Haemophagocytic syndrome
Primary pulmonary disease
Renal involvement
Amyloidosis

Table 1 Clinical features during the course of systemic-onset juvenile chronic (rheumatoid) arthritis

Extra-articular manifestations

The hallmark of systemic-onset juvenile chronic arthritis is the systemic toxicity and extra-articular features that occur during 'attacks' or flares of disease.

Fever

Fever is the one extra-articular manifestation that is absolutely essential to make a diagnosis. A typical fever pattern occurs in the majority of cases, and is described as a quotidian, or occasionally double quotidian, fever pattern (Fig. 1). During typical flares, the temperature will spike rapidly in the late afternoon or early evening, to at least 39°C, only to return fairly quickly to normal, or often below normal, even without antipyretics. This fever pattern is very different from the fever of other connective tissue diseases, acute rheumatic fever, malignancy, or infectious fevers, which tend to be more persistent or while spiking do not return to below the baseline. Occasionally, the classic fever pattern is only established when anti-inflammatory treatment is begun. Characteristically, the patient will appear toxic during the spike of fever, may have chills and rigors, and will complain of severe arthralgias and myalgias. The bed sheets are often soaked as the fever resolves. Frequently, rash (see below) is present only during the fever spikes. When the fever subsides, the patients are usually much more comfortable and appear less toxic. The fever must be present for at least 2 weeks to satisfy classification criteria, and may persist for months even with treatment. Rarely, fever may follow the development of arthritis (Prieur *et al*. 1984).

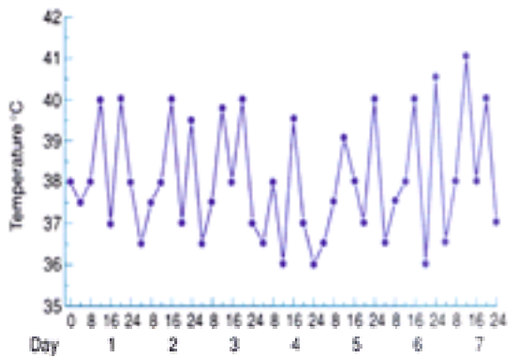

Fig. 1 Temperature chart of a patient demonstrating daily (quotidian) or double-daily fever spikes with rapid return to below the baseline of 37°C.

Rash

The rash of systemic-onset juvenile chronic arthritis is a salmon-pink colour, and is most prominent over the chest, abdomen, back, and intertriginous areas. Distal involvement of the extremities is uncommon but can occur, as can a facial rash. Individual lesions are 3 to 5 mm in diameter and often demonstrate central clearing within the surrounding pink border (Fig. 2(a)). The rash may coalesce into large lesions. The rash is usually macular but urticarial lesions may occur. While the rash typically comes and goes with the spikes of fever (evanescent), it may sometimes be persistent and even occur without fever or other systemic manifestations. The rash may also demonstrate the Koebner phenomenon—the exaggeration of rash in areas of minor trauma. In systemic-onset juvenile chronic arthritis this may be induced by the bed sheets 'squeezing' the skin with a resultant linear distribution of rash (Fig. 2(b)). If the rash is pruritic (10 per cent of patients), then scratching may also induce the Koebner phenomenon. As the rash does tend to come and go, it is unusual to obtain skin biopsies. Histologically, the lesion typically shows a sparse, perivascular infiltrate with a predominance of polymorphonuclear leucocytes (Isdale and Bywaters 1956).

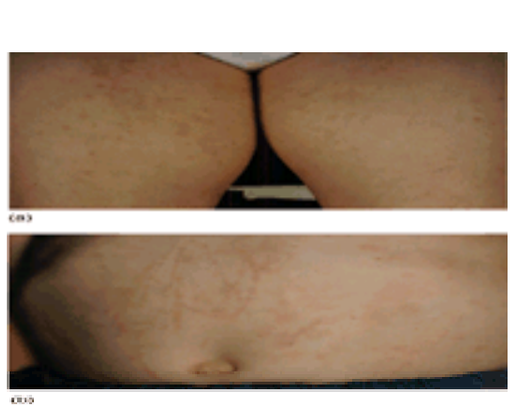

Fig. 2 (a) Rash of systemic-onset juvenile arthritis showing characteristic salmon-pink macular eruptions with central clearing. (b) Koebner phenomenon (appearance of exaggeration of rash in areas of minor trauma).

Reticuloendothelial involvement

Reticuloendothelial hyperplasia with hepatomegaly, splenomegaly, and generalized lymphadenopathy is a common feature of systemic-onset juvenile chronic arthritis. Although the organomegaly is usually asymptomatic, rarely patients with active systemic disease may develop massive hepatomegaly accompanied by a severe abdominal pain (Schaller *et al*. 1970). Mild elevations of serum transaminases occur frequently and are usually not clinically significant. The degree of transaminase elevation does not correlate with the extent of liver enlargement. Aspartate aminotransferase is more frequently elevated than alanine aminotransferase and significant hyperbilirubinaemia is rare. Liver histology in systemic-onset juvenile chronic arthritis is characterized by non-specific periportal inflammatory cell infiltration and Kupfer cell hyperplasia. Fatty change, intrahepatic cholestasis, and fibrosis have been reported less frequently (Tesser *et al*. 1982; Hadchouel *et al*. 1985; Agarwal *et al*. 1994). While transaminase elevations may be seen during active systemic disease, such elevations tend to occur rather sporadically and unpredictably (Rachelefsky *et al*. 1976). This may make it difficult to determine whether hypertransaminasaemia reflects disease activity or the effect of treatment with potentially hepatotoxic medications including salicylates, non-steroidal anti-inflammatory drugs (**NSAIDs**), gold, or methotrexate. Chronic liver disease does not occur in systemic-onset juvenile chronic arthritis but has been described in adult-onset Still's disease (Tesser *et al*. 1982).

Patients with systemic-onset juvenile chronic arthritis may rarely develop hepatomegaly with acute, severe hepatic dysfunction and even fulminant hepatic failure (Hadchouel *et al*. 1985). This potentially life-threatening syndrome has been associated with neurological involvement (drowsiness and coma) and disseminated intravascular coagulation and bleeding. (For a further description see below under ' Less common features'.)

Serositis

Involvement of serosal surfaces is one of the hallmarks of systemic-onset juvenile chronic arthritis (Yousefzadeh and Fishman 1979). Pericardial involvement is most common and pleuritis is more common than peritonitis. Pericarditis is frequently asymptomatic and is best detected by 2D echocardiography. In one series of children with all forms of juvenile chronic arthritis, pericardial involvement was seen in 45 per cent of autopsy cases, although it was only clinically recognized in 7 per cent, most of whom had systemic-onset juvenile chronic arthritis (Lietman and Bywaters 1963). In another series, 9 out of 57 patients had symptomatic pericardial involvement, which was isolated in five cases but associated with myocarditis in the remaining four (Goldenberg *et al*. 1992). In the majority, cardiac involvement occurred within the first year but it can occur at any time during the disease course, particularly in association with other systemic manifestations. Most children will have echocardiographic evidence of pericarditis during systemic flares but may not have any clinical signs of pericarditis (Brewer *et al*. 1977). Occasionally, patients present only with pericarditis and fever before a diagnosis of systemic juvenile chronic arthritis is considered. Therefore, pericardiocentesis may be performed, both for relief of symptoms and diagnosis. Manifestations include tachycardia (out of keeping with the fever), anterior chest pain, and a pericardial friction rub. More severe

involvement may lead to dyspnoea, tachypnoea, and even right-sided congestive heart failure. Rarely, cardiac tamponade and constrictive pericarditis may result (Yancey *et al*. 1981; Pearl 1982; Goldenberg *et al*. 1990). The electrocardiogram may be normal, show ST wave elevation, or non-specific ST segment changes. The chest radiograph may show enlargement of the cardiothoracic silhouette.

Pleuritis is much less common than pericarditis. Occasionally, large pleural effusions, associated almost invariably with pericarditis, may dominate the clinical picture. Sterile peritonitis may result in severe abdominal pain (Bhettay and Thomson 1985).

Arthritis

Most patients have arthritis at disease onset and those who do not commonly have arthralgias or myalgias with the fever spikes. Patients with only arthralgias or no joint symptoms pose substantial diagnostic challenges. To complicate this, the duration from the onset of fever to the development of arthritis may range from just a few weeks to several years. Most patients, however, develop arthritis within 3 months of disease onset (Ansell 1977). Chronic, persistent arthritis evolves in half to two-thirds of patients (Schaller and Wedgwood 1972; Calabro *et al*. 1976).

In our series of 38 patients followed for at least 2 years, pauciarthritis was present in 55 per cent at onset and polyarthritis in 35 per cent, while 10 per cent had no objective signs of arthritis. Although more patients had a pauciarticular onset, the majority of those with persistent arthritis evolved to a polyarticular disease. In more than 75 per cent of patients, the wrists, knees, and ankles are involved. Although somewhat less commonly affected, involvement of the cervical spine, hips, and temporomandibular joints is quite characteristic. In fact, hip involvement occurs in about 50 per cent of patients, is almost always bilateral, and is usually associated with polyarthritis. The hip and wrist joints are the most frequent sites of progressive and advanced destructive changes (Fig. 3(a, b), and Fig. 4), which may occur as early as the first year after onset (Svantesson *et al*. 1983). Almost one-third of patients who have hip involvement may require total hip arthroplasty (Hayem *et al*. 1994). Of the small joints, the hands are more commonly affected than the feet. Cricoarytenoid arthritis with resultant laryngeal stridor has been described (Jacobs and Hui 1977). Tenosynovitis of the carpus and tarsus is common.

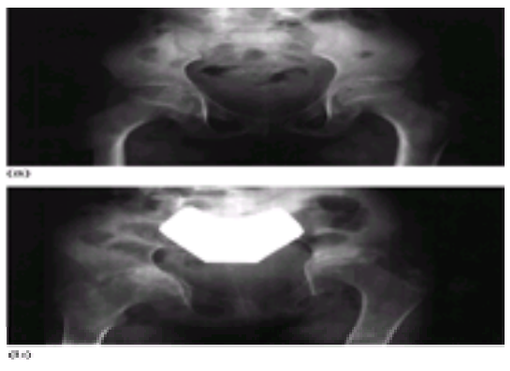

Fig. 3 Girl with systemic-onset juvenile chronic arthritis since 7 years. Hip radiographs show: (a) At 33 months after disease onset, osteopoenia, joint space narrowing, and erosions. (b) At 4.5 years after disease onset, increased loss of joint space, protrusio acetabulae, subchondral irregularity and erosions, and sclerosis of both sides of the joints. There is also flattening of the left femoral head.

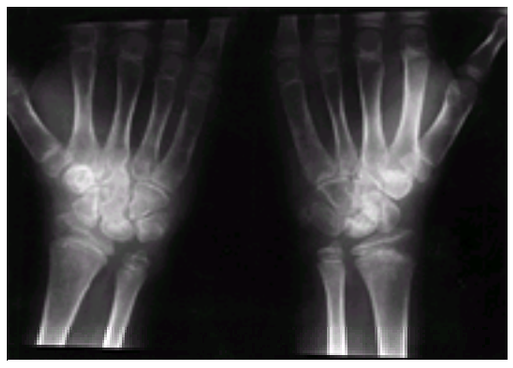

Fig. 4 Same patient as in Fig. 3. Wrist radiographs show advanced changes 2 years after disease onset with moderate narrowing of the carpus, sclerosis, carpal irregularity and erosions, and deformity of the distal radial epiphysis.

Less common features

Many organ systems can be involved in addition to those mentioned above. Pulmonary disease (other than pleuritis) is rare, but can involve the pulmonary parenchyma (Calabro *et al*. 1976; Athreya *et al*. 1980; Wagener *et al*. 1981; Zaglul *et al*. 1982). Primary pulmonary hypertension has been reported (Padeh *et al*. 1991).

Myocarditis, although rare, can be a serious event with considerable mortality. It has been reported to occur in up to 12 per cent of a series of patients with systemic-onset juvenile chronic arthritis from Brazil, and symptoms include tachycardia, dyspnoea, and congestive heart failure (Goldenberg *et al*. 1992). Typically, this occurs during systemic flares of disease and usually together with pericarditis. Myocarditis should be suspected in patients who have persistent tachycardia (out of keeping with fever or anaemia), cardiomegaly, and congestive heart failure. The diagnosis can be made by electrocardiography (showing increased PR interval and low voltages) and echocardiography (showing reduced ventricular function). Because of the high mortality associated with myocarditis, there must always be a high index of suspicion for its development. Although it has been suggested that digitalis may promote arrhythmias (Miller 1977), a recent report did describe using digitalis with good effect (Goldenberg *et al*. 1992). Although cardiac murmurs are common (resulting from anaemia and fever) valvular disease itself is almost never seen, and this helps differentiate systemic-onset juvenile arthritis from acute rheumatic fever with carditis, where valvular inflammation is prominent. However, there are rare reports of valvular abnormalities (Kramer *et al*. 1983; Heyd and Glaser 1990).

Over the last dozen years, several reports have described a syndrome in patients with systemic-onset juvenile chronic arthritis marked by fever, hematocytopenias, hepatic dysfunction, encephalopathy, and disseminated intravascular coagulation with bleeding. This syndrome has been reported under a variety of names. It has occurred following viral infections as well as following changes in medical therapy, but can also occur spontaneously. Most recently, Stephan *et al*. reported three patients with systemic-onset juvenile chronic arthritis (and one with polyarticular juvenile arthritis) who had 'macrophage activation syndrome' (Stephan *et al*. 1993). This seems to be an appropriate term to include the 'consumptive coagulopathy' described by Silverman *et al*. (Silverman *et al*. 1983), a syndrome of 'acute haemorrhagic, hepatic, and neurological manifestations' described by Hadchouel *et al*. (Hadchouel *et al*. 1985), and the several reports of haemophagocytic syndromes that have followed viral infections (Heaton and Moller 1985; Morris *et al*. 1985) in children with systemic-onset juvenile chronic arthritis. The features of this syndrome include persistent high fever (different from the quotidian fever of systemic-onset juvenile chronic arthritis), lymphadenopathy and hepatosplenomegaly, bruising and mucosal bleeding, hepatic dysfunction, drowsiness, and even coma. The laboratory features include anaemia, neutropenia, thrombocytopenia, and evidence of disseminated intravascular coagulation (low fibrinogen levels, raised levels of fibrin degradation products). Deficiency of clotting factors may result in a raised PT and PTT. In fact, children with systemic-onset juvenile chronic arthritis may have increased levels of factor VIII related antigen, fibrinopeptide A, fibrinogen, and fibrin split products, with normal levels of platelet factor IV, indicative of a vasculopathy (Scott *et al*. 1984), even in the absence of this syndrome. Bone marrow and lymph nodes usually show histiocytic consumption of red cells and platelets (Fig. 5). This syndrome is associated with considerable morbidity and mortality. Early recognition and supportive management is vital in reducing mortality. While some patients do recover with expectant management alone, treatment recommendations have included both corticosteroids and cyclosporin (Hadchouel *et al*. 1985; Stephan *et al*. 1993).

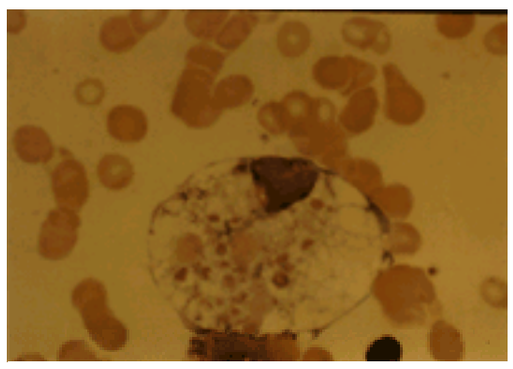

Fig. 5 Bone marrow examination of a patient with macrophage activation syndrome showing histiocytic phagocytosis of red blood cells and platelets (by courtesy of Dr A. Poon).

Central nervous system manifestations are dominated by irritability and lethargy during the fever spikes. True organic brain syndrome is rare and no case series has actually examined patients for central nervous system involvement. However, occasional cases of central nervous system vasculitis have been documented and electrocardiographic changes may be seen (Jan *et al*. 1972). Autopsy series have shown perivascular infiltrates of chronic inflammatory cells in the brain. Two patients with systemic-onset juvenile chronic arthritis treated with long-standing corticosteroids developed epidural lipomatosis and presented with signs of spinal cord compression requiring emergency laminectomy (Arroyo *et al*. 1988).

Renal involvement may occur as a complication of treatment or may indicate the onset of amyloidosis. Although mild abnormalities, including proteinuria and mild haematuria (Antilla 1972), may be seen, particularly with fever, significant renal disease is not a component of systemic-onset juvenile chronic arthritis and its presence should raise suspicion about the diagnosis. Significant proteinuria in the presence of long-standing systemic-onset juvenile chronic arthritis is an indication to exclude amyloidosis with appropriate tissue biopsies.

Ocular involvement is distinctly unusual relative to other forms of juvenile chronic arthritis, but asymptomatic uveitis does occur. It is recommended that these patients be screened annually (Anonymous 1993). Several cases of tenosynovitis of the superior oblique muscle (Brown's syndrome) have been reported (Wang *et al*. 1984; Moore and Morin 1985).

Amyloidosis

Amyloidosis is a serious complication of all subtypes of juvenile chronic arthritis and is associated with significant morbidity and mortality. The clinician should be particularly suspicious of the diagnosis in the systemic subtype in which it occurs most frequently. Although rarely reported in North America, 9 to 10 per cent of patients with systemic-onset disease in European series have developed this complication (Ansell and Wood 1976; Stoeber 1981; Svantesson *et al*. 1983). The reason for this discrepancy in incidence is unclear. No HLA allele has been associated with amyloidosis; however, a restriction fragment length polymorphism related to the amyloid-P component gene has been associated with the development of amyloidosis in patients with systemic-onset disease (Woo *et al*. 1987). Serum amyloid-A protein is usually elevated in amyloidosis but is not predictive of its development (Scheinberg and Benson 1980); however, persistent elevation of the C-reactive protein level may predict the development of amyloidosis (Gwyther *et al*. 1982).

David (David *et al*. 1993), in the largest series of patients with juvenile chronic arthritis and amyloidosis, reported that 57 per cent of these patients had systemic-onset disease. The interval between the onset of disease and the diagnosis of amyloidosis varied widely from 1.5 to 25 years. Ninety per cent of patients had active synovitis at the time of diagnosis. The presenting clinical features and causes of death in this series are summarized in Table 2. The age at disease onset and the duration of disease activity were not related to the development of amyloidosis (Schnitzer and Ansell 1977). The diagnosis should be suspected in patients with persistent proteinuria. The clinical features are generally accompanied by laboratory evidence of an acute-phase reaction with anaemia, thrombocytosis, elevation of the erythrocyte sedimentation rate and C-reactive protein, hypergammaglobulinaemia, and hypoalbuminaemia. Confirmation of amyloidosis is most reliably achieved by renal, rectal, or even subcutaneous fat biopsy. Scintigraphy using a radio-iodinated serum amyloid-P component has been shown to be a useful, non-invasive technique for detecting amyloid deposits in both suspected and occult sites and may be useful in monitoring the response to therapy (Hawkins *et al*. 1993).

	Percentage
Clinical features at diagnosis	
Proteinuria	100
Active juvenile chronic arthritis	90
Oedema	53
Hypertension	25
Abdominal pain	22
Hepatomegaly	22
Splenomegaly	19
Diarrhoea	13
Renal failure	3
Ascites	3
Causes of death	
Renal failure	82
Infection	12
Malignancy	3
Other	3

Modified from Ansell *et al*. (1980)

Table 2 Amyloidosis in juvenile chronic arthritis

Treatment is aimed at controlling the underlying inflammatory process since no therapy has been effective in removing amyloid deposits. In the British series (David *et al*. 1993), chlorambucil was found to have a significant impact on survival. Ten years after amyloidosis was detected, 80 per cent of patients treated with chlorambucil survived compared with less than 25 per cent of patients who did not receive cytotoxic therapy. After 15 years of follow-up, two-thirds of chlorambucil-treated patients were still alive. It should be noted that not all patients with systemic disease are chlorambucil-responsive (Deschenes *et al*. 1990) and its potential toxicities include malignancy and infertility. There is no conclusive role for other immunosuppressive agents.

Growth and nutrition

Children with systemic-onset juvenile chronic arthritis frequently have abnormalities of growth, as documented by Still himself (Fig. 6). The systemic features of the disease are associated with hypercatabolism, resulting in breakdown of tissue stores, and also lead to anorexia. Poor energy and nutrient intake has been noted in several studies (Bacon *et al*. 1990; Mortensen *et al*. 1990). In addition, the frequent requirement for corticosteroids will have an effect on growth. Daily intake of corticosteroids equal to or greater than 5 mg/m^2 will result in growth delay (Blodgett *et al*. 1956). While alternate-day steroid therapy will suppress growth to a lesser degree than daily treatment (Byron *et al*. 1983), this is often difficult to achieve in severely ill systemic-onset juvenile chronic arthritis patients. In addition, Bernstein *et al*. have documented that patients with systemic-onset juvenile chronic arthritis treated with corticosteroids had lower growth velocities than a similar group of systemic lupus erythematosus patients treated with steroids, suggesting that the disease itself has a growth suppressing effect (Bernstein *et al*. 1977).

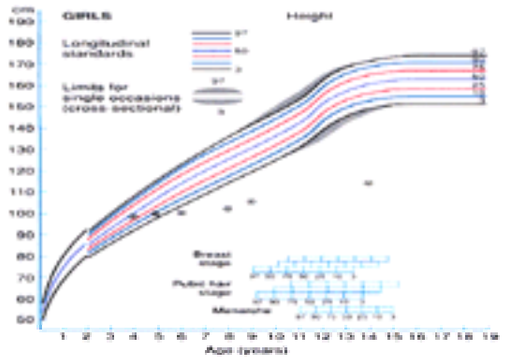

Fig. 6 Growth curve of a 15-year-old girl with severe systemic-onset juvenile arthritis, requiring long-term, high-dose prednisone treatment, showing severe growth delay.

The role of growth hormone in children with systemic-onset juvenile chronic arthritis is unclear. Levels of growth hormone have been reported as both normal and reduced (Butenandt *et al*. 1974; Allen *et al*. 1991). Low levels of insulin-like growth factors, which mediate the effects of growth hormone, have been reported (Bennett *et al*. 1988; Aitman *et al*. 1989). Several reports have studied the effects of treatment with growth hormone on children with different forms of juvenile chronic arthritis (Butenandt 1979; Svantesson 1991). Most recently, using doses of 12 and 24 IU/m^2, given three times per week, increased height velocities were documented. These were more significant in children receiving 24 IU/m^2 per week, and less marked in systemic-onset versus patients with either pauciarticular or polyarticular-onset disease. It is unclear from this study whether the ultimate height reached will be altered with growth hormone treatment (Davies *et al*. 1994). Most importantly, suppression of disease activity with medications other than corticosteroids and adequate nutrition must be achieved. Currently, treatment with growth hormone should be reserved for patients in prospective studies and for children whose growth is significantly below the third percentile.

Laboratory features

There are no specific laboratory features that are diagnostic of systemic-onset juvenile chronic arthritis. Rather, the common laboratory abnormalities reflect an activation of the acute-phase response, and taken together, are supportive of a diagnosis of systemic-onset juvenile chronic arthritis when other disorders are excluded by appropriate history, physical, and laboratory investigations.

The characteristic haematological abnormalities include anaemia, thrombocytosis, and leucocytosis (Table 3). The anaemia typically is an anaemia of chronic disease. This results in a normochromic normocytic smear, with haemoglobin levels ranging from 90 to 105 g/l. Occasionally, in the face of very active systemic toxicity, haemoglobin values will drop quickly, to values as low as 50 g/l. Frequently, the anaemia of chronic disease is compounded by the effects of medications and nutritional deficiency. For example, occult blood loss secondary to non-steroidal anti-inflammatory drugs and poor iron intake may lead to iron deficiency, thus accentuating the anaemia and resulting in hypochromia and microcytosis (Harvey *et al*. 1987). Despite blood loss and poor iron intake, however, serum ferritin is usually increased and is therefore not helpful in detecting iron deficiency as ferritin is an acute-phase reactant (Craft *et al*. 1977; Pelkonen *et al*. 1986). Bone marrow examination in patients with systemic-onset juvenile chronic arthritis (Fig. 7) usually shows a reactive marrow, with an increased number of plasma cells and with stainable iron. The mechanisms underlying the anaemia of systemic-onset juvenile chronic arthritis are unclear but may reflect an abnormal response to cellular mediators of haematopoiesis (Prouse *et al*. 1987; Silverman *et al*. 1988). Erythroid aplasia, similar to the syndrome of transient erythroblastopenia of childhood, has been reported (Rubin *et al*. 1978). Rarely, acute severe pancytopenia has developed in association with presumed viral haemophagocytic syndromes (Heaton and Moller 1985; Morris *et al*. 1985). Severe reaction to medications have been implicated in cases of consumptive coagulopathy (Silverman *et al*. 1983; Hadchouel *et al*. 1985).

Common
Anaemia of chronic disease
Iron deficiency anaemia
Neutrophilic leucocytosis
Thrombocytosis
Rare
Acute haemolysis
Haemophagocytic syndrome (disease or drug-induced)
Disseminated intravascular coagulation (disease or drug-induced)
Erythroid aplasia
Other nutritional deficiency anaemias
Leucopenia (disease or drug-induced)
Thrombocytopenia (disease or drug-induced)
Coagulopathy

Table 3 Haematological abnormalities in systemic-onset juvenile chronic arthritis

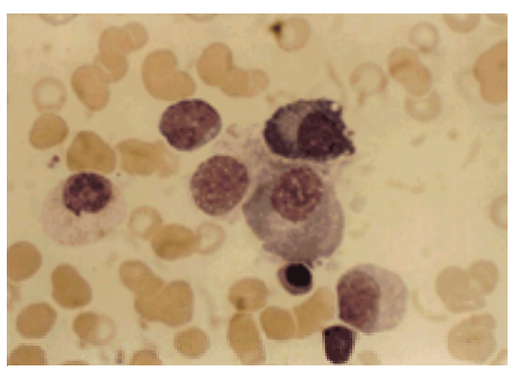

Fig. 7 Bone marrow examination of a patient with newly-diagnosed systemic-onset juvenile arthritis showing reactive plasmacytosis (magnification×1250, illustration by courtesy of Dr A. Poon).

Leucocytosis and thrombocytosis are also hallmarks of systemic-onset juvenile chronic arthritis, so much so that normal counts should always raise suspicion about the diagnosis. Typically, a peripheral blood smear will show a 'left shift' with an increase in the number of immature neutrophils. These neutrophils appear activated, with vacuoles and toxic granules, suggesting infection. White blood cell counts as high as 50×10^9/l may be seen. Similarly, thrombocytosis is characteristic of active disease. Rarely, both leucopenia and/or thrombocytopenia can occur, either as isolated events (Sherry and Kredich 1985) or as part of a disseminated intravascular coagulation-like syndrome.

The erythrocyte sedimentation rate is raised, often to greater than 100 mm/h (Westergren). Polyclonal hypergammaglobulinaemia is often observed, although not necessarily at onset (Petty *et al*. 1977); however, both transient and persistent IgA deficiency have been reported (Pelkonen *et al*. 1983). Other indicators of an acute-phase reaction include an elevated C-reactive protein (Gwyther *et al*. 1982) and significant hypoalbuminaemia, which may be multifactorial in aetiology (poor dietary intake, reduced hepatic synthesis, and intestinal leak). Serum complement levels are often raised, again indicating an acute-phase response (Hoyeraal and Mellbye 1974), and may help differentiate systemic-onset juvenile chronic arthritis from systemic lupus erythematosus. Renal function is normal, although mild proteinuria (which may be fever related) and red and white blood cells in the urine are occasionally observed (Antilla 1972). Elevation of serum transaminases are

frequent (see 'Reticuloendothelial involvement' above). Recently, dyslipoproteinaemia has been observed in all juvenile chronic arthritis subtypes, particularly those with systemic-onset juvenile chronic arthritis. This abnormality was felt to reflect active disease and may be mediated by cytokines (Ilowite *et al*. 1989).

While most children with systemic-onset juvenile chronic arthritis are seronegative for antinuclear antibody and rheumatoid factor, up to 37 per cent may be antinuclear antibody positive (Pauls *et al*. 1989; Siamopoulou-Mavridou *et al*. 1991) and 5 per cent rheumatoid factor positive (Cassidy *et al*. 1986; Lang and Shore 1990). No particular antinuclear antibody specificities have been consistently identified. Hidden rheumatoid factor has been reported in upwards of 50 per cent of patients (Moore *et al*. 1984). Immune complexes are found in up to 80 per cent of patients when assessed by a variety of methods (Moore *et al*. 1982). Evidence for complement activation may be found (Miller *et al*. 1986) and levels of complement receptor 1 (CR1) (complement C3b receptors) on erythrocytes were reduced in patients with systemic-onset juvenile chronic arthritis (Thomsen *et al*. 1987).

Abnormalities of immunoregulation, cell number and function, and cytokines have been reported. Unfortunately, most studies include patients with all types of juvenile chronic arthritis and do not specifically address systemic-onset disease alone. Studies of cellular immunity have shown B lymphocyte dysfunction (Tsokos *et al*. 1987; Barron *et al*. 1989), which may result from abnormal T-suppressor-cell function (Alarcon-Riquelme *et al*. 1988; Silverman *et al*. 1990a). In addition, anti-T-cell antibodies have been found in many children with systemic-onset juvenile chronic arthritis (Borel *et al*. 1984).

The clinical and laboratory features of systemic-onset juvenile chronic arthritis are very suggestive of a cytokine mediated process. The fever, skin rash, hypergammaglobulinaemia, hypoalbuminaemia, raised erythrocyte sedimentation rate, and fibrinogen that are characteristic of systemic-onset juvenile chronic arthritis may all be explained by an immune response involving the cytokines interleukin-1 and -6 (**IL-1** and **IL-6**) and tumour necrosis factor-a. In fact, several studies do suggest abnormalities in cytokine production and regulation. Levels of IL-1 are raised and in one study correlated with disease activity (Martini *et al*. 1986). Levels of IL-1b were uniquely raised in systemic-onset juvenile chronic arthritis as opposed to other types of juvenile chronic arthritis (Mangge *et al*. 1995). Prieur *et al*. found a naturally occurring inhibitor to IL-1 during the febrile phase in the urine of patients with systemic-onset juvenile chronic arthritis (Prieur *et al*. 1987). Increased levels of sIL-2R, indicative of immune activation, have been reported by various authors (Silverman *et al*. 1991; Fassbender *et al*. 1992; Lipnick *et al*. 1993). While raised sIL-2R levels are found in all types of juvenile chronic arthritis, levels do appear to be higher in patients with systemic onset, and correlate with active disease. Similarly, raised levels of serum IL-6 have correlated both with disease activity and thrombocytosis in patients with systemic-onset juvenile chronic arthritis (de Bennedetti *et al*. 1991). In addition, reduced levels of sIL-6 receptor but increased levels of IL-6/sIL-6R complexes have been reported (de Bennedetti *et al*. 1994). In preliminary studies, we have found increased levels of soluble tumour necrosis factor receptor P55 and P75, as have others (Mangge *et al*. 1995). Other abnormalities include elevated levels of tumour necrosis factor-a which correlated with disease activity (Mangge *et al*. 1995), elevated soluble CD8 levels (Lipnick *et al*. 1993), and, more recently, increased level of soluble phospholipase A_2 which correlated with active disease (Pruzanski *et al*. 1994). As mentioned, very few of these abnormalities are unique to systemic-onset juvenile chronic arthritis but they are more prominent relative to other subtypes, probably indicating a greater degree of immune activation. Results from studies of the interferon system are conflicting and have not shed light on the pathogenesis of systemic-onset juvenile chronic arthritis (Bacon *et al*. 1983; Arvin and Miller 1984).

Radiological features

The radiological features of juvenile chronic arthritis have been comprehensively reviewed (Reed and Wilmot 1991) but only two studies have detailed the radiological features specific for the systemic-onset subtype (Cassidy and Martel 1977; Lang *et al*. 1995). Table 4 shows the frequency of radiological abnormalities described by Lang *et al*. (Lang *et al*. 1995). The wrists were the most common sites of early and advanced radiological changes followed by the ankles, knees, tarsal joints, hips, and metacarpophalangeal joints. Similar findings were reported by Cassidy *et al*. (Cassidy and Martel 1977) with a significantly greater frequency of early periosteal new bone formation (50 per cent) and epiphyseal and vertebral compression fractures (attributed to the use of corticosteroids). Cervical spondylitis with narrowing, irregularity, and fusion of the apophyseal joints is also common. Ankylosis most commonly affects the C2–C3 level but may include the entire cervical spine (Fig. 8). Cervical spine ankylosis has been reported to be more frequent in systemic-onset disease than other subtypes (Espada *et al*. 1988). Other typical sites of ankylosis are the wrist and tarsus. It is noteworthy that metaphyseal rarefaction, a typical radiological finding of acute leukaemia, has been described in systemic-onset arthritis (Martel *et al*. 1962).

Radiological feature	Percentage
Soft tissue swelling/osteopenia	81
Joint space narrowing	50
Growth abnormalities	48
Erosions	43
Subluxation	21
Ankylosis	19
Joint destruction	14
Protrusio acetabulae	10
Periosteal new bone formation	10

Modified from Lang *et al*. (1995).

Table 4 Frequency of radiological abnormalities in 42 patients with systemic-onset juvenile chronic arthritis

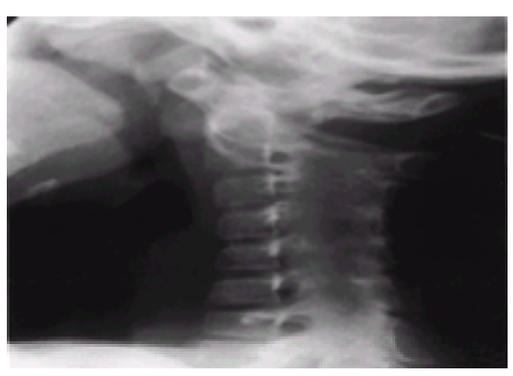

Fig. 8 Boy with systemic-onset juvenile chronic arthritis since 3.5 years. Cervical spine radiograph taken 5 years after disease onset shows ankylosis of the apophyseal joints (C2-C5).

A striking finding in the study by Lang *et al*. (Lang *et al*. 1995) was the early appearance of destructive changes. One-third of patients had erosions and joint space narrowing, 8 per cent had hip subluxation, and one patient developed ankylosis within 2 years of disease onset. These changes were sometimes seen within the first year of disease. Subtle changes of subchondral irregularity and sclerosis seemed to portend the development of erosions. These early destructive changes may be followed by progressive polyarticular disease.

Unusual radiological findings include large humeral cysts, soft tissue calcification unrelated to intra-articular corticosteroid injections (Lang *et al*. 1995), and shoulder synovial cysts (Barbaric and Young 1972). A ring of proliferative osteophytes at the junction of the femoral head and neck, similar to that described in patients with ankylosing spondylitis, has also been described (Mitnick and Mitnick 1980).

Differential diagnosis

When children present with a clinical picture that includes evening fever spikes, evanescent rash in association with the fever, polyarthritis, lymphadenopathy, hepatosplenomegaly, and polyserositis the diagnosis of systemic-onset juvenile arthritis is generally quite straightforward. However, many of these signs and

symptoms are often lacking and the clinician must be astute enough to recognize clues that lead to a diagnosis of systemic-onset juvenile arthritis. One of the most important clues is the variation in the clinical signs and symptoms that can occur over a 24-h period. Children may appear very well throughout most of the day, only to look toxic at the time of a fever spike. It is at this time that the rash usually appears. In addition, arthralgias and myalgias can be extremely severe with the fever spikes.

Of utmost importance is that in order to make a diagnosis of juvenile arthritis, a number of exclusions must be made. In the differential diagnosis of systemic-onset juvenile arthritis these include primarily infectious and postinfectious disorders, other inflammatory diseases, and malignancies in addition to some other more rare febrile disorders of childhood.

Infections

Bacterial and viral infections must be searched for diligently. Bacterial infections that may be difficult to diagnose and are associated with prolonged fever include 'hidden' processes such as abscesses and osteomyelitis or diseases associated with intermittent bacteraemia, such as subacute bacterial endocarditis. In the child with localized pain, technecium bone scanning may be indicated to search for osteomyelitis. Abscesses must be searched for by nuclear scanning, ultrasound, or computed tomography (**CT**) scans. Careful examination, assessment of the cardiovascular system for changing murmurs, search for mucocutaneous findings, and frequent blood cultures will lead to a diagnosis of subacute bacterial endocarditis. Mycobacterial and other granulomatous infectious diseases should be excluded with a thorough history of potential exposure to these organisms and appropriate radiographical and serological investigations.

Viral infections may present with fevers, rash, lymphadenopathy, and hepatosplenomegaly, and can therefore closely resemble systemic-onset juvenile arthritis. Important candidates in the differential diagnosis include Epstein–Barr virus, rubella, adenovirus, and hepatitis B in the prehepatitic phase. Serological assays will be helpful in confirming the diagnosis of a viral infection. As with most other diseases, the fever associated with viral illnesses tends to be persistent, rather than quotidian, and patients are not nearly as toxic as patients with systemic-onset juvenile arthritis during the fever spikes. Recently, parvovirus has been implicated as perhaps being of aetiological importance in adult rheumatoid arthritis and juvenile arthritis (Nocton *et al*. 1993). However, it has not been associated with a picture of systemic-onset juvenile arthritis.

Connective tissue diseases

'Connective tissue diseases' must be strongly considered in the differential diagnosis. The most important to consider are systemic lupus erythematosus, juvenile dermatomyositis, and systemic vasculitis. Features common to both systemic lupus erythematosus and systemic-onset juvenile arthritis include constitutional symptoms (fever, malaise, anorexia), arthritis/arthralgia, serositis, rashes, lymphadenopathy, and hepatosplenomegaly. However, vasculitic rashes seen in systemic lupus erythematosus are not typically seen in systemic-onset juvenile arthritis, and the rashes of systemic lupus erythematosus are not evanescent. Mucous membrane involvement is common in systemic lupus erythematosus but not in juvenile chronic arthritis. Fever tends to be persistent and not intermittent in systemic lupus erythematosus. Central nervous system and renal disease are almost never seen in juvenile arthritis but are common in systemic lupus erythematosus. Anaemia may be common to both, but leucopenia and thrombocytopenia are seen in systemic lupus erythematosus and almost never in juvenile chronic arthritis, where elevation of the white blood cell and platelet count are the rule. Specific autoantibodies are the hallmark of systemic lupus erythematosus but essentially absent in juvenile chronic arthritis. Reduced C3 and C4 complement levels in systemic lupus erythematosus result from immune complex deposition and consumption. In juvenile chronic arthritis, C3 and C4 tend to be elevated as a reflection of the acute-phase response. For further differences see Chapter 5.7.2.

Juvenile dermatomyositis may present as a systemic illness with arthritis but the heliotrope rash, Gottron's papules, and proximal muscle weakness should differentiate this presentation from systemic-onset juvenile arthritis. While myalgias are very common in patients with systemic-onset juvenile arthritis during fever spikes, true myositis does not occur. Serum levels of muscle enzymes will be helpful in differentiating the two.

Systemic vasculitis may present with fevers, malaise, anorexia, weight loss, arthralgias, and myalgias. The laboratory changes may be similar to those of systemic-onset juvenile arthritis in showing a marked elevation of the acute-phase response. The presence of nodules, vascular bruits, hypertension, mononeuritis multiplex, and cerebral disease help differentiate this from systemic-onset juvenile arthritis. Signs of internal organ involvement (e.g. lung and kidney) will also help in differentiating the two.

Malignancy

Malignancy forms one of the most important differential diagnostic categories—in particular, acute lymphoblastic leukaemia, lymphoma, and neuroblastoma (Schaller 1972). Important differentiating features are that children with malignancy have much more bone pain than patients with juvenile arthritis, and the pain tends to be persistent. Night-time pain is an important symptom in malignant disease (Ostrov *et al*. 1993) but both skin rash and serositis are uncommon. A low to normal white blood cell in the face of what appears to be systemic-onset juvenile arthritis is suggestive of a bone marrow infiltrative process. Lymphoma and neuroblastoma may present with fever and arthritis. Neuroblastoma is more common in young children and may not always be associated with a palpable abdominal mass. Screening of the urine for catecholamines and examining the chest and abdomen by CT scanning is helpful in excluding these. All malignancies may be especially difficult to diagnose in children who may have received even a very short course of corticosteroids for a presumptive diagnosis of juvenile chronic arthritis.

Postinfectious syndromes

Postinfectious syndromes must be considered in the differential diagnosis. The classic postinfectious syndrome is acute rheumatic fever following a group A b-haemolytic streptococcal throat infection. As with systemic-onset juvenile chronic arthritis, acute rheumatic fever may be associated with fever, rash, arthritis, and pericarditis, in association with laboratory markers of acute inflammation. However, the arthritis tends to involve only one or two joints at a time and then 'migrate' to other joints. Painful joints are prominent in acute rheumatic fever but much less so in systemic-onset juvenile arthritis, especially during the afebrile periods. Furthermore, the joints in acute rheumatic fever are often red, but are not in patients with systemic-onset juvenile arthritis. Pericarditis in acute rheumatic fever occurs only in the setting of endocarditis, which is extremely rare in systemic-onset juvenile chronic arthritis. Hepatosplenomegaly and lymphadenopathy are very rare in acute rheumatic fever. The rash, erythema marginatum, is uncommon and not as evanescent as the rash of systemic-onset juvenile arthritis. In acute rheumatic fever, a preceding history of streptococcal infection is necessary. One may have to rely on serology (antistreptolysin-O, antihyaluronidase) as evidence of infection, and a four-fold change in titre is necessary. At least 25 per cent of children with systemic-onset juvenile arthritis will have an increased antistreptolysin-O titre during the febrile phase, which is a reflection of the hypergammaglobulinaemia seen in these patients.

Reactive arthritis following bacterial infections involving the gastrointestinal or genitourinary tracts must be included in the differential diagnosis, and a history of preceding infections must be carefully addressed. Fever may occur in some cases of childhood reactive arthritis. However, the extra-articular features are very different from those of systemic-onset juvenile arthritis and involve the eyes, oral mucosa, and entheses. Inflammatory bowel disease may present with fever and arthritis before the onset of gastrointestinal symptoms. In addition, growth delay may be an early clue to this disorder.

Others

In the child under 1 year of age, chronic infantile neurological, cutaneous, and articular syndrome (**CINCA**) must be entertained in the differential diagnosis. It can be differentiated by its very young age of onset, associated chronic meningitis, uveitis, mental retardation, and epiphyseal changes (see Chapter 5.13.6). Juvenile sarcoidosis may also present with fever and rash; however, the rash is not transient and marked tenosynovial inflammation occurs. A biopsy of the skin or synovium will lead to the diagnosis (Hafner and Vogel 1993). Familial Mediterranean fever, an autosomal recessive disorder, presents with recurrent febrile episodes that generally last 48 to 72 h. These attacks may be associated with polyserositis and arthritis and a marked elevation of the acute-phase response accompanies the attacks. The short-lived, relapsing and remitting nature of the attacks, absence of chronic arthritis, and positive family history (when present) in a person of Mediterranean descent are suggestive of familial Mediterranean fever (Gedalia *et al*. 1992). The hyperimmunoglobulinaemia D syndrome begins in children below the age of 1 year and is associated with arthritis, lymphadenopathy, and splenomegaly. In contrast to systemic-onset juvenile chronic arthritis, there do not appear to be any residua of the arthritis, and, in contrast to familial Mediterranean fever, amyloidosis has not been reported to occur (Drenth *et al*. 1994).

The diagnostic workup must be focused to exclude all the entities considered in the American Rheumatism Association classification criteria (Brewer *et al*. 1977), particularly those mentioned above. It is vitally important to ensure that the child's temperature is recorded and plotted every 4 h to document the intermittent fever pattern of systemic-onset juvenile chronic arthritis. The recommended diagnostic investigations and clues to alternative diagnoses are summarized in Table 5 and

Table 6.

Table 5 Tests in the initial diagnostic investigation of suspected systemic-onset juvenile chronic (rheumatoid) arthritis

Leucopenia, thrombocytopenia
Child looks ill even during afebrile episodes
Pain out of keeping with degree of synovitis
Bony tenderness
