Disease course and prognosis

Patients with systemic-onset juvenile chronic arthritis may follow a monocyclic course with complete remission within 2 years of disease onset, a polycyclic course characterized by exacerbations of systemic disease activity, or a course of persistent polyarthritis (Calabro *et al*. 1976). The mean duration of active disease is 5 to 6 years but some patients have persistent disease activity well into their adult years (Schaller and Wedgwood 1972; Svantesson *et al*. 1983). Fifty per cent of patients will have recurrent episodes of fever of variable duration (Schaller 1977) and one-third of patients may have fever for more than 1 year after disease onset (Svantesson *et al*. 1983). Although some North American series report that few patients will have active, systemic disease for more than 5 years (Calabro *et al*. 1976; Baum *et al*. 1980), Prieur *et al*. (Prieur *et al*. 1984) and Häfner and Truckenbrodt (Häfner and Truckenbrodt 1986) report that 25 to 30 per cent of their patients in Europe had persistent systemic symptoms 10 to 15 years after disease onset. Occasionally, patients may have recurrences of active disease following prolonged remissions.

Although the outlook for the extra-articular manifestations is ultimately good, most series report that progressive destructive arthritis occurs in at least one-third of patients (Schaller 1977; Mozziconacci *et al*. 1983; Cabane *et al*. 1990) and accounts for the principal complications of this disease, with most of these patients in functional class III or IV after long-term follow-up. This subgroup of patients would seem to have the worst outcome of all patients with juvenile chronic arthritis. A recent report of 14 patients with systemic-onset disease who were followed for more than 10 years is more optimistic (David *et al*. 1994). These patients had relatively good functional and psychological outcomes, with none in modified Steinbrocker classes III or IV, but total hip replacement surgery was required in 57 per cent.

It has proved difficult to predict reliably the disease course and outcome for the individual patient. Several long-term studies have suggested the following to be possible predictors of poor outcome: disease onset under 5 to 7 years of age, female sex, persistent disease activity for 1 to 5 years (which may be associated with amyloidosis), cardiac disease, thrombocytosis, accelerated radiological changes, and raised IgA levels (Mozziconacci *et al*. 1983; Svantesson *et al*. 1983; Hull 1988). In our own series, prognostic indicators of destructive arthritis were identified within 6 months of disease onset. The two most highly predictive factors found were persistence of systemic symptoms and a platelet count of more than 600×10^9/l. Three-quarters of our patients with both of these predictors 6 months after disease onset developed joint destruction. In addition, these patients more commonly had pericarditis, hepatosplenomegaly, and hypoalbuminaemia at disease onset than those with a more benign course. They also more commonly developed polyarthritis, leucocytosis (>12×10^9/l) and anaemia (< 100 g/l) at 6 months after the onset of disease (Schneider *et al*. 1992).

Mortality

There are more deaths amongst patients with systemic-onset juvenile chronic arthritis than any other subtype of juvenile chronic arthritis. The reported mortality of 14 per cent in several large European studies (Ansell and Wood 1976; Stoeber 1981; Hafner and Truckenbrodt 1986) is significantly higher than the 2.9 per cent mortality reported for all types of juvenile chronic arthritis (Baum and Gutkowska 1977). The major causes of death associated with systemic-onset arthritis are shown in Table 7. Amyloidosis has been associated with almost half the deaths in European patients with juvenile chronic arthritis and with only 13 per cent of deaths amongst North American patients; this may account for the higher mortality in European series. Infection is the most common cause of death in North American patients and is often associated with corticosteroid therapy. Acute hepatic failure has emerged as a significant cause of death, and in a review of several series accounted for 17 per cent of juvenile chronic arthritis deaths, most in those with systemic-onset disease (Boone 1977). Most deaths occur within the first 10 years of disease onset.

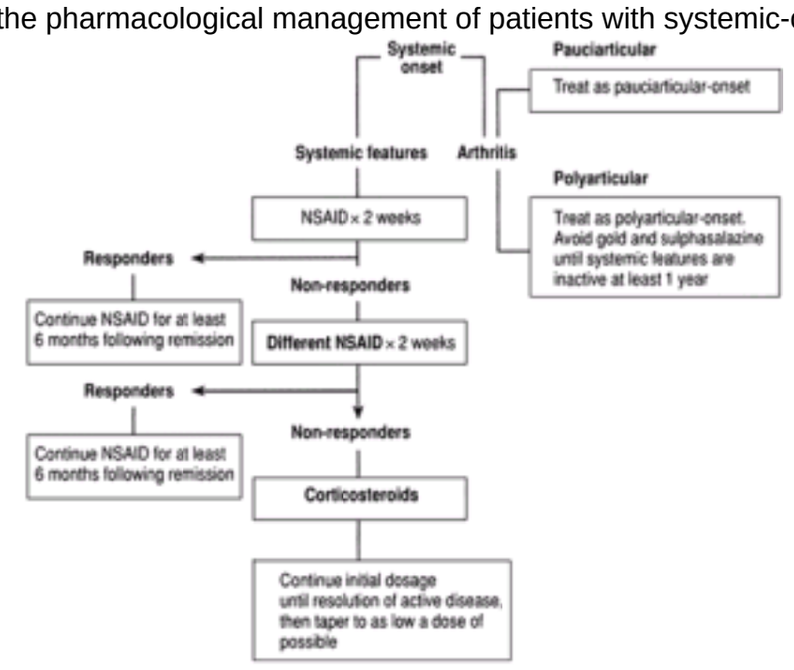
Management (Box 1)

The lack of randomized placebo-controlled trials in patients with systemic-onset juvenile arthritis makes it difficult to evaluate the efficacy of any therapy in this disease. Because of increased medication-related toxicity in these patients, all therapeutic interventions must be carefully monitored. The approach to the management of systemic-onset juvenile chronic arthritis must be a co-ordinated one involving all members of the health-care team. In addition to the articular and extra-articular features of the disease, growth and psychosocial development must be continuously addressed and monitored. The significant financial burdens placed upon families with a chronically ill child must not be overlooked.

Box 1 Guidelines to the pharmacological management of patients with systemic-onset juvenile arthritis



Extra-articular features

Initial attempts to control fever should be with NSAIDs. Many paediatric rheumatologists in North America have moved away from salicylates in view of their increased hepatotoxicity relative to other NSAIDs and the potential for Reye's syndrome (Rennebohm *et al*. 1985). Success in controlling fevers has been achieved with both ibuprofen and indomethacin (Brewer 1977). Doses as high as 60 mg/kg in four divided doses of ibuprofen (B.M. Ansell, personal communication) or indomethacin 2 to 3 mg/kg per day seem to be more effective, with less toxicity than acetylsalicylic acid, and should be used prior to treating with corticosteroids for fever alone. Tolmetin sodium in doses up to 40 mg/kg per day may also be effective (Gewanter and Baum 1981). Because NSAIDs are protein bound, it is essential that the serum albumin be measured and the dose adjusted downward if hypoalbuminaemia is present. Failing to do so will result in excessive free drug which can result in toxicity. A minimum of a 1-week trial of an NSAID should be given before it is deemed to have failed; if the patient is not too ill, a second NSAID trial with a different preparation should be attempted.

In our experience, at least 50 per cent of patients will have an inadequate response to NSAIDs. When NSAIDs fail to control systemic toxicity, corticosteroid treatment is indicated. If used in high enough doses, steroids will virtually always result in resolution of fever and systemic toxicity. However, the significant side-effects of daily corticosteroid therapy are well known and as they do not limit the duration of active disease or alter the long-term prognosis, they must be used judiciously. At times, patients, parents, and physicians may have to be willing to settle for some fever provided that the peaks are not too high and not associated with severe systemic toxicity or anaemia. While alternate day dosing is preferable, in our experience, patients who require steroids require at least 1 mg/kg per day, and often in divided doses. Occasionally, symptoms may be so severe that the daily dose may be better administered in three or even four doses over a 24-hour period for a short period of time. High-dose, intravenous pulse methylprednisolone may also be used with severe flares but we have found only very short-term benefits from this treatment.

While the presence of lymphadenopathy, hepatosplenomegaly, and rash usually correlate with more active systemic symptoms and are an indication of active disease, these alone do not justify an increase in treatment.

Anaemia is common in patients with systemic-onset juvenile chronic arthritis and is usually a result of chronic disease. Maintenance doses of iron supplementation may raise the haemoglobin concentration slightly (Koerper *et al*. 1978) but are rarely of great benefit. When the disease is extremely active patients will not respond to oral iron therapy, even if they are iron deficient. Intravenous iron oxide saccharate (Martini *et al*. 1994) at a cumulative dose calculated to reach an ideal haemoglobin of 125 g/l has been recommended as a safe and effective treatment for severe and persistent anaemia in some patients with systemic-onset juvenile arthritis who are unresponsive to oral iron treatment. In one small study, erythropoietin was also effective in raising the haemoglobin value in systemic-onset juvenile arthritis patients with the anaemia of chronic disease (Fantini *et al*. 1992).

Nutritional deficiencies of folic acid and vitamin B12 may need to be addressed. Rarely, during acute systemic flares, the haemoglobin concentration may fall rapidly to as low as 40 to 50 g/l, necessitating blood transfusion (particularly in the face of cardiac compromise) in addition to corticosteroid therapy.

Attempts to reduce steroid toxicity have led to the use of intravenous immunoglobulin. Three separate studies have now reported on the use of intravenous immunoglobulin in systemic-onset juvenile arthritis. In the first, eight patients with severe juvenile chronic arthritis were treated for at least 6 months, in an open-label study. An impressive improvement in both articular and extra-articular disease and in laboratory abnormalities, as well as in a reduction in the dose of steroids, were noted (Silverman *et al*. 1990b). A second study did not seem to show any long-term benefit of intravenous immunoglobulin, although there was an improvement in the laboratory markers of active disease (Prieur *et al*. 1990). The recently completed Pediatric Rheumatology Collaborative Study Group trial did not show a statistically significant improvement in patients treated with intravenous immunoglobulin compared to placebo, although there was a trend towards overall improvement in the intravenous immunoglobulin-treated group (Silverman *et al*. 1994). However, many patients entered the trial so early in the disease course that spontaneous remissions may have occurred. Future studies should be directed at patients who early in their course fall into poor prognostic groups. At the time of writing, intravenous immunoglobulin should still be considered experimental in the treatment of systemic-onset juvenile chronic arthritis and should probably be reserved for patients whose systemic symptoms are not controlled by steroids, or who have significant steroid toxicity.

Serositis, as with the fever of systemic-onset juvenile chronic arthritis, will often respond to NSAIDs. Indomethacin seems to be especially effective for the treatment of pericarditis (Sherry *et al*. 1982). Corticosteroids in low to moderate doses (0.5–1 mg/kg per day) are usually sufficient to control serositis if NSAIDs are not effective. We have found intravenous pulse methylprednisolone 30 mg/kg per day (maximum 1 g) daily for 3 days to be rapidly effective and without toxicity, although of only short-term benefit. If there is significant compromise of cardiac function, pericardiocentesis may be required. Some authors recommend a pleural or pericardial drain for several days. Ventricular tachycardia complicating pericardiocentesis has resulted in a few deaths (Goldenberg *et al*. 1990). There is a report of one patient who, despite these measures, required the emergency placement of a pericardial window (Alukal *et al*. 1984). The efficacy of intrapericardial corticosteroids has not been substantiated and we have not found this necessary.

Myocarditis may occasionally be of such severity that congestive heart failure ensues. Treatment with high-dose oral or intravenous pulse corticosteroids, together with other supportive measures, is indicated. The use of digoxin may result in arrhythmias and sudden death if inflammation is not adequately controlled (Miller 1977), but a recent report did document the efficacy of digoxin (Goldenberg *et al*. 1992).

Articular disease

Many children with systemic-onset juvenile chronic arthritis have arthritis that is only problematic during flares of systemic disease. These children generally have a good outcome and respond well to management of the systemic components of the illness. However, the subset of children with persistent polyarticular disease, even in the absence of systemic manifestations, has progressive erosive disease which is difficult to treat with the standard first and second line agents. Unfortunately, no adequately controlled studies have been conducted in this group of children and our current approach is based largely on anecdotal experience. Currently, it is very difficult to predict at onset the course that patients will follow. It would seem that the earlier definitive treatment is instituted, the more effective treatment will ultimately be. Therefore, prognostic indicators are very important in determining the pharmacotherapeutic approach (Svantesson *et al*. 1983; Schneider *et al*. 1992).

The general approach to the management of the chronic arthritis of systemic-onset juvenile arthritis assumes the same principles as for the management of arthritis in other forms of juvenile arthritis. However, the increased drug-related toxicity is perhaps unique to patients with systemic-onset juvenile arthritis. This may be seen with salicylates, NSAIDs, and disease modifying antirheumatic drugs, including gold (Silverman *et al*. 1983; Hadchouel *et al*. 1985) and sulfasalazine (Cassidy 1990; Hertzberger Ten Cate and Cats 1991; Caspi *et al*. 1992). In fact, many authors consider that both gold and sulfasalazine are contraindicated in patients with systemic-onset juvenile arthritis, particularly if the disease is systemically active. Currently, methotrexate is the drug of choice for most patients with juvenile arthritis, including systemic-onset juvenile arthritis, needing second-line agents (Giannini *et al*. 1992). To date, it has not been associated with increased toxicity in patients with systemic-onset juvenile arthritis. However, it is also unclear how effective methotrexate actually is for the arthritis of systemic-onset juvenile arthritis, and there is no evidence that it has any effect on systemic symptoms. In fact, there has been a suggestion that systemic-onset patients may be less responsive to methotrexate than patients with other types of juvenile arthritis (Halle and Prieur 1991). In a retrospective review, 63 per cent of patients were deemed to have responded to weekly, low-dose oral methotrexate by 6 months. Analysis showed that early treatment (within 2 years of onset), before the development of radiographical lesions at the time of starting methotrexate, may improve the response (Ravelli *et al*. 1994).

For patients who do not respond to methotrexate, other alternatives must be sought. Chlorambucil has been used in patients with systemic-onset juvenile chronic arthritis who also develop amyloidosis (Deschenes *et al*. 1990), with significantly improved survival (David *et al*. 1993), but systemic features may still not be well controlled (Manners and Ansell 1986). In addition, the risk of leukaemia seems to be particularly increased with this alkylating agent (Palmer and Ansell 1984). Azathioprine may be somewhat effective (Kvien *et al*. 1986). The use of cyclophosphamide has been limited in the literature to case reports (Skoglund *et al*. 1971; Walters *et al*. 1972).

Early studies of cyclosporin in systemic-onset juvenile chronic arthritis (Bjerkhoel and Forre 1988; Ostensen *et al*. 1988) showed only minimal effect on synovitis and systemic symptoms persisted in several patients. The toxicity of cyclosporin seemed to outweigh the benefits. However, a more recent study using somewhat lower doses (unfortunately, uncontrolled) did document efficacy at recommended doses of 5 mg/kg per day in two divided doses (Pistoia *et al*. 1993). Improvement in terms of reduction of arthritis, fever, and prednisone dose was noted as early as 1 month after starting treatment. It is unclear whether cyclosporin is truly remitting, if patients will be able to discontinue cyclosporin, and what the long-term efficacy and toxicity is.

A preliminary study of the use of recombinant g-interferon in nine patients showed clinical improvement in seven, and an overall marked improvement in laboratory abnormalities (Pernice *et al*. 1989). The immunomodulatory agent thymopentin was effective for the systemic features, but not well-established arthritis, in a small series of children with systemic-onset juvenile chronic arthritis (Bardare *et al*. 1990).

A preliminary, open trial reported the results of repetitive use of pulse treatment with intravenous methylprednisolone (30 mg/kg per day for three consecutive days) with cyclophosphamide (0.4 g/m^2) on the third day, together with methotrexate at a dose of 10 mg/m^2 per week. This 3-day regimen was repeated every 3 months if the disease activity persisted and the patients required oral corticosteroids. Cyclophosphamide was included in subsequent pulses only if the patient had extra-articular disease. While there was an improvement noted in both articular and extra-articular disease, the laboratory features did not show statistically significant improvement. These preliminary results are impressive, and ideally would need to be confirmed in a randomized, placebo-controlled trial. Given the difficulty of conducting these types of trials in juvenile arthritis, the long-term follow-up of these patients must be reported before this approach can be recommended (Shaikov *et al*. 1992).

Adult-onset Still's disease

An entity quite similar in clinical and laboratory manifestations to systemic-onset juvenile chronic arthritis, but occurring in adults, was reported by Bywaters (Bywaters 1971). The so-called 'adult-onset Still's disease' has subsequently been described at all ages and with a worldwide distribution. Females outnumber males slightly. Seventy-five per cent of reported cases range between the ages of 16 and 35 years at the onset, with the overall incidence decreasing with age. Cases have been reported up to age 70. The fever pattern is identical to that of systemic-onset juvenile chronic arthritis (Fig. 1). Approximately 90 per cent have a rash that follows the fever course and may demonstrate a Koebner phenomenon; the rash may be pruritic. One important feature not well appreciated in systemic-onset juvenile chronic arthritis is a complaint of a severe sore throat, during flares of disease (Bujak *et al*. 1973; Esdaile *et al*. 1980; Ohta *et al*. 1987). While arthritis is not necessarily present at the onset, arthralgias are present in virtually all patients with the fever spikes. Although initial series described the arthritis as being quite mild, chronic arthritis with disability may be a sequel in up to 20 per cent of cases (Elkon *et al*. 1982; Cush *et al*. 1987; Cabane *et al*. 1990; Pouchot *et al*. 1991). As in the childhood form, hepatosplenomegaly and lymphadenopathy are reported in 40 to 75 per cent of cases. Weight loss of at least 10 per cent was recorded in approximately one-third of cases (Ohta *et al*. 1987). Pericarditis is the most common cardiac manifestation and tamponade may rarely occur. Both myocardial (Sachs *et al*. 1990) and endocardial (Taillan *et al*. 1989) involvement are rarely seen. Pulmonary disease appears to be more common than in systemic-onset juvenile chronic arthritis and is usually transient and mild, but severe restrictive lung disease has been observed (Corbett *et al*. 1983; Cantor *et al*. 1987). Abdominal pain may relate to hepatitis, adenitis, and sterile peritonitis, although this complaint is usually overshadowed by the other manifestations of adult-onset Still's disease (Bujak *et al*. 1973; Pollet *et al*. 1990). Abnormal liver function tests have been reported in up to 76 per cent of patients (Pouchot *et al*. 1991). Hepatic dysfunction may occur as part of a disseminated intravascular coagulation syndrome, may be related to medications, or as part of the underlying disease (Esdaile *et al*. 1979). Neurological involvement may rarely occur during systemic flares (Denault *et al*. 1990) or as a result of infection or complications of therapy (Wouters and van de Putte 1986). A number of ophthalmological manifestations, including inflammatory orbital pseudotumour (Cush *et al*. 1985), panophthalmitis (Bujak *et al*. 1973), and Brown's syndrome (Kaufman *et al*. 1987), have been reported. One case of sensorineural hearing loss, responsive to prednisone, was observed (Markusse *et al*. 1988). Rarely, renal disease may occur (Wendling *et al*. 1990).

The disease may follow several courses (Cush *et al*. 1987; Pouchot *et al*. 1991). In one series, those with either a mono- or polycyclic systemic course had articular manifestations, primarily during systemic exacerbations, and a good functional outcome. On the other hand, patients with a chronic articular course (either monocyclic systemic or polycyclic systemic) do not fare as well. Those patients with a polyarticular onset, axial arthritis, need for steroids within 2 years of onset, a history suggestive of childhood attacks, and the presence of a juvenile chronic arthritis rash seem to be at a greater overall risk for progressive joint damage and an unfavourable outcome (Cush *et al*. 1987; Pouchot *et al*. 1991). Involvement of the carpus with ankylosis (Medsger and Christy 1975; Pouchot *et al*. 1991) is particularly common, as is tarsal ankylosis, and involvement of the cervical spine and hips with rapid progression of destructive disease. Distal interphalangeal involvement is also not unusual.

In comparison to same-sex siblings, patients with adult-onset Still's disease had significantly higher levels of pain, psychological disability, and physical disability. Despite these problems, educational achievement, occupational prestige, social functioning, social support, annual family income, and days lost from work did not differ between patients and same-sex siblings (Sampalis *et al*. 1995).

The treatment of adult-onset Still's disease should follow along the same lines as those of systemic-onset juvenile chronic arthritis. Initial attempts at fever control should be made with either high dose salicylates (100 mg/kg per day) or other NSAIDs, particularly indomethacin. These two agents may be effective together when neither alone gives sufficient therapeutic benefit (Esdaile *et al*. 1980; Wouters and van de Putte 1986; Cush *et al*. 1987). The majority of patients will ultimately require moderate to high-dose glucocorticoid therapy at some time during their course. At a median follow-up of 10 years, 50 per cent of patients still required treatment with second-line agents (gold, hydroxychloroquine, or methotrexate) and one-third of these continued to require low-dose prednisone (Sampalis *et al*. 1995). The effect of slow-acting antirheumatic drugs on the course of the articular disease has not been established and these agents do not have any effect on the systemic features.

The laboratory abnormalities, like those of systemic-onset juvenile chronic arthritis, are non-specific and include leucocytosis with neutrophilia, normochromic, normocytic anaemia, and thrombocytosis. Eosinophilia appears to be common in the Japanese cases (Ohta *et al*. 1987). Hypoalbuminaemia, hypergammaglobulinaemia, and increased serum complement levels are commonly observed. Raised serum levels of hepatic transaminases, while common, are usually transient and reflect active disease. No consistent HLA associations have been identified (Wouters *et al*. 1986; Pouchot *et al*. 1991).

Death may result in a very small number of patients from a wide variety of causes, including liver involvement and systemic amyloidosis (Ohta *et al*. 1987; Reginato *et al*. 1987).

5.6.3 Rheumatoid factor-negative polyarthritis in children ('seronegative' polyarthritis)

Anne-Marie Prieur

Polyarticular onset occurs in about 30 per cent of all patients with juvenile chronic arthritis. By definition, it occurs before the age of 16 years with the involvement of a minimum of five joints; the duration varies according to the adopted set of diagnostic criteria. The most accepted diagnostic criteria are either those of the European League Against Rheumatism (**EULAR**) (Wood 1978) or those of the American College of Rheumatology (**ACR**), previously the American Rheumatism Association (**ARA**) (Brewer *et al*. 1977). In the EULAR criteria, polyarthritis with positive rheumatoid factor is excluded, while in the ACR proposal, patients with positive rheumatoid factor are included in the group of polyarticular onset. This helps to explain why this disease is named juvenile chronic arthritis in Europe, but juvenile rheumatoid arthritis in North America. Arthritis must be present for at least 3 months in the EULAR criteria, or for 6 weeks in the ACR criteria. These proposed diagnostic criteria do not take into account the type of course, which obviously is extremely important for the prognosis and outcome. Pauciarticular onset with a polyarticular course will not be considered in this chapter.

The following description will not include the group of so-called 'seropositive' patients. We prefer, for obvious reasons, not to speak of seropositivity or seronegativity, but of rheumatoid factor (**RF**) -positive or -negative. The RF-positive group represents the early onset of adult rheumatoid arthritis and all data available in adults are also true in children (see Chapter 5.4.3). It is uncommon and occurs in less than 10 per cent of the whole polyarticular group in children. Polyarticular onset that is RF negative is the most common and is extremely heterogeneous. Some subgroups are easy to identifiy, but others need further evaluation to establish convenient and precise criteria for classification. Four subgroups can be identified in the RF-negative group (Table 1). The following discussion is based on the author's experience of more than 15 years in a paediatric rheumatology clinic with an annual referral of more than 1200 patients, one-third of them being first-time referrals.

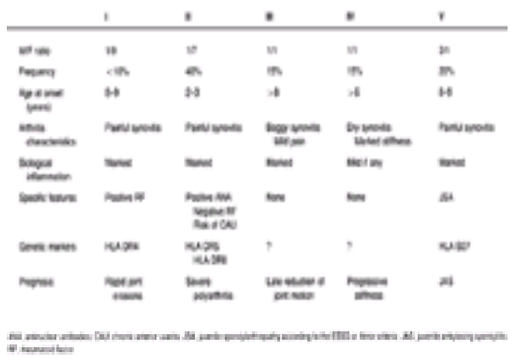

Table 1 A proposed classification of subgroups of juvenile chronic arthritis with polyarticular onset

Frequent manifestations of RF-negative polyarthritis

Extra-articular manifestations

Extra-articular manifestations may be present. Fever can be observed in one-third of patients. It is generally low grade, or a high fever often of short duration. By definition, long-lasting swinging fever as described in systemic onset is never observed in the polyarticular type. In very young children, a transient rash lasting 1 or 2 days can occur in the early stages. There is generally no lymphadenopathy, hepatosplenomegaly, or visceral involvement.

Joint manifestations

Joint manifestations dominate the clinical presentation. Generally, the mode of onset is rapidly progressive. The child is referred to the specialist often after several weeks of worsening joint stiffness and/or swelling.

A joint is a complex organ (Chapter 2.5) made up of synovial membrane, articular cartilage, fibrous capsule, ligaments, tendons with their site of attachment on bone (the enthesis), bursas, and tendon sheaths. In children, the joints also have growth cartilage. All these structures may be inflamed during the rheumatic process and chronic inflammation results in joint alterations and deformities. Chronic swelling and limited motion results in local demineralization. Muscular wasting is a consequence of the limitation of motion and it reduces joint motility. Chronic hyperaemia may induce local accelerated growth and growth cartilage fusion. Cartilage and bone erosions are late manifestations. There is potential for cartilage generation in children, which may delay severe functional impairment.

Upper limb involvement

Deformities in the hands and wrists are the consequence of an imbalance between the modified cartilage surfaces, local accelerated growth of bones, and modification of the forces between tendons and ligaments. Reduced carpal length, joint space reduction, and erosions can lead to carpal fusion. A carpal dislocation due to bone lysis is rare but can be observed in severe cases. Radial or ulnar growth reduction induces radial or ulnar deviation. Small joint and associated tendon involvement results in boutonnière or swan-neck deformities of the fingers (Fig. 1).

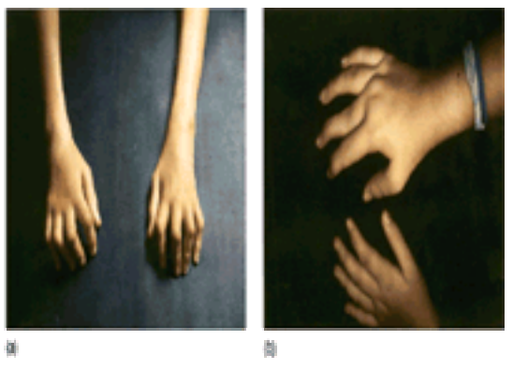

Fig. 1 Boutonnière deformity (a) and swan-neck deformity (b) of fingers.

Flexion contracture is the first manifestation of elbow involvement. It may be mild and of little functional significance. Limitation of supination is very common. The shoulders are frequently involved in severe cases, leading to limitation of movment, particularly abduction and external rotation of the glenohumeral joint. In severe cases, growth disturbances and humeral head modifications are observed (Fig. 2).

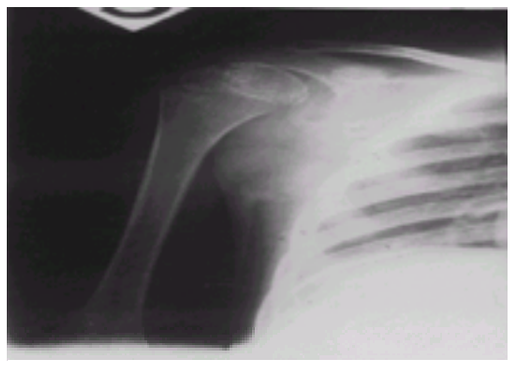

Fig. 2 Shoulder radiograph showing osteoporosis, joint space narrowing, and bony irregularity.

Lower limb involvement

Lower limb involvement may have significant functional consequences. Individual deformities can affect the performance of other lower limb joints. The foot is a complex joint with many articular surfaces in several planes. Foot deformities may also be increased by hip and knee involvement. Tenosynovitis and bursitis are nearly as common as ankle synovitis (Fig. 3). Subtalar joint involvement most often results in valgus deformity or, less commonly, in a varus deformity. As in the carpal area, bony fusion of the tarsus may occur. Mid-tarsal involvement affects the equilibrium of the foot. Metatarsal joint involvement leads to valgus toe deformities.

Fig. 3 Retromalleolar tenosynovitis, predominantly on the right side.

Flexion contracture of the knee is common, being particularly rapid and severe in the very young child. In the absence of correction, it may rapidly induce a posterior subluxation of the tibia due to capsular retraction (Fig. 4a). The overgrowth of the epiphysis induces a flexion contracture (Fig. 4b). In severe cases, the patella may fuse to the anterior femoral surface.

Fig. 4 Posterior tibial subluxation (a). Increased growth of the left lower limb due to chronic inflammation of the knee (b).

Hip involvement is characterized by flexion contracture and limitation of motion, particularly of abduction and rotation. This is secondary to the muscle spasm, mainly of the adductors, induced by local synovitis. Chronic inflammation induces anatomic modifications of the bone, with femoral head overgrowth, principally in the external part, and decreased development of the neck, which appears shorter and wider (Fig. 5(a)). Later, aseptic necrosis of the femoral head may occur. Acetabular modifications with erosions or protrusions are possible (Fig. 5(b)). Joint abnormalities at one site in the lower limb may have a reciprocal effect in aggravating deformities at other sites. For example, hip contracture induces a compensatory lumbar lordosis, knee overgrowth increases flexion contractures, and valgus of the knee increases talus deformity.

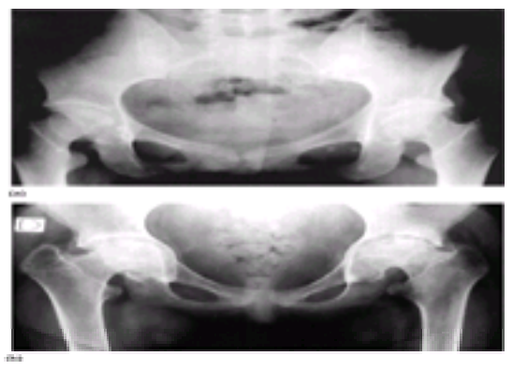

Fig. 5 Chronic involvement of the hip with shortened femoral neck, irregular head, and joint space narrowing (a); with acetabular protrusion (b).

Spine

Spine involvement is generally clinically expressed at the cervical level. Torticolis and limitation of motion are common (Fig. 6). Radiological changes develop progressively with apophyseal joint fusion most often of the C2–C3 vertebrae, but also of the other cervical spaces. Intervertebral instability below (Fig. 7) and above the fused cervical segment may occur. Subluxation of the atlas on the axis can be observed. A surgical arthrodesis is indicated in case of spinal cord compression. Anaesthetists should be aware of possible difficulties during intubation. Although rarely mentioned, synovitis of the thoracic and lumbar apophyseal joints is possible. A high frequency of spinal scoliosis is described in these children.

Fig. 6 Torticolis due to cervical spine involvement.

Fig. 7 Cervical spine fusion with underlying hypermobility.

Temporomandibular joint

Temporomandibular joint involvement is common. It is often discovered at routine examination. It reduces the normal growth of the mandible and results in micrognathia (Fig. 8). Dental malocclusion is common and may warrant surgical correction when growth is completed.

Fig. 8 Microretrognathia.

Laboratory abnormalities

Laboratory features are non-specific in RF-negative polyarthritis. Acute-phase reactants and erythrocyte sedimentation rate can be elevated or normal. The leucocyte count is normal or increased, as is the platelet count. Low blood-cell counts are unusual and suggest an alternative diagnosis.

Specific features of subgroups of RF-negative polyarthritis

Polyarthritis positive for antinuclear antibodies

Although less frequent than the oligoarticular type with positive antinuclear antibodies, this group of patients represents about 40 per cent of the polyarticular onset in our clinic. In a series of 136 children with arthritis positive for antinuclear antibodies, 21 were polyarticular at onset (Peralta and Prieur 1990). As in the

oligoarticular-onset group with antinuclear antibodies, there is a female preponderance, although the proportion of boys is higher than in the oligoarticular type. The disease is observed in very young children, two-thirds of the children reviewed in my series (Peralta and Prieur 1990) being less than 3 years old at onset. There is a risk of eye involvement as in the oligoarticular type (21 compared with 42 per cent). To my knowledge, no prognostic study of this particular group of polyarticular onset has been reported. In my experience, very young children with symmetrical involvement of both large and small joints within the first 3 months have a poorer outcome than those with symmetrical polyarticular involvement predominantly of large joints but not necessarily at the same time.

The presence of antinuclear antibodies in the serum characterizes this subgroup of patients. The most frequently used substrate for diagnosis is the HEp-2 cell. The titres of antinuclear antibodies are usually low and there are no obvious correlations between the titre of the autoantibody and the severity of the disease. The specificity of these antinuclear antibodies is antihistone (Malleson *et al*. 1989; Østensen *et al*. 1989; Pauls *et al*. 1989; Monestier *et al*. 1990), but there are discrepancies in the frequencies of histone subtypes recognized by the autoantibodies. Anti-H1 and anti-H3 are the most commonly described (Pauls *et al*. 1989). No correlation has been observed with the presence of uveitis except in one study in which a higher frequency of H3-reacting autoantibodies was found in children with uveitis (Østensen *et al*. 1989). The autoreactivity to histone fragments is demonstrated either to the C-terminal of H1 (Monestier *et al*. 1990) or to several fragments within H3 and H4 (Tuaillon *et al*. 1990; Leak *et al*. 1993). In a recent study, autoantibodies from sera of 138 children with juvenile chronic arthritis were assessed with 34 histone peptides covering the full length of the four core histones, and two peptides from H1. No correlation was found either with disease subtype or activity, or with the presence of chronic anterior uveitis (Stemmer *et al*. 1995).

Polyarthritis with boggy synovitis

Some children may present with very thick pannus involving joints in a symmetrical manner. Tenosynovitis is common. Pain remains mild and functional impairment is late. Laboratory tests show a high erythrocyte sedimentation rate (greater than 40 mm/h), marked leucocytosis, and increased levels of acute-phase reactants. There are no autoantibodies. Boys and girls are equally affected.

'Dry' polyarthritis

This group of patients is roughly the counterpart of the previous group. The diagnosis is often delayed as there is no joint swelling but very progressive stiffness. These joint manifestations lead to gait abnormalities including limping. It is not unusual for these children to be referred to a paediatric neurologist, or even to a psychiatrist! However, osteoarticular examination reveals a limited range of motion because of articular stiffness but without obvious synovitis. Joint stiffness seems to be due to capsular and tendon contraction. Muscle wasting occurs. The laboratory profile is normal or mildly inflammatory. There are no autoantibodies.

Polyarthritis with spondylarthropathy features (see Chapter 5.5.2)

Some older patients, particularly boys, can present with polyarthritis (more than four joints), most often in the lower limbs. A careful clinical examination and the presence of relatives with spondylarthropathy suggests the diagnosis of undifferentiated spondylarthropathy. They meet the criteria proposed by the European Spondylarthropathy Study Group or those of Bernard Amor (see Chapter 5.5.5) (Amor *et al*. 1990; Dougados *et al*. 1991). Generally in children, the only manifestation is peripheral arthritis with no spinal involvement. Joint pain is often marked. Non-steroidal anti-inflammatory drugs (**NSAIDs**) induce rapid pain relief. Biological evidence of inflammation is more pronounced than in the oligoarticular type of spondylarthropathy. There are no autoantibodies in this group of patients, except for the occasional presence of antinuclear antibodies in the group with psoriatic arthritis. In rare cases, there may be inflammatory bowel disease or reactive arthritis (Reiter's syndrome) with eye and mucosal manifestations. The risk of developing a spondylitis within 5 to 10 years is high. Psoriatic arthritis is considered by many authors to be a spondylarthropathy. However, a higher frequency of girls and a younger age at onset means that its place in the spondylarthropathy group is questionable (Table 2).

	Sex ratio (% male)	Age at onset (years)
Juvenile ankylosing spondylitis	84	10.7
Reiter's syndrome	75	10.1
Undifferentiated spondylarthropathies	66	11
Inflammatory bowel disease	62	11.4
Juvenile psoriatic arthritis	45	8.8

[a]According to the criteria proposed by the European Spondylarthropathy Study Group and Bernard Amor (Chapter 5.5.5).

Table 2 Sex ratio and age at onset in the different groups of spondylarthropathies in children [a]

Differential diagnosis (Table 3)

Table 3 Differential diagnosis of RF-negative polyarthritis

Polyarthritis related to an infectious agent

Viruses may induce a joint reaction, particularly in very young children. It may be preceded by an upper respiratory tract infection, with or without fever. Synovial fluid analysis shows a majority of lymphocytes. Joint involvement generally lasts less than 2 weeks. Parvovirus B19, hepatitis, and rubella are among the most common causes of arthritis. Rubella vaccination may be followed by a polyarthritis which can last several weeks. Streptococcal infection or acute rheumatic fever may cause a migratory arthritis (see Chapter 5.3.12). Other signs of rheumatic fever, such as carditis, chorea, and eruption, may be present. Treatment consists of anti-inflammatory drugs, aspirin and/or corticosteroids, and penicillin for at least 5 years. Although this condition now occurs very rarely, we should be aware of its possible resurgence (Kaplan 1990). Lyme borreliosis can be considered when the child has had a tick bite in an endemic area. Typical clinical symptoms are a flu-like illness with erythema chronicum migrans. Some weeks later other symptoms can occur, including neurological, cardiac, ocular, and articular manifestations. Joint involvement is less frequent in Europe than in North America. The diagnosis and treatment is described in Chapter 5.3.4.

Acute infections of the joint or bone are usually easily diagnosed (see Chapter 5.3.2). However, a polyarthritis-like disease can occur in immunodeficiencies (see Chapter 5.3.11). The most frequent immunodeficiency in which this is observed is the X-linked humoral deficiency or Bruton's disease, which occurs in young boys with a history of upper respiratory tract, pulmonary, or gut infection. The diagnosis is made by the absence of serum immunoglobulins. A multifocal, bacterial joint

infection should be ruled out first and treated. However, non-bacterial joint swelling is possible, probably resulting from chronic virus infection. Immunoglobulin infusion generally improves chronic joint involvement. Other immunodeficiencies such as acquired humoral deficiencies, or Wiskott–Aldrich and ataxia telangiectasia, can also be complicated by non-bacterial arthritis. In the latter, joint manifestations are rarely the initial symptom.

Autoimmune rheumatic disorders

Autoimmune rheumatic disorders such as systemic lupus erythematosus must also be considered. Polyarthritis is nearly always present in systemic lupus erythematosus and is one of the eleven diagnostic criteria of the ACR (see Chapter 5.7.2). The presence of skin manifestations, serositis, and renal involvement should prompt laboratory investigations to confirm the diagnosis. Cytopenia, anti-DNA antibodies, and decreased complement are the usual findings. Polyarthritis is also prominent in overlap syndromes and mixed connective tissue disease (see Chapter 5.12.1). Polymyositis or dermatomyositis are usually easily diagnosed, but a joint component is possible.

Systemic vasculitic syndromes

Systemic vasculitic syndromes (see Chapter 5.11.8) are not exceptional. Kawasaki disease is generally observed in very young children, but the joint symptoms are of secondary importance to the extra-articular manifestations. Polyarteritis nodosa may cause a very severe and painful polyarthritis associated with myalgia. As well as the painful joints, skin involvement includes nodules, with typical changes of medium-sized arteries on biopsy. Cutaneous and articular features without visceral involvement are possible. The differential diagnosis of RF-negative polyarthritis from other other forms of systemic vasculitis such as Wegener's granulomatosis, lymphomatoid granulomatosis, Henoch–Schönlein purpura, and hypocomplementaemic vasculitis is generally easy. Arthritis can occur in relapsing polychondritis. The diagnosis is generally obvious with inflammation of auricular cartilage and nasal chondritis with a saddle-nose deformity.

Behçet's syndrome (see Chapter 5.11.7) can occur in children. These patients may have polyarthritis. The diagnosis is made on the basis of possible familial clustering and ethnic origin, when genital and oral ulcerations are present. Inheritance is autosomal recessive. These children can also develop ocular, intestinal, and neurological manifestations (Koné-Paut *et al*. 1995). Familial Mediterranean fever (see Chapter 5.13.2) occurs in Sephardic Jews, Armenians, Greeks, Turks, and Arabs. Inheritance is also autosomal recessive and the gene has been mapped on the short arm of chromosome 16. Clinical manifestations include fever, skin rash, serositis, abdominal pain, and possibly arthritis. Colchicine is an effective therapy in preventing attacks and the occurrence of renal amyloidosis.

Sarcoid arthritis produces a distinctive syndrome in children under the age of 4 years, sometimes in the first year of life. The triad of skin rash, uveitis, and huge proliferation of boggy synovium with tenosynovitis is highly suggestive of sarcoid arthritis. Skin or synovial biopsy shows the typical sarcoid granulomata. Joint involvement is relatively painless. Visceral involvement is rare. A familial association has been described (Blau 1985). Vasculopathy has been reported and some authors suggest that this entity should be considered as a 'familial granulomatous arteritis'. Systemic corticosteroids are often necessary to control uveitis and arthritis. Polyarthritis can be observed in the adult type of sarcoidosis in older children.

Haematological disorders

In early childhood, joint involvement in sickle-cell disease may result in hand–foot syndrome. Swelling of the hands and feet is extremely painful. Later, migratory arthritis can be observed. Bone pain can be due either to bone infarction or to osteomyelitis. The diagnosis is based on ethnic origin and haemoglobin electrophoresis. Constitutional bleeding disorders such as haemophilias can be manifested by joint haemorrhage. Generally, the deficiency of clotting factor is identified. Modern therapeutic management aims to prevent haemarthrosis and joint destruction.

Acute leukaemia may induce bone pain and joint swelling due to infiltrates of leukaemic cells. The diagnosis must be confirmed rapidly by examination of a bone marrow smear and specific therapy started without delay. Neuroblastoma with bone metastasis must also be considered in a young child with osteoarticular pain.

Other causes of polyarticular manifestations

Patients with chronic, recurrent, multifocal osteomyelitis can present with bone pain. There is no joint swelling and careful examination localizes the pain to the metaphyseal area. Radiography confirms the diagnosis by the presence of osteolytic lesions in the metaphysis. The lesion is sterile and antibiotics have no effect. The course may be long and relapsing.

Patients with hip pain are sometimes referred as having possible polyarthritis. In an adolescent, the possibility of lamellar coxitis should be ruled out. It is generally unilateral and the laboratory screen is normal, while radiography shows narrowing of the hip space. The cause is unknown and the prognosis is unpredictable. Similarly, Legg–Calvé–Perthes' disease induces osteonecrosis of the femoral head in young boys around the age of 7 years. It is generally unilateral, rarely bilateral. Radiographs are normal at onset, but scintigraphy or MRI may show necrosis at this stage. Orthopaedic management is required. In younger children, transient synovitis of the hip is frequent. It occurs around 6 years of age and may be preceded by upper respiratory tract infection. An increased erythrocyte sedimentation rate is frequent. Bed rest with traction and NSAIDs are necessary. Recovery occurs within a few days. Occasionally hip dysplasia is evident. Some patients develop recurrent episodes of transient synovitis of the hip.

Diabetic arthropathy is observed in uncontrolled diabetes. Exceptionally it may be the first manifestation of diabetes. Diabetic cheiroarthropathy with progressive flexion contractures of the fingers, as a result of increased deposition of collagen in the tissues, is well recognized. Idiopathic juvenile osteoporosis is a painful disease. There are no joint manifestations. Usually, there are no abnormalities of phosphocalcium metabolism. Recovery occurs in adolescence, sometimes with sequellae resulting from spontaneous fractures or vertebral collapse.

Immunogenetics

Most of the immunogenetic studies in polyarticular-onset juvenile arthritis separate the group of 'seropositive' and 'seronegative' forms. RF-positive polyarticular arthritis in children and adults are both associated with HLA DRB1 (Ploski *et al*. 1993). Several authors have observed an association between RF-negative polyarticular arthritis in children and HLA DR8, mainly involving the HLA DRB1*0801 subtype (Morling *et al*. 1985; Hall *et al*. 1989; Fernandez-Vina *et al*. 1990; Barron *et al*. 1992; Ploski *et al*. 1993). Ethnic differences may be observed in some populations, such as the studies on Italian (Fantini *et al*. 1987) and Czech children (Cerna *et al*. 1994) in which no correlation with HLA DR8 could be found.

HLA DR8, in fact, is associated with several forms of juvenile arthritis including early-onset oligoarticular forms (Malagon *et al*. 1991) and juvenile spondylarthropathies (Ploski *et al*. 1995). In contrast, HLA DPB1*0201 is associated with the oligoarticular, but not with the polyarticular forms. The frequency of HLA DPB1*0301 is increased significantly in patients with polyarticular arthritis and juvenile spondylarthropathies. This association between HLA DRB1*0801 and HLA DPB1*0301 in polyarticular-onset disease has been confirmed by several authors. This combination, rarely observed in the normal population or in the oligoarticular types of disease, suggests an interaction between these two alleles, conferring an increased susceptibility to the polyarticular expression of the disease.

However, as seen in Table 4, there are discrepancies between the studies, probably due to various factors including ethnic background, the absence of clinical homogeneity of the patients, the definition of each clinical subgroup, and the number of patients studied. It is evident that uniformly agreed criteria for the improved subgrouping of patients is still required.

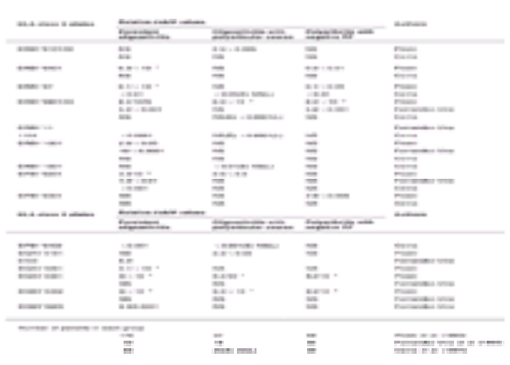

Table 4 HLA associations in RF-negative polyarthritis compared with oligoarthritis, with or without a polyarticular course, in three different geographical areas

Management

The principles of management are those of any childhood chronic disease of the joints, namely to offer pain relief, maintain satisfactory joint function, minimize drug toxicity, and allow the child to grow and be educated as normally as possible. It is sometimes difficult to meet all these requirements and complete trust between the family and the paediatric team must be established.

Non-steroidal anti-inflammatory drugs (NSAIDs)

The use of NSAIDs remains the basis of treatment. In children, only a certain number of drugs have been studied and their licence for use varies in different countries. Acetylsalicylic acid and other NSAIDs such as diclofenac, ibuprofen, and naproxen are available for use in most countries. Recommended doses are indicated in Table 5. In general, all NSAIDs have similar efficacy but tolerance may vary. Aspirin induces the most frequent side-effects, as shown in a comprehensive study (Barron *et al*. 1982). The mode of administration may be important for compliance. Ideally, aspirin must be administered every 4 h, while other NSAIDs can be given 1 to 3 times over 24 h. The few available pharmacokinetic studies in older children have shown only minor differences to adults. The half-life in synovial fluid is longer than in plasma (Hallé *et al*. 1991). NSAIDs are usually rapidly effective, but some authors have found that they take several weeks to have full effect (Lovell *et al*. 1984). The most frequent side-effects are gastrointestinal (mainly abdominal pain), cutaneous (urticaria, rash, and hypersensitivity), and haematological (anaemia). Rare cases of renal damage and disorders of the central nervous system (headache and dizziness) have been reported. Allergic reactions can also occur. Macrophage activation syndrome is exceptional in polyarticular disease, but it must be borne in mind, particularly when aspirin is used (Prieur and Stephan 1994).

Name	Dose per kg body weight per day (maximum daily dose)
Acetylsalicylic acid	50–100 mg (4 g)
Naproxen	15–20 mg (1.5 g)
Ibuprofen	40–60 mg (2.4 g)
Ketoprofen	3–6 mg (300 mg)
Fenoprofen	40–50 mg (3.2 g)
Flurbiprofen	3–4 mg (300 mg)
Diclofenac	2–3 mg (200 mg)
Sulindac	4–6 mg (400 mg)
Meclofenamate	4–7 g (300 g)
Piroxicam	0.3 mg
Indomethacin	1–3 mg (200 mg)
Tolmetin	20–30 g (1.6 g)

Table 5 Non-steroidal anti-inflammatory drugs in children

Slow-acting antirheumatic drugs

Slow-acting antirheumatic drugs are indicated in the polyarticular forms of juvenile chronic arthritis. The most commonly used agents are gold salts and D-penicillamine. Other thiol derivatives can be used, such as tiopronine and sulphasalazine. Synthetic antimalarials are used, particularly in Scandinavian countries. These treatments all take several weeks to work and carry a risk of side-effects that are now well documented in adults. Their use in children must take account of age and the clinical presentation. An improvement is usually observed during the first 6 months, and there is no point in continuing treatment if no result is obtained after this period. Table 6 summarizes the main preparations, their doses, and side-effects.

Name	Dose	Side-effects
Auranofin (oral)	0.3 mg/kg body weight per day (max. 9 mg)	Diarrhoea Same as above but less severe
D-Penicillamine (oral)	5, for 1 month then 10 mg/kg body weight per day (if necessary 15 mg/kg per day)	Rash Cytopenia Proteinuria Pneumopathy Autoimmunity: myasthenia, lupus
Tiopronine (oral)	10 for 1 month, then 20 mg/kg body weight per day	Same as D-Penicillamine
Sulphasalazine (oral)	20–30 mg/kg body weight per day	Rash Cytopenia Increased transaminases
Hydroxychloroquine (oral)	5–7 mg/kg body weight per day (max. 200 mg)	Retinopathy Cutaneous symptoms Neuropathies Cytopenia

Table 6 Slow-acting antirheumatic drugs in children

Several prospective studies have been carried out in the paediatric setting. D-Penicillamine has been the subject of three comparative trials, which yielded somewhat contradictory results. A French study comparing D-penicillamine with placebo showed that the active drug had a degree of efficacy (Prieur *et al*. 1985), while an American–Russian study comparing D-penicillamine, hydroxychloroquine, and placebo showed no difference in efficacy or tolerability among the three groups (Brewer *et al*. 1986). The frequency of side-effects in these two studies was acceptable, whereas a Norwegian team reported side-effects in 25 per cent of patients on D-penicillamine in a comparative study with gold salts (Kvien *et al*. 1985). Certain studies indicate that gold salts given by the oral route were slightly more effective than placebo (Giannini *et al*. 1990), an effect that persisted beyond 5 years (Giannini *et al*. 1991a) but did not reach statistical significance. Among the thiol derivatives, tiopronine had similar efficacy and tolerability to D-penicillamine when studied by the author. Several paediatric trials of sulphasalazine have been performed. Sulphasalazine appears to be beneficial in certain conditions, especially spondylarthropathies (Job-Deslandre and Menkes 1991). Published results on slow-acting antirheumatic drugs are only mediocre. A meta-analysis of 6-month efficacy on disease activity confirmed the lack of spectacular improvement (Giannini *et al*. 1991b). In addition, most of these studies did not distinguish between the different forms of juvenile chronic arthritis. There is no evidence that combinations of slow-acting antirheumatic drugs are effective in children, although this has not been studied in children in a systematic fashion.

Steroids

Steroids are a very powerful tool but often have unacceptable side-effects in children. They can be given systemically or locally.

Systemic steroids generally are not indicated in the polyarticular form of juvenile chronic arthritis. In severe crippling cases, they can be used to improve the functional status. The side-effects of systemic steroids are the main problem in paediatric use. Rapid weight gain can only be avoided by a strict diet, which must be not only sodium-free but also restricted in slow-resorption carbohydrates. The most troublesome cutaneous side-effects are permanent striae, but these are rare if weight gain is controlled by dieting. Arterial hypertension and diabetes can develop. Osteoporosis can lead to very painful vertebral collapse which necessitates immobilization in a corset. The use of deflazacort, available in some countries, apparently lessens the impact of steroids on bone metabolism (Loftus *et al*. 1993). Aseptic joint necrosis, especially of the hips, is far from rare and complicates underlying diseases that can also involve the joints. The onset of steroid-induced cataracts must be monitored closely. Finally, above all in children, daily steroid therapy arrests growth. This is overcome by alternate-day dosing when possible (Prieur 1993).

Local steroid therapy can be applied to the joints and eyes.

Intra-articular steroid injections have modified totally the prognosis of joint manifestations. They can be used in polyarticular forms when stiffness and flexion contractures cannot be controlled by general therapy. Among the many available products, only triamcinolone hexacetonide gives satisfactory results. It is fairly potent and must therefore be used with care to avoid local complications (mainly cutaneous atrophy at the injection site). Some attempts at multiple joint injection have given encouraging results (Pugh *et al*. 1995)

This procedure is straightforward for large joints such as the knee, but general anaesthesia may be necessary for small and/or tight joints, especially in the very young child. There is no lower age limit for this type of treatment as long as the precautions for use are respected; this also means that an experienced practitioner must treat the joints of small children. In general, the volume injected must be adapted to the volume of the joint, and the product must not be injected 'under pressure'. The joint must be rested with a splint for 3 days. Complications are rare and mainly consist of cutaneous atrophy at the injection site or asymptomatic intra-articular calcifications. Needless to say, the potency of this preparation contraindicates its use for injecting tendon sheaths, where only water-soluble steroids can be used.

Uveitis, a frequent complication of polyarticular forms of juvenile chronic arthritis with antinuclear antibodies, is treated with steroid-based eye drops and mydriatic agents.

Cytotoxic drugs

Cytotoxic treatments may be of value in severe forms. However, their efficacy is often difficult to determine objectively because of the small number of sound, prospective, multicentre trials. Too many specialists continue to use a given treatment in 'selected cases', meaning that the results are uninterpretable. Ideally, as in oncology, multicentre protocols should be established to accelerate the assessment of the efficacy and tolerability of experimental treatments.

Methotrexate is one of the most widely used immunomodulatory agents. The use of methotrexate in children with rheumatic diseases was proposed when its efficacy and acceptable tolerability were established in adults. The recommended dose, based on a double-blind, placebo-controlled trial, is 10 mg/m ^{2} per week (Giannini *et al*. 1992), but certain authors propose higher doses for particularly resistant forms (Wallace *et al*. 1991)

The tolerability of methotrexate in children is acceptable (Graham *et al*. 1992). In combination with NSAIDs, the level of methotrexate in the blood can increase (Dupuis *et al*. 1990). A few cases of severe liver damage have been reported (Keim *et al*. 1990). Side-effects, which are generally mild, must be monitored every 1 or 2 months. Many patients (almost 30 per cent) show increased transaminase levels. Values usually return to normal when the dose is reduced or treatment is suspended. After a few months of treatment, nausea is fairly frequent immediately after methotrexate intake, and these patients may benefit from a switch to the intramuscular route. Oral aphthae, cytopenia, and pulmonary manifestations are observed rarely.

Methotrexate seems to have clear efficacy in some cases, especially in pauciarticular juvenile chronic arthritis with the presence of antinuclear antibodies (Hallé and Prieur 1991). A European, multicentre, double-blind trial is underway to confirm this observation.

Azathioprine at a dose of 2 to 2.5 mg/kg body weight per day, is used by certain specialists. It is generally well tolerated. However, the possible long-term risk of cancer must be borne in mind, and this agent should probably only be used in severe cases (Silman *et al*. 1988). In juvenile chronic arthritis, azathioprine appears to be slightly more effective than placebo (Kvien *et al*. 1986).

Alkylating agents can be considered in exceptional cases when classical treatments fail to control disease progression. However, chlorambucil (0.2 mg/kg) has a very high mutagenic risk (Prieur *et al*. 1979). It is thus only recommended for life-threatening complications such as secondary amyloidosis, which hardly ever complicates polyarticular juvenile chronic arthritis. Similarly, the indication for cyclophosphamide in the polyarticular forms is only for exceptional cases.

Cyclosporin is effective in adult rheumatoid arthritis at doses below 5 mg/kg body weight per day (Dougados *et al*. 1988). Studies involving patients with juvenile chronic arthritis have failed to show marked improvement (Østensen *et al*. 1988), but further trials are required. The paediatric side-effects of cyclosporin are identical to those observed in adults.

Surgery (see Chapter 6.2)

Surgery plays an increasing role in the management of chronic rheumatic diseases when the medical means are insufficient. The orthopaedic surgeon must participate in the therapeutic discussion. The technical approaches are numerous. Arthroscopy is now efficient for small joints, with adapted equipment. It allows intra-articular examination, biopsies, and synovectomy. Surgery in the form of soft tissue release, osteotomies, surgical realignment, and arthrodesis may be necessary to treat fixed joint deformities. Surgical treatment of growth deformities is mandatory when functional impairment and secondary mechanical problems in adjacent joints develop. Finally, joint arthroplasty must be considered when joint destruction and joint failure lead to major handicap. Anaesthetists must be aware of cervical spine involvement and temporomandibular arthritis, which may make intubation difficult.

Rehabilitation (see Chapter 6.4)

Physical treatments are necessary for any child with chronic arthritis. The techniques involve applied heat (water, paraffin, or hot packs) to induce muscle relaxation. Flexion deformities must be stretched out either actively by the child or passively by the child, parent, or therapist. Correct positioning of the joint must be obtained at rest with appropriate splinting. Prone positions should be recommended for reading or watching television. Each joint requires a specific technique of rehabilitation to prevent deformities. The treatment must be adapted to the severity of the disease, the impact of each joint on total function, and radiological changes. In cases of surgical intervention, both preoperative and postoperative rehabilitation are necessary.

Conclusion

The management of polyarticular juvenile arthritis involves a common approach which is adapted according to the different subtypes of arthritis as shown in the practical guidelines presented in Box 1.

5.7.1 Systemic lupus erythematosus in adults

David A. Isenberg and Angela C. Horsfall

Introduction

Systemic lupus erythematosus has taken the mantle of syphilis as the great mimic of other conditions. It is probably better to think of it as a group of related disorders rather than a single disease entity. By analogy it might also be compared to the Hydra monster of ancient Greek mythology (Fig. 1). This beast, one of the offspring of Echidne and Typhon was notoriously unpleasant and possessed numerous heads. It was said that cutting off one head led to the growth of two or three others. Lupus presents in many unpleasant guises and the successful treatment of, say, joint pain in lupus may be followed by the emergence of skin rash or pleuropericardial involvement. There is another analogy with lupus as no one could agree precisely how many heads the Hydra had or about their appearance—similarly there is disagreement as to how disease activity in lupus should be assessed.

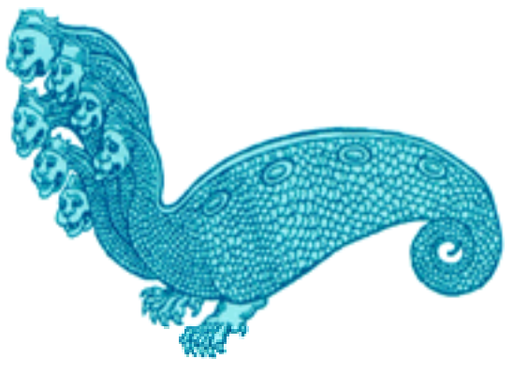

Fig. 1 The Hydra—a useful analogy of lupus (see text).

In this chapter we will detail the clinical features of lupus, analyse its serology, appraise the experimental models of the disease, and review studies of its immunopathology and treatment. Drug-induced forms of lupus are considered in Chapter 5.19.1 but the disease in the male and in elderly people is highlighted here, and several controversial areas are discussed. The major historical aspects of lupus, reviewed in detail elsewhere, are indicated in Table 1.

Table 1 Historical aspects of lupus

Definition and classification of lupus

Systemic lupus erythematosus is perhaps best defined as a clinical syndrome with a complex, multifactorial aetiology, characterized by inflammation and the involvement of most of the body's organs or systems. It is subject to many remissions and exacerbations and, although the musculoskeletal system and skin are invariably affected, frequently gives rise to manifestations in the kidney, heart, lungs, and central nervous system. The diversity among its clinical features is matched by an apparent diversity among the autoantibodies detectable in the serum.

The American Rheumatism Association (now the American College of Rheumatology, **ACR**) has published two sets of criteria in 1971 and 1982, which have been widely adopted. Strictly speaking the criteria are for the classification of the disease rather than use as a diagnostic tool, although in practice there is blurring of this distinction. The 1982 revised criteria are set out in Table 2.

Table 2 Revised criteria of the American Rheumatism Association for the classification of systemic lupus erythematosus (SLE)

The variable clinical and serological expression of lupus makes it easy to obtain a distorted view of the disease. Patients present to a variety of specialists, each of whom will see a different spectrum of the disease. Thus bias amongst the reporting physicians must be borne in mind when assessing reports about lupus. A broad overview of the cumulative percentage incidence of the features of systemic lupus in five large series is shown in Table 3. It must be remembered that the incidence of some clinical features varies between ethnic groups. A recent study of 137 Chinese patients with systemic lupus in Hong Kong reported a relatively low incidence of arthritis (71 per cent) compared with other groups but a high incidence of renal involvement (70 per cent) (Lee *et al*. 1993).

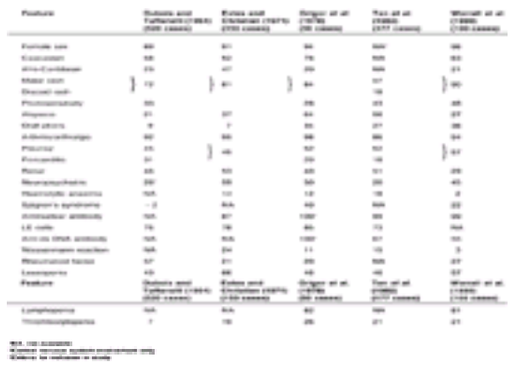

Table 3 Cumulative percentage incidence of systemic lupus features in 100 patients in comparison with other large studies

Epidemiology and natural history

Lupus is a worldwide disease. Although it has been estimated that approximately 1 in 250 black women in the United States and the West Indies, about 1 in 1000 Chinese, and 1 in 4300 Caucasians in New Zealand have systemic lupus, there are some curiously conflicting data. In particular, it seems that lupus is rare in most parts of Africa (Fessel 1988). Two recent studies from urban centres in the United Kingdom have highlighted the significant variation in the prevalence of lupus among different ethnic groups sharing much the same environment. The study from Nottingham (Hopkinson *et al*. 1993), while noting a prevalence of 45.4/100 000 per year in women (3.7/100 000 per year in men), implied that the numbers of lupus patients of Afro-Caribbean and Asian origin were overrepresented, but did not quote any figures. In contrast, the study from Birmingham (Johnson *et al*. 1995) reported prevalence rates of 36.2, 90.6 and 206/100 000 among women of Caucasian, Asian, and Afro-Caribbean origin respectively.

The important genetic contribution to the aetiology of lupus is emphasized by the study of twin concordance reported by Deapen *et al*. (1992). Of 107 twin pairs studied, concordance among monozygotic pairs was found to be 24 per cent compared with 2 per cent among dizygotic pairs. While the figure for monozygotic twins is lower than previously reported, it is still 12 times that for the dizygotic pairs and may in fact be an underestimate, as not all of the twins were examined personally by the authors and long-term follow-up of the pairs was restricted.

It is widely agreed that lupus is approximately 10 to 20 times more common in women than men. There is also little dispute that the overwhelming majority of patients with lupus will develop their disease between the ages of 15 and 40 years.

Although, in the early part of the century, lupus was considered as a serious and frequently fatal disease, perceptions of it have changed considerably. This seems to reflect the easier identification of milder cases with the introduction of widely available tests for measuring antinuclear antibodies. The introduction of corticosteroids and immunosuppressive drugs, dialysis, and renal transplantation has improved the chances of survival in the more serious cases. However, as will be discussed, lupus continues to cause considerable morbidity and 10 to 20 per cent of patients succumb from either the disease, a side-effect of its treatment, or both within 10 years of follow-up.

Clinical features

Non-specific features

Lupus, in common with many other chronic diseases, is accompanied by a variety of non-specific or general features. Of these, lethargy is frequently the most disabling and the least likely to attract the sympathy of the physician! It is, however, invariably present in active lupus (Wysenbeek *et al*. 1993) and often requires counselling. Careful examination frequently reveals the presence of lymphadenopathy, especially in the axillae, which persists long after patients have gone into remission. On occasion it may be so prominent in the neck or under the arms that a biopsy has to be taken to exclude any more sinister pathology. Patients with active lupus may experience weight loss and, on occasion, nausea. Most of these general features will improve when treatment is commenced.

Musculoskeletal involvement

Arthralgia occurs in about 90 per cent of patients with systemic lupus. The joint pain is polyarticular and frequently symmetrical, episodic, and flitting in nature. It is accompanied in about half the patients by early morning stiffness. Very often the patient's symptoms outweigh the objective signs, and major synovial effusions are rare. Severe clinically overt arthritis with joint deformity is probably confined to 5 to 10 per cent of these patients (Spronk *et al*. 1992). Furthermore, unlike patients with rheumatoid arthritis, the deformities (Fig. 2) are usually related to an intense tenosynovitis and less frequently to synovial hypertrophy, with or without bone erosion. These deformities in the hands are known as Jaccoud's arthropathy, which is generally a reversible subluxation.

Fig. 2 Severe hand deformity in a lupus patient due to chronic tenosynovitis, not an erosive arthritis.

Joint involvement is relatively mild and, therefore, it is uncommon for 'lupus joints' to be examined histologically but a 'lupus synovium' has been described with a characteristic minor cellular inflammation, occasional haemotoxylin bodies, and non-specific vasculitis and perivasculitis. Electron microscope studies have revealed cytoplasmic inclusions in vascular endothelial cells on occasion. Synovial fluid examination usually reveals a low white-cell count (less than 3000 cells/mm ^{3}), in which mononuclear cells predominate. The fluid is occasionally positive for rheumatoid factor or antinuclear antibodies. Immune complex deposition has been described in synovial tissues and is thought to be responsible for the observed inflammatory lesions. Approximately 2 to 3 per cent of patients classified as having lupus also meet the ACR's criteria for rheumatoid arthritis, with clear erosive disease.

An occasional complication of joint involvement in lupus is spontaneous tendon rupture, which is generally confined to the patella or Achilles tendon (Furie and Chartash 1988). Its aetiology is not well understood, but in some cases at least it seems to be related to inflammatory changes in and around the tendon as a result of the underlying disease process. It is also possible that corticosteroid therapy is in part responsible.

Other, less common, musculoskeletal features include subcutaneous nodules (present in about 5 per cent of patients with systemic lupus and indistinguishable from those found in patients with rheumatoid arthritis), calcinosis (less common in lupus than in scleroderma or dermatomyositis), chondritis, and avascular necrosis. The last of these features occurs in 5 to10 per cent of lupus patients, most cases being associated with prior corticosteroid therapy, and in many instances the avascular necrosis occurs at multiple sites. The remainder are caused usually by small vessel vasculitis or fat emboli.

Myalgia, muscle weakness, and tenderness have been reported in up to 60 per cent of patients with lupus, although a true myositis is confined to about 5 per cent of these patients (Isenberg and Snaith 1981). Treatment with corticosteroids and chloroquine may cause a myopathy, but in the main the myalgia experienced by patients seems to be a complication of adjacent joint involvement.

Histologically a vacuolar myopathy has been described in lupus. This is identified by the presence of plump, swollen sarcolemmal nuclei with other prominent vacuolated nuclei, centrally located within the muscle fibre. Immunoglobulin deposition is often seen in the muscles of patients with lupus (Isenberg 1983) but this is irrespective of whether they have clinically overt muscle disease and seems to relate better to minor fibre damage as a secondary event, rather than to a primary inflammatory myopathy.

Dermatological involvement

Although lupus takes its name from the classic butterfly rash found over the bridge of the nose and malar bones (see Fig. 3(a)), this is actually found in only about one-third of patients with systemic lupus. There are, however, numerous other forms of dermatological involvement (Pistiner *et al*. 1991, and see Table 4). These include maculopapular rashes and discoid lesions (Fig. 3(b)), splinter haemorrhages, dilated capillaries at the nail base, bullous lesions, angioneurotic oedema, and buccal and nasal ulceration (Fig. 3(c)). Vasculitis affecting the fingers and toes is common and frequently causes pain and tenderness (Fig. 3(d)). Many lupus rashes are clearly photosensitive and thus confined to the light-exposed areas. Not surprisingly, photosensitivity is commonest in white females. It is thus most important to advise patients with systemic lupus to avoid sun exposure and use sunscreen even when driving with an arm exposed through an open window.

Frequency	Manifestation
Common (20–50% approx.)	Butterfly rash Photosensitivity Non-specific maculopapular lesions Chronic discoid lesion Non-scarring alopecia Purpura/petechiae
Less common (5–20% approx.)	Mucous membrane lesions Urticaria Diffuse hyperpigmentation Leg ulcer Subcutaneous nodules
Occasional (<5%)	Periorbital oedema Jaundice Severe scarring alopecia Pruritus Bullae Panniculitis Psoriaform lesions

Table 4 Cutaneous manifestations in systemic lupus

Fig. 3 (a) Butterfly rash; (b) a discoid lupus rash; (c) nasal ulceration; (d) vasculitis affecting the toes, with associated hyperkeratosis.

Alopecia is a common feature of lupus. Although the lack of precision in interpreting and reporting it led to this feature being deleted from the American Rheumatism Associations's 1982 revised criteria for lupus, it remains an important component of the disease. It is usually diffuse but non-scarring, and more often a cause of limited upset. In contrast severe, scarring alopecia is uncommon but can be quite devastating for those who develop it.

Among the less common but important dermatological features of lupus are diffuse hyperpigmentation, usually most prominent on the light-exposed and extensor surfaces of the body, and lupus panniculitis. The latter is a form of lipoatrophy which usually develops as a relapsing, nodular, non-suppurative lesion. The nodules resemble those seen in Weber–Christian disease. The skin overlying the nodules may ulcerate, and scars invariably remain after healing takes place.

A variant of systemic lupus known as subacute cutaneous lupus erythematosus has been described. Early reports suggested that there were two types, annular and papulosquamous, and that the condition was associated with anti-Ro antibodies and HLA DR3. More recent evidence (Callen and Klein 1988) suggests that this group of patients is less distinctive but generally easily controlled.

Immunoglobulin deposition at the dermal/epidermal junction has been recognized for some 40 years. These immunoglobulins are usually of the IgG or IgM isotype. Intriguingly these depositions may be identified in areas of skin which are not light exposed (such as the buttocks) and which have no rash. This forms the basis of the so-called lupus band test (see Fig. 4). Complement components may also be found at the dermal/epidermal junction.

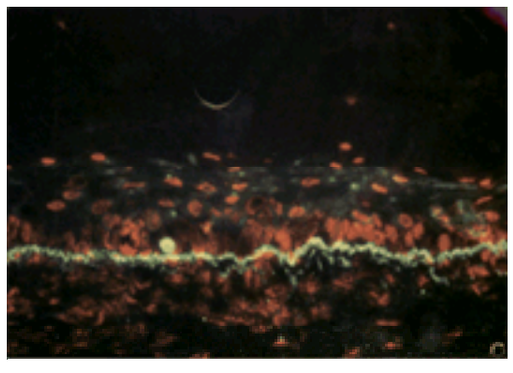

Fig. 4 Lupus band tests—the linear green staining is due to the deposition of IgM identified by a fluoresceinated antihuman antibody; the red counterstain is propidium iodide.

Cardiovascular and pulmonary involvement

Involvement of the heart in lupus has been recognized for nearly 100 years since Osler first described pancarditis. The names of Libman and Sachs are often thought of as synonymous with cardiac involvement, following their classic descriptions of non-bacterial verrucous endocarditis. There have now been multiple studies confirming the effects of lupus on the heart. These may be subdivided into pericardial, myocardial, or endocardial/valvular involvement.

Pericardial disease

Pericardial disease is the most common component of heart involvement in lupus. However, the frequency with which pathology is implied by various tests far outweighs the number of patients with clinically evident involvement. A pericardial rub is also more common than significant accumulations of pericardial fluid. Mandell (1987) reviewed 22 studies of pericardial involvement in lupus and concluded that whereas 29 per cent of the patients had clinical evidence of the disease, echocardiography revealed abnormalities in 37 per cent and necropsy studies showed that 66 per cent of patients had pericardial involvement. Abnormalities of the electrocardiogram, notably of the T waves, are detectable in up to 75 per cent of patients. Echocardiographic findings more commonly show pericardial thickening than large effusion. The results of pericardial fluid analyses may mimic those seen in bacterial pericarditis, and on occasions this latter diagnosis is difficult to distinguish. Studies of pericardial fluid have shown the presence of an antinuclear antibody, LE cells, and even hypocomplementaemia.

When large pericardial effusions have been discovered there may be further underlying complicating factors, such as uraemia and viral or bacterial infection. Constrictive pericarditis can develop within a few weeks of the first appearance of a pericardial effusion. There is some evidence that corticosteroid therapy may contribute to the development of constriction.

Histological abnormalities vary from occasional foci of fibrinoid degeneration and inflammatory infiltrates, to far more extensive lesions. Immune complex components have also been found throughout the pericardial tissue, even in areas where histologically the pericardium looks normal. There is no diagnostic pathological finding for lupus pericarditis, with the possible exception of haematoxylin bodies.

Myocardial disease

True myocardial involvement is less frequent than pericardial disease. Again, however, the results of investigations and necropsy studies suggest that involvement is much more common than is suspected clinically. Clinical myocarditis, usually defined by combinations of unexplained tachycardia, congestive heart failure, arrythmias, prolongation of the PR interval on electrocardiography, or cardiomegaly without pericardial effusion or valvular disease, occurs in up to 15 per cent of patients with lupus.

Echocardiographic studies have suggested that myocardial function can reversibly deteriorate in parallel with flares of generalized lupus activity. Perhaps not surprisingly the ability to correct abnormalities is more obvious in normotensive than in hypertensive patients. This probably reflects transient myocarditis or increased local ischaemia secondary to small vessel obstruction due to vasculitis, for example. It is thought that the risk of myocardial ischaemia is increased by concomitant steroid therapy.

Histological studies of myocardium have indicated that a mild non-specific perivascular infiltration with lymphocytes and neutrophils is relatively common. Intimal proliferation of the smaller intramyocardial arteries is also commonly reported, together with hyalinized vessels that may reflect either previous arteritis or primary thrombosis. The latter is of particular interest in view of the recognized links with antiphospholipid antibodies. The propensity for corticosteroid therapy to increase the risk factors, such as hypertension, hypercholesterolaemia, and obesity, for coronary artery disease has been emphasized recently (Petri *et al*. 1994). In contrast hydroxychloroquine was associated with a lowered serum cholesterol.

Valves

Conduction defects and rhythm disturbances are recognized as occasional features of lupus, but have rarely been found in more than 10 per cent of patients.

Systolic murmurs have been recorded in up to a third of patients with lupus, but in the majority of cases this probably represents the hypodynamic circulation secondary to the chronic anaemia often found in these individuals. In contrast, diastolic murmurs are rather rare.

The classic endocarditis described by Libman and Sachs (1924), although identified in up to 50 per cent of cases at autopsy, rarely causes clinically significant lesions. Histologically small (1 to 4 cm) vegetations (verrucae) comprising proliferating and degenerating valve tissue with fibrin and thrombi are seen. A recent prospective echocardiographic study of 132 consecutive patients with lupus reported a prevalence of valvular lesions of 22.7 per cent (Khamashta *et al*. 1990). These lesions were most commonly found adjacent to the edges of the mitral and aortic valves and have been shown to contain immunoglobulin and complement components, notably within the walls of the small junctional vessels in the active portions of the verrucous endocardial lesions. These deposits might therefore represent immune complexes deposited via the circulation. In the report referred to above, the valve vegetations were associated with the presence of antiphospholipid antibodies. Leung *et al*. (1990) also found a correlation between antiphospholipid antibodies and both valvular abnormalities and isolated left ventricular dysfunction in a study using M-mode, 2-D, and Doppler echocardiography.

In Mandell's review (Mandell 1987) of the reports of haemodynamically significant valvular disease in lupus, aortic incompetence and mitral regurgitation were the most frequently found among the paucity of published case reports.

Bacterial endocarditis has been reported on a number of occasions in patients with lupus. It has not been determined whether the most likely cause is a consequence of the underlying immunopathology of the disease or the predisposition to infection. However, reports of bacterial endocarditis in these patients do antedate

corticosteroid therapy, suggesting that in some patients at least it is the primary immunopathology which predisposes to secondary bacterial infection. As most of the lesions of Libman–Sachs endocarditis are too small to be assessed accurately by echocardiography, any vegetations which can be identified in a patient with lupus who is febrile should certainly raise the possibility of bacterial endocarditis.

Pulmonary disease

The nature and features of pulmonary disease are indicated in Table 5. By far the commonest feature is pain due to pleurisy, which affects approximately half of lupus patients at some time. This pain may be uni- or bilateral and is usually present at the costophrenic angles anteriorly or posteriorly. Pleural effusions, usually small, also uni- or bilateral, straw-coloured, with a protein level generally greater than 3 g/dl, high mononuclear cell count but normal glucose level, are found in a quarter of the patients. Low levels of pleural fluid complement are quite common compared with effusions in other conditions, such as heart failure and cancer, but a positive antinuclear antibody is recorded very infrequently.

1. Pleuritic pain/pleuritis is present in 20–60%
2. Pleural effusions are found in 20–30%. These are usually small volume, straw coloured, white cell count 3–5000/mm^3 mostly mononuclear cells and lymphocytes, glucose levels approximate to those in the blood (unlike rheumatoid arthritis in which the levels are lower), antinuclear antibodies may be detected, protein content varies from 2.75 g–6.4 g%.
3. Chest radiographs and lung function tests (and autopsy findings) invariably indicate a greater degree of pulmonary involvement than is evident clinically.
4. Interstitial fibrosis, pulmonary vasculitis, and interstitial pneumonitis are found in up to one-fifth of the patients.
5. Pulmonary hypertension is unusual and has been linked to the presence of antiphospholipid antibodies.

Table 5 Major pulmonary manifestations in lupus

Parenchymal involvement attributable to lupus has been reported in 18 per cent of patients (Haupt *et al*. 1981). These patients had interstitial fibrosis, pulmonary vasculitis, and interstitial pneumonitis. However, these authors argued that many pulmonary lesions such as alveolar haemorrhage, alveolar wall necrosis, and oedema, previously attributed to direct lupus involvement, are probably secondary to factors such as concurrent infection, congestive heart failure, renal failure, and oxygen toxicity. It must be remembered that the immunosuppressive therapy required by many lupus patients does predispose them to concurrent infection. A true lupus pneumonitis is recognized but is rare (less than 2 per cent).

Almost as uncommon is clinically symptomatic diffuse interstitial lung disease. Its manifestations resemble those found in patients with scleroderma and rheumatoid arthritis who may also develop this complication. Thus the slow onset of a chronic non-productive cough with shortness of breath is usually present. Occasionally a more acute presentation occurs after an episode of acute lupus pneumonitis (Weinrib *et al*. 1990).

There is great interest in antiphospholipid antibodies and thrombotic events in systemic lupus. It is accepted that around 10 per cent of patients develop thrombophlebitis and/or a pulmonary embolus. Antiphospholipid antibodies should be sought in patients with these presenting symptoms and also the small number who present with pulmonary hypertension.

Well recognized, but also uncommon, are patients with the so-called 'shrinking lung syndrome' (Hoffbrand and Beck 1965). It is evident that diaphragmatic dysfunction makes a significant contribution to this syndrome.

Abnormal pulmonary function tests (described in detail in Chapter 1.3.5) and notably diminished total lung capacity and flow rates, often show more serious involvement than expected. Haemoptysis is unusual, although commoner than major pulmonary haemorrhage which, while rare, may be life-threatening.

In the relatively few cases studied, immune complex deposition has been correlated with histological evidence of inflammatory lesions in the pleural and pericardial membrane.

Renal involvement

In many published series, renal disease has been the most common cause of death in patients with lupus. However, the clinical symptoms suggesting renal involvement, notably ankle swelling, shortness of breath related to secondary heart failure, and 'frothy' urine, rarely become evident until substantial damage has been done. Thus careful monitoring of the blood pressure for hypertension, the urine for protein, red cells, or casts, and the plasma for raised creatinine and urea levels is most important. Sequira and Balean at The London Hospital appear to have been the first to recognize that nephritis was a component of systemic lupus in 1902, although serious renal disease was thought rare until the 1940s. Histologically, it has been shown that lupus nephritis appears in many guises. The World Health Organization (**WHO**) have subdivided renal lupus into five major categories according to biopsy-derived information. In addition endstage renal disease with sclerosed glomeruli is recognized (see Fig. 5). Kidneys with this appearance are non-functional. These categories are shown in Table 6 and Fig. 5. In brief, the major manifestations are defined as minimal or mesangial change; mild or focal proliferative; severe or diffuse proliferative, and membranous. The glomerulus appears to bear the brunt of the attack in lupus. The range of glomerular changes include swelling, proliferation of mesangial, endothelial, and parietal epithelial cells, with infiltration by monocytes and polymorphonuclear leucocytes. In addition immune complexes, foci of necrosis, and haemotoxylin bodies can be identified in the glomeruli of lupus patients. While the WHO score has been widely adopted, it has drawbacks. It does not, for example, consider tubulointerstitial disease and makes no allowances for varying degrees of severity within individual categories; neither does it recognize the recently described overlap of lupus nephritis and the multiple small thrombi asssociated with antiphospholipid antibodies (see Fig. 5).

World Health Organization classification	Deposits			Proliferation			
	Mesangial	Subendothelial	Subepithelial	Mesangial	Endocapillary	Extracapillary	Necrosis

Table 6 Classification of renal lupus

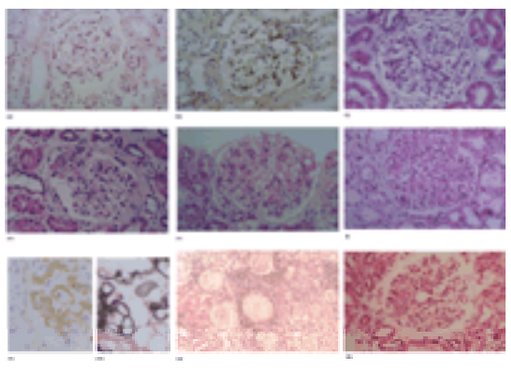

Fig. 5 Renal lupus (by courtesy of Dr M.H. Griffiths). (a) Systemic lupus erythematosus, no renal lesions, WHO class I. In addition to the mesangial immune deposit there is mesangial cell proliferation and the glomerulus appears hypercellular (haematoxylin and eosin). (b) Mesangial lupus nephritis, WHO class IIA. Immune complexes are demonstrable in the mesangium, seen here as granular brown deposits (immunoperoxidase technique for IgG). (c) Mesangial lupus nephritis, WHO class IIB. In addition to mesangial immune deposit there is mesangial cell proliferation and the glomerulus appears hypercellular (haematoxylin and eosin). (d) Focal proliferative lupus nephritis, WHO class III. Segmental proliferation (arrow) is seen in this glomerulus (haematoxylin and eosin). (e) Diffuse proliferative lupus nephritis, WHO class IV. The glomerular capillary walls are irregularly thickened forming, in places, classical 'wire loops' (arrow). There is variable cellular proliferation (haematoxylin and eosin). (f) Membranous lupus nephritis, WHO class V. There is diffuse capillary-wall thickening produced by abundant immune deposits in and on the basement membrane, seen in (i) as granular brown staining (immunoperoxidase technique for IgG). The basement membrane extends out between and around the deposits to produce a series of spikes and circles shown with silver staining in (ii) (hexamine silver technique). (g) Endstage renal disease showing completely sclerosed, non-functional glomeruli. (h) Hyaline thrombus in the glomerulus of a patient with systemic lupus and a high titre of antiphospholipid antibodies.

The role of renal biopsy in the management of lupus nephritis

There is a difference of opinion as to precisely when renal biopsy should be undertaken in patients with lupus, and about its value. The ability of lupus nephritis to transform from one variety to another and for the same biopsy to have more than one histological appearance is partly responsible for the conflict. In addition, few studies of the relationships between renal histology and clinical outcome have actually directly addressed the question as to what information the renal histology adds to the clinical data. Goulet *et al*. (1993) used regression tree techniques to show that combinations of serum creatinine, 24-h urine protein levels, nephrotic syndrome, and duration of prior renal disease provide accurate prognostic information about lupus nephritis without recourse to biopsy.

The biopsy itself is not without its problems, including quite heavy haematuria on occasion. It is obviously most important to assess the clotting capability of the patient before undertaking the biopsy. Fries *et al*. (1978) found that renal biopsy contains important prognostic information but that it was less than that of even the simplest clinical classification. Whiting-O'Keefe *et al*. (1982) applied a stepwise regression analysis to data collected over a 12-month period after renal biopsy in 130 patients with lupus to see if biopsy added any useful information to the clinical data. They found the histological classification did not add significantly to the predictive power of the 'before biopsy' model, but that certain features, notably the percentage of glomeruli which had undergone sclerosis in the presence of subendothelial deposits on electron microscopy, did increase the ability to predict the effect of 12 months of treatment of lupus nephritis. These authors felt that renal biopsy did not add important prognostic information over and above the clinical history examination and laboratory tests. A more recent study (Blanco *et al*. 1994) emphasized that chronicity markers, notably hyalinosis, tubular atrophy, and glomerular sclerosis on light microscopy and subepithelial, mesangial, and intramembranous deposits on electron microscopy, are the best indicators of a poor prognosis. More worryingly Schwarz *et al*. (1993) cast doubt upon the ability of pathologists to reproduce activity and chronicity scores accurately.

In contrast, Stamenkovic *et al*. (1986) described treatment based on renal histology of 56 patients with lupus. The mean follow-up period from first biopsy was 8.2 years, by which time 5.3 per cent were dialysis dependent, but nearly 95 per cent had resumed normal renal function. They found that the biopsy provided valuable information about the state of the kidney, independent of the clinical stage of the disease, and have argued that biopsy alone can improve predictions about 'renal survival' in lupus. McLaughlin *et al*. (1994) in a long-term follow-up study of 123 patients with systemic lupus who had a renal biopsy between 1970 and 1984, showed that the biopsy was helpful in assessing prognosis in patients with normal serum creatinine. In those with an elevated serum creatinine, the biopsy did not contribute additional information about the risk of dying.

Although it is not uniformly agreed, it can be recommended that patients with lupus who have haematuria and/or proteinuria and those with diminished glomerular filtration rate should be seriously considered for renal biopsy. However, as the above review of the controversy about the significance (and reproducibility in reporting) of renal biopsies indicates, the information they provide about prognosis should not be overestimated. The opinion of a pathologist with experience in assessing these biopsies is strongly advised.

Nervous system involvement

The first suggestion of involvement of the central nervous system in lupus was altered mental function, described at the end of the last century by Kaposi, and confirmed by Sir William Osler early this century.

Features of neurological disease range from the common, relatively harmless migraine headaches, to major psychotic episodes, and grand mal seizures, recognized in some lupus patients.

Manifestations of lupus affecting the nervous system can be subdivided into central or cerebral effects, peripheral lesions, and psychological aspects. Additional discussion of this topic is found in Chapter 1.2.1.2 and Chapter 1.3.4.

Central/cerebral involvement

Up to 40 per cent of lupus patients suffer from migraine, although this may be manifested by teichopsia alone. Of much greater concern are the grand mal seizures which may be an initial manifestation of lupus in perhaps 5 per cent of cases, but are present in up to 20 per cent of patients eventually. As with a number of other features it may be difficult to be certain whether the seizures represent true cerebral disease, or a manifestation of more general problems. They may, for example, be secondary to uraemia and other biochemical disturbances associated with renal involvement. Similarly, hemiplegia (and transverse myelitis) may be consequent upon primary neurological disease or could be secondary to hypertension, or associated with the more recently recognized antiphospholipid antibodies. Cerebellar disease in lupus appears to be uncommon as is aseptic meningitis. A variety of organic brain syndromes with impaired temporal–spatial orientation, poor memory, and intellectual deficit are all well recognized and remain difficult management problems.

There has been a resurgence of interest in a small group of patients with lupus who suffer from the movement disorders, chorea or ballismus. On occasion, chorea due to lupus may be difficult to differentiate from that due to rheumatic fever. However, in the more recently described patients, links with the presence of antiphospholipid antibodies have been stressed. This is discussed in more detail later in the chapter.

Ocular lesions in lupus are well recognized. These include conjunctivitis, episcleritis, and cytoid bodies (white patches seen on retinal examination). In addition, retinal haemorrhage, and occasional papilloedema (usually found in association with malignant hypertension) and macular degeneration have all been described. The potential retinal toxicity of antimalarial drugs is discussed later in the chapter.

Peripheral neuropathy

Approximately 10 per cent of patients with lupus develop a peripheral neuropathy in the course of their disease. These are usually sensory, occasionally sensorimotor. Cranial nerve involvement is rather less common, usually associated with active systemic disease and manifested by visual defects, tinnitus, vertigo, nystagmus, ptosis, and facial palsies. Feinglass *et al*. (1976) reported that the most commonly affected cranial nerves in their study were VII, III, VI, V, and IX in order

of decreasing frequency. Optic neuritis was also uncommon, although it may, on rare occasions, be a presenting feature.

Psychological aspects

It has been claimed that up to 70 per cent of patients with lupus suffer a variety of psychiatric abnormalities. However, this label includes depression and anxiety, and most studies have failed to separate the non-specific psychological stresses associated with a debilitating and sometimes painful disease like lupus, from those specifically caused by the disease itself. Whatever the precise cause, a recent report of seven suicides in patients with lupus serves to emphasize that depression must be taken very seriously in systemic lupus (Matsukawa *et al*. 1994).

A lack of significant correlation between indices of general disease activity and psychiatric morbidity has been acknowledged by several authors. However, as with other aspects of lupus, more detailed testing, in this case using psychometric tests and nuclear magnetic resonance imaging, has been claimed to identify subtle degrees of impairment which may not be immediately evident clinically. Thus using a variety of standardized neuropsychological tests Hanley *et al*. (1993) identified cognitive impairment in 21 per cent of their patients with lupus compared with 4 per cent of their rheumatoid and healthy controls. Shortall *et al*. (1995) using a wide ranging set of neurophysiological tests showed that mood and mood disorders in patients with lupus were unrelated to measures of disease activity but were associated with psychological and social factors.

Emotional lability, personality change, impairment of judgement, and difficulty in performing simple tests of cognitive function, such as recall of serial numbers, all suggest organic involvement in lupus. The major psychoses, notably paranoia, schizophrenia, and hypomania, are also well documented. During the 1950s and 1960s, after the introduction of corticosteroids, concern was expressed that large doses of these drugs given for therapeutic purposes might actually be responsible for some of the psychiatric manifestations. Later studies have tended to discount this possibility. For example, Feinglass *et al*. (1976) considered that only 2 of 140 patients had a steroid-induced psychosis.

Investigations of neurological disease

It seems generally agreed that examination of the cerebrospinal fluid in neuropsychiatric disease is not very useful. Patients with lupus may show moderately raised cell counts, some increase in protein and IgG levels, and occasionally low glucose in their cerebrospinal fluid. It has been suggested that C4 levels in the cerebrospinal fluid are low during active disease and return to normal as the patient improves. Its potential use, however, is limited by the need for serial determinations. A range of autoantibodies including anti-Sm, antineuronal, antilymphocytotoxic and, most recently, antiribosomal P has been linked to nervous system involvement. Invariably hopes raised in the initial reports have been dashed by later studies (reviewed in Hay and Isenberg 1993). For example, in 1987 in a retrospective study, antiribosomal P antibodies were reported to be highly specific for lupus psychosis (Bonfa *et al*. 1987). Since then there have been at least five other studies (reviewed by Teh and Isenberg 1994) with conflicting findings, and on balance there seems little value in a single measurement of antiribosomal P antibodies to identify patients with lupus psychosis, although serial estimations may be of value in a few individuals.

However, when brain infarction is suspected as a cause for a sudden cerebral event, it is clearly worthwhile testing for antiphospholipid antibodies (see later). The greatest value of cerebrospinal fluid examination is in ruling out concomitant infection, especially as many patients with lupus are treated with major immunosuppressive drugs.

Electroencephalographic studies have been shown by some to be helpful during flares of cerebral disease. The most commonly observed abnormality was diffuse slow-wave activity but focal changes have been found in some 30 per cent of the patients studied. Electroencephalographic changes tend to be associated with seizure activity or focal neurological signs, although on occasion these findings have been reported in patients with purely psychiatric symptoms. Other, more recent, studies have looked at visual, auditory, and somatosensory-evoked potentials. These tests have still to acquire widespread acceptance.

Computed tomography (**CT**) has been used to analyse patients with lupus for approximately 10 years. Unfortunately the results have been conflicting. Thus diffuse cerebral abnormalities have been found in some patients with active disease, but not in others. CT is, however, very helpful in distinguishing between cerebral infarction and cerebral haemorrhage. It has also been claimed that many patients with neuropsychiatric manifestations of lupus have increased cerebral atrophy as evidenced by enlarged sulci, either with or without ventricular enlargement. In fact corticosteroids may promote this atrophy.

The more recent introduction of nuclear magnetic resonance imaging (**MRI**) now offers a further means of investigating cerebral lupus. Figure 6 shows a patient who presented with severe depression, yet who had multiple small infarcts visible on MRI despite normal electroencephalographic and CT scans. High intensity spots are the most common MRI brain abnormality report in systemic lupus, present in at least one-third of patients (Ishikawa *et al*. 1994). However, these spots are neither specific for neuropsychiatric lupus nor do they show good correlation with central nervous involvement.

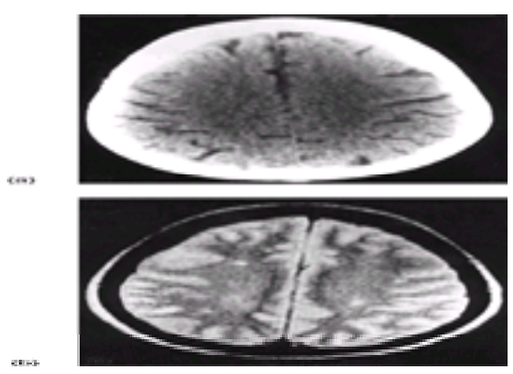

Fig. 6 Equivalent brain sections seen on CT scaning (a) and MRI scanning (b) in a patient with neuropsychiatric disease. Although some widening of the sulci is seen in (a), several discrete ischaemic areas are present in (b) which are not demonstrated on CT scanning.

Haemopoietic involvement

A normochromic, normocytic anaemia, the 'anaemia of chronic disease', is present in up to 70 per cent of patients with lupus. Levels of ferritin in these patients are usually normal. In some individuals other factors contribute to anaemia. Thus some patients have endstage renal disease and many patients are treated with non-steroidal anti-inflammatory drugs, which may cause gastric bleeding. Coombs' positive haemolytic anaemia occurs in approximately 10 per cent of all patients. Much less frequently, a microangiopathic haemolytic anaemia with disseminated intravascular coagulation has been described. It should be noted that a positive Coombs' test is not always associated with haemolysis. An association between pure red cell aplasia and systemic lupus has also now been established.

Leucopenia (< 4×10^9/l) and lymphopenia (< 1.5×10^9/l) are the most frequent abnormalities of the white blood-cell count in patients with lupus. Estimates for the former have ranged from approximately 45 to 65 per cent and for the latter up to 80 per cent. Both T and B lymphocytes are reduced while null cells are increased. Lymphocytotoxic antibodies have been found in over one-third of patients with lupus. In contrast, leucocytosis is rare in lupus in the absence of infection or major corticosteroid therapy.

There are at least three types of clinical presentation of thrombocytopenia associated with lupus. Of these, chronic thrombocytopenia (< 100×10^9/l) has been detected in approximately 20 per cent of most series. This is associated rarely with bleeding episodes in patients with lupus, unlike those unusual cases of acute thrombocytopenia where the fall in the platelet count may be both dramatic and life-threatening. Finally, some patients may present with what initially appears to be an idiopathic thrombocytopenia, usually treated successfully with corticosteroids, which only several years later is followed by other manifestations of the disease. A detailed overview of the haematological manifestations of lupus has been published recently (Keeling and Isenberg 1993).

Other clinical manifestations of lupus

Vascular lesions, notably Raynaud's phenomenon, cutaneous vasculitis, and ulcers and gangrene of the fingers and toes are all well recognized in lupus patients. Approximately one-third of patients have Raynaud's phenomenon, which may antedate the onset of the disease by several years. It is generally relatively easy to control with vasodilating drugs, but on rare occasions it may be associated with gangrene of the extremities (Fig. 7). Unlike the older population which suffers gangrene due to atherosclerosis, the potential for recovery in the patient with lupus is better as the patients are much younger. Active vasculitis in lupus may manifest as necrotic ulcers, small cutaneous infarction, or lupus profundus. Leg ulcers have been recorded in up to 5 per cent of patients with lupus, most commonly around or just above the malleoli.

Fig. 7 Gangrene affecting two terminal digits in a young female patient with lupus.

Although many patients with lupus develop some form of gastrointestinal complaint during the course of their disease, it is often difficult to be certain whether the lupus itself, the drugs used in its treatment, or other unrelated causes are responsible. Certainly anorexia, nausea, vomiting, or diarrhoea will occur at some point during the history of disease in over half of the patients, but frequently the cause will turn out to be iatrogenic. Abdominal pain is found in 10 to 20 per cent of the patients. The causes range from mild non-specific gastroenteritis to life-threatening mesenteric vasculitis. On occasions, an aseptic peritonitis may occur which often requires laparotomy to exclude a perforated ulcer or gangrenous piece of valve.

Pharyngitis and dysphagia are occasional features of lupus as is pancreatitis. A problem with treating pancreatitis is that several of the drugs used to manage lupus (corticosteroids, azathioprine, and vasodilators) can precipitate an attack. The subject has been fully reviewed elsewhere (Watts and Isenberg 1989).

Hepatomegaly, which can be detected in approximately a quarter of patients with lupus, is usually a minor enlargement and rarely accompanied by major abnormalities in liver function tests. It is generally agreed that jaundice occurs in less than 5 per cent of patients with lupus. Equally rare is hepatic vasculitis and the Budd–Chiari syndrome, although this latter feature has also been linked to the presence of antiphospholipid antibodies. Splenomegaly is present in approximately 10 per cent of the patients, although the spleen is rarely greatly enlarged.

Apart from the autoantibodies detected in lupus (described later in this chapter) a number of other common blood tests are frequently abnormal in the patients. For example, hypoalbuminaemia has been described in up to 50 per cent of patients, and hypergammaglobulinaemia in up to 60 per cent. IgG and IgM levels, in particular, have been reported to be elevated in patients with lupus; IgA and IgE levels much less frequently so.

The erythrocyte sedimentation rate is increased in the vast majority of these patients, over 90 per cent in some series. Occasionally, however, normal levels are found even in the presence of active disease. In contrast, levels of C-reactive protein are generally, although not always, normal in patients with lupus except for those with a concurrent infection, an erosive arthritis or possibly serotosis. A normal level is thus of some value in helping to rule out infection in these patients although, as levels of C-reactive protein may reflect disease activity in certain individuals, its value is far from absolute.

Lupus and the risk of infection

As indicated in the section on the relationship between lupus and malignancy, the combined effect of the disease itself and its treatment is to render the immune system more prone to infection. It is often impossible to apportion responsibility for such infections to one or the other, but there are major consequences for outcome, discussed later in this chapter. In addition a variety of (generally) non-fatal infectious diseases, such as herpes zoster (Kahl 1994), salmonella (Abramson *et al*. 1985), and candida (Sieving *et al*. 1975), are quite common.

Diseases complicating lupus

Sjögren's syndrome is present in approximately 20 per cent of patients. The dryness of the eyes and mouth differs little from those cases of primary disease, although antibodies to Ro and La are present less frequently. Sjögren's syndrome is reviewed fully in Chapter 5.10. Autoimmune thyroid disease (generally hypo-rather than hyperthyroid) has been identified in 5 to 10 per cent of patients with lupus. However, antibodies to thyroglobulin and thyroid microsomes have been found in up to one-third of the patients. The treatment of under- or over-active autoimmune thyroid disease in patients who also have lupus is similar to those without it. Likewise myositis, also detectable in up to 5 per cent of patients with lupus, is treated no differently from patients with the idiopathic disease. A smaller percentage of patients with lupus (perhaps no more than 1 per cent) has myasthenia gravis. This may antedate or postdate the onset of the lupus itself.

Much has been written as to whether systemic lupus and rheumatoid arthritis can coexist. It is certainly very rare to have lupus glomerulonephritis occurring in patients with seropositive erosive rheumatoid arthritis. However, it is generally accepted that up to 5 per cent of patients do have an erosive arthropathy, suggesting that an overlap between these two conditions may exist in some individuals.

Lupus in special situations

Pregnancy and lupus

Even in healthy individuals, pregnancy results in drastic immunological changes. These have been the subject of much interest in the past few years. Oestrogens, for example, are thought to decrease T-suppressor cell function, while androgens have the opposite effect. Oestrogens also tend to increase immune complex clearance thus decreasing their renal deposition. The CD5 + B lymphocytes are also thought to be under oestrogen control. Progesterone is thought to have immunosuppressive properties and its production increases throughout pregnancy. Prolactin, another hormone associated with pregnancy, is a known modulator of lymphocyte responses to antigen in rodents, and human B and T cells are known to have receptors for it. It is thus evident that the effects of pregnancy on the immune system in general are complex and therefore not surprising that patients with lupus with their significantly disordered immune system may suffer deleterious effects during pregnancy.

There are many conflicting data about the effect of pregnancy on the patient with lupus. Despite earlier reports suggesting that sterility might be common among patients, more recent studies have noted that sterility and fertility were little changed by lupus. An exception to this are those patients in renal failure who do have reduced fertility. Similarly, whereas some reports of an increase in maternal mortality in the patients during pregnancy were described in the 1950s and 1960s, the current view is that the majority of pregnancies do not adversely affect the mother with lupus. Thus in a case–control study of 46 patients with 79 pregnancies, lupus flares occurred no more frequently than in non-pregnant controls (Urowitz *et al*. 1993). The frequency of non-renal complications during pregnancy is relatively low but is a little higher in the period immediately after parturition. Flares of disease, especially renal involvement, may require the introduction of or increase in corticosteroids, and on occasion the baby may have to be induced as early as 30 weeks of gestation.

In contrast to the relatively encouraging outcome for the mother with lupus, fetal outcome is much less certain. A combination of spontaneous abortion and still birth causes a fetal mortality of around 20 per cent. Up to 25 per cent of babies born to mothers with lupus may have to be delivered prematurely, for a combination of

reasons relating to fetal distress as well as maternal ill health.

In the past decade the link between recurrent spontaneous abortion and the presence of antiphospholipid antibodies has been established. This is discussed in detail elsewhere in the chapter. The precise mechanism of these fetal deaths remains uncertain.

Mothers with lupus who have antibodies to Ro and/or La also appear to be prone to develop the so-called neonatal lupus syndrome. It appears that approximately 1 in 20 women who have either of these antibodies will have a child with this syndrome, which is notable for its congenital conduction defects or skin rashes. This subject is discussed in detail in the next chapter on lupus in children.

Lupus in males

Although lupus in males, especially Caucasian males, is uncommon, many different groups have attempted to identify characteristics of male patients with lupus that distinguish them from women with the disease. A comparison of several reported series (Table 7) shows, however, that no clearly defined criteria have been identified. As discussed by Isenberg and Malik (1994) virtually every claim of a distinctive feature in one series is rebutted in others. In the United States, however, it has been reported that the prognosis is worse for male patients with lupus. Among males with lupus there appears to be no evidence of androgen deficiency, although in one large series 50 per cent had elevated plasma oestrogen levels (Miller *et al*. 1983), but corticosteroid administration might have been expected to decrease these values.

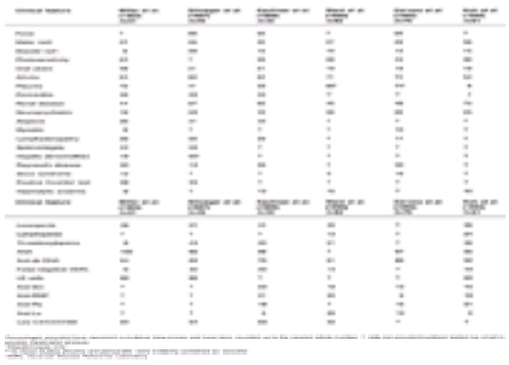

Table 7 Comparison of clinical features and serological abnormalities in six published series of male patients with systemic lupus (%)

Individuals with Klinefelter's syndrome, who have an unusual XXY karyotype, are more susceptible to systemic lupus. Abnormalities in oestradiol metabolism in these patients may be linked to the persistent oestrogenic stimulation, which might explain the predisposition.

Several families in which systemic lupus predominates in males have been described (Lahita *et al*. 1983) where sons may have inherited the disease from their fathers, analogous with disease in the BXSB mouse, an experimental model of lupus which is described later in this chapter.

Lupus in the elderly

It is clearly a matter of opinion at which point lupus in the young or middle aged becomes lupus in the elderly! Most reports have taken 50 or 55 years as a cut off, although there has been very little attempt to relate chronological age to the menopause, a fact which may well be important in the aetiology of the disease in these patients.

In most large series, lupus commencing in the sixth decade of life represents about 10 per cent of the study population. However, there are conflicting reports on the patterns of presentation, organ involvement, serological findings, and prognosis in this group. It appears that the clinical onset of lupus in the elderly is more insidious, milder, has a lower incidence of severe renal and neurological complications, a lower frequency of antibodies to double-stranded DNA, and hypocomplementaemia, but an increased frequency of serositis, interstitial lung disease, and antibodies to Ro and La. The last of these features suggests that the overlap between lupus and Sjögren's syndrome is frequent in an elderly population.

Among less frequent modes of presentation in the elderly, a polymyalgia rheumatica-like picture has been described, and neuropsychiatric manifestations which might easily be confused with other types of organic disease are important in this group. The time between onset of disease and presentation, and between presentation and diagnosis, are increased compared with younger patients, although this should change with increasing awareness that lupus can occur for the first time well into old age—the oldest case reported so far was diagnosed aged 87.

The antiphospholipid antibody syndrome and lupus

Associations between anticardiolipin antibodies and the lupus anticoagulant with systemic lupus erythematosus have attracted considerable interest in the past 15 years.

Anticardiolipin antibodies are part of an overlapping spectrum of antiphospholipid antibodies of which the lupus anticoagulant is part. Detailed analysis of anticardiolipin antibodies has distinguished two major varieties. In patients with infectious diseases the antibodies recognize epitopes on cardiolipin itself. However, in many patients with lupus, the antibodies are probably binding to a complex or neo-epitope formed by phospholipid and a plasma cofactor b $_2$-glycoprotein 1 (Galli *et al*. 1990). Thus b$_2$-glycoprotein 1 dependency was noted for anticardiolipin (40 per cent), antiphosphatidyl serine (20 per cent), and antiphosphatidylinositol (18 per cent) antibodies but not for syphilis or normal sera (Matsuda *et al*. 1994).

A list of the clinical features widely believed to be associated with patients with lupus who have these antiphospholipid antibodies is shown in Table 8. A metanalysis undertaken by Love and Santoro (1990) suggests caution in the interpretation of the published results. In their analysis of 29 published series, they estimated an average frequency of 34 per cent for the lupus anticoagulant and 44 per cent for anticardiolipin antibodies in studies representing over 1000 patients with lupus. However, anticardiolipin antibodies are also prevalent in patients with a wide variety of diseases other than idiopathic lupus, including drug-induced lupus, rheumatoid arthritis, and acute infection. In patients with lupus a statistically significant association has been shown between the presence of either antibody and a history of thrombosis, neurological disorders, and thrombocytopenia (see also Chapter 5.7.3). In a large prospective cohort study of 389 primiparous women assessed at study entry and delivery, 24 per cent were positive for antiphospholipid antibody, 15.8 per cent of whom had fetal loss compared with 6.5 per cent of antibody-negative patients (Lynch *et al*. 1994). Elevated IgG antiphospholipid antibody levels were statistically associated with recurrent fetal loss but not with low birth weight, neonatal distress, or maternal complications.

Venous and arterial thrombosis

Thrombocytopenia

Cerebral disease (including cerebrovascular accident, transient ischaemic attacks, chorea, amaurosis fugax)

Recurrent fetal loss

Pulmonary hypertension

Livedo reticularis

Table 8 Clinical features which have been linked to antiphospholipid antibodies in patients with lupus

A small cohort of patients with lupus with anticardiolipin antibodies has been shown to develop impaired renal function due to multiple small thrombi (Leaker *et al*. 1991). These patients have minimal proteinuria and only gradually increasing renal damage. This type of pathology may coincide with the more typical glomerulonephritis.

A number of contentious issues about antiphospholipid antibodies remain. For example, the precise links with other autoantibodies have been the subject of debate. It is widely accepted that anticardiolipin antibodies are associated with the biologically false-positive Venereal Disease Research Laboratory (VDRL) test. However, early studies undertaken with monoclonal antibodies which suggested significant overlap between those binding cardiolipin and DNA were not supported by studies in patients with lupus. Although low affinity (generally IgM) antibodies to DNA may bind cardiolipin, higher affinity (generally IgG) antibodies to DNA do not. This would imply separate subpopulations of anti-DNA and antiphospholipid antibodies. This is probably an oversimplification, as a single amino-acid substitution can convert an antiphospholipid antibody into an anti-DNA antibody, supporting the view that these antibodies are very closely related (Diamond and Scharff 1984).

Neither the lupus anticoagulant nor anticardiolipin antibodies appear to correlate with age, duration of disease, or a variety of well-known lupus clinical features, including polyarthritis, vasculitis, or serositis.

Lupus and malignancy

Given that the immune system is so disordered in patients with lupus and that many patients are treated with major immunosuppressive drugs, there has been much recent interest in whether there is an increased risk of malignancy in systemic lupus. Table 9 reviews several published series. A rather low frequency of malignancy change (with no obvious predilection for any particular site) is evident. However, in the most recent series quoted (Menon *et al*. 1993), 7 out of 150 patients developed a malignancy, 5 of whom have died (4 as a direct result of the tumour). An occasional association between systemic lupus and Hodgkin's lymphoma has been described (Bhalla *et al*. 1993).

Number of patients with lupus studied	Total number of deaths	Number of deaths from malignancy	Reference
365	68	0	Urman and Rothfield (1977)
428	94	0	Karsh *et al.* (1979)
609	128	4	Wallace *et al.* (1979)

150	16	4	Menon *et al.* (1993)

Table 9 Deaths from malignancy in patients with systemic lupus erythematosus

Assessing lupus disease activity

The assessment of disease activity in lupus is clearly central to patient management, but until recently there has been no consensus on measurement. Liang *et al*. (1988) reviewed, more than 60 different systems (attempting to establish a disease activity index) that have been described in the literature. This, in itself, is good evidence that no one system has won general acceptance. It also reflects the continuing difficulty in determining whether lupus should be thought of as an individual disease or a group of closely related conditions in the absence of a gold standard, by which to judge disease activity.

In the past 12 years more determined attempts to compare and contrast some of the different activity indices have been undertaken. Thus the **SLAM** (systemic lupus activity measures), **SLEDAI** (systemic lupus erythematosus disease activity index), and **ECLAM** (European Community lupus activity measure) are three global score systems which have been shown to correlate well with each other (Vitali *et al*. 1992). They also correlate well with the **BILAG** system (British Isles Lupus Assessment Group) which was established to provide more detailed information about disease activity in each of eight organs or systems (Hay *et al*. 1993). The BILAG index is based upon the principle of the 'physician's intention to treat.' There has been an encouraging international effort to compare the SLAM, SLEDAI, and BILAG systems in combined studies of both 'paper' and real patients. These systems have repeatedly been shown to correlate with one another and to be reliable in evaluating disease activity in systemic lupus. Most recently they have been shown to be sensitive to change in disease activity over time (Gladman *et al*. 1994). Information about these three indices and a comparison between them, based on an assessment of real, as opposed to 'paper' patients, by seven different physicians is shown in Table 10.

	VAS[a]	SLEDAI[a]	SLAM[a]
SLEDAI	0.261	0.732	
SLAM	0.209	0.732	
BILAG[b]	0.152	0.763	0.797

[a]VAS, visual analogue scale completed by the observer. Figures are based on real patient assessments by seven different physicians.
[b]BILAG, British Isles Lupus Assessment Group. This activity index is based on the physician's 'intention to treat' the patient. Lupus activity is divided into eight areas: general features, locomotor system, nervous system, renal involvement, dermatological involvement, pleuropericardial disease, vasculitis, and haematological involvement. Within each system the patients are designated A (active), implying that major immunosuppressive therapy needs to be initiated or increased; B (benefit), the patient is known to have active disease but the therapy does not require alteration; C (contentment), remission or symptoms in that organ/system; D (discount), there is no current involvement in this organ/system; or E, there is no (evidence) of activity in the organ/system now or previously (see Hay *et al*. (1993) for further details).
[c]SLAM (systemic lupus activity measures) devised by Dr Liang (Boston) and SLEDAI (systemic lupus erythematosus disease activity index) described by Drs Linnaeus, Gladman, and Bombardier are two good global score indices (see Liang *et al*. (1988) for further discussion).

Table 10 Correlations (*r* values) between three indices of activity for systemic lupus erythematosus

Equally constructive have been attempts by 'lupologists' to agree an index that distinguishes damage (due to lupus or its treatment) from disease activity. The distinction in not simply an academic one. For example, a patient with shortness of breath may have active but reversible vasculitis which could improve with major immunosuppressive therapy. Alternatively the symptom may be due to fibrosis causing irreversible damage for which there would be no requirement for such treatment. Thus a **SLICC** (systemic lupus international collaborating clinics) damage index has been developed (see Table 11) and is currently being assessed by many groups in North America and Europe.

Table 11 Systemic lupus international collaborating clinics (SLICC) damage index [a]

Immunopathology of lupus

In this section we review the immunopathology of the disease, both in strains of lupus-prone mice and in humans, by describing the specificity of autoantibodies, dysregulation, and abnormalities at the cellular level, and the genetic background that predisposes to the autoimmune response. Since the first edition of this textbook much interest has focused on apoptosis and the genes or 'autogenes' encoding the proteins important in regulation of apoptosis. Programmed cell death, or apoptosis, is quite distinct from the death of cells by necrosis and is a normal feature of cellular regulation. The current state of knowledge in this area will be addressed in both experimental models and human disease.

Experimental models of lupus

Several strains of mice spontaneously develop clinical and serological symptoms that resemble lupus. The most frequently studied strains are summarized in Table 12 and reviewed by Yoshida *et al*. (1990). Comparison of inbred mouse strains with outbred humans may not be relevant genetically but experimental manipulations in mice have made an important contribution to understanding the immunopathology of lupus.

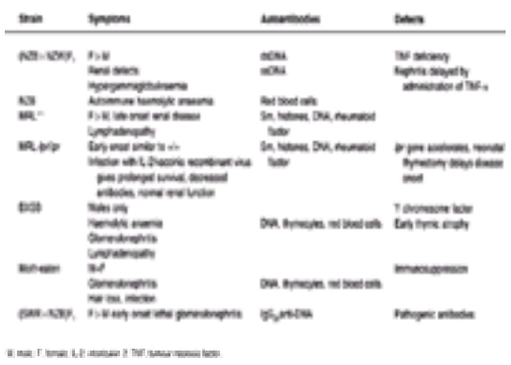

Table 12 Lupus-prone mouse strains

At the genetic level, three genes have been shown to influence the pattern of disease in susceptible strains. The MRL $^{+/+}$ mice spontaneously develop late-onset lupus with a 50 per cent survival time of 18 months. The MRL-*lpr/lpr* differs by only one gene (*lpr* gene) but this single gene accelerates the disease process to give a 50 per cent survival time of between 2 and 4 months. The introduction of the *gld* gene into non-autoimmune C3H/HeJ mice results in lymphoproliferation and autoimmune disease. In contrast the *xid* gene confers protection against autoimmunity in the NZB/W F_1 model by preventing terminal B-cell proliferation and the emergence of autoreactive B-cell clones.

F_1 hybrids between an autoimmune strain (NZB) and a non-autoimmune strain (SWR) have an accelerated autoimmune disease with a high incidence of nephritis. All females are dead by 1 year of age. These mice have IgG2b anti-dsDNA antibodies which are cationic and deposit in the glomerular basement membrane. The pathogenic antibodies are derived from the normal SWR parent and carry a nephritogenic idiotypic marker which is not found in the circulation of either parent. The normal parents have deleted 50 per cent of their T-cell receptor Vb chains and are I-E negative (equivalent to HLA DR in humans), thus they have peripheral T cells with I-E reactive T-cell receptors. The autoimmune parent and the F_1 offspring are I-E positive. Autoimmunity arises from the expression of 'forbidden' T-cell receptors by double-negative T-helper cells and suggests an abnormality in thymic selection/deletion.

Additional evidence from lupus mouse models shows that both cellular oncogenes (C-*myc*, N-*ras*, and C-*myb*) and retroviral genes may contribute towards the autoimmune process. Retroviruses have been implicated in murine lupus. A major envelope glycoprotein antigen, gp70, of type C murine retroviruses is present in the sera of all mice. This antigen can thus be regarded as autologous. The antigen may exist free in the circulation, similar to gp120 in HIV-positive patients, or it may exist as part of a xenotropic endogenous retrovirus. It can behave as an acute-phase reactant (stimulated by lipopolysaccharide, etc.). Circulating complexes of gp70 and anti-gp70 antibodies have been identified in the sera of lupus-prone mice, although free anti-gp70 antibodies cannot be detected (Izui *et al*. 1981). Levels of $gp70^{+}$ immune complexes correlated with nephritis, and gp70 was identified within immune deposits in the kidney (Maruyama *et al*. 1983). A recent report described the preliminary identification of the gp70 receptor as a 100 kDa glycosylated heterodimer on thymic leukaemia cells in mouse and humans.

The *Yaa* gene (Y-chromosome-linked autoimmune acceleration) accelerates disease in MRL $^{+/+}$ mice. These mice have increased levels of gp70–anti-gp70 immune complexes but no increase in the levels of circulating antibodies to DNA. Disease expression has been postulated to be controlled by at least four genes, three of which have been mapped to chromosomes 7 and 17.

Mutations in three autosomal recessive autoimmune genes have been identified in autoimmune strains of mice, reviewed by Mountz *et al*. (1994). All of these genes lead to defects in programmed cell death or apoptosis. The Fas protein has been intimately linked with apoptosis and is normally expressed on the cell surface (CD95). MRL-*lpr/lpr* mice have an endogenous retroviral DNA sequence integrated into the *Fas* gene which results in incorrect membrane expression of the Fas protein and loss of apoptosis. This abnormality would result in failure of self-reactive T cells to undergo apoptosis in the thymus and may account for the accumulation of double-negative T cells (CD4-CD8-) which infiltrate many tissues in these mice. The coining of the expression 'autogene' by Talal encompasses a group of non-MHC, non-immunoglobulin or T-cell receptor genes whose abnormal function contributes to the development of autoimmune disease (Talal 1994). *Fas* may be considered as the first identified autogene. *bcl-2* is an oncogene which inhibits apoptosis, particularly of T cells, and may therefore be considered as a second autogene. Transgenic mice expressing *bcl-2* within B cells show prolonged B-cell survival, production of autoantibodies, prolonged B-cell memory, and inhibition of clonal deletion of self-reactive B lymphocytes, while *bcl-2* transgenic thymocytes display enhanced survival rates in the absence of growth factors and in the presence of lymphotoxic factors (summarized in Aringer *et al*. 1994). The autoimmune consequence of the defect in the *Fas* molecule was highlighted by amelioration of disease in CD2-*Fas* transgenic MRL-*lpr/lpr* mice (Wu *et al*. 1994). The CD2 promoter and enhancer was used to restore *Fas* expression in these mice and resulted in greatly reduced features of autoimmune disease, autoantibody production, and the complete elimination of the development of lymphoproliferative disease. These findings force us to consider that the hyperproliferation and production of abnormal cells in autoimmune disease may be due to defects in the appropriate removal of cells rather than the traditional definition of defects of excessive proliferation and stimulation of certain cells.

Recently a non-autoimmune strain of mice has been used to study human systemic lupus. These mice carry the SCID gene (severe combined immunodeficiency disease) and consequently lack T and B lymphocytes. This deficiency allows human peripheral blood lymphocytes to be grafted into the peritoneum of the mice and survive for up to 7 months. When peripheral blood lymphocytes from patients with lupus were injected into SCID mice over 3 mg/ml of human IgG was found in the

circulation. Furthermore, deposits of mouse C3 were found in the renal glomeruli, indicating complement activation by immune complexes. However, no abnormal histology nor deterioration in renal function was associated with these deposits (Duchosal *et al*. 1990). Subsequently, lack of clinical or histological signs of vasculitis associated with lupus in either the skin or kidneys of SCID mice receiving xenografts of lymphocytes from patients with lupus was confirmed by another group (Ashany *et al*. 1992a). Production of autoantibodies by SCID–systemic lupus chimeras requires both T and B cells but is still insufficient to initiate pathological lesions (Geppert and Jasin 1990).

SCID mice have since been used to study aspects of murine lupus. SCID mice were reconstituted with spleen cells from young or old MRL- *lpr/lpr* mice or with *lpr* bone marrow. Seventy per cent of SCID mice receiving mature *lpr* splenocytes produced antibodies to Sm and dsDNA and one-third of these mice had extensive mononuclear and granulocytic infiltrates in lymphoid tissue, liver, and kidneys. However, histology revealed no glomerulonephritis, a marked reduction in the CD4-CD8- T-cells subset compared with the donor spleens, and the absence of massive lymphadenopathy which is associated with infiltration by double-negative T cells in the donor MRL-*lpr/lpr* mice. Nearly all recipients of young donor splenocytes developed acute graft-versus-host disease, dying within 4 weeks of cell transfer, while the majority of the recipients of bone marrow cells developed a wasting disease characterized by lymphoid atrophy and fibrosis in the absence of autoantibody production (Ashany *et al*. 1992b).

The role of self-reactive T cells in renal pathology has been demonstrated by cloning T cells from the interstitium of MRL- *lpr/lpr* mice with lupus nephritis. These T cells are unique and are regulated by the *lpr* gene. They have the phenotype CD4-CD8-abTCR +, proliferate in response to renal tubular cells, and secrete interferon-g which induces major histocompatibility (**MHC**) class II antigens and intercellular adhesion molecule 1 (**ICAM-1**) on renal tubular epithelial cells, making these cells capable of triggering T-cell hybridomas to proliferate and secrete interleukin 2 (**IL-2**) (Kelley *et al*. 1993). These double-negative T cells proliferate mostly in the liver and migrate to the periphery. Hepatic mononuclear cells vigorously secrete IL-6 which can be neutralized by antimouse IL-6 antibody and prevent the induction of ICAM-1 on hepatic sinusoidal endothelial cells seen in MRL- *lpr/lpr* mice (Ohteki *et al*. 1993). Upregulation of cell adhesion molecules (ICAM-1, VCAM-1) has also been demonstrated in kidneys of autoimmune mice and may mediate the adherence of pathogenic inflammatory cells in murine lupus nephritis (Wuthrich *et al*. 1990; Wuthrich 1992).

A form of 'experimental lupus' has been induced in normal strains of mice by two 1 µg injections of a human monoclonal anti-DNA antibody bearing the pathogenic 16/6 idiotype. Subsequently mouse IgG carrying the same idiotype was found in mesangial deposits in the kidneys. The mice developed proteinuria, an increased erythrocyte sedimentation rate, and leucopenia and had circulating autoantibodies reactive with a variety of autoantigens (Mendlovic *et al*. 1988). Independent confirmation of this data is awaited as it has not been confirmed by several other laboratories, implicating an environmental factor in the development of this lupus model (Williams and Isenberg 1994). However, transfer of splenocytes from Balb/c mice, in which systemic lupus had been induced by injection of 16/6Id, into SCID mice resulted in transfer of lupus disease, the characteristics of which were more severe if 16/6Id was given at the same time as cell transfer. The SCID recipients had high titres of autoantibodies, multiple immune complex deposits in the kidneys, and glomerular histological changes, including thickening of the glomerular basement membrane, mesangial proliferation, and some fibrotic changes (Segal *et al*. 1992).

Autoantibodies in systemic lupus

The serological hallmark of systemic lupus is the presence of circulating autoantibodies directed against a wide variety of nuclear, cytoplasmic, and plasma membrane antigens which are outlined in Table 13. In a recent study 98 per cent of patients had antinuclear antibodies and 56 per cent had elevated levels of antibodies to dsDNA (Worrall *et al*. 1990).

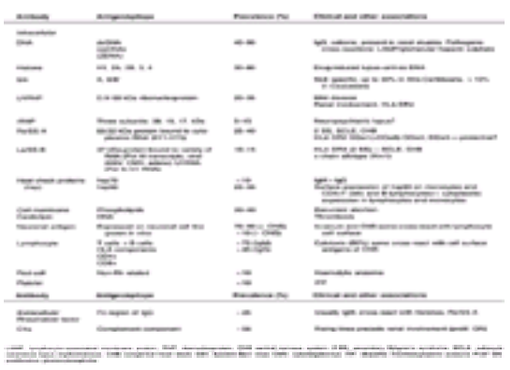

Table 13 Autoantibodies in systemic lupus

Antibodies to dsDNA are usually of the IgG isotype. Studies of kidney biopsies from patients with glomerulonephritis show deposition of IgG and complement components indicating a localized immune response and subsequent inflammation. Eluates from affected kidneys show that the IgG has specificity for dsDNA. In addition these antibodies are cationic in charge, clonally restricted, and high affinity (Kalunian *et al*. 1989). Not all circulating anti-DNA antibodies possess these characteristics, suggesting a subpopulation of 'pathogenic' antibodies preferentially localized in the kidney. Two mechanisms may account for this deposition. First, circulating immune complexes of DNA–anti-DNA antibodies may become trapped in the glomerulus, activate complement, and lead to local inflammation and tissue damage Second, non-complexed anti-DNA antibodies may cross-react with heparan sulphate, the glycosaminoglycan side-chain of heparan sulphate proteoglycan, which is a major constituent of glomerular basement membrane; this anionic side-chain is predominantly responsible for the negative charge of the membrane and may merely reflect antigen non-specific binding of cationic anti-DNA antibodies. Recently this binding was reported to be mediated via bound complexes containing both DNA and histones. Histones have very high affinity for heparan sulphate (Termaat *et al*. 1990) and antihistone antibodies are also a feature of systemic lupus. Evidence of direct pathological consequences of human anti-dsDNA antibodies has been described recently by Ehrenstein *et al*. (1995) using the SCID mouse model.

Heparin has been shown to inhibit the DNA binding of antibodies eluted from kidneys of humans and MRL- *lpr/lpr* mice but did not inhibit DNA binding of erum antibodies. Low, non-anticoagulant doses of heparin administered to MRL- *lpr/lpr* mice prevented the development of severe lupus nephritis and may be useful in treating humans with lupus (Naparstek *et al*. 1990).

Molecular biology techniques have revealed some interesting new data on the nature of the DNA antigen involved in lupus. DNA purified from immune complexes isolated from the sera of patients with lupus was found to be enriched in the deoxynucleotide bases guanosine and cytidine compared with normal genomic DNA. It was highly immunogenic in rabbits, unlike commercial DNA, and bound to anti-DNA antibodies with high avidity. Cloning and sequencing of this DNA revealed 82 per cent homology with the *gag*/*pol* fragment encoded by the ENV gene of the human immunodeficiency virus, HIV. This finding lends support to a viral aetiology of systemic lupus but a survey of sera from 100 patients with lupus revealed no antibodies to retroviral proteins (p24) (Krapf *et al*. 1989).

Recently a human monoclonal IgG antibody (B3) with specificity for dsDNA has been modelled on the computer, enabling a molecular map of the antigen–antibody interaction to be visualized (Fig. 8). This type of approach will facilitate site-directed mutagenesis experiments to determine the key amino acids for the recognition of DNA (Kalsi *et al*. 1996).

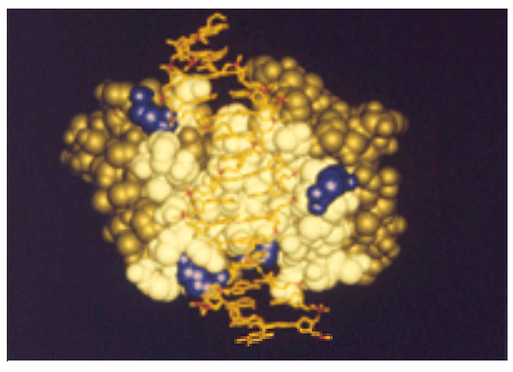

Fig. 8 Computer modelled possible docked complex between an IgG monoclonal anti-dsDNA antibody designated B3 and dsDNA. The light chain is shown on the left-hand side and the heavy chain on the right-hand side. Olive colour=framework residues; white=complementarity determining regions. The arginines (blue) at positions 227A, L54, and H53 all make interactions with the DNA phosphate backbone. (Reproduced from Kalsi *et al*. 1996, with permission from Pergamon Press.)

While antibodies to DNA occur in many patients, antibodies to some of the other nuclear antigens show an association with ethnic origin. Antibodies to Sm are more frequently associated with Afro-Caribbeans than Caucasians. This also relates to the HLA status of the individual (see later) in that many of the Afro-Caribbean patients carry the DR2 haplotype (Olsen *et al*. 1993). Antibodies to U1RNP are usually associated with mild disease, a lower incidence of renal involvement, and the MHC haplotype, DR4.

Antibodies to Ro and La are more frequently associated with Sjögren's syndrome secondary to a diagnosis of lupus. Occasionally these antibodies can be detected in saliva, but not in serum prior to the symptoms associated with salivary gland infiltration (Horsfall *et al*. 1989).

Claims have been made suggesting an association of autoantibodies to ribosomal P protein in patients with lupus with cerebral involvement and psychosis but these findings remain controversial.

Autoantibodies to C1q may be elevated in systemic lupus and are indicative of proliferative glomerulonephritis (Siegert *et al*. 1993).

Abnormalities and dysregulation at the cellular level

Systemic lupus is characterized by multiple functional defects among cells of the immune system—T and B lymphocytes, natural killer cells, and accessory cells (antigen presenting cells) (Table 14). Numbers of circulating lymphocytes may be altered profoundly. Hyperactive B cells may be increased in number with coexistent T lymphocytopenia. Numbers of both lymphocyte populations are extremely variable and fluctuate between normal and abnormal levels with respect to disease activity and duration.

Table 14 Cellular abnormalities and cytokine dysregulation

The increase in activated B cells contributes to the hypergammaglobulinaemia associated with reactivity to self antigens outlined in Table 13. On circulating B cells, receptors for the cytokine, IL-2, are increased while CR1 (the receptor for C3b) expression is decreased. There is increased cytoplasmic expression of the heat shock protein, **hsp**90, in B cells and CD4 + T cells (but not CD8 + T cells) compared with normal cells. Some of the excess hsp90 in patients with elevated levels is localized on the lymphocyte cell surface and therefore accessible to the immune system (Erkeller-Yuksel *et al*. 1992).

Among the two major T-cell populations, CD4 + (helper/inducer) and CD8 + (suppressor/cytotoxic), there is a marked reduction of a subset of T cells bearing the CD4 + and CD45R + phenotype. This population of cells helps to induce suppression by providing a signal to the CD8 + population. The reduction in this subset may explain the failure of T cells to suppress the hyperactive B cells. Anti-T-cell autoantibodies may be responsible for the depletion of this particular subset. A study has reported that the titre of anti-T-cell antibodies is directly proportional to the ratio of CD4/CD8 killing and that flares of disease are associated with an increase in CD4/CD8 killing and disease remission is accompanied by a corresponding decrease in the ratio. Parallel changes in anti-T-cell titres reflect the disease activity (Yamada *et al*. 1993). Many of the T cells with the classical ab T-cell receptor (**TCR**) chains lack the CD4 or CD8 phenotypes normally associated with these cells. As 'double negatives' they have probably escaped thymic deletion. A recent report described that of all activated T cells cloned *in vitro* from patients with lupus only 15 per cent actually provided 'help' for B cells to make pathogenic anti-DNA antibodies, i.e. antibodies of IgG isotype, cationic charge, specific for native DNA, and clonally restricted in spectrotype. The majority (83 per cent) of these T cells were CD4 + and expressed the classical ab TCR, responded to endogenous antigen presented by autologous B cells, and were class II restricted. The remaining 17 per cent were CD4-CD8- (double negative) and were not class II restricted. Of these, 70 per cent expressed the alternative g TCR and proliferated in response to endogenous heat shock or stress proteins of the hsp60 family expressed by lupus B cells (Rajagopalan *et al*. 1990). Sequencing of the T-cell receptors showed Vd and Vg gene usage not found in normal healthy adults and resembled that of fetal thymocytes early in ontogeny (Rajagopalan *et al*. 1992).

Increased DNA mutations have been observed in T cells in patients with lupus, which may result in T-cell death and increased release of non-degraded DNA by necrosis rather than apoptosis, in turn contributing to the production of anti-DNA antibodies (Gemelig-Meyling *et al*. 1992).

Several authors have suggested that a biochemical defect of T cells underlies the impairment of T-cell responses in systemic lupus. There are two possible defects in the T-cell cAMP pathway; one at the level of adenylate cyclase and another at the level of cAMP-dependent protein kinase. Cross-linking of cell surface receptors and lymphocyte movement to sites of inflammation (homing) have effects on the cAMP pathway. These events enhance the intracellular turnover of cAMP, promote occupancy of cAMP receptors, activate cAMP-dependent phosphorylation, and induce directed mobility of surface molecules to a pole of the cell (capping). The cAMP pathway thus mediates the mobility of certain transmembrane and glycolipid-anchored cell surface molecules resulting in ligands bound to T-cell membrane molecules to be selectively internalized or cleared from the cell surface by capping and endocytosis or by shedding.

In comparison with normal T cells, lupus T cells showed markedly abnormal capping of cell surface proteins (CD4 and 8) during active and inactive disease and showed decreased cAMP production in response to adenosine, associated with an inability to switch phenotype and express suppressor activity. Cell permeable cAMP did not bypass potential adenylate cyclase defects nor restore suppressor activity (reviewed by Kammer and Stein 1990).

The appearance of class II molecules, usually HLA DR, on T cells is taken as a marker of activation. Peripheral T cells with increased expression of HLA DP at the cell surface and as mRNA transcripts have been found in patients with lupus. The frequency of HLA DP expression exceeded that of HLA DR and correlated well with disease activity. The ratio of HLA DP + T cells is inversely proportional to the extent of IL-2 production during *in vitro* response to mitogen (Hishikawa *et al*. 1990; Kanai *et al*. 1993).

Some patients with lupus show decreased responses to immunization *in vivo* (primary immune response) and decreased responses to B-cell challenge *in vitro*. Other patients show normal or even increased responses to immunization. Disease activity and immunosuppressive therapy obviously influence the response in individual patients (reviewed by Turner-Stokes and Isenberg 1988).

Antigen-specific T cells have now been cloned from patients with lupus. Patients who have circulating antibodies to the ribosomal P2 protein have T cells which can proliferate *in vitro* to recombinant P2 and are inhibited in the presence of antibodies to MHC class II antigens. These T cells are CD4 + and thus may help B cells to produce antigen-specific antibodies (Crow *et al*. 1994). HLA DR restricted T cells have also been cloned from a patient with lupus and shown to induce IgG anti-DNA antibodies *in vitro* from high density (activated) B cells from DR-matched patients with lupus, and IgM anti-DNA antibodies from B cells from DR-matched normal

individuals (Murakami *et al*. 1992). An HLA DR4-restricted T-cell clone has been derived from a healthy individual and recognized the protein but not the RNA moiety of UsnRNP. The T-cell clone had a cytokine profile characteristic of Th1 cells (see the following section) and did not provide helper activity for autoantibody synthesis *in vitro* (Wolff-Vorbeck *et al*. 1994).

Cytokines

In the first edition of this textbook we wrote that 'the role of cytokines in the immunopathology of lupus is uncertain although likely to be of importance'. This prudent statement is underlined by the explosion of literature in this area and the demonstration of effective anticytokine antibody therapy of autoimmune disease. The characterization of different subsets of T-helper (**Th**) cells is directly related to their cytokine profiles and several autoimmune diseases may now be classified according to the predominance of a particular T-helper cell subset. We present a simplified summary of the major findings in this area and refer the reader to a recent excellent review by Horwitz and Jacob (1994).

Table 15 summarizes the major differences between Th1 and Th2 cells in terms of cytokine profiles and function, and outlines the cytokines found in serum or produced spontaneously after stimulation of peripheral blood mononuclear cells. Th1 cells support cell-mediated immunity while Th2 cells provide B-cell help and also suppress cell-mediated immunity. The balance between cytokines from Th1 and those from Th2 cells is thus critical in determining the outcome of the immune response and any imbalance could have profound pathological effects.

Subsets of CD4+T cells

	T-helper 1 cell	T-helper 2 cell
Function	Cell-mediated immunity	B-cell help
Cytokines:	IFN-γ IL-10 (some) IL-12 TNF-α	IL-4 IL-10

Cytokine profiles in patients with active systemic lupus

Cytokine	Serum level*	Spontaneous	Stimulation *in vitro*
IFN-γ	↑	low	↓
TNF-α	↑ (or normal)	↓ (DR2 DQw1; ↑ reports) ↑ (DR3,4 - negative)	↓
IL-1	n.d.	↑ PGM production	↓ monocyte production
IL-2	↑	low	↓
IL-4	n.d.	low	low
IL-6	↑	↑	↔
IL-10	↑ (or normal)	↑ (or normal)	normal

Table 15 T-cell subsets and cytokines

At the most simplistic level systemic lupus could be expected to be a disease where Th2 cells predominate resulting in too much help for B cells and overproduction of antibodies. In support of this concept, increased levels of IL-10 have been found in patients with lupus; this cytokine suppresses Th1 cells and thus impairs cell-mediated immunity, a characteristic feature of the disease. In mice continuous administration of anti-IL-10 delays the onset of disease.

Tumour necrosis factor (**TNF**-a) is produced by T (Th1) and B lymphocytes, natural killer cells, and mononuclear phagocytic cells. Another cytokine (TNF-b), originally called lymphotoxin, is produced by activated lymphocytes. The genes for both TNF-a and -b are closely linked and located within the major histocompatibility complex (MHC). *In vitro* TNF-a production by mitogen-activated peripheral blood lymphocytes varies according to the HLA class II haplotype of the donor. Elevated production is found in DR3 and DR4 subjects, whereas low production is found in DR2 and DQw1 positive donors. The DR2, DQw1 genotype in patients with lupus is associated with lupus nephritis. DR3 + patients with lupus are not predisposed to lupus nephritis and have elevated levels of TNF-a production. The DR4 haplotype is associated with high TNF-a inducibility and negatively correlated with lupus nephritis (Jacob *et al*. 1990a).

Paradoxically high levels of TNF-a are more frequently associated with rheumatoid arthitis and, as such, therapeutic benefit has been reported using monoclonal antibodies to TNF-a. Two of 20 patients treated with anti-TNF-a antibody developed anti-dsDNA antibodies and other serological abnormalities characteristic of lupus, although neither developed clinical symptoms of the disease. All antibodies disappeared when therapy was stopped (Maini *et al*. 1994).

Both macrophage and natural killer cell-mediated cytotoxicity are frequently impaired in patients with lupus. g-Interferon-induced enhancement of both types of cytotoxicity is also impaired despite normal levels of g-interferon production by lupus Th1 cells. Lupus natural killer cells fail to release soluble factors necessary for killing. Recombinant g-interferon has been used to induce remission in patients with rheumatoid arthitis, but it exacerbated disease in both patients with lupus (Machold and Smolen 1990) and lupus-prone strains of mice (Jacob *et al*. 1990b).

Accessory cells in lupus seem to produce insufficient amounts of IL-1 to provide the necessary activation signal for T cells. This effect cannot be overcome *in vitro* by the addition of exogenous IL-1, suggesting that a defect may exist at the level of the IL-1 receptor on T cells. Alternatively the defect could exist at a distal point in some biochemical pathway.

Both CD4 + and CD8 + T cells have been described to produce either normal or decreased amounts of IL-2 in response to exogenous antigens, mitogens, allo- and autoantigens. Reduced IL-2 generation would have a profound effect on T-cell responses. This impairment is not reversed by the addition of exogenous IL-2. However, *in vitro* treatment of lupus accessory cells with g-interferon plus the addition of IL-2 has been shown to restore T-cell proliferation and the expression of T-suppressor activity. The variability of experimental data in this context raises the question of whether IL-2 functional activity varies between patients rather than merely reflecting levels of IL-2.

Studies *in vitro* on the response to IL-2 of the CD4 + T-cell subset (helper/inducer) indicate that there is altered expression of IL-2 receptors. The CD8 + T-cell subset (suppressor/cytotoxic) has IL-2 receptors but fails to respond as there is no IL-2 signal from CD4 + T cells. This is a secondary defect. The primary disorder relates to the CD4 + subset which expresses IL-2 receptors of low affinity. Functional IL-2 receptors are of high affinity. Variable synthesis of both types of receptors may be governed by altered intracellular synthesis and/or transport.

Apoptosis

The study of programmed cell death in human lupus is now an active area of research. As with experimental models of lupus, an underlying defect of apoptosis prevails in human disease. Decreased apoptosis in systemic lupus has been described in association with an increased production of the soluble form of the *Fas* molecule, which is capable of inhibiting apoptosis after a stimulus to proliferate (Cheng *et al*. 1994).

bcl-2 is a proto-oncogene located at the inner membrane of mitochondria, the endoplasmic reticulum, and the nuclear membrane and exerts a regulatory function during development and maintenance of adult tissue by preventing apoptosis in specific cell types. It is involved in T-cell development and thymic selection and is found in long-lived B lymphocytes within the follicular mantle zone. Over-expression of *bcl-2* in circulating lymphocytes from patients with lupus has been described in both CD4 + and CD8 + T cells but not B cells, and levels of *bcl-2* expression have been shown to correlate with disease activity (Aringer *et al*. 1994). A more recent study of a larger group of patients with lupus has described enhanced *bcl-2* expression in a subpopulation of CD3 + T cells lacking CD4 and CD8 (double-negative T cells). The percentage of these cells expressing *bcl-2* correlated strongly with disease activity (Rose *et al*., unpublished observations). Defects in apoptosis in systemic lupus may therefore involve two genes—either abnormal transcription of the *Fas* gene resulting in a soluble rather than cell membrane-associated product, or increased transcription and expression of the *bcl-2* gene product, both of which are capable of inhibiting apoptosis.

Cell adhesion molecules

Interest in the adhesive mechanisms which facilitate cell–cell and cell–matrix interactions has expanded considerably over the past few years. Adhesion is mediated by several molecules which vary in affinity and structure on the surface of the cells which express them. Adhesion molecules belong to one of three main families: selectins, integrins, or the immunoglobulin superfamily; the important members and their cell distribution, function, and ligands are summarized in Table 16. The mechanism of leucocyte emigration through the vascular endothelium into tissue is simplistically summarized in Fig. 9. As leucocytes roll in the direction of blood flow, random contact is made with the endothelium. Transient adhesion of leucocytes to the endothelium occurs through low affinity binding to E-selectins. The cells

become activated and then bind with higher affinity to vascular integrins. Once cells are firmly attached transendothelial migration occurs and, under the influence of extravascular chemoattractants, subendothelial migration into the extracellular matrix occurs.

Family	Member	Cell	Ligand	Function
Selectins	ELAM-1	Endothelial	Leucocyte Sulfated Carbohydrate	Inflammation, leucocyte extravasation
	CD62	Platelets	?	T-cell recruitment to inflammatory sites
	LECAM-1	T and B cells	?	PMN, lymphocyte binding to endothelium
Integrins	LFA-1 (CD11a/CD18)	Lymphocytes, PMN, monocytes, Macrophages	ICAM-1,2,3	Tc/target cells, MLR, antigen-specific T-cell proliferation, leucocyte adhesion to endothelium
Immunoglobulin supergene	ICAM-1 (CD54)	Monocytes Endothelial cells CD40	LFA-1 (CD11a/18) MAC-1 (CD11b/18)	T-T, T-B, T-APC interactions. Induced by IFN-γ, IL1β, TNF-α
	VCAM-1	Endothelial cells (act), tissue Mo	VLA-4	Leucocyte recruitment

ELAM, endothelial leucocyte adhesion molecule; CD, cluster differentiation; LECAM, leucocyte adhesion molecule; LFA, leucocyte function associated molecule; ICAM, intercellular adhesion molecule; PMN, Lymphocytes, monocytes; Tc, T-cytotoxic cells; MLR, mixed lymphocyte reaction; APC, antigen-presenting cell; VCAM-1, vascular cell adhesion molecule; Mo, macrophages; VLA-4, very late antigen

Table 16 Adhesion molecules

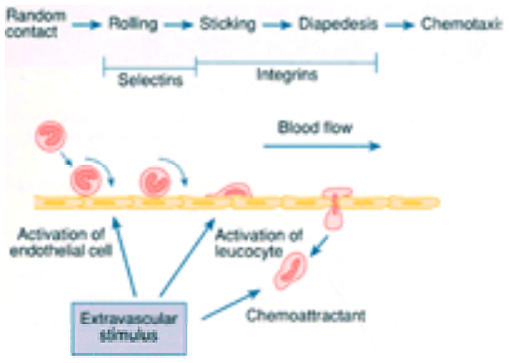

Fig. 9 Adhesive interactions during leucocyte emigration

Up-regulation of the surface expression of three distinct adhesion molecules, E-selectin, VCAM-1, and ICAM-1, has been shown in biopsies of skin, which is non-lesional and has not been exposed to the sun, from 16 patients with lupus. Levels of adhesion molecules were directly correlated with disease activity and in serial biopsy specimens they decreased with clinical improvement (Belmont *et al*. 1994). These findings suggest that excessive complement activation in association with primed endothelial cells induces leucocyte–endothelial cell adhesion and leuco-occlusive vasculopathy. Furthermore, UV irradiation of keratinocytes *in vitro* induces release of epidermal and dermal cytokines and increases ICAM-1 expression, which *in vivo* may lead to vascular activation culminating in the photosensitive lupus syndromes (Norris 1993).

Soluble forms of adhesion molecules are elevated in the circulation of patients with lupus compared with healthy controls. Elevated levels of soluble ICAM-1 (sICAM-1) have been reported to show significant association with skin involvement and disease activity (Sfikakis *et al*. 1994). Lupus patients also have elevated levels of a soluble form of VCAM-1 (Wellicome *et al*. 1993). The importance of these observations may become apparent from studies in murine lupus which have demonstrated up-regulation of ICAM-1 in nephritic MRL-*lpr/lpr* and NZB/W kidneys, particularly in the brush borders of proximal tubules, glomerular mesangium, and endothelium of larger vessels (Wuthrich *et al*. 1990). Similarly VCAM-1 is also up-regulated in MRL-*lpr/lpr* kidneys, not only in the endothelium but also in cortical tubules and glomeruli. Kidney tissue sections from nephritic MRL-*lpr/lpr* mice also display increased adhesiveness for T-cell and macrophage cell lines which can be blocked by monoclonal antibodies to ICAM-1 and VCAM-1 (Wuthrich 1992).

Genetic components

The idea that genetic factors may play a role in susceptibility to lupus stems from the high rate of concordance for disease in monozygotic twins, increased frequency of lupus and immunological abnormalities in relatives of patients with lupus, and the prevalence of lupus among certain ethnic groups. The genes which may influence or predispose to lupus include those which determine sex, colour, complement haplotype, tissue type (HLA), antibody variable regions, and T-cell receptors (Table 17).

Genetic factors	
Complement	C1, C4 deficiencies (~ 75% prevalence, severe disease) C2 deficiency (~ 20% prevalence, severity similar to non-C deficient lupus patients) C4 null-ness, or extreme partially deficient C3(B) deficiencies (acquired rather than genetic)
MHC associations	HLA A1, B8, DR3 – strongest positive DR2 and DR4/5 – some definite contributions DQw1 – most DR contributors Altered C4 – more anti-nuclear DR2 – often Caucasian patients with anti-Sm DR3, DR4/5 (DR4/8, B18) – susceptibility to nephritis DR2, DR3/5 – protective? DR4/8 – early onset, SLE (~ 60 years) Decreased expression of class II on APC Homozygosity may depend upon a single amino acid substitution (tyrosine at position 57 in sequence of DRbeta 1 MHC gene from single SLE patient compared with healthy control)
T-cell receptor	
Human	Little data on human TCR family usage Germline sequence related to TCR-V gene product in SLE Restriction DNA restriction fragment length polymorphism in humans no deletions, insertions in TCRb-J-C chain genes
Mouse	Cry deletions in TCR-alpha/delta and beta-delta-V, assay can reveal TCR (deletion) (in light TCR-Cb-Bb allele) some increases as animals age and as disease and lymphadenopathy develop
Antibody V genes	
Germline encoded	Human monoclonal anti-DNA/Sm germline encoded but use some V gene families as do in non-self. But they can result somatic mutation (germline predisposition to develop anti-Sm etc in SLE patients and not degree mutation measured)
Somatic mutation	V somatic mutation (e.g. like autoantibodies between homologous family) Autoantibody response generally light somatic mutation (increases with immunoglobulin class switch
Idiotype analysis	Preferential use of V gene family with or without autoantibody activity (produced by family members). Specific deposition of anti-DNA pathogenic/nephritogenic idiotypes in kidney
	12/13 14/20 20/21
Percentage SLE	20 75 27
Percentage disease controls	4 4 4
Genetic factors	
Ethnic origin	Blacks, whites, most probably linked to MHC
Sex and hormonal factors	Females > whites, androgens enhances the immune response, testosterone is immunosuppressive

MHC, major histocompatibility complex; APC, antigen-presenting cell; TCR, T-cell receptor

Table 17 Genetic components associated with systemic lupus erythematosus (SLE)

Sex and ethnic background

At the most basic genetic level systemic lupus affects females more than males and shows an ethnic bias in that Afro-Caribbeans are more affected than Orientals, in turn more affected than Caucasians. These basic differences are reflected in other ways. Sex hormones are known to influence disease in both mice and humans with autoimmune disease. Androgens are immunosuppressive and oestrogens are immunoenhancing. This explains the susceptibility of women to autoimmune diseases compared with men (Ansar Ahmed *et al*. 1985).

For example, androgens reduce while oestrogens enhance the spontaneous antibody production in mixed strains of mice (NZB × CBA and NZB × C3H). In MRL-*lpr/lpr* mice, testosterone treatment reduces lupus-like symptoms without affecting lymphoproliferation. In humans where pregnancy occurs during active disease, exacerbations often occur as oestrogen levels rise.

Complement

Lupus is associated with deficiencies of the early classical pathway of complement components C1, C4, and C2. Two alleles are inherited for each complement component thus deficiencies may be partial or complete (homozygous). Congenital deficiencies of C2 and C4 are frequently in linkage disequilibrium with HLA DR3 and DR2, HLA haplotypes associated with lupus. C4 is composed of two distinct but homologous proteins, C4A and C4B. These bind to immune complexes and

prevent precipitation. C4A deficiency is rare in the general population but complete (homozygous) deficiency has been found in 10 to 15 per cent of white patients with lupus. Partial C4A deficiency occurs in 10 to 20 per cent of controls but in 50 to 80 per cent of patients with lupus (Kemp *et al*. 1987). A single null C4A allele increases the relative risk for lupus by 3 and two null alleles by 17. Deficiencies of C4A can arise by two mechanisms; one is a 30 kilobase deletion of the DNA encoding all C4A along with a small portion of C4B and occurs in DR3 + patients (Kemp *et al*. 1987), and the other does not involve a deletion but may be the result of a regulatory gene linked to the MHC causing reduced synthesis of C4A (Fronek *et al*. 1988). The consequence of C4A deficiency in lupus is that immune complex clearance and solubilization is seriously impaired, leading to deposition in lungs and kidneys and subsequent inflammation. C4 is important in drug-induced lupus as the drugs bind to the active site of C4 and prevent covalent binding to immune complexes. C4A is inhibited more than C4B, resulting in a relative deficiency of C4A with consequent defective clearance of immune complexes (Gatenby 1991).

Complement receptors, CR1 and CR2, have been studied in lupus. The CR1 ligands are C3b and C4b bound to immune complexes. The receptor is present on peripheral B lymphocytes, erythrocytes, monocytes, and tissue macrophages and binds, internalizes, processes, and transports immune complexes which have activated complement. Low expression of CR1 on erythrocytes and peripheral blood leucocytes was described in patients with lupus and their healthy family members (Walport and Lachmann 1988). This was originally interpreted as an inherited defect which could predispose to the disease. More recently this defect is thought to be acquired, as normal erythrocytes infused into patients with lupus also showed a decrease in CR1 receptors. Levels of CR1 deficiency in patients with lupus correlate with disease activity. Controversy still abounds in this area as to the precise nature of this defect and is confounded further by the possibility of a functional defect of CR1 receptors on polymorphonuclear neutrophils.

Complement receptor 2, **CR2** (CD21), has recently been described on peripheral T cells in healthy individuals. The ligands for CR2 are C3d, C3g, and Epstein–Barr virus (EBV). The receptor is present on mature, circulating, and lymph node cells, follicular dendritic cells and on 10 to 40 per cent of peripheral blood CD4 + or CD8 + T cells. In patients with active or inactive lupus, B-cell CR2 expression is significantly diminished. This may be a consequence of the activated state of lupus B cells reflecting the loss of CR2 as cells differentiate into immunoglobulin-secreting cells and then plasma cells, or the levels may be modulated by high levels of circulating immune complexes or cytokines. Expression of CR2 on T cells from patients with inactive lupus is similar to that found in healthy individuals, but is increased in some patients with active lupus (90 per cent of CD4 + and CD8 + peripheral T cells expressing increased levels of CR2). In this context CR2 is important in signalling and its increased expression on T cells may play a role in cell adhesion or cytotoxicity (Levy *et al*. 1992).

Major histocompatibility complex

The associations between the MHC and systemic lupus must take into account the ethnic origin of the patient. A recent report highlights this aspect by demonstrating that only in Caucasian patients of English/Irish descent is lupus associated with an MHC extended haplotype (HLA B8, SCO1, DR3) (Schur *et al*. 1990). In black American people DRw52b is positively associated with renal disease and negatively associated with antinuclear RNP antibodies. DR3 (DRw17) and DQw2 are highly associated with the ability to produce anti-Ro/anti-La antibodies. These antibodies are associated with subacute cutaneous lupus, lymphopenia, neonatal lupus and complete congenital heart block. DR4 is associated with the ability to make anti-RNP and with a reduced risk for lupus nephritis. In contrast to the protection conferred by DR4, DR2 confers susceptibility to nephritis. Associations with DQw1 and with DQb1.AZH and DQb2 are more recent findings. Early-onset systemic lupus (before 20 years of age) is associated with DRw8 and the frequency of neuropsychiatric involvement correlates negatively with a DQa fragment (Reveille *et al*. 1989). Compared with the normal ethnic population, Afro-Caribbean patients with antibodies to Sm have an increased frequency of DR2 and a reduced frequency of DR3, regardless of anti-DNA antibody status (Olsen *et al*. 1993).

DQw7 correlates significantly with lupus anticoagulant, although there are patients who have lupus anticoagulant but lack the DQw7 haplotype. However, these patients all have DQw8. Amino acids in position 71 to 77 of the third hypervariable region of DQB1 chains were identical in DQw7, DQw6, and DQw8 individuals, leading to the proposal that this region might constitute the 'epitope' for mediation of this autoimmune response (Arnett *et al*. 1991). For a more complete description of the known associations between MHC class II genes and autoantibody subsets the reader is referred to an excellent review by Arnett and Reveille (1992) .

T-cell receptors (TCR)

Patients with anti-Ro antibodies show association with TCR-b gene products compared with patients with lupus lacking this antibody specificity (Frank *et al*. 1990). The association with this particular gene segment is with the specificity of the autoantibody produced rather than risk factors for the disease. The anti-Ro antibody response is also associated with HLA-DQw1 (Harley *et al*. 1986) which may be important for recognition by the Ro-specific TCR (Scofield *et al*. 1994). In the lupus-prone mouse strains no evidence of unusual or abnormal TCR gene usage has been demonstrated compared with non-autoimmune mice of the same genetic background (Theofilopoulos *et al*. 1989).

The p70 (Ku) autoantigen has been described as a non-histone nuclear protein recognized by antibodies from patients with lupus. It has been shown that the p70 antigen is a DNA-binding protein and specifically binds to the TCR-b-chain gene enhancer thus playing a role in regulation of TCR-b gene expression (Messier *et al*. 1993).

A human non-specific suppressor factor has been isolated and characterized from lupus ascitic fluid and can inhibit proliferation of T and B cells and suppress IgG production *in vitro*. Suppression was inhibited by anti-TCR-a antibodies but not by those directed against the b chain (Xavier *et al*. 1994).

B-cell immunoglobulin receptors and antibody V genes

The most frequently studied antibodies are those directed against DNA, particularly since anti-idiotypic antibodies raised against the variable regions of murine anti-DNA antibodies have been shown to cross-react with V regions on human anti-DNA antibodies. Many idiotypic markers have been defined on antibodies to DNA and the interpretation of the data has led to much confusion. Only the major findings and their significance with respect to lupus will be discussed.

Several groups have described anti-DNA associated idiotypes defined by anti-idiotype antibodies raised either as monoclonal antibodies in mice or as polyclonal antibodies by immunization of rabbits. In most cases, the immunogen, or anti-DNA antibody-bearing idiotypes, is a human monoclonal antibody made by fusing human B lymphocytes with an immortalized human myeloma/lymphoblastoid cell line to form stable hybridomas which secrete the human antibody of interest. The 16/6 idiotype is located on the heavy chain of a human IgM_ monoclonal anti-DNA antibody derived from a human lupus spleen hybridoma. The anti-idiotype to the monoclonal antibody bound not only to the parent molecule but to anti-DNA antibodies from different patients with lupus and to IgG lacking anti-DNA activity from healthy relatives, spouses, and family members of patients. Serum levels of the 16/6 idiotype correlated with disease activity and deposits of 16/6 positive immunoglobulin were found in skin and kidney biopsies from patients with lupus (reviewed by Watts and Isenberg 1990).

Among the other DNA antibody idiotypes which have been described are two idiotypic markers which distinguish between nephritogenic antibodies and non-nephritogenic antibodies (Hahn *et al*. 1990). Neither of these idiotypes correlated with HLA class II haplotypes known to be associated with lupus nephritis. High serum levels of idiotypes associated with lupus nephritis are thought to arise from polyclonal B cell activation rather than from idiotype-specific up-regulation associated with one or more of the class II genes that predispose to nephritis. On the contrary, two lupus-associated idiotypes on a somatically mutated anti-DNA antibody have been described, providing evidence that such an antibody reflects the selection pressure of antigen (Davidson *et al*. 1990). However, new data on hybridomas from non-autoimmune strains of mice (Balb/c) shows that pathogenic IgG antibodies with specificity for DNA can be produced by these mice. These antibodies were derived from germ-line genes and were not the products of somatic mutation normally found on antibodies of the same specificity from autoimmune strains of mice. This suggests that such germ-line encoded antibodies are under extremely strict regulation in normal animals. The defect in autoimmunity appears to lie in the products of somatic mutation, possibly at the level of anti-idiotypic regulation (Shefner and Diamond 1990).

The immunoglobulin receptors on B cells are also able to 'present' antigen to T cells. This occurs by binding to antigen-specific immunoglobulin receptors which are then able to internalize antigen and express processed antigen on the cell surface in the context of MHC class II. This process has been demonstrated in mice using snRNP autoantigens which are presented to autoreactive T cells (Mamula *et al*. 1994).

Summary of immunopathological events in systemic lupus

Systemic lupus erythematosus is a multifactorial disease in which the relative contribution of each factor increases the relative risk of disease susceptibility. A significant contribution arises from genetic components, such as those encoding tissue type (MHC), complement components, cell receptors, cytokines, and their respective receptors, together with environmental elements, such as drugs, toxins, diet, and infectious agents. The acquisition of each gene will increase the relative risk of disease development. Genetic predisposition may be so strong that a relatively minor environmental insult may be sufficient to trigger disease, whereas a

modest genetic predisposition together with a strong environmental stimulus would be sufficient to lead to manifestations of disease. The latter would encompass idiopathic lupus and drug-induced lupus.

Systemic lupus is characterized by abnormal immune function. Increased numbers of hyperactive B cells, together with impaired cell-mediated immunity, suggest the dominance of Th2 cells and their cytokines in mediating hypergammaglobulinaemia and the appearance of IgG antibodies with specificity for both self and non-self antigens. There is evidence that B cells expand both in response to specific antigen and in a polyclonal fashion.

Molecular mimicry may also contribute to the autoantibody response seen in lupus. Do autoantibodies arise by molecular mimicry (e.g. with viral or bacterial proteins such as anti-U1RNP antibodies and influenza B virus (Guldner *et al*. 1990)) or do they become anti-self and/or pathogenic through somatic mutation of evolutionary 'useful' antibodies and thus bind to host structures/determinants (Diamond and Scharff 1984)?

The transfer of peripheral blood lymphocytes from patients with lupus into SCID mice, described above, which showed deposition of mouse complement and human IgG in the kidneys, suggests that all the information required to cause the histological change associated with lupus resides in the peripheral blood lymphocytes (Duchosal *et al*. 1990). The exact nature of this information remains to be elucidated.

The treatment of lupus

It is evident that the diverse effects of lupus require a variety of treatments. These will be divided into pharmacological and other approaches. However, it must be stressed that a number of general measures may be most useful (see Table 18).

1. Rest as appropriate; try to avoid stress.
2. Avoid over-exposure to heat and sunlight. Use sun protection factor 15+ (30+ in USA) if in a sunny country; avoid exposing an arm on an open car window.
3. Try to adhere to a low fat diet and consider adding fish oil derivatives.
4. Vaccination, for foreign travel etc., apart from 'live' vaccines in patients on immunosuppressives, is not contraindicated though the precise nature of the immune response differs from that in healthy individuals.
5. Medium or high oestrogen contraceptive pills should be avoided—progesterone only or the lowest possible oestrogen pill (or other methods of contraception) are advised.
6. The use of hormone replacement in the menopause remains controversial. Many patients do tolerate it without flaring, but not all.

Table 18 Treatment of lupus—general measures

Pharmacological

Patients with lupus are treated with four main groups of drugs, often in combination. Recommendations about precisely when to commence therapy, the initial dose of a given drug, the likely response of a given symptom, and the duration of treatment vary widely. In Table 19 the broad indications for use of these four types of drugs are shown. In Table 20 suggestions are provided as to the initial doses and duration of treatment with the antimalarials, corticosteroids, and cytotoxic drugs. These are intended purely as guidelines and there will undoubtedly be patients who require larger doses for longer periods of time.

	NSAID	Antimalarial	Corticosteroids	Cytoxic agents
Malaise	–	+	+	–
Fever	+	–	+	–
Serositis	+	–	+	+
Arthralgia	+	+	+	+
Arthritis	+	+	+	+

+ = usually beneficial; – = not beneficial; †=effective/indicated in
*=safety precautions must always be taken when steroids are prescribed in early pregnancy

Table 19 Drug therapy in systemic lupus

Symptom	Drugs to try	Dose and duration
Arthralgia	Non-steroidal anti-inflammatory drugs	No special recommendations
Myalgia Lethargy Arthralgia	Hydroxychloroquine	Start 400 mg/day for 3–4 months then reduce to 200 mg/day for 3–4 months, then to 200 mg five times week for 3 to 4 months; repeat courses may be necessary and retinal checks every 6–9 months are generally recommended
Arthritis Pleuritis Pericarditis	Prednisolone	20–40 mg per day initially for 3–4 weeks, reducing in 5–10 mg decrements per week. If patient is responding, treatment is likely to be required for several months
Autoimmune haemolytic anaemia/thrombocytopenia	Prednisolone often accompanied by azathioprine	60–80 mg prednisolone for 1–2 weeks reducing in 10 mg increments in response to the blood test results; aim for 2.5–5 mg/kg azathioprine. Treatment will last for several months
Renal	Prednisolone plus azathioprine or cyclophosphamide	Depending upon the severity of the renal lesion, anything from 30–60 mg/day is required; cyclophosphamide can be given by intravenous boluses (750 mg–1 g) monthly for 6 months, then every 3 months for 2 years, some groups prefer prednisolone and azathioprine at 2–3 mg/kg in the first instance. Treatment is likely to be required for several years
Central nervous system	Prednisolone plus an appropriate drug, e.g. an anticonvulsant, antidepressant, etc.	Controversial — but 20–100 mg prednisolone have been prescribed sometimes accompanied by azathioprine or intravenous cyclophosphamide (rubenic). Treatment is likely to be required for months

Table 20 Recommendations for drug usage in lupus

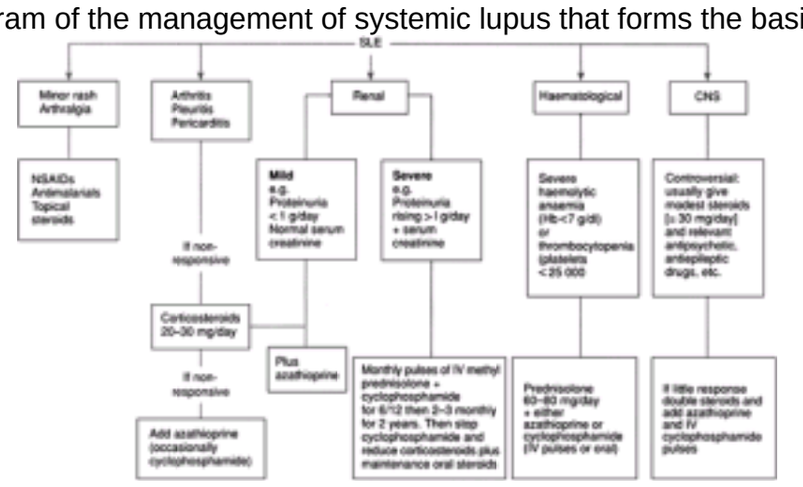
In general the patient with mildly active lupus can be managed with combinations of non-steroidal anti-inflammatory drugs and antimalarials. Patients with lupus are at no lesser risk of gastrointestinal and renal complications of the non-steroidal anti-inflammatory drugs than other patients and thus the usual type of monitoring (clinical history, blood tests) is required. Hydroxychloroquine (Plaquenil) is the antimalarial drug of choice. It is still recommended by some authorities that ophthalmological examinations are undertaken approximately every 9 months to ensure that no retinal damage is occurring.

Corticosteroids in the main are required when non-steroidal anti-inflammatory drugs and antimalarials are insufficient to relieve the patients symptoms. Thus severe arthritis, pleuritis, pericarditis, autoimmune haemolytic anaemia, thrombocytopenia, nephritis, and a wide range of neuropsychiatric problems frequently require treatment with corticosteroids.

Corticosteroids are usually prescribed and taken by mouth but they may also be given intramuscularly and intravenously. Intravenous or pulse therapy has been widely used in the past 15 years. If given over a 15 to 20-min period there is a danger of reactive arthropathy, and in our experience intravenous pulses are best given slowly over a 3 to 4-h period. We use pulse therapy: for example, 1 g on 3 successive days for patients with severe disease which does not seem to be responding to oral corticosteroids. Although some claims have been made about the advantages of this type of approach, the evidence that anything more than a temporary benefit

is obtained is controversial.

Box 1 Flow diagram of the management of systemic lupus that forms the basis of our practice



Some centres have attempted to use alternate-day oral steroid regimes, although the evidence that there is a reduction in the number or the severity of side-effects compared with daily use is lacking. The major side-effects, however corticosteroids are prescribed, are increased risk of infection, osteoporosis, diabetes, hypertension, cushingoid facies, abdominal striae, and insomnia. Corticosteroids are thus no panacea.

Various control trials of cytotoxic drugs in lupus have been reported. The group from the National Institutes of Health at Bethesda has argued strongly that intravenous boluses of cyclophosphamide, monthly for 6 months, subsequently once every 3 months for 2 years, are the treatment of choice in patients with severe renal involvement (Boumpas *et al*. 1991; Boumpas *et al*. 1992; Boumpas *et al*. 1993). The problems of side-effects with this drug (profound nausea, alopecia, infertility especially in patients over 30, and bone marrow suppression) have made others more wary about its routine use. In common with many European groups we prefer to use steroids and maintenance azathioprine in the first instance for patients with mild/moderately active renal disease. Occasionally however, we have seen patients being treated with steroids and azathioprine for other manifestations who develop severe renal disease and require cyclophosphamide urgently. For patients with endstage renal disease, kidney dialysis and kidney transplantation are available. Interestingly, it is rare for a patient with lupus with a transplanted kidney to develop lupus nephritis in the new organ. A flow diagram of the way we use drugs to treat the various aspects of lupus is shown in Box 1.

Other treatments

In the late 1970s and early 1980s there was a great vogue for using plasma exchange. The concept was that the removal of circulating, presumptively pathogenic, immune complexes offered a therapeutic advantage. In practice, it became evident that in some patients a 'rebound' phenomenon occurred in which patients' symptoms and signs dramatically improved but returned within a few days or weeks. This form of treatment requires good venous access, much patience on the part of both physician and patient, and is extremely expensive. A double-blind study using a sham exchange procedure has been performed in mild lupus. The frequency and degree of clinical improvement was the same in both groups (Wei *et al*. 1983). In common with most units we now reserve plasma exchange for those patients seemingly resistant to conventional drug therapy. Attempts are currently being made to achieve a more synchronized deletion of immunoglobulins followed by cytotoxic therapy. Autologous stem cell transplants are also now being considered for lupus.

Lymphoid radiation

Fractionated total lymphoid irradiation, a radiotherapy technique adapted from the method used to treat Hodgkin's disease was shown to improve the survival of NZB/W mice. There have been conflicting opinions as to its value in human patients with lupus. This treatment had not found widespread acceptance. Another form of radiation using ultraviolet A1, has been shown to reduce disease activity in patients in a provisional study (McGrath 1994).

Diet therapy

Many patients with lupus are anxious to know if some form of dietary modification might be of help. It is now well established that diet content can affect the course of disease in NZB/W and MRL-*lpr/lpr* mice. Although some benefits have been demonstrated from total calorie restriction, a restricted amino acid diet, and one in which dietary zinc is reduced, the influence of dietary fat on autoimmunity, certainly in the mouse, appears to be particularly important. In addition, supplementation of the diet by fish oils has been shown to be beneficial. In a recent double-blind, cross-over study in which patients with lupus were put on to low fat diets, those who were concurrently taking 10 g of fish oil per day were shown to have done significantly better over a 3-month period (Walton *et al*. 1991).

Intravenous high-dose gammaglobulins

Intravenous high-dose gammaglobulins may be effective in the treatment of immune thrombocytopenic purpura, immune neutropenia, and myasthenia gravis. It has also been used with moderate success in patients with lupus with low platelet counts. A claim that it was of value in patients with severe renal lupus has not been substantiated. When this approach does not work for patients with thrombocytopenia, splenectomy is beneficial in four or five out of six cases, provided the problem has not been left to become long-term and chronic (Silvestris *et al*. 1994).

Sex hormone therapy

Given the marked predilection of lupus for females, it is not surprising that attempts have been made to treat the condition by manipulating the level of sex hormones.

However, the clinical use of sex hormones in lupus and other autoimmune diseases has neither been extensive nor particularly successful. One drug, danazol, an androgen with reduced virilizing capacity has been used by several groups; as is so often the case with new drugs, the initial optimism has given way to the view that it adds little to the treatment of lupus.

Treatment of experimental lupus

The occurrence of spontaneous lupus in mice has the advantage that manipulation of the disease *in vivo* may be studied. Early studies in the MRL-*lpr/lpr* strain showed that neonatal removal of the thymus delayed the onset of disease to resemble that of the congenic MRL $^{+/+}$ strain. This implicated T cells in the pathogenesis of the disease. Attempts to down-regulate autoantibody production by treatment with anti-idiotype were initially successful in suppressing idiotype-positive anti-DNA antibodies in MRL-*lpr/lpr* mice. Subsequently new clones of idiotype-negative anti-DNA-positive antibodies emerged (Hahn and Ebling 1984). Treatment of both NZB/W F1 and MRL-*lpr/lpr* mice with a monoclonal antibody directed against the CD4 receptor on T helper/inducer cells also improved the clinical status of these animals (Wofsy and Seaman 1985; Santoro *et al*. 1988).

Infection of lupus-prone NZB/W F_1 mice with the parasite *Plasmodium chabaudi* retards the development of their autoimmune disease. Survival was prolonged and high-grade proteinuria and IgG anti-DNA antibodies were delayed for 6 months when parasite inoculation was given either before (3 months) or after (7 months) the onset of the clinical symptoms. Similar beneficial effects, although less pronounced, were obtained when mice were treated with IgG or IgM or cryoglobulin preparations isolated from *P. chabaudi*-infected BALB/c mice, while similarly prepared fractions from uninfected mice had little effect. In surviving mice, levels of anti-DNA antibodies, particularly the IgG1 isotype, were significantly decreased. Flow cytometric analysis of various T-cell subsets showed that the number of T cells expressing Vb 8.1,2, Vb 10 and Vb 14 TCR antigens, which increased with age, were significantly reduced. The mode of therapeutic action is thought to arise from the malarial induction of high levels of natural antibodies bearing the D23 idiotype characteristic of polyreactive natural autoantibodies with enhanced activity against Fab and Fc fragments of IgG. These antibodies have immunoregulatory properties and attempt, at least transitorily, to rescue a natural autoantibody network that is deficient in B/W mice (Hentati *et al*. 1994). These experiments may parallel the findings of human disease treated with intravenous gammaglobulin.

As with human disease, experimental models of lupus have become the focus of much research into cytokine-directed therapeutic intervention. In NZB/W F_1 mice, administration of interferon-g aggravated the autoimmune response, whereas monoclonal antibodies to interferon-g (Jacob *et al*. 1990b) and replacement therapy with recombinant tumour necrosis factor-a (TNF-a) delayed disease development (Jacob and McDevitt 1988). Significantly serum TNF-a levels increased in anti-IL-10

treated NZB/W mice while disease onset was delayed. Simultaneous treatment with a neutralizing antibody to TNF-a at the same time as anti-IL-10 treatment resulted in the rapid onset of lupus and increased mortality supporting the concept that TNF-a is protective in this model. Similarly the role of IL-10 was confirmed to accelerate disease by direct administration of recombinant IL-10 (Ishida *et al*. 1994).

In the same strain of mice, chronic treatment with rat monoclonal antibodies to IL-6 prevented anti-dsDNA antibody production, decreased proteinuria, and prolonged life, provided that mice attained tolerance to rat immunoglobulin by a single injection of anti-CD4 antibodies at the start of therapy (Finck *et al*. 1994). Treatment of MRL-*lpr/lpr* mice for 5 weeks at 15 weeks of age with neutralizing antibodies to the IL-6 receptor showed improvements in glomerular structure and function and a decrease in anti-dsDNA antibodies after 2 weeks of treatment but a gradual increase by week 4 (Kiberd 1993).

A novel 'T-cell vaccination' in MRL-*lpr/lpr* mice has shown a highly significant amelioration of disease parameters. Intravenous administration of irradiated *lpr* cells recovered from hyperplastic lymph nodes of adult diseased animals to young MRL-*lpr/lpr* mice resulted in selective depletion of Vb 8.2 T cells in lymph nodes, in addition to eliciting a surge in peripheral T cells capable of conferring disease protection in adoptive transfer experiments (De Alboran *et al*. 1992).

The major reversal of disease in MRL-*lpr/lpr* mice has been described in the section on experimental models of lupus and refers to the introduction of the *Fas* gene under the control of the CD2 promoter and enhancer (Wu *et al*. 1994).

Treatment of autoimmune mice with drugs used for humans allows not only efficacy but also the mode of action to be tested. For example, dexamethasone given to MRL-*lpr/lpr* mice from 4 weeks of age, prevents lymphadenopathy and renal injury (proteinuria), suppresses a fourfold increase in MHC class II antigen expression (22 weeks), but has no effect on the costimulatory molecules ICAM-1 and TNF-a (Jevnikar *et al*. 1992). Similarly, methylprednisolone down-regulates renal expression of endothelin-1 and its receptors, TGF-b and TNF-a mRNA in NZB/W mice and suppresses development of renal histological lesions (Nakamura *et al*. 1993).

A low fat diet has been reported to delay disease symptoms in MRL-*lpr/lpr* mice (Morrow *et al*. 1986). Since then the nature of marine long-chain fatty acids in the diet has been investigated in female NZB/W mice fed diets containing 10 per cent fish oil, with control mice fed diets containing 10 per cent corn oil. Compared with control mice those maintained on a diet rich in marine oils had an extended life span, later onset of proteinuria, increased proliferative responses to T-cell mitogens, and decreased circulating anti-dsDNA antibodies. Splenocyte analysis compared with controls showed decreased Ig +, higher lymphocyte ECAM-1 expression, elevated mRNA for IL-2, IL-4, and TGF-b, and higher TGF-b, lower c-Myc and c-Ha-Ras proteins. Changes in membrane fatty acid composition may contribute to the altered immune function and gene expression during the development of murine lupus (Fernandes *et al*. 1994).

Prognosis and survival

Studies on duration of disease and overall survival rates have frequently been confounded by the numbers of patients lost to follow-up and inadequate attention paid to the ethnic group, age of onset, and socio-economic status of individual patients. With these possible confounding factors in mind, and the division of patients with lupus into those with overt nephritis and those without, it is reasonable to state that the 5-year survival in lupus is presently 90 per cent or greater, but at 15 years only 60 per cent of those with nephritis will still be alive compared with around 85 per cent of those without nephritis. In the United States, it has been claimed that black patients with lupus, males, those from poorer socio-economic groups, and possibly children, have poorer survival, especially if nephritis is present. It has also been suggested that there exists a bimodal mortality curve. Patients who die within 5 years usually have very active disease, with a requirement for substantial doses of steroids and other immunosuppressives. Those patients dying much later tend to do so from cardiovascular disease and possibly infection. Overall most patients with lupus die from active generalized disease, nephritis, sepsis, and cardiovascular disease. Evidence that patients are more predisposed to malignancy has been discussed earlier in the chapter but this seems to be a relatively minor cause of death in lupus.

Summary

In the introduction to this chapter an analogy was drawn between systemic lupus erythematosus and the Hydra monster of Greek legend. In Fig. 10 this analogy is reiterated to confirm the multiple factors involved in the aetiology and pathogenesis of lupus. It is evident that this remarkable disease presents a wide spectrum of clinical features and is characterized by multiple autoantibodies, although clearly not due to random polyclonal B-cell activation. The treatment and general management of lupus continues to present a challenge. While lupus may for some patients represent a relatively mild set of problems, many others require large doses of immunosuppressive drugs which carry long-term concerns about side-effects.

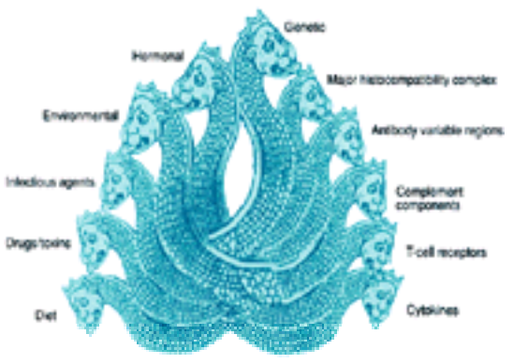


Fig. 10 The Hydra—an analogy of the multiple factors involved in lupus.

5.7.2 Systemic lupus erythematosus in children

Earl D. Silverman and Alison A. Eddy

Systemic lupus erythematosus (SLE) in children and adolescents has many features in common with adult-onset SLE. This chapter, rather than fully reviewing all the possible presentations and manifestations of SLE will highlight the differences between paediatric SLE and adult-onset lupus. This chapter will not cover many topics such as immunopathogenesis, cytokines, and animal models which are outlined in Chapter 5.7.1, nor will it cover antiphospholipid antibodies in depth. Rather, it should serve as a complementary chapter and will place its emphasis on unique features and provide an overview of general features of paediatric SLE. We suggest reading both chapters on SLE. A separate section of this chapter will cover neonatal lupus erythematosus, a disease caused by maternally-transmitted autoantibodies.

Incidence

Although SLE has been recognized for many decades, most physicians rarely consider it in the paediatric age group. Currently there has been no good epidemiological study focusing on paediatric SLE and very few large population studies give details of its incidence prior to the age of 20. A large population study from New York showed an incidence of 6 cases per 100 000 white females of less than 15 years of age as compared with an overall incidence of 25 cases per 100 000 white females of all ages. The incidence rate rapidly rose to 18.9 cases per 100 000 white females aged between 15 and 25 years. Therefore, the true incidence of SLE beginning prior to age 19 was between 6 and 18.9 cases per 100 000 in white females, and was higher in black (20 to 30 per 100 000) and Puerto Rican females (16 to 36.7 per 100 000) (Siegel and Lee 1973).

Most other series of SLE patients with a large number of paediatric cases state that 20 per cent of all cases of SLE have onset prior to age 18 (Kaufman *et al*. 1986; Reeves and Lahita 1987). Therefore, using the best available data, the incidence of SLE beginning prior to age 18 is 10 to 20 cases per 100 000 children and adolescents, with an overall prevalence of 10 to 20 cases per 10 000 people less than 18 years old. These rates are higher in Hispanic, black and oriental people.

Early reports had suggested that there was a high percentage of male cases prior to puberty, while after puberty the percentage of cases occurring in females rose to make up 85 to 90 per cent of cases (as seen in most adult studies). In our series we had an overall male:female ratio of 1:4.3. When further divided by age, we found a male:female ratio of 1:5.5 between 6 and 10 years (prepubertal); 1:3.4 in the age 11 to 13 group (peripubertal); and 1:4.5 between the ages of 14 and 18 (postpubertal). Our data are consistent with more recent larger reviews (King *et al*. 1977; Lehman *et al*. 1989b). These data may reflect both an increased awareness of the possibility of SLE in males and the larger series size would eliminate any potential false bias of previous small studies. Whatever the reasons, the overall ratio of male:female cases of approximately 1:4.5 suggests that there is a higher percentage of male cases in paediatric SLE than in adult cases of SLE.

In the paediatric series, the average age at diagnosis varied from 11 to 14 years (median 12.2 years). The time from onset of symptoms to diagnosis varied from 8 months to 3.3 years (median 1.2 years). This median time of 1.2 years from symptoms to diagnosis emphasizes the difficulty in diagnosis or the lack of awareness of SLE in this age group. The features of SLE at presentation are shown in Table 1; while features at any time during the course of the disease are shown in Table 2 (Zetterstrom and Berglund 1956; Gribetz and Henley 1959; Cook *et al*. 1960; Jacobs 1963; Robinson and Williams 1967 ; Walravens and Chase 1976; Fish *et al*. 1977; King *et al*. 1977; Abeles *et al*. 1980; Caeiro *et al*. 1981; Yancey *et al*. 1981; Schaller 1982; Glidden *et al*. 1983; Emery 1986; Kaufman *et al*. 1986; Lehman *et al*. 1989a; El-Garf and Salah 1990; Lacks and White 1990). These are shown as the range of each feature in: (i) previously published paediatric series; and (ii) our series of 86 patients. Details are given in the organ-specific sections. However, general systemic symptoms such as fever, malaise and weight loss are common, as is evidence of systemic inflammation shown by lymphadenopathy and/or hepatosplenomegaly—this is both at diagnosis and throughout the course of the disease.

	Other series (%)	Our series (%)
Fever	60–90	55
Arthritis	60–88	78
Skin rash (any)	60–78	79
Malar rash	22–60	36
Renal	20–80	51

Central nervous system	20–44	34
Gastrointestinal*	24–40	24
Hepatosplenomegaly	19–43	30
Lymphadenopathy*	13–45	34

*Not included in follow-up data in many paediatric series.

Table 2 Clinical features: any time during the course

Musculoskeletal disease

Arthritis and arthralgia are among the most common symptoms in paediatric SLE occurring in more than 90 per cent of cases. Most patients with arthritis have a symmetric polyarthritis affecting both large and small joints. The arthritis usually responds to the treatment of other major organ involvement or to treatment of the general systemic symptoms. Unlike juvenile chronic arthritis, the arthritis is usually episodic and is easy to treat. Severely painful joints are common and usually the pain is out of proportion to the physical findings. The peripheral joints including the fingers, hands, wrists and knees are the commonest joints involved, with involvement of hips and ankles more unusual. In most cases there is no radiographic evidence of joint destruction. However, in 1 to 2 per cent of cases of lupus arthritis there is a deforming erosive arthritis as seen in seropositive juvenile chronic arthritis. This type of arthritis is usually associated with a positive rheumatoid factor, and at least in adults, has been referred to as 'Rhupus'. A more common cause of joint deformities is secondary to ligamentous laxity and periarticular fibrosis, the so-called Jaccoud's arthritis. This can result in deformity of the hand with multiple joint subluxations but with good preservation of function. Radiographs show only osteoporosis without evidence of erosions or joint space loss. Jaccoud's arthritis is more of a periarticular rather than an articular disease (Martini *et al*. 1987). However, in most patients with arthritis of SLE, the arthritis does not result in deformity. Both 'Rhupus' and Jaccoud's arthritis combined occur in less than 5 per cent of paediatric SLE patients with arthritis. Tenosynovitis is common and patients with knee effusions can develop Baker's cysts. Of particular interest have been the reports of patients with American College of Rheumatology (ACR) criteria for juvenile chronic arthritis who develop SLE years later. We have seen a patient with 'classic' systemic-onset juvenile chronic arthritis, including evanescent rash and spiking fever, who after 2 years in remission for her juvenile chronic arthritis developed SLE, including a photosensitive rash and positive antinuclear antibodies (which previously had been negative). Initial reports had shown a transformation from polyarticular rather than systemic juvenile chronic arthritis to SLE (Ragsdale *et al*. 1980; Saulsbury *et al*. 1982), however a more recent report has also demonstrated transformation from systemic juvenile-onset chronic arthritis to SLE (Citera *et al*. 1993).

Analysis of synovial fluid usually shows only mild inflammation with a total white blood-cell count of generally less than 2000 cells/ml. Synovial biopsies show a mild vasculitis or perivasculitis and the diagnostic histological lesion is the hematoxylin body. This may be the equivalent of the LE cell in the joint. However, synovial biopsies are indicated rarely.

Myalgia, as part of the generalized disease process, occurs in approximately 50 to 60 per cent of paediatric cases, while true myositis with proximal muscle weakness or tenderness occurs in less than 10 per cent of cases. When present there is usually a slow progression of weakness and rarely is there involvement of the intercostal or cricopharyngeal muscles. It is seen more commonly in patients with so-called 'overlap syndromes' or with mixed connective tissue disease. Primary muscle involvement must be differentiated from muscle weakness secondary to steroid treatment. This complication is a much talked about steroid side-effect but in our experience it is uncommon. The treatment of steroid-induced myopathy would be to decrease rather than increase the steroid dose and would result in an improvement in muscle strength.

The other steroid-induced musculoskeletal side-effects include avascular necrosis, osteoporosis with fracture or vertebral body collapse, and even growth failure if prolonged high-dose steroids are required. Growth failure may be alleviated partially by alternate-day dose regimens but even using these it still remains a problem. One hope may be through the use of recombinant growth hormone to promote growth, but no studies have been undertaken yet in this group of patients.

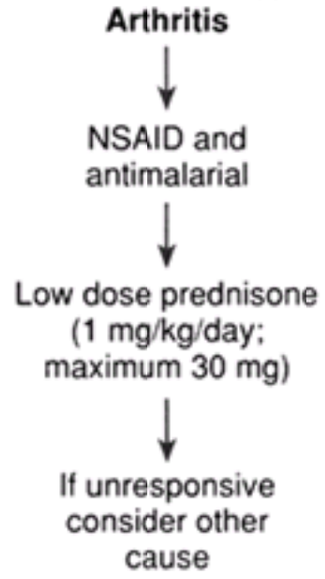
Avascular necrosis occurs in approximately 10 to 15 per cent of paediatric cases and appears to be more common in children than adults (Smith *et al*. 1976). In our experience, avascular necrosis occurs more commonly in SLE than other paediatric autoimmune diseases where prolonged high-dose steroids are used. The reason for this is not readily apparent. Unlike adults, in our experience, paediatric patients with Raynaud's phenomenon and vasculitis do not appear to be at a greater risk of this complication. Usually avascular necrosis is related to the dose and duration of therapy but there have been case reports of it developing prior to or without steroid usage (Abeles *et al*. 1978; Kalla *et al*. 1986). In contrast to avascular necrosis, vertebral collapse is rarer in SLE than in other autoimmune rheumatic diseases and in particular juvenile dermatomyositis. The incidence of vertebral collapse is probably related not only to steroid dose and duration but also to the amount of weight gain and physical activity. The most common lesion involves the thoracolumbar spine with cervical spine lesions occurring more rarely.

The last musculoskeletal side-effect of steroid therapy is increased incidence of fractures secondary to steroid-induced osteoporosis. This appears to be less common in children than adults and may reflect relative differences in bone mineral content between the groups. Treatment or prevention of steroid-induced side-effects is controversial in adults and there has not been a good study in children. The best hope lies with the new generation of 'bone-sparing' steroids and keeping patients active while minimizing weight gain.

Treatment of musculoskeletal involvement

The arthritis of SLE frequently occurs with disease flares elsewhere and usually responds to the treatment for the more serious complication. However, if isolated, the use of a non-steroidal anti-inflammatory drug with an antimalarial drug has a high success rate. The only word of caution is that SLE patients seem to be more susceptible to hepatotoxicity induced by non-steroidal anti-inflammatory drugs, particularly aspirin. We commonly use naproxen (10 to 20 mg/kg per day), tolmetin (20 to 30mg/kg per day) and avoid ibuprofen because of the reports of aseptic meningitis occurring in SLE patients. When the arthritis is more severe or unresponsive we commonly add hydroxychloroquine at a dose of 5 mg/kg per day, although others have advocated the use of chloroquine. Antimalarial therapy appears to be of benefit not only for the arthritis but also for rash and overall disease control. The major side-effects are retinal macular deposition of the drug and gastrointestinal distress. Therefore, we recommend ophthalmological examination every 6 months and taking the drug immediately before bed to lessen gastrointestinal upset. Prednisone at low to moderate dose may be required. For suggested therapy of arthritis see Box 1.

Box 1 Arthritis therapy flow chart



Mucocutaneous involvement

Cutaneous involvement has been reported in 50 to 80 per cent of paediatric SLE patients at the time of diagnosis and in up to 85 per cent of patients during the course of the disease. A malar rash, in the classic 'butterfly distribution', is the most common rash occurring in 30 to 60 per cent of cases at diagnosis and in up to 80 per cent of patients during the course of the disease. The rash may be mild, requiring no treatment, but can be severe and cosmetically unacceptable requiring treatment with steroids, either topically or systemic, and/or antimalarial drugs. The appearance of a malar rash often heralds a disease flare and while usually non-scarring it can be present as a crusted or scaling rash. A truly photosensitive rash only occurs in approximately one-third of paediatric patients. The photosensitive rash can occur not only on the face but in any sun-exposed area, especially the arms and legs (Fig. 1). This photosensitive rash may be maculopapular or papulosquamous and may be associated with anti-Ro and anti-La antibodies. The other anti-Ro/La antibody-associated rash is annular erythema. This rash is

commonly photosensitive and occurs on the face or neck (Deng *et al*. 1984) (Fig. 2). True discoid lupus lesions are seen rarely in patients under the age of 18 years. In patients with a photosensitive rash, sun exposure may not only exacerbate the skin disease but may cause a systemic flare. Therefore, we recommend avoidance of sunbathing along with the use of sun-blocking agents, with high SPF (sun protecting factor) blocking both ultraviolet A and B wavelengths, and protective clothing including long-sleeved shirts and hats. It must also be remembered that unshielded fluorescent lamps may emit ultraviolet B radiation.

Fig. 1 A patient with known SLE developed a severe, vasculitic rash on arms and legs following sun exposure.

Fig. 2 Annular erythema on the neck of an SLE patient with anti-Ro and anti-La antibodies.

A true vasculitic skin rash has been reported in 10 to 20 per cent of patients. It occurs commonly in fingers or toes and can result in splinter haemorrhages and digital infarcts. Oral or nasal ulcers are caused by the same vasculitic process and they are probably a reflection of alterations seen in other vascular beds. Even when isolated, they may signify active disease. Painless ulcers are more common on the hard palate but may occur on the soft palate. A petechial rash on the hard palate may precede true ulceration while a chronic sore throat may represent mildly active vasculitis. Similarly, hyperaemia of the nasal mucosa usually precedes ulceration or perforation (Fig. 3). Most paediatric series do not comment on the incidence of these lesions but they probably occur in 10 to 20 per cent of patients. For suggested therapy of mucocutaneous disease see Box 2.

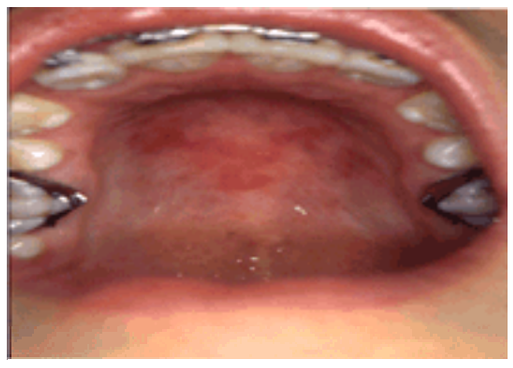


Fig. 3 Hyperaemia and petechiae on hard palate secondary to vasculitis.

Alopecia, no longer part of the revised ACR criteria for SLE, is common and occurs in up to 50 per cent of paediatric patients. Diffuse hair loss during washing or brushing is more common than patchy hair loss. In some patients there is a delay in the hair loss, which may follow a disease flare or increase after the introduction of steroids. Rarely is the hair loss significant enough to cause a cosmetic problem. Scarring is unusual.

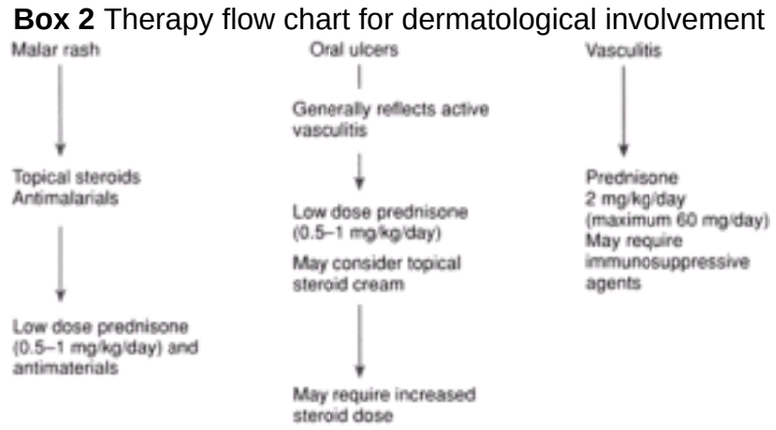
Raynaud's phenomenon appears to be less common in paediatric lupus, occurring in only 10 to 20 per cent of patients. In some patients local therapy including avoidance of cold, use of insulated mittens rather than gloves and hand/feet warmers will suffice. However, many patients will have more severe disease requiring the use of calcium-channel blocking agents or other vasodilating medication, including topical therapy with prostaglandins or nitroglycerin paste. Paediatric patients appear to tolerate calcium-channel blocking agents better than adults do. Patients with Raynaud's phenomenon rarely have normal vascular tone and will often have vasodilation at rest or severe vasoconstriction after only slight provocation. Raynaud's phenomenon may precede overt clinical SLE by months and may initially involve only a few digits and later involve all fingers and toes. Although usually easy to control, Raynaud's may result in distal digital infarction or gangrene.

Central nervous system

Involvement of the central nervous system, which occurs in 20 to 50 per cent of paediatric patients, can be the most interesting yet frustrating target in SLE. The interest stems from the protean manifestations but the frustration stems from the difficulty in diagnosis and assessment of patients with neuropsychiatric SLE (NP-SLE). Central nervous involvement can occur in isolation or it may be associated with disease flares in other organs. The only correlation between central nervous disease and disease elsewhere appears to be the association with vasculitis and thrombocytopenia. Table 3 lists the different manifestations of nervous system involvement seen.

Table 3 Neuropsychiatric lupus

Box 2 Therapy flow chart for dermatological involvement



Neuropsychiatric SLE

The most difficult SLE patients to diagnose and treat are the patients with psychiatric disorders. As a group psychiatric disorders are seen in 10 to 20 per cent of paediatric SLE cases. When a known lupus patient presents with florid psychosis or organic brain syndrome, the diagnosis is easy. However, many patients present with affective or mood disorders. The difficulty is determining whether the abnormalities detected are a direct result of the disease, secondary to steroid treatment, or 'reactive' to the disease or changes in body image. Several different investigations have been proposed to differentiate active disease from other causes of central nervous abnormalities (see below).

It can be very difficult to differentiate neuropsychiatric SLE-induced cognitive impairment and concentration difficulties from other causes of poor school performance. Studies in adults have suggested that cognitive impairment may occur in up to 80 per cent of all SLE patients (Carbotte *et al*. 1986). Defects in cognitive function may reflect active disease or residual defects from previous central nervous involvement (Fisk *et al*. 1993). This is emphasized by a longitudinal study which demonstrated that cognitive functional abnormalities may resolve and therefore they do not necessarily reflect irreversible damage (Hanly *et al*. 1994). To date there has been only one study in paediatric SLE that suggests that cognitive function defects are common (Papero *et al*. 1990). This has also been our experience. Although affective disorders occur less frequently than cognitive impairment, it must be recognized that patients can present with a major affective disorder with very few other signs of lupus.

Seizures occur in approximately 10 to 20 per cent of paediatric SLE cases and may be the presenting sign. Focal seizures are more common than *grand mal* seizures. Seizures are generally easily treated with anticonvulsant medication and usually do not require high-dose steroids for control. Seizures may not be primary but rather secondary to metabolic disturbances caused by uraemia, hypertension, cerebral infarction or central nervous infection. Structural abnormalities should be ruled-out in all patients with new onset or increasing frequency of seizures.

Movement disorders including chorea, cerebellar ataxia, hemiballismus, tremor and Parkinsonian-like movements, occur in 5 to10 per cent of cases. Interestingly chorea appears to be over-represented in the paediatric age group. In one review of 52 cases of SLE-associated chorea, 34 had chorea that developed before the age of 18 years, with the chorea preceding other manifestations of SLE by more than 1 year in 20 per cent of all cases (Bruyn and Padberg 1984). Recently we have had cases of chorea that preceded the development of overt SLE by many years and chorea that developed in patients with long-standing SLE. It has been demonstrated that there is an association between chorea and antiphospholipid antibodies. The exact mechanism which leads to chorea is unknown, although it rarely appears to be the result of an infarction that can be demonstrated on neuroimaging studies. The decline in the incidence of rheumatic fever means that the diagnosis of SLE or antiphospholipid antibody syndrome should be considered in all patients presenting with chorea.

Neuropathies

Both cranial and peripheral neuropathies can occur, with cranial nerve involvement being the more common. Cranial nerve involvement usually affects cranial nerves II, III, IV, and VI resulting in abnormalities of vision, pupils, or extraocular movements. Less frequently facial palsy (VII), trigeminal neuropathy (V) or nystagmus and vertigo (VIII) occur. When peripheral neuropathies occur, a sensory or mixed sensorimotor involvement is more common than an isolated motor neuropathy. However, mononeuritis or mononeuritis multiplex can occur and isolated cases of Guillain–Barré-like syndrome have been seen.

Paresis, while seen in approximately 5 per cent of adult cases, is less common in children. Hemiparesis in association with other major neurological findings, rarely seen in children, is usually secondary to cerebral vascular accident. Hemiparesis and/or cerebral vascular accidents may occur as the result of active SLE but also may occur when the SLE is complicated by the presence of hypertension, antiphospholipid antibodies, or thrombocytopenia. Transverse myelitis may present with acute paraplegia or quadriplegia; in this latter syndrome antiphospholipid antibodies must be sought.

Headache

Headache requires a separate category as this is a common symptom occurring in approximately 20 per cent of cases. The differentiation of the type of headache is important. The severe, unremitting lupus headache is the most serious and reflects active disease or may represent cerebral vein thrombosis (see below). A special problem occurs with migraine headache secondary to SLE, which must be differentiated from non-lupus associated vascular instability, particularly in patients with a family history of migraine headaches (Isenberg *et al*. 1982). A headache may be the presentation of pseudotumour cerebri, which has been described as the presenting diagnosis in paediatric SLE. Migraine headaches may reflect active central nervous SLE (Miguel *et al*. 1994).

Most worrying is the association of severe headache with cerebral vein thrombosis. Although cerebral vein thrombosis has been felt to be rare, we have recently recognized this complication in patients with headache. The headache associated with cerebral vein thrombosis may occur without any other neurological manifestation (Uziel 1995). We recommend neuroimaging studies for patients with persistent or severe headaches (see below).

Investigation

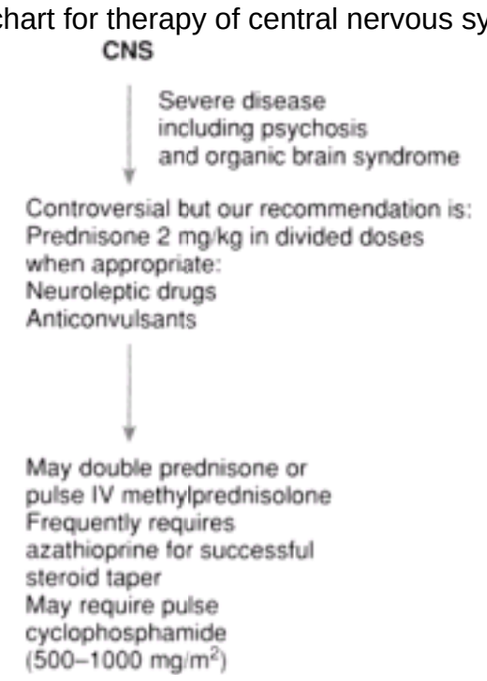
As the differential diagnosis neuropsychiatric SLE is large, so is the list of investigations. Abnormalities of cerebrospinal fluid cell count, protein and complement levels have been described. However, the findings are inconsistent and complement levels cannot be routinely obtained. It has been suggested that measurements of the integrity of the blood–brain barrier and of immunoglobulin synthesis in the cerebrospinal fluid may correlate with neuropsychiatric SLE, but the demonstration of these abnormalities is not specific for SLE (Hirohata *et al*. 1985; McLean *et al*. 1995). Furthermore, large controlled, prospective studies are not available in SLE to test the utility of measuring these parameters. However, the simplest test, examination and culture of cerebrospinal fluid, remains important when the possibility of infection or haemorrhage exists. An elevated cerebrospinal fluid protein and/or white blood-cell count, in the absence of infection, is suggestive of cerebritis.

The correlation of antineuronal antibodies and cognitive function has sparked much interest recently. One prospective adult study suggested that a combination of the

measurement of antineuronal antibodies with a large battery of sophisticated neurophysiological cognitive function tests correlated well with fluctuations of disease (Long *et al*. 1989). Our limited experience has suggested that this combination of testing may be of benefit in diagnosis and disease monitoring. Despite its promise, cognitive function testing requires more time and expertise than is routinely available. Furthermore, longitudinal studies of cognitive function may be required to determine whether a defect is old, permanent or temporary (Hanly *et al*. 1994).

Serial measurement of more routine autoantibodies and routine blood tests may not correlate with neuropsychiatric SLE (Miguel *et al*. 1994). Patients may have normal serology and complement levels despite active SLE of the central nervous system. One exception may be the association of antiribosomal P antibody and depression. Initial studies had suggested that although antiribosomal P antibodies are present in approximately 15 per cent of all lupus patients, these autoantibodies occur in most lupus patients with depression (Bonfa *et al*. 1987). However, other studies have failed to demonstrate this high degree of association with psychosis or depression (Teh *et al*. 1993). Importantly, preliminary studies suggest that the presence of the antiribosomal P antibodies may distinguish depression secondary to SLE from other causes including reactive, steroid-induced or other non-SLE causes of depression (Schneebaum *et al*. 1991). We have recently examined antiribosomal P antibodies in paediatric SLE and found that the antibodies were present only in patients with psychosis secondary to SLE and not in patients with other causes of psychosis. However, many patients with psychosis did not have these antibodies, and many SLE patients with the antibodies did not have psychosis. Therefore, although anti-ribosomal P antibodies were specific for psychosis secondary to SLE, they had a low sensitivity in SLE patients with psychosis and a low specificity for psychosis in our SLE population (Press *et al*. 1996).

Box 3 Flow chart for therapy of central nervous system disease



Radiological investigation of the central nervous system may be helpful in demonstrating specific structural lesions such as infarction, embolus and subdural or intracranial haemorrhage. However, neither computed tomography (CT) nor magnetic resonance imaging (MRI) have been shown to be consistently helpful in measuring overall disease activity in the central nervous system (O'Connor 1988). The use of MRI to determine the presence of diffuse disease activity in the central nervous system remains controversial (Isshi *et al*. 1994; Jarek *et al*. 1994). Although abnormalities have been described, these findings may not correlate with clinical disease.

An SLE patient with persistent or severe headache should be investigated for the presence of intracranial thrombosis and in particular cerebral vein thrombosis. The best investigation is by a combination of CT and MRI scans. A CT scan, with 'wide-windows' should be performed in all patients when this diagnosis is considered (Uziel 1993). This examination will detect the presence of infarction and thrombosis. The use of 'wide-windows' will allow for the appropriate visualization of the cerebral veins. The neuroradiologist should be advised of the possibility of this diagnosis as the use of 'wide-windows' is not part of the routine CT scan. The diagnosis of cerebral vein thrombosis may be confirmed by the absence of flow on an MR venogram. An MR venogram is a very sensitive examination but it may not be readily available and may require sedation, while a CT scan is easier to perform and more readily available.

In most series, the use of nuclear medicine brain scans has not been shown to be of any diagnostic use. However, the use of single-photon-emission computed tomography nuclear brain scans (SPECT) holds promise. These scans may be a functional assessment of brain activity (Holman 1991). SPECT scans appear to be a sensitive test, both in adults and children, to measure active disease in the central nervous system (Rubbert *et al*. 1993; Szer *et al*. 1993; Kodama *et al*. 1995). However, the ability of this test to differentiate active SLE from other causes of abnormalities in the central nervous system remains to be determined. In addition patients without overt central nervous disease may have an abnormal SPECT scan. Whether the perfusion abnormalities in this latter group of SLE patients reflects subclinical dysfunction of the central nervous system or the generalized disease process, remains to be determined. Positron-emission tomography (PET) scans are not universally available and are considered generally as a research tool.

Treatment of central nervous system disease

The therapy of central nervous system disease varies with the manifestation. Currently the treatment of isolated cognitive disorders is controversial, although one adult study has suggested that these defects may be steroid-responsive. Obviously when infection is present the therapy is dictated by the microbiological identification of the organism. However, it must be remembered that these patients are susceptible to encapsulated organisms, Gram-negative organisms and opportunistic infections.

Active psychosis and/or organic brain syndrome are potentially life-threatening complications of central nervous system disease and should be treated aggressively with high-dose corticosteroids. In our experience these patients frequently require immunosuppressive therapy with azathioprine, to allow for the successive tapering of the steroid dose. For resistant central nervous disease, treatment with cyclophosphamide may be required. In addition, the use of psychotropic drugs may be needed for the control of the psychosis. We do not recommend the isolated use of psychotropic medication without the use of steroids. Although reported by others, we have not seen a case of steroid-induced psychosis. For suggested therapy of severe central nervous system disease see Box 3.

Treatment of seizures should be directed at finding their cause, whether they are secondary to infarction, active central nervous system disease or metabolic disturbance. Anti-convulsant medication may be required to control the seizures, but in many cases it is needed only for a short-term if the underlying cause of the seizure can be corrected.

As previously described, headaches can occur for a variety of reasons in these patients. The treatment is therefore dictated by the cause. If the headache is mild and it resolves with the use of routine analgesia then no further investigation or therapy is required. However, persistent headache resistant to analgesia may reflect active SLE or may be secondary to an intracranial thrombosis (in particular cerebral vein thrombosis). The management of 'lupus' headache secondary to active SLE requires better control of the SLE, which may include the use of steroids. We suggest that cerebral vein thrombosis requires anticoagulation, initially at high dose for 3 to 6 months followed by long-term low-dose anticoagulation (Uziel 1995). However, the need for and duration of long-term anticoagulation is controversial.

Renal disease

Renal involvement occurs in a significant number of children with SLE. In a literature review of 540 children followed at centres other than our own, 72 per cent developed nephritis during the course of their disease, similar to our overall incidence of 61 per cent in 138 children with SLE. The high susceptibility of the kidneys to injury in this disease is not entirely understood but it is due in part to haemodynamic factors; to the unique architecture of the glomerular capillary wall that permits direct exposure of blood-borne molecules to the glomerular basement membrane; and to the expression of renal antigens that may react with the autoantibodies present in these patients. The pathogenesis of SLE is reviewed in Chapter 5.7.1.

In most published series of childhood SLE, prognosis is most closely related to the severity of the renal disease. The World Health Organization (WHO) developed a morphological classification of lupus nephritis that was modified by the Pathology Advisory Group for the International Study of Kidney Disease in Children in 1980 (Table 4). Although the latter classification is more complex, it is our impression that it provides more useful information when making patient management decisions.

Unfortunately, neither classification accurately evaluates extraglomerular (tubular, interstitial and vascular) disease. It has been our practice to biopsy any child with clinical or laboratory evidence of renal involvement, because a diagnosis of diffuse proliferative lupus nephritis (DPLN) adversely affects long-term outcome and thus influences our initial patient management; an approach that is supported by the experience of others (Esdaile *et al*. 1994). In the report by Platt *et al*. (Platt *et al*. 1982), 59 per cent (21) of the children with biopsy-proven DPLN were alive without endstage renal failure 10 years after diagnosis compared with an 85 per cent 10-year survival rate for all 70 children with SLE (Fig. 4). It is important to note that the outcome of patients with DPLN did not deviate from that of the entire group for 7 years, emphasizing the need for long-term clinical trials to validate the efficacy of treatment protocols. A more recent paediatric series (McCurdy *et al*. 1992) reported a 62 per cent incidence of renal insufficiency in 24 children who developed DPLN between 1970 and 1983. Hopefully, earlier diagnosis of, and newer therapeutic approaches to, DPLN will improve the long-term outcome.

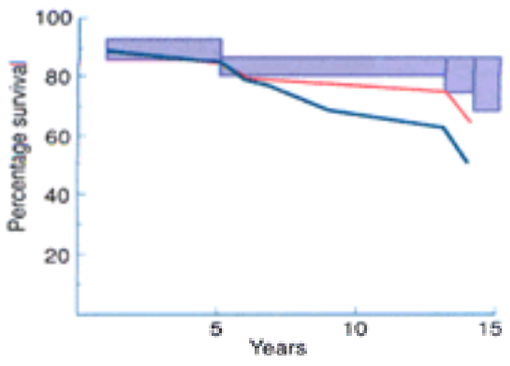


Fig. 4 Long-term survival of 70 children with SLE followed at The University of Minnesota. The patient survival rates for the subset of 21 children with diffuse proliferative lupus nephritis (DPLN) begins to deviate from the entire group (shaded area) at 7 years. Survival of the DPLN group without dialysis or renal transplantation is illustrated by the bolder line (Platt 1982).

I. *Normal*
A. Nil
B. Normal by light microscopy, but deposits present
II. *Pure mesangiopathy*
A. Mild (+)
B. Moderate (++)
III. *Segmental and focal proliferative glomerulonephritis*
A. Active necrotizing
B. Active and sclerosing
C. Sclerosing
IV. *Diffuse proliferative glomerulonephritis*
A. Without segmental necrotizing lesions
B. With segmental necrotizing lesions
C. With segmental active and sclerotic lesions
D. Inactive, sclerotic
V. *Diffuse membranous glomerulonephritis*
A. Pure membranous
B. Associated with lesions II (A or B)
C. Associated with lesions III (A, B, or C)
D. Associated with lesions IV (A, B, C, or D)
VI. *Advanced sclerosing glomerulonephritis*

Pediatr Nephrol (1988)

Table 4 International Study of Kidney Disease in Children: classification of lupus nephritis

Unfortunately, approximately 40 per cent of patients with SLE nephritis have the most severe subtype, DPLN. Since 1979, when electron microscopy was introduced as a routine part of the evaluation of renal biopsies performed at our institution, 39 per cent of 79 children with biopsy-confirmed lupus nephritis had DPLN (Table 5). Three additional patients underwent histological transformation to DPLN from focal proliferative and mesangial lupus nephritis within 9, 14, and 17 months respectively. Although it is relatively easy for the clinician to predict that a patient presenting with SLE and severe clinical manifestations of nephritis will have DPLN confirmed on renal biopsy, we have been impressed that this lesion may be present even in children with mild clinical manifestations. The profile of 29 children at the time of biopsy-confirmed DPLN illustrates this point (Table 6).

	General (%)[a] (n=368)	Seven paediatric series (%)[b] (n=424)	HSC 1979–1995 (%) (n=79)
Mesangial	27	24	19
Focal proliferative	18	24	20
Diffuse proliferative	39	44	39
Membranous	16	8	22

[a]Diffuse proliferative lupus nephritis diagnosed at our institution since 1979; clinical data available on 29/33 children.
[b]GFR, glomerular filtration rate determined by ^{51}Cr-EDTA or iothalamate clearance.
[c]C3, third component of complement; normal value is 0.81–1.8 g/l in our laboratories.

Table 6 Clinical manifestations at the time of biopsy of children with diffuse proliferative lupus nephritis [a]

Severe proteinuria, even in the nephrotic range, does not always predict the presence of DPLN. Two children in our series with an unequivocal diagnosis of SLE had nephrotic syndrome at presentation and minimal glomerular histological changes consistent with the diagnosis of mesangial lupus nephritis (Fig. 5). Electron microscopy revealed that the foot processes of the glomerular epithelial cells were fused. The nephrotic syndrome responded quickly to high-dose prednisone therapy and both girls were in complete remission within 10 days. We believe that their nephrotic syndrome was more typical of a 'minimal lesion-type disease' similar to previously reported cases (Abuelo 1984; Bakir *et al*. 1989). Since 1979, our incidence of membranous lupus nephritis has been 22 per cent, a frequency that is higher than most published paediatric series (8 per cent of 424 published cases). Whether this is because of an increase in the appreciation of this lesion by ultrastructural studies or due to a changing incidence of epimembranous disease in the past decade is unclear. A previous report of 70 children, who had biopsies taken at this

institution between 1970 and 1985, revealed an 8 per cent incidence of membranous lupus nephritis (Baumal *et al*. 1987). Nephrotic-range proteinuria was present at the time of renal biopsy in 56 per cent of the current series of children with membranous nephropathy, and nephrotic syndrome subsequently developed in another 13 per cent; microscopic haematuria was present in 63 per cent of patients. Importantly, a diagnosis of SLE should be considered in any child with membranous nephropathy, a form of nephropathy that is rare in children and usually not of the idiopathic type.

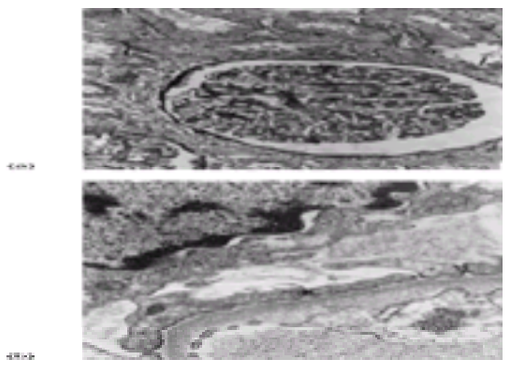

Fig. 5 Renal biopsy of a 14-year-old girl with SLE associated with nephrotic syndrome. (a) A few glomeruli showed a mild increase in mesangial matrix without mesangial cell proliferation. Several immune deposits were demonstrated in mesangial regions by immunofluorescence and electron microscopy. (b) Marked fusion of the foot processes of glomerular epithelial cells (star) was present. The nephrotic syndrome was in complete remission after 10 days of prednisone therapy. These clinical and histological features are typical of a 'minimal lesion-type disease'.

In our experience the presence of focal necrotizing lesions, even in patients with focal proliferative lupus nephritis, is a bad prognostic sign. These lesions were present in 50 per cent of our patients with biopsy-proven focal proliferative disease, all of whom required treatment with a cytotoxic drug (azathioprine, cyclophosphamide or methotrexate) before their disease could be controlled adequately. In a long-term follow-up study of childhood lupus nephritis of all classes, renal insufficiency was reported in 53 per cent of patients who had focal necrotizing glomerular lesions on the initial biopsy (McCurdy *et al*. 1992). Although rare, focal necrotizing glomerulonephritis in the absence of significant glomerular immune deposits (pauci-immune) has been reported in patients with SLE (Akhtar *et al*. 1994).

In addition to providing a histological classification, renal biopsies can be used to evaluate the degree of active and chronic renal damage. Semiquantitative scoring indices have been developed and although some controversy regarding the utility of these scores exists, they are particularly valuable in predicting the long-term outcome in patients with DPLN. A high score for the chronicity index is a bad prognostic sign. Austin and his colleagues from the National Institute of Health (NIH) (Austen *et al*. 1984) reported that patients with DPLN and any evidence of chronic damage on the initial renal biopsy had a much higher incidence of renal failure (Fig. 6). This group has recently reanalysed their experience, following the introduction of intensive treatment regimes that include intravenous pulse cyclophosphamide or methylprednisolone for patients with severe lupus nephritis (Austin *et al*. 1994). By multivariant survival analysis the combination of cellular crescents and interstitial fibrosis was shown to be the strongest histological predictor of a poor long-term prognosis at 80 months (p = 0.0003). In our series of patients followed since 1979, the three patients who have developed endstage renal disease all had advanced chronic disease on the renal biopsy done at the initial presentation and they developed irreversible renal failure within 3 years of diagnosis.

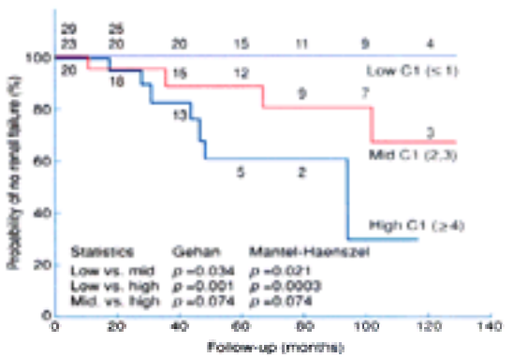

Fig. 6 Cumulative survival curves of 72 lupus patients with diffuse proliferative lupus nephritis (DPLN) demonstrating the negative impact of histological evidence of chronic renal damage on the long-term outcome of renal function. The chronicity index (CI; maximum score of 12 points) adversely affects renal survival rates (reproduced from Austin *et al*. (1984) with permission).

The evaluation of acute tubulointerstitial injury in lupus nephritis has been neglected until recently. Acute interstitial inflammation is commonly observed in patients with DPLN (75 per cent in our series) where it may or may not be associated with tubulointerstitial immune deposits. In our patient population, four patients without DPLN also had significant interstitial inflammation: three with membranous lupus nephritis (Fig. 7) and in one with atypical mesangial lupus nephritis associated with the nephrotic syndrome. Two of the later four patients had foci of immune deposits along tubular basement membranes. A study by Alexopoulos *et al*. (Alexopoulos *et al*. 1990) reported a positive correlation between the number of interstitial mononuclear cells and both renal function and the degree of chronic renal damage. Magil *et al*. reported a poorer outcome in patients, with tubulointerstitial immune deposits present in more than 20 per cent of the renal biopsy specimen (Magil *et al*. 1984). Lupus interstitial nephritis should be considered in the differential diagnosis of older children presenting with renal tubular disorders (Bagga *et al*. 1993). We hope soon to gain a better understanding of the pathogenesis and treatment of the tubulointerstitial disease in lupus nephritis since chronic tubulointerstitial damage predicts a poor long-term prognosis.

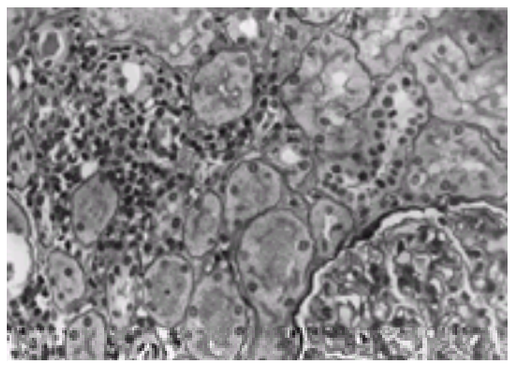

Fig. 7 Light photomicrograph of the renal biopsy of a 14-year-old girl with lupus nephritis illustrating the presence of interstitial inflammation. In this patient immunofluorescence and electron microscopy demonstrated the presence of immune deposits along tubular basement membranes. Interstitial inflammation is a common finding in lupus nephritis and often occurs in the absence of extraglomerular immune complex deposition.

As recently reviewed by Appel *et al*., a variety of renal vascular lesions may be observed in SLE patients, including those associated with vascular immune complex deposits, non-inflammatory necrotizing vasculopathy, thrombotic microangiopathy and true renal vasculitis (Appel *et al*. 1994). Studies of renal vascular lesions in

childhood SLE have not been published. Experience in adults suggests a worse prognosis than in patients without vascular lesions.

Regular evaluation of the urine is important in all SLE patients. Many patients with renal involvement develop urinary abnormalities within 3 years of diagnosis, but a longer lag period can occur (Tucker *et al*. 1995). One of our patients recently developed focal proliferative lupus nephritis 5 years after the initial diagnosis of SLE which was made at 11 years of age. The importance of follow-up is illustrated by the fact that there is now a 72 per cent incidence of renal disease in our patients that were reported in the 1993 edition of this chapter, while only 42 per cent of patients referred to our clinic since 1991 have so far had clinical evidence of nephritis.

Hypertension is a common manifestation in patients with SLE. An elevated blood pressure prior to steroid therapy suggests that the patient has DPLN or renovascular disease. The latter is unusual but has been observed in patients with the antiphospholipid antibodies who have a hypercoaguable state. One patient followed at our institution presented with an infarct to the lower pole of one kidney as the result of a segmental occlusion of the renal vein, in the absence of evidence of glomerulonephritis.

It is rare that patients present with haematuria due to a bleeding diathesis. We treated an 11-year-old girl who had gross haematuria resulting from factor-II deficiency. The bleeding reversed with plasma therapy and factor-II levels were normalized by treatment with steroids (Eberhard *et al*. 1994).

Urological manifestations of SLE are not widely recognized but are clearly documented in the literature. Urinary frequency may occur as a result of autoimmune cystitis. However, it is always important to rule out an infectious cause, particularly in immunosuppressed patients.

Treatment of nephritis

There is probably no topic in medicine more disputed than the management of patients with SLE. Once renal involvement is documented, immunosuppression is indicated and steroids remain the mainstay of therapy. The majority of patients with mesangial and focal proliferative disease are successfully managed with steroids alone, although those with associated focal segmental necrotizing lesions have a poorer prognosis and are likely to require additional treatment including the use of cytotoxic agents. Evaluation of newer treatment protocols for patients with DPLN is impeded by the need to follow adequate numbers of patients for 10 to 15 years in order to observe meaningful differences. Although our patients with DPLN are not managed by a rigid protocol, several principles of therapy have evolved.

1. Initial treatment always includes high-dose steroids (prednisone 2 mg/kg per day; maximum 60 mg/day), divided three times daily for 4 to 8 weeks, consolidated to once daily and then tapered slowly over several months. Most patients are maintained on low-dose prednisone for years in an attempt to minimize the risk of subsequent relapses.
2. Azathioprine (2 to 3 mg/kg per day) is initiated within the first month of diagnosis because we believe that the best information available today suggests that patients given cytotoxic drugs in addition to prednisone have a better long-term outcome. Although preliminary data suggests that cyclophosphamide might be a better cytotoxic drug for these patients (Austin *et al*. 1986), the majority of our patients do well without it. Since the long-term toxicities of cyclophosphamide (especially malignancy and infertility) are correlated with the lifetime accumulated dose, we are reluctant to use this drug initially in these children facing a lifetime of chronic illness. Concern about accelerated atherosclerosis by prolonged steroid use (Rubin *et al*. 1985) further rationalizes our use of azathioprine as a steroid-sparing agent. An interesting alternative that we have not used (Cameron 1994) is a protocol that includes an initial 8- to 12-week course of oral cyclophosphamide (3 mg/kg ideal body weight for height, reduced if renal insufficiency is present) followed by maintenance therapy with azathioprine.
3. Intravenous pulse cyclophosphamide given in a slightly modified version of the NIH protocol is used primarily to treat patients whose renal disease is controlled inadequately by steroids plus azathioprine. To date we have treated seven DPLN patients with intravenous cyclophosphamide. Although cyclophosphamide is an important addition to the therapeutic armamentarium, renal relapses following cessation of therapy clearly occur and cyclophosphamide is not universally effective. We have only seen a sustained remission in one in seven patients treated at our institution. Two patients experienced significant disease reactivation (carotid artery thrombosis and renal failure; recurrence of nephrotic syndrome and deterioration of renal function) after completion of the 6 monthly doses during the 3-month period before the seventh dose was administered. One patient who was also maintained on high-dose prednisone appeared resistant to intravenous cyclophosphamide. After 8 monthly doses she remained hypocomplementaemic, serologically active and had a deterioration in her protein excretion from 0.7 to 2.4 g/24 h. Two additional patients were treated with cyclophosphamide for non-compliance with prednisone and azathioprine. One of these patients had normal renal function after a 2-year course of treatment but in follow-up remained non-compliant. He now has chronic renal failure after 9 years of the disease. The second patient refused to take prednisone during cyclophosphamide therapy. The protocol was discontinued after 7 doses due to non-responsive disease. One year ago this patient consented to treatment with prednisone and azathioprine and is currently in remission. The final patient that we treated had significant chronic renal disease at presentation. Her therapy was discontinued after 4 doses. Although she required dialysis during her initial admission and eventually came off dialysis for 2.5 years, we would no longer recommend cyclophosphamide therapy in this kind of patient (see next point).
4. The chronicity index should be taken into consideration when making decisions about the use of cytotoxic drugs. If advanced chronic disease is present indicating that endstage renal disease is inevitable and severe extrarenal manifestations of SLE are not present, then cytotoxic drugs are not justified. The survival of SLE patients on dialysis and following renal transplantation is very good (Bumgardner 1988; Nossent *et al*. 1991). The risk of recurrent lupus nephritis in renal allografts is very low. Unfortunately the overall incidence of malignancy following solid organ transplantation is approximately 4 per cent (Penn 1988) and we are concerned about increasing this risk, particularly by treating such a patient with cyclophosphamide.
5. High-dose pulse steroids and plasmapheresis may have a role in the management of patients presenting with acute fulminating renal disease. Methotrexate therapy may be useful in selected patients with long-term disease that is difficult to control (Abud-Mendoza *et al*. 1993), but its role has not been established. Methotrexate should be restricted to patients with good renal function to avoid serious drug toxicities.
6. Over the past couple of years we have treated an increasing number of renal flares with intravenous methylprednisolone at a dose of 30 mg/kg (maximum 1000 mg) daily for 3 consecutive days each month for 6 months. Two of the five children recently treated were patients with DPLN unresponsive to intravenous cyclophosphamide. Short-term results have been encouraging but whether a sustained long-term benefit will be achieved is not yet clear.

Close follow-up of these patients is essential in order to monitor disease activity, complications of therapy, the patient's understanding of their disease and compliance with treatment. In the evaluation of the renal response to therapy, follow-up urinalysis and quantification of urinary protein excretion rates are obvious. The presence of either red cell or white cell casts may precede a renal relapse. Persistent proteinuria one year after the initiation of treatment predicts a worse long-term prognosis (Fraenkel *et al*. 1994). We feel that two additional parameters are useful markers of renal disease activity. The first is the serum complement profile, particularly levels for the third component of complement (C3). As demonstrated by Laitman *et al*., patient outcome is improved if CH50 levels are normalized during the initial phase of therapy and if they remain normal during the maintenance phase (Laitman *et al*. 1989). Since SLE relapses tend to be mimetic, nephritis is likely to recur during this period. Although we do not consider serological abnormalities alone (i.e., hypocomplementaemia, increasing anti-DNA antibody levels) an indication to re-treat a patient, clinically active disease frequently ensues and these patients need to be followed closely (Fig. 8).

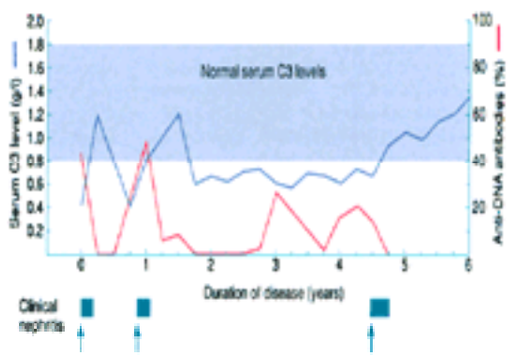

Fig. 8 Schematic summary of the clinical course of a girl with congenital C4 deficiency who developed SLE at 4 years of age associated with diffuse proliferative lupus nephritis. The value of monitoring serum C3 levels (solid line) is highlighted by her clinical course. Initial prednisone therapy (arrow) failed to maintain the C3 level in the normal range. She developed a clinical relapse of nephritis 10 months after the initial presentation, that was treated with prednisone and azathioprine (arrow). One year later the C3 level fell below the normal range. However, she remained clinically well for 3.5 years before findings of recurrent nephritis were documented and high-dose immunosuppression was reinitiated (arrow).

Preservation of renal function is an obvious goal in patients with lupus nephritis. Unfortunately, obtaining an accurate measurement of the glomerular filtration rate is

not easy. Taking inulin clearance as the 'gold standard', Meyers and his colleagues (Shemesh *et al*. 1985) have demonstrated that creatinine clearance determinations overestimate the glomerular filtration rate during the acute phase of lupus nephritis, probably as a result of tubular secretion of creatinine (Table 7). Isotopic tests (e.g. 99Tc-DTPA) appear to provide a more accurate measure of glomerular filtration rate in these patients.

Inulin clearance (ml/min per 1.73m^2)	n	Creatinine /inulin clearance
>80	13	1.20 ± 0.08
40–80	10	1.57 ± 0.11
<40	21	2.21 ± 0.16

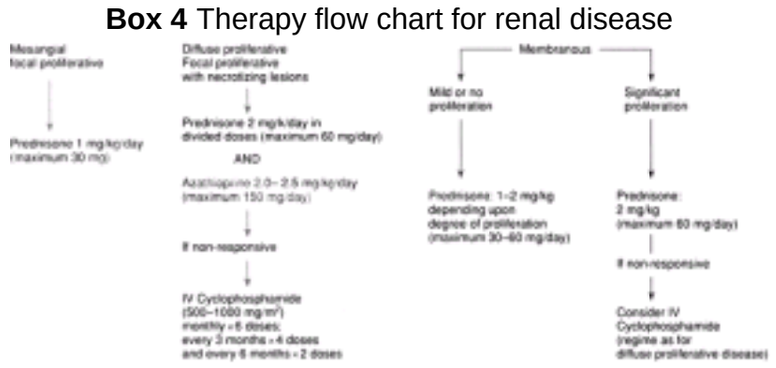
[a]As illustrated by the study of Shemesh *et al*. (1985) the creatinine clearance does not provide an accurate measure of the true glomerular filtration rate (assessed by inulin clearance rates) in patients with lupus nephritis. The more severe the reduction in renal function, the greater is this discrepancy.
C = clearance.

Table 7 Creatinine clearance is an unreliable measure of glomerular filtration rate in lupus nephritis [a]

The optimal treatment of patients with lupus membranous nephropathy is unknown. We agree with Appel *et al*. that the long-term outcome of these patients is less favourable than was suggested originally (Appel *et al*. 1987). A subset of these patients appears destined to develop chronic renal failure and we believe that they should be treated with high-dose steroids. Less clear is the indication for alkylating agents. There is some encouraging preliminary evidence that alkylating agents are beneficial in the treatment of patients with the severe idiopathic form of membranous nephropathy (Imperiale *et al*. 1995) and it is tempting to speculate that alkylating agents may also be useful in patients with membranous nephropathy due to SLE. Unfortunately appropriate clinical trials have not yet addressed these important issues. A recent review by Sloan *et al*. (1996) reported that long-term prognosis in patients with SLE membranous nephritis was determined by the degree of associated glomerular inflammation seen on biopsy. The only patient at our institution with membranous SLE and diffuse endocapillary proliferation developed endstage renal disease.

For an overview of suggested therapy for renal disease see Box 4.

Box 4 Therapy flow chart for renal disease

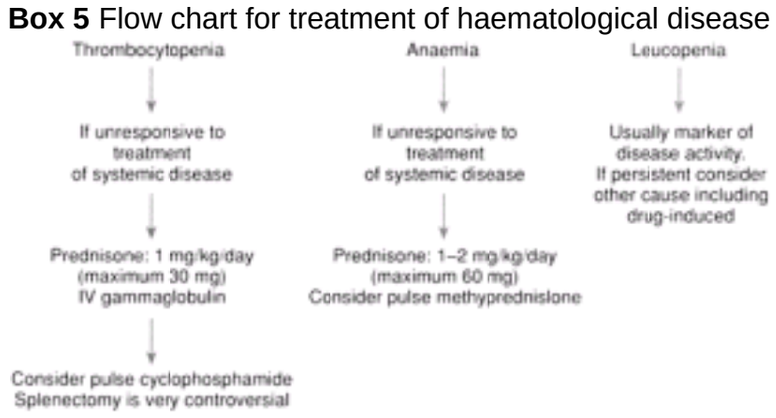


Haematological involvement

Anaemia, thrombocytopenia, and leucopenia are very common laboratory abnormalities seen in 50 to 75 per cent of patients with SLE. The most common anaemia is normochromic normocytic, which when persistent usually becomes a microcytic and hypochromic anaemia. There is both a decrease in the serum iron level and in the iron-binding capacity, with increased iron in macrophages. The serum ferritin is normal or elevated, as ferritin production is increased as part of the acute-phase response. In our experience, in the absence of an immune-mediated haemolytic anaemia (see below), the anaemia is rarely severe.

The Coombs' test is positive in approximately 30 to 40 per cent of our patients but less than 10 per cent of patients have overt haemolysis. Haemolysis is seen generally only in the presence of immunoglobulin on the surface of erythrocytes. The likely explanation for the lack of haemolysis when only complement is present is that red blood cells bind immune complexes through their C3b receptor (Wilson *et al*. 1989). Therefore, the presence of complement components (C3b) on the red blood cell probably represents the presence of immune complexes rather than of autoantibodies directed against erythrocytes. Furthermore, complement activation products, C4d and C3b, may non-specifically coat red blood cells and therefore, can be detected in a Coombs' test. When present, the autoimmune haemolytic anaemia may be a warm or cold. Although rarer than the warm, cold autoimmune haemolytic anaemia is usually associated with Raynaud's phenomenon or cold intolerance and patients more commonly present with haemolysis. Drug-induced haemolytic anaemia in our patients is not a common problem. Haemolysis secondary to autoimmune haemolytic anaemia is usually mild but occasionally it may be severe enough to require treatment with high-dose steroids for prolonged periods of time or even azathioprine or cyclophosphamide. Occasionally transfusions are required, but if the anaemia is secondary to an indirect Coombs' test then the cross-match will be incompatible and type O Rh-negative blood is recommended. For an overview of suggested therapy for anaemia see Box 5.

Box 5 Flow chart for treatment of haematological disease



Thrombocytopenia is present in 15 to 45 per cent and in our experience, it may be the initial presentation in up to 15 per cent of paediatric cases. The thrombocytopenia is secondary to peripheral destruction rather than bone marrow suppression. It can occur early in the disease course and may present as classic idiopathic thrombocytopenic purpura, which would be better referred to as autoimmune thrombocytopenic purpura. We have found that these patients have a positive antinuclear antibody and most patients will have decreased complement levels (uncommon in isolated idiopathic thrombocytopenic purpura). Patients with autoimmune thrombocytopenic purpura may have a transient response to intravenous immunoglobulin treatment. The presentation of isolated idiopathic thrombocytopenic purpura progressing to SLE is more common in children than adults. The development of SLE may take 20 years or more. Most patients with idiopathic thrombocytopenic purpura and autoimmune haemolytic anaemia, so-called Evans syndrome, will probably develop SLE. Interestingly, many patients with thrombocytopenia secondary to SLE will respond to therapy with intravenous immunoglobulin.

Despite the high incidence of thrombocytopenia in paediatric SLE, bleeding is unusual and usually occurs only when the platelet count is less than 10 000. Most patients with thrombocytopenia will respond to steroid therapy. If the patient becomes either steroid-resistant or steroid-dependent then pulse steroid therapy or intravenous immunoglobulin therapy should be tried, with cyclophosphamide reserved for resistant cases (Lipnick *et al*. 1990). Splenectomy is very controversial as some reports have suggested not only a lack of effect but also an unacceptably high increase in infections of these patients postsplenectomy. These findings are not universal and splenectomy may have a role in resistant, persistent life-threatening thrombocytopenia. For an overview of suggested therapy for thrombocytopenia see Box 5.

In addition to thrombocytopenia, acquired abnormalities of platelet function have been described. These include serum inhibitors that decrease aggregation and block

uptake and storage of adenosine diphosphate and serotonin. Collagen-induced aggregation may be absent and adenosine diphosphate and adrenaline-induced aggregation impaired (Decker *et al*. 1979). These defects generally present as purpura while overt bleeding is rare.

Leucopenia is seen in 20 to 40 per cent of cases of paediatric SLE. Both lymphopenia and granulocytopenia can be seen. The lymphopenia may be secondary to the presence of circulating lymphocytotoxic antibodies which may be cold- or warm-reacting; IgM or IgG; and directed against resting or activated cells (Peake *et al*. 1988). In many patients lymphopenia is a sensitive marker of general disease activity and will rarely if ever require specific therapy. A lymphopenia may also be secondary to therapy with azathioprine or cyclophosphamide. Granulocytopenia is usually secondary to a central depression of granulopoiesis or splenic sequestration and more rarely antigranulocyte antibodies. Drugs including prednisone, azathioprine, and cyclophosphamide decrease granulocyte function and/or numbers. All of these problems probably contribute to the increased susceptibility to infection seen in SLE patients.

Other unusual haematological problems in SLE include myelofibrosis, and thrombotic thrombocytopenic purpura. Myelofibrosis, although rarely seen, is more common in the paediatric age group while there have been reports of thrombotic thrombocytopenic purpura progressing to SLE. Thrombotic thrombocytopenic purpura, as opposed to haemolytic-uraemic syndrome, is rarely seen in childhood. When it does occur, the diagnosis of SLE should be considered. An interesting association is the development of SLE in adolescents with sickle-cell anaemia; the SLE usually develops prior to the age of 18 (Katsanis *et al*. 1987).

Following thrombocytopenia, the presence of the lupus anticoagulant is the most common coagulation defect. This abnormality presents with an elevated partial thromboplastin time and occurs in 20 to 30 per cent of paediatric cases. The prothrombin time is usually normal or minimally elevated and if markedly prolonged a second defect is probably present (see below). The lupus anticoagulant reacts with the phospholipid portion of the prothrombin activator complex. This antibody cross-reacts with anticardiolipin antibodies, which are seen commonly in paediatric SLE (Shergy *et al*. 1988), and may be responsible for the false-positive VDRL (Veneral Disease Research Laboratory). Patients with the lupus anticoagulant do not bleed but rather have an increased incidence of deep vein thrombosis, thromboemboli, and less commonly arterial thrombosis. The increased partial thromboplastin time will usually resolve with steroids; however, treatment should not be directed to this laboratory finding alone, but reserved for patients who have clotting problems. When a venous or arterial thrombosis occurs, then patients should be subjected to anticoagulation with heparin followed by warfarin. We recommend that these patients receive full anticoagulant treatment for 3 to 6 months followed by long-term low-dose anticoagulation. We suggest that the INR should be maintained between 1.5 and 2.0. A recent adult study supports the view of long-term anticoagulation although the suggested INR range is higher (Khamashta *et al*. 1995). In many patients the presence of the anticoagulant correlates with disease activity, especially with vasculitis. The anticoagulant may be IgG, IgM or both. The full spectrum of diseases associated with antiphospholipid antibodies and the lupus anticoagulant is fully discussed in Chapter 5.7.1 and Chapter 5.7.3. However, it must be remembered that patients with antiphospholipid antibodies may not only present with venous or arterial events, but chorea may be the only manifestation of these autoantibodies. These patients with chorea are at risk for thrombosis or other manifestations of the antiphospholipid antibody syndrome.

Specific inhibitors of other factors of the coagulation cascade have been described. The most common of these is prothrombin deficiency which is associated usually with the lupus anticoagulant. These patients, unlike those with the anticoagulant only, present with bleeding and a prolonged prothrombin and partial thromboblastin time. This defect is reported in approximately 5 per cent of adult patients with the lupus anticoagulant or in less than 1 per cent of all adult SLE patients. Prothrombin deficiency appears to be more common in paediatric SLE and a review of our patients demonstrated this abnormality in approximately 4 per cent of our SLE patients (Eberhard *et al*. 1994). As expected these patients presented with bleeding rather than clotting. Many patients with prothrombin deficiency have an associated mild thrombocytopenia, but the platelet counts are generally greater than 50 000. The aetiology is unknown and it may result from an acquired production defect or secondary to the presence of an antiprothrombin antibody. We have found that the prothrombin deficiency will rapidly respond to steroid therapy. More rarely a steroid-responsive acquired von Willebrand's defect has been described.

Splenomegaly is quite common occurring in 20 to 30 per cent of paediatric cases. In our series of patients splenomegaly was seen commonly in patients less than 10 years of age and may be the result of the generalized inflammatory state. Functional asplenia has been described and this abnormality of splenic function may increase the incidence of sepsis (Malleson 1989).

The final haematological complication we will discuss is the association of SLE and cancer. Despite the frequent use of immunosuppressive therapy and abnormal immunoregulation, malignancy as a cause of death is rare. There may be a higher incidence of neoplasia than in the general population, but most tumours are of epithelial origin and are easily treated. There have been case reports of lymphoma, including Burkitt's lymphoma, in patients with SLE; from the other perspective, patients with lymphoma may have many features suggestive of SLE, including the presence of a high titre of antinuclear antibodies (Posner *et al*. 1990). We have seen cases of lymphomas presenting as 'SLE' including a positive, high-titre, speckled antinuclear antibody. Therefore, the presence of a high-titred antinuclear antibody does not help in differentiating these two disorders.

Cardiac involvement

Symptomatic pericarditis is the most common cardiac manifestation occurring in approximately 5 to 25 per cent of patients with SLE and is commonly associated with pleurisy (De Inocencio and Lovell 1994). The diagnosis is made by physical examination, chest radiography, electrocardiogram and confirmed by echocardiogram. Cardiac tamponade rarely occurs. Studies in adults have suggested that echocardiographic evidence of pericarditis may occur in up to 75 per cent of patients (Doherty and Siegel 1985). Similar studies have not been performed in children. Most cases of pericarditis will rapidly respond to either non-steroidal anti-inflammatory drugs alone, or low to moderate dose of corticosteroids. We suggest the initial use of indomethacin at a dose of 3 mg/kg per day divided into three doses. Indomethacin appears to work well in patients with SLE and is well tolerated in the paediatric patient. Rarely pulse intravenous methylprednisolone is required and on occasion pericardiocentesis is necessary if tamponade is impending. Antimalarials may be of benefit in the long-term management of pericarditis.

The diagnosis of myocarditis or endocarditis is uncommon, with clinically detectable or significant myocarditis in less than10 per cent of patients (Badui *et al*. 1985). However, autopsy studies in adults have shown evidence of myocarditis in 25 to 50 per cent of patients. There is no similar autopsy data available in children. Occasionally, patients with myocarditis may present with first degree atrioventricular block or arrhythmia. A study from 1985 showed that Libman–Sacks endocarditis as present in 30 to 50 per cent of all hearts from patients with SLE at autopsy, while echocardiographic evidence of small vegetations may occur in 2 to 5 per cent of cases (Doherty and Siegel 1985). These vegetations commonly occur at valvular rings and commissures. However, clinically significant lesions causing aortic or mitral stenosis or regurgitation are very rare.

Unlike Libman–Sacks endocarditis which appears to be declining with steroid usage, atherosclerotic heart disease and myocardial infarction are increasing with greater steroid usage and longevity of patients (Rubin *et al*. 1985). Other risk factors, especially hypertension and hyperlipidaemia further increase the risk of myocardial infarction. The presence of either the lupus anticoagulant or antiphospholipid antibodies may further predispose to thrombosis and myocardial infarction. Hyperlipidaemia can either be the result of a primary hyperlipidaemia of SLE or secondary to treatment with steroids, which alters lipid profiles including cholesterol, triglycerides and both high-density and low-density lipoprotein levels (Ilowite *et al*. 1988). Although myocardial infarction during childhood or adolescence is rare, the incidence of myocardial infarction in young adults (under 25 years of age) with initial onset of SLE in the paediatric age is increasing. When myocardial infarction or chest pain occurs in young patients or shortly following the diagnosis of SLE, the presence of coronary arteritis must be suspected (Friedman *et al*. 1990). Although it occurs in less than1 per cent of cases, aggressive treatment of this potentially life-threatening complication with high-dose steroids and immunosuppressive agents is required. We have found recently that many paediatric patients may have asymptomatic abnormalities of cardiac perfusion, which can be demonstrated by nuclear cardiac imaging. The clinical significance of these abnormalities is unknown but they may predispose these patients to early ischaemic heart disease.

Congenital heart block and neonatal lupus erythematosus will be dealt with in another section.

Pulmonary involvement

Pulmonary involvement is common in paediatric SLE occurring in 25 to 75 per cent of cases. The manifestations range from severe life-threatening pulmonary haemorrhage or infection to asymptomatic abnormalities of pulmonary function tests (see Table 8 for a complete list of pulmonary complications). Decreased carbon monoxide diffusing capacity is the most common abnormality in both paediatric and adults patients; in one paediatric series it was seen in 100 per cent of unselected patients (Delgado *et al*. 1990). The next most common abnormality in the pulmonary function test is a restrictive pattern in 35 to 60 per cent of cases, while an obstructive defect is uncommon. The functional defects are probably secondary to chronic fibrotic changes that in turn are secondary to mild subclinical lupus pneumonitis, as suggested by the diffusing capacity abnormalities and restrictive rather than obstructive defects. These abnormalities rarely require specific therapy.

Pleuritis
Diaphragm involvement including shrinking lungs
Pneumonitis (acute or chronic)
Vasculitis
Pulmonary haemorrhage
Pulmonary emboli
Isolated pulmonary function test abnormalities
Drug-induced changes
Pulmonary hypertension

Table 8 Pulmonary involvement in childhood SLE

Pleural involvement occurs in up to 50 per cent of cases at some time during the disease course and is seen commonly in association with pericarditis. However, isolated pleuritis, presenting as chest pain, can occur during a systemic flare and may be unilateral. Pleural fluid examination reveals decreased levels of C3 and C4, an increased white blood-cell count, normal glucose and can show a positive antinuclear antibody. There have been reports of a positive antinuclear antibody only in the pleural fluid but not the peripheral blood. When the pleuritis is mild, treatment can consist of anti-inflammatory doses of non-steroidals, but usually prednisone, at a low to moderate dose, is required for complete resolution of symptoms. Similar to patients with pericarditis, antimalarials may be of benefit in the long-term management of pleuritis.

Dyspnoea, a common symptom, can be secondary to acute or chronic pneumonitis, pulmonary infection, pulmonary haemorrhage or shrinking lung syndrome. The dramatic presentation of acute pneumonitis with fever, cough, dyspnoea, hypoxia and chest pain occurs in only 3 to10 per cent of patients (Carette *et al*. 1984). Pulmonary haemorrhage has a reported death rate of up to 50 per cent and in many paediatric studies this complication accounts for 10 to 20 per cent of deaths despite its occurrence in less than 5 per cent of patients (Nadorra and Landing 1987). Pulmonary haemorrhage or acute pneumonitis must be differentiated from congestive heart failure, pulmonary infection, and non-cardiogenic pulmonary oedema that are the side-effects of drugs and secondary to uraemia, pancreatitis, or sepsis. The clinical differentiation of acute SLE pneumonitis from pulmonary haemorrhage may be aided by a fall in haemoglobin, the presence of haemoptysis and an increased carbon monoxide diffusing capacity on pulmonary function tests seen in pulmonary haemorrhage. The treatment for both is similar and the acute management may require intubation and ventilation in addition to aggressive immunosuppressive therapy, which may include high-dose prednisone and cyclophosphamide. Pulmonary haemorrhage may be the initial and sole manifestation of paediatric SLE and this disease should be considered in young patients presenting with pulmonary haemorrhage even in the absence of other disease manifestations.

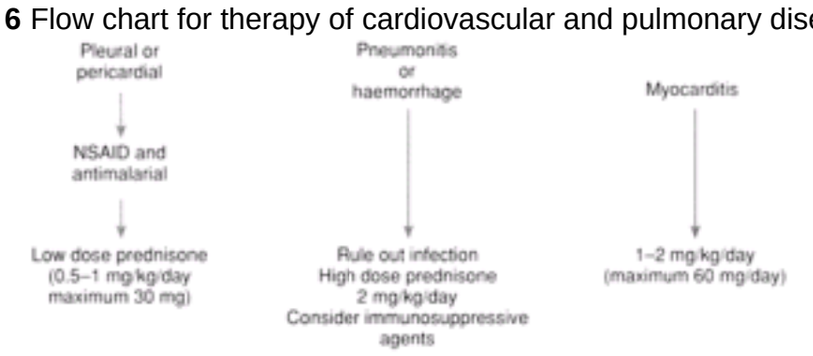
In the acutely ill patient the possibility of pulmonary infection must be considered. There is an increased incidence of infection even prior to steroid or immunosuppressive treatment. In addition to the more common bacterial and viral causes of pneumonia, these patients are at risk for opportunistic infection including fungal, parasitic and protozoan infection. We have seen a patient on prednisone and azathioprine who developed *Pneumocystis carinii* pneumonia and others have described patients with this complication while on methotrexate and prednisone. When patients present with acute respiratory failure and fever, we recommend treatment with broad-spectrum antibiotics and high-dose steroids including pulse therapy. If the above-mentioned opportunistic relevant infections are suspected clinically, then antifungal, antiprotozoan, antilegionella, antipneumocystis and even antinocardia therapy should be considered. If the patient does not improve quickly then a diagnostic open lung biopsy is necessary. The use of bronchial washings obtained via bronchoscopy should be considered early, especially if intubation is required.

In contrast to acute pneumonitis, chronic or interstitial pneumonitis has an insidious onset. Clinically significant disease is uncommon and usually follows long-standing SLE. When severe, most patients have clinically evident pulmonary involvement and present with cough and chest pain leading to dyspnoea and a decreased diffusing capacity. An autopsy study of 26 paediatric patients with SLE showed a mild chronic interstitial pneumonitis in all patients, with additional pulmonary lesions in 18 patients (Nadorra and Landing 1987). Most of the chronic lesions were asymptomatic prior to death.

A more unusual cause of dyspnoea is the shrinking lung syndrome. This disorder is diagnosed by chest radiography that demonstrates an elevated diaphragm in the clinical setting of dyspnoea, which might be mild. A paediatric review demonstrated radiographic evidence of an elevated diaphragm in 12 per cent of patients (Delgado *et al*. 1990). They hypothesized that this syndrome was caused by a combination of inspiratory muscle dysfunction, recurrent pleuritis and atelectasis. The long-time outcome is generally good despite the lack of effective therapy, as it is usually a slowly progressive disease. Pulmonary function tests show abnormal diaphragm function and restrictive airway disease.

One of the most fascinating pulmonary manifestations of SLE is pulmonary hypertension (Asherson and Oakley 1986). Difficult to treat, pulmonary hypertension fortunately is rare and is seen usually only with long-standing disease. These patients present with classic signs and symptoms of primary pulmonary hypertension but it may evolve from one of five processes. The first is best regarded as primary pulmonary hypertension of SLE. There is no known cause or predisposing clinical setting. The second cause is secondary to pulmonary artery thrombosis or emboli and is seen in patients with antiphospholipid antibodies and/or with severe Raynaud's phenomenon. The third cause is secondary to chronic left ventricular failure. The fourth is secondary to chronic hypoxic from diffuse interstitial lung disease, with the hypertension usually out of proportion to the parenchymal disease. The final cause is obstruction of peripheral pulmonary vasculature secondary to vasculitis. Overall, the outcome of pulmonary hypertension is poor but luckily it is a rare manifestation, especially in children. An overview of suggested therapy for cardiovascular and pulmonary disease is given in Box 6.

Box 6 Flow chart for therapy of cardiovascular and pulmonary disease



Gastrointestinal disease

Gastrointestinal involvement occurs in 20 to 40 per cent of paediatric patients. The most common complaint is abdominal pain that can be the result of peritoneal inflammation (serositis), vasculitis, pancreatitis and/or direct bowel wall involvement (enteritis). In many patients, the abdominal pain heralds a disease flare in another system. The presentation of serositis may vary from mild crampy or colicky pain to severe pain with a rigid abdomen. It can be difficult to differentiate peritoneal inflammation as a manifestation of the underlying SLE from infective peritonitis.

Bowel wall inflammation presenting as crampy, abdominal pain and diarrhoea can be caused by a primary enteritis or be secondary to a mesenteric vasculitis or thrombosis (Hoffman and Katz 1980). The latter two are generally more acute and may be accompanied by bloody diarrhoea and nausea or vomiting. These disorders must be differentiated because vasculitis with thrombosis may require urgent surgery owing to the risk of bowel ischaemia, while most cases of non-thrombotic enteritis will respond to steroids. Involvement of other organ systems may aid in the diagnosis as there is an association of severe enteritis with central nervous system disease and lupus cystitis (Orth *et al*. 1983). This disorder requires aggressive immunosuppressive therapy and although this is an unusual association, paediatric cases have been described. We have seen a patient present with cystitis who rapidly developed severe enteritis with bowel perforation, disease of the central nervous system and nephritis. Despite aggressive immunosuppressive therapy, the patient died (Eberhard *et al*. 1991a).

An autopsy study of 26 young patients demonstrated that abdominal pain occurred in 65 per cent of all paediatric patients and gastrointestinal bleeding in 46 per cent. Dysphagia and symptoms of reflux were unusual. In 15 out of 25 autopsies a gastrointestinal 'vasculopathy' was found with ischaemic lesions, and a non-specific

infiltrate was found in 96 per cent. In 20 per cent of the cases, autopsy findings of ischaemic bowel were clinically asymptomatic (Nadorra *et al*. 1987). These authors suggested that chronic lupus enteritis, as defined by the presence of a non-specific infiltrate, was common at autopsy. However, these patients probably had severe SLE, as they died before reaching adulthood.

Pancreatitis, although it must always be considered, is a rare cause of abdominal pain in paediatric patients. There are very few reports in the literature, with an overall incidence of less than 2 per cent. In order to determine the true incidence of pancreatic dysfunction in SLE, we prospectively evaluated pancreatic function and performed pancreatic ultrasonography in 36 patients. We did not find any significant pancreatic pathology over the 2 year study period and could not find any association of pancreatic function abnormalities with steroid or azathioprine use (Eberhard *et al*. 1992). However, others have reported pancreatitis associated with disease flares, some of which responded to increased steroid dose (Nadorra *et al*. 1987). Rarely a pancreatic pseudocyst may be present at diagnosis.

Liver disease

Hepatomegaly occurs in 40 to 50 per cent of paediatric patients, while abnormalities of liver function tests may occur in up to 25 per cent. However, the elevation of liver enzymes is usually mild and transient. When there is marked elevation of liver function tests another cause must be sought (Miller 1977). The clinical features of autoimmune chronic active hepatitis, so-called 'lupoid hepatitis', may mimic SLE. Both these diseases preferentially occur in adolescent females. Many patients with the autoimmune form of chronic active hepatitis have a malar rash, arthritis and autoantibodies including anti-DNA antibodies, but they rarely have renal involvement (Hall *et al*. 1985; Hall *et al*. 1986). The differentiation between SLE and autoimmune hepatitis may require a liver biopsy. When jaundice is a prominent feature in a known SLE patient then a second disease such as obstruction, haemolysis or viral hepatitis is probably the cause.

Liver involvement may be part of the generalized vasculitis and may explain the increased salicylate sensitivity seen in 10 to 20 per cent of SLE patients. However, salicylate toxicity rarely results in significant, permanent pathological changes. A similar percentage of patients with systemic juvenile arthritis, another disease with systemic vasculitis, develop salicylate sensitivity. An increased incidence of hepatotoxicity to other drugs including azathioprine, and even cyclophosphamide, has been reported. Rarely systemic vasculitis has resulted in hepatic rupture secondary to liver infarction. These patients present with an acute abdomen and usually have evidence of active vasculitis and Raynaud's phenomenon elsewhere.

Endocrine involvement

Thyroid involvement is the most common endocrine organ involved in SLE. In a prospective study we found that antithyroid antibodies are present in 45 per cent of paediatric patients and clinical hypothyroidism was present in 15 per cent (Eberhard *et al*. 1991b). The development of hypothyroidism usually preceded or was coincidental with the development of SLE. The association of these two diseases may reflect similar genetic susceptibility or a common inciting agent. Hyperthyroidism, although less common than hypothyroidism, occurs with an increased incidence in SLE patients than the general paediatric population. Steroid-induced diabetes mellitus occurs in up to 10 per cent of patients but a lower percentage require insulin treatment. There does not appear to be an increased incidence of diabetes mellitus in the absence of steroid therapy. Delayed puberty and menstrual abnormalities are seen commonly. However, these abnormalities are probably secondary to chronic illness and active disease, rather than as a direct result of the disease process. Rarely hypoparathyroidism has been reported in association with SLE. This diagnosis should be considered in the presence of unexplained hypocalcaemia.

Autoantibodies

The hallmark of SLE is the production of autoantibodies. There is a long list of antibodies directed against histone, non-histone, RNA-binding, cytoplasmic and nuclear proteins. Many articles have reviewed the structure and function of the autoantigens and their role in autoimmune disease. A good review of autoantibodies is found in Chapter 5.7.3 and therefore, in this section we will focus on the limited literature regarding specific autoantibodies and disease manifestation in paediatric SLE.

The most common autoantibody is antinuclear. Depending on the series and method of detection, a positive antinuclear antibody is seen in 85 to 100 per cent of paediatric patients. As in adults, adolescent patients negative for this antibody have been described. The incidence of true antinuclear antibody-negative SLE has decreased with the use of human cell line substrates and procedures that eliminate the loss of some of the extractable nuclear antigens. Historically, anti-DNA antibodies were present in 78 to 87 per cent of cases depending on the series. The older series tend to have a higher incidence than the more recent series. This probably reflects the increase in awareness of paediatric SLE without anti-DNA antibodies and we have found anti-DNA antibodies in approximately 70 per cent of our cases. Studies in adults have suggested that patients with renal disease have higher avidity antibodies than patients with central nervous system disease, in whom anti-DNA antibodies are less common. Similar studies have not been undertaken in children. A paediatric study demonstrated that a lower percentage of paediatric SLE patients had a lower percentage of patients with IgG anti-DNA antibodies than adults, while conversely IgM anti-DNA antibodies were present in a higher percentage of paediatric patients. The anti-DNA antibodies measured were directed against single-stranded DNA (Shergy *et al*. 1989). Similarly there was an increased percentage of paediatric patients with IgM anti-Sm, anticardiolipin and anti-70 kDa ribonucleoprotein antibodies when compared with adult SLE patients (Ward *et al*. 1990). The authors suggested that this was the result of a time-related maturation of the immune response. Therefore, evidence for not only IgG antibodies but also IgM antibodies should be sought in paediatric patients. In enzyme-linked immunosorbent assays (ELISA), the overall incidence of anti-Sm antibodies was 58 per cent, anticardiolipin antibodies were present in 50 per cent of patients, and anti-70 kDa ribonucleoprotein antibodies were present in more than 90 per cent of patients.

Rheumatoid factor has been seen in 12 to 29 per cent of patients by conventional methods. To date there has been no study of the incidence of rheumatoid factor as detected by ELISA. Anticardiolipin antibodies may be present in up to 30 per cent of patients and the lupus anticoagulant is present in approximately 20 per cent of cases. No studies have examined the incidence of anti-Ro and/or anti-La antibodies in paediatric patients, but similar to adults, the presence of anti-Ro and anti-La antibodies defines a population which is at risk of a photosensitive rash and subacute cutaneous lupus.

As previously stated in the haematology section, the presence of anticardiolipin antibodies, the lupus anticoagulant and antiphospholipid antibodies is associated with an increased risk of thrombosis. These autoantibodies are common in paediatric patients and these patients are at increased risk for thrombosis (Shergy *et al*. 1988; Molta *et al*. 1993; Ravelli *et al*. 1994). In our experience, thrombosis may occur in up to 50 per cent of patients with detectable antiphospholipid antibodies. The thrombosis may be arterial or venous. Furthermore, these patients are at risk for the development of other manifestations of the antiphospholipid antibody syndrome including chorea, avascular necrosis, epilepsy, migraine headache, and livedo reticularis (Ravelli *et al*. 1994). There have been recent reports of neonatal thrombosis as the result of the transplacental passage of maternal antiphospholipid antibodies (see section on neonatal lupus erythematosus).

Antiribosomal P antibodies have been addressed in more detail in the section on central nervous system disease. These antibodies appear to be present in approximately 15 per cent of all patients with SLE and there is an increased incidence of antiribosomal P antibodies in patients with psychosis. In patients with psychosis titres of antiribosomal P antibodies may vary with disease activity in the central nervous system. These autoantibodies may be either IgM or IgG.

Similar to the findings seen in spouses of adults with SLE, autoantibodies have been found to be increased in the sera of relatives of paediatric SLE patients. More recently, the presence and titre of anti-Ro antibodies in the asymptomatic mothers of children with SLE correlated with the onset of SLE prior to age 10 and with the male sex (Lehman *et al*. 1989a). The reasons for these observations are not clear.

Neonatal lupus erythematosus

The neonatal lupus erythematosus syndrome (NLE) is a disease of the newborn defined by the demonstration of maternal autoantibodies and characteristic clinical features in the neonatal period. NLE is assumed to be the result of fetal and/or neonatal damage caused by the transplacental passage of maternal IgG autoantibodies. The major clinical manifestations are cardiac and dermatological, with complete congenital heart block being the most significant lesion (Reed *et al*. 1983; Watson *et al*. 1984; Lee *et al*. 1986). More rarely haemolytic anaemia, thrombocytopenia, urinary abnormalities and liver dysfunction are seen (Watson *et al*. 1984; McCune *et al*. 1987). Most early reports suggested that children with NLE are born to mothers with anti-Ro antibodies (Reed *et al*. 1983; Watson *et al*. 1984; Lee *et al*. 1986). However, in larger studies, we and others have demonstrated that the presence of anti-La antibodies in association with anti-Ro antibodies is a more specific disease maker, especially in patients with congenital heart block, and that the presence of anti-La antibodies was a greater risk factor for the development of congenital heart block than the presence of anti-Ro antibodies alone (Buyon and Winchester 1990; Silverman *et al*. 1991). In addition, antibodies directed against 52 kDa Ro were more specific than antibodies directed against the 60 kDa form in determining the risk of development of NLE, although other studies have suggested the importance of antinative 60 kDa Ro antibodies (Buyon *et al*. 1993; Lee *et al*. 1994; Reichlin *et al*. 1994).

The clinical spectrum

Cardiac lesions

The characteristic cardiac lesion of NLE is isolated congenital heart block although there have been case reports of congenital heart block in association with endomyocardial fibroelastosis, valvular insufficiency and patent ductus arteriosus. Ho *et al*. described the histopathology of eight hearts with complete congenital heart block, seven of which were associated with maternal anti-Ro antibodies (Ho *et al*. 1986). There was no mention of the maternal anti-La antibody status. These seven hearts all showed identical abnormalities in the conducting system, namely, a lack of contact between atrial myocardial tissue and the more distal part of the atrioventricular conduction (Lev *et al*. 1971).

In some cases of congenital heart block, in addition to the above mentioned changes, ventricular endomyocardial fibrosis and small inflammatory infiltrates have been described (Hogg 1957). The histopathology of the lesion suggests either early interference with normal organogenesis, or intrauterine inflammatory lesions resulting in subsequent scarring (Carter *et al*. 1974). We believe the latter hypothesis to be true for the following reasons: (i) bradycardia is usually a later intrauterine event corresponding to the time when maternal autoantibodies begin to cross the placenta; (ii) immunofluorescent studies have shown deposition of IgG, complement components and fibrin indicating at least an initial inflammatory event; and (iii) case reports of mothers with SLE which describe the sudden onset of fetal bradycardia and congestive heart failure at 23 to 24 weeks and the reversal of intrauterine congestive heart failure and myocarditis but not the heart block with treatment of the mother with dexamethasone, with or without plasmapheresis. Taken together these data suggests there is initially an inflammatory lesion in the fetal heart. The inflammatory lesion hypothesis is supported by the pathological demonstration of fibrosis at the chordae tendinae and the ventricular septum (Smith and Ho 1994; Weber and Myers 1994).

Investigators have attempted to use animal models to determine the cause of congenital heart block. Anti-Ro and/or anti-La antibodies may alter membrane action potential of rabbit conduction tissue and these abnormalities may resemble the cardiac conduction disorders seen in NLE (Alexander *et al*. 1992; Garcia *et al*. 1994). However, these conduction changes were not specific for anti-Ro/La sera derived from mothers of children with NLE, and sera obtained from mothers who had delivered unaffected children had similar effects on the rabbit conducting tissue (Garcia *et al*. 1994).

Congenital heart block was described originally as a relatively benign condition. However, studies of large series of patients with this condition are not as optimistic. Of our 60 patients with congenital heart block, approximately 50 per cent have required pacemaker therapy. The pacemaker may not be necessary neonatally but rather in later life. We have had neonatal deaths and later deaths as a result of pacemaker failure. A follow-up report of 14 children with congenital heart block showed that 3 of the children (21 per cent) died neonatally of congestive heart failure secondary to the block and a further 5 required pacemakers (McCune *et al*. 1987). Therefore, although congenital heart block has been felt to be rather benign, most series have demonstrated both intrauterine and neonatal deaths with the potential for further deaths to occur secondary to pacemaker failure.

Skin lesions

The skin lesions of NLE are very similar to those of subacute cutaneous lupus erythematosus in which at least 80 per cent of patients have anti-Ro antibodies (Deng *et al*. 1984). Both Ro and La antigens have been documented in human skin (Harmon *et al*. 1984; Lee *et al*. 1985), and exposure to ultraviolet light increases the expression of Ro on the surface of keratinocytes (LeFeber *et al*. 1984). This feature may explain the photosensitive nature of the skin rash in both NLE and subacute cutaneous lupus erythematosus (Fig. 9). Maternally transmitted factors other than anti-Ro and anti-La antibodies may play a role in the development of cutaneous NLE. Although cutaneous NLE is almost universally associated with anti-Ro and/or anti-La antibodies, there have been reports of the condition with anti-U1 ribonucleoprotein antibodies, instead of anti-Ro or anti-La antibodies. In our prospective study, we demonstrated maternal anti-Ro antibodies in 100 per cent of cutaneous NLE patients, while anti-La antibodies were present in 75 per cent of sera.

Fig. 9 The face of a 3-month-old baby delivered to a healthy mother with anti-Ro and anti-La antibodies. Note the scaly erythematosus areas around the eyes. This rash healed without scarring following the use of topical steroid cream.

Liver disease

Enlargement of the liver, spleen or both occurs in approximately 30 per cent of cases of NLE. The enlargement of these organs may be secondary to congestive heart failure, but there may also be primary hepatic enlargement. In most cases, the liver disease is associated with other clinical manifestations of NLE. These patients presented with liver enlargement, elevated levels of hepatic enzymes and evidence of cholestasis (Laxer *et al*. 1990). The histological changes seen on biopsy include giant cell transformation, ductal obstruction and extramedullary haematopoiesis. The liver changes generally are not severe and recovery from the liver disease usually occurs despite the presence of residual fibrosis on repeat biopsy. However, we and others have seen cases of severe intrahepatic cholestasis secondary to NLE (Lee *et al*. 1993; Rosh *et al*. 1993).

Haematological problems occasionally occur including thrombocytopenia, rarely leading to bleeding, and a mild haemolytic anaemia. Urinary abnormalities include transient pyuria or urethritis, but to date there have been no cases of nephritis.

Treatment

Cutaneous NLE rarely requires treatment as usually it is self-limited and usually heals without scarring. In the unusual case with more severe or scarring lesions, topical steroids may be required. The liver disease of NLE will usually spontaneously resolve by the age of six months and does not require steroid treatment. However, if the cholestasis is severe, these infants may require a formula high in medium-chain triglycerides.

The treatment or prevention of congenital heart block is much more complex than the treatment of cutaneous NLE. Previously, it had been suggested that all mothers at risk for delivering a child with congenital heart block should be treated with plasmapheresis and dexamethasone throughout the pregnancy (Buyon *et al*. 1988). However, this form of treatment will subject both the mother and the fetus to significant risks during the pregnancy, and up to 90 per cent of mothers will deliver a normal child without congenital heart block, despite having previously delivered a child with this condition (McCune *et al*. 1987; Buyon *et al*. 1988). Therefore, the current recommendation is to monitor the fetus using fetal echocardiography to assess the developing heart, prior to the initiation of potentially toxic treatment. When congenital heart block and fetal hydrops is discovered during gestation, treatment of the mother with dexamethasone and plasmapheresis may reverse the fetal congestive heart failure but not the heart block. However, the efficacy of this therapy in altering the natural history of congenital heart block is controversial and unproven. Children diagnosed with this condition should be delivered in a high-risk neonatal centre which can provide cardiac pacing. If the fetal bradycardia is recognized as congenital heart block rather than fetal distress, then unnecessary early, emergency delivery may be prevented. However, further prospective collaborative studies are required to determine the population at risk for this block and how to prevent it.

5.7.3 The antiphospholipid antibody syndrome

Munther A. Khamashta and G. R. V. Hughes

Introduction

In 1983, few rheumatologists would have predicted the interest that the introduction of the anticardiolipin test would generate in subsequent years (Harris *et al*. 1983). New autoantibodies turn up frequently in patients with systemic lupus erythematosus and there may have seemed little reason why anticardiolipin antibodies should have merited any more than passing interest. However, these particular autoantibodies had unusual characteristics that attracted the attention of investigators from a variety of disciplines (Fig. 1). One reason may have been the novelty of phospholipid molecules as antigens, given that most attention up to that time had focused on protein, DNA, and even polysaccharide antigens (Harris *et al*. 1994). In addition, these antibodies exhibited an easily detectable biological effect, as evidenced by their ability to prolong clotting times of plasma. More intriguing was their association with an unusual combination of clinical complications that included venous and arterial thrombosis, pregnancy loss, and thrombocytopenia (Hughes 1983; Hughes 1993).

Fig. 1 Antiphospholipid antibodies—linking many specialties (reproduced with permission of the Editor of *Clinical and Experimental Rheumatology*).

During the last decade, considerable progress has been made in understanding antiphospholipid antibodies and the disorder with which they are associated, but many questions remain unanswered, particularly those of pathogenesis and optimal treatment (Khamashta and Asherson 1995). A chronology of the major developments in the unfolding of the antiphospholipid syndrome story is listed in Table 1.

1906	Wassermann reaction (reagin)
1941	Reagin binds cardiolipin
1952	False positive test for syphilis
1959	Cofactor requirements for lupus anticoagulant activity
1960s	Lupus anticoagulant: association with thrombosis
1970s	Lupus anticoagulant is due to immunoglobulin
1975	Lupus anticoagulant: association with recurrent abortions
1983	Anticardiolipin antibodies: detection by radioimmunoassay
1985	Anticardiolipin antibodies: detection by ELISA
1980s	Clinical description of the antiphospholipid syndrome
1987	Diagnostic criteria for the antiphospholipid syndrome
1989	Lupus anticoagulant and anticardiolipin: separate antibody subgroups
1990	Cofactor requirements for anticardiolipin antibody binding
1990	Anticardiolipin cofactor: β_2-glycoprotein I
1991	Lupus anticoagulant cofactor: prothrombin
1991	Animal models: passive immunization
1992	Animal models: active immunization
1992	Lupus anticoagulant cofactor: β_2-glycoprotein I
1992	Anti-β_2-glycoprotein I: association with thrombosis
1994	Phospholipid binding site: fifth domain of β_2-glycoprotein I

ELISA, enzyme-linked immunosorbent assay.

Table 1 Antiphospholipid antibodies and the antiphospholipid syndrome—history

Detection of antiphospholipid antibodies

Antiphospholipid antibodies are detected by a variety of laboratory tests, the most useful for identifying patients with the antiphospholipid syndrome being the lupus anticoagulant and the anticardiolipin antibody tests. These antibodies are distinct and separable immunoglobulins present alone or in combination in the plasma of people with the antiphospholipid syndrome. The autoantibodies sometimes bind phospholipids utilized in the Venereal Disease Research Laboratories (**VDRL**) test; hence, some patients may have a false-positive test for syphilis. However, the VDRL test is not positive frequently enough to make it valuable in diagnosing the antiphospholipid syndrome.

The lupus anticoagulant is a functional assay measuring the ability of antiphospholipid antibodies to prolong clotting via their inhibition of the conversion of prothrombin to thrombin or the activation of factor X (both reactions are catalysed by phospholipids). Tests for the lupus anticoagulant have been difficult to standardize, and no single test appears to be adequate (Permpikul *et al*. 1994; Triplett 1994). The test begins with an attempt to demonstrate an abnormal coagulation screening test, such as a prolonged activated partial thromboplastin time, dilute Russell viper venom time, or kaolin clotting time. If any of these is positive, the test is repeated, using a sample in which the patient's plasma has been mixed with normal plasma. If the patient's disorder is a clotting deficiency, the test should become normal. If, on the other hand, lupus anticoagulant or some other clotting inhibitor is present, the clotting time will remain prolonged. The presence of lupus anticoagulant is confirmed by the return to normal of the clotting test after addition of freeze–thawed platelets or excess phospholipids, either of which bind the antibodies. The lupus anticoagulant test must be performed on platelet-poor plasma. The test cannot be performed reliably if the patient is receiving heparin or oral

anticoagulants.

The most sensitive test for antiphospholipid antibodies is the anticardiolipin antibody test, introduced in 1983 and extensively improved since that time (Gharavi *et al*. 1987; Harris *et al*. 1987; Harris *et al*. 1990; Khamashta and Hughes 1993). This test uses enzyme-linked immunosorbent assay to determine antibody binding to solid plates coated either with cardiolipin or other phospholipids. Serum or plasma samples may be used for the anticardiolipin assay. The availability of reference sera which are isotype specific (IgG and IgM) has greatly improved interlaboratory testing and quantification of anticardiolipin antibodies (Harris *et al*. 1990). IgG and IgM isotype concentrations are expressed as GPL and MPL units, respectively. One unit represents the binding activity of 1 μg/ml of affinity purified anticardiolipin antibody. Results are expressed as low, medium, and high positive according to levels below 20 units, between 20 and 80 units, and above 80 units, respectively. IgA anticardiolipin reference sera are now also available. Many laboratories currently measure all three isotypes and sensitive kits are commercially available. Flow cytometry has also been used to test for anticardiolipin antibodies (Stewart *et al*. 1993). This sytem allows the simultaneous measurement of antiphospholipid antibody isotypes with different phospholipid specificity. The routine detection of other phospholipids, such as phosphatidylserine, phosphatidylinositol, and phosphatidic acid, gives little additional information.

In our experience, although a strong association between the anticardiolipin and the lupus anticoagulant results was found, these tests were discordant in 40 per cent of cases. The majority of patients with positive anticardiolipin antibodies were found to be positive for the IgG isotype (93 per cent). IgM anticardiolipin antibodies were demonstrated in only a quarter of the patients (Khamashta *et al*. 1995). The unrelated behaviour of lupus anticoagulant and anticardiolipin antibodies in the course of disease and in individual patients indicates that both assays are required if most cases with the antiphospholipid syndrome are to be identified.

Clinical features

The antiphospholipid syndrome is a thrombophilic disorder in which patients may develop both venous and arterial occlusion. The clinical ramifications are extensive (Table 2). Table 3 illustrates the frequency of the major manifestations of the antiphospholipid syndrome in our patients.

Table 2 Clinical features of the antiphospholipid syndrome

Clinical features	No. of patients	Percentage
Thrombosis	147/171	86
Venous:	80/147	54
Lower limbs DVT	54/80	67
Pulmonary embolism	19/80	24
Other	7/80	9
Arterial:	67/147	46
Stroke	32/67	48
TIA	24/67	36
Other	11/67	16
Thrombocytopenia	40/171	23
Pregnancy loss	48/147 (female)	33
First trimester	61/109 (pregnancies)	56
Second trimester	78/109 (pregnancies)	46
Third trimester	30/109 (pregnancies)	18

"St. Thomas' Hospital Lupus Clinic database (1985–1994).
DVT, deep venous thrombosis; TIA, transient ischaemic attack.

Table 3 Clinical manifestations of 171 patients with antiphospholipid syndrome [a]

Thrombosis

Although some antiphospholipid antibodies prolong *in vitro* clotting tests, haemorrhage is rare in patients with these antibodies. When haemorrhage does occur, other causes such as severe thrombocytopenia or clotting factor inhibitors should be excluded (Harris *et al*. 1993).

Instead of being associated with haemorrhage, antiphospholipid antibodies are paradoxically associated with thrombosis. Thrombosis can occur anywhere in the venous or arterial circulation. Vessels of all sizes may be affected, and the vascular pathological appearance has consistently been of bland occlusion without inflammatory infiltrate (Fig. 2) (Lie 1994). Thus, it is unlikely that thrombotic occlusion of blood vessels in patients with the antiphospholipid syndrome is caused by vasculitis, which may be seen in other patients with autoimmune rheumatic disorders. The distinction is important not only for discovering the pathogenesis of the vascular lesions, but also for the choice of treatment.

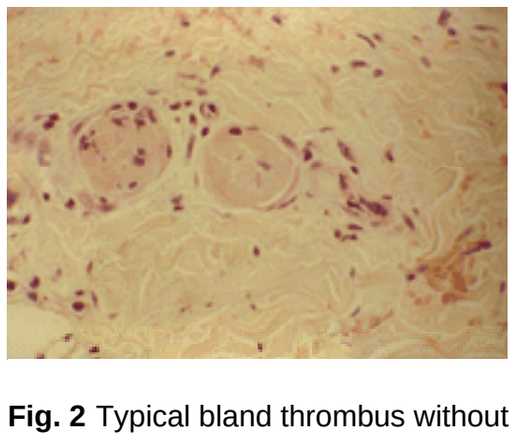

Fig. 2 Typical bland thrombus without inflammatory infiltrate in the vessel of a patient with primary antiphospholipid syndrome.

In the venous circulation, thrombosis of the deep and superficial veins of the lower extremities has been reported most frequently (occasionally after the use of oral contraceptive pills containing oestrogen). It is often recurrent and may be accompanied by pulmonary embolism. It has been estimated that up to 19 per cent of patients with deep vein thrombosis and/or pulmonary thromboembolism are suffering from antiphospholipid coagulopathy and may demonstrate a positive lupus anticoagulant test, antibodies to cardiolipin, or both. Some patients with antiphospholipid antibodies also have pulmonary hypertension, perhaps caused by recurrent pulmonary emboli or intravascular thromboses (Asherson *et al*. 1990). Other reported venous sites of thrombosis include the axillary, ocular, renal, and hepatic veins and the inferior vena cava. The antiphospholipid syndrome is now considered one of the most frequent causes of the Budd–Chiari syndrome (Fig. 3) (Pelletier *et al*. 1994). Antiphospholipid antibodies have recently been implicated in the development of adrenal vein thrombosis leading to Addison's disease (Asherson and Hughes

1991). Interestingly, most documented cases with adrenal insufficiency associated with antiphospholipid antibodies were in patients with history of previous venous thromboses.

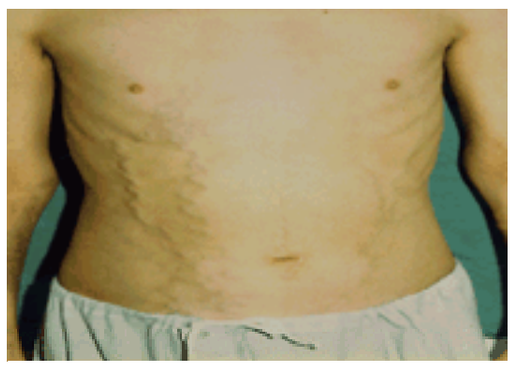

Fig. 3 Budd–Chiari syndrome in a 20-year-old patient with primary antiphospholipid syndrome (by courtesy of Dr L. Pallares, Servicio de Medicina Internal, Hospital Son Dureta, Palma de Mallorca, Spain).

Unlike other known clotting disorders, arterial thromboses are a major feature of the antiphospholipid syndrome. Occlusion of the intracranial arteries has been reported most frequently, with the majority of patients presenting with stroke and transient ischaemic attacks. Magnetic resonance imaging scans show changes that vary from single lesions to multiple widely-scattered infarcts (Fig. 4) (Asherson *et al*. 1989a; Stimmler *et al*. 1993). In some patients, untreated recurrent cerebral thrombosis has led to multi-infarct dementia and psychiatric features have been prominent in the presentation of some of our patients with the antiphospholipid syndrome. Antiphospholipid antibodies are now internationally recognized as an important aetiological factor and may be present in 7 per cent of all patients who have suffered a stroke (Montalban *et al*. 1991). They should be sought especially in young patients with strokes, where they may account for up to 18 per cent (Nencini *et al*. 1992). The prevalence of myocardial infarction in patients with antiphospholipid antibodies has yet to be established. A figure of 4 per cent was derived from our studies assessing patients with lupus and related disorders (Asherson *et al*. 1989b). Another study, found that one-fifth of all young patients with myocardial infarction had antiphospholipid antibodies (Hamsten *et al*. 1986). Other arterial thromboses have involved the retina, mesenteric and peripheral arteries. Malignant hypertension with renal insufficiency secondary to thrombosis of the renal glomeruli and renal thrombotic microangiopathy (without classical lupus nephritis) has also been associated with the presence of antiphospholipid antibodies (Fig. 5) (Amigo *et al*. 1992; Asherson *et al*. 1993a; Piette *et al*. 1994).

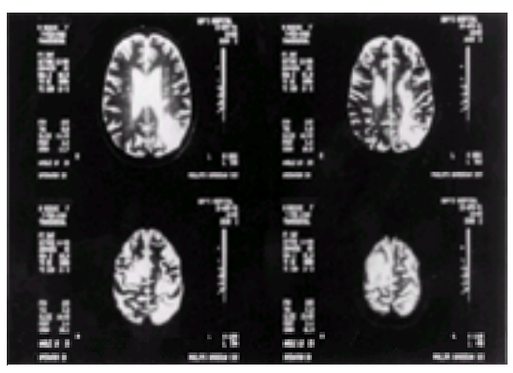

Fig. 4 Cerebral magnetic resonance imaging scan showing multiple widely-scattered infarcts in a patient with primary antiphospholipid syndrome.

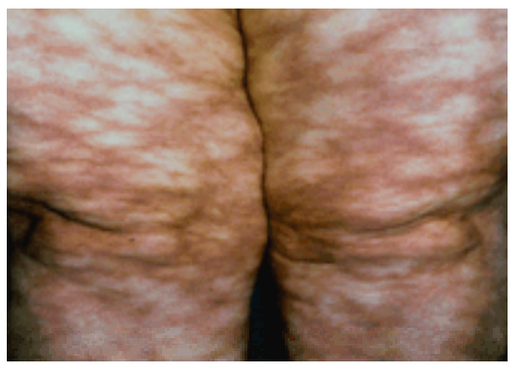

Fig. 5 Extensive livedo reticularis in a patient with primary antiphospholipid syndrome.

Occasionally, patients positive for antiphospholipid antibody develop acute medical collapse with severe thrombocytopenia, adult respiratory distress syndrome, and multiple organ (notably cerebral and renal) failures. The aetiology of this usually fatal condition is unknown, though the limited reports available suggest widespread thrombosis as the pathogenesis. The syndrome often appears to have had a trigger, such as preceding viral infection. We have chosen to call this rare but life-threatening presentation the 'catastrophic antiphospholipid syndrome' (Asherson 1992a).

Fetal loss

Recurrent spontaneous pregnancy losses are one of the most consistent complications of the antiphospholipid syndrome. Losses can occur at any stage of pregnancy, although miscarriages associated with antiphospholipid antibody are strikingly frequent (about 50 per cent of cases) during the second and third trimester. This differs from the pattern of pregnancy loss in the normal population, which usually occurs during the first trimester and is most often due to non-immunological factors, i.e. morphological or chromosomal abnormalities (Branch 1994). The rate of miscarriage in patients positive for antiphospholipid antibody is still uncertain, although the epidemiology is being studied and, increasingly, testing for this antibody is becoming a routine investigation in women with recurrent miscarriages. Fewer than 2 per cent of apparently normal pregnant women have either anticardiolipin antibody or lupus anticoagulant in any titre and less than 0.2 per cent have high titre antibody (Lockwood *et al*. 1989; Harris and Spinnato 1991). Hence, screening normal pregnant women has little value. Previous pregnancy history is of importance in determining the significance of a positive laboratory test for antiphospholipid antibodies. It has been estimated that if a patient with lupus has a positive lupus anticoagulant, or at least moderate levels of IgG anticardiolipin antibodies, the risk of spontaneous abortion during the first pregnancy is 30 per cent and if she has a history of at least two spontaneous abortions, the risk is 70 per cent during the following pregnancy (Lockshin *et al*. 1987). In our series, the presence of antiphospholipid antibodies was an important predictor of poor fetal outcome, as was a poor obstetric history (Buchanan *et al*. 1992; Lima *et al*. 1995). These findings are in keeping with the results of other authors (Branch I>et al. 1992).

The mechanism of pregnancy loss associated with antiphospholipid antibody remains uncertain. Progressive thrombosis of the microvasculature of the placenta and subsequent infarction resulting in placental insufficiency, fetal growth retardation and, ultimately, fetal loss, is a plausible explanation. Not all placentas examined, however, have shown areas of thrombosis or infarction and other mechanisms may be operative in these patients (Out *et al*. 1991). The aborted fetus is often normal except for evidence of growth retardation. It seems, therefore, that placental disease rather than fetal abnormality is responsible for fetal deaths related to antiphospholipid antibody. Pre-eclampsia is common in pregnant patients with the antiphospholipid syndrome and may provide clues to the pathogenesis of

pregnancy loss related to this antibody (Branch *et al*. 1992).

Thrombocytopenia

Thrombocytopenia is common in patients with antiphospholipid antibodies, though not severe enough to cause haemorrhage (Khamashta and Machin 1991). The platelet count often remains stable for many years; then, for reasons that are often obscure, the count drops, sometimes catastrophically. A survey of sera from patients presenting with idiopathic thrombocytopenic purpura, found anticardiolipin antibodies in 30 per cent of the cases (Harris *et al*. 1985). This finding raises the possibility that patients with the antiphospholipid syndrome may present only with severe thrombocytopenia and will later develop pregnancy loss or thrombosis. This form of presentation was observed in a very small number of our patients with the syndrome. Some patients with antiphospholipid antibodies and thrombocytopenia also develop haemolytic anaemia with positive direct Coombs' test. This is widely known as Evans' syndrome. In a study of 12 patients with Evans' syndrome and systemic lupus, 10 patients had evidence of antiphospholipid antibodies (Deleze *et al*. 1989). Similarly, in 70 patients with the primary antiphospholipid syndrome, 10 per cent were described as having Evans' syndrome (Asherson *et al*. 1989c).

Other manifestations

Epilepsy and chorea are less frequent manifestations of the antiphospholipid syndrome and have, intriguingly, been seen to improve in some patients treated with anticoagulants (Asherson *et al*. 1987; Herranz *et al*. 1994). Transverse myelopathy, though rare, is strongly associated with the presence of antiphospholipid antibodies (Alarcon-Segovia *et al*. 1989). Occasionally, in some patients with bizarre, transient/recurrent neurologial signs (resembling multiple sclerosis), antiphospholipid antibodies have been detected in the absence of other immunological abnormalities. Its recognition is important as anticoagulation therapy may be effective in these patients. Migraine is a common finding in patients with the antiphospholipid syndrome, and often pre-dates the diagnosis by many years. However, recent prospective studies have not demonstrated a significant statistical association between migraine headaches and the presence of antiphospholipid antibodies (Montalban *et al*. 1992; Tsakiris *et al*. 1993).

Heart valve disease, particularly mitral valve involvement, is strikingly associated with antiphospholipid antibodies (Khamashta *et al*. 1990; Cervera *et al*. 1991; Galve *et al*. 1992). In some cases this is due to a combination of valvular thrombosis and degeneration. In our prospective echocardiographic studies, the valves were involved in more than one-third of the patients with lupus or primary antiphospholipid syndrome. Most patients with heart valve disease associated with antiphospholipid antibodies are asymptomatic, though heart insufficiency requiring surgical valve replacement has been reported. Emboli from sterile valvular vegetations can cause multiple cerebral lesions. Large intracardiac thrombosis associated with antiphospholipid antibodies can mimic atrial myxoma.

One of the most striking physical signs in patients positive for antiphospholipid antibody is livedo reticularis (Fig. 5), sometimes widespread, sometimes subtle, e.g. confined to a small area on the back of the wrist. In one prospective study of patients with livedo reticularis, 43 per cent had anticardiolipin antibodies (Asherson *et al*. 1989d). We found that surprisingly few patients with Sneddon's syndrome (a triad of livedo reticularis, ischaemic cerebrovascular disease, and hypertension) were positive for antiphospholipid antibody, suggesting either that this syndrome results from many coagulopathies or that antiphospholipid antibodies are indeed important but that in our study the antibodies had long since disappeared. More dramatic skin manifestations associated with vascular thrombosis include widespread skin ulceration, notably in the lower extremities. Clinically, some patients with antiphospholipid antibodies may develop nail splinter haemorrhages (Fig. 6) and clubbing, posing major diagnostic difficulties, in those with heart valve disease, in differentiating from bacterial endocarditis (Mujic *et al*. 1995a).

Fig. 6 Subungual splinter haemorrhages in a patient with primary antiphospholipid syndrome.

Avascular necrosis of bone is an uncommon complication in lupus patients and clearly associated with high steroid dosage. We have noted an increased risk of avascular necrosis in individuals positive for antiphospholipid antibody, possibly as a result of small arterial occlusions, notably of the head of the femur (Asherson *et al*. 1993b).

Many patients with the antiphospholipid syndrome seem to develop widespread arteriopathy. The systemic narrowing of major arteries is similar in many respects to the widespread endarterial disease seen in some patients after heart–lung transplantation. Thus, antiphospholipid antibodies might be associated with accelerated vascular disease, including atherosclerosis (Lahita *et al*. 1993; Vaarala *et al*. 1993; Vaarala *et al*. 1996).

Epidemiology

The epidemiology of antiphospholipid antibodies is still being investigated worldwide. Efforts are being made in clinics throughout the world to assess the importance of this factor in recurrent abortion, stroke, myocardial infarction, epilepsy, and so on. In cardiovascular disease, Hamsten *et al*. (1986) found that 21 per cent of young patients in Sweden with myocardial infarction were antiphospholipid positive—this figure has not been reached in other studies. A collaborative United Kingdom/Spanish study found a prevalence of antiphospholipid positivity of 6.8 per cent in a large cohort of patients with stroke (Montalban *et al*. 1991). More recently, Nencini *et al*. (1992) in a study of 'young' stroke patients found that 18 per cent were positive for antiphospholipid antibody. In many of the other specialties, there is not enough data for adequate analysis. In obstetrics, the associations are now more clearly defined, though still with wide disparity between series, due possibly more to variations in test standardization than to clinical selection. Lynch *et al*. (1994) in a recent, large, prospective cohort study of 389 nulliparous mothers assessed at study entry and delivery, showed that 95 (24 per cent) were positive for antiphospholipid antibody of which 15.8 per cent had pregnancy loss, compared with 6.5 per cent of the women who were negative for antiphospholipid antibody.

Antiphospholipid antibodies are detected in patients with a variety of autoimmune, infectious, malignant, and drug-induced disorders, as well as in some apparently healthy individuals. Other than patients with the antiphospholipid syndrome, the single disorder in which these antibodies have been reported most frequently is systemic lupus erythematosus, in which lupus anticoagulants are reported in 10 to 20 per cent of cases, and anticardiolipin antibodies in 20 to 40 per cent of cases (Love and Santoro 1990; Cervera *et al*. 1993).

The specificities of antiphospholipid antibodies probably differ in various disorders. Large retrospective studies of patients with thrombotic complications suggest that those with high concentrations of IgG anticardiolipin antibodies appear to be at greatest risk for thrombosis, whereas the risk of clotting appears to be much lower in patients with infection-related or drug-induced antiphospholipid antibodies. Families positive for antiphospholipid antibody exist, and HLA studies have suggested associations with DR7, DR4, DRw53, DQw7, and C4 null alleles (Wilson *et al*. 1988; Arnett *et al*. 1991; Asherson *et al*. 1992; Wilson *et al*. 1995).

Diagnosis

Tests for anticardiolipin and lupus anticoagulant are essential to a diagnosis of the antiphospholipid syndrome. This syndrome is best defined as the occurrence of venous or arterial thrombosis, pregnancy losses, or thrombocytopenia associated with persistently positive tests for anticardiolipin or lupus anticoagulant. Patients may have one, two, or all three clinical features present, but they must also be positive for at least one of the two laboratory tests (Table 4). Many of the patients reported to have the syndrome have lupus and can be regarded as having secondary antiphospholipid syndrome. Some patients do not have any underlying systemic disease. These patients may be regarded as having primary antiphospholipid syndrome (Alarcon-Segovia and Sanchez-Guerrero 1989a; Asherson *et al*. 1989c;

Mackworth-Young *et al*. 1989). For research and classification purposes, the term primary is useful, although there appear to be few differences in complications related to antiphospholipid antibody or in antibody specificity in the presence or absence of systemic lupus erythematosus (Vianna *et al*. 1994). Although some patients with primary antiphospholipid syndrome progress to systemic lupus, most do not show such progression (Mujic *et al*. 1995b).

Clinical	Laboratory
Venous thrombosis Arterial thrombosis Recurrent fetal loss Thrombocytopenia	IgG anticardiolipin antibodies (moderate/high titres) IgM anticardiolipin antibodies (moderate/high titres) Positive lupus anticoagulant test

[a]Patients with the syndrome should have at least one clinical plus one laboratory finding during their disease. Antiphospholipid antibody test must be positive on at least two occasions more than 3 months apart.

Table 4 Criteria for the classification of the antiphospholipid syndrome [a]

Apart from lupus and primary antiphospholipid syndrome, antiphospholipid antibodies can occur in a wide variety of rheumatic, inflammatory, drug-induced, malignant, or infectious disorders. Usually, they are of low titre, of the IgM isotype, and unassociated with thrombotic events (Asherson 1992b). Antiphospholipid antibodies, using standardized techniques, are detected in less than 1 per cent of apparently normal persons and in up to 3 per cent of the elderly population without clinical manifestations of the antiphospholipid syndrome.

Differential diagnosis

Careful family and personal history and physical examination of patients with unexplained thromboses are of the utmost importance as thrombotic events and, notably, venous thromboses, often have explanations other than the antiphospholipid syndrome. It is advisable that thrombophilia testing, as suggested in Table 5, be performed in all patients, before initiating anticoagulant treatment.

Full blood count including platelets and blood microscopy (e.g. schistocytes)
Protein C
Activated protein C resistance (ratio)
Protein S (free and total)
Antithrombin III
Activated partial thromboplastin time
Prothrombin time
Reptilase time
Fibrinogen concentration
Fibrin split products
Plasminogen concentration
Serum and urine homocysteine
Antinuclear antibodies
Complement profile (C3, C4 and CH50)
Lupus anticoagulant
Anticardiolipin antibodies (IgG and IgM)
Syphilis serology
Others[a] Anticardiolipin antibody (IgA) Anti-β_2-glycoprotein I antibody Antibodies against other phospholipids: antiphosphatidylserine, antiphosphatidic acid, antiphosphatidylinositol, antiphosphatidylethanolamine, antiphosphatidylcholine

[a]For patients with a clinical picture highly suggestive of the antiphospholipid syndrome but negative for standard tests for anticardiolipin antibodies and lupus anticoagulant.

Table 5 Laboratory investigation of unexplained thromboses

Deficiencies in protein C, protein S, or antithrombin III are usually associated with recurrent venous thromboses. Echocardiographic studies should be performed in patients with cerebral infarcts as arterial emboli originating from cardiac valvular lesions are particularly common.

The most striking feature of the antiphospholipid syndrome is the frequent observation of life-threatening thrombosis in the setting of thrombocytopenia. A number of other conditions can result in thrombocytopenia and thrombosis, including heparin-induced thrombocytopenia and thrombotic thrombocytopenic purpura.

Heparin-induced thrombocytopenia develops in 1 to 5 per cent of patients receiving standard heparin and somewhat less frequently in those who receive preparations of low molecular weight. Approximately 10 to 20 per cent of patients with substantial heparin-induced thrombocytopenia have venous or arterial thrombosis, including pulmonary, cardiac, and cerebral thrombosis. Thrombocytopenia typically develops approximately a week after exposure in persons not previously treated with heparin and sooner in those with previous exposure.

Thrombotic thrombocytopenic purpura is associated with neurological syndromes, but it is chiefly a microvascular disorder and confusion, seizures, or changes in the level of consciousness are more frequent than isolated, cerebral, large vessel thrombosis. Microangiopathic haemolysis with evidence of schistocytes in peripheral blood is usually a prominent finding. Elevation in the serum level of lactate dehydrogenase is found in nearly all cases and is a sensitive marker of the severity of the disorder.

We suggest that the tests for IgA anticardiolipin, anti-b $_2$-glycoprotein I, and antibodies against other phospholipids be ordered only for patients strongly suspected of having the antiphospholipid syndrome despite negative assays for IgG and IgM anticardiolipin and for lupus anticoagulant (Viard *et al*. 1992; Amengual *et al*. 1996).

Pathogenesis

Precisely how antiphospholipid antibodies relate to thrombosis is unknown. Several mechanisms have been proposed to explain the prothrombotic nature of the antiphospholipid syndrome. The range of possible mechanisms include effects of antiphospholipid antibodies on platelet membranes, on endothelial cells, and on clotting components such as antithrombin III, protein C, and protein S (Table 6) (Khamashta *et al*. 1989; Roubey 1994).

Decreased prostacyclin production and/or release by endothelial cells
Inhibition of factor XII/prekallikrein-mediated fibrinolytic activity
Decreased protein C activation
Decreased free protein S levels
Interference with thrombomodulin function on endothelial cells
Decreased antithrombin III activation
Increased platelet activation and aggregation
Interference with the function of plasma β_2-glycoprotein I
Increased tissue factor expression
Decreased function of annexin V (placental anticoagulant protein I)
Direct vascular damage
Complement activation
Vascular activation and release of von Willebrand factor multimer

Table 6 Proposed mechanisms of thrombosis mediated by antiphospholipid antibody

In 1990, three groups independently reported that the anticardiolipin antibodies detected by enzyme-linked immunosorbent assay are not directed against cardiolipin alone, because purified IgG from anticardiolipin-positive patients did not bind to cardiolipin unless a plasma protein cofactor was present (Galli *et al*. 1990; Matsuura *et al*. 1990; McNeil *et al*. 1990). This protein was b$_2$-glycoprotein I. It has since become clear that anticardiolipin antibody in patients with the syndrome is dependent on both cardiolipin and b$_2$-glycoprotein I for optimum binding, though the relative importance of the two molecules, or their combination, is uncertain. Recent data indicate that certain lupus anticoagulants also require a plasma protein cofactor. This cofactor has been identified as prothrombin or b $_2$-glycoprotein I (Bevers *et al*. 1991; Oosting *et al*. 1992).

b$_2$-Glycoprotein I (apolipoprotein H) is a 50-kDa protein present at approximately 200 µg/ml in normal plasma. Although its physiological role is not known, *in vitro* data suggest that b$_2$-glycoprotein I may play a role in coagulation. b $_2$-Glycoprotein I binds to anionic phospholipids and inhibits the contact phase of intrinsic blood coagulation, platelet aggregation dependent on adenosine diphospate, and the prothrombinase activity of platelets. Although these data suggest an anticoagulant role for b$_2$-glycoprotein I, deficiency of this protein is not a clear risk factor for thrombosis. Patients with antiphospholipid antibodies have normal or somewhat elevated levels of b$_2$-glycoprotein I (Roubey 1994).

b$_2$-Glycoprotein I has its critical role in the recognition of cardiolipin by anticardiolipin antibodies in patients with autoimmune disease, but not from patients with infection (Hunt *et al*. 1992; Hunt *et al*. 1994). Anticardiolipin antibodies associated with syphilis bind to cardiolipin in the absence of b $_2$-glycoprotein I but this binding is inhibited by its presence, presumably because the antibodies and b $_2$-glycoprotein I bind to similar phospholipid structures. This difference in antigenic specificity may explain why the autoimmune type of anticardiolipin antibody is associated with the lupus anticoagulant and clinical complications such as thrombosis and recurrent fetal loss, whereas anticardiolipin antibodies associated with infection are not (Roubey 1994).

One hypothetical model for the mechanism of thrombosis proposes persistent endothelial cell damage and/or platelet activation, resulting in increased exposure of anionic phospholipid surfaces. Plasma proteins such as b $_2$-glycoprotein I and prothrombin are relatively abundant and may bind to the lipid surface, exposing novel epitopes. The immune response is directed to modified plasma proteins, therefore, rather than to lipids (Fig. 7) (Comfurius *et al*. 1995).

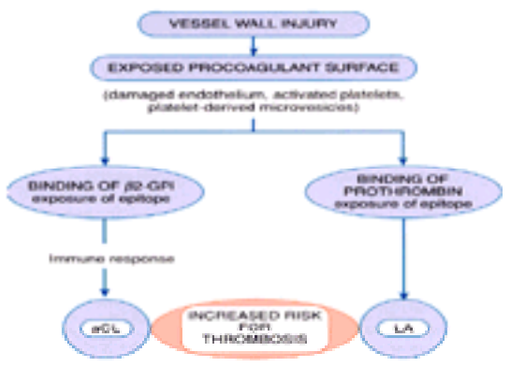

Fig. 7 Hypothesis explaining the generation of antiphospholipid antibodies as a normal response of the body to a potentially dangerous situation. This hypothesis predicts the possible existence of antibodies directed against all lipid-binding plasma proteins. As a consequence, it also explains the coexistence of anticardiolipin antibodies and lupus anticoagulant that is frequently observed in patients with the antiphospholipid syndrome. (Reproduced with the permission of the Editor of *Lupus* and from Dr P. Comfurius.)

We have recently established five, monoclonal, IgManticardiolipin antibodies from three patients with the antiphospholipid syndrome and showed that binding to anionic phospholipids was absolutely dependent on the presence of b $_2$-glycoprotein I (Ichikawa *et al*. 1994). Furthermore, a mixture of b$_2$-glycoprotein I and cardiolipin inhibited the binding of monoclonal anticardiolipin antibodies to b $_2$-glycoprotein I, but cardiolipin or b $_2$-glycoprotein I alone did not. These results suggest that anticardiolipin antibodies may recognize a cryptic epitope, which appears as a result of b $_2$-glycoprotein I binding to anionic phospholipids. Recent studies by Matsuura *et al*. (1994) confirmed that anticardiolipin antibodies bind to an epitope on b $_2$-glycoprotein I that is expressed when b$_2$-glycoprotein I binds to g-irradiated microtitre plates. Interestingly, immunization of healthy mice and rabbits with b $_2$-glycoprotein I resulted in high titres of anti-b $_2$-glycoprotein I and anticardilipin antibodies, whereas cardiolipin alone was not immunogenic (Gharavi *et al*. 1992).

It has recently been demonstrated that the fifth C-terminal domain of b $_2$-glycoprotein I contains the major phospholipid binding site, a region critical for binding anticardiolipin antibodies (Hunt *et al*. 1993). Using synthetic peptides spanning the fifth domain, it has been shown that the major phospholipid binding site is restricted to the sequence Cys^{281}–Lys–Asn–Lys–Glu–Lys–Lys–Cys^{288} (Hunt and Krilis 1994). A preparation of b$_2$-glycoprotein I clipped in the C-terminus between Lys^{317} and Thr^{318} completely loses both its ability to bind negatively-charged phospholipid and to act as a cofactor. In addition, anticardiolipin antibodies purified from patients with autoimmune disease could bind directly to b $_2$-glycoprotein I but not to wells coated with the preparation of b $_2$-glycoprotein I cleaved between Lys^{317} and Thr^{318}. These results were confirmed recently using monoclonal, anticardiolipin antibodies derived from patients with the antiphospholipid syndrome (Wang *et al*. 1995).

Animal models are providing useful clues to the pathogenesis of the antiphospholipid syndrome (Blank *et al*. 1991; Bakimer *et al*. 1992). Passive transfer and active immunization of BALB/c mice with human or mouse anticardiolipin monoclonal antibodies induced features of the antiphospholipid syndrome. The experimental antiphospholipid syndrome was characterized by serological markers (a panel of antiphospholipid antibodies, prolonged activated partial thromboplastin time, indicating the presence of the lupus anticoagulant), haematological findings (thrombocytopenia), and clinical manifestations (recurrent fetal resorption, the equivalent of human fetal loss). A role for antiphospholipid antibodies in causing thrombosis has been more difficult to demonstrate. Pierangeli and Harris (1994) provided recently the most persuasive evidence yet for a cause-and-effect role for antiphospholipid antibodies in thrombosis. In an *in vivo* mouse model, the femoral vein was exposed and damaged by a standardized 'pinch' injury. A fibreoptic transilluminator was placed underneath the vessel and the clotting process observed through a stereoscopic operating microscope. Infusion of anticardiolipin antibodies dramatically enhanced both the size of the thrombus formed locally as well as the time of persistence of the clot.

The basis of the heterogeneity of the clinical features of the antiphospholipid syndrome is not well understood. If one hypothesizes that these antibodies are pathogenic on the basis of their antigenic specificity, it is not clear why certain patients have venous thrombosis as opposed to arterial thrombosis or thrombocytopenia or recurrent fetal loss, or some combination of these manifestations (Roubey 1994). It is also not clear why only about 30 per cent of individuals with antiphospholipid antibodies will develop the clinical syndrome, although greater risk is associated with higher antibody titres (Harris *et al*. 1986; Ginsburg *et al*. 1992).

Treatment

One of the reasons for the widespread interest in the antiphospholipid syndrome has been its effect on approaches to therapy. Before its recognition, most features of systemic lupus erythematosus were attributed to inflammatory phenomena, requiring anti-inflammatory measures such as corticosteroids. Now it is recognized that features as diverse as fits, miscarriage, endocardial disease, and hypertension may all be the result of a thrombotic process. This concept has spread beyond the confines of systemic lupus, and pinpointing antiphospholipid-associated thrombosis and taking appropriate anticoagulation measures have become important considerations in specialties as diverse as neurology and obstetrics (Hughes and Khamashta 1994). Table 7 shows our preferred treatment for the different clinical features associated with antiphospholipid antibodies.

Clinical situation	Suggested treatment
1. Asymptomatic individuals	Observations ± low-dose aspirin
2. Thrombotic events	
Deep vein thrombosis ± pulmonary embolism	Life-long oral anticoagulants (INR = 3)
Large vessel arterial occlusion (e.g. stroke)	Life-long oral anticoagulants (INR = 3) ± low-dose aspirin
Transient ischaemic attack	Low-dose aspirin
Catastrophic antiphospholipid syndrome	Oral anticoagulants (INR = 3) ± plasmapheresis ± corticosteroids or immunosuppressants
3. Pregnancy	
No previous history of thrombosis or abortions	Observation ± low-dose aspirin
History of 1st trimester abortions	Low-dose aspirin
History of 2nd or 3rd trimester fetal loss	Low-dose aspirin ± subcutaneous heparin
Previous history of thrombosis ± pregnancy loss	Low-dose aspirin+subcutaneous heparin
4. Thrombocytopenia	
Mild (100 000–150 000)	Observation
Moderate (50 000–100 000)	Observation ± low-dose aspirin
Severe (< 50 000)	Corticosteroids ± intravenous gammaglobulin

INR, international normalized ratio

Table 7 Preferred treatment for the different clinical manifestations associated with antiphospholipid antibodies

Identification and treatment of additional risk factors for thrombosis

In treating patients with the antiphospholipid syndrome, attention should first be given to removal or reduction of other risk factors that might predispose to thrombosis. Treatment of hypertension and hypercholesterolaemia is required, along with advice to stop smoking and, for female patients, counselling against use of oral contraceptives containing oestrogen (Levine *et al*. 1992; Vianna *et al*. 1994). Prophylaxis with heparin administered subcutaneously at the time of surgery should be considered for all patients.

Prophylactic treatment of asymptomatic patients with antiphospholipid antibodies

Antiphospholipid antibodies persist for many years, possibly a lifetime. Thus, one of the unresolved key clinical questions is what additional factors lead to the sudden development of thrombosis, which occurs only in a minority of these patients (Hughes 1993).

The controversy concerning whether or not prophylactic treatment is indicated for patients with antiphospholipid antibodies who have no history of thrombosis remains unresolved. Most clinicians do not consider this sufficient reason for prophylactic anticoagulation, though prophylaxis should certainly be given to cover high-risk situations such as surgery. In our daily practice, we recommend that patients with a persistently positive test for lupus anticoagulant and/or with moderate to high levels of IgG anticardiolipin antibody and no history of thrombosis, be treated with low-dose aspirin (75 mg/day). These patients should be monitored carefully because they have the greatest risk of thrombosis (Khamashta and Wallington 1991; Hunt and Khamashta 1996).

In pregnancy, inappropriate treatment of women who do not have the antiphospholipid syndrome must be avoided. Anticardiolipin tests are positive at low titres in up to 2 per cent of the normal obstetric population, and such findings do not appear to be associated with an adverse outcome (Lockwood *et al*. 1989; Harris and Spinnato 1991). The risk is relatively low for primiparas, even if they have high titres of antiphospholipid antibody, and therefore their recommended prophylactic treatment is either close observation only or observation plus low-dose aspirin (Lockshin 1993).

Prevention of recurrent thrombosis

Optimal management of patients with thrombotic features associated with antiphospholipid antibodies remains a problem. Controlled treatment trials have proved difficult to perform in these patients because of the limited number of eligible patients with antiphospholipid syndrome available for study at a single centre and the necessity of long-term follow-up. There is now good evidence that those with thrombosis will be subject to recurrences, but there is still no consensus regarding the duration and extent of prophylactic antithrombotic treatments in these patients (Khamashta 1996). Many patients with the antiphospholipid syndrome in whom anticoagulation has been stopped have had major recurrent thromboses (Asherson *et al*. 1985; Rosove and Brewer 1992; Derksen *et al*. 1993). We have recently assessed our experience of the management of antiphospholipid-associated thrombosis in 147 patients over a 10-year period (Khamashta *et al*. 1995). Our study showed that long-term and intensive oral anticoagulation (international normalized ratio 3) was the most effective therapeutic option in the secondary prevention of venous and arterial thrombosis in these patients. Moreover, our study has shown that the first 6 months after stopping warfarin therapy were associated with the highest rate of recurrences (1.30 thrombotic events per year). This high probability of recurrent thromboses in patients with antiphospholipid antibodies and previous thromboembolic disease without oral anticoagulation, suggests that these patients require indefinite warfarin therapy. The benefits of long-term anticoagulation should, however, be balanced by the risks of bleeding. In our series, bleeding complications occurred in 29 patients (0.071 occasions per patient–year) and in 7 (0.017 occasions per patient–year) they were severe, suggesting that the benefits of warfarin in the antiphospholipid syndrome are greater than the risks. There was no evidence that low-dose aspirin (75 mg/day) alone prevented further thrombotic events in our patients. A similar finding was observed in the study of Rosove and Brewer (1992). It should be emphasized, however, that some patients with transient ischaemic attacks may respond to low-dose aspirin or dipyridamole therapy.

A significant number of patients require high doses of warfarin (up to 20 mg/day) to maintain the international normalized ratio in therapeutic range (3.0 to 4.0). In our experience, most of these patients were receiving other drugs and, notably, azathioprine at the same time as warfarin therapy. An important drug interaction has been pointed out recently between azathioprine and warfarin (Singleton and Conyers 1992; Rivier *et al*. 1993). When azathioprine is reduced or discontinued, anticoagulation may increase with the potential for bleeding if the international normalized ratio is not carefully monitored in these patients.

The role of steroids and immunosuppressive drugs in treatment of patients with antiphospholipid antibodies and thrombosis is uncertain. Such drugs have severe side-effects when given for prolonged periods and we, and others, have found that antiphospholipid antibodies are not always suppressed by these agents (Out *et al*. 1989; Harris *et al*. 1993). Furthermore, in our series of patients with the antiphospholipid syndrome, corticosteroids and immunosuppressive therapy, prescribed in some patients to control lupus activity, did not prevent further thrombotic events (Asherson *et al*. 1991; Khamashta *et al*. 1995). The use of these drugs is probably justified only in patients with repeated episodes of thrombosis despite adequate anticoagulant therapy, i.e. catastrophic antiphospholipid syndrome. In this rare but life-threatening condition, plasmapheresis has also been used (Asherson 1992; Asherson and Piette 1996).

It is of interest to note that our studies have shown that there were no broad significant differences in the levels of anticardiolipin antibodies between those patients who developed recurrent thromboembolic events and those who did not (Asherson *et al*. 1991; Khamashta *et al*. 1995). These findings further support the recommendation that treatment aimed at suppressing antibody formation is not warranted in patients with thrombosis associated with antiphospholipid antibodies.

The use of intra-arterial fibrinolysis has been described to be of benefit in patients with acute myocardial infarction associated with antiphospholipid antibodies. Prostacyclin analogues (iloprost) were also successfully used in patients with severe ischaemic necrotic toes associated with antiphospholipid syndrome (Zahavi *et al*. 1993). Elective pulmonary thromboendarterectomy can be very effective and lifesaving in selected patients with chronic large-vessel thromboembolic pulmonary hypertension (Sandoval *et al*. 1996).

Prevention of fetal losses

The treatment of patients with recurrent pregnany loss associated with antiphospholipid antibodies remains controversial and there are no clear guidelines for management. However, consensus is being reached on some aspects. An appropriate approach would be to assemble a multidisciplinary team (rheumatologist, obstetrician, and clinical haematologist), exclude causes of pregnancy loss other than the antiphospholipid syndrome, and select a drug regimen which has some reported efficacy and which will cause the least harm for the mother and fetus. Most importantly, the woman should be followed carefully throughout her pregnancy with frequent ultrasound evaluation for early detection of intrauterine growth retardation, and Doppler studies to monitor the flow-velocity waveforms of umbilical and uterine arteries (Harris 1990; Kerslake *et al*. 1992; Buchanan *et al*. 1993; Kamashta and Hughes 1996).

Over the past 7 years there has been a re-evaluation of the significance of antiphospholipid antibodies in pregnancy and, whilst an increased rate of fetal loss is seen in this group, experience suggests that with close monitoring this can be significantly reduced (Trudinger *et al*. 1988; McHugh *et al*. 1989). Recent data from our pregnancy clinic show that the greatest impact on fetal outcome in our series of patients with systemic lupus erythematous and antiphospholipid syndrome has been the regularity and quality of obstetric care, judicious monitoring, and timely intervention (Buchanan *et al*. 1992; Lima *et al*. 1995). In view of these findings, many of the high-dose (40 to 60 mg/day) prednisolone strategies, which were the treatments of choice in the early 1980s for patients with recurrent abortions associated with

antiphospholipid antibodies, are being abandoned. These doses regularly produce severe cushingoid effects, hypertension, and diabetic manifestations. Furthermore, controlled clinical trials now favour low-dose aspirin (75 mg/day) and subcutaneous heparin (10 000 to 15 000 IU/day) in those with a history of thrombosis, over corticosteroid therapy (Lockshin *et al*. 1989; Cowchock *et al*. 1992). In our recently reported study of pregnant women with the antiphospholipid syndrome, pregnancy outcome improved from 19 to 70 per cent using low-dose aspirin in all patients and subcutaneous heparin in those with previous thrombosis (Lima *et al*. 1996).

The presence of antiphospholipid antibodies in pregnant women in the absence of a previous history of thrombosis or fetal loss is not an indication for treatment. If, however, the patient does have a history of previous thrombosis and is being given warfarin, careful management is needed. Warfarin may be teratogenic, even early in the first trimester. The risks of continuing warfarin and also the problems with using heparin should be carefully explained to the patient. For the benefit of the fetus, warfarin should ideally be converted to subcutaneous heparin prior to conception, as heparin does not cross the placenta. Some women prefer to continue with warfarin until the first missed period, and then convert at this time.

Standard heparin or heparins of low molecular weight can be used during pregnancy, although the latter are not licensed for this purpose. There is no theoretical advantage of either. However, as one can monitor the levels of heparin with a low molecular weight very accurately with anti-Xa activity, we prefer to use them (Hunt *et al*. 1997). Their other practical advantage is that the patient can be started on one injection daily, in contrast to the necessary two or even three injections a day with standard subcutaneous heparin. Heparin doses need to be increased during pregnancy as the plasma volume expands. The patients can be converted back to warfarin after delivery.

Despite widespread use of heparin in pregnancy, there are relatively few reports of obstetric complications. The risks associated with heparin treatment include dose-related problems such as bleeding or osteopenia and idiosyncratic reactions such as immune thrombocytopenia, alopecia, and local reactions. The possibility of maternal osteoporosis is a limiting factor in the use of heparin. Heparin of low molecular weight, which has a long half-life and can be given once daily, may have less effect on bone. The combined use of corticosteroids and heparin may result in severe osteopenia.

Aspirin has been an integral part of treatment for women with the antiphospholipid syndrome. It was used on the basis of several reports suggesting that prostacyclin synthesis or release by endothelial cells was decreased *in vitro* by antiphospholipid antibodies. This would lead to an imbalance in the thromboxane/prostacyclin ratio and to platelet aggregation and vasospasm. Aspirin given in doses of under 150 mg/day preferentially blocks arterial thromboxane synthesis. Such dosages are associated with few (if any) maternal or fetal risks.

For patients who continue to have pregnancy loss despite a heparin and low-dose aspirin regimen, high-dose intravenous gammaglobulin (0.4 g/kg on 4 days each month) might be considered. The treatment should be initiated as soon as pregnancy is ascertained and continued throughout the pregnancy; it has proved very effective but is expensive. Fluid overload and hypertension are the major complications.

Clearly, optimal management of patients with recurrent pregnancy loss associated with antiphospholipid antibodies remains a problem, but the recent establishment of animal models for the antiphospholipid syndrome provides an excellent opportunity to develop rational and more-targeted therapies. A recent example is the demonstration by Fishman *et al*. (1993) that mice with experimental antiphospholipid syndrome are deficient in interleukin-3 and that fetal losses in these mice could be prevented by administration of recombinant interleukin-3. This novel approach has not yet been used in patients with antiphospholipid syndrome.

Treatment of thrombocytopenia

Mild thrombocytopenia with platelet counts between 100 000 and 150 000/mm^3 are common in patients with antiphospholipid antibody and usually does not require intervention (Khamashta and Machin 1991). In a minority of cases it can be severe. In these cases, corticosteroid therapy should always be the treatment of choice. However, it should be noted that there have been several case reports of peripheral thrombocytopenia unresponsive to steroid therapy, with platelet counts returning to normal following low-dose aspirin therapy (Alarcon-Segovia and Sanchez-Guerrero 1989b). Aspirin, by reducing the degree of spontaneous platelet activation, also presumably reduces binding of antiphospholipid antibody and immune-type platelet destruction (Khamashta *et al*. 1988). Intravenous gammaglobulin infusion, danazol, and dapsone have been given successfully to some patients with severe thrombocytopenia associated with antiphospholipid antibody. There is no published experience reported with splenectomy in these patients, though we have one patient (a 33-year-old male) with severe thrombocytopenia and antiphospholipid antibodies in whom splenectomy failed to improve the platelet count. This procedure should be considered with caution in view of an increased thromboembolic risk related to post-splenectomy thrombocytosis.

Antiphospholipid syndrome in childhood

There have been relatively few reports of clinical associations of antiphospholipid antibodies in children and the spectrum of clinical findings remains at present unknown. Antiphospholipid antibodies in childhood-onset systemic lupus erythematosus have been described in several small clinical reports, occurring in one-third of the patients. The clinical manifestations are similar to those encountered in adults, particularly recurrent deep-vein thrombosis, strokes, and chorea. Devastating thrombotic complications of the antiphospholipid syndrome in children have been reported including digital ischaemia and myocardial infarction (Tucker 1994). The risk of maternal transmission of antiphospholipid antibodies to infants during pregnancy is unknown, though there have been several case reports of thrombotic events in neonates of mothers with the antiphospholipid syndrome (Silver *et al*. 1992).

Prognosis

Although there are a number of studies of prognostic factors in systemic lupus erythematosus, only a few have addressed the possible role of the antiphospholipid syndrome in the mortality rates of these patients. Drenkard *et al*. (1994) have recently analysed the influence of the antiphospholipid syndrome in the survival of their series of 667 patients with systemic lupus erythematosus. Thrombocytopenia and arterial occlusions were the manifestations related to antiphospholipid antibody that were associated with decreased survival. The syndrome itself was also associated with increased mortality rate, independently of other variables. A negative impact of positivity for IgM anticardiolipin antibody on the probability of survival of lupus patients also was found in another study (Gulko *et al*. 1993).

5.8 Scleroderma and related disorders in adults and children

Carol M. Black and Christopher P. Denton

'Scleroderma', a word meaning hard skin, is a part of many syndromes including localized, limited, and generalized scleroderma. Related to these are environmentally induced 'scleroderma-like' diseases, overlap syndromes, undifferentiated autoimmune rheumatic disease, and localized fibroses (Table 1). Most of these disorders in the scleroderma spectrum can occur at any stage of life, although the pattern of scleroderma occurring in childhood is different from that in the adult (see below). The disease we call scleroderma or systemic sclerosis has been confused with other diseases that have cutaneous features resembling it, for example scleromyxoedema, scleroedema, and primary amyloidosis (Table 2).

Raynaud's phenomenon	Primary Raynaud's
	Secondary Raynaud's
Scleroderma — localized	Morphoea (plaque, guttate, generalized)
	Linear
	En coup de sabre
Scleroderma — systemic	Limited cutaneous systemic sclerosis
	Diffuse cutaneous systemic sclerosis
	Scleroderma sine scleroderma
Chemically induced*	Environmental/occupational
	Drugs
Scleroderma-like diseases	Metabolic
	Immunological/inflammatory
	Localized systemic sclerosis and visceral diseases

*See Table 2

Table 1 Spectrum of scleroderma and scleroderma-like syndromes

Metabolic/inherited	Scleredema of Buschke Scleromyxoedema } with or without paraproteinaemia
	Insulin-dependent diabetes mellitus (digital sclerosis)
	Carcinoid syndrome
	Acromegaly
	Phenylketonuria
	Porphyrias (congenital and porphyria cutanea tarda)
	Lichen sclerosis et atrophicus
	Acrodermatitis chronica atrophicans
	Amyloidosis
	Inherited premature ageing syndromes — progeria, Rothmund's, Werner's
Immunological/inflammatory	Chronic graft-versus-host disease
	Eosinophilic fasciitis
	Overlap syndromes (systemic sclerosis with rheumatoid arthritis, systemic lupus, Sjögren's, polymyositis/dermatomyositis)
	Undifferentiated autoimmune rheumatic disease
Localized systemic sclerosis and visceral diseases	Idiopathic pulmonary fibrosis
	Amyloidosis
	Sarcoidosis
	Infiltrating carcinomas
	Infiltrating panniculopathy
	Oesophageal and intestinal hypomotility syndromes

Table 2 Scleroderma-like syndromes

The milestones in the history of scleroderma (see Table 3) bear testimony to the gradual realization of the heterogeneity of the disorder. The last 50 years have seen an explosion of interest in the disease and its mechanisms, which has fostered collaboration between many branches of basic science and clinical medicine. For a more detailed discussion of the fascinating history of this disease the reader is referred to the excellent historical review by Rodnan, the 'father' of modern-day clinical scleroderma (Rodnan and Benedek 1962).

1753	Curtis	Description of young woman of Naples with 'excessive hardness of skin — possibly scleroderma, but probably scleredema of Buschke'
1847	Grimaud	First use of name 'Sclerodermie'
1847	Forget	First description of pelvic involvement in scleroderma
1854	Addison	First description of linear scleroderma
1862	Raynaud	Description of 'local asphyxia and symmetrical gangrene of the extremities'
1878	Weber	Coexistence of scleroderma and calcinosis noted
1892	Osler	Tendency for scleroderma patients to die of pulmonary or renal disease noted
1903	Hutchinson	Association of scleroderma and Raynaud's phenomenon noted
1903	Ehrmann	Association of scleroderma and dysphagia recorded
1910	Thibierge and Weissenbach	'Rediscovery' of coexistence of scleroderma and calcinosis
1924	Rosow	First clear description of visceral involvement, with sclerosis of lungs, gastrointestinal tract and kidneys
1943	Weiss	Clear description of myocardial involvement in scleroderma
1945	Goetz	Coined the term 'progressive systemic sclerosis'
1964	Winterbauer	Described the CREST subset (calcinosis, Raynaud's, oesophagitis, sclerodactyly, and telangiectasia)

Table 3 History of scleroderma

The group of syndromes called localized scleroderma includes morphoea (limited and guttate), linear scleroderma with the *en coup de sabre* variety, and generalized morphoea. These syndromes are almost never associated with systemic involvement but may demonstrate abnormal autoimmune serology and inflammatory

histological changes in skin (Falanga 1989). These forms of scleroderma predominate in childhood.

Raynaud's phenomenon now best classified as either primary or secondary (the terms Raynaud's disease and Raynaud's syndrome should be abandoned and replaced by these more accurate, simple descriptive terms) and can be a forerunner one of the autoimmune rheumatic diseases such as generalized scleroderma (see below).

When generalized scleroderma is called systemic sclerosis the term is preferable to progressive systemic sclerosis because not all systemic sclerosis is progressive.

Systemic sclerosis is a multisystem disease, predominantly affecting females and of unknown cause. It is characterized pathologically by the overproduction of several elements of the connective tissue, notably collagen (Mauch *et al*. 1993), widespread vascular damage with the development of microvascular obliteration, and tissue infiltration of mononuclear inflammatory cells often in a perivascular distribution (Prescott *et al*. 1992). It embraces a clinical spectrum ranging from widespread skin thickening (diffuse scleroderma) to skin thickening either limited to the face and distal extremities (limited scleroderma) or absent (systemic sclerosis *sine* scleroderma).

There is no single diagnostic test for systemic sclerosis and, for the purposes of separating it from other autoimmune rheumatic diseases and identifying cases to permit comparison of reported series, preliminary criteria were developed and published in 1980 (Subcommittee for Scleroderma Criteria of the American Rheumatism Association Diagnostic and Therapeutic Criteria Committee 1980; Pope and Bellamy 1993). These criteria had a 97 per cent sensitivity and 98 per cent specificity for definite systemic sclerosis, but they are less sensitive for limited cutaneous disease, which is the largest subset, and they fail to identify at least 10 per cent of such patients. In the future, criteria taking full account of the limited-disease subset, and also including clinical, pathological, and immunological data (such as recent-onset Raynaud's phenomenon, capillary abnormalities, and circulating antibodies) should be developed. There is a readily identifiable group of presclerotic patients who should be included in diagnostic criteria, classification, and subsetting.

Classification of systemic sclerosis is difficult (Masi 1988), and a number of different systems have been proposed (LeRoy *et al*. 1988). Central to all of them is the extent of skin involvement, and whether a two-subset or three-subset model is superior is still debated. Currently the most widely used classification defines two subsets, based on the extent of skin involvement together with a number of reliable clinical laboratory and natural history associations. The two-subset model divides the disease into limited cutaneous systemic sclerosis and diffuse cutaneous systemic sclerosis (Table 4) (LeRoy *et al*. 1988). Over 60 per cent of patients with systemic sclerosis fall into the limited cutaneous subset, where visceral involvement is a late event and tends to occur 10 to 30 years after the onset of Raynaud's. The term limited cutaneous systemic sclerosis is preferable to CREST (**C** alcinosis, **R** aynaud's, (O)**E** sophageal dysphagia, **S** clerodactyly, **T** elangiectasia syndrome), because cutaneous manifestations often extend beyond sclerodactyly and calcinosis may be present only late or radiologically. Diffuse cutaneous systemic sclerosis, the more serious form of the disease, is much more rapid in onset, with organ failure often present within 5 years of the first symptoms.

Table 4 Classification of the subsets of systemic sclerosis (SSc)

This model will almost certainly be changed and developed as knowledge of the pathogenesis of the disorder advances, and the ever-increasing numbers of autoantibodies are matched to clinical subsets. Within each subset, there is great variability in the pace of the disease: for example, some patients with diffuse cutaneous systemic sclerosis develop extensive internal-organ complications within 2 to 4 years; others have widespread skin disease but only grumbling interstitial lung disease. Some patients with limited cutaneous systemic sclerosis may never develop clinically apparent pulmonary hypertension or mid-gut disease whereas other individuals develop this complication, usually late on, but occasionally as early as 5 to 7 years after diagnosis. Thus, not only is there disease heterogeneity, but differential progression within a subset. Notwithstanding these problems a useful and practical scheme is to divide the disease into early and late stages (see Table 5). This is a useful concept because it permits the doctor, patient, and patient's family to anticipate certain developments, which will concentrate attention on early detection and correct management of complications.

Table 5 Characteristic findings in the early and late stages of systemic sclerosis subsets

Epidemiological considerations

Scleroderma is an uncommon disorder and virtually all of the descriptive epidemiology is derived from retrospective or prospective reviews of patients attending hospitals or institutions serving a defined denominator population: there is only one true population-based study (Maricq *et al*. 1989). A summary of salient epidemiological data is given in Table 6 (Silman 1995). The demographic conclusions that may be drawn from these data are that the disease is rare in childhood, and that its incidence increases steadily with age amongst adults. Its rarity suggests that the genetic and/or environmental exposures necessary for disease susceptibility occur infrequently in the population. Scleroderma is a disorder with a female excess (4F:1M overall, and in the child-bearing years 15F:1M. The disease occurs most frequently and severely in young black women, but overall there are no prominent racial, seasonal, or socioeconomic differences. Of great interest is the possibility that the disease clusters in certain areas. A clustering has been described close to international airports in the United Kingdom (Silman 1995), a cluster of patients with a variety of autoimmune rheumatic diseases is reported from The Republic of Georgia (Freni-Titulaer *et al*. 1989), and a clearer cluster of systemic sclerosis in a region of Italy close to Rome (Valesini *et al*. 1993). Unlike some other autoimmune rheumatic diseases, the genetic contribution to the disease would appear to be relatively weak, although it is stronger for individual organ involvement (e.g. the lung). Finally, again in contrast to other autoimmune rheumatic diseases, a growing number of environmental agents have been implicated in systemic sclerosis (see Table 7).

Mortality	USA 1968–77	1.5 males and 3.5 females per million population
	UK 1974–85	1.9 males and 4.0 females per million population
Incidence (new cases detected/ population at risk/time period)	Rates variable Before 1980 report	2–10 per million population per year
	Pittsburgh study (1963–82)	10.9 per million population per year
	UK 1980–85	3.7 per million population per year
Prevalence (number of cases living at particular time or during time interval)	Estimates 1947–52 1977–79 1985 1986 1986 1988	4 per million (hospital studies) 128 per million (hospital studies) 253 per million (community studies) 292 per million (point prevalence) 36.8 per million (hospital and community) 93 per million (hospital study)
Survival		
Cumulative survival rates using life-table methods	Overall	65–70% @ 5 years 40–59% @ 10 years
	By subset localized cutaneous diffuse cutaneous	80% @ 5 years 50% @ 12 years 30% @ 5 years 10% @ 12 years
	Older patients: reduced survival	

Factors associated with decreased survival: increasing skin involvement, organ involvement etc.

Table 6 Epidemiological facts in systemic sclerosis

Table 7 Environmental agents implicated in the development of scleroderma

Aetiology and pathogenesis

Although the basic aetiology of systemic sclerosis is unknown, it is almost certainly multifactorial with genetic and environmental factors playing a part (Briggs *et al*. 1990). As mentioned earlier, systemic sclerosis occurs mostly in females and sex may be the strongest genetic marker. There are, however, several lines of evidence that indicate familial or genetic predisposition to systemic sclerosis. First, although rare, there are familial clusters of systemic sclerosis and related diseases, particularly Raynaud's phenomenon. Autoantibodies associated with systemic sclerosis are found in high frequency in blood relatives of patients with systemic sclerosis, although the incidence of antinuclear antibodies in spouses suggests an environmental component. Thirty-six per cent of relatives with antinuclear antibodies had clinical features of autoimmune rheumatic disease not observed in spouses (Briggs *et al*. 1993). The presence of autoantibodies in the blood of patients' spouses in the United Kingdom study was not confirmed in an Australian study. Thirdly, many centres worldwide have observed abnormal frequencies of the major histocompatibility complex (**MHC**) antigens associated with systemic sclerosis. The association is complex (see Table 8) and the strongest link is between HLA-DRw52a and patients with systemic sclerosis who have lung fibrosis (relative risk 16.7).

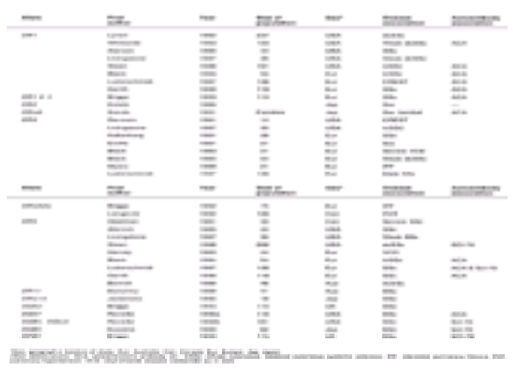

Table 8 Immunogenic associations of scleroderma

As one of the primary roles of MHC class II molecules is the presentation of processed antigen to the T-cell receptor on helper T lymphocytes resulting in an antigen-specific immune response, autoantibody subsets in scleroderma might be expected to show correlations with class II MHC polymorphism and indeed they do, although again, they appear to be complex. In the initial reports, anticentromere antibody was found to be associated with HLA-DR5 (-DR11), -DR4 (-D13 subtypes), -DR1, and -DR8. These findings appear to reflect linkage disequilibrium of *HLA-DR5* (*-DR11*) and many *HLA-DR4* (*-D13* subtypes) with *HLA-DQ7*, and *-DR1* with *-DQ5*. These HLA-DR specificities share no unique amino-acid sequences, which raised the possibility that another linked gene might be more highly correlated with this antibody response. More recently, in a study by Reveille *et al*. (1992a), oligotyping showed that the anticentromere antibody response was most closely associated with *HLA-DQB1* alleles in linkage disequilibrium with *HLA-DR1, -DR4, -DR5* (*DR11*), and *-DR8*. These *HLA-DQB1* alleles had in common a polar tyrosine or a glycine at position 26 of the outermost domain of the HLA-DQB molecule, as opposed to a hydrophobic leucine residue. In a British study (Briggs *et al*. 1993) implication of the *HLA-DQB1* locus was inferred, as virtually all of the anticentromere antibody-positive patients had either HLA-DR1 or -DR4. However, McHugh *et al*. (1994) have indicated that, although at least one *HLA-DQB1* allele not coding at position 26 of the first domain appears necessary, it may not be sufficient for the generation of anticentromere antibody. Reveille and colleagues have also extended the known associations of antitopoisomerase antibodies with HLA-DR5, -DR2, and -DR52a to include four *HLA-DQB1* alleles (Reveille *et al*. 1993b). Japanese workers have found a similar allele association (Kuwana *et al*. 1993). Localization of 'susceptible epitopes', however, has been less definitive. Suggestions include an American population in which a tyrosine at position 30 or the TRAELDT sequence spanning positions 71 to 77 of the *HLA-DQB1* outermost domain is seen (Reveille *et al*. 1992), and a Japanese population with systemic sclerosis in which a tyrosine at position 26 of the *HLA-DQB1* outermost domain is present (Kuwana *et al*. 1993). In a British study an HLA-DPB1 association was suggested, with the presence of an acidic amino-acid residue at position 69 in the third hypervariable region of the outermost domain. Autoantibodies to the anti-Pm/Scl antigen (see below) are nearly 100 per cent correlated with the presence of the *HLA DR3-DQw2* haplotype (Reveille *et al*. 1992).

Important racial and ethnic differences in the frequencies of these autoantibodies have been described, with Western Europeans and North American whites having a significantly higher frequency of anticentromere autoantibodies and a lower frequency of antitopoisomerase-1 than American blacks, Choctaw native Americans, Thai, and Italians (Kallenberg 1994). Particular forms of the disease may not be so strongly influenced by sex. For example, certain chemically induced systemic sclerosis-like disorders tend to be associated with males, partly due to an occupational bias. The range of known agents that can induce a systemic sclerosis-like disease is large and growing (Table 7), although it must be noted that in formal epidemiological studies, no excess was found. It is almost certain that sporadic cases can follow certain occupational exposures, but that both the absolute and attributable risks are low. There are some MHC associations with the environmentally induced cases, for example toxic oil syndrome is characterized by a raised incidence of HLA-DR4, while vinyl chloride disease is primarily associated with HLA-DR5, HLA-DR3 being a marker of severity. There is (see Table 8) inconsistency in the frequencies for genetic markers of susceptibility between patients from different study centres. This may reflect at least in part different agents present at these various geographical locations. The newest arrivals to the group of environmentally induced, systemic sclerosis-like syndromes are the eosinophilic–myalgic syndrome associated with the oral ingestion of the essential amino acid l-tryptophan (discussed elsewhere) and a renewed interest in the possible association between disease development and silicone breast implants. Much of the work in this area has been generated by the need to obtain accurate data because of considerable litigation, particularly in the United States. Hochberg (1994) has carefully reviewed the epidemiological aspects of the literature and has reasonably concluded that none of the available studies has demonstrated a statistical association between

augmentation mammoplasty with silicone gel-filled prostheses and scleroderma or other autoimmune rheumatic disorders.

Autoimmune considerations

An increasing number of immune abnormalities are being reported in systemic sclerosis and the designation of systemic sclerosis as an autoimmune disease now has widespread support. Some of the clinical features of scleroderma bear similarities to other autoimmune disorders such as systemic lupus erythematosus, dermatomyositis, and rheumatoid arthritis, and there are also patients who have overlap syndromes or who have sequential development of more than one autoimmune rheumatic disease. Cases of familial systemic sclerosis and familial associations of systemic sclerosis with other autoimmune diseases such as rheumatoid arthritis and systemic lupus erythematosus occur and have already been mentioned.

There is considerable evidence that abnormalities in both humoral and cell-mediated immunity occur in systemic sclerosis, although the precise importance of these immunological events in the pathogenesis remains uncertain. Some of this evidence is summarized in Table 9, and discussed below. The lack of a generalized immune dysfunction in systemic sclerosis suggests that the derangement of immune-cell dysfunction may be *specific* to certain antigens or cell types (Padula *et al*. 1986; Lupoli *et al*. 1990).

Immunogenetic associations (see Table 8)
Autoantibody associations (see Table 10)
Increased circulating levels of soluble CD4, soluble IL2 receptor and lymphocyte-derived cytokines (IL2, IL4, IL6, IL8) in some patients
Circulating T cells that are reactive to laminin, collagen (type I), and show increased adhesion to endothelial cells and fibroblasts
Elevated levels of IL5 and IL8 in bronchoalveolar lavage fluid
Perivascular T-cell infiltrates (DR+, 1, 2 integrin expression) in lesional skin
Increased tissue expression of lymphocyte-binding cell-surface adhesion molecules in lesional and prelesional skin and lung tissue
Clinical and pathological similarities with chronic graft-versus-host disease

IL, interleukin

Table 9 Summary of evidence for immune-system involvement in systemic sclerosis

The association of systemic sclerosis with particular major HLA antigens and the close association of certain HLA alleles with scleroderma-specific antibodies (see Table 8) is indirect evidence for T-cell involvement in systemic sclerosis. There is considerable evidence for T-cell activation in systemic sclerosis, including an increased ratio of circulating CD4+:CD8+ cells (Degiannis *et al*. 1990; White 1994), reflecting an increased number of CD4+ and/or a reduced number of CD8+ lymphocytes. A particular role for gd T-cells has been suggested (White 1994) and others have reported increased numbers of lymphokine-activated killer and natural killer cells (Kantor *et al*. 1992) in blood samples from patients with systemic sclerosis. Furthermore, several studies have found increased soluble interleukin-2 receptor in scleroderma, sometimes appearing to correlate with disease activity (Kahaleh 1991). Support for the possibility that activated T-cells are important in pathogenesis is provided by the presence of infiltrates of CD3+, CD4+, CD450+, interleukin 2-producing, HLA-DR-positive+, leucocyte function-associated antigen-1-positive, a/b^{+} T cells in lesional tissues (Prescott *et al*. 1992). Also, chronic graft-versus-host disease in humans shows several histological and clinical similarities with systemic sclerosis, and is known to be a T-cell-mediated process (Chosidow *et al*. 1992). Humoral abnormalities in systemic sclerosis are most clearly reflected by the presence of autoantibodies with well-defined target epitopes; mapping of the precise binding sites for some of these is currently being undertaken in several centres (Bona and Rothfield 1994). Although circulating immune complexes have been reported in systemic sclerosis, most studies have not found functional complement abnormalities (Seibold *et al*. 1982), probably because most systemic sclerosis-associated autoantibodies do not activate the complement cascade (White 1994).

Nevertheless, autoantibody production is an early and almost universal feature of systemic sclerosis. The number of autoantibody targets identified in systemic sclerosis continues to grow (see Table 10) but the major ones are topoisomerase-1, centromeric proteins, and RNA polymerases I, II, and III. About 97 per cent of patients have detectable antinuclear antibodies when HEp-2 lines are used as the detection tissue. Characteristic staining patterns for antinuclear antibodies within the nuclear and subnuclear structures are relatively specific (Tan 1989) and can be confirmed by more sophisticated tests. A diffusely grainy pattern of staining is associated with the presence of antibodies to topoisomerase-1 (Scl-70), a nuclear enzyme important in the unwinding of DNA for replication and RNA transcription. Antibodies to Scl-70 occur in up to 40 per cent of patients with diffuse systemic sclerosis and 15 per cent of those with limited disease. The occurrence of this antibody varies considerably between laboratories and studies have shown that the immunoblot technique is more sensitive than indirect immunofluorescence and should be the 'gold standard' for this test. An anticentromere staining pattern occurs in up to 80 per cent of patients with the limited form of systemic sclerosis. Antigens recognized by positive sera have been identified as CENP-A, CENP-B, and CENP-C, with molecular weights of 19, 80, and 140 kDa, respectively (Earnshaw *et al*. 1986). A correlation has been shown (Jabs *et al*. 1993) between anticentromere antibodies and aneuploidy in patients with systemic sclerosis, and it is possible that anticentromere antibodies could disrupt centromere function and allow chromosomes to segregate inappropriately during mitosis, leading to a high rate of chromosomal breakage and sister chromatid exchange, although to date no correlation has been found between the presence of anticentromere antibody and chromosomal changes. Anti-RNA polymerase (**RNAP**) antibodies are the latest systemic sclerosis-specific antibodies to be described. They occur mainly in patients with diffuse disease, and antibodies against RNAPI, -II, and -III have been described (Bona and Rothfield 1994). The RNAPs are multiprotein complexes and are components of the transcription complex (Reeves *et al*. 1994). Each RNAP is composed of collections of smaller proteins shared by other RNAPs and two large distinct proteins. RNAPI synthesizes ribosomal RNA precursors in the nucleoli, whereas RNAPs II and III are found in the nuclei. RNAPII synthesises most of the small nuclear RNAs found in ribonucleoprotein particles that mediate pre-mRNA splicing and synthesize precursors of mRNA, and RNAPIII synthesizes small RNAs including single-strand ribosomal RNA and transfer RNA. Anti-RNAP antibodies target both the smaller shared subunits and the larger distinct proteins, which explains antibody reactivity against several RNAPs in one serum sample.

Antigen	Molecular identity	Immunofluorescence pattern	Disease subtype and frequency
Scl 70 (topoisomerase I)	100-kDa protein degrades to 70 kDa	Nuclear (diffuse fine speckles)	Up to 40% with diffuse cutaneous SSc[a] 10–15% limited
Kinetochore-centromere	17-, 80-, 140-kDa proteins at inner and outer kinetochore plates	Centromeric	75–80% in limited cutaneous SSc 5–20% with primary biliary cirrhosis
RNA polymerase I, II, III	Complex of 12 proteins 12.5–210 kDa	Nucleolar (punctate)	20% — especially diffuse; high prevalence of internal organ involvement
PM-Scl	Complex of 11 proteins 20–110 kDa	Nucleolar (homogeneous)	3% — high prevalence of myositis, more renal involvement
To or Th	65-kDa protein associated with 7.2 & 8.2 kDa RNAs	Nucleolar (homogeneous)	Rare — localized cutaneous SSc
Mitochondrial M2	70-kDa protein — dihydrolipoamide acyltransferase	Cytoplasmic (rod like)	25% of CREST[a] (95% primary biliary cirrhosis)

[a]Eds: systemic sclerosis; [a]CREST (see Table 8); RNAP, ribonucleoprotein

Table 10 Autoantibodies in scleroderma

The relation between HLA status and autoantibody production is also of increasing interest in scleroderma. It would appear that certain of these antibodies are closely related to particular HLA alleles, for example it has recently been shown that class II MHC haplotype is an important factor determining *in vitro* responsiveness to topoisomerase antigen, both in patients with systemic sclerosis and in healthy control individuals (Kuwana *et al*. 1995). It is important to consider that there may be racial differences in HLA associations for the various autoantibodies (see Table 8). These antibodies not only mark out certain subsets of patients with systemic sclerosis but are of increasing importance in defining a subgroup of Raynaud's patients likely to develop scleroderma.

The antinuclear antibody profile is not as clear-cut in juveniles as in the adult form, although some trends are emerging. Serum antinuclear antibodies have been reported in 25 to 55 per cent of juveniles with localized scleroderma, the association being most marked in the linear group and in patients with extensive cutaneous

lesions. Antibodies to single-stranded DNA also appear to be correlated with the extent of localized disease, whereas antibodies to double-stranded DNA are rarely found. It is interesting that in the generalized form of childhood scleroderma no anticentromere antibodies have been reported, even in those children with disease identical to that found in the adult.

A pathogenetic role for autoantibodies in systemic sclerosis has long been sought. Defined epitopes seem to be targets for the autoantibodies and there has been recent work showing homology between target autoantigens in systemic sclerosis and retroviral proteins, suggesting molecular mimicry, which may have significance in disease pathogenesis. There are reports that some of these antibodies are also able to enter intracellular compartments (Levine *et al*. 1991; Ma *et al*. 1991) and thereby to mediate intracellular events, such as the reported ability of anticentromeric antibodies to disrupt the centromere. In addition, autoantibodies might be able to activate cells that bear the target autoantigens; for example, patients with systemic sclerosis produce antibodies that bind *Fc* gRI (CD64), II (CD32), and III (CD16) (Boros *et al*. 1993). It has been suggested that some of the autoantibodies in serum from systemic sclerosis may mediate antibody-dependent cytotoxicity, and potential effector cells have been found in the skin of some patients (White 1994). Another speculation is that these antibodies might contribute to the pathology if they mediated complement-dependent cellular lysis or phagocytosis. However, these ideas must be kept in perspective balanced against the lack of correlation of antibody titre with disease duration or activity. Circulating antibodies to the extracellular matrix proteins, collagens I, III, IV and VI, and laminin have also been found in systemic sclerosis, but their role is undetermined (Mackel *et al*. 1982).

Macrophages, mast cells, eosinophils, and basophils are found in increased numbers and in an activated state in tissues of patients with systemic sclerosis. These cells are capable of producing soluble mediators and can thereby modify endothelial and fibroblast function; for example, mast cells produce histamine, which stimulates both proliferation and matrix synthesis by fibroblasts and causes retraction of endothelial cells.

The initiating stimulus in idiopathic scleroderma is unknown, although the identification of chemical precipitants for environmentally induced systemic sclerosis as discussed above (e.g. vinyl chloride and epoxy resin) may provide some clues to the processes involved, particularly in view of the similar immunogenetic associations for both idiopathic and chemically induced disease (Black *et al*. 1983).

The most obvious major targets for the immune response in systemic sclerosis are endothelial cells and the fibroblasts. Stimulation of collagen synthesis could involve an increasing number of cytokines known to modulate the properties of fibroblasts. It is possible that cascades of such cytokines or autocrine/paracrine loops stimulate or maintain the disease process. It is now appreciated that the repertoire of mediators and cytokines produced by immune cells, fibroblasts, and endothelial cells is large. It is possible that the aberrant properties of connective tissue cells (e.g. excess synthesis of collagen, fibronectin, and glycosaminoglycans) and the endothelial-cell damage and vasculopathy, are consequences of the immunological events in systemic sclerosis.

To date, the only well-established animal model of an immune, scleroderma-like disorder is that of the chronic graft-versus-host disease in mice (Bocchieri and Jimenez 1990). There is also a human counterpart following bone marrow transplantation in which patients develop Raynaud's, dermal sclerosis, and vasculopathy (Roumm *et al*. 1984; Chosidow *et al*. 1992). Although these models are interesting, they should be viewed with caution. Graft-versus-host disease is certainly induced by T cells but the final lesion is damage to endothelium, epithelium, or both, related to the actions of natural killer cells, lymphokines (e.g. interleukin 1) and tumour necrosis factor. This damage can occur in many organs, for example lung, gut and skin, and can therefore mimic the end-point of many damaging processes. Such mimicry may be totally irrelevant to the initiating process or even the damaging events.

Pathogenesis

Although the pathogenesis of systemic sclerosis is still uncertain, it is likely that the development of both the *fibrous* and the *vascular* lesion is complicated and involves events that may occur simultaneously or in sequence (Fig. 1).

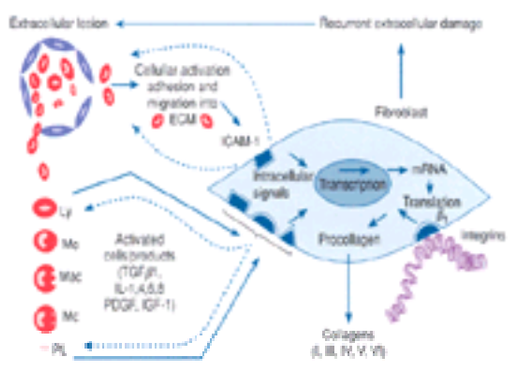

Fig. 1 Hypothesis for the pathogenesis of the scleroderma lesion. Complex interactions between cells of the immune system, vasculature, and connective tissue matrix lead to the development of an activated fibrogenic fibroblast phenotype.

Fibrosis is a hallmark of a number of diseases that includes scleroderma, pulmonary fibrosis, atherosclerosis, liver cirrhosis, and keloids. It is important to remember that the formation of fibrous tissue can be a normal physiological response, for example in wound healing. However, in fibrotic disorders the regulation of this normal response is altered, and in systemic sclerosis it is a widespread, non-organ-specific phenomenon. Excess deposition of collagen and extracellular matrix protein in the skin and internal organs of patients with systemic sclerosis was first demonstrated histopathologically many years ago, and this was confirmed by physical and biochemical means. Subsequently, techniques for culturing fibroblasts have provided valuable insight into the mechanisms involved in the synthesis of extracellular matrix components. Skin fibroblasts from scleroderma, or at least a subset of them, synthesize increased quantities of fibronectin, proteoglycan core proteins, and particularly collagens types I and III and to a lesser degree IV and VI.

Fibroblasts grown from areas of dermal sclerosis continue to synthesize increased amounts of collagen for several passages *in vitro* (LeRoy 1974; Uitto *et al*. 1979). It has also been demonstrated that the amounts of mRNA for these matrix proteins are increased and have been localized predominantly to areas surrounding dermal blood vessels. Nucleic-acid hybridization techniques have since confirmed that not all fibroblasts are activated to produce more normal collagen but rather a group of high-collagen producers is responsible. The increase in collagen RNA could arise through increased an transcription rate or by a reduction in the breakdown of the mRNA, and there is evidence that both mechanisms may operate. The transcriptional rate of genes encoding pro-a2(I) collagen (*COL1A2*) is increased in fibroblasts from systemic sclerosis, suggesting a change in regulatory transcription factors in these cells.

The mechanism for transcriptional regulation of collagen synthesis is still unproven but De Crombrugghe *et al*. (1990) have demonstrated a pathway that could have a direct bearing on the transcriptional defect in scleroderma. Following stimulation by transforming growth factor-b, fibroblasts containing the promoter–enhancer regions of the a2(I) collagen gene linked to a chloramphenicol acetyl transferase reporter show a marked enhancement of collagen gene expression. This appears to be through the interaction of a transacting DNA-binding protein, nuclear factor 1, and the specific promoter of the collagen gene. Such elegant experiments provide a prototype for the study of the activation of a pleomorphic genetic response such as fibrosis, which is not, of course, restricted to systemic sclerosis. Neither is the cytokine stimulus likely to be transforming growth factor-b alone. The activation and perpetuation of systemic sclerosis is a complex affair and other mediators such as platelet-derived growth factor, interleukins 1 and 4, and fibroblast growth factors may be involved. The cytokines possibly act in a cascade, and the timing and site of a biopsy might be critical for its correct interpretation.

One aspect of control that seems to be normal in fibroblasts from systemic sclerosis is that provided by negative feedback from propeptides. In addition, it should be noted that fibroblasts in scleroderma have changes in their proliferative properties. Scleroderma fibroblasts, unlike those from normal skin, display persistent proliferation in serum-free medium, but they are not transformed or immortalized cells, and they have similar doubling times, life-span and monolayer culture patterns to those of normal fibroblasts. What is, however, without doubt is that they are dysregulated with respect to the synthesis of extracellular matrix; whether this abnormality is wholly acquired or whether it is partially inherited and then activated by an inciting event is unknown.

Vascular lesions

Vascular injury is critical to the pathogenesis of systemic sclerosis and may be the primary event (Campbell and LeRoy 1975). The damage in systemic sclerosis is widespread and can be recognized as:

1. Vasomotor instability or Raynaud's phenomenon with repeated 'transient' interruption of tissue perfusion in the digits and internal organs (systemic Raynaud's), which is often an early event in disease development.
2. Microvascular abnormalities with structural changes characterized by proliferative intimal arterial lesions and obliteration of the vessels, leading to chronic ischaemia. Vascular damage can be visualized in the nailfold capillaries but it is also present in the small blood vessels of virtually all the viscera, muscle, subcutaneous tissues, and skin.
3. Intravascular pathology that is manifest by decreased red-cell deformability, increased platelet activity, and enhanced thrombus formation.

Many factors may be important in the vascular damage but it is the endothelial cell that is thought to have a pivotal role. The endothelium is now known to produce numerous molecules (see Table 11) and to regulate many aspects of vascular stability including control of vascular tone, permeability, thrombotic potential, and leucocyte trafficking (Pearson 1990; Kahaleh and Mattuci-Cerinic 1995).

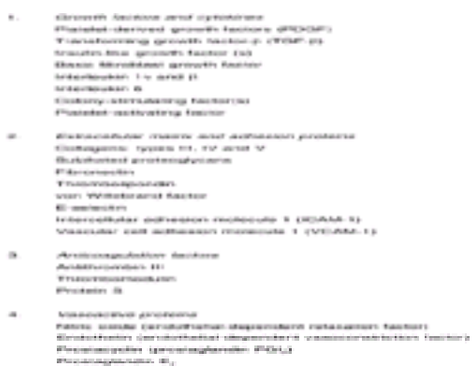

Table 11 Molecules synthesised by the vascular endothelium

Evidence for endothelial-cell dysfunction

The considerable evidence for endothelial-cell dysfunction in scleroderma is summarized below:

1. direct observation of abnormal nailfold capillaries;
2. increased capillary permeability to tracer molecules, with a slowing of flow and increased periods of stasis;
3. changes in circulating levels of endothelial-cell products such as von Willebrand factor, endothelin 1, plasminogen activator, angiotensin-converting enzyme, and prostacyclin/thromboxane metabolites;
4. the presence of a circulating cytotoxic factor identified as granzyme 1, a serine protease present in granules of activated T cells;
5. the presence of autoantibodies that bind to endothelial cells—these autoantibodies are distinct from other circulating antibodies characteristic of scleroderma.
6. increased endothelial cell-surface expression *in vivo* and elevated circulating levels of the adhesion molecules, intracellular adhesion molecule 1 (**ICAM-1**), vascular cell adhesion molecule 1 (**VCAM-1**), and E-selectin.

The mechanism for vasospasm in systemic sclerosis is likely to be complex. Interactions between extracellular matrix products such as nitric oxide, endothelin 1 and prostacyclins, platelet-released products (serotonin and b-thromboglobulin) and neuropeptides (calcitonin gene-related peptide and vasoactive intestinal polypeptide) may all contribute to the abnormal vascular tone (Kahaleh and Mattuci-Cerinic 1995).

The mechanism for the development of injury in the extracellular matrix is unknown but both immune (cell-mediated and humoral) and non-immune cytotoxicity have been implicated, and recently, several reports have shown that extracellular matrix can be damaged before there is an obvious inflammatory infiltrate. Prescott *et al*. (1992) studied sequentially the pathological changes in the perivascular spaces in the skin of patients with scleroderma and normal controls. Functional and structural endothelial change with subendothelial oedema was recognized as the first defect, followed by platelet aggregation and lymphocyte migration of both CD+ and CD8+ T cells. Tissue fibrosis occurred after the inflammation had subsided. Supporting evidence for this finding comes from the work of Harrison *et al*. (1991) in which damage to endothelial/epithelial surfaces is shown to be the first ultrastructural change to occur in lung biopsies from patients with systemic sclerosis. Lung sections appearing normal under light microscopy, with no evidence of infiltrating inflammatory cells, were, on electron microscopy, shown to contain widespread endothelial/epithelial damage. The nature of the primary vascular trigger to immune stimulation is critical to our understanding of the disease: environmental agents or an endothelium-seeking virus are possible candidates. In addition, intense vasospasm, which occurs both in the extremities and in internal organs in patients with systemic sclerosis, could lead by reperfusion injury and free-radical damage to structural and functional change in the endothelium and subsequent immune activation (Blann *et al*. 1993).

Following injury to, and activation of, the vascular endothelium adhesion molecules such as E-selectin, VCAM-1 and ICAM-1 are up-regulated in response to cytokines and other factors. These endothelial adhesion molecules bind to specific ligands on T and B lymphocytes, platelets, neutrophils, monocytes and natural killer cells, facilitating their adhesion to vascular endothelium and subsequent migration through what have now become 'leaky vessels' into the extracellular matrix, ultimately with the potential for fibroblast activation. Therefore if endothelial change could be detected, and stabilized at an early stage, it would almost certainly influence the clinical expression and progression of the disease.

The clinical picture

Scleroderma, as discussed earlier, is not one condition but a spectrum of heterogeneous conditions occurring at any age and including localized and systemic forms. Within each subtype the rate of progression and extent of damage varies. Occasionally, localized scleroderma may become systemic and sometimes localized scleroderma and eosinophilic fasciitis merge or overlap, either appearing together or sequentially. In addition, there are sclerotic conditions induced by a variety of occupational, environmental, and metabolic stimuli.

Juveniles may develop any form of scleroderma, but fortunately, there is a predilection for the localized forms in which the skin, subcutaneous fascia, muscle, and bone are the main organs to be attacked. In the localized form the skin at first shows a marked inflammatory reaction, followed by matrix deposition, fibrosis, and ultimately atrophy. The linear lesions are most associated with subcutaneous involvement and growth defects, but in general there are no systemic features (Hanson 1976).

Childhood-onset scleroderma is rare in comparison to the adult disease and to juvenile chronic arthritis. Fewer than 3 per cent of all cases of scleroderma are childhood-onset (Dabich *et al*. 1974), and such children comprised fewer than 3 per cent of all patients seen in a paediatric rheumatology clinic (Hanson 1976). Ascertainment of childhood scleroderma may be biased by referral patterns and subspecialty orientation. In a paediatric rheumatology centre, systemic sclerosis is seen much less frequently than localized scleroderma, approximately one case to every 15 of localized disease. In a busy dermatology clinic, morphoea is more commonly seen and scleroderma *en coup de sabre* may be misdiagnosed as alopecia areata: consequentially, the real prevalence of these conditions is unknown. Like its adult counterpart, childhood-onset scleroderma occurs in all races, with a female predominance. There appears to be no significant familial incidence. HLA studies with sufficient numbers of children in each group are only now being undertaken, and preliminary information presented would suggest that the HLA associations in the childhood disease are quite different from those found in adult scleroderma.

Localized scleroderma

This is separated from systemic sclerosis not only by the absence of vasospasm, structural vascular damage and involvement of internal organs, but also by the

distribution of the dermal lesions, which may, depending on the subtype, follow a dermatomal pattern. The varied clinical features have led to the separation of three main varieties of localize scleroderma, morphea, linear, and *en coup de sabre*.

Morphoea

This may be circumscribed or generalized. In circumscribed morphoea (Fig. 2) there may be just one or two lesions with no generalized spread. The changes often begin with small, violaceous or erythematous skin lesions, which enlarge and progress to firm 'hidebound' skin with variable degrees of hypo- or hyperpigmentation. These lesions eventually settle into a waxy, white appearance with subsequent atrophy. Pruritis is often a problem with the early lesion. Lesions vary in diameter between 1 and 10 cm. The condition generally resolves within 3 to 5 years, although sometimes a patch may persist for over 25 years. In generalized morphoea there are many patches covering a large surface area. The acral parts are usually spared, but the trunk and legs are often involved. Generalized morphoea can be disfiguring and may continue to extend, resulting in contractures, disability, and troublesome ulceration that may occasionally become malignant. In guttate morphoea there are multiple small, hypopigmented and pigmented papules 2 to 10 mm in diameter, with minimal sclerosis, and the lesions closely resemble those of lichen sclerosus et atrophicus. These lesions usually localize to the neck, shoulders, and anterior chest wall.

Fig. 2 Localized morphoea showing discrete lesions with central depigmentation and circumferential inflammation.

Linear scleroderma

The sclerotic areas occur in a linear, band-like pattern, often in a dermatomal distribution (Fig. 3). They often cross joint lines, and are associated with atrophy of the soft tissue, muscle, periosteum, bone, and occasionally synovium; they can lead to extensive growth defects in a limb or a part thereof, which can be extremely disfiguring. Fixed valgus or various deformities also occur, and scoliotic changes in the spine can develop as a result of inequalities in limb length. If the toes or fingers are involved, 'hammer toes' or 'claw hand' may develop. All of these changes are much more noticeable in a growing child and most cases of linear systemic sclerosis tend to occur in childhood, as do most cases of *en coup de sabre*, a specialized form of linear disease.

Fig. 3 Linear scleroderma occurring in childhood. Defective growth of the involved limb if a major clinical problem in childhood-onset disease.

En coup de sabre

Linear scleroderma occurring on the face or scalp may assume a depressed, ivory appearance. The lesion was considered originally reminiscent of the scar from a sabre wound so it was termed '*coup de sabre*'. The linear lesion is often associated with hemiatrophy of the face on the same side. It may also be associated with vascular abnormalities of the brain (David *et al*. 1991), and also with morphoea lesions elsewhere. It is also not uncommon for patients to present with morphoea and then later develop linear lesions (Falanga *et al*. 1986). This evolution should be anticipated extremely carefully, as the linear lesions tend to have much greater morbidity than the circumscribed patches of morphoea. The linear lesions may be quietly progressive for a long period, and lengthy follow-up is important.

In addition, in children there has been described a small group with morphoea and/or linear lesions who also have a synovitis, which can be demonstrated by infrared thermography (Allen *et al*. 1987). These patients have a raised erythrocyte sedimentation rate, rheumatoid factor, and circulating autoantibodies. Such cases are unusual, but they have an accelerated course with rapid development of contractures. An additional intermediate and interesting group of juveniles was described by Ansell *et al*. (1976). These children's disease is often mistaken for polyarticular juvenile chronic arthritis, since they may present with extensor and/or flexor tendon nodules in the hands, nodules at the elbows, knees or ankle joints, stiffness and a limitation of joint movement, but with little evidence of synovitis. At the time of presentation, there may only be a small area of localized or linear scleroderma, distant from the joint symptoms. The erythrocyte sedimentation rate and rheumatoid factor are usually normal, but autoantibodies are often present. There is both a clinical and a biochemical association, the nature of which is unclear, between localized scleroderma and eosinophilic fasciitis, in which large sclerotic patches may also occur.

Evaluation of all forms of scleroderma is difficult. In the localized forms, charting of the involved areas is often cumbersome and imprecise. However, the size of the lesion can be recorded, leg length, limb circumferences, and posture can be monitored, and muscle function and neurological status assessed. Charting of new lesions is also essential. In addition, thermography can be used to assess the activity of localized disease (Birdi *et al*. 1992).

Raynaud's phenomenon and the presclerotic state

It is fortunate that almost all cases of generalized systemic sclerosis arise in patients with Raynaud's phenomenon. The overall prevalence of this phenomenon has been variably assessed as between 3 and 10 per cent of adults worldwide, although it may affect as many as 20 per cent of young women. The prevalence varies somewhat depending on climate, skin colour, ethnic background, and occupational exposure to vibrating machines (Belch 1989).

The clinical syndrome was first described by Maurice Raynaud in 1862 as episodic digital ischaemia provoked by cold and emotion. It is classically manifest by episodic pallor of the digits followed by cyanosis, suffusion, and/or pain and tingling. The blanching reflects vasospasm in the digital vessels, the cyanosis the deoxygenation of static venous blood, and the redness reactive hyperaemia following the return of blood flow. Continuous blanching, blueness or pain is not Raynaud's phenomenon and to have implications for autoimmune rheumatic disease the phenomenon must be biphasic and episodic.

The episodic vasospasm can also be observed in the tip of the nose, the nipples, the mouth, and the ear lobes. More recently, and of great interest, there are reports of a systemic 'vasospasm', which may affect the cerebral, coronary, pulmonary, renal or upper gastrointestinal blood supply. With the published evidence of vasospasm in many organs, it is interesting to speculate that abnormalities of the vasculature may exist throughout the whole Raynaud's patient (Belch 1990). A

careful history is still the best way to diagnose the phenomenon, although this can be supported in the laboratory with measurements of digital and organ blood flow.

Important clues to secondary Raynaud's on clinical evaluation are: the development of Raynaud's either in very young children or after the age of 45 years; severe symptoms occurring all year round; digital ulcerations, which rarely, if ever occur in primary Raynaud's; asymmetry of symptoms; and the reoccurrence of chilblains in an adult (Lally 1992). Two simple, inexpensive, non-invasive procedures have high predictive power for detecting patients in the Raynaud's group who will have systemic sclerosis in the future; serum autoantibody determination and nailfold capillary microscopy. These tests should be performed in all Raynaud's patients. The antinuclear antibodies were discussed earlier in the chapter and the presence of disease-specific autoantibodies plus abnormal nailfold capillaries is a powerful predictive tool.

Autoantibodies

The number of autoantibodies present in the serum of patients with scleroderma is varied (Table 9) (Pollard *et al*. 1989; Bona and Rothfield 1994). However, three of these antibodies have particular importance: anticentromere, antitopoisomerase-1 (Scl-70), and antinucleolar antibodies. Anticentromere antibodies react with the centromere portion of chromosomes and particularly with the kinetochore plates that attach the centromere to the spindle during mitosis; they appear to be a constant finding over time, appear early in the disease, and have a predilection for the subset of limited cutaneous systemic sclerosis. In contrast, antitopoisomerase 1 is an antibody found in up to 60 per cent of patients with diffuse cutaneous systemic sclerosis. This proportion tends to vary considerably between laboratories, and retrospective analysis and patient selection may have influenced results. The specificity of antinuclear antibodies as determined by immunoblots was also found to be predictive of the subtypes of systemic sclerosis. A prospective study of primary Raynaud's and undifferentiated autoimmune rheumatic disease (Kallenberg *et al*. 1988), using the immunoblot method, found that the presence of antinuclear antibodies at the time of entry into the study was associated with the evolution of an autoimmune rheumatic disease, usually scleroderma. Furthermore, in those who initially presented with Raynaud's disease alone, anticentromere antibody had a predictive value for the development of limited cutaneous systemic sclerosis (sensitivity 60 per cent, specificity 98 per cent) and Scl-70 for diffuse cutaneous systemic sclerosis (sensitivity 38 per cent, specificity 100 per cent). Antinucleolar antibodies now being characterized biochemically are present in many patients with scleroderma and further definition may improve their diagnostic specificity. Thus it seems that the presence of antinuclear antibodies, particularly anticentromere antibody and Scl-70, in a patient with apparent Raynaud's disease may mark the probability of later progression to one of the subsets of systemic sclerosis (Wollersheim *et al*. 1989).

Nailfold capillaroscopy

The most distal parts of the skin and its appendages receive their nutrient blood supply from capillary loops that arise from and return to a vascular plexus deeper in the skin. These capillary loops can be seen in the skinfold of the finger nail, where the capillary is visible over its long axis (Fig. 4). Direct observation of the nailfold capillary bed dates back almost 70 years and was introduced by German investigators. Recent refinements have permitted permanent photographic recording of a row of horizontal capillary loops at the nailfold, just proximal to the cuticle (Carpentier and Maricq 1990). The characteristic patterns seen in patients destined to develop autoimmune rheumatic disease are:

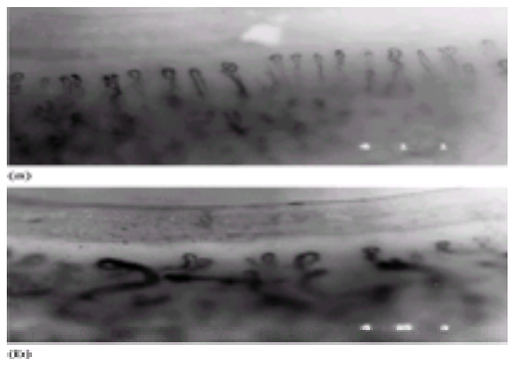

Fig. 4 (a) Photographs if normal nailfold capillaries showing normal spacing, orientation, and indentations. (b) Photograph of nailfold capillaries of a patient with scleroderma showing avascular areas and capillaries that area dilated and irregular in shape and distribution with distributed orientation. Original magnification ×65. (By courtesy of Dr Frances Lefford, Department of Anatomy and Developmental Biology, University College London.)

1. the enlargement of all three portions of the capillary loop—arterial, apical and venular;
2. the loss of capillaries either diffusely or in localized areas often adjacent to enlarged capillaries.

Dilatation without avascular areas is reported to be characteristic of limited cutaneous systemic sclerosis and dilatation with avascular areas characteristic of diffuse cutaneous systemic sclerosis. The capillary patterns are present early in the disease and are remarkably constant over time.

Comment

Tests for autoantibodies and nailfold capillaroscopy together detect more than 90 per cent of patients destined to have generalized systemic sclerosis. Of the 3 to 10 per cent of the population with Raynaud's up to 15 per cent are positive for one or both procedures. These recent observations are now leading to a shrinkage in the number of patients with true Raynaud's disease and an expansion in the number of patients who potentially have autoimmune rheumatic disease.

There is no evidence that symptomatic treatment of Raynaud's phenomenon in any way influences the evolution of scleroderma. However, once the mechanisms of fibrosis and vascular damage are better understood, the predictive power of these two tests, possibly coupled with other serological or genetic markers, ought to allow for a more preventive approach.

Scleroderma once established is a multisystem, multistage disease and each target organ progresses through stages of inflammation, fibrosis, atrophy, not necessarily at the same time or with the same speed. The eventual effect of these pathological processes is to impair organ function. In the following sections some organs, particularly those whose involvement may be fatal, will be discussed in detail; others will be summarized and/or tabulated.

Cutaneous involvement (Fig. 5 and Fig. 6)

The changes in the skin usually proceed through three phases: early, classic, late. The early stage can be difficult to diagnose and a high level of suspicion is needed in the oedematous phase when the only feature may be puffiness of the hands and feet, most marked in the mornings. The face may feel slightly taut at this stage and Raynaud's may be present. On examination there is a non-pitting oedema with intact epidermal and dermal appendages. The subsequent, often sudden, development of firm, taut, hidebound skin proximal to the metacarpophalangeal joints, adherent to deeper structures such as tendons and joints, causing limitation of their movement and subsequent contractures, permits a definitive diagnosis in over 90 per cent of patients. The skin may be coarse, pigmented, and dry at this stage. The epidermis thins, hair growth ceases, sweating is impaired, and skin creases disappear.

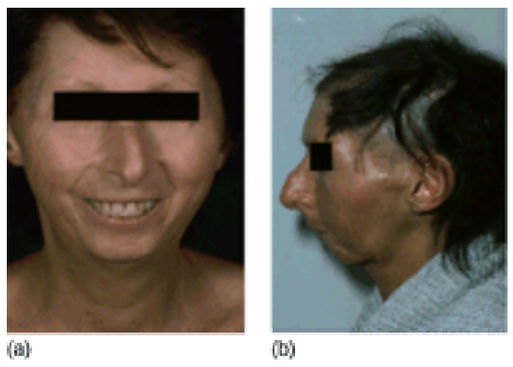

Fig. 5 (a,b) Typical facial appearance of diffuse cutaneous systemic sclerosis, with tight shiny skin, contrasting with the widespread facial telangiectasis often present in advanced, limited cutaneous systemic sclerosis

Fig. 6 The three phases of skin involvement in the hands of a patient with systemic sclerosis; (a) initial puffiness of the skin; (b) tight shiny skin with iduration, loss of finger pulp, and contractures; (c) late changes of contractures with atrophic skin and ulceration.

Changes limited to the fingers alone (sclerodactyly) do not carry the same implication. The classical changes, once fully developed, can remain static for many years. Careful mapping of the degree and extent of skin involvement is the single best clinical technique for detecting the patient at risk for life-threatening involvement of internal organs. A number of scoring systems to quantify skin sclerosis have been developed. Most are two-dimensional instruments that attempt to summate the severity of skin involvement at a number of different sites in the body. A modified version of the original Rodnan skin score, consisting of a 0 to 3 grading at 17 skin sites (maximum score 51), has been shown to be better in terms of greater observer agreement and lower bias than a method in which the observer attempts to shade on a mannequin the full extent of skin involvement. The interobserver variability in the use of the modified Rodnan skin score in studies from both the United Kingdom and United States is similar (Clements *et al*. 1990). An overall within-patient variability in scoring (derived from multiple examinations) is about five skin-thickness units, which is similar to the variability found in scoring joint tenderness in rheumatoid arthritis (Ritchie score), justifying its use in clinical trials to follow-up the outcome of skin involvement.

Taut hypo- or hyperpigmented skin proximal to the elbows, knees or clavicles qualifies a patient as having diffuse cutaneous systemic sclerosis and such patients require more frequent multisystem evaluation. Patients with diffuse cutaneous systemic sclerosis have a preponderance of visceral involvement in the first 5 years of symptoms. The exact beginning of the late phase is usually impossible to define, but at some point, and this may be 2 to 15 years after the appearance of the classical changes, the pattern moves into a final phase. The taut truncal arm and leg skin softens, and in some patients, but for the pigmentation, it would be difficult to know that they had ever had systemic sclerosis. Nevertheless, the hands in diffuse cutaneous systemic sclerosis nearly always show the ravages of the early, actively fibrotic period, and tautness and contractures usually remain even after resolution elsewhere. Other skin manifestations include digital pitting scars, loss of fingerpad tissue, ulcers, telangiectasias, and calcinosis. Skin biopsy is usually no more sensitive than the experienced touch in diagnosing the full-blown disease, but may provide useful suggestive information in the early oedematous phase.

In the early phase there are collections of mononuclear cells in the dermis, particularly around blood vessels. The soluble products of these monocytes and lymphocytes may have pathogenetic significance in the disease process. In the classic phase, fibrosis replaces the cellular infiltrate and may extend deep into the connective tissue to surround tendons, nerves, muscle bundles, and joint capsules. In the final stage, the fibrosis may be less evident, with epidermal thinning and loss of appendages the major findings.

Systemic features of disease

General manifestations

The patient with systemic sclerosis must cope with a complex set of symptoms that range from features common to chronic diseases through to complaints attributable to specific visceral involvement; fatigue and lethargy are common throughout the illness, although usually more pronounced in its early phases. Weight loss is almost universal in the diffuse cutaneous form and is less common in the limited variety. Fever is uncommon and if present, other causes such as infection or underlying malignancy should be excluded. Reactive depression is a frequent accompaniment to this often relentless and disfiguring disorder. Patients often feel isolated and support groups provide an invaluable service.

Gastrointestinal tract

The gastrointestinal tract is probably the most commonly involved internal organ system in systemic sclerosis (Shorrock and Rees 1988; Silver 1990). Over 90 per cent of patients with limited cutaneous and diffuse cutaneous systemic sclerosis have oesophageal hypomotility and serious gastrointestinal disease has been estimated to occur in 50 per cent of patients with limited cutaneous systemic sclerosis. It is probable that when systemic sclerosis affects an area of the gastrointestinal tract it does so in a sequential manner with progressive dysfunction (Cohen *et al*. 1980; Greydanus and Camilleri 1989). This concept is important when designing therapeutic regimens. The earliest lesion is neural dysfunction. The basis for this lesion is uncertain, although in the oesophagus there is both physiological and anatomical evidence that it is due to arteriolar changes in the vasa nervorum (D'Angelo *et al*. 1969; Russell *et al*. 1982; Greydanus and Camilleri 1989). An alternative explanation would be compression of nerve fibres by fibrous tissue (Dessein *et al*. 1992). This produces functional change before the next step, which is impairment of muscle contractility. These functional changes may remain asymptomatic for a long period but, if looked for, they usually respond well to prokinetic drugs. Once smooth-muscle atrophy is established, symptoms usually appear. The muscle can respond partially to prokinetic drugs but the response is weak. The final lesion, as with all other organs in systemic sclerosis, is muscle fibrosis superimposed on neural dysfunction and atrophy. At this stage, restoration of function is not possible.

The earliest clinical symptoms may be quite subtle. Patients can often recall a specific event when there was difficulty in swallowing a pill or bolus of hard food. They may also experience retrosternal discomfort or even overt pain, which can be nocturnal. There are patients (forming part of the continuum of systemic sclerosis and who should be included in the group with limited cutaneous systemic sclerosis) who demonstrate Raynaud's phenomenon, abnormal nailfold capillaries, anticentromere antibodies, and decreased motility or at least decreased lower oesophageal-sphincter pressure, but no skin sclerosis. Measurement of lower oesophageal pressure is frequently unacceptable to the patient and therefore in clinical practice the oesophageal transit time (quantitative oesophageal scintigraphy) is usually the preferred screening test. It is non-invasive, cost-effective, and is highly acceptable to patients. In those who have an abnormal scan and those who have frank dysphagia or heartburn, barium studies and/or direct oesophagoscopy may be required to identify structural divisions such as hiatus hernia and oesophageal strictures. Fortunately, Barrett's metaplasia and oesophageal stricture are rare. All patients with systemic sclerosis should be recommended to raise their bed ends with blocks, take small frequent meals, and not eat late at night. The therapies available for oesophageal disease are numerous and their place in management is

summarized in Table 12.

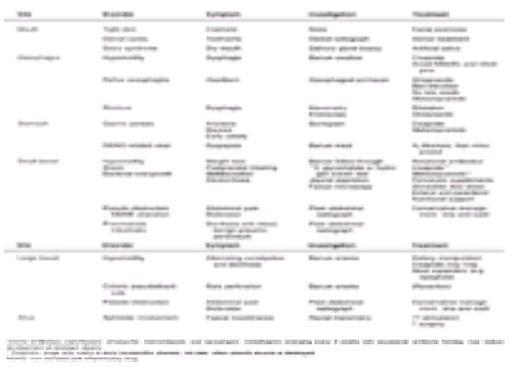

Table 12 Gastrointestinal-tract pathology in systemic sclerosis

Recent studies have also emphasized that oesophageal disease is not predicted by disease subset or duration and may be relatively asymptomatic. Often investigations are not undertaken in the non-complaining patient, but perhaps we should pursue studies early in the disease so that distal hypomotility can be detected and treated aggressively. Such action may delay or prevent irreversible, pathological change.

Small-bowel disease with hypomotility is a major problem in scleroderma and can lead to weight loss, cachexia, malabsorption, and death. The classical symptoms are of a change in bowel pattern, with loose, frequent, floating, foul-smelling stools, and abdominal distension, but a patient may also present with weight loss (otherwise unexplained) or a nutritional anaemia. There are numerous possible ways of investigating the small bowel (some as yet research tools), and each test has its exponent. Details are given in Table 12.

Once the disease is established, bacterial overgrowth with its associated malabsorption is a recurring problem, often punctuated by abrupt episodes of distension and adynamic ileus or pseudo-obstruction as it is now called. The management of such patients is difficult and includes the rotational use of antibiotics, attempts to stimulate the bowel directly with cisapride, and ultimately total parenteral nutrition administered by the patient at home. There are greater than 50 per cent 5- and 10-year survival rates for patients on total parenteral nutrition, which is a distinct improvement over survival rates before total parenteral nutrition was available.

Atony and hypomotility of the rectum and sigmoid colon is frequent and occurs early. It is often missed clinically because patients are reluctant to discuss symptoms such as anal incontinence, a problem for which there is no relief. Constipation is usually manageable with the use of dietary manipulation and stool volume expanders. Codeine can cause constipation and should be avoided.

Surgery to the large bowel or any other part of the gastrointestinal tract must be viewed with great caution. Careful manometry and radiographic localization of affected segments of stomach, small intestine, and colon may allow judicious surgical resection or venting procedures, but these are not without risk and are not always successful.

Pancreatic exocrine function is frequently reduced, but rarely to an extent that is clinically important. Primary biliary cirrhosis may occur and it is associated with the subgroup of limited cutaneous systemic sclerosis. As the gastrointestinal manifestations of systemic sclerosis are frequent, and debilitating if not life-threatening, the goal in this area must be early detection, support, and control, thus permitting as active a life as possible.

Cardiac disease

Vascular, microvascular, and a vasospastic phenomena are, as in all other organs, a feature of cardiac scleroderma (Follansbee 1986). The clinical symptoms are diverse and sometimes difficult to separate from pulmonary or renal disease. They are largely non-specific, including dyspnoea, orthopnoea, paroxysmal nocturnal dyspnoea, oedema, palpitations, and atypical chest pain. Angina pectoris is uncommon and such a history should be regarded as a potential indicator of an underlying complicating factor such as coronary atherosclerosis. No definite predisposition to coronary atherosclerosis has been demonstrated in this disease, although recently the occurrence of large-vessel disease in association with systemic sclerosis has been emphasized. Youssef *et al*. (1993) found a threefold increase in evidence of large-vessel disease among patients with systemic sclerosis compared with the predicted population prevalence of 2.3 per cent for symptomatic vascular disease. Large-vessel disease seems to be associated with limited cutaneous systemic sclerosis and anticentromere antibody-positive patients. Cardiovascular manifestations of systemic sclerosis include myocardial fibrosis, pericarditis, a variety of arrhythmias, conduction abnormalities and pulmonary hypertension, and rarely myocarditis. Cardiac involvement has a poor prognosis, which is probably most directly related to the extent of myocardial fibrosis present. There are many diagnostic techniques useful in evaluating cardiac scleroderma, but the investigation must be carefully matched to the clinical feature (see Table 13).

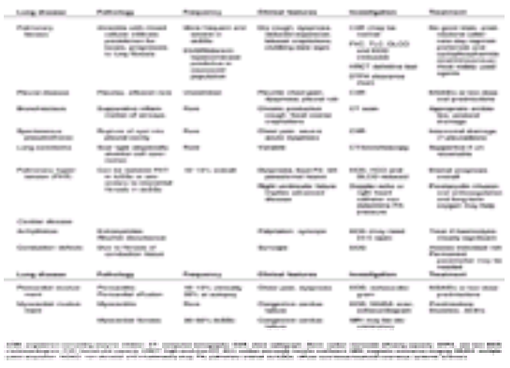

Table 13 Cardiopulmonary manifestations of systemic sclerosis

Two features have been singled out for discussion, myocardial fibrosis because it is the hallmark of cardiac scleroderma, and pulmonary hypertension, with its sequelae including right heart failure, which often presents abruptly and which has such a devastating course. The nature and distribution of the myocardial fibrosis has a number of distinctive features. It is distributed randomly throughout both ventricles and develops throughout the entire thickness of the ventricular wall. It bears no relation to the extramural vascular supply and in some areas is so confluent that it gives the appearance of a circumscribed myocardial infarction. An additional distinctive histological feature of the myocardial fibrosis is the coexistence of contraction-band necrosis. This is typically seen in circumstances of myocardial ischaemia followed by reperfusion. In patients with scleroderma this suggests that vasoconstriction of the small, intramyocardial coronary arteries (a myocardial Raynaud's phenomenon) might be contributing to the pathogenesis of myocardial scleroderma. It would appear from work by Follansbee *et al*. (1990) that patients who develop left ventricular dysfunction in the absence of other apparent underlying causes commonly have advanced myocardial fibrosis associated with contraction-band necrosis, whilst patients who develop ventricular dysfunction in the clinical context of altered myocardial loading conditions (that is, systemic hypertension, pulmonary fibrosis, pulmonary hypertension) tend to have less myocarditis.

Pulmonary hypertension occurs in systemic sclerosis, usually in patients with the limited cutaneous type. It is attributable directly to pulmonary vascular disease, which can be suspected if on testing pulmonary function there is an isolated marked decrease in diffusing capacity for carbon monoxide (<50 per cent of predicted normal) in the absence of significant restrictive ventilatory abnormalities. Pathologically, pulmonary arteries of all sizes show marked intimal and medial hyperplasia; of great interest is the finding by Follansbee *et al*. (1990) that, although the clinical syndrome seems confined to the group with limited cutaneous systemic sclerosis, intimal thickening and narrowing, albeit to a lesser degree, occurred in patients with diffuse cutaneous systemic sclerosis. In addition to the obstructive vascular

lesions, the pulmonary vasculature appears to be abnormally reactive, with significant pulmonary vasoconstriction occurring on exposure to cold, again analogous to a peripheral Raynaud's phenomenon. That systemic sclerosis can be an overwhelmingly vascular disease is perhaps nowhere more convincingly demonstrated than in the subset of patients with severe pulmonary hypertension. It has an extraordinarily poor prognosis; death is usually due to rapidly progressive respiratory insufficiency accompanied by severe right-ventricular hypertrophy and failure.

The treatment of the cardiac manifestations of systemic sclerosis is primarily supportive, empirical, and of moderate value (see Table 13). Caution is necessary when treating patients with large pericardial effusions in diffuse scleroderma to avoid intravascular volume depletion, because of their predisposition to develop renal failure. Patients with systemic sclerosis and coexisting coronary arterial disease are often not good candidates for bypass surgery because of the distal vascular and interstitial disease that will reduce flow despite the presence of a satisfactory graft.

Pulmonary involvement

Pulmonary involvement ranks only second to oesophageal in frequency of visceral disease, and with considerable improvements in the management of renal disease it is now the major cause of death in scleroderma.

A study (Altmann *et al*. 1990) on patients with diffuse skin disease, pulmonary involvement but no cardiac or renal disease found a median survival of 78 months with 60 per cent dead at 5 years. Early diagnosis enabling the institution of effective therapy to halt disease progression is therefore a critical aim in the management of the patient with systemic sclerosis. Fortunately, this is becoming possible with the aid of modern techniques such as high-resolution computed tomography (Wells *et al*. 1993b; Wells *et al*. 1994), [$^{99}Tc^{m}$]diethylene triamine pentacetate (**DTPA**) scanning and analysis of bronchoalveolar lavage fluid (Wells *et al*. 1993a). There is also evidence that the genetic markers HLA-DR3/DR52a (Briggs *et al*. 1990; Langevitz *et al*. 1992) and specific autoantibodies Scl-70, anti-U3 ribonucleoprotein, and antihistone antibodies may help separate this group at presentation.

The two major clinical manifestations of lung involvement are fibrosing alveolitis and pulmonary vascular disease. Other potential complications include aspiration pneumonia, pleural disease, spontaneous pneumothorax, drug-induced pneumonitis, associated pneumoconiosis, and neoplasm. Pulmonary fibrosis occurs in more than three-quarters of the patients with systemic sclerosis and pulmonary vascular disease in approx. 50 per cent. Autopsy studies have always yielded higher percentages than clinical studies.

In contrast to pulmonary hypertension, as discussed above, with other cardiac manifestations, interstitial lung disease often develops insidiously but established fibrosis is irreversible with present-day therapy. Early diagnosis is therefore vital and in the future genetic markers may help to identify this group at presentation. Pulmonary manifestations of systemic sclerosis are listed in Table 13.

The most common symptoms of respiratory involvement are breathlessness, especially on exertion, and a dry cough. Chest pain is infrequent and haemoptysis rare, and if either are present then the presence of additional pathology should be sought. On physical examination the most frequent finding is of bilateral basal crepitations (Alton and Turner-Warwick 1988).

The classical radiographic features consist of reticulonodular shadowing, usually symmetrical and most marked at the lung bases. However, the chest radiograph is an insensitive indicator of fibrosing alveolitis, and should be used only as an initial screen or to exclude infection or aspiration secondary to oesophageal abnormalities. There are many symptomatic patients (often mildly so) with normal chest radiographs despite interstitial lung disease, and lung function tests can be discriminatory. The single-breath diffusion test (*DL* CO) is abnormal in over 70 per cent of patients with diffuse cutaneous systemic sclerosis (including asymptomatic patients with no complaints and an unremarkable chest radiograph). A reduction in *DL* CO is the earliest proven abnormality in patients with systemic sclerosis who develop interstitial lung disease; lung function tests that show normal volumes but reduced transfer of gases in the face of normal imaging are suggestive of pure pulmonary vascular disease (see above). Measurement of the alveolar–arterial oxygen difference during exercise also appears to be a sensitive indicator of lung disease in systemic sclerosis.

Over the past 5 years the application of thin (3 mm)-section, high-resolution CT scanning of the lungs has revolutionized the approach to diffuse lung diseases and has revealed the character and distribution of fine structural abnormalities not visible on chest radiographs (Harrison *et al*. 1989) (Fig. 7). Using this technique, the earliest detectable abnormality is usually a narrow, often ill-defined, subpleural crescent of increased density in the posterior segments of the lower lobes. When more extensive, the shadowing often takes on a more characteristic reticulonodular appearance yet frequently retaining a subpleural distribution. It also becomes associated with fine, honeycomb air spaces and ultimately larger, cystic air spaces—an appearance that mirrors the macroscopic appearance. In a semiquantitative comparison of the predictive value of these CT appearances to mirror the biopsy evidence of an inflammatory alveolitis, a 'ground glass' pattern of opacification on CT was associated with a predominantly cellular biopsy whereas a reticular pattern of abnormality was found in patients whose subsequent lung biopsy confirmed a particularly fibrotic disease process (Muller and Miller 1990; Wells *et al*. 1992). CT scans also confirm the presence of pleural disease or mediastinal lymphadenopathy, which is commonly present. It is important to perform prone as well as supine scans, particularly in more subtle cases, to exclude the contribution of gravity to the radiographic appearances from vascular and interstitial pooling in the dependent areas. In addition to identifying early disease, high-resolution CT scanning can identify a pattern of disease that predicts a better response to therapy and a better prognosis (Wells *et al*. 1993). Furthermore, the extent of disease present, as defined by CT within the lavaged lobe, correlates with the predominant type of inflammatory cell obtained by bronchoalveolar lavage of that same lobe: lymphocytes are present in excess before CT identifies disease; eosinophils appear as the lung becomes abnormal; neutrophils are found in most abundance when at least 50 per cent of the lavaged lobe is involved in the disease process. In other words, the predominant type of inflammatory-cell traffic into the lungs depends upon extent of disease, and this would suggest that different inflammatory cells are involved in different stages of the pathogenesis.

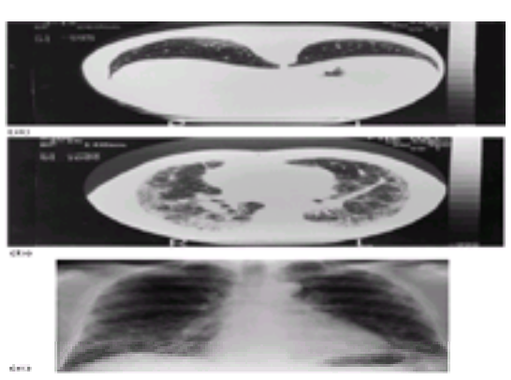

Fig. 7 Thin-section CT scan images illustrating; (a) ground-glass appearance of early pulmonary involvement posteriorly, associated with a normal chest radiograph; (b) extensive honeycomb shadowing and cystic air spaces involving both lower lobes, with corresponding chest radiographic appearances of advanced interstitial lung disease (bibasilar reticulonodular shadowing) (c). (With grateful acknowledgement to Drs A Wells, R du Bois and B Strickland, Departments of Respiratory Medicine and Radiology, Royal Brompton Hospital, London.)

In predicting the histological pattern CT, although useful, has not replaced lung biopsy as the 'gold standard' investigation (Fig. 8). As yet, patients who appear to have early changes on CT should still be considered for a thorascopic biopsy for staging of the disease. In the evaluation of diffuse lung disease, bronchoalveolar lavage has now been used for almost 20 years to sample cells and non-cellular material from the lower respiratory tract. The presence of abnormal numbers of granulocytes, particularly neutrophils and eosinophils (Harrison *et al*. 1989; Miller *et al*. 1990), is typical for a patient with fibrosing alveolitis occurring alone or in the context of systemic sclerosis. Excess lymphocytes are found in some individuals. In a typical patient with fibrosing alveolitis, bronchoalveolar lavage would produce an increase in total cell returns of three- to sixfold (up to 6×10^{5}/ml of fluid return); of these, up to 20 per cent may be neutrophils or eosinophils. Excess lymphocytes may be found (up to 20 per cent of the total cells) and an increase in mast cells may be observed in a small percentage of patients.

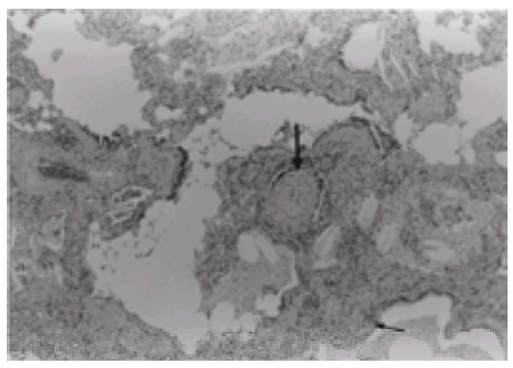

Fig. 8 Open lung biopsy of patient with systemic sclerosis showing interstitial chronic inflammation and fibrosis (small arrow) and thick-walled arteriole showing intimal fibrosis (large arrow). Haematoxylin and eosin, ×300. (Courtesy of dr Mary N Sheppard, Department of Lung pathology, Royal Brompton Hospital, London.)

The prognostic value of bronchoalveolar lavage has been demonstrated in several studies (Harrison *et al*. 1989; Silver *et al*. 1990). Silver *et al*. (1990) reported that patients with scleroderma with persistent alveolitis have greater deterioration in their pulmonary function than alveolitis-negative patients with systemic sclerosis.

The use of DTPA clearance in the management of systemic sclerosis has been the subject of extensive study and has been shown to be of value. It identifies early disease and also identifies a group of patients whose disease will run a more stable, non-progressive course; that is, those with normal clearance (Wells *et al*. 1993). The speed of clearance of the isotope is dependent upon the integrity of the epithelial barrier and therefore anything that disrupts this, either inflammation or fibrosis, will increase the rate of clearance (Barrowcliffe and Jones 1987). DTPA clearance is highly sensitive: cigarette smoking will produce increased clearance rates and the test is, therefore, only of value in non-smokers or those who have given up smoking for at least 1 month before the assessment (Mason *et al*. 1983).

In systemic sclerosis, clearance of DTPA may be abnormal even when chest radiography and pulmonary function tests are normal (Harrison *et al*. 1989). In established disease, clearance is enhanced in comparison with normal individuals. Furthermore, the speed of, and change in, clearance can predict subsequent changes in pulmonary function tests. Patients whose clearance is persistently abnormal are more likely to have a deterioration in pulmonary function tests at follow-up subsequent to the DTPA measurements. In contrast, persistently normal DTPA clearance predicts stable disease and therefore provides a good prognostic index; a study showed significant improvement in pulmonary function tests in 75 per cent of patients whose clearance returned to the normal range whereas similar improvements were not seen in those whose clearance remained normal or abnormally fast (Wells *et al*. 1993).

Considerable space has been devoted here to the lung because it is the organ that represents a major challenge in systemic sclerosis for the next decade, and because the available diagnostic tests have improved. The frequency of reassessments depends on the subset and length of disease. Those with diffuse cutaneous disease should be studied yearly or more frequently if necessary, whilst those with limited cutaneous disease have less need for frequent follow-up in the first 5 years of their illness and could be assessed at 2 years, but with increasing time must be watched on an annual basis for the development of pulmonary complications, either fibrosis or vascular disease.

Renal disease

Although renal disease has now been superseded by lung involvement as the major cause of systemic sclerosis-related death, it remains one of the most important complications of scleroderma and, despite its life-threatening nature, it is amenable to treatment, although the prognosis is much better if appropriate management is instituted early. Both post- and ante-mortem studies suggest that epithelial and endothelial renal lesions occur before there is clinical evidence of renal disease in systemic sclerosis (Kovalchik *et al*. 1978), and certainly precede any histological evidence of fibrosis. This supports the view that epithelial, and particularly endothelial, damage are important early events in the pathogenesis of scleroderma (Prescott *et al*. 1992). The best characterized pattern of renal involvement in systemic sclerosis is an acute or subacute renal hypertensive crisis. This generally occurs in patients with diffuse systemic sclerosis within 5 years of disease onset. The overall incidence of scleroderma renal crisis is uncertain, with differences in the reported frequency even in series from the same unit. This variation probably reflects differences in incidence in the various subsets of systemic sclerosis. In high-risk patients the incidence may be as great as 20 per cent but overall is probably less than 10 per cent (Steen 1984). Traub (1994) proposed the following criteria to diagnose scleroderma renal crisis: abrupt onset of arterial hypertension greater than 160/90 mmHg; hypertensive retinopathy of at least grade III severity; rapid deterioration of renal function and elevated plasma renin activity. Other typical features include the presence of a microangiopathic haemolytic blood film and hypertensive encephalopathy, often complicated by generalized convulsions. It is generally considered important to perform a renal biopsy, once hypertension has been adequately controlled, especially if renal replacement therapy is being contemplated. This allows histological confirmation of the diagnosis and the exclusion of other causes for renal failure of abrupt onset, such as glomerulonephritis or the haemolytic–uraemic syndrome. Histologically, systemic sclerosis renal crisis typically shows fibrinoid necrosis, mucoid or fibromucoid proliferative intimal lesions (when extensive, termed onion skinning) in renal arteries, particularly the arcuate and interlobular vessels; glomerular thrombi occur and ultimately glomerulosclerosis (Fig. 9). The extent of the glomerular lesion can be useful in predicting the eventual degree of functional recovery. Patients usually present with the clinical features of severe hypertension, including headaches, visual disturbances, hypertensive encephalopathy (especially seizures), and pulmonary oedema. Occasionally a similar pattern of renal dysfunction occurs without hypertension (normotensive renal crisis), suggesting that the pathological features are not simply the end-organ consequences of raised arterial pressure (Helfrich *et al*. 1989). A more insidious pattern of renal involvement in systemic sclerosis is also reported in which there is a slow reduction in glomerular filtration rate accompanied by proteinuria. This is believed to reflect a more benign vascular and fibrotic process than scleroderma renal crisis.

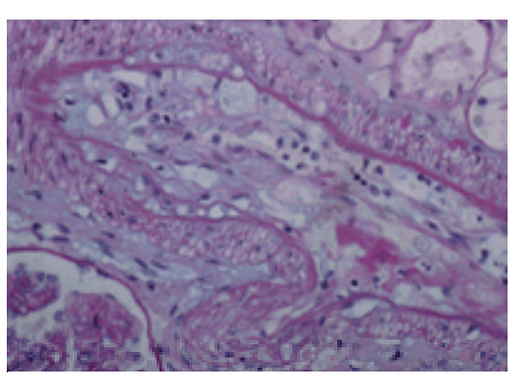

Fig. 9 An artery in the corticomedullary region. This section has been stained by the Alcian-blue/diastase-periodic acid-Sciff method. The lumen of the blood vessel has been entirely effaced by proliferation and swelling of the intima. Intimal cells can be seen to have developed an unusual bubbly, blue (mucoid) cytoplasm that is characteristic of scleroderma-related acute renal arteriopathy. There is scattered small-lymphocyic infilltrate as well. (By courtesy of Dr A. P. Dhillon, Department of Histopathology, Royal Free Hostpital Medical School, London.)

Management of renal systemic sclerosis requires a high index of suspicion to enable early diagnosis and treatment of the renal crisis. Creatinine clearance or isotope glomerular filtration rate should be checked twice yearly in diffuse cutaneous systemic sclerosis for the first 5 years and annually thereafter. In limited cutaneous systemic sclerosis there is much less risk and a less frequent measurement of the glomerular filtration rate is sufficient. Blood pressure should be well controlled (often antihypertensive treatments also help Raynaud's symptoms) and in diffuse cutaneous systemic sclerosis the use of angiotensin-converting enzyme inhibitors is particularly appropriate since there is some anecdotal evidence that they protect from hypertensive crisis (Steen *et al*. 1990). High-dose corticosteroids have now been formally demonstrated in a case–control study to increase the risk of renal crisis in diffuse cutaneous systemic sclerosis and doses above 20 mg prednisolone equivalent daily should be avoided (Steen *et al*. 1994).

Once diagnosed, an acute renal crisis in systemic sclerosis must be treated as a medical emergency. The patient should be admitted immediately and reasonable control of the blood pressure is a priority. Extreme caution must be taken, however; to avoid a precipitous or excessive drop in arterial pressure and also to prevent relative or actual hypovolaemia associated with vasodilatation of constricted vascular beds, both of which can further diminish renal perfusion and compound the renal lesion of systemic sclerosis with acute tubular necrosis. For this reason, powerful parenteral antihypertensives (e.g. intravenous nitroprusside or labetolol) should be avoided; an internal jugular or subclavian venous cannula should be inserted to monitor central venous filling pressure; and an indwelling arterial cannula for pressure monitoring should be considered. Hypertension should be treated with angiotensin-converting enzyme inhibitors (captopril or enalapril up to maximum dose) and calcium-channel blockers (starting with long-acting nifedipine initially), aiming to reduce both diastolic and systolic pressure by 20 mmHg in the first 48 h and ultimately maintaining diastolic pressure at 80 to 90 mmHg. Intravenous prostacyclin, which is believed to help the microvascular lesion without precipitating hypotension, is often administered from diagnosis. Fish-oil capsules are sometimes prescribed in view of their unproven but theoretically beneficial properties (McCarthy and Kenny 1992). Renal function should be closely monitored by twice-weekly creatinine clearance and daily serum creatinine estimations. Regular full blood counts, clotting screening, and estimations of fibrin degradation product are important to monitor the degree of microangiopathic haemolytic anaemia, which often reflects the activity of the disease process. Short-term haemodialysis should be given if necessary and peritoneal dialysis often works well if long-term renal replacement therapy is needed. Interestingly, it has been observed that after a renal crisis, skin sclerosis and other features of systemic sclerosis improve (Denton *et al*. 1994), particularly if a patient is undergoing maintenance dialysis. The reason for this is unknown; it may result from the removal or inactivation of circulating mediators or simply reflect the natural history of the disease. It should be remembered that there is also often considerable recovery in renal function after an acute crisis, sometimes allowing dialysis to be discontinued, and improvement can continue for up to 2 years. Therefore any decisions regarding renal transplantation should not be made before this time.

Musculoskeletal system

Muscle

Skeletal muscle is often involved in scleroderma (Russell 1988). In many instances the weakness and atrophy results from disuse secondary to joint contractures or chronic disease. However, about 20 per cent have a primary myopathy (Medsger 1979), which is a subtle process distinctive for the disease. This chronic myopathy is characterized by mild weakness and atrophy of muscles, minimal elevation of creatine phosphokinase, few or no changes on electromyography, and subtle histological features showing focal replacement of myofibrils with collagen and perimysial and epimysial fibrosis without inflammatory change. This form of myopathy, which can last for many years, is non-progressive, does not warrant intervention, and is often unresponsive to anti-inflammatory mediation. A minority of patients exhibit an inflammatory myositis, indistinguishable from polymyositis; caution must be observed if this occurs in the context of early diffuse disease, when treatment with high-dose steroids might precipitate renal failure, and an alternative treatment should be considered. An atypical inflammatory myositis that requires special histochemical stains to demonstrate the differences in fibre size and composition has been reported in association with myocarditis in a few cases of systemic sclerosis. This form of myopathy, which can last for many years, is often unresponsive to non-steroidal or glucocorticoid anti-inflammatory medications.

Joints

A symmetrical polyarthritis, usually seronegative, anodular and non-erosive, is the presenting feature in a small number of patients destined ultimately to develop systemic sclerosis. By 2 years, frequently much earlier, the synovitis has subsided and classic cutaneous systemic sclerosis is present, often developing abruptly over 1 to 3 months.

The fibrosis characteristic of the classical disease affects the tendons (causing tendon friction rubs), the ligaments, and joint capsules, restricting movement; fibrosis is also found in the synovium. The synovium in systemic sclerosis is often covered by an excessive amount of fibrin; the reason for this is unknown.

Joint destruction is unusual. Management of soft tissue and joint problems is closely linked to skin care and to overall skeletal mobility. True bone changes in the form of distal tufts are usually a late change occurring in the second and third decade of the disease, and are thought to be due to a lack of a vascular supply adequate enough to preserve viable bone. This can occur in patients with long-standing Raynaud's phenomenon without connective tissue disease. Other sites of bone reabsorption, for example the mandible and ribs, have been recorded late in the disease.

Other organ involvement

Other organs involved in systemic sclerosis are listed in Table 14.

Organ	Effect	Pathological process	Frequency
Thyroid	Spectrum of autoimmune thyroid disorders — especially hypothyroid	Thyroid antibodies present in > 50%	20–40%
Liver	Primary biliary cirrhosis (PBC)	Antimitochondrial antibodies in 25% patients with systemic sclerosis. Anticentromere antibodies in 5–20% patients with PBC	3% CREST
	Abdominal pain, bile peritonitis	Inspissation of gallbladder	Rare
	Calcification of liver		Very rare
	Extrahepatic obstructive jaundice	Mucosal ulceration	Very rare
	Nodular regenerative hyperplasia of the liver		Very rare
Nervous system	Trigeminal neuralgia	Collagen deposition in sphenotrium	Most common neurological change
	Carpal tunnel syndrome		3%
	Sensorimotor peripheral neuropathy	Vascular damage of vasa nervorum	
	Autonomic neuropathy		Possibly up to 60% — under-recognized
	Prolonged action of local anaesthetics		
	Subacute combined degeneration of the cord	Malabsorption of vitamin B_{12} (secondary to small-bowel involvement)	Rare
Impotence	Erectile failure (libido intact)	Vascular fibrosis of cavernosal arteries	25–50% males

Table 14 Other organ involvement in scleroderma

Systemic sclerosis and pregnancy

The greater incidence of scleroderma in women has focused interest on the potential interrelations between scleroderma, hormones, and pregnancy. It is of interest that women with Raynaud's phenomenon have an increased likelihood of low birthweight babies and fertility problems both before and after the onset of disease. It is unknown whether these findings are a reflection of the vasospasm affecting pregnancy or whether they reflect a common aetiological link.

The question of pregnancy in systemic sclerosis can be approached from two angles: the effect of scleroderma on pregnancy and its outcome, and the effect of pregnancy on the development and course of systemic sclerosis (Black 1990b).

Case-controlled studies have provided conflicting evidence on the outcome of pregnancy. British and Italian studies have shown an increase in the spontaneous abortion rate in women destined to develop systemic sclerosis. The British workers also found a higher rate of infertility, habitual abortion, and a higher probability that the pregnancy would end in stillbirth or neonatal death. An American study, however, showed only an increase in intrauterine growth retardation and prematurity, but not in miscarriage or fetal death.

The outcome of the pregnancy for the mother is also a subject of discussion. The American workers found no increase in maternal morbidity or mortality. However, the 23 case reports since 1932 (which may well select more interesting and thus severe cases) gave nine deaths, eight in patients with diffuse cutaneous systemic sclerosis, and at least five due to renal failure. Disease progressed in twelve of these patients, regressed in two, regressed during pregnancy but progressed afterwards in two, and developed during the pregnancy in one. In reports of larger series, totalling 103 pregnancies (mainly in women with limited disease), the disease developed during pregnancy in 9, progressed in 32, remitted in 11, and was stable in 35. There were 24 spontaneous abortions, 5 perinatal deaths, 6 cases of toxaemia, and 2 maternal deaths. These reports reinforce the worse prognosis in diffuse disease. Of some encouragement are three more recent case reports. One describes a successful pregnancy in a patient with renal involvement, controlled with angiotensin-converting enzyme inhibitors throughout. The second patient, who had a renal crisis 6 years before treated with angiotensin-converting enzyme inhibitors for 5 years, managed without therapy to reach 38 weeks' gestation before becoming hypertensive and needing caesarean section for delivery of a healthy baby. The third case described a patient with limited cutaneous systemic sclerosis,

livedoid vasculitis with foot ulceration, and a positive ribonucleoprotein autoantibody, and three previous spontaneous abortions, one neonatal death (28 weeks' gestation) and a 4-year period of secondary infertility. She was delivered of a healthy baby at 33 weeks, taking nifedipine before and throughout pregnancy for the foot ulceration.

The most feared complication in pregnancy is renal disease, which usually presents with hypertension especially in the third trimester, and is thus difficult to distinguish from toxaemia. Renal scleroderma should be considered in all but the most typical cases of pre-eclamptic toxaemia. In contrast to ordinary pre-eclamptic toxaemia, patients with systemic sclerosis can be vulnerable in the postpartum period, and must be watched very carefully.

Advice to patients with systemic sclerosis at pregnancy is difficult, since studies are limited and retrospective. Patients with diffuse skin involvement, especially with lung, renal or cardiac involvement, tend to have a worse prognosis, and should be offered therapeutic abortion. The patient with limited disease should be told of the possible development of complications, and the variable and unpredictable outcome, and may then request abortion. Very close monitoring of any patient with systemic sclerosis is then necessary throughout pregnancy.

Drug therapy

Although there is currently no treatment that can induce complete remission of the disease there are therapies available that can offer partial relief, control end-organ damage, and improve quality of life for the patient with scleroderma. The choice and evaluation of any treatment regimen are not easy. This is because (a) the disease is complex and the relation between immune dysfunction, vascular damage, and fibrosis speculative; (b) the disorder is heterogeneous and its extent, severity, and rate of progression are highly variable—therapy must therefore be closely tailored to the individual patient systems involved; (c) there is a tendency towards spontaneous stabilization and/or regression after a few years, particularly within the more benign and numerically larger subset of limited cutaneous systemic sclerosis; and (d) there is a paucity of both clinical and laboratory features for ascertaining improvement (or deterioration) in the disease, especially with respect to visceral change. Therapeutic trials of disease-modifying drugs are essential but their design is critical in this disease. There is growing acceptance that any trial of disease-modifying drugs must be controlled (preferably placebo-controlled), that patients should have early diffuse disease (less than 3 years' duration), and that studies must be of sufficient duration (1 year minimum).

Such is the frustration of the condition that numerous vitamins, hormones, 'alternative' medicines, acupuncture, and surgical procedures have been used. Most have been heralded with great enthusiasm, only to be abandoned once critically assessed.

There are no truly effective antifibrotic therapies. Some of the newer, putative antifibrotic agents that have been used in scleroderma are summarized in Table 15. D-Penicillamine and colchicine have been used in the treatment of scleroderma for many years. Neither drug stops the fibrotic process, but consensus opinion is that D-penicillamine is the more useful. To derive maximum benefit the drug must be used correctly. The most suitable subjects for treatment are those with diffuse active skin disease. Long-term treatment in a dose between 500 and 750 mg is needed. D-Penicillamine should be used throughout the active phase into the stable period and the dose maintained until there is no further improvement in skin thickening. The drug may then be reduced, but low-dose treatment should be maintained for many years—some recommend 10 years.

Therapy	Mechanism	Comments
Anticytokine antibodies	Block mediators of fibroblast activation (e.g. TGF-β)	Toxicity likely to be problematic
Enzyme antagonists	Lysyl and prolyl hydroxylase inhibitors to block post-translational modification of collagen	No data yet
Pretranslational inhibition	Block collagen gene transcription or mRNA translation using antisense nucleotides or gene therapy	Hypothetical and dependent upon progress in understanding of collagen gene regulation

Table 15 Novel potential antibiotic therapies for systemic sclerosis

The ideal group to target and treat would be the 'at risk' patients, those in the presclerotic state. Many such patients can now be identified by circulating antibodies, cytokine production, and nailfold changes. Unfortunately, adequate preventative therapy is still wanting. An extension of this idea and one that can, for example, be applied to the lung is the earliest possible diagnosis of internal organ involvement so that containment therapy may be attempted.

As the immune system may be involved early in the disease, immunomodulatory and immunosuppressive agents have been employed, particularly for early diffuse systemic sclerosis. Table 16 summarizes their use and evaluation. Both antimetabolites and alkylating agents have been used. Chlorambucil, a hopeful therapy in 1985, failed in a placebo-controlled trial. The same fate befell 5-fluorouracil. Cyclophosphamide still has an undetermined place; as a single agent its efficacy is unproven. In combination with steroids or plasma exchange it may also have a role—unfortunately as yet there are no controlled data. The use of the antimetabolites 6-thioguanine and azathioprine has been reported but again all the data are anecdotal. Methotrexate is now being approached in a more rational manner. Pilot studies have been hopeful and controlled trials are being undertaken. Attempts to target the immune system by lymphoplasmapheresis and total lymphoid irradiation again failed and currently under investigation are the use of rabbit antithymocyte globulin, and photophoresis. Monoclonal antibody therapy may hold hope for the future.

Treatment	Mechanism of action	Comments	Efficacy in clinical trials
1. Selective immunosuppression			
Cyclosporin	Inhibits T helper cell activity by reducing IL-2 release	Reported beneficial effects on skin sclerosis may be secondarily increased into decline of renal crisis	Two open study (Kahrilas et al 1985) Two open study (Caldwell et al 1986)
Antithymocyte globulin Antilymphocyte globulin	Temporary suppression of cell-mediated immunity	Possible benefit; confirmation of pilot work is essential, especially because of non-selective therapy once caused morbidity	Two open study (Takeuchi et al 1988) Possible benefit in placebo-controlled pilot study (Sinclair et al 1992, unpublished communication)
Photopheresis	8-Methoxypsoralen photoactivated & methoxypsoralen exhibits activated T cells	Benefit has been reported but good placebo-controlled clinical trial is needed	No-blind study (Scheinfeld et al 1988) Two controlled trial comparing with cyclophosphamide therapy, Williams et al. 1990) Multicentre placebo controlled trial currently in progress
Pooled human gammaglobulin	Possible inhibition of lymphocyte function via regulatory idiotype cross-reactivity	Expensive results but unsubstantiated	Not formally evaluated
2. Non-selective immunosuppression			
Methotrexate	Folic acid antagonist	Currently under formal study (RAID 21 0009)	Controlled trial in progress
Cyclophosphamide Chlorambucil Azathioprine	Alkylating agents suppressing production of immunocompetent lymphocytes	Anecdotal benefit reported in open studies but controlled trial of chlorambucil failed to show superiority over placebo Cyclophosphamide often combined with corticosteroids	Two cyclophosphamide in SSc lung disease – open study (Medsger et al. 1990) No 5-fluorouracil controlled trial (Clements et al. 1984)

Table 16 Immunology therapies for systemic sclerosis

Cyclosporin has been used in a few patients with positive results but high doses of the drug were followed by reports of hypertension and renal failure, both of which might be attributed to either the drug or systemic sclerosis (Denton *et al*. 1994). Physicians must be mindful of the fact that trough blood levels are multiplied two- to fourfold in patients taking calcium-channel blockers. Therefore a lower dose (5 mg/kg body wt per day) has been tried with encouraging results, but awaits confirmation in a controlled study.

The interferons a and g are currently being investigated in controlled trials after initial pilot studies. Recombinant interferon-g has immunoregulatory activities and is a potent inhibitor of collagen production by normal and scleroderma fibroblasts *in vitro*. Interferon-a, although theoretically less potent than interferon-g as an inhibitor of collagen synthesis, does not activate the class II cell-surface antigens—this may be a distinct advantage in a disease that is HLA-linked. None of these drugs should

be used for late-stage, stable, diffuse or limited cutaneous disease.

Long-term high-dose steroids have no place in the management of systemic sclerosis; indeed they are potentially toxic (Steen *et al*. 1994) and may be implicated in 'normotensive renal crisis'. Steroid usage has been restricted to patients with myositis, symptomatic serositis, the early oedematous phase of the skin disease, and refractory arthritis and tenosynovitis. The lowest possible but therapeutically effective dose should be sought.

Raynaud's, as described above, is a prominent feature of systemic sclerosis and occurs in over 97 per cent of cases. It is an aspect of the disease that can be relieved, though the response is variable. This idiosyncratic response may reflect the stage of the disease. If structural damage is present and severe, the patient will respond rather poorly to vasodilators alone. In uncomplicated cases, simple measures may suffice. As the attacks become more frequent, prolonged oral drug therapy, possibly on an intermittent basis, may be needed. Intravenous therapy and limited surgery are restricted to the most severe cases (see Table 17).

Treatment	Examples	Comments
1. *Simple measures*		
Non-drug	Hand warmers Protective clothing	Universally helpful; also useful to minimize cold exposure and ambient temperature changes in work environment
Pharmacological	Evening primrose oil	Evening primrose oil has been shown effective in controlled clinical trial
	Fish oil capsules	
2. *Oral vasodilators*		
Calcium-channel blockers	Nifedipine Nicardipine Felodipine Amlodipine	Relaxant equipotent, other dihydropyridines therefore best to try nonretard drugs in relation to first most effective
5-Hydroxytryptamine antagonist	Ketanserin	Only available on named-patient basis but shown effective in clinical trials
ACE inhibitors	Captopril Enalapril	In Raynaud's secondary to SSDs may protect from hypertensive renal crisis
3. *Topical vasodilators*	GTN patches	Shown effective in short-term use but often cause headaches
4. *Parenteral vasodilators*	Carbaprostacyclin (tromboxane prostaglandin E$_1$	Effective and reasonably tolerated Given for severe frequent attacks of Raynaud's, digital ulceration or gangrene, and before digital surgery
5. *Antibiotics*	Flucloxacillin Erythromycin	Important in secondary infection in Raynaud's; prolonged oral administration may be necessary
6. *Surgical procedures*		
Lumbar sympathectomy	Chemical or operative	For severe Raynaud's of lower limbs
Digital sympathectomy (radical denervation)		Useful treatment for isolated ischaemic of 1 or 2 digits
Debridement amputation	Surgical or auto	Such surgery should be conservative to allow maximum possibility of spontaneous healing

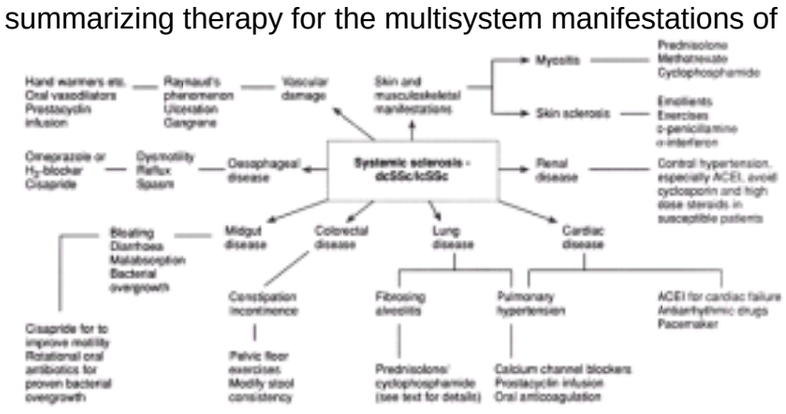
ACE, angiotensin-converting enzyme; GTN, glyceryl trinitrate; SSDs, diffuse connective tissue diseases.

Table 17 Treatment options for Raynaud's phenomenon

Because of the widespread vascular damage there has been a search to find drugs to protect injured endothelial cells and to prevent platelet aggregation and subsequent release of platelet-derived mediators. This search has been disappointing to date. Ketanserin, a serotonin antagonist, although useful in Raynaud's phenomenon, does not improve structural vascular disease. Dipyridamole and aspirin, although reducing the circulating plasma concentrations of b-thromboglobulin or circulating platelet aggregates, were not clinically effective in a randomized double-blind trial. Captopril, the angiotensin-converting enzyme inhibitor that has been so successful in the treatment of renal crisis, has been considered for the primary and possibly prophylactic treatment of vascular disease.

Our own approach to the management for some of the important subgroups of patients within the scleroderma spectrum of disorders is summarized below, and in Box 1. The management of localized scleroderma in adults and children is summarized in Table 18.

Box 1 Algorithm summarizing therapy for the multisystem manifestations of systemic sclerosis



Pattern of disease	Clinical features	Treatment	Prognosis
Localized morphoea	One or a few circumscribed sclerotic plaques with hyper- or hypopigmentation and often inflamed violaceous border	Often unnecessary Serial measurement to assess progress	Good prognosis; lesions less active within 3 years but pigmentary changes often persist
Generalized morphoea	Widespread pruritic lesions, often symmetrical and following the distribution of superficial veins	Suppress inflammatory component using corticosteroids: in children oral doses up to ½ mg/day have been recommended; infusion i.v. may be better D-Penicillamine is often used: in children 3 mg/kg day initially (maximum 13 mg/kg/day), adult daily maintenance dose at least 500 mg Methotrexate and systemic or intralesional interferon may be effective, and cyclosporin has been used in refractory cases	Internal organ pathology very rare. Raynaud's seldom associated Generally improves within 3 years of onset, although textural and pigmentary changes can remain
Linear scleroderma	Sclerotic areas occurring in linear distribution often on limbs and asymmetrical; in childhood can lead to serious growth defect of affected limbs; careful serial measurement of muscle bulk and limb length essential	Suppression of inflammation with oral or i.v. steroids (as above) Maintenance treatment with D-penicillamine or methotrexate Physiotherapy and appropriate regular exercise to minimize growth defect in childhood-onset foci	Long-term effects of childhood-onset foci minimized by effective suppression of inflammatory process, and by good physiotherapy Ultimately the disease tends to resolve, but in part remain active for many years
En coup de sabre	Linear scleroderma affecting the face of scalp, involving underlying subcutaneous tissues, muscles, periosteum and bone; underlying cerebral abnormalities have been reported	Therapeutic options as for linear scleroderma; systemic treatment only for active inflammatory lesions	Scarring, growth deficits, and alopecia persist but inflammatory component usually resolves

Table 18 Management of localized scleroderma in adults and children

Our approach to management of Raynaud's and scleroderma

1. Raynaud's phenomenon without other features of autoimmune rheumatic disease

At presentation

Detailed history and examination to look for evidence of asymptomatic autoimmune rheumatic disease. Thoracic-inlet radiographic imaging to exclude simple structural lesion (e.g. cervical rib). Baseline nailfold capillaroscopy and autoantibody profile (antinuclear antibodies, extractable nuclear antigen, anticentromere antibody) are important to determine whether the patient has primary Raynaud's phenomenon or is likely to develop features of an autoimmune rheumatic disease in the future. Infrared thermography with a standard cold challenge can be used to confirm diagnosis in equivocal cases and assess severity of vasospasm.

Follow-up

If capillaroscopy and autoantibodies are normal/negative, then simple approaches with advice on non-pharmacological relief (hand-warmers, thermal gloves), supplemented as necessary by vasodilator drugs. If the Raynaud's is of short duration (i.e., less than 2 years) the patient is followed annually until the fourth year after onset of symptoms. If capillaroscopy or autoantibody studies are positive, then give the same advice and treatment but follow up at 6 months, and then yearly for 5 years, with repeat capillaroscopy and autoimmune profile. Discharge from regular follow-up at 5 years if no other disease features have developed, and Raynaud's has not required parenteral vasodilator drugs.

2. Diffuse cutaneous systemic sclerosis

At presentation

History and physical examination generally establish the diagnosis. Assess the extent of visceral disease by baseline hand and chest radiography, lung function tests,

oesophageal motility study (scintigraphy or barium swallow), creatinine kinase, creatinine clearance and urinary protein excretion, Doppler echocardiography (with estimation of pulmonary arterial systolic pressure), and electrocardiogram. High-resolution CT lung scan, DTPA clearance, and bronchoscopy with studies of bronchoalveolar lavage fluid are usually performed in highly specialized units. Right-heart catheter studies and open lung biopsies are occasionally necessary to supplement the information obtained from other less invasive investigations. Once diagnosis is confirmed, tissue typing and autoantibody profiles may be useful to identify groups with poor prognosis. Raynaud's symptoms, if prominent, can respond well to intravenous prostacyclin infusions. Immunosuppressive therapy (e.g. antithymocyte globulin) may be considered for the most severe cases within 3 years of onset. Antifibrotic therapy is clearly the most appropriate approach for established diffuse cutaneous systemic sclerosis but unfortunately agents of proven efficacy are lacking. In our unit, for patients with progressive and extensive diffuse cutaneous systemic sclerosis, interferon-a is the first-line agent, monitored by serial skin sclerosis score. The results of formal controlled trials in diffuse cutaneous systemic sclerosis are keenly awaited. Lung fibrosis is treated by combination therapy with prednisolone and cyclophosphamide, as outlined in detail above.

Follow-up

This is especially important during the first 5 years from disease onset. Vigilant monitoring for renal involvement should include regular checks of blood pressure, 6-monthly 24-h urine collection for protein excretion and creatinine clearance. Six-monthly lung function tests and electrocardiograms, with yearly oesophageal motility and echocardiographic studies are generally performed in our own unit.

3. Limited cutaneous systemic sclerosis

At presentation

By the time of presentation the history is usually of some years duration and the physical signs, even if minimal, are generally diagnostic. Diligent attention to the assessment of internal organs is necessary, especially as the disease duration lengthens. The main risks in this scleroderma subset are of pulmonary hypertension, often in the absence of significant interstitial fibrosis, and involvement of the small and large bowel.

Treatment in this group is largely symptomatic and as yet no satisfactory drugs to halt the underlying processes are available. It may, however, be important to treat these patients at an asymptomatic stage in the hope of preventing or slowing down the chronic vascular damage. Current treatment in this group is directed mainly towards the vascular features (Raynaud's and pulmonary vascular disease, when present) and gastrointestinal complications. Reflux oesophagitis is almost universal but fortunately responds well to proton-pump inhibitors such as omeprazole, which we prefer to use rather than H_2-blockers, although the latter also often give good symptomatic relief. Oesophageal spasm may respond to cisapride. In contrast, although midgut disease and anorectal complications are less frequent, they are far more difficult to manage.

Follow-up

Annual follow-up is generally undertaken, with assessment of visceral disease, including renal function by creatinine clearance. These patients often require long-term vasodilator therapy, usually intensified during the winter months. Later in the disease (especially after 10 years of established limited cutaneous systemic sclerosis), pulmonary hypertension more likely. Patients carrying antitopoisomerase 1 (Scl-70) antibody are particularly susceptible to lung fibrosis and their lung function should be carefully monitored.

Education and support forms a particularly important component of the management of patients with systemic sclerosis, who should be made aware of the various support groups and the importance of non-pharmacological aspects of care including appropriate exercises, skin care, and the importance of being in a stable, warm ambient temperature.

Conclusion

Currently therefore, although there is no curative treatment for scleroderma, a careful consideration of the subset and stage of disease of the individual patient can maximize the use of the drugs currently available. It is hoped, more importantly, that the level and degree of activity of research into the cause and pathogenesis of the condition may eventually result in early rational effective treatment.

Acknowledgement

The authors are grateful to Dr Aine Burns, Consultant Nephrologist at the Royal Free Hospital, London, for her help with the section on renal disease in scleroderma.

5.9.1 Polymyositis and dermatomyositis in adults

Ira N. Targoff

Introduction

Polymyositis and dermatomyositis are the most common forms of 'idiopathic inflammatory myopathy', a category that also encompasses inclusion body myositis, and several rare forms. Inflammatory myopathy may also be induced by drugs or infections. Dermatomyositis is distinguished from polymyositis by the presence of a characteristic rash. Weakness affecting skeletal muscle is the major clinical manifestation of most patients, although the skin rash or other extramuscular features may predominate in some.

Wagner first described a case as polymyositis in 1863, while Unverricht first used the term dermatomyositis in 1887. Early studies often included cases that would not fit our present concept. The wide acceptance of the diagnostic criteria of Bohan and Peter (1975) has served to standardize subsequent studies and promote recognition.

Epidemiology

Incidence and prevalence

Estimates of the annual incidence of polymyositis/dermatomyositis have ranged from 1 to 9 cases per million per year, and prevalence from 2.4 to 10.7 cases per 100 000 (Cronin and Plotz 1990; Sigurgeirsson *et al*. 1992; Ahlstrom *et al*. 1993). For example, Oddis *et al*. (1990a) in Pittsburgh, Pennsylvania, found 5.5 per million per year, with an increased incidence over time (2.5 cases per million per year in the first decade, 8.9 per million per year in the second) that could reflect better detection and recognition, or a true increase.

Polymyositis is more common than dermatomyositis in most studies of adults (Bohan *et al*. 1977; Tymms and Webb 1985), but the ratio (less than 2:1) is low and may vary with the population, referral patterns, or criteria for dermatomyositis. Some studies found dermatomyositis to be more common (Ramirez *et al*. 1990; Love *et al*. 1991; Koh *et al*. 1993). Overlap syndromes with other autoimmune rheumatic diseases occur in 15 to 20 per cent.

Risk factors

Polymyositis/dermatomyositis is fourfold more common in the United States in black patients than white patients (Cronin and Plotz 1990). The female:male ratio is 2:1 overall, but lower in myositis with malignancy, and higher during the childbearing years (5:1) and in patients with associated autoimmune rheumatic diseases (Bohan *et al*. 1977). Polymyositis and dermatomyositis may begin at almost any age, but the peak in adults is usually from 40 to 60 years; it tends to develop later in white than in black women (Oddis *et al*. 1990a), and later with cancer (Love *et al*. 1991).

Cases of adult polymyositis and dermatomyositis among family members are very rare, but have been observed (Gurley *et al*. 1992; Garlepp 1993). A family history of myopathy should make one question the diagnosis of polymyositis/dermatomyositis. Other autoimmune disease in relatives of polymyositis and dermatomyositis patients is not unusual (Mbauya *et al*. 1993).

Temporal and geographic factors

Most studies have not found variation in the incidence of adult-onset polymyositis /dermatomyositis with time of year, although one study found a higher rate from March to May (Manta *et al*. 1989). However, certain autoantibody-defined subgroups show significant seasonal differences in the onset of myositis: anti-Jo-1-associated myositis begins more often in the spring, and anti- **SRP**-(signal recognition particle)-myositis more often in the autumn (Leff *et al*. 1991).

Polymyositis and dermatomyositis occur in all parts of the world, but in developing countries infectious myositis is more common. Occasional local clusters of myositis have been reported, which may have atypical features (Nagaraja *et al*. 1992). Certain autoantibodies appeared to differ in prevalence in different regions (Love *et al*. 1992).

Clinical picture

Classification

Several classification systems have been proposed to define subgroups of patients with idiopathic inflammatory myopathies that are more clinically homogeneous (Dalakas 1988a; Miller 1994; Medsger and Oddis 1995), and able to predict course and responsiveness. Disagreement remains, however, due to our lack of knowledge of aetiology.

Most recent studies have used the Bohan and Peter (1975) classification (Table 1), or modifications. Pure polymyositis is separated from dermatomyositis, but not in the presence of malignancy, juvenile onset, or an associated autoimmune rheumatic disease. Patients are usually considered to have dermatomyositis rather than polymyositis only when the rash is observed, but some also include patients without overt skin lesions who have characteristic muscle pathology (Byrne and Dennett 1993). Inclusion-body myositis is a clinically and histologically distinct entity, and should probably be classified separately even when associated with malignancy or autoimmune rheumatic diseases (see later section). Several rare but distinctive forms of idiopathic myositis have also been defined (Table 1).

I. Primary idiopathic polymyositis
II. Primary idiopathic dermatomyositis
III. Polymyositis or dermatomyositis with malignancy
IV. Juvenile dermatomyositis (or polymyositis)
V. Overlap syndrome of polymyositis or dermatomyositis with another autoimmune rheumatic disease
VI. Inclusion-body myositis[b]
VII. Rare forms of idiopathic myositis (a) Granulomatous myositis (b) Eosinophilic myositis (c) Focal myositis (d) Orbital myositis

[a]Classes I to V correspond to Bohan and Peter's original classification (Bohan and Peter (1975).
[b]Patients with inclusion body myositis in association with malignancy or other autoimmune rheumatic diseases should be considered to be class VI.

Table 1 Classification of idiopathic inflammatory myopathies [a]

Certain specific autoantibodies can define subgroups of patients that differ from the overall myositis population with regard to clinical features, response to therapy, prognosis, and HLA type (Love *et al*. 1991). These autoantibodies can be used to classify patients in a way that is complementary to clinical classification.

Clinical features

Myositis

Weakness

Muscle weakness is the main clinical feature of both polymyositis and dermatomyositis, occurring in almost all patients. It usually develops insidiously over weeks to months, generally more slowly in polymyositis than dermatomyositis (Casademont *et al*. 1993). More indolent cases may be seen, progressing over years (more in polymyositis than dermatomyositis), that must be distinguished from inclusion-body myositis. More rapid onset occurs occasionally.

The weakness is typically symmetrical, affecting the large proximal muscles around the shoulders, hips, thighs, trunk and neck. The lower extremities are often involved first, but in most patients both upper and lower extremity involvement occurs (Plotz *et al*. 1989; Henriksson and Lindvall 1990). Patients often have impairment in performance of daily activities such as standing from a chair, getting out of a car, climbing stairs, reaching (e.g. into cabinets), working overhead (hanging clothes, etc.), or combing their hair. The gait may be affected. Getting out of bed, sitting from a supine position, or raising the head off the pillow may become difficult. Weakness of distal muscles is uncommon in polymyositis/dermatomyositis, but may occur late in the course (in about 10 per cent of caes, Love *et al*. 1991). Patients may note impairment of chewing or dysphagia (see below). Involvement of the face is unusual, and involvement of extraocular muscles is rare, and should suggest other diagnoses (Dalakas 1991). Within regions of weakness, there is usually diffuse involvement, unlike some myopathies in which weakness and atrophy may be highly selective for specific muscles.

Other muscle manifestations

Myalgia and muscle tenderness occur in about half of patients, usually as mild aching or soreness. They are usually not predominant, but may be more severe when myositis develops acutely, and occasionally can lead to confusion with polymyalgia rheumatica (Hopkinson *et al*. 1991). There may be atrophy in chronic disease, seen in 9 per cent by Love *et al*. (1991), more commonly in polymyositis than dermatomyositis. Contractures may occur with disease of long duration.

Examination

Muscle strength can be assessed as part of initial evaluation and later monitoring of progress by observing activities and by direct muscle testing. Walking, standing from a squatting position or low chair without using the arms, sitting up or raising the head from a supine position, and raising the arms overhead, should be tested, or multiple repetitions timed (Csuka and McCarty 1985; Moxley 1994). Deltoids, biceps, iliopsoas, quadriceps, and other proximal muscles should be manually tested directly, and graded by systems such as the Medical Research Council scale. In order to overcome insensitivity and subjectivity, and standardize and quantify such testing, there is continuing interest in the use of biomechanical measures of muscle strength with machines that can measure applied force (Moxley 1994). Fafalak *et al*. (1994) found that improved strength by a mechanical measure correlated well with a functional assessment scale. All types of muscle strength testing depend on effort, and may be complicated by fatigue or pain of arthritis or myalgia.

Cutaneous manifestations

Rash

The dermatomyositis rash, found in about 30 to 40 per cent of adults with myositis, most commonly precedes the weakness by weeks to several months, or even longer (Hochberg *et al*. 1986; Rockerbie *et al*. 1989). At presentation, 93 per cent of adult dermatomyositis patients of Bohan *et al*. (1977) had a rash but only 53 per cent weakness. The activity of the rash may parallel that of the weakness or may be independent, and can persist after the myositis resolves.

Gottron's lesions

Erythematous or violaceous, sometimes scaly, papules or plaques (Gottron's papules) or macular patches (Gottron's sign) may occur over the metacarpophalangeal and proximal (and less often distal) interphalangeal joints (Fig. 1) (Franks 1988), and also over the extensor surfaces of the knees, wrists, elbows or medial malleoli

(Fig. 2). These lesions may be found in 70 to 80 per cent of dermatomyositis patients, and are considered pathognomonic (Euwer and Sontheimer 1994). Telangiectasia and atrophy can occur. The erythematous finger rash of systemic lupus erythematosus differs in that it usually occurs between the knuckles.

Fig. 1 Skin over the metacarpophalangeal joints of a patient with dermatomyositis shows the characteristic erythematous lesions of Gottron's sign. (By courtesy of the Department of Dermatology, University of Oklahoma Health Sciences Center.)

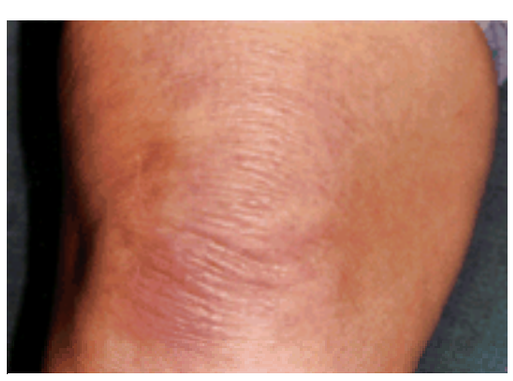

Fig. 2 Skin over the knee of a patient with dermatomyositis shows a characteristic erythematous, violaceous lesion. (By courtesy of the Department of Dermatology, University of Oklahoma Health Sciences Center.)

Erythematous and/or poikilodermatous rash

A macular erythematous or violaceous eruption may involve the upper chest, neck, shoulders, extremities, hands, scalp and face. It may develop into poikiloderma, varied hyper- and hypopigmentation with atrophy and fine telangiectasias. Typical of dermatomyositis are the 'V' sign (involvement at the anterior base,'V', of the neck; 36 per cent of cases), and the 'shawl' sign (back of neck, upper torso, and shoulders in a shawl-like pattern; 22 per cent) (Love *et al*. 1991). Erythema may extend from the joints along the course of the extensor tendons (linear extensor erythema, Franks 1988; Fig. 3). Kasteler and Callen (1994) noted a high frequency of scalp involvement (82 per cent), marked by erythema, atrophy, scale, and sometimes alopecia that can be misdiagnosed as psoriasis or seborrheic dermatitis. Rash on the malar areas, forehead and chin may lead to confusion with systemic lupus erythematosus, although involvement of the nasolabial folds may be a clue (Plotz *et al*. 1989).

Fig. 3 Hand of a patient with dermatomyositis shows Gottron's papules over the proximal interphalangeal and metacarpophalangeal joints, with marked linear extensor erythema extending from the joints along the tendons. In black patients, the lesions may appear hyperpigmented. (By courtesy of Dr Frank C. Arnett, University of Texas at Houston Health Sciences Center.)

Patients often report exacerbation or development of new lesions after sun exposure (Callen 1987), and this has also been documented after therapeutic ultraviolet or experimental solar-simulated light (Cheong *et al*. 1994; Euwer and Sontheimer 1994). The distribution also suggests photosensitivity, but can occur without sun exposure (Franks 1988).

Heliotrope

The heliotrope rash, found in about 30 to 60 per cent of dermatomyositis, is a purplish, lilac-coloured suffusion (resembling a heliotrope flower) around the eyes, particularly the upper eyelids and surrounding area (Fig. 4), often associated with periorbital oedema. It is characteristic but not pathognomonic of dermatomyositis, since a similar appearance may occasionally be seen in allergy, trichinosis, lupus, or other conditions (Euwer and Sontheimer 1994). It may be difficult to see in black patients.

Fig. 4 A severe heliotrope rash of dermatomyositis, with the characteristic lilac colour and accompanying periorbital oedema. (By courtesy of the Department of

Dermatology, University of Oklahoma Health Sciences Center.)

Other cutaneous features

Periungual telangiectasia and/or haemorrhages are also seen in dermatomyositis (Franks 1988). Nailfold capillaries may show marked changes similar to those in scleroderma, including thrombosis and haemorrhage, giant capillary loops, and capillary loss, that may parallel disease activity (Fig. 5). The cuticles may be thickened, roughened, and irregular (Fig. 6) (Caro 1988).

Fig. 5 Nailfold vascular changes in a patient with amyopathic dermatomyositis for 4 years. Capillary dilatation, dropout, and haemorrhage are evident without microscopy. Gottron's papules were present over the proximal interphalangeal joints of the index and middle fingers, with suggestive lesions visible over the distal interphalangeal joints. (By courtesy of Dr Lela Lee, Department of Dermatology, University of Oklahoma Health Sciences Center.)

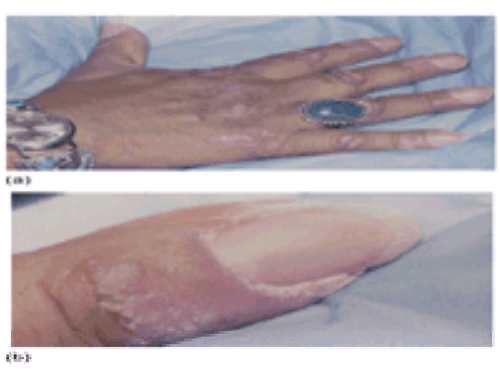

Fig. 6 (a) Hand of a patient with anti-Mi-2-positive dermatomyositis with severe weakness of 2 months duration. Typical Gottron's papules are seen over the metacarpophalangeal, and proximal and distal interphalangeal joints, with more scale than in Fig. 7. There is cuticular hyperkeratosis around many nails, and mechanic's hand change on the thumb. (By courtesy of Dr E. Taylor-Albert, University of Oklahoma Health Sciences Center). (b) Thumb of the patient in (a). Cuticular changes are evident. A Gottron's papule is over the interphalangeal joint.

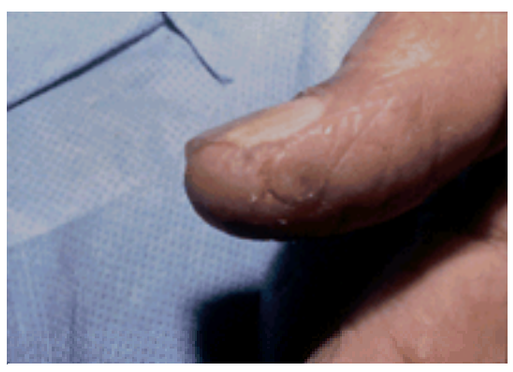

Fig. 7 Thumb of a patient with anti-Jo-1-positive polymyositis. The edge of the thumb shows fissuring and some hyperkeratosis as in mechanic's hands. (By courtesy of Dr Frank C. Arnett, University of Texas at Houston Health Sciences Center.)

Hyperkeratosis and scaling with fissuring and hyperpigmentation may appear as dirty horizontal lines along the lateral and palmar aspects of the fingers ('mechanic's hands') (Fig. 7). This lesion was associated strongly with antisynthetase autoantibodies (Love *et al*. 1991) (see below). Although often seen without other signs of dermatomyositis, the histology resembles dermatomyositis (Mitra *et al*. 1994).

Calcinosis can occur in adults but is more common in juvenile dermatomyositis. It can be extensive, and usually occurs late. Cutaneous vasculitis, especially of the fingers, is not infrequent in adult dermatomyositis (Ramirez *et al*. 1990); cutaneous ulcers associated with severe vasculopathy of juvenile dermatomyositis (Roberts and Fink 1988) may rarely be seen in adults (Fig. 8). Other rare manifestations include panniculitis (Fusade *et al*. 1993), and erythroderma (Ramirez *et al*. 1990).

Fig. 8 Cutaneous ulcer in a 32-year-old woman with dermatomyositis. Endothelial cell swelling and change (vasculopathy) without inflammatory invasion of the vessel wall (vasculitis) was seen by biopsy. (By courtesy of the Department of Dermatology, University of Oklahoma Health Sciences Center.)

Amyopathic dermatomyositis

There is increasing recognition of patients with typical cutaneous dermatomyositis who do not develop myositis (Fig. 9). Some of the patients have subclinical myositis demonstrable by testing (see below), and some later develop overt myositis, but some have no sign of myositis for as long as 12 years (Rockerbie *et al*. 1989; Stonecipher *et al*. 1993). 'Amyopathic dermatomyositis' (or 'dermatomyositis sine myositis') is applied to those with rash alone for at least 2 years without treatment. Such patients cannot satisfy criteria for dermatomyositis, which are based on the myositis, and alternative criteria and a separate classification category have been proposed (Euwer and Sontheimer 1993). The risk of malignancy and systemic complications appears similar to usual dermatomyositis (Euwer and Sontheimer 1993; Euwer and Sontheimer 1994).

Fig. 9 Skin over the finger joints of a patient with cutaneous dermatomyositis for less than 6 months, but without evident muscle disease, showing characteristic lesions. The metacarpophalangeal region shows Gottron's papules (raised erythematous lesions with fine scale) with additional erythema extending along the tendons, most evident on the middle finger, consistent with linear extensor erythema. Classic Gottron's papules have formed over the proximal interphalangeal and, to a lesser extent, the distal interphalangeal joints. (By courtesy of Dr Lela Lee, Dept. of Dermatology, University of Oklahoma Health Sciences Center.)

Manifestations in other systems

Systemic signs

Fatigue and malaise are common and must be distinguished from muscle weakness. Weight loss may be impressive in some patients (Tymms and Webb 1985). Fevers are seen in about 40 per cent overall, but are associated strongly with antisynthetases (87 per cent, versus 23 per cent without antibody, Love *et al*. 1991).

Pulmonary disease

Pulmonary involvement resulting from muscle weakness, treatment, or the underlying disease (Table 2), occurs in 40 to 50 per cent of patients (Dickey and Myers 1984), contributing to morbidity and mortality (Arsura and Greenberg 1988).

Pulmonary	
Due to weakness:	
Ventilatory failure	
Aspiration pneumonia	
Due to treatment:	
Hypersensitivity pneumonitis	
Opportunistic infection	
Due to disease:	
Interstitial lung disease	
Pulmonary hypertension	
Pulmonary vasculitis	
Cardiac	
Heart block	
Arrhythmias	
Cardiomyopathy	
Gastrointestinal	
Oesophagus (dysphagia)	
Striated muscle dysfunction	
Oropharyngeal dysfunction	
Lower oesophageal dysfunction	
Stomach, intestines	
Decreased motility	
Arthritis	
Mild, responsive	
Deforming, minimally erosive	

Table 2 Features of polymyositis/dermatomyositis in addition to muscle and skin involvement

Respiratory muscle weakness

Clinical respiratory muscle weakness develops in 4 to 7 per cent of patients (Dickey and Myers 1984), but a measurable decrease in respiratory muscle strength may be more common (Braun *et al*. 1983). Both inspiratory and expiratory muscles may be affected, including the diaphragm. Total lung capacity and vital capacity are decreased, while residual volume may be increased. Respiratory failure requiring assisted ventilation may result, and may develop rapidly. It is usually responsive to or prevented by treatment. Most of these patients have had involvement of the pharyngeal and tongue muscles with dysphagia and impaired speech. Patients at risk should be monitored closely, commonly in hospital, using serial pulmonary function testing to judge respiratory muscle strength (expiratory pressure, peak flow, etc.). Rarely, weakness may involve respiratory muscles selectively or disproportionately, and be the presenting feature (Sano *et al*. 1994). Pharyngeal and tongue involvement also increase risk of aspiration, as does impaired cough and difficulty turning or sitting up in bed. Most patients with aspiration have had dysphagia (Lakhanpal *et al*. 1987).

Pulmonary complications of treatment

New interstitial infiltrates in patients with polymyositis/dermatomyositis on immunosuppressive agents may cause diagnostic confusion between the disease itself (see below) and effects of treatment, including opportunistic infections and drug reactions. Methotrexate hypersensitivity pneumonitis can occur in polymyositis/dermatomyositis, which can present acutely with fever, cough, dyspnoea, bilateral interstitial infiltrates, and with lymphocytic infiltrates on biopsy. It usually improves after withdrawal of the drug, but corticosteroids may be required. Pulmonary reactions may rarely occur with azathioprine.

Interstitial lung disease

Interstitial lung disease is found in 10 to 30 per cent of polymyositis and dermatomyositis overall (Hochberg *et al*. 1986; Love *et al*. 1991), and may be more easily diagnosed by pulmonary function testing than by chest radiography. It is much more frequent in patients with antisynthetases. Interstitial lung disease in polymyositis/dermatomyositis is similar to idiopathic interstitial lung disease (Targoff 1990). A small proportion have a fulminant course with fever and rapidly progressive dyspnoea that may be fatal within weeks. A second group has a more chronic course, and a third group may have asymptomatic test abnormalities. Chest radiography shows a reticulonodular pattern, often more prominent in the lower lobes (Fig. 10), and pulmonary function tests show a restrictive defect with decreased diffusing capacity and hypoxaemia with exercise, early signs that can be used to assess progress.

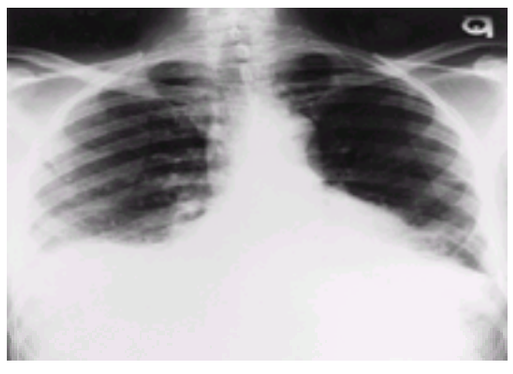

Fig. 10 Chest radiograph from a patient with anti-Jo-1-positive polymyositis that shows severe interstitial fibrosis affecting predominantly the lower lobes.

Interstitial lung disease may occur in polymyositis/dermatomyositis of any type (including cancer-associated). The severity of the interstitial lung disease is unrelated to that of the myositis, even occurring in amyopathic dermatomyositis (Euwer and Sontheimer 1994). It may precede myositis in up to 40 per cent of cases (Schwarz *et al*. 1976), and limitations from interstitial lung disease may mask muscle weakness in others. Elevated creatine kinase, myositis-specific autoantibodies, or the dermatomyositis rash may be clues to underlying polymyositis/dermatomyositis.

Lung histology shows interstitial mononuclear cell infiltrates (Fig. 11) with a variable amount of fibrosis. Often there is a loss of type I cells, proliferation of type II cells, and increased numbers of free alveolar macrophages. Tazelaar *et al*. (1990) identified four histological patterns among 15 patients: bronchiolitis obliterans with organizing pneumonia (6 patients), usual interstitial pneumonitis, diffuse alveolar damage, and cellular interstitial pneumonia. Those with bronchiolitis obliterans had the best prognosis, as in other studies (Hsue *et al*. 1993), while all three with diffuse alveolar damage died. Direct immunofluorescence has been negative for immunoglobulin or complement deposition in most studies.

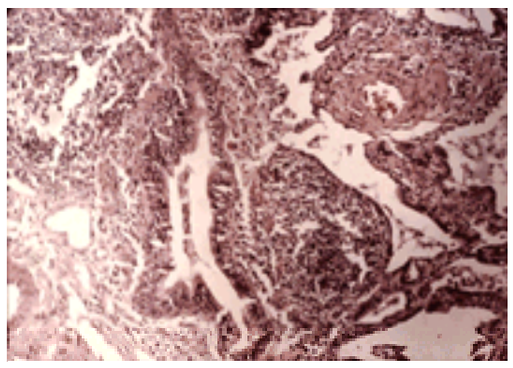

Fig. 11 Lung pathology from a patient with anti-Jo-1-positive polymyositis, showing severe mononuclear cell infiltration and thickening of the interstitium.

There may be medial and/or intimal thickening of small pulmonary arteries or arterioles as in pulmonary hypertension, which may occur in association with interstitial fibrosis (Schwarz *et al*. 1976). Pulmonary vasculitis may also occur (Lakhanpal *et al*. 1987). Hebert *et al*. (1990) found pulmonary hypertension in 7 of 11 patients using echocardiography, but the clinical significance is unclear.

There have been at least 21 case reports of spontaneous pneumomediastinum in dermatomyositis (adult and juvenile, not polymyositis), usually associated with interstitial lung disease, often with normal creatine kinase (Matsuda *et al*. 1993). The mechanism for this potentially fatal complication is unclear.

Cardiac disease

The potential for cardiac involvement in polymyositis/dermatomyositis was recognized early, but was considered unusual. More recent studies have found signs of cardiac involvement in excess of 70 per cent of cases (Taylor *et al*. 1993). It is commonly asymptomatic, but may contribute to mortality (Hochberg *et al*. 1986). The activity of the cardiac disease may be independent of the myositis (Rechavia *et al*. 1985). The major manifestations include conduction disturbances, arrhythmias, and myocarditis.

The frequency of conduction block varies, but only occasionally does advanced heart block occur requiring a pacemaker. Taylor *et al*. (1993) found ECG abnormalities in 81 per cent, but 58 per cent were non-specific ST and T-wave changes, and significant conduction block was uncommon. Fibrosis of the conducting system was correlated with conduction disturbance in some cases (Haupt and Hutchins 1982), and inflammation has also been seen.

The most common arrhythmias seen are extrasystoles and tachyarrhythmias, and are usually mild (Taylor *et al*. 1993). Love *et al*. (1991) found palpitations in 26 per cent, more in polymyositis (57 per cent) than dermatomyositis (19 per cent) or other subgroups. A Holter monitor should be considered in patients with palpitations or ECG abnormalities.

Congestive heart failure resulting from myocarditis is uncommon in polymyositis and dermatomyositis, and is found in about 3 per cent (Bohan *et al*. 1977). Myocarditis was seen in a quarter of patients in an autopsy study (Haupt and Hutchins 1982), where severe cardiac disease would be overrepresented. A diffuse interstitial and perivascular mononuclear cell infiltrate may be seen, similar to that in skeletal muscle, with replacement fibrosis and sometimes small vessel disease with medial smooth muscle hyperplasia (Denbow *et al*. 1979).

A reported increase in mild mitral valve prolapse, possibly from myocarditis, was not seen in other studies (Taylor *et al*. 1993). Pericardial effusions are seen in 5 to 25 per cent of polymyositis/dermatomyositis by echocardiogram, but are usually asymptomatic (Tami and Bhasin 1993). Significant pericarditis without systemic lupus erythematosus overlap is rare.

Gastrointestinal disease

Dysphagia may occur in up to 30 per cent (Tymms and Webb 1985), particularly with more severe disease. It predisposes to aspiration and has been associated with a poor prognosis. Dysphagia can result from weakness of the muscles of swallowing (pharyngeal muscles or striated muscles of the upper oesophagus), correlating with disease activity and responding to treatment (Dietz *et al*. 1980). It may be worse while recumbent, and can cause regurgitation of liquids into the nose with attempted swallowing. Changes in the voice (nasal speech or hoarseness) may be associated. Histology is similar to that of other striated muscle, dysphagia but may occasionally be the presenting or sole complaint.

Abnormalities of oesophageal motility have been reported to be common, involving both upper and lower oesophagus (DeMerieux *et al*. 1983). Involvement is similar to scleroderma, but can occur without other evidence of overlap. It is not associated with inflammation, and does not respond to treatment. Decreased motility and lower oesophageal sphincter pressure may lead to dysphagia, heartburn, reflux, and stricture. Gastric emptying may also be delayed (Horowitz *et al*. 1986).

Cricopharyngeal muscle dysfunction from inflammation and/or fibrosis may lead to a distinctive dysphagia marked by a sensation of food sticking in the back of the throat, or coughing with swallowing. It can be distinguished from weakness by cine-oesophagoscopy and oesophageal manometry, and is important to identify since it

may require surgical myotomy (Kagen *et al*. 1985).

Intestinal vasculitis with perforation, as well as pneumatosis cystoides intestinalis, well recognized in juvenile dermatomyositis, are extremely rare in adults, but reported (Ramirez *et al*. 1990).

Malignancy

Association

The link with malignancy was noted in 1916, and was at one point thought to be frequent. Later studies found a much lower frequency, and some questioned the reality of an association (Lakhanpal *et al*. 1986). Most recent studies, however, find a modest increase in malignancies within 1 to 2 years of onset in dermatomyositis, and possibly also polymyositis. Malignancy may be antecedent, concurrent, or subsequent to myositis onset.

The frequency of malignancy in dermatomyositis has ranged from 6 to 43 per cent (Bernard and Bonnetblanc 1993). A large population-based study in Sweden (Sigurgeirsson *et al*. 1992) found increased malignancy in dermatomyositis and polymyositis: 15 per cent of 392 dermatomyositis patients (relative risk, **RR**=2.4 for men, 3.4 for women) and 9 per cent of 396 polymyositis patients (RR=1.8 for men, 1.7 for women). Cancer deaths were increased in dermatomyositis but not polymyositis, supporting a true association in dermatomyositis, rather than intensive searching. The case–control study of Manchul *et al*. (1985) found that 71 adult polymyositis/dermatomyositis patients had significantly more total antecedent plus concurrent malignancies (21.1 per cent) than matched controls (5.6 per cent with inflammatory disease, 1.4 per cent others), with no difference beyond 6 months after myositis. A meta-analysis that included these studies found a significant overall association with cancer (odds ratio = 4.4 for dermatomyositis, 2.1 for polymyositis), with risk before and after onset for dermatomyositis (Zantos *et al*. 1994).

The activity of the myositis may appear linked to that of the malignancy ('paraneoplastic', 22 per cent of dermatomyositis cancers, Bonnetblanc *et al*. 1990), supporting the validity of an association. The myositis may resolve with treatment of the cancer, be resistant until it is resected, or flare with its recurrence. In the majority, cancer and myositis have an independent course (Callen 1993).

Tumours

A wide variety of tumours have been reported in polymyositis/dermatomyositis patients. Tumours that are frequent in the general population (lung, breast, etc.) are frequent in polymyositis/dermatomyositis. However, a number of studies have indicated an increase in ovarian cancer out of proportion to that of other tumours (Cox *et al*. 1990; Cherin *et al*. 1993b; and others). Sigurgeirsson *et al*. (1992) found a relative risk of 8.2 for ovarian cancer in women with dermatomyositis, and 16.7 during the 5 years after dermatomyositis diagnosis. Three of five patients of Whitmore *et al*. (1994) had amyopathic dermatomyositis; the skin disease was resistant until treatment of the cancer. Tumours were typically stage III or IV serous carcinoma. In Asia, an increase in nasopharyngeal carcinomas has been suggested (Koh *et al*. 1993), which may reflect an increase in such tumours in the population of the region.

Evaluation

The extent of testing that should be performed to uncover an occult malignancy in recent-onset polymyositis/dermatomyositis is controversial. Most of the associated malignancies show abnormalities detectable by a thorough initial evaluation, and all agree with the importance of this step (Callen 1994; Bernard and Bonnetblanc 1993). It should include careful history and physical examination, rectal examination and stool occult blood testing, breast examination and screening mammography and pelvic examination with Pap smear in women, complete blood counts, chemistries, urinalysis, and chest radiograph, and a prostate-specific antigen test in men. Any abnormalities should be pursued, and the evaluation should be repeated yearly, at least during the 2 to 3 year theoretical risk period.

In addition, most would give special attention to excluding ovarian cancer in women. Ovarian cancer is often missed in dermatomyositis patients, even sometimes by pelvic CT or ultrasound (Sigurgeirsson *et al*. 1992). Whitmore *et al*. (1994) recommend routine serial gynaecological examinations, transvaginal ultrasound, and CA-125 levels (even after oophorectomy).

There is disagreement as to the extent of further searching recommended in the absence of abnormalities. Schulman *et al*. (1991), citing examples of occult cancers, recommend routine upper and lower gastrointestinal barium studies and abdominal and chest CT, with repeat evaluation for myositis flares. Others limit additional testing to those with higher risk, resistant disease, or weight loss. The highest risk is in those aged over 45 with dermatomyositis rather than polymyositis, with no autoimmune rheumatic diseases overlap syndromes or myositis-specific autoantibodies (**MSAs**) (Love *et al*. 1991) (although cases with MSAs have occurred). Malignancy may be higher with cutaneous vasculitis, or with capillary damage even without a dermatomyositis rash (Casademont *et al*. 1993).

Other features, overlap syndromes, and associated conditions

Raynaud's phenomenon and arthralgia/arthritis, common features of autoimmune rheumatic diseases, may occur as part of polymyositis/dermatomyositis. They are more common in polymyositis/dermatomyositis when antisynthetases are present. Patients with polymyositis/dermatomyositis may have overlap syndromes in which diagnostic criteria for other conditions are also fulfilled. Conditions commonly overlapping with polymyositis/dermatomyositis include systemic lupus erythematosus (found in almost half of overlap patients by Love *et al*. 1991), scleroderma, Sjögren's syndrome (about 20 per cent), and rheumatoid arthritis (6 per cent). The distinction between an autoimmune rheumatic disease overlapping with polymyositis/dermatomyositis versus an autoimmune rheumatic disease with myositis as a manifestation, is not well defined. The relative severity of clinical features, and the serological picture may be helpful.

Renal disease is very rare in pure polymyositis/dermatomyositis without overlap, but focal mesangial proliferative glomerulonephritis has been seen (Frost *et al*. 1993), including cases with antisynthetases. Renal injury may occur from myoglobinuria.

A variety of other autoimmune conditions have been reported in association with polymyositis and dermatomyositis, including Graves' or Hashimoto's disease, inflammatory bowel disease, cryoglobulinaemia, primary biliary cirrhosis, dermatitis herpetiformis, coeliac disease, Behçet's disease, thrombotic thrombocytopenic purpura, myasthenia gravis, and others. Whether these conditions have a true association with polymyositis/dermatomyositis is unclear.

Pregnancy and polymyositis/dermatomyositis

Active polymyositis/dermatomyositis appears to confer increased risk to both the mother and the fetus, with potential for exacerbations, fetal loss and premature births. However, in established polymyositis/dermatomyositis, controlled at the time of pregnancy, most patients do not have flares, and many pregnancies are successful (Ishii *et al*. 1991; Oddis and Hill 1993). Those with myositis onset during pregnancy (and those with relapse) often have severe myositis requiring high-dose steroids, and have a high rate of adverse fetal outcome (Rosenzweig *et al*. 1989; Satoh *et al*. 1994). Thus, patients should optimally be in remission before becoming pregnant. If treatment is needed during pregnancy, prednisone is often used. Immunosuppressive medications should be avoided if possible, particularly methotrexate. Intensive evaluation for malignancy in pregnant patients who develop polymyositis/dermatomyositis without other indications would be inadvisable. No effect of polymyositis/dermatomyositis on fertility has been identified.

Laboratory investigations

Muscle factors

Enzyme

Creatine kinase

Serum levels of enzymes released from damaged muscle can be helpful for diagnosis and disease monitoring (Targoff 1988; Rider and Miller 1995). Creatine kinase is the most widely used due to its sensitivity, relative specifity for muscle, ready availability, and correlation with disease activity.

Elevations

Elevated creatine kinase levels are present in most patients (80 to 90 per cent) when first seen, and in more than 95 per cent at some time during their course (Bohan *et al*. 1977; Hochberg *et al*. 1986). The mean increase of creatine kinase (about 10-fold), and the potential to rise 100-fold or more, is greater than that of other enzymes measured. The creatine kinase usually rises with exacerbations, and can precede them by 5 to 6 weeks or more. A fall in the enzyme usually indicates improvement, and can precede recovery of strength by 3 to 4 weeks. There is a general correlation of creatine kinase level and disease activity for most individual patients over time (Kroll *et al*. 1986).

Normal creatine kinase

The creatine kinase may be normal in some patients despite active myositis. This is more common in dermatomyositis (Rider and Miller 1995) than polymyositis, possibly due to easier diagnosis of dermatomyositis when the creatine kinase is normal. Some dermatomyositis patients have normal creatine kinase because myositis has not yet developed. Lesser elevations may be seen in advanced or chronic disease, especially with severe atrophy, but elevations may still occur. Creatine kinase levels are lower in patients with autoimmune rheumatic diseases in general (Wei *et al*. 1981), possibly leading to lower levels in overlap patients. Creatine kinase has been correlated inversely with measures of inflammation in rheumatoid arthritis (Sanmarti *et al*. 1994). The enzymatic measurement of creatine kinase (generation of ATP from creatine phosphate and ADP) may be reduced falsely by an inhibitor found in some myositis sera (Kagen and Aram 1987). Steroids may lower the creatine kinase level even if they do not suppress disease activity. Levels that are within the normal range in patients with active disease may still be higher than the baseline for that individual.

One study of seven polymyositis/dermatomyositis patients with a normal creatine kinase found that the prognosis was worse than expected, with more interstitial lung disease and malignancy (Fudman and Schnitzer 1986); others have also found more interstitial lung disease (Koh *et al*. 1993; Matsuda *et al*. 1993), but many see no relation (Rider and Miller 1995).

Other causes of creatine kinase elevation

Creatine kinase may be elevated in a wide variety of conditions other than myositis (Table 3). It is released in conditions leading to muscle necrosis, but not usually simple atrophy (as in disuse, denervation, steroid myopathy, hyperthyroidism). Strenuous, prolonged exercise, particularly when unaccustomed, may raise the creatine kinase level in normal people for 2 days (Rider and Miller 1995). Physical injury to muscle can raise the creatine kinase, including intramuscular injections, electromyography, or muscle biopsy. Drugs can raise the creatine kinase level through a variety of mechanisms, including toxic effects, induction of myositis or myopathy, or decreasing excretion of the enzyme (see below). Various myopathies, as well as carrier states, may increase creatine kinase, including dystrophies, metabolic myopathies, and others. Some disease states other than myopathies may lead to increased creatine kinase, such as diabetic nephrotic syndrome associated with oedema (Taniyama *et al*. 1987). Others may raise total creatine kinase through effects on the creatine kinase-BB isoenzyme, such as gastrointestinal or lung tumours.

Table 3 Factors affecting creatine kinase (CK) levels

The normal range for creatine kinase may differ between patient groups. It is higher for men than for women, higher for black than for white people, and higher with increased muscle mass (Black *et al*. 1986). The composition of the group used to determine the normal range is therefore important in interpretation of the result.

Isoenzymes

Serum creatine kinase-MB isoenzyme can be elevated in polymyositis and dermatomyositis, but this has not correlated with cardiac involvement (Hochberg *et al*. 1986). High levels of creatine kinase-MB may occur without evidence of cardiac involvement, and severe cardiac involvement may occur despite a normal level of this isoenzyme (Targoff 1988). Regenerating or chronically stressed skeletal muscle fibres may contain significant creatine kinase-MB (Wolf 1991), and are the likely source in polymyositis/dermatomyositis.

Macro-creatine kinase type 1, a complex of antibody with creatine kinase, was found in 36 of 8322 patients tested for isoenzymes, and half had myositis (Lee *et al*. 1994). Modification of creatine kinase-MM after release leads to formation of subisoenzymes. A high MM3:MM1 subisoenzyme ratio suggests deteriorating disease (Annesley *et al*. 1985).

Other enzymes

Several other enzymes are released during muscle damage that may occasionally be helpful for disease monitoring. More than 98 per cent of patients will have an elevation of at least one serum enzyme at some time during their course (Hochberg *et al*. 1986). Aldolase is elevated usually in polymyositis and dermatomyositis, in some cases when creatine kinase is not, but is not as specific for muscle and does not correlate as well with disease activity (Bohlmeyer *et al*. 1994). Lactate dehydrogenase (LDH) is also elevated, predominantly LDH-5, although LDH-1 may increase without necessarily correlating with cardiac involvement (Targoff 1988). Aspartate transferase correlates very well with biopsy-proven muscle inflammation, and was found useful in combination with creatine kinase and aldolase in assessing enzyme elevations (Hood *et al*. 1991). Carbonic anhydrase III, an isoenzyme found exclusively in skeletal and not cardiac muscle, rises with skeletal muscle damage, including polymyositis/dermatomyositis (Osterman *et al*. 1985).

Myoglobin

Myoglobin is unique to skeletal and cardiac muscle. Very little is present normally in serum or urine, but it is detectable in the serum of most patients with active polymyositis/dermatomyositis (Targoff 1988). It can serve as a disease activity marker, rising with exacerbation and falling with remission, and can predict exacerbation in some cases. It may occasionally be elevated when the creatine kinase is not. It has the advantages of tissue specificity, rapid clearance, and sensitive, non-enzymatic detection. A new immunoturbidimetric assay may make testing more available, but is slightly less sensitive than radioimmunoassay (Lovece and Kagen 1993). It should be measured in samples taken at a standard time during the day because of diurnal variation.

Other muscle factors

Creatine is produced in the liver, pancreas, and kidney, and taken up by the muscle. Creatine excretion rises with muscle disease due to defects in uptake and retention. The creatine or the creatine/ [creatinine+creatine] ratio in a 24 h urine sample (normal less than 6 per cent) is elevated in most polymyositis/dermatomyositis patients, and can vary with disease activity. Its clinical utility is limited by many disadvantages. Elevation, found whenever muscle mass is reduced, is less specific than creatine kinase, and may persist in inactive polymyositis/dermatomyositis as a result of atrophy. It is cumbersome to collect and

difficult to obtain clinically.

Measures of muscle mass correlate with strength, but not necessarily inflammation; they can be used to provide a longer-term view. Tests that measure muscle mass, including 24 h urinary creatinine, 3-methyl histidine excretion (reflecting skeletal muscle protein turnover), and total body potassium (measuring total body mass), have been used in studies but are not currently practical for clinical use (Moxley 1994). Dual radiography/absorptiometry may be used in the future (Kanda *et al*. 1994).

Autoantibodies

Indirect immunofluorescence is positive in 50 to 80 per cent of patients with polymyositis or dermatomyositis (Reichlin and Arnett 1984; Love *et al*. 1991). Nuclear or speckled patterns are most common, nucleolar may be seen, and cytoplasmic patterns provide clues to an antisynthetase or anti-SRP (Fig. 12). A high antinuclear antibody (**ANA**) titre favours polymyositis or dermatomyositis over other myopathies or neuropathies, and a MSA strongly supports polymyositis/dermatomyositis when present (see below). Antisynthetases may alert the physician to an increased risk for interstitial lung disease, or identify underlying polymyositis/dermatomyositis in patients who present with prominent extra-muscle features.

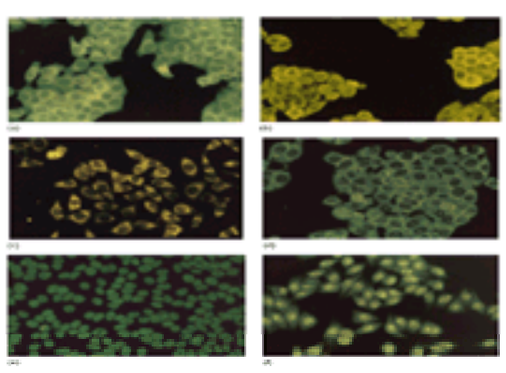

Fig. 12 Indirect immunofluorescence on HEp-2 cells using sera with myositis-associated autoantibodies. (a) Anti-Jo-1 autoantibodies (reacting with histidyl-tRNA synthetase): finely speckled cytoplasmic pattern of fluorescence. (b) Anti-PL-7 autoantibodies (antithreonyl-tRNA synthetase): cytoplasmic pattern (more homogeneous at higher concentration). (c) Anti-SRP autoantibodies (antisignal recognition particle): cytoplasmic pattern. (d) Anti-KJ autoantibodies (reacting with a translation factor): cytoplasmic pattern with slight nucleolar staining. (e) Anti-Mi-2 autoantibodies (reacting with an unidentified nuclear protein): nuclear pattern, sparing nucleoli, without cytoplasmic staining. (f) Anti-PM-Scl autoantibodies (reacting with a complex of 11 proteins): intense nucleolar staining with significant nuclear staining.

A general correlation of anti-Jo-1 titre with disease activity has been observed (Miller *et al*. 1990b), and in some cases a rise in anti-Jo-1 predicted exacerbation. Occasional disappearance of anti-Jo-1 correlates with disease remission. The usefulness of titres as an index of disease activity is not established, but they may provide support if serial measurements are available.

Other tests

The erythrocyte sedimentation rate is elevated in about half of active cases, but is correlated poorly with disease activity or response to treatment. Similarly, the C-reactive protein may be normal or slightly high despite active disease (Gabay *et al*. 1994). Rheumatoid factor is positive in about 10 to 20 per cent of patients, most commonly in the overlap group. Circulating immune complexes and cryoglobulins have been reported in some patients, but their significance is unclear. Elevated gammaglobulins may be seen; hypogammaglobulinaemia should raise the suspicion of echovirus or other infection. Patients with polymyositis with monoclonal gammopathies have been described, including some in which sarcolemmal deposition of paraprotein was found (Kiprov and Miller 1984). Complement is usually normal, but myositis has occurred in C2 deficiency (Targoff 1988). Proteinuria is usually the result of myoglobinuria, with rare exceptions (see below).

Diagnosis

The criteria of Bohan and Peter (1975) (Table 4), often with modifications such as that of Dalakas (1991), have been used widely for diagnosis and clinical studies. Muscle enzymes, electromyography and muscle biopsy remain essential in evaluation of patients and establishing the diagnosis of polymyositis and dermatomyositis. Autoantibody testing and magnetic resonance imaging (MRI) can also greatly aid in diagnosis. Recent attempts have been made to devise new criteria that take advantage of newer tests and other features (Medsger and Oddis 1995; Tanimoto *et al*. 1995). Even when the criteria are satisfied, other causes of muscle disease must be excluded.

Table 4 The diagnosis of polymyositis and dermatomyositis

Electromyography

Electromyography and nerve conduction studies cannot establish the diagnosis of polymyositis/dermatomyositis with certainty, but can demonstrate that the process is myopathic and consistent with these diseases, and can help to exclude many other neuropathies and certain myopathies. Electromyography may reveal muscle involvement in patients presenting with rash or extra-muscle features, and can identify areas of involvement to help direct biopsies (on the contralateral side) and provides some information regarding activity. Ninety per cent of patients with active polymyositis/dermatomyositis have an abnormal electomyograph (Bohan *et al*. 1977; Henriksson and Lindvall 1990). Testing of multiple muscles is important, since involvement may be limited, and to demonstrate the distribution of involvement. Paraspinal muscle involvement is common, and may be the only abnormal area.

Motor unit action potentials in polymyositis/dermatomyositis typically are myopathic (low amplitude, short duration). Polyphasic potentials (complex potentials with increased turns) are increased, and may be attributed to asynchronous firing of fibres (Bertorini 1988a). Over time, long-duration, high amplitude polyphasic potentials may be seen (attributed to reinnervation of regenerating or denervated fibres) (Uncini *et al*. 1990). Patients with myositis have early recruitment and full interference patterns (more fibres required to achieve a given force), in contrast to the decreased recruitment and interference seen in neuropathies (Greenlee 1988).

Spontaneous activity at rest is seen in three-quarters of patients (Henriksson and Lindvall 1990). Increased insertional activity generated by needle trauma to the muscle fibre is very common, as are fibrillations and positive sharp waves, sometimes more evident in the paraspinal muscles. Often associated with denervation,

fibrillations in polymyositis/dermatomyositis have been attributed to damage to intramuscular nerves, nerve endings or motor end plates, or to segmental muscle fibre necrosis that denervates the distal fibre (Greenlee 1988). Complex repetitive discharges (bizarre high-frequency discharges) may also be seen in a third to a half of patients. In contrast to myotonic discharges, these start and stop abruptly, and usually have constant amplitude. They have been attributed to inflammatory damage to the sarcolemma. Spontaneous activity has been associated with active inflammation; it is less common with chronic disease, and may subside with treatment.

Single-fibre electromyography in myositis shows increased jitter and blocking, although less prominent than in myasthenia gravis. Computerized quantitative analysis may reveal increased fibre density (more potentials per motor unit) (Bertorini 1988a). A myopathic interference pattern was the most common abnormality (83 per cent) on quantitative electromyography (Barkhaus *et al*. 1990).

Imaging

Magnetic resonance imaging (MRI)

Numerous studies in recent years have demonstrated the value of MRI in polymyositis/dermatomyositis for diagnosis and assessment of disease activity. MRI can identify sensitively areas of muscle inflammation, atrophy, or fatty replacement (Reimers *et al*. 1994). It is non-invasive and can be repeated sequentially. Use is often limited by cost or availability, but in certain situations it can provide critical information that may not be available by other methods, affecting treatment decisions (Park *et al*. 1994).

T_2-weighted images are best for showing areas of active muscle inflammation, where increased water content is seen as increased intensity; this is not seen with T_1-weighted images (Park *et al*. 1990). Increased fat is seen on both images. Some studies have used fat suppression techniques to improve image contrast (Fraser *et al*. 1991; Hernandez *et al*. 1992). Gadolinium was not helpful (Reimers *et al*. 1994). The thighs are most often studied.

Involvement seen using MRI is often focal and patchy, with differences in intensity between and within muscles, and the technique can therefore be more sensitive than biopsy for detecting clinical activity (Fraser *et al*. 1991). Park *et al*. (1990) found that the vastus lateralis was the most involved muscle in their dermatomyositis patients, with a predominance of anterior over posterior thigh muscle involvement. Fraser *et al*. (1991) did not find anterior predominance in dermatomyositis or polymyositis patients, but found a correlation of atrophy and disease duration. Fatty infiltration is more common in polymyositis than dermatomyositis, and in chronic disease.

Fraser *et al*. (1991) also noted a correlation between MR images or quantitative signal intensity scores with disease activity, although Reimers *et al*. (1994) did not. By correlating with clinical activity, MRI can help assess therapeutic response; abnormalities can return to normal within months on treatment (Fujino *et al*. 1991; Park *et al*. 1994). Persistent abnormalities can indicate activity. MRI may show high intensity in active disease, even when enzymes, electromyography, and/or biopsy are normal (Park *et al*. 1994; Stonecipher *et al*. 1994), although exceptions with negative MRI in active disease may occur (Stiglbauer *et al*. 1993).

Magnetic resonance spectroscopy (MRS)

P-31 MRS has been used in the study of various myopathies to assess energy utilization and reserve by measuring phosphate metabolites in muscle. The inorganic phosphate/phosphocreatine ratio rises in myopathies indicating a decrease in energy reserve, and is correlated with disease activity (Park *et al*. 1994). Phosphocreatine and ATP are decreased at rest, decrease further with exercise, and show delayed recovery to baseline (Park *et al*. 1990). Phosphocreatine changed more than ATP, and was thus better for assessing disease activity. However, the decline of ATP with exercise was felt to relate to the severe fatigue that may occur. The impaired energy utilization and muscle metabolism may contribute to muscle weakness in polymyositis/dermatomyositis.

While not specific, MRS may help monitor disease activity and response to therapy. It can be abnormal in some patients with normal creatine kinase (Park *et al*. 1994), but can continue to be abnormal in some patients whose inflammation has resolved (reflecting persistent muscle abnormalities). When MRI and MRS were discordant, MRS was felt to be more useful for assessing disease status. Park *et al*. (1995) also found that patients with amyopathic dermatomyositis, who have normal MRI and MRS at rest, often have subtle MRS abnormalities with exercise (reduced total oxidative capacity, V_{max}), which may explain their fatigue.

Other methods

Ultrasound of muscle was abnormal, most often with hyperechogenicity as a result of fat and atrophy, in 83 per cent of 70 patients with myositis, including some with normal creatine kinase or electromyographs (Reimers *et al*. 1993). It is less expensive and more readily available than MRI, but is less sensitive and specific (Stonecipher *et al*. 1994), and does not provide as much information. It may help direct the biopsy.

Technetium-99m and thallium uptake may be increased in muscles affected by active polymyositis. Although non-specific, this also might be useful for directing a biopsy. Gallium-67 scanning has been used to identify myositis in Lyme disease and other infections. Scanning with indium-labelled antimyosin can reveal areas of muscle necrosis in dermatomyositis (DeGeeter *et al*. 1989). With a monoclonal antibody specific for cardiac myosin, the scan can detect myocarditis in polymyositis (Le Guludec *et al*. 1993).

Biopsy

Indications

Most patients in whom polymyositis or dermatomyositis is suspected should have a muscle biopsy. It can provide the most convincing evidence supporting the diagnosis, and can definitively exclude certain relevant conditions. There are cases in which the diagnosis can be established for clinical purposes without the biopsy. With proximal weakness, elevated enzymes, and a typical electromyograph, those with a classic dermatomyositis rash, confirmed myositis-specific autoantibodies, or autoimmune rheumatic diseases overlap syndromes with specific antibodies (anti-U1RNP, anti-PM-Scl) do not usually require a biopsy, although others feel that all adults should have a biopsy (Urbano-Marquez *et al*. 1991).

Methods

Open muscle biopsy gives the best picture of the muscle architecture. A large specimen may decrease sampling error, allows proper orientation, and provides enough muscle for all studies. Complications from the procedure (bleeding, infection, nerve damage, etc.) are very low (Pamphlett 1988), but the 4 to 8 cm incision commonly used creates a significant scar, especially in obese patients. Needle biopsy, with a 0.5 cm incision, causes substantially less morbidity, is often more easily and rapidly arranged, and is adequate for diagnosis of polymyositis/dermatomyositis in most cases (O'Rourke *et al*. 1994). Multiple specimens may be taken through the same incision site for enzyme histochemistry and electron microscopy (**EM**), and to reduce sampling error (Haddad *et al*. 1994). The low morbidity allows repeat biopsy or later open biopsy if needed. However, processing of samples is more difficult, more artefact is encountered (particularly in EM), and open biopsy is required for certain functional enzyme studies.

The best information is obtained from muscle with active disease but not endstage fibrosis or atrophy. Muscles used for electromyography or intramuscular injection should not be used for biopsy. The quadriceps or deltoid are most often used due to accessibility, but focal disease may result in non-diagnostic samples. As noted, certain diagnostic procedures have been used to localize disease activity to direct the biopsy (electromyography, MRI, ultrasound). MRI is most promising since it can show focal involvement, but is not always successful (Pitt *et al*. 1993; Reimers *et al*. 1994).

EM should be performed when inclusion-body myositis or mitochondrial myopathies are considerations, or to exclude certain other conditions. Enzyme histochemistry may be helpful to exclude myophosphorylase deficiency and other metabolic myopathies which may masquerade as polymyositis. Co-ordination with the pathologist can help to optimize processing and evaluation of specimens.

Muscle pathology

Inflammation is a hallmark of myositis. The infiltrates are predominantly lymphocytes, but include macrophages, plasma cells, and sometimes eosinophils, basophils,

and neutrophils. The amount of inflammation is variable, and up to 25 per cent may show no inflammation, usually attributed to a focal process.

In polymyositis, inflammatory infiltrates more often predominate in the endomysial area around the muscle fibres, usually without perifascicular atrophy (Fig. 13). Necrosis of individual muscle fibres may be observed. The fibres appear swollen with homogeneous contents, losing the normal striations of the contractile proteins. There is invasion of mononuclear cells, phagocytosis, and regeneration (Fig. 14), the latter marked by sarcoplasmic basophilia, large vesicular, internalized nuclei, and prominent nucleoli. In later stages, there is atrophy, fibrosis, and fatty replacement. Steroid treatment may enhance type II fibre atrophy. Non-caseating granulomas were recently observed in muscle from anti-Jo-1-associated polymyositis (Moder *et al*. 1993).

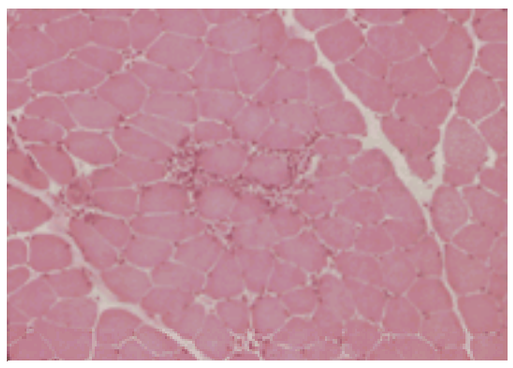

Fig. 13 Muscle biopsy (haematoxylin and eosin stain) from a patient with polymyositis. Endomysial inflammation (infiltration with mononuclear cells between fibres within the fascicle) is seen; a pattern characteristic of biopsies from patients with polymyositis.

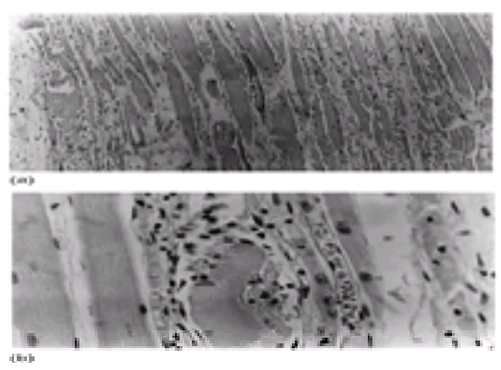

Fig. 14 Muscle biopsy from a patient with anti-Jo-1-positive polymyositis. (a) Inflammation with necrosis and degeneration of muscle fibres. (b) Necrosis with loss of characteristic striations and integrity of fibre. (By courtesy of M. Reichlin, MD.)

In typical dermatomyositis, infiltration predominates in the perimysial area (around the fascicles) and around small blood vessels, sometimes extending into the endomysial area (Fig. 15). Microvascular changes are often seen, with perifascicular atrophy (decreased fibre size at the periphery of the fascicle), a characteristic (although not specific) feature of dermatomyositis (Fig. 15 and Fig. 16). This may result from capillary loss, which is greater in the perifascicular region, or to a direct effect of perifascicular inflammation (Kalovidouris 1994). It is most common in juvenile dermatomyositis (90 per cent), and also occurs in adult dermatomyositis (50 per cent) (Bertorini 1988b). Circumscribed areas of myofibrillar loss are also typical, attributed to ischaemic damage. There is some overlap of the polymyositis and dermatomyositis patterns (Ringel *et al*. 1986). Despite prominent vascular damage, frank necrotizing vasculitis is unusual (Fig. 17).

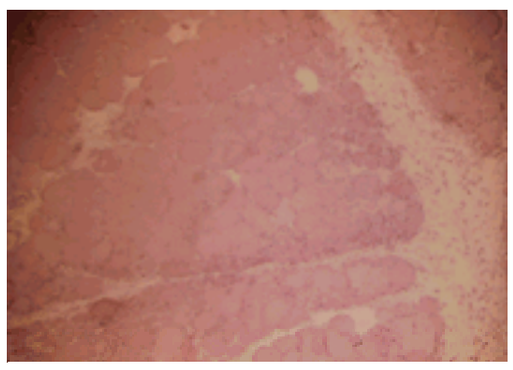

Fig. 15 Muscle biopsy (haematoxylin and eosin stain) from a patient with anti-Jo-1-positive myositis. The histological appearance is characteristic of dermatomyositis, but the patient had no cutaneous manifestations. The most intense infiltration is perimysial, with some extension into the endomysial area in a perifascicular distribution. Perifascicular atrophy (atrophy of the fibres at the periphery of the fascicle) is marked. Involvement of the vessel in the interstitial area is seen.

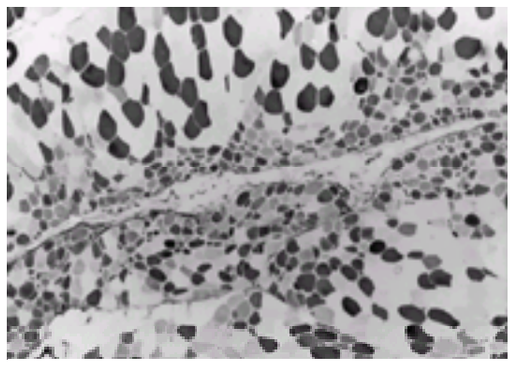

Fig. 16 Muscle biopsy (ATPase stain) from a patient with dermatomyositis. The pattern of perifascicular atrophy is evident.

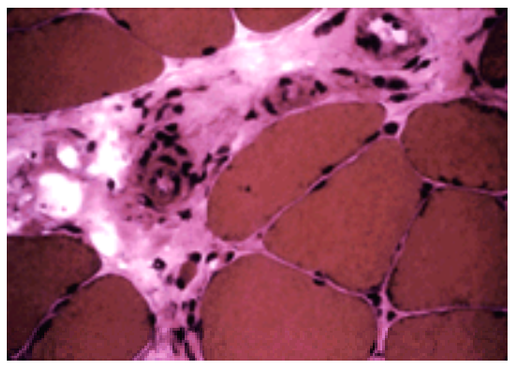

Fig. 17 Muscle biopsy from a patient with severe myositis associated with Sjögren's syndrome, showing inflammation surrounding small vessels.

EM shows endothelial cell injury, with swelling, hyperplasia, vacuolization, degeneration, and regeneration. There is endothelial cell necrosis and capillary thrombosis, and loss of capillaries resulting in decreased capillary density (Emslie-Smith and Engel 1990). The endothelial cells contain characteristic tubuloreticular inclusions ('undulating tubules'), that resemble viral structures but are believed to result from endothelial cell damage (Fidzianska and Goebel 1989). They may be seen in endothelial cells in other tissues (skin, lungs, joints, and lymphocytes). They can be induced by interferon-a, and may occur in other diseases, although usually not polymyositis.

Other EM findings are non-specific (Carpenter 1988). In dermatomyositis, Z disc streaming may be found. In polymyositis, aggregates of dense, membrane-bound material may be seen in some cases, and reduplication of the basal lamina.

Skin pathology

Skin biopsy can support the diagnosis of dermatomyositis, but generally cannot establish it. The biopsy should be taken from lesional skin (rather than as part of the muscle biopsy), usually from the chest or extremities. Liquefaction degeneration of the basal cell layer with prominent vacuolar changes is seen (Janis and Winkelman 1968). There is often a mild mononuclear cell infiltrate in the upper dermis and dermal–epidermal junction. There may be basement membrane thickening. Oedema and increased mucin can be seen in the dermis. The mucin (mostly hyaluronic acid) may be severe enough to be clinically evident (Igarashi *et al*. 1985). With poikiloderma, there is telangiectasia and epidermal atrophy. In Gottron's papules, typical dermatomyositis changes may be seen, with less atrophy, but with the addition of epidermal changes, including acanthosis and mild papillomatosis (Hanno and Callen 1985).

These findings may resemble systemic lupus erythematosus, but the dermal–epidermal infiltrate is milder in dermatomyositis, and there is more dermal mucin. Immunoglobulin deposition is much less prominent in dermatomyositis. Occasionally, mild deposition is seen at the dermal–epidermal junction in dermatomyositis lesional (but not non-lesional) skin (Kasper *et al*. 1988).

Differential diagnosis

The diagnosis of dermatomyositis is easier than that of polymyositis when the rash is florid. In polymyositis and less typical dermatomyositis, other conditions that can cause muscle weakness, myalgias, or elevated creatine kinase levels must be excluded. In all patients, tests for thyroid disease should be performed, and the role of medications should be considered. Most patients, particularly those with risk factors, should be tested for retroviral infection, and those at risk for other specific infections should be tested, such as specific exclusion of parasitic infection in those with eosinophilia or who are from endemic areas.

In patients with weakness without systemic features, other myopathies (inclusion-body myositis, metabolic or mitochondrial myopathies, drug-induced myopathies) or neuropathies (myasthenia gravis, amyotrophic lateral sclerosis) should be considered. In patients with weakness and signs of acute illness or autoimmune rheumatic disease, such as fever, arthritis, etc., the major conditions to be distinguished may be infectious or rheumatic. In a small number of cases, the patient will present with extra-muscle features only, either cutaneous lesions or autoimmune rheumatic features, resembling other autoimmune rheumatic diseases, or undifferentiated autoimmune rheumatic disease syndromes. Conditions that may be confused with polymyositis/dermatomyositis are listed in Table 5; special considerations are discussed below.

Table 5 Differential diagnosis of polymyositis/dermatomyositis

Human immunodeficiency virus (HIV)

Patients with HIV infection may develop myositis indistinguishable from polymyositis. Weakness, myalgia and elevated creatine kinase are seen, but rarely a rash. Electromyography shows myopathy, and biopsy shows inflammation with lymphocytic infiltration and necrosis (Dalakas 1993).

The pathogenesis of HIV-myositis appears similar to idiopathic polymyositis. CD8+ cytotoxic T cells and macrophages predominate, with very few CD4+ cells (Illa *et al*. 1991). As in polymyositis, there is endomysial infiltration, surrounded and invaded fibres, and expression of MHC-1 on most muscle fibres, all consistent with cell-mediated attack (Dalakas 1993). Numerous studies had failed to find HIV inside intact muscle fibres (Leon-Monzon *et al*. 1993), and it did not infect muscle cells *in vitro*, but HIV was found in cells infiltrating muscle or in degenerating fibres. However, a recent study using the more sensitive *in situ* polymerase chain reaction (**PCR**) found HIV in myocyte nuclei in four of seven cases (Seidman *et al*. 1994), plus HIV RNA indicating transcriptional activity. It remains to be shown whether myositis results from primary infection, secondary infection with a myositis-inducing virus, induction of autoimmune responses, or dysregulation.

HIV-myositis must be distinguished from the myopathy that can occur with zidovudine (Dalakas *et al*. 1990), which can cause weakness, myalgias, wasting, elevated creatine kinase, and myopathic electromyographs (Dalakas 1993). It is more frequent with longer therapy and higher doses. Zidovudine inhibits mitochondrial DNA synthesis, resulting in muscle mitochondrial toxicity *in vitro* and in experimental animals. Muscle shows ragged red fibres and abnormal mitochondrial structure and function (Mhiri *et al*. 1991). Inflammation is sometimes seen, but may relate to coexistent HIV-myositis; this combination may be required for symptomatic myopathy (Dalakas *et al*. 1990; Lane *et al*. 1993).

HIV has also been associated with a nemaline rod myopathy (Simpson and Bender 1988) and other non-inflammatory myopathy and muscle wasting. Patients with AIDS are also at risk for myositis from other infections, such as tuberculosis or microsporidia (Preston 1993), and for pyomyositis. Symptoms related to a myopathy may occur in up to 30 per cent of patients with AIDS, although a recognized inflammatory myopathy requiring treatment is much less common. Since polymyositis may

be the first manifestation of disease, testing for HIV infection is recommended in most patients with myositis.

Human T-cell lymphotropic virus type I (HTLV-1)

HTLV-1 has also been associated with myositis, with or without HTLV-1-associated myelopathy, and may be a major cause of polymyositis in endemic areas. In Jamaica, Morgan *et al*. (1989) found HTLV-1 antibodies in 11 of 13 polymyositis patients, but only in 7 of 93 others. The polymyositis was clinically similar to idiopathic polymyositis, with weakness, elevated creatine kinase, and compatible histology, and none of the patients had other HTLV-1-associated conditions. HTLV-1 was also increased in polymyositis patients in an endemic area in Japan, although not as dramatically (Higuchi *et al*. 1992). HTLV-1 is infrequent in polymyositis in non-endemic areas (Nishikai and Sato 1991; Nelson *et al*. 1994), but it may occur. HTLV-1 testing should be performed in patients at risk.

As with HIV, studies of infiltrating lymphocytes and MHC-1 expression in HTLV-1-myositis suggest T-cell mediated cytotoxicity (Leon-Monzon *et al*. 1994). One study found evidence of HTLV-1-associated proteins in muscle fibres (Wiley *et al*. 1989), but this was not confirmed (Higuchi *et al*. 1992; Leon-Monzon *et al*. 1994), and HTLV-1 did not infect muscle cells *in vitro*. The reason myositis develops in HTLV-1 infection is not known.

Bacterial pyomyositis

Pyomyositis has been well known in tropical areas for many years (Chiedozi 1979), most commonly affecting young males, with one or more spontaneous muscle abscesses, usually from *Staphylococcus aureus*. Pyomyositis in non-tropical areas is now increasingly reported, affecting older patients, often non-staphylococcal, with AIDS, diabetes, and chronic illness as predisposing factors (Rodgers *et al*. 1993; Gomez-Reino *et al*. 1994). Other muscle disease may be a factor in some cases. Although usually localized, a syndrome that could be confused with polymyositis has been seen (Wolf *et al*. 1990). Diagnosis can be made with ultrasound, CT, or MRI.

Other neurological conditions

Sensory abnormalities are against polymyositis/dermatomyositis, but diseases with exclusively diffuse motor involvement, such as amyotrophic lateral sclerosis or myasthenia gravis, can resemble polymyositis. Fasciculations and prominent atrophy may be clues in the former, and extraocular or eyelid muscle involvement in the latter.

Many myopathies are inherited and a family history of myopathy is an important point against polymyositis/dermatomyositis. Adult onset narrows the myopathies to consider, although a few associated with early onset occasionally present later (Table 5). In favour of dystrophy would be lack of inflammation on biopsy; myotonia; involvement of selective muscles (such as pectorals, biceps, triceps, etc.); and lack of response to therapy.

Mitochondrial myopathy may sometimes present in adults with pure limb myopathy without extraocular muscle involvement or encephalopathy. 'Ragged red fibres' on biopsy, due to subsarcolemmal accumulation of abnormal mitochondria, should prompt further testing with EM. Varga *et al*. (1993) described two cases of asymptomatic primary biliary cirrhosis associated with a severe, new onset mitochondrial myopathy with fatal outcome resembling polymyositis, raising the possibility of antimitochondrial antibody-induced mitochondrial myopathy.

Genetic defects in glycogen or glucose metabolism usually present with episodic fatigue, cramping, or pain related to exercise (Martin *et al*. 1994). Some, however, such as deficiencies of myophosphorylase (McArdle's disease), phosphofructokinase, myoadenylate deaminase, or acid maltase, may have an atypical presentation with late-onset progressive weakness that can be misdiagnosed as polymyositis (Higgs *et al*. 1989; Plotz 1992). The forearm ischaemic exercise test (Martin *et al*. 1994) is often used to screen for such disorders; several cause impaired rise in lactate but not ammonia, while myoadenylate deaminase causes impaired rise in ammonia but not lactate. There may also be clues on muscle biopsy (such as increased glycogen deposition). When metabolic myopathies are suspected, enzyme histochemistry and other tests for specific enzyme defects should be performed.

Drug-induced myopathies

Numerous drugs can induce myopathy (Table 6). Most have a toxic effect rather than inducing autoimmunity, and some have associated neuropathy, but the picture of weakness, myalgia, and elevated creatine kinase, often with electromyographic changes characteristic of myopathy, can look like polymyositis/dermatomyositis (Le Quintrec and Le Quintrec 1991; Zuckner 1994). D-Penicillamine is discussed later.

Table 6 Drugs causing myopathy

Colchicine may cause a non-inflammatory, vacuolar neuromyopathy (Kuncl *et al*. 1987), most often occurring with maintenance therapy at usual doses with renal insufficiency. A rise in creatine kinase is a sensitive indicator. A vacuolar myopathy may also be caused by chloroquine or less severely hydroxychloroquine, with characteristic myeloid and curvilinear bodies (Estes *et al*. 1987; Plotz 1992). Cardiomyopathy and neuropathy with loss of reflexes may be seen. Case reports of vacuolar myopathy with other drugs have appeared.

Muscle toxicity is a common side-effect with various cholesterol-lowering agents, possibly related to effects on sarcolemma (Dalakas 1992a). It can occur with HMG-CoA-reductase inhibitors (especially lovastatin) or fibrates or nicotinic acid alone, but is more severe with higher creatine kinases when combined (Pierce *et al*. 1990). Renal insufficiency may predispose to fibrate myopathy. Lovastatin myopathy is also more frequent in combination with cyclosporine, as after heart transplants.

Alcohol abuse may lead to either an acute necrotizing myopathy with prominent pain and high creatine kinase, or a chronic myopathy with proximal-muscle weakness, atrophy, and milder creatine kinase elevation (Charness *et al*. 1989). Several drugs of abuse, including cocaine, may lead to myopathy, creatine kinase elevation, or rhabdomyolysis, either due to pressure injury during unconsciousness, or without trauma (Rubin and Neugarten 1989). Abuse of ipecac in bulimia can induce a proximal, polymyositis-like myopathy, and as with other drug abuse, may be hidden (Plotz 1992).

In the eosinophilia–myalgia syndrome associated with L-tryptophan ingestion (Kaufman 1994), proximal myopathy was seen in two-thirds of cases. Aldolase was sometimes elevated, but not creatine kinase. Mononuclear and eosinophilic interstitial infiltrate (perimyositis) was seen, but fibre necrosis was rare. Similar findings occurred in the Spanish toxic oil syndrome.

Endocrine and steroid myopathies

Hypothyroidism is a common cause for elevated creatine kinase level with or without weakness, and can resemble polymyositis (Plotz 1992). Thyroid function should be tested in all patients when myositis is considered. Hypokalaemia from any cause can lead to myopathy, with creatine kinase elevation; severe hypokalaemic

myopathy has been associated with chronic licorice ingestion (Sintani *et al*. 1992). Other endocrine or metabolic problems can also cause myopathy (Table 5).

Use of corticosteroids for treatment of any condition may lead to proximal muscle weakness, associated with accentuated type II fibre atrophy (Khaleeli *et al*. 1983). Its onset is usually insidious, with lower extremity predominance. It tends to occur with higher doses for extended periods, and is more likely with multiple daily doses or longer acting, fluorinated preparations. In 10.6 per cent of patients taking dexamethasone steroid myopathy developed, with peak onset between the 9th and 12th weeks (Dropcho and Soong 1991). It usually improves if the dose is lowered. An acute form can occur associated with high-dose intravenous therapy and neuromuscular blocking agents in patients on respirators (Zuckner 1994).

In polymyositis/dermatomyositis, steroid myopathy can be confused with recurrent myositis. Elevated creatine kinase, increased spontaneous activity on electromyography, and inflammation detected by MRI or biopsy should all be absent in pure steroid myopathy. It may develop while the myositis is still active, indicating the likely need for a steroid-sparing drug. Often, if the situation is not life-threatening and remains unclear, dosage reduction is tried.

Aetiology and pathogenesis

Aetiology

Abundant evidence supports an autoimmune pathogenesis for polymyositis and dermatomyositis, but the reason they develop is unknown. It is generally felt that an inciting factor, exogenous or endogenous, acts in a genetically susceptible host, and that different inciting agents can lead to similar pictures. For example, D-penicillamine, HIV infection, various malignancies, and autoimmune rheumatic diseases, have been associated with autoimmune inflammatory myopathies that may be clinically indistinguishable from each other or from cases without recognized associations. Despite the paucity of familial cases, genetic predisposition is undoubtedly important, evident in the HLA associations, and suggested by animal models.

Potential aetiological factors

Infectious

A variety of infections can induce a syndrome resembling polymyositis/dermatomyositis in humans or animals, and unrecognized infections could be responsible for at least some idiopathic cases. Studies noting temporal variation in onset overall or for MSA-defined subgroups support this (Plotz *et al*. 1995). Mechanisms that might explain how infections such as viruses could induce autoimmune inflammatory myopathy include: persistent infection, molecular mimicry with cross-reaction of infectious agent and muscle protein, presentation or alteration of muscle antigens, production of immune complexes, effects on the immune system, or others (Targoff 1991; Behan and Behan 1993).

Picornaviruses

A variety of viruses (influenza, hepatitis, etc.) can cause myositis that resembles polymyositis, but repeated efforts to culture viruses from muscle in typical polymyositis and dermatomyositis have been unsuccessful. Picornaviruses, small RNA viruses that include enteroviruses (coxsackie, polio, echo), animal viruses such as encephalomyocarditis, and others, have been suspected as possible aetiologic factors in polymyositis/dermatomyositis (as well as myocarditis and other autoimmune conditions). One reason is their tendency to infect muscle, evident in animal models (see below) and human infection (e.g. myocarditis, rhabdomyolysis, chronic coxsackievirus A9 myopathy; Kuroda *et al*. 1986). Although self-limited in normal patients, enteroviral infection, particularly echovirus, can cause a dermatomyositis-like syndrome, usually accompanied by meningoencephalitis and sometimes by arthritis, in patients with agammaglobulinaemia (McKinney *et al*. 1987).

There is some evidence to support a viral role in polymyositis/dermatomyositis. More frequent antibodies to coxsackievirus-B, but not other viruses, were found in recent-onset juvenile dermatomyositis (83 per cent versus 25 per cent in matched controls; Christensen *et al*. 1986). Similarly, antibodies to coxsackievirus-A or B were more frequent in adult dermatomyositis, polymyositis, or myositis/malignancy (but not overlap, anti-Jo-1, or polymyositis/interstitial lung disease) compared with normal or rheumatoid arthritis controls (Nishikai 1994). Picornaviruses cannot be demonstrated by culture or immunofluorescence in typical polymyositis/dermatomyositis (Ytterberg 1994), and the picornavirus-like structures reported in early studies of diseased muscle by EM were probably not of viral origin. Data using molecular probes has been conflicting. Some studies have found evidence of coxsackievirus by hybridization (Yousef *et al*. 1990; Bowles *et al*. 1993), but others found no evidence of any enterovirus by *in situ* methods (Rosenberg *et al*. 1989; Hilton *et al*. 1994). Rosenberg *et al*. (1989) did find 60 per cent of adult dermatomyositis biopsies (but not polymyositis or controls) to be positive in muscle macrophages with a mouse picornavirus probe (Theiler's). Reactive material in the positive studies has not been characterized further, and Hilton *et al*. (1994) suggested they were detecting non-specific effects. Most studies using the PCR have been negative for enterovirus and other viruses (Leff *et al*. 1992; Leon-Monzon and Dalakas 1992; Jongen *et al*. 1993). In contrast, Behan and Behan (1993), using large samples, found polymerase chain reaction evidence of enterovirus in 56 per cent, with positives in all polymyositis/dermatomyositis groups, and in 4 per cent of controls; hybridization was seen in macrophages, endothelial cells, and occasional muscle fibres.

Thus, evidence is not consistent or convincing, and a role for ongoing picornavirus infection in polymyositis/dermatomyositis seems unlikely for most cases, although a potential role for subgroups of patients or isolated cases remains. Persistent infection is not necessarily required for an initiating role.

Retroviruses

HIV and HTLV-1 myositis discussed above suggest that polymyositis/dermatomyositis may be induced by as yet unidentified retroviruses, and understanding the mechanisms of these conditions may provide insight into the aetiology and pathogenesis of idiopathic polymyositis. No evidence of retrovirus by PCR was found (Leff *et al*. 1992; Nelson *et al*. 1994). Retroviruses are also under study in other autoimmune conditions, such as rheumatoid arthritis, Sjögren's syndrome and systemic lupus erythematosus (Kalden and Gay 1994).

Toxoplasmosis

Cases have been reported of *Toxoplasma gondii* infection causing a picture resembling polymyositis/dermatomyositis (reviewed in Ytterberg 1994), with some responding at least partially to treatment of the *Toxoplasma*. Antibodies to *Toxoplasma* were more frequent in polymyositis patients than controls, and IgM antibodies, suggesting recent or active infection, were also more frequent in polymyositis/dermatomyositis patients (24 per cent versus 3 per cent of systemic lupus erythematosus) (Magid and Kagen 1983). The significance of the tests is unclear, and a role for *Toxoplasma* in the polymyositis/dermatomyositis of these patients has not been established. Active *Toxoplasma* infection is not found in the muscle in most typical cases of these diseases by culture or biopsy. Bretagne *et al*. (1994) failed to find *Toxoplasma* DNA by a PCR method in the muscle of three patients with polymyositis/dermatomyositis with elevated titres. Reactivation of *Toxoplasma* by disease or treatment has been suggested as a cause for the positive titres (Behan *et al*. 1983). It remains possible that some cases of apparently idiopathic polymyositis/dermatomyositis result from unrecognized *Toxoplasma* or related infection.

Non-infectious causes

Drug, chemical, and environmental factors

Unlike most other drugs that cause myopathy, D-penicillamine induces a polymyositis-like inflammatory myopathy (Takahashi *et al*. 1986). The mechanism is unknown, and there is no clear relation to dose or duration. It usually responds when the drug is stopped, but steroids are often needed and deaths have occurred. Cardiac involvement can occur (Wright *et al*. 1994), as well as the dermatomyositis rash and even anti-Jo-1 (Jenkins *et al*. 1993). This emphasizes that ingested environmental agents could induce idiopathic polymyositis/dermatomyositis. A small number of other drugs, such as cimetidine and propylthiouracil, have been associated with an inflammatory myopathy.

An important lesson from D-penicillamine polymyositis/dermatomyositis is that genetic factors may affect the risk for disease among patients with equal exposure to the aetiological agent (Garlepp 1993). It was more frequent among Japanese patients (1.2 per cent) and Asian Indian patients (1.4 per cent) than Caucasian patients (0.2 to 0.4 per cent). It was associated with HLA DR4 in Caucasians, in contrast with idiopathic polymyositis/dermatomyositis. This may relate to the use of the drug in rheumatoid arthritis, but a link with DR4 was not seen in Asian Indians with rheumatoid arthritis, who did show an association with DR2 (80 versus 47 per cent)

(Taneja *et al*. 1990). Thus, immunogenetic background may affect susceptibility.

Environmental toxins are also of potential significance in the induction of autoimmune disease (Love and Miller 1993). Possible examples include cases of polymyositis developing after poisoning by the natural fish toxin ciguatera (Stommel *et al*. 1991), or with silica exposure. There has been recent focus on polymyositis/dermatomyositis after cosmetic procedures. Cukier *et al*. (1993) identified eight patients with dermatomyositis (and one with polymyositis) developing an average of 6.4 months after bovine collagen dermal implant or test exposure. However, an analysis by Rosenberg and Reichlin (1994), including review of individual cases, found the observed frequency to be lower than the estimated expected frequency. A link between polymyositis/dermatomyositis and silicone breast implants has also been postulated. Love *et al*. found that 13 women with polymyositis/dermatomyositis after implants differed in the frequency of clinical features, autoantibodies, and HLA types from 76 without implants (Love *et al*. 1992). However, its significance as an aetiological or adjuvant factor remains to be demonstrated (Houpt and Sontheimer 1994).

Malignancy

The mechanism for the association of dermatomyositis and malignancy (noted above) is unknown. The tumour might lead to polymyositis/dermatomyositis by causing immune dysregulation, producing immune complexes, or inducing specific antimuscle reactions, but a common factor might lead to both conditions (persistent viral infections, toxins, genetic predispositions, immunological abnormalities).

Other factors

A large survey to determine risk factors for developing polymyositis/dermatomyositis found an increased frequency of recent heavy muscular exertion and emotional stress in patients (Lyon *et al*. 1989), but immunization was not correlated, and recent upper respiratory infections were negatively associated.

Immunogenetics

Associations with MHC genes indicate the importance of genetic susceptibility in polymyositis/dermatomyositis (Garlepp 1993). HLA DR3 has been associated with polymyositis in several studies, such as those of Love *et al*. (1991) (DR3 in 45 per cent in polymyositis/dermatomyositis versus 23 per cent in controls), and Ehrenstein *et al*. (1992) (DR3 in 75 per cent polymyositis versus 27 per cent in controls). The association is clearer in white than in black patients. C4A null, associated with B8/DR3, showed no independent association with polymyositis/dermatomyositis (Moulds *et al*. 1990). MHC associations do not differ between clinically defined subgroups, but are stronger with myositis-specific autoantibodies than with polymyositis/dermatomyositis overall. Compared with other patients, HLA DR3 is more frequent in patients with anti-Jo-1 (Goldstein *et al*. 1990; Love *et al*. 1991), but not other antisynthetases. Both anti-Jo-1 and other antisynthetases were associated with HLA DRw52, with or without DR3. This suggested that a short sequence on the DRb1 chain may be crucial in antisynthetase production (Goldstein *et al*. 1990). DQa associations have also been reported, including an association of anti-Jo-1 with DQa4 (Gurley *et al*. 1991). Reveille *et al*. (1992) found that most black or white antisynthetase patients showed DQA1*0501 or DQA1*0401 (associated with DR52-bearing DR types), and Japanese antisynthetase patients showed DQA1*0101, *0102, or *0103. Immunoglobulin allotypes may also predispose to development of antisynthetases; patients with anti-Jo-1 had higher Gm 3;5, and the combination of Gm 3;5 and DR3 was markedly increased (92 versus 15 per cent) (Enz *et al*. 1992).

Anti-PM-Scl is most common among Caucasians, and was not found in a large study of Japanese patients (Hirakata *et al*. 1992). It is strongly associated with DR3, as first noted by Genth *et al*. (1990) (DR3 in all 12 patients with anti-PM-Scl versus 23.5 per cent of controls, $p<0.001$), and later Marguerie *et al*. (1992) (DR3 in all 22 patients with anti-PM-Scl and 50 per cent homozygous), and Oddis *et al*. (1992) (DR3 in 15 out of 20 patients with anti-PM-Scl versus 22 per cent of controls). DR7 was associated with anti-Mi-2 (75 per cent versus 16 per cent without MSA), and DR5 with anti-SRP (57 per cent versus 20 per cent) (Love *et al*. 1991).

Pathogenetic mechanisms

Autoimmunity in polymyositis/dermatomyositis is suggested by the inflammatory picture, the response to steroids, and the association with other autoimmune diseases. Studies of both the cellular and humoral immune abnormalities have supported this impression, and have provided important insight into the mechanisms involved (Kalovidouris 1994; Plotz *et al*. 1995).

Cellular immunity

Infiltrating lymphocytes

Lymphocytes in muscle inflammatory infiltrates have been characterized using monoclonal antibodies to cell surface markers (Engel *et al*. 1990). T cells, many of which are activated (expressing DR antigens), are prominent in areas of severe inflammation (Rowe *et al*. 1983). CD4+ T cells are most abundant in untreated adults with acute disease, and decrease with treatment. In moving from the perivascular to the endomysial area, the proportion of CD8+ suppressor/cytotoxic T cells increases, and that of CD4+ T cells and B cells decreases (Arahata and Engel 1984; Mantegazza *et al*. 1993). Dermatomyositis biopsies show a higher proportion of B cells and a lower proportion of CD8+ T cells than polymyositis.

In polymyositis, many non-necrotic muscle fibres are surrounded and invaded by mononuclear cells; such fibres are very rare in dermatomyositis. A majority of surrounding and most of the invading cells are CD8+ T lymphocytes (Engel and Arahata 1984), indicating direct involvement of CD8+ T cells in fibre injury. A high proportion of invading cells are activated, and most are cytotoxic rather than suppressor (Arahata and Engel 1988a). Killer and natural killer cells do not seem to contribute to muscle damage (Arahata and Engel 1988b). Necrotic fibres become infiltrated predominantly by macrophages. By EM, cytotoxic T cells and macrophages become apposed against the fibre and send 'spike-like processes' into it, which then proliferate, but the membrane remains intact (Arahata and Engel 1986). Many endomysial (not perimysial) cells may show perforin and granzyme A, granule proteins of cytotoxic T cells that may participate in fibre damage, as well as TIA-1 protein related to apoptosis (Cherin *et al*. 1993a; Orimo *et al*. 1994).

The T-cell receptors of the infiltrating lymphocytes also suggest an antigen-directed T-cell attack in polymyositis. T-cell receptor rearrangements and marked restriction in V gene usage are seen, although the V genes used differed between studies. Using PCR techniques, Mantegazza *et al*. (1993) found preferential usage of Va1, Va5, Vb1, and Vb15, while O'Hanlon *et al*. (1994a) showed predominance of Va1 and Vb6, with Jb gene conservation, among anti-Jo-1 patients with polymyositis, but not dermatomyositis. By histochemistry, V-gene usage differed between cells in the perimysial areas and those in the endomysial areas that are attacking the muscle fibres (Lindberg *et al*. 1994a). Bender *et al*. (1995), confirming this, found that sequences of T-cell receptor V genes from different invading T cells of an individual were often identical, suggesting local clonal expansion, evidently in response to a muscle antigen. One patient had a unique form of polymyositis, in which the infiltrating T cells had almost exclusively g/d-T-cell receptors (Hohlfeld *et al*. 1991b). It was hypothesized that the antigens may be heat-shock proteins, a common target of such T cells. The T cells may have been derived from a single T-cell clone (Pluschke *et al*. 1992).

Thus, the predominant mechanism for immunologically mediated muscle injury in polymyositis, but not dermatomyositis, appears to be T-cell cytotoxicity, directed at an unidentified antigen, presumably on the muscle fibre surface. The fibre is surrounded and invaded by activated, clonally expanded, cytotoxic T cells. Additional mechanisms, such as cytokines, may come into play in the final destruction of the fibre.

T-cell attack on muscle fibres does not appear to occur in dermatomyositis, but cellular immunity may still play a role, possibly contributing to the vessel injury. Saito *et al*. (1989) found that mononuclear cells (mostly CD8+ T cells) from patients with dermatomyositis, but not polymyositis, showed cytotoxicity against cultured fibroblasts in a non-MHC restricted manner.

Muscle fibres

While expression of MHC-1 antigens on muscle fibres is normally low or absent, in polymyositis and inclusion-body myositis muscle many fibres strongly express MHC-1, making them vulnerable to antigen-directed T-cell mediated cytotoxicity (Karpati *et al*. 1988). MHC-1 was seen on all fibres that were invaded by CD8+ lymphocytes (Emslie-Smith *et al*. 1989). However, it can also be seen in dermatomyositis, where surrounded and invaded fibres are rare. MHC-2 antigens have been found on muscle fibres in most active polymyositis and dermatomyositis biopsies (Kalovidouris 1994), but not in normal muscle or that of other myopathies. ICAM-1 (intercellular adhesion molecule 1) is induced on muscle fibres under attack, in the area of invasion, and may be important in adhesion of invading cells (De Bleecker and Engel 1994).

Since strength often returns with treatment of polymyositis and dermatomyositis sooner than would be expected if regeneration were required, much of the weakness may relate to muscle cell dysfunction. This may result from cytokines or other factors released by infiltrating mononuclear cells, that can interfere with calcium binding to the sarcoplasmic reticulum and suppress muscle contractility (Kalovidouris 1986). A possible additional mechanism may be relative acquired enzyme deficiencies such as myoadenylate deaminase (Sabina *et al*. 1990).

Peripheral blood lymphocytes

Early studies of peripheral blood lymphocytes in polymyositis/dermatomyositis showed increased proliferation in response to muscle extract in some studies (Targoff 1991), greater in active untreated cases, but generally of a low level, and not myositis-specific. Kalovidouris *et al*. (1989) later found significant lymphocyte stimulation in response to autologous or allogeneic muscle much more frequently in active (76 per cent) than treated myositis (12.5 per cent) or controls, consistent with sensitization of lymphocytes to muscle.

Peripheral lymphocytes from patients with polymyositis/dermatomyositis showed toxicity for muscle cells in culture in some studies (Targoff 1991), but this was not specific for polymyositis/dermatomyositis and did not require MHC compatibility, suggesting a non-antigen-specific mechanism such as natural killer cells. Recently, Hohlfeld and Engel (1991a) tested cultured muscle-infiltrating cytotoxic T cells against cultured autologous muscle, and some lines did show some evidence of cytotoxicity by chromium-51 release, but further study is needed to demonstrate clearly antigen-directed T-cell cytotoxicity in polymyositis/dermatomyositis.

In active polymyositis/dermatomyositis, a high proportion of peripheral blood T cells show activation markers (Miller *et al*. 1990a), decreasing with treatment. As expected, those with dermatomyositis show fewer activated T cells, but more B-cells than those with polymyositis. There is increased trafficking of lymphocytes to muscle. Peripheral lymphocytes show decreased mitogen responsiveness in polymyositis, and decreased autologous mixed lymphocyte responses (Plotz *et al*. 1989).

Cytokines

Cytokines could be important in the development, enhancement, or perpetuation of the autoimmune response, or in tissue injury and cytotoxicity. Lymphocytes cultured with autologous muscle elaborate cytotoxic factors (Johnson *et al*. 1972). Interferon-g, present in polymyositis/dermatomyositis muscle (Isenberg *et al*. 1986), can enhance MHC-1 and induce MHC-2 expression on cultured muscle fibres *in vitro* (Kalovidouris 1992) and enhance T-cell adhesion to muscle by increasing ICAM-1 expression (Kalovidouris *et al*. 1994). Interferon-g can inhibit proliferation and differentiation, an effect enhanced by tumour necrosis factor-a (TNF-a), thus possibly directly injuring or preventing repair of muscle fibres (Kalovidouris *et al*. 1993). Polymyositis has occurred after interferon therapy.

The serum levels of IL-2 receptor and IL-1a are elevated in active polymyositis and dermatomyositis (Wolf and Baethge 1990) and fall with treatment, possibly reflecting activated lymphocytes. IL-1 receptor antagonist was markedly elevated in some patients with active disease, and fell with treatment (Gabay *et al*. 1994), while spondylarthropathies and rheumatoid arthritis show instead higher IL-6 and C-reactive protein, possibly reflecting the relative prominence of activated T cells in polymyositis/dermatomyositis.

Humoral immunity

Microvascular injury

Direct T-cell mediated attack against muscle fibres does not seem to be important in dermatomyositis, with little endomysial infiltrate, and few surrounded and invaded non-necrotic fibres. However, the intense B-cell and CD4+ T-cell infiltrate in the perivascular area suggests a local humoral response (Arahata and Engel 1984) (Table 7).

	Dermatomyositis	Polymyositis
Skin rash	Yes	No
Microvascular injury	Yes	No
Perifascicular atrophy	Common	Uncommon
Endomysial infiltration	Less common	Common
Surrounded and invaded fibres	Rare	Frequent
Deposition of membrane attack complex	Yes	No
Anti-Mi-2	15–20%	<1%
Anti-SRP	<1%	6%

Table 7 Differences between polymyositis and dermatomyositis

Vasculopathy involving the small vessels and capillaries, with resultant ischaemic damage and perifascicular atrophy, is an important mechanism of muscle injury in dermatomyositis (Emslie-Smith and Engel 1990; Heffner 1993). Long associated with juvenile dermatomyositis, it is often found in typical adult dermatomyositis, but generally not polymyositis. Casademont *et al*. (1993) found that 87 per cent of patients with muscle capillary damage had a dermatomyositis rash.

Emslie-Smith and Engel (1990), studying muscle biopsies from adults with clinical dermatomyositis that showed little or no structural change by routine examination ('early dermatomyositis'), found definite microvascular abnormalities by EM in all cases, including endothelial cell injury, microtubular inclusions, and decreased capillary density (confirmed quantitatively), not seen in polymyositis or inclusion-body myositis. Biopsies showing overt dermatomyositis had even lower capillary density and more advanced vascular changes, including capillary necrosis.

Microvascular damage in muscle is felt to be mediated by complement. Kissel *et al*. (1986) found deposition of complement membrane attack complex (**MAC**) in the walls of muscle microvasculature, indicating local activation of complement, in most cases of juvenile dermatomyositis and some cases of adult dermatomyositis, but not polymyositis. It is greater in areas where ischaemic damage is recent (fibres with 'punched-out' central myofibrillar loss) than in those with perifascicular atrophy (a later change), and is less evident in long-standing disease (Kissel *et al*. 1991). Emslie-Smith and Engel (1990) found membrane attack complex deposition in 9 of 10 'early dermatomyositis' biopsies. Since injury to the microvasculature can occur before inflammatory infiltrates and muscle fibre damage are evident, it may be the primary target in the pathogenesis of dermatomyositis.

The factors leading to complement activation are not known. Deposition of immunoglobulin in muscle blood vessels, not seen in normal people, has been found in dermatomyositis in some studies, especially juvenile dermatomyositis and autoimmune rheumatic disease overlap, and less commonly polymyositis, but is not specific (Isenberg 1983). Its relation to the membrane attack complex deposition is unknown. Deposition has also been seen in the periphery of the fibre (sarcolemma and basement membrane), and in the fibre itself.

Autoantibodies

The clearest evidence of abnormality of humoral immunity in polymyositis/dermatomyositis is the presence of autoantibodies to nuclear and cytoplasmic antigens in up to 89 per cent of patients (Reichlin and Arnett 1984) (Fig. 12). A positive ANA is found in 40 to 80 per cent, more commonly in overlap and less in myositis with malignancy. The specificities of these antibodies have been studied in detail (Targoff 1994), and are heterogeneous, possibly reflecting heterogeneity of the disease (Table 8). About half of patients have autoantibodies of recognized specificity, some of which are found primarily in polymyositis/dermatomyositis, referred to as MSAs (Miller 1993). Others have an association with myositis, but may be found in other conditions. Most MSAs are associated with a characteristic clinical picture, and an individual generally has only a single MSA, so that MSAs can define clinical subgroups (Love *et al*. 1991).

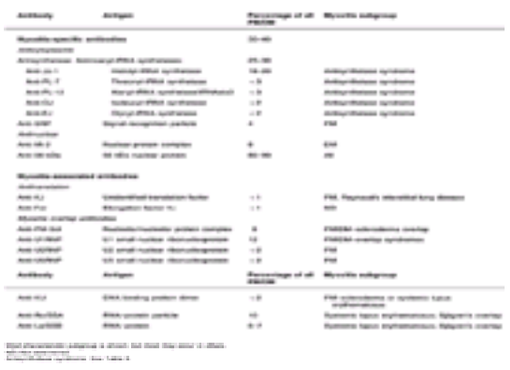

Table 8 Autoantibodies in polymyositis/dermatomyositis (PM/DM)

Myositis-specific antibodies (MSAs)

Antisynthetases

About 30 per cent of patients with polymyositis/dermatomyositis have antibodies to an aminoacyl-tRNA synthetase, an enzyme that attaches one specific amino acid to its cognate tRNAs. Five antisynthetases occur in polymyositis/dermatomyositis sera (Table 8). These enzymes are antigenically distinct, and an individual patient has antibodies to only one. By far the most common is antibody to histidyl-tRNA synthetase (anti-Jo-1) (Mathews and Bernstein 1983), found in 20 per cent of patients with polymyositis/dermatomyositis.

A group of clinical features have been associated with anti-Jo-1 in several studies (Table 9; Marguerie *et al*. 1990; Love *et al*. 1991). The limited number of patients with non-Jo-1 antisynthetases studied have had a similar clinical picture (Targoff and Arnett 1990; Targoff *et al*. 1992; Targoff *et al*. 1993). Apart from myositis, the most striking feature is interstitial lung disease, found in 50 to 90 per cent with the antibodies, but less than 10 per cent of other patients with polymyositis/dermatomyositis. The interstitial lung disease can dominate the picture, and some patients have this without overt myositis (more common with anti-PL-12). Two-thirds of patients with anti-Jo-1 have inflammatory polyarthritis (Oddis *et al*. 1990b), usually mild and responsive to treatment, but a third of these may have finger deformity, usually non-erosive, occasionally with calcinosis (rare erosive disease may represent rheumatoid arthritis overlap; O'Neill and Maddison 1993). Raynaud's phenomenon (62 per cent), fever (87 per cent), and mechanic's hands (71 per cent) are other important features (Love *et al*. 1991). Marguerie *et al*. (1990) found that sclerodactyly (72 per cent) and sicca (59 per cent) were also frequent. Their response to therapy may be less complete, with more relapses. A third to a half of the patients have dermatomyositis (some find a lower proportion among anti-Jo-1 patients). Malignancy is uncommon but has occurred. Patients with these antibodies are also immunogenetically distinctive (see above).

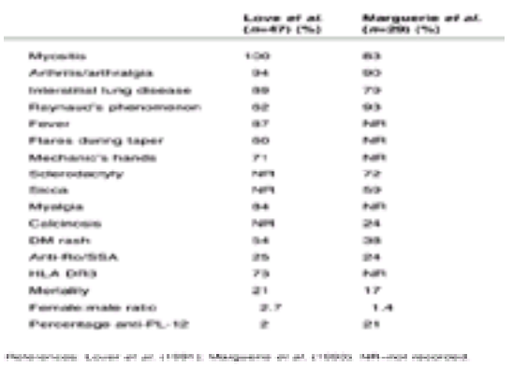

Table 9 Features of antisynthetase syndrome

The set of clinical features associated with antisynthetases has been referred to as the 'anti-synthetase syndrome' (Targoff 1994). It may resemble other autoimmune rheumatic diseases syndromes, including mixed connective tissue disease (with joint disease, scleroderma and Raynaud's phenomenon; Marguerie *et al*. 1990) or systemic lupus erythematosus (fever, pneumonitis, polyarthritis, and positive ANA). However, myositis is usually more prominent and less responsive to treatment, significant interstitial lung disease is more frequent, and features of systemic lupus erythematosus are rare in the absence of other autoantibodies.

Other anticytoplasmic myositis-specific antibodies

Antibodies to other cytoplasmic antigens are found in a small proportion of patients with polymyositis/dermatomyositis (Table 8), the most important of which is antibody to the signal recognition particle (anti-SRP), a ribonucleoprotein involved in protein translocation into the endoplasmic reticulum. Anti-SRP is found almost exclusively in adult polymyositis (Targoff *et al*. 1990), with no increase in interstitial lung disease, arthritis, or Raynaud's phenomenon. Some patients with anti-SRP have an acute, fulminant course, resistant to treatment (Love *et al*. 1991). Antibodies to translation factors have been identified rarely in patients with polymyositis/dermatomyositis, including anti-KJ, which was associated with a picture similar to the antisynthetase syndrome (Targoff *et al*. 1989). Anti-Mas, directed at a tRNA-related antigen, was identified in rare patients with inflammatory myopathy and alcoholism (Love *et al*. 1991), but is not myositis-specific. Several MSAs are directed at cytoplasmic antigens related to tRNA or protein synthesis, but more patients with polymyositis/dermatomyositis have antinuclear than anticytoplasmic antibodies.

Antinuclear myositis-specific antibody

Anti-Mi-2, which reacts with a nuclear antigen of unknown function, is strongly associated with dermatomyositis (Targoff 1994). Ninety-five per cent of patients with anti-Mi-2 have dermatomyositis, and 15 to 20 per cent with dermatomyositis have the antibody. The rash is often florid (Fig. 6), with a higher frequency of the 'V' and 'shawl' signs than others with dermatomyositis (Love *et al*. 1991). Patients with anti-Mi-2 tend to do better than those with antisynthetases. No increase in interstitial lung disease or Raynaud's phenomenon is seen.

Myositis-overlap antibodies

Several autoantibodies are seen in patients with myositis–scleroderma or other overlap syndromes. Although not MSAs, since some patients do not have myositis, these antibodies can be very helpful in evaluating a patient with suspected myositis.

Anti-PM-Scl

Anti-PM-Scl reacts with a nucleolar protein complex of unknown function containing at least 11 polypeptides. Patients with anti-PM-Scl have myositis (5 to 10 per cent of patients with polymyositis/dermatomyositis), scleroderma, or, most commonly, a myositis–scleroderma overlap syndrome, often with arthritis (Marguerie *et al*. 1992; Oddis *et al*. 1992). Cutaneous scleroderma is usually limited when present. The myositis is often mild and tends to be responsive to treatment. Raynaud's phenomenon and interstitial lung disease are common and calcinosis may be increased. Jablonska *et al*. (1993) describe 'scleromyositis', a syndrome with features of polymyositis/dermatomyositis and scleroderma with anti-PM-Scl that may resemble mixed autoimmune rheumatic disease. In Japan, anti-PM-Scl is rare, but anti-Ku is commonly found in polymyositis–scleroderma overlap (Hirakata *et al*. 1992). Anti-Ku is rare in polymyositis/dermatomyositis in the United States, but found more often

in systemic lupus erythematosus and scleroderma.

Anti-snRNPs

Anti-U1RNP is found in 10 to 15 per cent of polymyositis/dermatomyositis, often with autoimmune rheumatic disease overlap features such as Raynaud's phenomenon, arthritis or dactylitis. Myositis is often found in patients with overlap syndromes or systemic lupus erythematosus who have U1RNP. The myositis tends to be more responsive to treatment (Lundberg *et al*. 1992; Jablonska *et al*. 1993). Three per cent of patients with polymyositis/dermatomyositis have anti-Sm, usually with systemic lupus erythematosus overlap. Antibodies specific for the U2 snRNP (usually with anti-U1RNP) occur in a small number of patients with polymyositis–scleroderma (Craft *et al*. 1988), and anti-U5RNP (without anti-U1RNP/Sm) appears to be myositis-specific (Rider *et al*. 1994).

Patients with anti-U3RNP, a scleroderma-specific antibody, have a higher frequency of inflammatory myositis than others with diffuse scleroderma (Okano *et al*. 1992). Anti-Ro/SSA, often with anti-La/SSB, is found in 10 per cent of polymyositis/dermatomyositis, more commonly with antisynthetases; Sjögren's syndrome or systemic lupus erythematosus overlap may be present, but is not always evident. Antibodies associated with other autoimmune rheumatic diseases, such as anticentromere, occur in occasional patients with polymyositis/dermatomyositis, usually as part of overlap syndromes.

Other myositis-associated autoantibodies

The sera of 87 per cent of patients with polymyositis/dermatomyositis reacts with a 56-kDa protein of nuclear ribonucleoprotein particles (Arad-Dann *et al*. 1989). Anti-56 kDa is common in all subgroups, but more in dermatomyositis than polymyositis. It is not completely specific, being found in 10 per cent of other autoimmune rheumatic diseases (usually in lower titre), but was not found in serum of normal subjects or patients with other muscle diseases. The titre varied with disease activity. It may be a more general marker for myositis, and have a different significance than other MSAs.

Antiendothelial cell antibodies, of interest in view of the endothelial injury in dermatomyositis, and antibodies to heat shock proteins, occur in some patients with polymyositis and dermatomyositis, but they are common in other conditions, and their significance in polymyositis/dermatomyositis is unknown (Cervera *et al*. 1991). Antibodies to muscle proteins such as myosin occur in up to 90 per cent of polymyositis/dermatomyositis (Wada *et al*. 1983; Koga *et al*. 1987), and may vary with disease activity. Although more frequent in polymyositis/dermatomyositis than other muscle diseases, they are not specific, and could be secondary to muscle damage. The possibility that they contribute to muscle injury is of interest, but their role is unknown.

Possible relation to pathogenesis

The reason for production of these antibodies is unknown, and may relate to aetiological factors (Targoff 1994). HLA and other genetic factors seem to be important (see above). There is increasing evidence that production is driven and perpetuated by the recognized antigens (Miller *et al*. 1990c), but they may not initiate the responses. It is often speculated that myositis-inducing viruses lead to the antibodies through such mechanisms as molecular mimicry, formation of immunogenic complexes between host and viral factors, etc. (Targoff 1991). Hypotheses must explain how patients with antibodies to different members of the same enzyme family, present in every cell, have a similar clinical syndrome manifested in specific organs.

It is not known if the antibodies play a direct role in pathogenesis (Naparstek and Plotz 1993). Antisynthetases consistently inhibit antigen function, but they have not been shown to enter intact cells. They could injure muscle through immune complexes, reaction with cell surface antigens, etc., but there is as yet no evidence of this. A correlation of anti-Jo-1 titre with myositis activity (Miller *et al*. 1990b), including the development of anti-Jo-1 shortly before the onset of weakness (Miller *et al*. 1990a), suggests a pathogenetic role, but against such a role is their common occurrence in polymyositis, where cell-mediated fibre damage is most important, and low frequency in juvenile dermatomyositis, where humoral injury occurs.

The epitopes of the myositis-associated autoantibodies are under study; predominant epitopes are often found (Raben *et al*. 1994). They generally differ from those of animal antisera, and tend to be conformational (Targoff 1994). Specific immunological features of the antibodies may provide clues to their origin.

Animal models

Experimental autoimmune myositis

Certain strains of guinea pig, rat, or mouse develop myositis (but not weakness or rash) as a result of immunizations with homologous or heterologous muscle homogenates in adjuvant (Rosenberg 1993). Inflammation and necrosis occur, but no vascular changes or perifascicular atrophy. Muscle damage is mediated by cellular immune mechanisms, and lymphoid cells can transfer disease. Humoral reaction to muscle is seen, and serum could transfer disease in one (Matsubara *et al*. 1993) but not other studies. The histology resembles human polymyositis, but with more macrophages in the inflammatory infiltrate (80 to 90 per cent). Experimental autoimmune myositis demonstrates that cell-mediated immunity can mediate muscle injury, but is limited by differences from human polymyositis/dermatomyositis.

SJL/J mice are uniquely susceptible to experimental autoimmune myositis, and with aging, develop a similar and more severe myositis spontaneously. Immunological defects and neoplasms occur in these mice, which may contribute. This spontaneous model may provide insight into aetiological factors (Rosenberg 1993).

Viral models

Picornaviruses

Coxsackie and several other picornaviruses can produce a polymyositis-like myositis in mice. Neonatal Swiss mice infected with coxsackie-B1 Tuscon strain develop an acute illness followed by a chronic inflammatory myositis resembling polymyositis, with proximal muscle weakness, myopathic electromyographs, and mononuclear cell infiltration, with degenerating and regenerating muscle fibres (Strongwater *et al*. 1984). Myositis progresses beyond the period in which the virus can be cultured (6 months versus 2 weeks), but viral nucleic acid persists longer than culturable virus (Tam *et al*. 1994). Production of the myositis depends on the strain of virus and of mouse used, and requires cell-mediated immunity (Ytterberg *et al*. 1987).

Infection of adult mice with a myotropic strain of encephalomyocarditis virus produces an inflammatory myositis and myocarditis in some mouse strains (Miller *et al*. 1987). As with coxsackievirus, development of the myositis requires specific strains of virus and genetic background (susceptibility was H2 restricted). Further, viral nucleic acid could be detected at 4 weeks, when virus could no longer be cultured but muscle inflammation persisted (Cronin *et al*. 1988); thus viral persistence may be important in chronicity. The mice do not develop myositis-associated autoantibodies. Thus, picornaviruses can produce an immune-mediated myositis, supporting their potential as aetiological agents in some cases of idiopathic polymyositis/dermatomyositis.

Retroviruses

Macaque monkeys develop a syndrome resembling AIDS after infection with the D-type simian retrovirus SRV-1. Up to half of infected monkeys develop a myositis that closely resembles polymyositis as part of their disease (Dalakas *et al*. 1987), with weakness, elevated enzymes, and a biopsy showing inflammation, necrosis, phagocytosis, and fibrosis. The mechanism is unclear, although the virus could infect cultured muscle cells. The model may be useful in the study of retrovirus-associated myositis, as well as idiopathic polymyositis/dermatomyositis.

Canine dermatomyositis

A condition resembling dermatomyositis occurs spontaneously in collies and Shetland sheep dogs (Hargis and Prieur 1988), with autosomal dominant inheritance. Juvenile dogs develop muscle weakness and atrophy, difficulty eating, and an erythematous, scaly rash over the periorbital areas, face, and distal extremities. Muscle histology shows inflammation, fibre necrosis, regeneration, and atrophy, and vasculitis may occur. Serological tests are usually negative. The model has significant differences from human myositis, but is most similar to juvenile dermatomyositis. Dogs may spontaneously develop an eosinophilic myositis of the muscles of mastication. Occasionally, polymyositis is seen.

Management

Treatment should be started promptly, since significant delay has been associated with poorer outcome (see below). Treatment is most urgent, and sometimes initiated pending completion of the evaluation, in patients with rapid onset of severe weakness, dysphagia, respiratory insufficiency, myocardial involvement, or systemic signs. Most cases can be managed outside the hospital, but admission may be required for patients with respiratory insufficiency or severe dysphagia, those requiring intravenous medications, or clarification of diagnosis.

A general approach to treatment is outlined in Table 10. Guidelines for initial treatment, dosage reduction, and choice of agents should be adapted to the situation of the patient. Most patients are first given a trial of corticosteroids alone. Initial therapy with a combination of steroids and immunosuppressives also has some support (Bunch 1981). Some have recently suggested other agents for first-line treatment, such as cyclosporine (Grau *et al*. 1994) or for certain patients, intravenous gammaglobulin (Dalakas 1994a). Immunosuppressives and recently intravenous gammaglobulin are used when additional therapy is required.

Table 10 A strategy for treatment of newly diagnosed, active, idiopathic polymyositis or dermatomyositis

Corticosteroids

While not demonstrated by prospective randomized controlled trials, the effectiveness of steroids in improving muscle strength is accepted generally, and readily apparent from observation of treated patients. It is further suggested by studies demonstrating improved outcome with earlier treatment.

Initial treatment

Treatment is usually begun at high doses (prednisone 1 mg/kg per day, usually 60 to 80 mg/d, or equivalent), often in divided doses that are considered to increase effectiveness. Dalakas (1994a); Dalakas (1994b) recommends 80 to 100 mg/d as a single morning dose, feeling that this increases its benefits.

The high initial dose (prednisone more than 60 mg/d) is continued until the creatine kinase has returned to normal and the strength has substantially improved, usually 1 to 2 months (Oddis 1991). Adequate initial treatment is important, and is associated with better responses (Oddis and Medsger 1988). When begun as divided doses, the daily amount is usually consolidated to a single morning dose after the acute period or before beginning dosage taper.

Very high-dose intravenous 'pulse' methylprednisolone, in regimens such as 1 g/day for 3 days, is sometimes used initially to achieve a more immediate effect in severely ill patients, or later when disease is unresponsive to oral steroids, or for exacerbations during steroid taper (Oddis 1993). Matsubara *et al*. (1994) found that pulse therapy (0.5 g/day for 3 days per week for 1 to 9 weeks) added to oral therapy increased the rate of and shortened the time to remission. Although some have used alternate-day steroids in milder cases from the outset to reduce side-effects (Hoffman *et al*. 1983), it is less reliable, and not recommended in most cases (Dalakas 1994b).

Response

It is important to monitor patients closely during treatment for degree of improvement, new complications, or side-effects. Both muscle strength (assessed as above) and creatine kinase levels are used to judge improvement. The response to steroids in polymyositis/dermatomyositis tends to be slower than that in systemic lupus erythematosus or rheumatoid arthritis, and it may take months to achieve the full effect (Plotz *et al*. 1989), with a mean time to recovery of normal strength of more than 3 months (Tymms and Webb 1985). The creatine kinase usually normalizes weeks to months earlier than the strength, generally indicating adequate suppression of disease activity. Creatine kinase levels in the high normal range may indicate disease activity and may decrease with treatment.

Oddis and Medsger (1989) found that treatment using the following guidelines was more likely to result in prolonged suppression of disease: (i) start with 60 mg/day or more of prednisone for at least 1 month; (ii) continue initial treatment until or after the creatine kinase becomes normal; and (iii) taper steroids slowly, with average reduction from first reduction to maintenance dosage of 10 mg/month or less.

Most patients respond at least partially to treatment with steroids. If there is no improvement or if significant weakness persists, possibilities include: (i) incorrect diagnosis: the basis for the diagnosis should be reviewed, and further evaluation considered, such as repeat biopsy looking in particular for inclusion-body myositis or metabolic myopathy; (ii) malignancy: although myositis with malignancy may be quite responsive (Joffe *et al*. 1993), failure to respond or weight loss on steroids should suggest a more extensive search (Plotz 1992); (iii) steroid myopathy: when creatine kinase falls but weakness persists, not explained by the expected lag of strength behind creatine kinase, steroid myopathy should be considered; (iv) permanent loss of strength: some patients cannot recover full strength despite complete suppression of disease activity, often those with prolonged delay before treatment, atrophy, or prominent fibrosis on biopsy; (v) resistance: disease activity may be unresponsive to steroid therapy. Persistent elevation of the creatine kinase usually means that the disease has not been controlled. Occasional patients have resolution or stabilization of weakness while creatine kinase remains elevated, often at low levels. Such elevations may not reflect ongoing disease activity (Oddis 1994); MRI may help to assess activity in these situations.

Dosage reduction

When the initial goals are reached, the dosage is gradually reduced over 6 to 8 months, usually at 15 to 25 per cent per month (Table 10). Some recommend routine conversion to an alternate-day regimen after the initial high-dose daily regimen (Dalakas 1988b), usually accomplished gradually, as by reduction of the low-day dosage by about 10 mg per week. This may be advantageous in patients who have developed or are at high risk for significant steroid side-effects. Steroids are usually continued for 1 to 2 years or longer at a low, maintenance dose (Oddis 1994) that is high enough to successfully prevent recurrence but low enough to keep the risk of side-effects low (prednisone 5 to 10 mg/day or 10 to 20 mg every other day).

Less aggressive or less prolonged therapy may be adequate in some patients. In a primary care setting, Hoffman *et al*. (1983) could successfully discontinue treatment in 41 per cent of patients without recurrence. The myositis in the autoimmune rheumatic diseases overlap syndromes associated with anti-U1RNP and anti-PM-Scl may be more responsive and require less therapy than other myositis (Jablonska *et al*. 1993). However, the standard regimens should be considered more reliable for most patients with polymyositis/dermatomyositis.

Exacerbations of disease may occur during taper, and are more likely if dosage is reduced rapidly. A rise in the creatine kinase level, sometimes within the normal range, frequently precedes exacerbation (Oddis and Medsger 1989). If creatine kinase elevation occurs after initial response, causes other than disease flare should be considered, particularly when no other signs are present. Exacerbation without creatine kinase elevation may occur, even if the enzyme was elevated originally, but if weakness increases without creatine kinase elevation, steroid myopathy should be considered. Other tests, such as MRI, electromyography, or repeat needle biopsy, can help assess disease activity in these cases. Exacerbation is treated usually with an increase in steroid dosage above those which last maintained control

of the disease, although full-dose is usually not necessary, and/or addition of an immunosuppressive agent (Oddis 1991).

The side-effects of corticosteroids in polymyositis/dermatomyositis are similar to those in other situations. Steroid myopathy poses a special problem, as noted above. Steroid-induced hypokalaemia may also lead to further weakness and should be avoided. Due to the prolonged high-dose steroids used in polymyositis/dermatomyositis, osteoporosis and aseptic necrosis are significant problems, contributing to disability. Adequate calcium and vitamin D intake should be maintained. Tymms and Webb (1985) found aseptic necrosis in 8.6 per cent of patients with polymyositis/dermatomyositis receiving high-dose steroids. Gastric protection is commonly used. Diabetes, hypertension, cataracts, and opportunistic infections (including tuberculosis) may be seen.

Immunosuppressives

Immunosuppressive agents are required in about a quarter to a half of patients. Indications include: (i) steroid resistance, with failure to respond to high-dose steroids after 6 to 12 weeks, (excluding considerations mentioned above); (ii) persistent disease activity after prolonged therapy despite initial improvement; (iii) inability to taper the prednisone without recurrence; or (iv) severe steroid side-effects. Immunosuppressives would be considered earlier in those with very severe or acute disease, or factors suggesting poorer response, such as certain autoantibodies (antisynthetases or anti-SRP) (Plotz *et al*. 1995). Generally, the trend is toward earlier and more frequent use of immunosuppressive agents because of steroid side-effects and possibly improved response (Steinberg 1993).

Methotrexate and azathioprine are the immunosuppressives used most extensively. Retrospective analysis (Joffe *et al*. 1993) suggests a higher response rate and more rapid onset of effect with methotrexate, and some (Oddis 1994) use it first if an immunosuppressive is required and there are no contraindications. However, azathioprine may have less toxicity and has demonstrated efficacy in a controlled study (Bunch 1981), and some prefer it as first choice (Ramirez *et al*. 1990; Urbano-Marquez *et al*. 1991; Dalakas 1992b).

Joffe *et al*. (1993) found that patients with antisynthetases were more likely to respond to methotrexate than to azathioprine. Methotrexate should be used with caution in this setting because of the frequent interstitial lung disease in antisynthetase patients, which can lead to diagnostic confusion with hypersensitivity pneumonitis, or difficulty tolerating it. They also found that men were more likely to respond to methotrexate than azathioprine.

Methotrexate

Methotrexate has been used over a broad dosage range in polymyositis/dermatomyositis. Early studies frequently employed a high-dose regimen administered intravenously (intramuscular injections may interfere with creatine kinase monitoring in polymyositis/dermatomyositis), begun at 10 to15 mg/week, and gradually increased to 0.5 to 0.8 mg/kg per week (30 to 50 mg/week). After an adequate response, methotrexate was tapered by extending the dosing interval to 2, 3, and 4 weeks, or by decreasing the weekly dose. Metzger *et al*. (1974) found good to excellent responses in 15 of 22 patients (68 per cent), at an average of 13 weeks.

Weekly low-dose oral regimens are now more often used (Plotz *et al*. 1989; Oddis 1994), starting at 7.5 to 10 mg/week and increasing gradually as required to a maximum of 20 to 25 mg/week. Parenteral therapy should be considered for the higher dose ranges, or if gastrointestinal intolerance develops. Response times may range from 3 to 44 weeks. The prednisone dose can usually be reduced ('steroid-sparing'). Exacerbations may occur with methotrexate taper in responsive patients.

Although methotrexate toxicity in polymyositis/dermatomyositis is usually mild, severe toxicity (hepatotoxicity, fatal hypersensitivity pneumonitis) has occurred. As in rheumatoid arthritis, patient selection is important (avoid in renal insufficiency, hepatic damage, alcoholism). The monitoring guidelines for rheumatoid arthritis should be considered a minimum; the higher doses often used in polymyositis/dermatomyositis may require closer observation, and elevated transaminases from muscle injury may interefere with their use in monitoring. Zieglschmid-Adams *et al*. (1995) observed hepatic fibrosis (grade IIIA) with methotrexate in 2 of 10 patients with dermatomyositis on usual doses; diabetes was a risk factor. Euwer and Sontheimer (1994) feel that toxicity in dermatomyositis may resemble that of psoriasis more than rheumatoid arthritis. Other side-effects include stomatitis, infections, teratogenicity, bone marrow suppression, and gastrointestinal bleeding. A methotrexate-associated reversible lymphoma was reported in dermatomyositis (Kamel *et al*. 1993).

Azathioprine

Bohan *et al*. (1977) noted improvement with azathioprine in about 35 per cent of polymyositis/dermatomyositis, and a steroid-sparing effect in 50 per cent. Ramirez *et al*. (1990) noted benefit in 75 per cent of those with an adequate course. In a controlled trial (Bunch 1981), patients beginning therapy with azathioprine plus prednisone had better long-term outcome with less disability and less prednisone requirement than those receiving prednisone alone, although there was no difference in short-term outcome after 3 months. It is used orally at 1.5 to 3.0 mg/kg per day, with doses of 100 to 150 mg/d being most common. Dalakas (1992b) recommends 3 mg/kg per day, with an adequate trial requiring 3 to 6 months. Steroids may be gradually reduced as response occurs. Cytopenias or bone marrow suppression may occur, and complete blood counts including platelets must be monitored. The possibility of malignancy is a concern, but the risk appears low in polymyositis/dermatomyositis. Other side-effects are similar to those in other situations.

Alkylating agents

Cyclophosphamide and chlorambucil are generally reserved for those who have failed to respond to other agents (Steinberg 1993), or have other manifestations such as severe interstitial lung disease. They generally have a higher risk of serious side-effects, particularly increased malignancy but also bone marrow suppression, infertility, and, for cyclophosphamide, haemorrhagic cystitis.

Reports regarding the value of oral cyclophosphamide in polymyositis/dermatomyositis have been conflicting (Plotz *et al*. 1989); some found it lacked efficacy, but others had success. It is usually used at a dose of 1 to 2 mg/kg per day, with close monitoring of the white blood count. Monthly intravenous pulse cyclophosphamide has been used in an effort to limit side-effects. Cronin *et al*. (1989), used this in patients with long-standing, refractory disease, and found poor efficacy and high toxicity (fever, nausea, infections, etc.). Bombardieri *et al*. (1989), however, had a high success rate in patients without previous cytotoxic therapy using short courses (2 to 3 weeks) of 0.5 g intravenous pulses at 1 to 2 week intervals, with a repeat course for flares. De Vita and Fossaluzza (1992) had good results with a similar regimen, beginning with 3 weeks of low pulses, then 0.5 to 1 g/m^2 per month for non-responders, with individual regimens as needed.

Chlorambucil has also been successful in a small number of reported patients. Of five patients treated with chlorambucil at 4 mg/day by Sinoway and Callen (1993), all had some improvement by 4 to 6 weeks, and normal strength by 13.5 months, but with minimal effect on the skin disease. Little toxicity was seen (two with leucopenia), and the drug could be stopped in four patients.

Cyclosporin (Neoral)

Several case reports or small series have described beneficial effects of cyclosporin in polymyositis/dermatomyositis, more in children but some in adults, including in severe, resistant disease (Oddis 1994). Grau *et al*. (1994) compared their experience in 10 consecutive patients with dermatomyositis treated initially with cyclosporin (usually 5 mg/kg per day), with their previous 45 patients treated initially with prednisone. Cyclosporin-treated patients responded earlier and achieved complete remission in less than half the time (mean 8.6 weeks), with a comparable failure rate and less frequent serious toxicity. Nephrotoxicity is the greatest concern. Although many reports used doses of greater than 5 mg/kg per day, following the recent guidelines of Feutren and Mihatsch (1992) would be prudent (doses of 5 mg/kg or less per day, and creatinine kept less than 30 per cent over baseline). Tacrolimus (FK506) was also effective in a preliminary report (Oddis *et al*. 1994).

Combination therapy

Combinations of immunosuppressives, such as methotrexate and azathioprine or chlorambucil and methotrexate, often with prednisone, have been used in patients with refractory disease, or to limit toxicity by using smaller doses. The methotrexate/azathioprine combination and high-dose methotrexate with leukovorin rescue are under study (Steinberg 1993).

Intravenous gammaglobulin

There is increasing evidence of the efficacy of high-dose intravenous gammaglobulin in polymyositis and dermatomyositis, and increasing experience with its use. Dalakas *et al*. (1993) showed that intravenous gammaglobulin was significantly better than placebo in a double-blind, cross-over trial in 15 adults with

dermatomyositis. There was major improvement in 9 of 12 with intravenous gammaglobulin (0 of 11 with placebo) and none worsened (versus 5 of 11 with placebo). The rash improved in most. There are a number of reports of success in polymyositis as well (Cherin *et al*. 1991).

A major advantage of intravenous gammaglobulin is its low risk. Dalakas (1994b) recommends testing for IgA deficiency to avoid anaphylaxis, for high viscosity due to its significant rise with intravenous gammaglobulin, and for renal impairment. Side-effects are similar to those in other conditions, and usually controllable. Although transmission of hepatitis C has occurred, current risk is felt to be low.

The monthly dose of 2 g/kg per day is usually given over 2 to 5 days. The effectiveness of an individual treatment appears to be of limited duration (usually 4 to 6 weeks). Prolonged monthly courses may have continuing effect; Cherin *et al*. (1991) found significant improvement in 15 of 20 patients, with minimal side-effects, after nine treatments. Whether prolonged courses can have long-term benefit after cessation is not yet clear, although exacerbations may occur, and some have suggested tachyphylaxis (Reimold and Weinblatt 1994). Tapering and maintenance regimens are empirical. One study found lesser efficacy as a first-line therapy than as treatment for refractory disease (Cherin *et al*. 1994). The major impediment to more widespread use is the very high cost.

Dalakas *et al*. (1993) demonstrated by repeat biopsies that capillary density increased, MAC deposition was prevented, and expression of ICAM-1 on endothelial cells and MHC-1 on muscle fibres was normalized by intravenous gammaglobulin. Thus, this treatment acts on early pathogenetic mechanisms, not simply on symptoms. Basta and Dalakas (1994) showed that intravenous gammaglobulin blocked deposition of activated C3 fragments *in vitro*, suggesting that it works in dermatomyositis by binding fragments, protecting muscle capillaries from complement-mediated injury. Other mechanisms are likely to be operative in polymyositis. If persistent infection is a factor, this could be a target for intravenous gammaglobulin, but effects on the immune system are more likely (Dwyer 1992).

Experimental

Case reports and collected series have described improvement in polymyositis/dermatomyositis with plasmapheresis, including 32 of 35 patients of Dau (1981). Most reported patients have received cyclophosphamide or chlorambucil, so that the independent contribution of plasmapheresis was unclear. In a controlled, double-blind trial, Miller *et al*. (1992) found no improvement in strength or functional outcome with plasmapheresis or leucapheresis (12 treatments in 1 month). Prednisone but no immunosuppressives were used. Creatine kinase fell from direct removal, without correlation with improvement. Subgroups of patients might still benefit from these procedures, or they may enhance the benefit of other treatments.

Total body irradiation has resulted in dramatic, prolonged responses in several cases of severe, life-threatening polymyositis/dermatomyositis unresponsive to other treatments, often with minimal ill effects (Dalakas and Engel 1988). However, some have not responded (Cherin *et al*. 1992), and at least one patient died. Late malignancy is a concern. Total nodal irradiation has also been tried. Irradiation is a treatment of last resort. Successes have also be reported with thymectomy, another rarely-used last resort (Cumming 1989).

Treatment of extra-muscle manifestations

Dermatomyositis rash

The dermatomyositis rash may respond to treatment of the myositis with steroids, immunosuppressives, or intravenous gammaglobulin. If dermatomyositis lesions persist, hydroxychloroquine at a dose of 200 to 400 mg/d may be helpful (Woo *et al*. 1984). It would not be expected to help the myositis. The rash may be photosensitive, and sunscreens are recommended. Topical steroids are commonly used, but are often unsuccessful. Oddis (1994) had success with isotretinoin (0.5 to 1.0 mg/kg per day) for rash unresponsive to other measures, with caution to avoid it in pregnancy.

Treatment of amyopathic dermatomyositis is controversial. Sunscreens, topical therapy, and hydroxychloroquine are tried first. In some very severe cases refractory to these measures, steroids or immunosuppressives are justified for the cutaneous manifestations (Euwer and Sontheimer 1994). Zieglschmid-Adams *et al*. (1995), noted improvement of the skin lesions with methotrexate (average maximal dose 20 mg/week orally) in two of three patients with amyopathic dermatomyositis, and all seven with dermatomyositis; myositis improved in only four. When such treatment is withheld because of the absence of detectable myositis, the patient must be followed closely, especially in the first 2 years, to avoid delay in treatment if myositis appears.

Calcinosis

Calcinosis is more of a problem in juvenile dermatomyositis but may occasionally occur in the adults. Several treatments may be tried (Boyd and Neldner 1994), but none is of consistent or proven benefit. Surgical excision can be helpful for accessible deposits that cause problems. An inflammatory component may respond to colchicine. Treatment of the disease helps prevent calcinosis, but it does not affect established calcinosis.

Interstitial lung disease

Treatment for interstitial lung disease in polymyositis/dermatomyositis should be considered for clinically significant active and progressive disease. Interstitial lung disease may sometimes be more amenable to treatment, in myositis than in other conditions but can be unresponsive and contribute to mortality. Treatment is more effective when the biopsy shows active inflammation, or possibly bronchiolitis obliterans organizing pneumonia (Hsue *et al*. 1993). Prednisone is usually given initially, but cytotoxic agents are often needed. Cyclophosphamide has been successful in case reports (Al-Janadi *et al*. 1989). Although conventionally this is used orally for interstitial lung disease, intravenous pulse has also been used.

Gastrointestinal

Dysphagia resulting from pharyngeal weakness usually responds to treatment of the myositis, but may be resistent in some cases. In persistent dysphagia, cricopharyngeal muscle dysfunction should be considered, and cricopharyngeal myotomy may be needed (Kagen *et al*. 1985). Distal oesophageal dysmotility will generally not respond to immunosuppression, but measures similar to those used in oesophageal reflux can be helpful.

HIV myositis

Treatment of HIV-associated myositis is complicated by the increased risk of using steroids and immunosuppressives. Antiretroviral therapy may help in some patients not already receiving it, but the risk of zidovudine myopathy must be considered. For patients shown to have inflammatory myopathy by biopsy, who clinically require treatment, Dalakas (1993) recommends intravenous gammaglobulin, but steroids, daily or alternate-day, have been used despite the risk. In patients on zidovudine, especially if biopsy is unavailable for diagnosis, reduction in zidovudine dosage might be considered.

Rehabilitation

Active exercise is discouraged in the acute period when muscle inflammation is prominent. Passive range of motion exercises may be started early to help prevent joint contractures. When inflammation subsides, active exercise, cautiously introduced and slowly advanced, may help recover lost strength from disease, immobility, and steroid-related atrophy (Hicks 1988). It may help to start with isometric exercises (Oddis 1994). Active resistive exercise can be considered cautiously in stable patients even if some disease activity remains (Escalante *et al*. 1993). The patient may also require assistance with activities of daily living and assistive devices while severely disabled, and possibly vocational rehabilitation if permanent disability develops.

Prognosis

Mortality

Current survival rates for polymyositis/dermatomyositis are higher than those prior to the availability of corticosteroids, and continued improvement is apparent after their introduction. Medsger *et al*. (1971) found a 5-year survival rate of 65 per cent, and a 7-year rate of 53 per cent between 1947 and 1968, while Hochberg *et al*. (1986) found a 5-year survival rate of 80.4 per cent and an 8-year rate of 72.8 per cent between 1970 and 1981. Love *et al*. (1991) also found a low mortality rate of 14 per cent (36 per cent with cancer). Many factors contribute to this improvement, such as better use of medications and better general medical care. Also, better

recognition of polymyositis/dermatomyositis may lead to inclusion of milder cases or exclusion of other diseases.

The most common causes of mortality in polymyositis/dermatomyositis are malignancy, infection, and cardiac and lung manifestations. Factors which increase mortality include older age of onset, cardiac involvement, or interstitial lung disease (Arsura and Greenberg 1988). Dysphagia has been associated with increased mortality in some studies, possibly due to aspiration, but probably because it is found in more severely affected cases (Hochberg *et al*. 1986). Some (but not all) studies find decreased survival in myositis with malignancy, such as Bohan *et al*. (1977) (46 per cent compared with 87 to 91 per cent for polymyositis/dermatomyositis). Other possible factors suggested to increase mortality include: more severe or rapid onset, resistance to treatment, or long delay before treatment. Other measures of disease severity, such as the findings of laboratory tests or biopsy, have not been found to correlate with poor prognosis. Lilley *et al*. (1994) found that most deaths occurred within the first 6 months, and that those treated with immunosuppressives seemed to do better.

Clinical subgroups of patients with polymyositis/dermatomyositis excluding malignancy do not differ significantly in prognosis for survival. However, Love *et al*. (1991) found that those with antisynthetases and those with anti-SRP had higher mortality rates than myositis overall (21 per cent and 43 per cent versus 7 per cent).

Recovery of strength

Prognosis for recovery of full strength is worse if treatment is delayed (Joffe *et al*. 1993; Fafalak *et al*. 1994), or if the course is chronic and progressive (possibly due to delayed treatment). Patients whose treatment begins more than 6 to 12 months after onset may not recover full strength even with complete suppression of disease activity (Tymms and Webb 1985). Older patients may respond less well, and tend to require a longer duration of treatment (McKendry 1987). In general, those with adult dermatomyositis do better than those with pure polymyositis, and those with autoimmune rheumatic disease overlap syndromes do best (Lundberg *et al*. 1992; Joffe *et al*. 1993). Patients with antisynthetases usually respond initially, but patients with either antisynthetase or anti-SRP have a higher frequency of incomplete response and flare with taper (Love *et al*. 1991).

Inclusion-body myositis

Inclusion-body myositis is a distinct clinicopathological entity, comprising 15 to 28 per cent of idiopathic myositis, the most common form other than polymyositis/dermatomyositis (Dalakas 1991), although it may be overrepresented in referral centres as a result of treatment resistance. It usually begins after age 50, and is the most common muscle disease beginning in this group (Askanas *et al*. 1994b). It is two- to threefold more common in males. It can be difficult to distinguish from polymyositis, and is often misdiagnosed at first (Calabrese *et al*. 1987); this, plus insidious onset, lead to a time to diagnosis of 3 to 6 years.

Clinical picture

The onset is insidious and progression is slow. Although most patients with inclusion-body myositis have proximal muscle weakness, distal weakness is common, sometimes greater than proximal. Distal weakness occurs in 50 to 95 per cent of patients at some point (Lotz *et al*. 1989; Love *et al*. 1991). It more often involves lower extremities before upper, and spares the face. It tends to be symmetric, but Love *et al*. noted asymmetry significantly more often (61 per cent) than in polymyositis/dermatomyositis. Falling is a common problem (96 per cent, versus 1 to 17 per cent in polymyositis/dermatomyositis) possibly related to the severe quadriceps weakness or associated neuropathy. The knee reflex is reduced or absent within 5 years in most patients, probably from similar factors. Forearm thinning is notable, with resultant finger weakness (Askanas *et al*. 1994b). Distal weakness and depressed reflexes suggest a neuropathy, and a portion of cases show other neuropathic signs (Lindberg *et al*. 1994b). Dysphagia may be seen in 40 per cent of cases, occasionally as the presenting manifestation (Riminton *et al*. 1993), and myalgia in 20 per cent.

Laboratory

The creatine kinase is usually elevated but typically less than 10-fold normal. The electromyography picture usually shows myopathy similar to that of polymyositis, with myopathic potentials and fibrillations, but some show a higher than expected frequency of neuropathic (polyphasic, high-amplitude) potentials, and a portion may have abnormal nerve conduction, consistent with a neuropathic component (Chou 1993). MRI typically shows focal, predominantly anterior thigh involvement (Fraser *et al*. 1991) as observed clinically. Biopsy is required to make the diagnosis, but it is frequently missed, and repeat biopsy may be required. Criteria for the diagnosis have been proposed (Table 11) (Lotz *et al*. 1989; Calabrese and Chou 1994).

Pathological criteria
Electron microscopy:
1. Microtubular filaments
Light microscopy:
2. Lined vacuoles

Clinical criteria
1. Insidious onset of proximal muscle weakness
2. Distal muscle weakness
3. Electromyographic evidence of generalized inflammatory myopathy, with/without neuropathic features
4. Elevation of creatine kinase and/or aldolase
5. Failure of muscle weakness to substantially improve on a corticosteroid regimen of at least prednisone 40–60 mg/d

Exclusions
1. History of hereditary muscle disease[b]

Definite IBM: One pathological criterion, plus any two clinical criteria 1–5
Probable IBM: One pathological criterion, plus any one clinical criterion
[a]Reference: Calabrese and Chou (1994)
[b]Family history can support a diagnosis of hereditary inclusion-body myopathy

Table 11 Diagnostic criteria for inclusion-body myositis (IBM) [a]

Pathology

The distinctive features of inclusion-body myositis on light microscopy are vacuoles rimmed by basophilic material, and small, refractile, eosinophilic cytoplasmic and nuclear inclusions. EM shows that the vacuoles are filled with cytoplasmic degradation products including myeloid structures, membrane fragments, and debris. Cytoplasmic inclusions, usually found near vacuoles, are composed of distinctive filaments of 15 to 21 nm. Askanas *et al*. (1994a) found that they were actually paired helical filaments which resembled those of Alzheimer's, and contained hyperphosphorylated tau protein and ubiquitin. Smaller inclusions are found in the nucleus. Chou (1993) suggests that the microtubular filaments are formed in the nucleus, causing the nuclei to swell and rupture, releasing the contents. Injured nuclei become surrounded by vacuoles and multilamellar myelin bodies.

The vacuoles and inclusions are not considered specific for these conditions, and the diagnosis must be based on a combination of findings (Calabrese and Chou 1994). Similar structures are found in an autosomal-recessive familial distal myopathy (Cole *et al*. 1988) and oculopharyngeal muscular dystrophy, indicating a relationship of these conditions to inclusion-body myositis.

Inclusion-body myositis usually shows typical features of inflammatory myopathy, with endomysial inflammatory infiltrates, necrosis and regeneration. In some patients (about 10 per cent), inflammation is very sparse or not evident, despite the presence of inclusions and vacuoles (Figarella-Branger *et al*. 1990). The inflammatory features are more prominent in the early stages, and the vacuoles are more abundant later (Askanas *et al*. 1994b), possibly accounting for some initial misdiagnosis; polymyositis is not generally felt to 'evolve' into inclusion-body myositis. Grouped atrophic fibres and hypertrophied fibres are seen, reminiscent of neuropathy and usually not seen in polymyositis/dermatomyositis.

Aetiology

The aetiology is unknown, but as with polymyositis/dermatomyositis, viruses have been suspected. Although adenovirus was isolated from muscle in one case of inclusion-body myositis, viral cultures are usually negative (Chou 1993). The inclusions of inclusion-body myositis resemble viral structures, especially the nucleocapsid proteins of paramyxovirus (Chou 1986). Although Chou found specific reaction of inclusion-body myositis inclusions with mumps virus antisera, the presence of mumps virus proteins was not confirmed by immunological techniques, *in situ* hybridization (Nishino *et al*. 1989), or PCR (Leff *et al*. 1992; Calabrese and

Chou 1994).

The origin of the vacuoles and inclusions is unknown. In addition to the similar paired helical filaments noted, inclusion-body myositis shares with Alzheimer's the accumulation of several proteins, in structures of similar appearance, including Congo-red positive amyloid deposits (Mendell *et al*. 1991), and b-amyloid protein colocalized with ubiquitin (Askanas and Engel 1993; Askanas *et al*. 1993a). Accumulation of prion protein is also seen (Askanas *et al*. 1993b). These findings suggest the possibility of non-autoimmune mechanisms in inclusion-body myositis, an attractive hypothesis in view of the limited response to immunosuppression and the lack of inflammation in some cases.

Unlike polymyositis/dermatomyositis, a familial form of inclusion-body myositis may occur in a small proportion of cases, usually without inflammation, with younger average onset, referred to as hereditary inclusion-body myopathy. Cases of inclusion-body myositis with malignancy have been reported (Ytterberg *et al*. 1993), but an increased frequency of malignancy has not yet been demonstrated. A small percentage of patients have an association with autoimmune rheumatic diseases such as systemic lupus erythematosus, scleroderma, Sjögren's syndrome, or sarcoidosis, and even dermatomyositis. In the absence of such associated conditions, features of autoimmune rheumatic diseases (arthritis, etc.) are usually not found.

Garlepp *et al*. (1994) found a significant increase of DR3 (92 per cent) in 13 patients with inclusion-body myositis, including 10 with the B8/DR3/C4A*QO extended haplotype, and 2 others with the B18/C4B*QO haplotype. Love *et al*. (1991) found no significant association with DR3.

Pathogenesis

The strongest evidence of autoimmunity is the finding of non-necrotic fibres surrounded and invaded by lymphocytes (see above), and the analysis of infiltrating lymphocytes suggesting T-cell-mediated immune attack on muscle fibres. However, the possibility that this response is secondary has not been excluded. O'Hanlon *et al*. (1994b) found prominence of T-cell receptors with Vb3 and Vb6, but in most patients these were polyclonal, suggesting possible superantigen stimulation rather than the antigen-driven response seen in polymyositis. Muscle fibres in inclusion-body myositis usually show expression of MHC-1 antigen, consistent with the cytotoxic T-cell response, but it is not seen in non-inflammatory biopsies (Figarella-Branger *et al*. 1990). There is little evidence of significant humoral autoimmunity in inclusion-body myositis; autoantibodies are uncommon (23 per cent) and MSAs are not seen (Love *et al*. 1991).

The reason some patients' biopsies do not show inflammation is not known; sampling error or variation in activity over time may be factors, but inflammation may be truly absent in such patients. This is supported by the hereditary group of inclusion-body myositis, which seldom show inflammation.

Treatment

Patients with inclusion-body myositis do not respond to treatment as well as those with polymyositis. They are less likely to show any response, and those that do will not return to normal. This may result partially from the long delay between onset and diagnosis, since delayed treatment is associated with limited response. The commonly observed atrophy and fibrosis support this. Alternatively, the inflammatory process might be secondary, with a degenerative process being primary. Response is more likely when autoimmune features are seen, inflammation is more prominent by biopsy, creatine kinase is higher, or when extensive atrophy has not yet occurred (Leff *et al*. 1993; Calabrese and Chou 1994).

Recent studies indicate that treatment may slow or stop the inexorable deterioration, and a small proportion of patients may improve (Sayers *et al*. 1992; Leff *et al*. 1993). A trial of therapy is generally worthwhile, but treatment goals and expectations must be different than for polymyositis/dermatomyositis. Patients may receive extensive treatment inappropriately if this is not recognized.

Some patients benefit from prednisone (Sayers *et al*. 1992; Leff *et al*. 1993), although often temporarily and usually incompletely. However, those treated with more aggressive therapy appear to do better. The few patients of Sayers *et al*. with long-term improvement received methotrexate with prednisone. Leff *et al*. obtained stabilization or, less often, improvement with a combination of methotrexate and azathioprine or high-dose methotrexate with leukovorin rescue. Intravenous gammaglobulin produced improvement in a few reported cases (Soueidan and Dalakas 1993), but it was unsuccessful in others (Askanas *et al*. 1994b), and its role remains unclear.

Treatment usually begins with steroids, but immunosuppressives are commonly added. Improvement in creatine kinase does not necessarily predict a clinical response. Calabrese and Chou (1994) recommend starting with prednisone at 40 to 60 mg for 3 months, then adding methotrexate or azathioprine for steroid-sparing effect if there is clinical improvement, or for additional immunosuppression if warranted by clinical predictors. They would otherwise stop treatment.

Dysphagia may become a severe problem. As with polymyositis/dermatomyositis, some cases relate to cricopharyngeal dysfunction, and respond to myotomy.

Prognosis

Over time, weakness will progress in most patients (Lotz *et al*. 1989), with gradually increasing disability, but progression is very slow. Patients often need assistance with usual activities within 10 years, and may be wheelchair bound within 15, although more prolonged courses may be seen.

5.9.2 Polymyositis and dermatomyositis in children

Lauren M. Pachman

Introduction

The range of inflammatory muscle disease in children includes acute viral or bacterial myositis, and chronic myositis–juvenile dermatomyositis, polymyositis, and inflammatory myopathy associated with other autoimmune rheumatic diseases or with parasitic infection. Worldwide, most of the inflammatory myopathies accompany bacterial or parasitic infections, but in North America and Europe a viral aetiology is seen more commonly.

The major advances in the study of these diseases include more definite clinical characterization of subsets and an emerging appreciation of their epidemiology as shown by their specific as well as their shared clinical and laboratory features. Recent evidence suggests that genetic and infectious factors may play a part in disease susceptibility. The primary clinical feature of both juvenile dermatomyositis and polymyositis is chronic and progressive weakness of proximal muscles. In juvenile dermatomyositis the vasculopathy and distinctive skin manifestations are associated commonly with muscle involvement; in polymyositis the skin is spared. Fulfilment of the criteria of Bohan and Peter (1975) is needed to establish the diagnosis of either type of myopathy (Table 1). The diagnosis of definite juvenile dermatomyositis is made if, in addition to the typical rash, three of the four criteria are present; of definite polymyositis, if three of the four criteria are found. Myositis is often a part of other autoimmune rheumatic diseases and, therefore, it is essential to exclude such conditions as systemic lupus erythematosus, mixed connective tissue disease, juvenile chronic arthritis (especially of systemic onset), the spondylarthropathies, and Sjögren's syndrome.

	Juvenile dermatomyositis	Polymyositis
Characteristic rash	+	–
Symmetrical proximal muscle weakness[b]	+	+
Elevated muscle-derived enzymes	+	+
Muscle histopathology[c]	+	+
Electromyographic changes; inflammatory myopathy	+	+

[a] In addition to presence (or absence) of characteristic rash and exclusion of other rheumatic diseases, three of four criteria must be met to confirm diagnosis.
[b] Exclusion of other rheumatic diseases.
[c] The histology of childhood polymyositis is different from juvenile dermatomyositis.
Definite JDMS: rash plus three or four criteria; Probable JDMS: rash plus two criteria; possible JDMS: rash plus one criteria.
Modified from Bohan and Peter (1975). *New England Journal of Medicine*, **292**, 344–7.

Table 1 Criteria for diagnosis of juvenile dermatomyositis and polymyositis in childhood [a]

Epidemiology

Demographic data

The bimodal age distribution of populations of combined polymyositis/dermatomyositis is well known with a childhood peak (at 5 to 9 years of age, 3.7 cases/million per year and at 10 to 14 years of age, 4.3 cases/million per year) and an adult peak (at 45 to 64 years or age, 10 cases/million per year) (Medsger *et al*. 1970). Children of African or Asian origin may be at increased risk for chronic myositis (Benbassat *et al*. 1980), but in the United States, Caucasian children with juvenile dermatomyositis are reported more frequently, and twice as many girls as boys are affected; in the United Kingdom and Ireland, five times as many girls were diagnosed as boys, with a incidence of 1.9/million children under the age of 16 years (Symmons *et al*. 1995). A similar trend is found in China (Wang *et al*. 1993), in contrast to Japan where a ratio of 1.3 boys to 1 girl was identified; none had associated malignancy or interstitial lung disease (Hiketa *et al*. 1992). In children, dermatomyositis occurs at least 10 to 20 times more often than polymyositis. In marked contrast to earlier reports of one-third mortality and one-third morbidity (Bitnum *et al*. 1964), both of these adverse outcomes have decreased in childhood since the advent of steroid therapy (Hochberg 1988; Ansell *et al*. 1990). In Japan, during a 10-year period (1973 to 1983) there was a 2.9 per cent mortality rate (Hidano *et al*. 1986).

Although an increased frequency of malignancy may be associated with adult dermatomyositis within 2 years of disease onset (Masi and Hochberg 1988), this does not appear to be the case in children with either juvenile dermatomyositis or polymyositis (Hidano *et al*. 1986); only sporadic cases of children with both an inflammatory myopathy and malignancy have been cited (Sherry *et al*. 1993), and a population-based survey did not find malignancy in any patient less than 16 years of age (Sigurgeirsson *et al*. 1992).

There is some data to suggest that in the United States children are more likely to have onset of disease in the early months of the year. A comparison of disease onset of juveniles with dermatomyositis and adults with polymyositis–dermatomyositis living in Memphis, Tennessee, revealed a seasonal onset (February to April) in 55 per cent of the children but not in the adults (Medsger *et al*. 1970). In contrast, a case–control study (all paediatric inflammatory myopathy, numbers of juvenile dermatomyositis unknown) conducted in a different region of the country did not document a specific season of onset (Koch *et al*. 1976). In the next decade, in north

central region, children with definite juvenile dermatomyositis (diagnosed within 4 months of onset) were more likely to have their first symptoms in the months of January to June than at other periods of time in each of 7 years (1974 to 1980) (Christensen *et al*. 1983); in Canada clustering was observed as well, suggesting an environmental influence (Rosenberg 1994). In the United Kingdom and Ireland, several clusters of disease onset were identified, the largest of which was in April and May in 1992; the timing of these clusters appeared to vary from year to year (Symmons *et al*. 1995). In Athens, Greece, of those adults (children were not included) with polymyositis–dermatomyositis who were admitted to hospital, 39 per cent were in March, April, or May with onset of symptoms in the same months (Manta *et al*. 1989). It is not yet firmly established if prevalence for season of onset is the same for both adults and children living in the same region or if the peak onset of polymyositis is in the same period as that of dermatomyositis in either age group. A national study is ongoing in the United States to determine if there is in fact seasonality or symptoms of antecedent illness in children with juvenile dermatomyositis.

Infectious agents and juvenile dermatomyositis

Several agents have been associated with the onset (and on occasion, flare) of juvenile dermatomyositis, of which the most prominent have been the RNA picornaviruses, group A b-haemolytic streptococci, and *Toxoplasma gondii*. Coxsackievirus B (CVB) 2 was isolated from the stool, and the titre of CF (complement fixing) antibody rose in a child with chronic myositis (Schiraldi and Iandolo 1978); others have measured rise in B4 antibodies (Travers *et al*. 1977). As noted above, there may be temporal, seasonal, and regional differences in agents associated with disease onset. Sera from newly diagnosed children during 1974 to 1980 from the Chicago area had an increased frequency of antibody (both neutralizing and complement fixing) to coxsackievirus B, as well as increased frequency of the histocompatibility antigens HLA B8/DR3 (Christensen *et al*. 1986) (see Genetics below), which was not reproduced by the same group of investigators in a study of 20 children with dermatomyositis from the same region with onset of disease in the years 1987 to 1992 (Pachman *et al*. 1995b). Enteroviral RNA was identified in the muscle of English patients with polymyositis/dermatomyositis (Bowles *et al*. 1987; Yousef *et al*. 1990), but other investigators have not found viral RNA in cases from the United States, either in Jo-1 positive adults (Leff *et al*. 1992), or in MRI-directed muscle biopsies of 20 newly diagnosed, untreated, children with active dermatomyositis (Pachman *et al*. 1995b). Other infectious agents have been thought to play a role in juvenile dermatomyositis, including toxoplasmosis (Schroter *et al*. 1987; Lapetina 1989) and hepatitis B (Peters *et al*. 1991), but antibody titres to these agents were not increased either in a regional study (Christensen *et al*. 1983) or in a case–control national study of new onset juvenile dermatomyositis spanning the years 1987 to 1992 (Pachman *et al*. 1992a; Pachman *et al*. 1995b). Although Theiler's murine encephalomyelitis virus (TMEV) was identified in adult polymyositis, none of the children with dermatomyositis were positive for this agent (Rosenberg *et al*. 1989). Taken together, the above data suggests that the aetiology of juvenile dermatomyositis is multifactorial, perhaps permitting a role for molecular mimicry. Evidence that may support this hypothesis is found in a report of skeletal myosin (which has sequence homology with the streptoccal type 5 M protein) stimulating lymphocytes from a child with recurrent dermatomyositis following streptococcal infections (Martini *et al*. 1992).

Clinical presentation

Cutaneous findings

In juvenile dermatomyositis, the rash may predate or follow the onset of symmetrical weakness in proximal muscles. Periorbital erythema and oedema, and/or eyelid telangiectasia, are seen in 50 to 90 per cent of affected children. The eyelid telangiectasia (as well as that elsewhere) may persist long after other signs and symptoms of disease activity have resolved. The rash has a violaceous or heliotrope hue, and is often most prominent on the eyelid, where small infarctions may be seen (Fig. 1). The rash may also cross the bridge of the nose and be precipitated by even a brief unprotected exposure to the sun. Sunlight may simply exacerbate the skin manifestations or may activate symptoms of myositis. Other areas of erythema involving the upper torso, the extensor surfaces of the arms and legs, medial malleoli of the ankles, as well as the buttocks may occur in the absence of raised serum concentrations of muscle-derived enzymes (see below). The skin over the knuckles is often either hypertrophic or pale red, evolving into colourless bands of atrophic skin (Gottron's sign). Similar patches can occur in a variety of places including over the metacarpal phalangeal joints, the extensor aspect of the elbows or knees, or the medial canthus of the eyelid. Lipoatrophy which is not tender despite a lymphohistiocytic panniculitis (Commens *et al*. 1990), as well as acanthosis nigricans, associated with insulin-resistant diabetes, have also been seen in children with juvenile dermatomyositis. Diffuse vasculopathy (nailbed telangiectasia, infarction of oral epithelium and skin folds, or digital ulceration) associated clearly with more severe disease, is correlated with the child's clinical course (Silver and Maricq 1989), and can be quantified to aid in diagnosis and in monitoring response to therapy (Pachman *et al*. 1995d). Although calcinosis without known antecedent muscle disease has been reported as a presenting sign of dermatomyositis in childhood (Martini *et al*. 1987), it may be considered to be related to disease severity and duration (Pachman *et al*. 1985). Delay in diagnosis by 6 months, which may be a consequence of difficulty in identification of the rash on pigmented skin, was associated with an increased incidence of calcinosis (Pachman *et al*. 1992b). None of 20 recently diagnosed and treated children with juvenile dermatomyositis developed calcinosis, suggesting that aggressive therapy early in the disease course may be of substantial benefit (Callen *et al*. 1994).

Fig. 1 (a) This young girl has the typical rash of juvenile dermatomyositis. Erythema and oedema involving the eyelids are seen, with healed microinfarcts at the medial aspect of the right upper eyelid (open arrow). The rash crosses the bridge of the nose and has areas of relative decreased vascularity as well as erythema. (b) Gottron's papules on the elbow of a 4-year-old child with recurrent juvenile dermatomyositis.

Musculoskeletal symptoms

Proximal muscle weakness as evidenced by difficulty in climbing stairs, getting up from a chair, combing hair, or using the hands to push off the body in an attempt to stand (Gower's sign) is common; weakness of the neck flexors is a particularly sensitive indicator of muscular impairment. Complaints of pain on compression of the muscles are found in over 60 per cent of cases, but are less severe than in the bacterial-related myopathies. Fatigue is common, and also expressed by children with the dystrophies (most commonly those of Duchenne and Becker). The most common symptoms are listed in Table 2. Usually the child is more comfortable when the limbs are held in the flexed position, promoting the development of flexion contractures. Inflammation can be detected by electromyography or muscle biopsy despite the appearance of clinical quiescence (Miller *et al*. 1987). The use of MRI-directed biopsies minimizes error in sampling uninvolved areas in this focal disease (Pitt *et al*. 1993), and can monitor a child's response to therapy (Yanagisawa *et al*. 1983; Keim *et al*. 1991; Hernandez *et al*. 1993). The MRI may become normal several months after the muscle enzymes return to the normal ranges (Huppertz and Kaiser 1994). P-32 spin MRI has been in use for the past few years and gives useful information about the child's muscle strength and performance (Park *et al*. 1994). Decreased bone density (associated with a depressed serum osteocalcin) is frequent in untreated juvenile dermatomyositis and places the child at risk of bony fracture (Reed *et al*. 1990), which is further augmented by steroid administration.

Symptoms	Percentage at diagnosis
Weakness	100
Rash	100
Muscle pain	72
Fever	65
Difficulty swallowing	45
Abdominal pain	37
Arthritis	36
Calcifications	22

Table 2 Juvenile dermatomyositis symptoms at diagnosis

Gastrointestinal involvement

One of the most troubling prognostic indicators is impairment of the flow of secretions associated with decreased oesophageal motility, which can be documented by radiographic contrast studies showing retained barium in a widened atonic, pyriform sinus. The swallowing of liquids may also be impaired; oesophageal reflux may result in aspiration pneumonia and appropriate precautions should be taken to prevent this (e.g. using thickened foods, raising the bed head, and bronchial drainage). Smooth muscle dysfunction can also result in decreased lower-gastrointestinal dysmotility, making constipation an annoying symptom. Involvement of the masseter may result in difficulty in chewing; chronic masseter atrophy is often apparent once the disease has become quiescent, and may endow the child with a characteristic chipmunk appearance. Vasculopathy affects any part of the gastrointestinal tract; in severe disease there is weight loss and mucosal ulceration with life-threatening perforation. In the young child, development of normal speech patterns can be disturbed; soft palate involvement is often revealed by nasal, high-pitched speech (for example by saying the alphabet) and usually resolves with a decrease in the inflammatory component of the myositis.

Cardiorespiratory abnormalities

The ECG is abnormal at disease onset in over half the children with definite juvenile dermatomyositis. Asymptomatic conduction abnormalities predominate, with an occasional complete block of the right bundle branch (Pachman and Cooke 1980), which usually resolves with decrease in disease activity. In the absence of respiratory complaints, a decrease in ventilatory capacity, with a normal diffusion of carbon dioxide was found in 78 per cent of children with juvenile dermatomyositis whose sera were subsequently found to be negative for antibody to the tRNA synthetase, Jo-1 (Pachman and Cooke 1980). The decrease in ventilatory capacity can be associated with diminished speech volume; several of our children have developed vocal cord nodules, presumably as a result of the stress of trying to be heard. Pulmonary fibrosis may occur in both adults and children with inflammatory myopathy, but it is more commonly found in individuals who carry antibody to the tRNA synthetases, of which anti-Jo-1 is the most common in adults (see Pathophysiology). Myositis-specific antibodies (MSA) are rare in children and are just starting to be identified (Rider *et al*. 1994). A young woman with Jo-1-positive myositis with onset in childhood has been recently described; her initial complaints included a reactive airway component (were called 'asthma'), but progressed to include arthritis and were accompanied by pulmonary fibrosis and a markedly decreased diffusion of carbon dioxide. The severe myopathy occurred 7 years after onset of respiratory symptoms (Bowles *et al*. 1987). In general, the few children with Jo-1 who have been identified recently are similar to adults with antisynthetase antibodies and are characterized by dyspnoea on exertion, a pulmonary perfusion deficit with evidence of pulmonary fibrosis on both histological and radiographical examination, and disease flares with the reduction of therapy. Most have severe arthritis; some have 'mechanic's hands' (Rider *et al*. 1995), which is much more common in adults, and rarely seen in children.

Genitourinary involvement

Massive breakdown of muscle elements as well as primary compromise of the renal parenchyma itself, may occur in children with an active myopathic process requiring prompt hydration and monitoring of renal function. If unchecked, renal failure can occur. On histochemical examination, cytoplasmic tubular arrays (may be a correlate of a-interferon production) are found in the renal glomerular endothelium as well as cutaneous fibroblastic cells (Pachman and Maryjowski 1984). Necrosis of the ureter has been reported, involving the middle one-third (iliac) segment, which is more vulnerable to vascular compromise as a consequence of inflammation. This vulnerability occurs because of the relatively sparse blood supply to this region compared with the upper (lumbar) or lower (pelvic) segments (Borrelli *et al*. 1988).

Eye signs

The most common finding is persistent thrombosis of dilated vessels at the margin of the upper eyelid, which may persist years after other clinical signs of inflammation have disappeared. In active disease, transient retinal exudates and 'cotton wool' spots may occur after the occlusion of small vessels, leading to intraretinal oedema with injury to retinal nerve fibres, optic atrophy, and sustained visual loss. Neovascularization of the retina with spontaneous regression has also been reported (Fong and Yeung 1990). Disease of conjunctival vessels can also lead to an avascular zone with a potential for infarction. Children treated with steroids should be monitored for both glaucoma and for the development of sublenticular cataracts, which are related to the dose of corticosterids given (Callen *et al*. 1994). If there is a family history of red–green colour blindness, the use of hydroxychloroquine should be avoided.

Other disease manifestations

Vasculopathy involving the central nervous system may be associated with depression and/or wide mood swings, which may be exacerbated by steroid therapy (see below). It is not usual for a child with juvenile dermatomyositis to present with Raynaud's phenomenon; these symptoms are found more frequently in overlap syndromes.

Differential diagnosis of juvenile dermatomyositis

General

The differential diagnosis of this inflammatory myopathy includes many of the major neuromuscular disorders of infancy and childhood as well as metabolic and infectious diseases which can be symptomatic at any age. Table 3 presents most of the potential candidates for consideration.

Table 3 Classification of the major neuromuscular disorders of infancy and childhood

Skin

Many of the other autoimmune diseases exhibit some of the cutaneous signs of juvenile dermatomyositis. As in systemic lupus, exposure to sun can exacerbate both the malar rash as well as the systemic complaints in children with dermatomyositis. Gottron's sign can be mimicked by psoriatic lesions, accompanied by healing foci of hypopigmentation found in areas usually unaffected in juvenile dermatomyositis, such as the pretibial region. These rashes may clear with sun exposure, rather than becoming more prominent. A description of a child with psoriatic arthritis and myopathy underlines the differences in clinical presentation (Thompson *et al*. 1990). Telangiectasia, a prominent feature of scleroderma, also occurs in overlap syndromes in which myositis is a component. Capillary destruction with resulting avascularity and healing can be monitored using nailfold capillary microscopy, which can help to differentiate juvenile dermatomyositis from some of the other vasculopathies (Pachman 1995). For example, a 2-year-old child had progressive unilateral focal calcinosis since the age of 5 months, as well as elevated muscle enzymes, but no muscle weakness or rash. Her capillary microscopy was abnormal, but not in the pattern seen in juvenile dermatomyositis, ultimately leading to the

correct diagnosis of progressive osseous heterotopia (Sachrison *et al*. 1995).

Muscle-derived enzymes

Skeletal muscle is rich in enzymes which can be released from the sarcoplasm to the peripheral circulation as a consequence of reduced vascular supply, trauma, or immunological cytotoxicity. Increased serum concentrations of enzymes result from either tissue necrosis or leakage through damaged cell membranes; sera to be analysed must be free of haemolytic products. Functional myopathies and those that result from denervation are accompanied by decreased muscle mass, weakness, pain, and loss of function or, in severe cases, paralysis. In these diseases, the serum creatine kinase, its muscle and brain isoenzymes, as well as the pyruvate kinase, lactate dehydrogenase, and aldolase are normal. In contrast, in some of the dystrophies, creatine kinase and aldolase may be increased by as much as 30 times the normal level; creatine kinase muscle isoenzymes are elevated after an acute myocardial infarction and after back surgery, and may also be raised in Duchenne's as well as Becker's muscular dystrophy. Increases are also seen in myocardial and skeletal muscle disease or trauma ranging from vigorous physical exercise (e.g. marathon runners) and surgical and accidental crush injuries to intramuscular injections. Drugs that enhance the permeability of muscle membranes, also result in elevated concentrations of the muscle isoenzyme form of creatine kinase; for example, aminocaproic acid, D-penicillamine, halothane (hyperpyrexia), and quinidine. Overdose with amphetamines, barbiturates, ethanol, or heroin results in a massive increase in creatine kinase (Lott and Landesman 1984). Disorders of calcium metabolism such as hypocalcaemia (either isolated or associated with rickets, hypoparathyroidism) or chronic renal failure can be accompanied by increased creatine kinase. Once the low levels of ionized calcium become normal, the rise in creatine kinase usually resolves. Aldolase has a short half-life and can be increased in viral hepatitis, metastatic liver disease, some prostate tumours, and in some of the leukaemias and anaemias (Lott and Landesman 1984). Lactate dehydrogenase has five isoenzymes: the anodal forms are increased in cardiac and renal disease, and in some diseases of skeletal muscle, while the cathodal forms are elevated in skeletal muscle and liver dysfunction. Other less specific enzymes that may also be found in higher concentrations in muscle damage are aspartate aminotransferase and alanine aminotransferase. Myoglobin is present only in skeletal and cardiac muscle. This oxygen-binding haem protein is elevated in serum from children with myopathies; persistent or massive myoglobinuria can result in renal failure, which should be prevented by infusion of adequate intravenous hydration.

Muscle complaints

Children with juvenile dermatomyositis may complain of pain on compression of the proximal muscles, or of muscle cramps, but weakness of symmetrical proximal muscles is still the predominant symptom. Other conditions associated with muscle cramps and contractures include hypothyroidism, uraemia, and electrolyte imbalance such as hypokalemia (either iatrogenic or in conjunction with familial periodic paralysis). Pretibial tenderness is seen with erythema nodosum, but is not a feature of juvenile dermatomyositis. Pain that awakens the child at night should be investigated for another cause such as malignancy, osteoid osteoma, or osteomyelitis. Muscle weakness can be see in hormonal derangements, either endogenous or iatrogenic, such as in adrenal dysfunction, or after long-term high-dose steroid administration. In addition, thyroid, pituitary, and parathyroid dysfunction may be accompanied by skeletal complaints. Metabolic muscle diseases include defects of glycolysis (e.g. phosphofructokinase deficiency) and are associated with contractures, exercise intolerance, myoglobinuria, and a positive ischaemic lactate test. There may be a defect in lipid metabolism such as a carnitine deficiency state (Breningstall 1990), which may be exacerbated by non-steroidal anti-inflammatory drugs; or a myalgia syndrome, which can be detected by a positive ischaemic ammonia test. Inclusion-body myositis, which often runs a steroid-resistant course, has also been described in children (Serratrice *et al*. 1989).

Acute infectious viral myositis in children, most frequently attributed to influenza A or B, is differentiated clinically from chronic myositis by its localization to the muscles of the calf, severe pain, and rapid resolution in 1 to 4 weeks (Mejlszenkier *et al*. 1973). The agent of this acute myositis has been isolated from cultures of muscle biopsy, accompanied by rise in complement-fixing antibody titres to influenza and by myoglobinuria, electomyographic changes, and elevated creatine kinase. As in adults with HIV or HTLV-1, children with these illnesses may also have muscle complaints.

Other autoimmune rheumatic disorders may also be accompanied by inflammatory muscle disease. For example, children with systemic-onset juvenile arthritis may have spiking fevers and an evanescent rash. Often they do not wish to be held and have increased concentrations of muscle enzymes, making the appropriate diagnosis of the specific connective tissue disease imperative. Confusion may be created by a child who has classical Gottron's papules, elevated muscle enzymes, and muscle biopsy evidence of perifascicular atrophy in the presence of antibody to RNP or PM/Scl. Such children with overlap syndrome are less likely to have complete resolution of their disease, requiring long-term therapy.

Electromyogram

Evidence of an inflammatory myopathy on electromyography is not specific to juvenile dermatomyositis and is similar in other autoimmune rheumatic disorders which have a myopathic component. Selection of a site of active involvement is facilitated by MRI identification of focally involved muscles. Once the location of the electrodes has been chosen (not the site of a future biopsy), insertional irritability, followed by spontaneous electrical activity at rest is often observed. This pattern can be also seen in the muscular dystrophies and in early acute myositis. Abnormal early full recruitment of muscle fibres with moderate effort occurs in about 45 per cent of patients with juvenile dermatomyositis, and bizarre, high-frequency discharges occur in 15 to 20 per cent of patients tested. Reduced motor unit activity is seen in Duchenne muscular dystrophy as well as in juvenile dermatomyositis. Myasthenia gravis can coexist with an inflammatory myopathy, resulting in a greater degree of instability of motor-unit potential than is found in the uncomplicated inflammatory myopathies.

Pathophysiology of juvenile dermatomyositis

Vascular findings

The vasculopathy of this disease may occur in the absence of a prominent inflammatory component, and is a characteristic of children with dermatomyositis (Banker and Victor 1966); vascular occlusion in the absence of an inflammatory infiltrate in adults with early lesions of dermatomyositis has also been well described (Emslie-Smith and Engel 1990). In juvenile dermatomyositis, damage to capillaries, venules, and small arteries causes loss of the capillary network resulting in structural change in the nailfold capillary bed as well as in muscle, with a subsequent decrease in the capillary/fibre ratio. Appropriate controls must be age, gender, and activity related, for there is a progressive increase in mean fibre diameter, capillary/fibre ratio, and number of capillaries surrounding a single fibre, together with a decrease in capillary density (capillaries/mm ^{2} of muscle fibre) which was documented when data from normal infants, children, and teenagers were compared (Carry *et al*. 1986). In adults with dermatomyositis, both large and small vessels (less than 20 µm in diameter) are involved (Kalovidouris *et al*. 1988).

Muscle pathology

The muscle pathology in juvenile dermatomyositis reflects vascular compromise and capillary dropout, with perifascicular atrophy of both type I and type II fibres (Fig. 2). Multiple satellite cells are frequently seen in atrophic fibres; focal repair takes place concomitantly with fibre atrophy (Woo *et al*. 1988). In muscle biopsies from children aged 3 to 11 years with juvenile dermatomyositis, mitochondria in muscle appeared to be increased in number, but were reduced in size and in the total content of cytochrome C oxidase as measured both histochemically and biochemically. The biochemical changes were physically associated with perifascicular atrophy, suggesting that ischaemia could lead to structural change (Woo *et al*. 1988). Low-grade ischaemia may also be related to expression of class I and class II major histocompatibility complex gene products, which also were found primarily in the perifascicular area (Karpati *et al*. 1988). In some children with juvenile dermatomyositis who despite normal serum levels of muscle-derived enzymes have elevated levels of von Willebrand-factor antigen and/or neopterin (see below), the muscle biopsy can reveal active foci of inflammation (Pachman *et al*. 1996). In contrast, in polymyositis there appears to be less primary involvement of vessels—they may be normal in number and structure. It is not known if dermatomyositis in the adult has the identical pathophysiology as in the child, but comprehensive national studies in the United States are under way which should clarify this issue. In adult dermatomyositis, the infiltrate is composed of DR+ B cells and there is an increased CD4/CD8 ratio (it should be noted that few children have been extensively studied). It appears that informed discussion of specific immunohistopathology must include classification of the patients with respect to myositis-specific antibodies, as well as the duration of inflammatory disease, the presence of previous therapy at the time of biopsy, verification that the biopsy site was appropriate (for example, positive on MRI or ultrasound), data concerning the child's HLA phenotype with respect to the presence or absence of DQA1*0501, and the specific anatomic site of the biopsy under consideration (perivascular, endomesial, perifascicular, etc.). Overall, in dermatomyositis, there appears to be a close relationship between CD4+ cells and B cells as well as macrophages, suggesting a cytotoxic mechanism, perhaps directed against immune complex-modified endothelial cells (Engel and Arahata 1986; Hohlfeld and Engel 1994). The relationship of the tissue localization of cells from the immune system to those that are circulating is just beginning to be understood (see below). The various possible mechanisms of immunological injury have been discussed in Chapter 5.9.1, but this information is poorly defined for children at different stages of disease duration and activity.

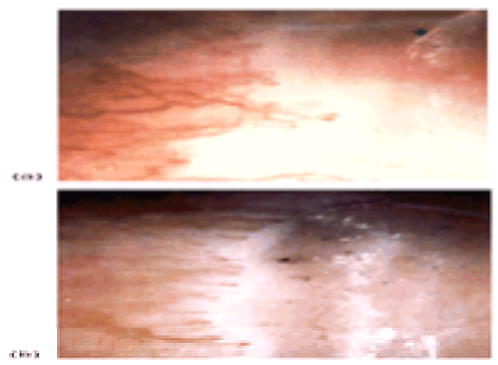

Fig. 2 (a) Nailfold capillary studies of a child with dermatomyositis of 2 years duration with severe active disease (not able to walk, flexion contractures) referred for evaluation. Her nailfolds display a prominent subcapillary venous plexus and marked avascularity with decreased numbers of end capillary loops. The few end capillaries that are present are tortuous and show terminal bushing characteristic of this disease. The black arrow indicated the edge of the nail. (b) The same nailfold 2 years and 4 months later: the child is now walking, attending school, but still requires intensive therapy. The prominent subcapillary venous plexus has been replaced by new capillary formation which has decreased the areas of avascularity. The end capillary loops are still not normal: there is increased dilation and open loop formation.

Calcification in soft tissues

The aetiology of the calcinosis must be determined and clearly differentiated from other syndromes in which calcinosis occurs, such as in heterotopic calcinosis or following trauma. In juvenile dermatomyositis, calcification in soft tissue may be a correlate of disease severity and duration (Pachman *et al*. 1985) Delay in diagnosis (Pachman *et al*. 1992b) and/or insufficient therapy (Callen *et al*. 1994) appears to be correlated with the development of calcinosis. Therefore, early recognition of the disease and institution of appropriate therapy can prevent the development of calcinosis (Callen *et al*. 1994). The therapeutic dilemma for the physician is to identify indicators of disease activity that are useful for an individual child. Those children with juvenile dermatomyositis who do develop calcifications may have one of several outcomes. The calcifications may resolve spontaneously, draining as a white, cheesy or serosanguinous exudate, and leaving dry pitted, scars. The calcifications do not decrease when chelating agents are given. In some children with persistent, active disease, the calcifications progress to become a sheath, impairing flexion and function, braking the barrier of the skin to form a site of entry of infection. Sepsis is not uncommon in this event and contributes to morbidity and mortality from this disease.

Calcinosis is accompanied by increased urinary excretion of g-carboxyglutamic acid (**GLA**), which is a component of the vitamin K-dependent coagulation pathway. This increased excretion of GLA (when compared with age-/sex-matched controls) was present both in children with juvenile dermatomyositis who had no clinical or radiological evidence of calcinosis (whose mean values for GLA excretion were twice normal) and in those who did have calcinosis (whose mean values were three time normal) (Lian *et al*. 1982). Routine measures of coagulation, including the prothrombin and activated partial thromboplastin times were normal (Lian *et al*. 1982). Calcifications are not correlated with antinuclear antibody, immune complexes, or class II HLA antigens (Pachman *et al*. 1985).

Immunological, genetic, and haematological data

Immunological data

Children with active untreated juvenile dermatomyositis are lymphopenic (O'Gorman *et al*. 1995). Despite this lymphopenia, there is a relative increase in the percentage of B cells (defined by anti-CD19 monoclonal antibody), which is correlated with a clinical disease activity score (in contrast, the percentages of CD4, CD8, and CD25 are not correlated with disease activity) (Eisenstein *et al*. 1995). This increased percentage of B cells may reflect response to medical therapy by returning to normal ranges at a time when other serological indicators of disease activity have already become normal (Pachman 1994). The CD4:CD8 cell ratio is increased, suggesting that there is a decrease in circulating CD8+ cells in the periphery (O'Gorman *et al*. 1995). Efforts to identify clonal expansion of T cells in the muscle of children with new-onset untreated juvenile dermatomyositis have not yet demonstrated a specific increase in T-cell receptor variable gene expression (V) as determined by polymerase chain reaction and sequencing of the CDR3 region in six children positive for the HLA antigen DQA1*0501 (Pachman *et al*. 1995a).

Humoral immunity may be abnormal in a minority of patients: in early disease, IgM (Pachman and Cooke 1980) or IgG (O'Gorman *et al*. 1995) may be elevated or IgA deficiency may be present (Pachman and Cooke 1980). Peripheral blood lymphocytes from children with juvenile dermatomyositis appear to have a high spontaneous rate of immunoglobulin synthesis *in vitro* (Cambridge 1990). Tests for an array of antibodies with tissue or organ specificity were negative when comparing sera from 89 patients with newly diagnosed juvenile dermatomyositis with 105 age-/sex-matched controls. Only the antinuclear antibodies (**ANA**) and antibody to the polymyositis antigen 1 (PM-1) were more frequent in patients than controls ($p<0.005$, $p< 0.001$ respectively) (Pachman *et al*. 1985; Montecucco *et al*. 1990). The ANA is speckled and cytoskeletal in pattern in 60 to 70 per cent of children (often in high titres), but negative for Jo-1 (Pachman *et al*. 1984). A similar speckled ANA was found in sera from children with a primary cardiomyopathy (who were positive on culture for CVB) and in CVB type-specific mouse monoclonal antibody, suggesting that a response to a viral antigen may play a role in juvenile dermatomyositis (Patterson *et al*. 1989). Other unconfirmed investigations identified an antibody specificity for heat shock protein 60 in the juvenile dermatomyositis sera (Patterson *et al*. 1993).

As in adults, identification of the ANA specificity in a person with an inflammatory myopathy may allow greater understanding of the aetiology and pathogenesis of theses heterogenous diseases (Love *et al*. 1991). Five children have been identified with Jo-1, the most common of the antisynthetases (Rider *et al*. 1995); in addition nine out of eleven other children had antibody to Mi-2 and their disease onset and course was the same as other ANA-positive, MSA-negative children; seven out of the nine were Hispanic, one was Asian, the other child was black. They had no obvious pattern in the season of onset of their weakness; fevers and joint contractures without associated arthritis were frequent in this group, but cardiopulmonary symptoms were uncommon (Rider *et al*. 1994). This was in contrast to the child with anti-SRP who had a sudden onset in the autumn of proximal and distal muscle weakness without the rashes characteristic of dermatomyositis, or cardiac involvement or palpitations prominent in adults with anti-SRP disease. Once her specific inflammatory myopathy was recognized, she was switched from corticosteroids (which worsened her disease) to cytotoxic agents and intravenous immunoglobulin to achieve remission (Rider *et al*. 1994).

Complement activation has been implicated in several studies which included children with juvenile dermatomyositis: the C5b–9 membrane-attack complex was localized to the intramuscular microvasculature in 10 of 12 patients (Kissel *et al*. 1986); the duration of the clinical disease was correlated with this finding (Kissel *et al*. 1991). Immune complexes appear to participate in the pathophysiology of this disease: there is data demonstrating complement activation (despite normal levels of total complement, C3 and C4) accompanied by increased levels of fibrinopeptide A and von Willebrand factor antigen (Scott and Arroyave 1987).

Another useful indicator of disease activity is neopterin, a member of the pteridine family derived from GTP via guanosinetriphosphate cyclohydrolase and released from macrophages as a consequence of T-cell dependent interactions (Barak *et al*. 1989) involving interferon-g. Early reports of increased neopterin levels in active dermatomyositis in children (Myones *et al*. 1989) were confirmed (DeBenedetti *et al*. 1993). Further studies demonstrated that neopterin levels were a correlate of a clinical disease activity score in over 65 per cent of cases (Pachman *et al*. 1995c).

Genetic studies

Records of juvenile dermatomyositis in more than one family member are sporadic, but the disease has been reported in monozygotic twins, who developed muscle-related abnormalities 2 weeks after an upper respiratory tract infection (Harati *et al*. 1986). In a large, cross-sectional study of children with juvenile dermatomyositis and their families, there was a marked increase in Caucasians with HLA B8 (relative risk 2.8, $p< 0.01$) (Friedman *et al*. 1983a) and DR3 (relative risk 3.8, $p< 0.01$); in Latin Americans, the relative risk for HLA DR3 was 18.5 ($p< 0.05$) (Friedman *et al*. 1983b). The association of the supratypes A1, Cw7, B8, and DR3 suggests that there might be a genetic component to disease susceptibility or expression. Further examination showed that there was an increased association of HLA DQA1*0501 but not C4a when 30 Caucasian children with juvenile dermatomyositis were compared with regional controls matched for HLA DR3 (Reed *et al*. 1991). This observation was sustained when other racial groups in the United States were studied (Reed and Stirling 1995), but did not appear to be true for Czech children with this disease (Vavrincova *et al*. 1993).

Haematological data

In children with juvenile dermatomyositis, the usual indicators of an acute-phase reaction are often within normal range, although children with acute severe disease or infected sites of calcinosis may have elevated values. The lymphopenia is not commonly accompanied by an abnormal platelet count, although a mild microcytic anaemia may be present. A sensitive indicator of inflammatory disease is an elevated von Willebrand factor antigen (Bowyer *et al*. 1989; Guzman *et al*. 1994) which may precede a disease flare (when muscle enzyme data is normal), or remain elevated once the enzymes have returned to normal (Scott and Arroyave 1987). The von Willebrand factor antigen is correlated with disease activity in some but not all children (Bloom *et al*. 1995). In over 50 per cent of children, levels of this antigen correlate with a clinical score of disease activity; analysis of the multimers confirms that it is endothelial in origin, reflecting endothelial cell damage (Miller *et al*. 1995).

These clues to disease activity—the MRI, neopterin, von Willebrand factor antigen, and percentage of B cells—are still imperfect guides to therapy (Pachman 1995), but may be of substantial aid in the characterization of the severity of the immunologically mediated inflammatory process (Pachman 1994).

Course and therapy

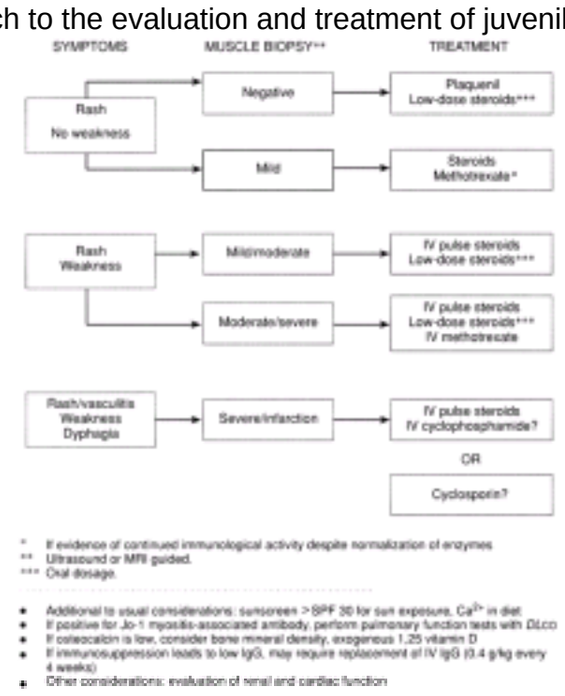
Course

The outcome of juvenile dermatomyositis has improved greatly since the 1960s when one-third of the children died, one-third were crippled, and the remainder recovered (Bitnum *et al*. 1964). Several types of disease course have been described—monocyclic, recurrent, and continuous (Spencer *et al*. 1984)—but they may be attenuated by early diagnosis and aggressive therapy. The frequency of calcinosis (which was associated with loss of mobility) has decreased from over 60 per cent of cases (Bowyer *et al*. 1983) to none (Callen *et al*. 1994). Late disease recurrence after years of apparent inactivity has been reported (Lovell and Lindsley 1986), suggesting the need for periodic monitoring with more sensitive indicators of disease activity. It is difficult to predict outcome at the onset of illness, although the magnitude of the initial creatine kinase appears to be a direct correlate of disease severity (Van Rossum *et al*. 1994). Several groups have found that prognosis is related directly to the degree of vascular involvement (Crowe *et al*. 1982; Bowyer *et al*. 1983).

Therapy

There is continuing controversy over the type, duration, and route of medication to be instituted (Malleson 1990). Recommendations are impaired because of lack of long-term outcome data; medical practices have changed in the recent past, and it is not known how this will affect the children's course in the future—both the consequences of the autoimmune disease and its therapy. Given these caveats, there is sparse data on long-term outcome. A summary of the treatment of juvenile dermatomyositis is given in Box 1.

Box 1 An approach to the evaluation and treatment of juvenile dermatomyositis



Several investigators have observed the utility of high-dose intravenous intermittent (pulse) methylprednisolone for the treatment of juvenile dermatomyositis over the past 2 decades (Miller 1980; Yanagisawa *et al*. 1983; Laxer *et al*. 1987). When children with similar clinical disease activity scores were compared, one group had been given 2 mg/kg per day of prednisone to treat their active disease, and required about 4 years until all therapy was discontinued. The other group was given intravenous intermittent high-dose methylprednisone at 30 mg/kg, supplemented with vitamin D and a calcium-sufficient diet, and low daily doses of about 0.5 mg/kg on days when they did not receive intravenous methylprednisolone. The children receiving the intravenous therapy had a shorter disease course with respect to persistence of rash (1.5 years compared with 3.9 years), weakness (1.5 years compared with 2.7 years), and did not have calcinosis or growth retardation, although the frequency of cataracts was the same in both groups (Pachman *et al*. 1994). When a subset of this group, who had a monocyclic disease course, was subjected to a cost analysis, the intravenously treated group had 2 disease-free years, but their bill was about $US10 000 higher than those given oral therapy (Klein-Gitelman *et al*. 1996). Cost differences associated with long-term outcomes are not known.

In our centre, the child with active juvenile dermatomyositis is thoroughly evaluated on admission, using the parameters appropriate to the child. Adequate hydration lessens the possibility of renal damage. If there is evidence of dysphagia or difficulty in handling secretions, then serious consideration is given to the immediate use of weekly intravenous methotrexate at a starting dose of 15 mg/m^2, to be administered immediately following the administration of high-dose intermittent pulse methylprednisolone at 30 mg/kg per day in 100 ml D5W to be given over at least 30 min with monitoring of vital signs every 15 min for 30 min after the infusion is completed. The frequency of the intravenous steroid administration is determined by the rate of response of the child, using the parameters that reflect that child's inflammatory response. Low-dose oral steroids, at 0.5 mg/kg per day are given in the morning on the days that the intravenous methylprednisolone is not infused. The protocol for each child is individual. In general, an intensive course of intravenous methylprednisolone is used until the laboratory tests become normal, with gradual reduction in therapy. The use of high-dose methylprednisolone is not without some side-effects. In an analysis of the drug usage over a 5-year period in which 213 children with various types of serious rheumatic disease were given over 2622 doses, 46 children (22 per cent) experienced an adverse reaction of which 21 had behavioural changes ranging from euphoria to emotional lability. There was one case of anaphylaxis (Klein-Gitelman and Pachman 1995).

When there is severe skin involvement, hydroxychloroquine (7 mg/kg per day) is given if there is no family history of red–green colour blindness. With milder involvement, the cutaneous symptoms often resolve within several weeks, making the use of this drug unnecessary. Topical agents to lessen dryness help the occasional pruritis as do topical steroids, which should be used sparingly (Stonecipher *et al*. 1993). For breaks in the integument, a 'skin substitute' (e.g. 'Second skin', duoderm) should be considered. Sepsis secondary to infected calcinosis must be treated aggressively.

Children who have severe onset, or who do not respond to steroids, have been treated with methotrexate for the past 2 decades (Jacobs 1977). More recently, earlier use of this drug at doses of 15 mg/m^2 per week has reduced the morbidity of the disease (Miller *et al*. 1992), and permits the use of lower doses of steroids. In active disease, intravenous administration of methotrexate assures drug absorption; as the disease becomes quiescent, oral administration is tolerated. Complaints of nausea can be circumvented by dividing the dose but giving the full amount in a 24-h period. The function of the liver and bone marrow must be monitored. If it appears that a child remains severely ill (sometimes despite the muscle enzymes becoming normal), evaluation of the immune system may help to guide therapy (e.g. the percentage of B cells remains elevated in 40 to 60 per cent) (Eisenstein *et al*. 1995). Intravenous cyclophosphamide therapy, starting at 500 mg/m^{2}every 3 weeks (following adequate hydration), with mesna for bladder protection, is instituted and the methotrexate is discontinued (Pachman 1994). As with most modes of immunosuppression, levels of IgG must be checked on a periodic basis to ensure that they are adequate; if not, replacement therapy (0.4 g/kg every 3 to 4 weeks) is needed to prevent recurrent infections.

When considering therapies other than steroids, high-dose (not replacement) intravenous gammagloblin may initially dampen the inflammatory process, especially the rash (Roifman *et al*. 1987; Lang *et al*. 1991) if given early in the disease course (Basta and Dalakas 1994), but it is unclear if prolonged control of disease activity can

be achieved with this modality alone. Plasmapheresis alone does not appear to be effective in adults (Miller *et al*. 1992) and no data is available for children. Evaluation of the efficacy of cyclosporin has been proposed (Heckmatt *et al*. 1989) but has been hampered by coexisting therapies (Pistoia *et al*. 1993). FK506 has been useful in the therapy of adults with Jo-1 myopathy (Oddis *et al*. 1994), but no published data are available for children.

At the moment there are no successful therapies for long-standing calcinosis in children with inactive disease. In those children who do have calcinosis and residual evidence of an active immunological process, an MRI may reveal more inflammation than expected, permitting more aggressive therapy, which may result in regression (and occasionally radiological resolution) of the calcinosis. Treatment with low-dose warfarin early in the disease has been suggested (Berger *et al*. 1987), but is a considerable hazard for the active child, is not useful in advanced disease (Lassoued *et al*. 1988), and has not yet been proved effective in a case–control study.

The progression of osteopenia, a consequence of disease activity as well as therapy, can be slowed with a calcium-sufficient diet, and the addition of thrice-weekly (Monday, Wednesday, Friday) 1,25-vitamin D (20 µg under 30 kg; 50 µg over 30 kg) in conjunction with disease control. Administration of vitamin D and increasing the calcium intake may aid in calcium absorption from the gastrointestinal tract in the face of steroid therapy (which inhibits calcium absorption), and diminishes the occurrence of one of the most serious consequences of steroid therapy, osteopenia, which can progress to spinal cord compression fractures (Callen *et al*. 1994).

Combined drug treatment (to suppress inflammation) and physiotherapy (gentle, passive stretching) are required in the early phase of the disease, and more intensive, graded physiotherapy is effective later in the disease, once the inflammation has abated. Prevention of sunburn, both by avoidance and barriers (clothing, UVA/UVB PABA-free sunblocks over SPF 30) helps keep the disease in remission.

In summary, juvenile dermatomyositis, characterized by genetically restricted and immunologically mediated vasculopathy, is under intense investigation. It is axiomatic that as more knowledge of the specific pathophysiology of the disease(s) is accrued, more effective therapeutic interventions will be devised.

5.10 Sjögren's syndrome

Athanasios G. Tzioufas, Pierre Youinou and H. M. Moutsopoulos

Introduction

Sjögren's syndrome is a chronic autoimmune disease of unknown aetiology, characterized by lymphocyte infiltration of exocrine glands resulting in xerostomia and keratoconjunctivitis sicca. This syndrome is particularly interesting among the autoimmune diseases for two reasons. First, it has a broad clinical range extending from autoimmune exocrinopathy to extraglandular (systemic) disease affecting the lungs, kidneys, blood vessels, and muscles; it may occur alone (primary Sjögren's syndrome) or in association with other autoimmune diseases (secondary Sjögren's syndrome) (Table 1). Secondly, it is a disorder in which a benign autoimmune process can terminate in a lymphoid malignancy. Thus, Sjögren's syndrome is a 'cross-roads disease' that offers potential insight into the mechanisms whereby immunological dysregulation may predispose to malignant transformation of B cells that are already involved in an autoimmune process.

Rheumatoid arthritis
Systemic lupus erythematosus
Systemic sclerosis
Mixed connective tissue disease
Primary biliary cirrhosis
Myositis
Vasculitis
Thyroiditis
Chronic active hepatitis
Mixed cryoglobulinaemia

Table 1 Association of Sjögren's syndrome with other autoimmune diseases

Historical reviews (Moutsopoulos *et al*. 1980)

The clinical features of the disorder were first described by Hadden in 1888. Four years later, Mikulicz described the case of a German farmer who suffered from bilateral enlargement of the parotid glands. A biopsy of the parotid showed an intense, focal, lymphocytic infiltrate that is known today as the hallmark of the disease. In the 1920s Gougerot described the disease in France and in 1933, Sjögren, a Swedish ophthalmologist, wrote the classic monograph on the disease in which he emphasized that the eye manifestations are local findings of a systemic disorder. In 1953, Morgan and Castleman showed that the histopathological findings in Sjögren's syndrome and Mikulicz disease are identical. In the 1960s the diverse clinical range of the syndrome was recognized and the study of its autoantibodies was initiated. The genetic predisposition to the disease was substantiated with the study of HLA in the 1970s; in the 1980s, with progress in molecular biology, the specificity of autoantibodies to the cellular components Ro(SSA) and La(SSB), and the composition of the focal lymphocytic infiltration of the exocrine glands, were dissected.

Epidemiology

The syndrome primarily affects women (nine women to every one man), mainly in the fourth and fifth decades of life (Pavlidis *et al*. 1982). However, it can occur in people of all ages, including children and elderly persons (Drosos *et al*. 1988; Siamopoulou-Mavridou *et al*. 1989). Autopsy studies revealed that approximately 2 to 3 per cent of individuals without connective tissue disease had unexplained focal lymphocytic infiltrates of the minor labial salivary glands compatible with Sjögren's syndrome (Scott 1980). On the other hand, clinical studies from Great Britain and Greece have found that Sjögren's syndrome occurs in 3 to 5 per cent of geriatric populations (Whaley *et al*. 1972; Drosos *et al*. 1988).

In an epidemiological study of 705 Swedish adults the calculated prevalence for the disease was 2.7 per cent (Jacobsson *et al*. 1989). Symptoms of dry eyes and dry mouth were correlated with elevated levels of anti-Ro/SSA and anti-La/SSB antibodies (Jacobsson *et al*. 1992). In another study, using as a tool the recently proposed questionnaire and diagnostic criteria for Sjögren's syndrome, as suggested by the European Union concerted action (Vitali *et al*. 1992a), it was found that among 837 females (age range from 18 to 90 years), the prevalence of definite and probable Sjögren's syndrome was 0.6 per cent and 3 per cent, respectively (Tzioufas *et al*. 1994).

Aetiology and pathogenesis

Over the past two decades, research in immunopathology, autoantibodies, immunogenetics, and viruses has further refined the concepts of the pathophysiology and pathogenesis of Sjögren's syndrome. One may speculate that the disease develops in three steps: first, autoimmunity may be triggered by a given environmental factor that acts on a particular genetic background; second, the autoimmune reactivity becomes chronic through abnormal immune regulatory mechanisms; and third, the lesion occurs as a consequence of the continuing inflammatory process.

The triggering of autoimmunity

Environment

Autoimmune reactions against host tissue following viral infection have been reported in both man and experimental animals. Viruses are therefore suspected as being major contributing factors in certain autoimmune disorders. One chronic infection that is especially emphasized is with cytomegalovirus. This involves many organs; among them the salivary glands are prime targets (Hudson *et al*. 1979). Antibodies to cytomegalovirus of both IgG and IgM classes have been found in the serum of patients with primary Sjögren's syndrome, using an enzyme-linked immunosorbent assay (Shillitoe *et al*. 1982). However, no controls were used in that study

and Venables *et al*. (1985) were not able to confirm those observations.

Epstein–Barr virus (**EBV**), another herpesvirus, could well be a better candidate than cytomegalovirus. Its replication also occurs in the salivary glands during primary infection (Wolf *et al*. 1984). The virus remain latent at this site in immunologically intact adults. Expression of EBV-associated antigens in the salivary glands of some patients with Sjögren's syndrome and increased content of EBV-DNA in their saliva (Fox *et al*. 1986a) have been demonstrated. However, EBV reactivation may arise as a consequence rather than as a cause of lymphoproliferation in these patients.

Hepatitis C virus may produce a chronic lymphocytic sialadenitis, which mimics that observed in Sjögren's syndrome, since more than 50 per cent of patients infected with hepatitis C virus have been reported, in one study, to present with histological changes compatible with Sjögren's syndrome in their minor salivary glands (Haddad *et al*. 1992). On the other hand, patients with Sjögren's syndrome do not usually have antibodies to hepatitis C virus in their sera (Vitali *et al*. 1992b).

The retroviruses are another group of viruses that should be seriously considered in the pathogenesis of autoimmune diseases in general and Sjögren's syndrome in particular. Antibodies to the p24 capsid glycoprotein of human immunodeficiency virus have been detected in approximately 30 per cent of patients with Sjögren's syndrome, whilst the frequency of these antibodies in the serum of healthy, age-matched controls is 1 to 4 per cent (Talal *et al*. 1990). Transgenic mice bearing the *tax* gene of the human T-lymphotrophic virus type 1 develop an autoimmune exocrinopathy resembling that of Sjögren's syndrome: an initial increase and proliferation of the acinar epithelial cells is followed by a gradual infiltration of lymphocytes and plasma cells, leading to destruction of the acini (Green *et al*. 1989). Furthermore, a type A retroviral particle has been identified in extracts from labial gland biopsies in two out of six patients with Sjögren's syndrome after coculture with the lymphoblastoid cell line, RH9: this was distinguishable from the human immunodeficiency virus particles by several physicochemical and ultrastructural criteria (Garry *et al*. 1990).

The c-*myc* proto-oncogene is involved in the pathogenesis of B-cell malignancies and especially Burkitt's lymphoma caused by EBV. Increased expression of c- *myc* mRNA has been found in peripheral mononuclear cells of patients with Sjögren's syndrome as well as in those of normal people after stimulation (Boumpas *et al*. 1990). Skopouli *et al*. (1992), using *in situ* hybridization with specific c-*myc* probes, have demonstrated the expression of c-*myc* mRNA in minor salivary glands of patients with Sjögren's syndrome. The minor labial salivary glands of normal individuals and of patients with rheumatoid arthritis and sarcoidosis did not show this picture. Immunostaining of the hybridized tissue with monoclonal antibodies and correlation with the clinicoserological and histological findings showed that the proto-oncogene is expressed on the acinar epithelial cells and its appearance is correlated strongly with the duration of disease as well as with the intensity of the T-cell infiltration. It is not known yet whether this aberrant *c-myc* expression in the epithelial cells is a primary phenomenon resulting from a viral infection or an epiphenomenon attributable to the action of cytokines or cytokine-like molecules.

All the above data suggest viral involvement in Sjögren's syndrome. Transient or persistent infection of the epithelial cells by a putative virus may be the initiating event; accumulation of the helper/inducer memory T cells and B cells may be the second step; and monoclonal expansion of B cells under selective antigenic or T-cell-induced pressures the final step.

Genetic background (immunogenetics)

It is well known that members of the family of patients with Sjögren's syndrome have a higher prevalence of the syndrome and a higher incidence of serological autoimmune abnormalities than age- and sex-matched controls.

Numerous investigators have shown associations between primary Sjögren's syndrome and factors encoded by the major histocompatibility complex; HLA-DR3 has been reported in 50 to 80 per cent of patients with Sjögren's syndrome. The association, however, of HLA-DR3 and Sjögren's syndrome has been reported to be weaker than that of HLA-DR3 with Sjögren's syndrome and anti-Ro/SSA antibody positivity (Mann 1987).

As shown in Table 2 the ethnic origin of the patients, studied so far, influences the association with the HLA-DR phenotype. Given the linkage disequilibrium that exists between alleles of HLA loci, it is unclear whether the disease susceptibility is dependent on the associated allele or on a closely related gene. *HLA-DQ*, and to a lesser extent *HLA-DP*, alleles are tightly linked to *HLA-DR* (Navarrette *et al*. 1985). Thus, common amino acid sequences of the hypervariable region of these genes may be shared between different HLA-DR specificities, hence influencing disease susceptibility (shared epitope hypothesis) (Gregerson *et al*. 1987). The application of molecular biological techniques has made possible an understanding of the association of autoimmune diseases with different HLA haplotypes in various patient populations. In this regard, a DNA sequence-specific, oligonucleotide probe typing and a sequence analysis of Israeli Jewish and Greek non-Jewish patients with Sjögren's syndrome has been carried out (Tambur *et al*. 1993). It was found that the majority of patients in both groups presented either *DRBI* 1101* or *DRBI* 1104* alleles that were linked in a linkage disequilibrium with *DRBI*0301* and *DQA1*0501*. Molecular analysis of *DQB1* and *DQA1* alleles found in American Caucasian and American black patients with Sjögren's syndrome revealed high frequencies of *DQB1*0201* and *DQA1*0501* (Reveille *et al*. 1991). Therefore, the majority of patients with Sjögren's syndrome, independent of their racial and ethnic background, carry a common allele, the *DQA1*0501* allele. Furthermore, it has been shown that a glutamine residue at position 34 of the outermost domain of the *DQA1* and/or leucine at position 26 of the outermost domain of the *DQB1* chain have a 'gene dosage' role in the anti-Ro/SSA and anti-La/SSB antibody response. The *DQA1*0501* gene is one of the genes that possess glutamine at position 34 and is found in the majority of patients with anti-Ro/SSA and anti-La/SSB. Taken together, it appears that the DQA1*0501 molecule is probably an important determining factor for the predisposition of certain individuals to primary Sjögren's syndrome.

Table 2 Ethnic variations in the association between antigens encoded by the major histocompatibility complex and Sjögren's syndrome

Development and continuation of the autoimmune process

The two major autoimmune phenomena observed in Sjögren's syndrome are the B-lymphocyte hyper-reactivity and the focal lymphoplasmacytic infiltrates in the exocrine glands. Numerous studies have sought to describe and delineate (a) the nature of these phenomena and (b) the mechanisms involved in their perpetuation.

Humoral studies

Polyclonal hyper-reactivity

The most common serological finding in Sjögren's syndrome is hypergammaglobulinaemia. The increased amount of immunoglobulins in these patients often contains a number of autoantibodies directed against non-organ-specific antigens such as other immunoglobulins (rheumatoid factor), antinuclear antibodies (which usually give a speckled pattern on immunofluorescence), cellular antigens [Ro(SSA), La(SSB), RANA], and organ-specific antigens such as salivary ductal cells, thyroid gland cells, and gastric mucosa (Harley 1987). The most common autoantibodies to cellular antigens in patients with Sjögren's syndrome are directed against two ribonucleoprotein antigens known as Ro or SSA and La or SSB. These autoantibodies are not specific for the syndrome and may be found in other autoimmune diseases, especially systemic lupus erythematosus (see Chapter 5.7.1). Anti-Ro and anti-La are detected by immunodiffusion in approximately 45 and 20 per cent, respectively, of patients with Sjögren's syndrome but in up to 95 and 85 per cent, respectively, by more sensitive techniques such as enzyme-linked immunosorbent assay. Characterization of these ribonucleoproteins has led to the observation that the fine specificity of antibodies to the polymorphic forms of Ro differs in Sjögren's

syndrome and systemic lupus (reviewed in Chapter 4.5). Thus, autoantibodies to the 52-kDa Ro protein are frequently found in serum from patients with the syndrome, while antibodies to a 60-kDa Ro protein are found more often in serum from patients with systemic lupus (Ben Chetrit *et al*. 1990).

The presence of anti-Ro(SSA)/La(SSB) autoantibodies is associated with certain clinical manifestations of primary Sjögren's syndrome: they are correlated with earlier onset and longer duration of disease, recurrent enlargement of the parotids, and with splenomegaly/lymphadenopathy and vasculitis. In addition, the incidence of these antibodies correlates with the intensity of the infiltration of minor salivary glands (Manoussakis *et al*. 1986).

Oligomonoclonal hyper-reactivity

Several patients with primary Sjögren's syndrome have been shown to have circulating monoclonal immunoglobulins. In a study of serum and urine from unselected patients with the primary syndrome, using high-resolution agarose electrophoresis combined with immunofixation, approximately, 80 per cent of those with extraglandular (systemic) disease had monoclonal light chains or immunoglobulins in the serum. Furthermore, all patients excreted monoclonal light chains in the urine. In contrast, only one-quarter of patients with disease limited to the exocrine glands had monoclonal light chains or immunoglobulins in their serum, while only 43 per cent of these excreted light chains in the urine (Moutsopoulos *et al*. 1983a; Moutsopoulos *et al*. 1985).

Subsequent analysis of cryoglobulins from patients with Sjögren's syndrome by high-resolution agarose gel electrophoresis combined with immunofixation demonstrated that these are mixed monoclonal cryoglobulins (type II), containing an IgM-k monoclonal rheumatoid factor (Tzioufas *et al*. 1986) (Fig. 1). The above data suggest that patients with Sjögren's syndrome express circulating monoclonal immunoglobulins very early in the disease, together with the polyclonal B-cell activation. Monoclonality is observed more often in those patients with systemic, extraglandular disease. This is of particular interest, as patients with extraglandular manifestations are at higher risk for developing lymphoid malignancy. In this regard, serial follow-up studies have shown that the presence of mixed monoclonal (type II) cryoglobulinaemia correlates with lymphoma in patients with primary Sjögren's syndrome (Tzioufas *et al*. 1996).

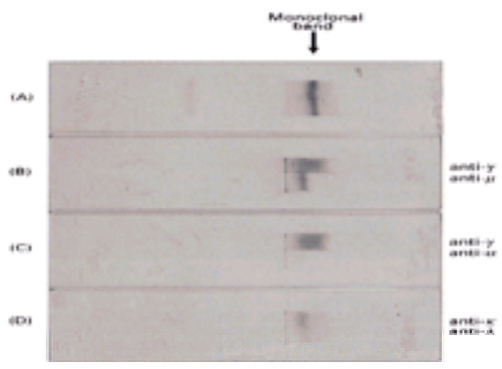

Fig. 1 High-resolution agarose gel electrophoresis of the cryoglobulins of a Sjögren's syndrome patient reveals a monoclonal band (A). Immunofixation, using anti-human k, l light and a, g, μ heavy chains, identified the monoclonal bands as an IgM-k monoclonal immunoglobulin (B, C, and D).

Schmidt *et al*. (1982) suggested that the benign lymphoepithelial lesion of salivary glands in Sjögren's syndrome, which has areas of confluent lymphoid proliferation and contains plasma cells that have monoclonal IgM-k immunoglobulins in their cytoplasm, represents an ' *in situ*' malignant lymphoma. This suggestion was further substantiated by immunogenotypic and immunophenotypic studies (Fishleder *et al*. 1987; Moutsopoulos *et al*. 1990), which showed that in the lymphoepithelial lesion there were rearrangements of oligo- or monoclonal immunoglobulin genes. In one study, three patients with benign lymphoepithelial lesion developed non-Hodgkin's lymphoma 2 to 8 years after the initial biopsy (Freimark *et al*. 1989). The presence of circulating monoclonal immunoglobulins is associated with a monoclonal B-cell expansion in the salivary glands. This has been demonstrated by a peroxidase–antiperoxidase bridge technique for the detection of intracytoplasmic immunoglobulins in the salivary lymphocytic infiltrates. Seven of 12 patients with Sjögren's syndrome with cryoprecipitable IgM-k monoclonal immunoglobulins had a predominance of k-positive plasma cells in the minor salivary glands, while patients without cryoglobulins or with polyclonal cryoglobulins had almost equal numbers of k- and l-positive cells (Moutsopoulos *et al*. 1990).

Monoclonal rheumatoid factors share cross-reactive idiotypes. Monoclonal rheumatoid factors from patients with Waldenström's macroglobulinaemia have been divided into three groups (Wa, Po, and Bla) (Kunkel et al.1973; Agnello *et al*. 1980). The light chains of the monoclonal rheumatoid factor that reacted with anti-Wa antibodies belong to the V_{IIIb} subgroup (Kipps *et al*. 1987). The 17.109 monoclonal antibody reacted with half of the monoclonal rheumatoid factors. The 17.109 idiotype is associated with the expression of the Humkv325 germ-line gene (Kipps *et al*. 1989). Cross-reactive idiotypes are shared by rheumatoid factors from autoimmune diseases. Some of them are shared by patients with Sjögren's syndrome and rheumatoid arthritis, while others (such as 17.109), have been found only in rheumatoid factors from patients with Sjögren's syndrome (Fox *et al*. 1986b). In fact, 12 out of 15 monoclonal rheumatoid factors from patients with Sjögren's syndrome reacted with the 17.109 monoclonal antibody. Furthermore, B cells containing immunoglobulin, bearing the 17.109 idiotype, were detected in the salivary gland biopsies of 11 out of 12 patients with Sjögren's. Further analysis of the B cells bearing the 17.109 idiotype in the salivary glands of patients with primary Sjögren's syndrome has shown that these are of multiclonal origin, in which somatic mutations accumulate in a non-random fashion, strongly suggesting an antigen- or T-cell-driven process in the expansion of these cells (Kipps *et al*. 1989). Two-thirds of patients with primary Sjögren's share a common idiotype, detected with a polyclonal anti-idiotype antibody directed against an IgM-k monoclonal rheumatoid factor from patients with Sjögren's syndrome. The presence of this idiotype is correlated with extraglandular manifestations, autoantibodies, and monoclonal immunoglobulins (Katsikis *et al*. 1990).

Comparative studies of three cross-reactive idiotypes in patients with primary Sjögren's syndrome have shown that these are expressed very early in the clinical spectrum of the syndrome and that their prevalence increases as the disease evolves. The presence of 17.109 and G6 (a VH1-associated cross-reactive idiotype), were found mainly in patients with Sjögren's syndrome with lymphoma, suggesting that these idiotypic determinants may serve as markers for lymphoma development in the syndrome (Tzioufas *et al*. 1996).

Lymphocyte studies

Peripheral blood lymphocytes

The absolute number of the total lymphocytes as well as T and B cells in peripheral blood does not differ substantially from that observed in normal individuals. Studies of T-lymphocyte subsets in Sjögren's syndrome were inconclusive (Fauci and Moutsopoulos 1981). Although decreased numbers of CD4+ and CD8+ T cells have been reported, this finding has not been substantiated by other investigators (Moutsopoulos and Manoussakis 1989). Peripheral blood B lymphocytes from patients with Sjögren's syndrome and normal controls, unlike lymphocytes from patients with systemic lupus, did not spontaneously secrete increased amounts of immunoglobulins. Thus, the activated B cells in patients with systemic lupus are distributed widely but in patients with Sjögren's syndrome they are probably localized to, and infiltrate, organs such as the minor labial salivary glands or the spleen.

Tissue lymphocytes

During the 1970s there some efforts were made to determine the composition of the lymphocytic infiltrates in the salivary glands but the results were controversial (Moutsopoulos and Talal 1987).

The application of molecular biological techniques, including the use of monoclonal antibodies and nucleic acid probes, heralded a more precise understanding of the immunopathological lesion in the exocrine glands of patients with Sjögren's syndrome. Several studies using monoclonal antibodies against specific lymphocyte markers have evaluated the composition of round-cell infiltrates in the labial salivary glands of primary Sjögren's syndrome. It was shown that the majority of the infiltrating lymphocytes are T cells, while B lymphocytes constitute 20 to 25 per cent of the round cells. Monocytes, macrophages, as well as natural killer cells, are less that 5 per cent (Moutsopoulos and Talal 1987). Studies of T-lymphocyte subpopulations have shown that 60 to 70 per cent of the T lymphocytes bear the CD4 phenotype and that the majority of them exhibit the memory/inducer marker (CD45 Ro). Almost all infiltrating T cells express the a T-cell receptor (**TCR**) (Skopouli *et al*. 1991). Analysis of the receptor repertoire of the infiltrating T lymphocytes from minor salivary-gland biopsies of patients with Sjögren's syndrome by a quantitative

polymerase chain reaction revealed that the repertoire of the *TCR V* gene was not restricted, although V_{b2} and V_{b13} were predominantly expressed in the inflammatory infiltrates (Sumida *et al*. 1992). Interestingly, V_{b2}- and V_{b13}-positive T cells can be stimulated by minor lymphocyte determinants of bacterial toxins, the so-called superantigens (Kappler *et al*. 1989). Thus, exposure to these molecules (e.g. after a bacterial infection) may lead to the stimulation and expansion of T cells expressing these two genes. In this regard, the junctional sequences of cDNA encoding the V_{b2} and V_{b13} genes of TCR from T lymphocytes infiltrating the minor salivary glands of patients with Sjögren's syndrome were investigated (Yonaha *et al*. 1992). Despite the fact that V_{b2}- and V_{b13}-positive T cells were polyclonal, the junctional usage was found to be restricted, supporting the notion that autoreactive T cells that contribute to the immunopathological lesion in Sjögren's syndrome are of oligoclonal origin.

The activation status of T cells was evaluated by searching for membrane expression of HLA class II molecules, interleukin-2 (**IL-2**) receptor (**r**), the lymphocyte function-associated antigen 1, and IL-2 production (Moutsopoulos and Talal 1987 ; Skopouli *et al*. 1991). Although none of the tissue lymphocytes was positive for IL-2 and IL-2r when monoclonal antibodies were used, studies using *in situ* hybridization with oligonucleotide mRNA probes demonstrated both IL-2 and its receptor in the infiltrating lymphocytes of the labial salivary glands of patients with primary Sjögren's syndrome (Boumba *et al*. 1995).

B lymphocytes infiltrating the labial salivary glands are activated, since they are able to produce increased amount of immunoglobulins with autoantibody activity (Anderson *et al*. 1972). In addition, evaluation with an immunoperoxidase technique of the isotypes of intracytoplasmic immunoglobulins of the plasma cells infiltrating the salivary glands of patients with Sjögren's syndrome showed that the IgG and IgM isotype predominates, in contrast to the plasma cells of the normal salivary glands, where the IgA isotype is dominant (Lane *et al*. 1983). This observation prompted some investigators to support the notion that quantitation of cells containing IgA and IgG intracytoplasmic immunoglobulins may serve as diagnostic criterion with high specificity and sensitivity for Sjögren's syndrome (Bodeuitsch *et al*. 1992).

B-cell activation is one of the most prominent immunoregulatory aberrations in patients with Sjögren's syndrome. This aberration can follow various stages of evolution. It begins as polyclonal activation, evolves to polyclonal–oligoclonal–monoclonal activation, and ends up as malignant monoclonal proliferation.

Immunopathology

As clearly shown in the previous sections, both the B and the T lymphocytes that contribute to the tissue lesion of primary Sjögren's syndrome are activated. This is of particular interest since the classic antigen-presenting cells, monocytes/macrophages, are poorly represented in this lesion. These findings suggest that possibly another cell may play the part of the antigen presenter in the immunopathological lesion of Sjögren's syndrome. Several recent studies suggest that the glandular or acinar epithelial cells may be play that part; these are summarized in the following list.

1. Histopathological studies in newly diagnosed cases of Sjögren's syndrome reveal that the focal lymphocytic infiltrates start around the ducts.
2. Staining of the labial salivary glands with anticlass-II HLA monoclonal antibodies showed that the ductal and acinar epithelial cells inappropriately express these molecules (Skopouli *et al*. 1991). Interferon-g and tumour necrosis factor-a have been shown to up-regulate the expression of both histocompatibility antigen classes on the surface of epithelial and other cells. These cytokines are produced locally by the activated T cell. Therefore it is not known whether the HLA-DR expression and possible antigen presentation by epithelial cells predates, or is a consequence of, the lymphocytic infiltration.
3. Studies on the expression of proto-oncogene mRNA in the minor salivary glands of patients with Sjögren's syndrome revealed that c- *myc*, in contrast to c-*fos* and c-*jun*, is selectively expressed by the epithelial glandular cells (Skopouli *et al*. 1992). Since the expression of the c-*myc* is so restricted, this phenomenon cannot be attributed to microenvironmental factors. The expression of HLA class II antigen and c- *myc* by epithelial cells may indicate a specific way of activating these cells.
4. Acinar epithelial cells coexpress accessory adhesion molecules and autoantigens, which in conjunction with the expression of class II antigen may potentially prime an autoimmune response. In fact, translocation and membrane localization of the nuclear antigen La/SSB has been observed in conjunctival epithelial cells of patients with Sjögren's syndrome (Yannopoulos *et al*. 1992). In addition, the infiltrating lymphocytes express a diverse array of cell adhesion molecules (lymphocyte function-associated antigen 1 and 3, CD2), while the intercellular adhesion molecule 1 was expressed on acinar epithelial cells adjacent to sites of intense inflammation (St Clair *et al*. 1992).
5. In recent years, cytokine production in the immunopathological lesion of Sjögren's syndrome has been studied extensively by *in situ* hybridization and reverse-transcriptase, quantitative, polymerase chain reaction (Fox *et al*. 1994; Boumba *et al*. 1995). Both techniques demonstrated the presence of proinflammatory cytokines IL-1 and IL-6 in the labial salivary glands of patients with Sjögren's syndrome. These cytokines were produced by both infiltrating and epithelial cells, which reinforces the concept that epithelial cells are active counterparts in the inflammatory response rather than targets of the immune-mediated injury.

Pathology

The common finding in all affected organs in patients with Sjögren's syndrome is a potentially progressive lymphocytic infiltration. These infiltrates cause functional disability of the affected organs, producing the various clinical manifestations.

So far, the salivary glands are the best-studied organs, because (i) they are affected in almost all patients and (ii) they are readily accessible. Microscopic examination of the enlarged major salivary glands reveals a benign lymphoepithelial lesion, characterized by lymphocytic replacement of the salivary epithelium and the presence of epimyoepithelial islands, which are composed of keratin-containing epithelial cells. Sometimes, the salivary gland biopsy does not show benign lymphoepithelial lesions, but instead contains various degrees of focal lymphocytic infiltration [defined as focal aggregates of 50 or more lymphocytes and histiocytes (Daniels *et al*. 1987)]. It is not known whether the focal lymphocytic infiltration is a precursor of the benign lymphoepithelial lesion.

The need for a practical and easy way to assess the salivary component of Sjögren's syndrome led to the introduction of labial gland biopsy. The histopathological characteristics of the biopsy of the minor salivary glands include (i) focal aggregates of at least 50 lymphocytes/plasma cells and macrophages, adjacent to and replacing the normal acini, and (ii) the consistent presence of these foci in all or most of the glands in the specimen (Fig. 2). Larger foci often show the formation of germinal centres but epimyoepithelial islands are very uncommon. These pathological lesion are, in fact, typical findings for a chronic lymphocytic sialadenitis (Batsakis and Howard 1982). However, a biopsy of minor salivary glands can be very specific for Sjögren's syndrome if it is obtained through normal-appearing mucosa, includes 5 to 10 glands, separated from the surrounding connective tissue, and shows focal lymphocytic infiltrates in all or most of the glands in the specimen, with a focus score above a chosen diagnostic threshold. Therefore, several methods of scoring the number of foci have been applied. Chisholm and Mason (1968) used a semiquantitative method to assess inflammation in salivary gland biopsies from 40 patients with several autoimmune diseases; only in patients with Sjögren's syndrome was there more than one focus of lymphocytes per 4 mm^2 of gland. Using a modification of this method, Greenspan *et al*. (1974) enumerated scores from 1 to 12 foci/4 mm^2 and found a significant positive correlation between a higher score and larger foci in biopsies of minor salivary glands of patients with Sjögren's syndrome. In another study, grading of 86 biopsies from primary and secondary Sjögren's syndrome showed, by qualitative criteria, larger lymphocytic foci in the primary syndrome (Tarpley *et al*. 1974). Biopsies from labial and sublingual salivary glands have been compared: there was a better correlation between infiltration of the ductal structure and the focus score in the sublingual glands (Pennec *et al*. 1990).

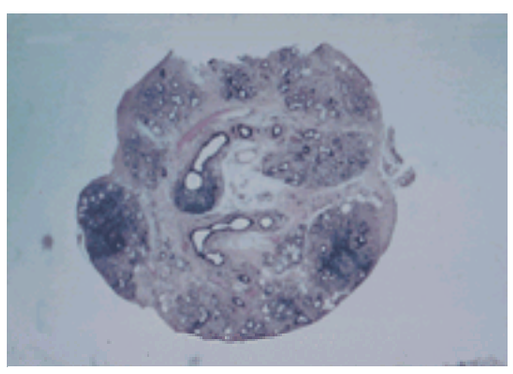

Fig. 2 Minor salivary gland biopsy of a patient with Sjögren's syndrome, showing moderate and large focal lymphocytic infiltrates around the acini and ducts.

In a recent study, comparison of patterns in the minor salivary gland biopsy taken from 618 patients with keratoconjunctivitis sicca and suspected Sjögren's syndrome showed that suspected Sjögren's syndrome was better associated with focal lymphocytic sialadenitis rather than chronic sialadenitis or even xerostomia (Daniels and Whitcher 1994).

Although there is no perfect diagnostic criterion for the salivary component of Sjögren's syndrome, the finding of the characteristic focal sialadenitis in biopsies of minor salivary glands is the best single criterion in terms of its disease specificity, convenience, availability, and low risk.

Animal models

There are several animals in which clinical manifestations resembling Sjögren's syndrome can be experimentally or spontaneously induced. Experimental models of sialoadenitis have been produced in rats, guinea-pigs, and mice using salivary gland extracts, adjuvants, and allogeneic antisera (Hoffman and Walker 1987). Infection of rats with a specific coronavirus results in swelling of the neck and ophthalmic lesions (Innes and Stanton 1961). Several days after exposure, the affected rats present with necrosis of ductal epithelial cells and infiltrates consisting of histiocytes, lymphocytes, and polymorphonuclear leucocytes. These findings are more prominent in lacrimal glands; submaxillary and parotid salivary glands are less commonly affected. Viral particles can be found by electron microscopy in ductal epithelial cells.

Spontaneously induced disease with features resembling those of human Sjögren's syndrome has been recognized in autoimmune strains of mice that develop a lupus-like syndrome. These include the NZB, NZB/NZW, and MRL/1pr, MRL/n (lacking the *lpr* gene) strains. All experimental animals have various degrees of lymphoplasmacytic infiltration in the lacrimal and salivary glands, with the milder form in the NZB mice and the more severe form in the MRL/n mice. Antibodies to Ro(SSA) and/or La(SSB) autoantigens were not detected in their sera.

Other experimental models of 'Sjögren's-like disease' include the canine keratoconjunctivitis sicca and the chicken dysgammaglobulinaemia that is associated with Coombs'-positive haemolytic anaemia, cryoglobulins, rheumatoid factor and infiltration of several parenchymal organs with mononuclear cells (Hoffman and Walker 1987).

In the last few years, the lymphoproliferation in Sjögren's syndrome has been studied in **SCID** (severe combined immunodeficient) mice. The CB17 scid/scid mice are born with severe combined immunodeficiency, lacking mature T and B lymphocytes. Injection of peripheral blood mononuclear cells from anti-La(SSB)-positive patients with Sjögren's syndrome into these mice resulted in the development of lymphoid infiltrates in several tissues consistent with disseminated lymphoid neoplasia (Whittingham *et al*. 1991).

In another study, after implantation of minor salivary gland biopsies under the kidney capsules of SCID mice, the proportion of human CD4+ T cells gradually decreased while the number of CD19+ B cells increased. The animals died after 6 to 12 weeks with human lymphoid tumours (Kang *et al*. 1991). These results suggest that, in an immunoincompetent environment, B cells of patients with Sjögren's syndrome tend to proliferate and develop malignancy.

Clinical picture

Sjögren's syndrome can occur alone (primary) or in association with other autoimmune diseases (secondary). In most patients the primary syndrome runs a rather slow and benign course. The initial manifestation can be non-specific (Table 3) and usually 8 to 10 years elapse from the initial symptoms to the full-blown development of the syndrome (Pavlidis *et al*. 1982).

	n	%
Sicca manifestations:		
Subjective xerophthalmia	63	47.0
Subjective xerostomia	56	42.5
Parotid gland enlargement	24	24.0
Dyspareunia	7	5.0
Fever/fatigue	13	10.0
Arthralgias, arthritis	37	28.0
Raynaud's phenomenon	28	21.0
Lung involvement	2	1.5
Kidney involvement	2	1.5

Table 3 Initial manifestations of primary Sjögren's syndrome (data from 132 Greek patients with Sjögren's syndrome)

Glandular manifestations

Oral component

Symptoms and signs

The principal oral symptom of Sjögren's syndrome is dryness (xerostomia). Patients describe this as difficulty in swallowing dry food, inability to speak continuously, changes in sense sensation, a burning sensation, an increase in dental caries (Fig. 3), and problems in wearing complete dentures. Examination shows a dry, erythematou **s**, sticky oral mucosa and often dental caries, while saliva from the major glands is either not expressible or is cloudy. Atrophy of the filiform papillae of the tongue is apparent (Fig. 4) and in some cases overgrowth of *Candida* is observed.

Fig. 3 Dental caries in Sjögren's syndrome; note also the remarkable periodontitis in both lower and upper teeth.

Fig. 4 Dry tongue of a patient with Sjögren's syndrome. Note the remarkable atrophy of filiform papillae.

Enlargement of the parotids or other major salivary glands occurs in two-thirds of patients with the primary syndrome, but is uncommon in those with Sjögren's syndrome and rheumatoid arthritis (see below). In many patients the salivary gland enlargement is episodic, but some have chronic enlargement. The swelling of the parotids may begin unilaterally but often becomes bilateral (Fig. 5). In Table 4, conditions other than Sjögren's syndrome causing parotid enlargement are depicted.

Fig. 5 Bilateral parotid-gland enlargement in a 65-year-old patient with Sjögren's syndrome.

Unilateral
Salivary gland neoplasm
Bacterial infection
Chronic sialadenitis
Bilateral
Viral infection (mumps, influenza, Epstein–Barr, coxsackie A, cytomegalovirus, HIV)
Sjögren's syndrome
Sarcoidosis
Miscellaneous (diabetes mellitus, hyperlipoproteinaemia, hepatic cirrhosis, chronic pancreatitis, acromegaly, gonadal hypofunction)
Recurrent parotitis of childhood

Table 4 Differential diagnosis of parotid gland enlargement

Diagnosis

A variety of medical conditions other than Sjögren's syndrome can cause xerostomia (Table 5). To evaluate the oral component of the syndrome, various tests are used with different specificity and sensitivity for the disease.

Drugs:
Psychotherapeutic
Parasympatholytic
Antihypertensive
Viral infections
Dehydration:
Diabetes mellitus
Trauma
Psychogenic
Irradiation
Congenital (absent or malformed glands)

Table 5 Causes of xerostomia

Sialometry

Salivary flow rates can be measured clinically for whole saliva or for separate secretions from the parotid or submandibular and sublingual glands, with or without stimulation. Patients with clinically overt Sjögren's syndrome have reduced flow. However, flow rates depend on many factors such as age, sex, medication, and time of day. Therefore, setting a cut-off point between the normal and abnormal is difficult because of the wide range of flow rates among normal individuals (Skopouli *et al*. 1989).

Sialography

This is a radiocontrast method of assessing anatomical changes in the salivary ductal system. It has been widely used in patients with Sjögren's syndrome, in whom various degrees of sialectasis have been found (Fig. 6). Sialography with oil-based contrast material shows an increased incidence of sialectasis in these patients (Daniels *et al*. 1987). However, sialography causes pain and swelling of the parotid glands and sometimes allergic reactions to the radiopaque material. In addition, some have suggested that sialography is insensitive and non-specific (Moutsopoulos and Talal 1989). However, Vitali *et al*. (1988) described sialography with water-soluble media in 84 patients with primary and secondary Sjögren's syndrome and compared it with the findings of minor salivary gland biopsy, as well as with the patients' clinical and the serological picture. They reported that sialography was as sensitive and specific as the biopsy. Furthermore, hypergammaglobulinaemia, anti-Ro(SSA) antibodies, extraglandular manifestations, and parotid swelling were all correlated with both sialographic and histological abnormalities, suggesting that

both tests are necessary for the evaluation of salivary gland involvement in Sjögren's syndrome.

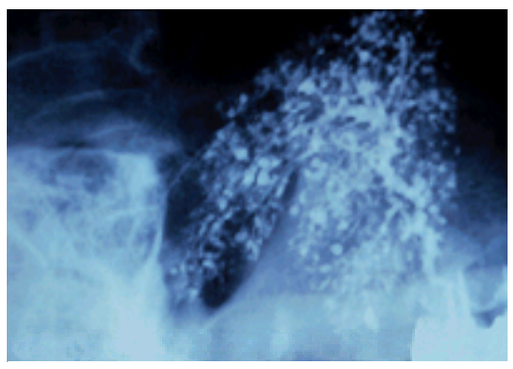

Fig. 6 Sialography of the parotid gland of a patient with Sjögren's syndrome. The retention of the sialographic medium at the end-points of the duct system reveals several degrees of sialectasis.

Scintigraphy

Isotope scanning provides a functional evaluation of all the salivary glands by observing the rate and density of uptake of the [$^{99}Tc^{m}$]pertechnetate and the time taken for it to appear in the mouth during a 60-min period after intravenous injection. In patients with Sjögren's syndrome the uptake of the label by the glands and the secretion of labelled saliva is delayed or absent. An abnormal scan was found to correlate with the presence of reduced salivary flow, the sialographic picture, and the intensity of lymphocytic infiltrates in minor salivary glands (Daniels *et al*. 1987).

In a study of 320 patients with oral dryness who had primary or secondary Sjögren's syndrome, graft-versus-host disease and other autoimmune diseases, scanning had high sensitivity but no well-established disease specificity (Parrago *et al*. 1987).

Sialochemistry

Chemical and immunological factors in saliva of patients with Sjögren's syndrome have been examined extensively in the past. So far, the results are conflicting and controversial (Baum and Fox 1987), offering very limited diagnostic value.

Ocular component

Ocular involvement is a major glandular manifestation of Sjögren's syndrome. Diminished secretion of tears leads to the destruction of the corneal and bulbar conjunctival epithelium termed keratoconjunctivitis sicca. The patients usually complain of a burning, foreign-body sensation, a sandy or scratchy sensation under the lids, itchiness, redness, and photosensitivity. Clinical signs include dilation of the bulbar conjunctival vessels, pericorneal injection, irregularity of the corneal image, and sometimes enlargement of the lacrimal glands. All tests for the evaluation of this condition are very sensitive but not specific for Sjögren's syndrome, as keratoconjunctivitis sicca may occur in a number of other conditions.

The Schirmer's test is used for the evaluation of tear secretion. The test is made with strips of filter paper 30 mm in length. The strip is slipped beneath the inferior lid, with the remainder of the paper hanging out (Fig. 8). After 5 min the length of paper wetted is measured. Wetting of less than 5 mm is a strong indication of diminished secretion. The presence of decreased tear secretion is not diagnostic of keratoconjunctivitis sicca. In contrast, it can easily be diagnosed using rose bengal staining. Rose bengal is an aniline compound that stains the devitalized or damaged epithelium of both the cornea and conjunctiva. Slit-lamp examination after rose bengal staining shows a punctate pattern of filamentary keratitis (Fig. 8).

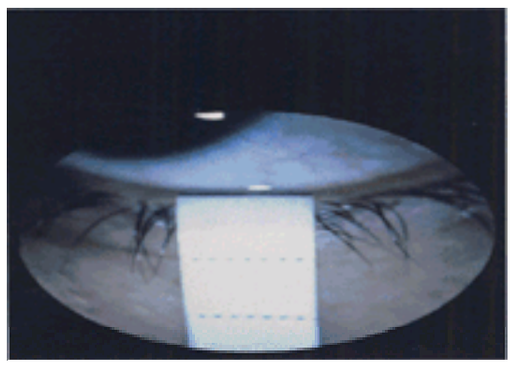

Fig. 7 The Schirmer's test in a patient with Sjögren's syndrome: the filter-paper strip is slipped under the lid, with part hanging out; the length of paper wetted, measured after 5 min, is less than 5 mm in this case.

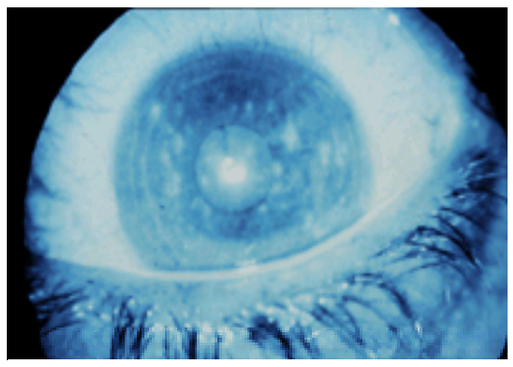

Fig. 8 Slit-lamp examination of the eye of a patient with Sjögren's syndrome after rose bengal staining. The retention of the stain in the corneal conjunctiva shows damaged epithelium and filaments, which are diagnostic of keratoconjunctivitis sicca.

The break-up time of tears is another useful measure. A drop of fluoroscein is instilled in the eye and the time between the last blink and appearance of dark, non-fluorescent areas in the tear film is measured. An overly rapid break-up of the tear film indicates an abnormality of either the mucin or the lipid layer (Kincaid 1987).

Systemic (extraglandular) manifestations

Extraglandular (systemic) manifestations are seen in one-third of patients with primary Sjögren's syndrome (Moutsopoulos *et al*. 1980) (Table 6). These patients complain most often of being easily fatigued, of low-grade fever, and of myalgias and arthralgias.

Clinical manifestation	*n*	%
Arthralgias/arthritis	79	60
Raynaud's phenomenon	49	37
Lymphadenopathy	19	14
Vasculitis	15	11
Lung involvement	18	14
Kidney involvement	12	9
Liver involvement	8	6
Splenomegaly	4	3
Peripheral neuropathy	3	2
Myositis	1	1
Lymphoma	0	0

Table 6 Incidence of extraglandular manifestations in primary Sjögren's syndrome (data from 132 Greek patients)

Arthritis

Seventy per cent of patients with primary Sjögren's syndrome experience an episode or episodes of arthritis during the course of their disease. In some cases it can precede the sicca manifestations. Joint symptoms and signs include arthralgias, myalgias, morning stiffness, intermittent synovitis, and chronic polyarthritis that sometimes lead to Jacoub's arthropathy (Maini 1987). In contrast to rheumatoid arthritis, radiographs of the hand usually do not reveal pathological changes (Castro-Poltronieri and Alarcon-Segovia 1983; Tsampoulas *et al*. 1990).

Raynaud's phenomenon

This occurs in 35 per cent of patients with primary Sjögren's and usually precedes sicca manifestations by many years. Patients with the primary syndrome and Raynaud's phenomenon present with swollen hands, but, in contrast to those with scleroderma, they do not experience digital ulcers and telangiectasias are not seen. Radiographs of the hands of these patients may show small tissue calcifications (Skopouli *et al*. 1990). Non-erosive arthritis has also been shown to be significantly more frequent in patients with Raynaud's phenomenon than in those without (Youinou *et al*. 1990a).

Skin involvement

Cutaneous lesions are seen frequently in patients with primary Sjögren's syndrome. Patients with dry skin complain of dermal stinging and itching. Nasal dryness with crusting, vaginal dryness syndrome with dyspareunia, and cheilitis have also been described. Other cutaneous manifestations include skin hyper- or hypopigmentation, patchy alopecia, and hypersensitivity vasculitis (Fye and Talal 1984). Some patients with Sjögren's syndrome may present with annular erythema affecting mainly the face and the trunk; it extends centrifugally and fades without leaving pigmentation (Teramoto *et al*. 1989).

Pulmonary involvement

Manifestations from the trachea to the pleura have been described in patients with Sjögren's syndrome. These are frequent but rarely important clinically. They can present with a range of symptoms from dry cough secondary to dryness of the tracheobronchial mucosa (xerotrachea) to dyspnoea from interstitial disease or even airway obstruction (Constantopoulos and Moutsopoulos 1987).

Interstitial lung disease in Sjögren's syndrome was thought to be a very common manifestation, since chest radiographs revealed an interstitial pattern in approximately half of patients with Sjögren's syndrome studied. High-resolution CT scanning of the lungs performed in 21 patients with the most prominent abnormalities, however, demonstrated that in 14 patients the main findings were either thickened bronchial walls at the segmental level or a mild interstitial pattern distributed around the bronchi. Transbronchial biopsy performed in 12 of these patients disclosed bronchiolar lymphoid infiltrates and follicular bronchiolitis (bronchus-associated lymphoid tissue hyperplasia). Fibrosing alveolitis was absent from all tissue specimens (Papiris *et al*. 1994).

Pseudolymphoma or frank lymphoma should always be suspected when lung nodules or hilar and/or mediastinal lymphadenopathy are found on chest radiographs (Constantopoulos and Moutsopoulos 1987).

There are differences in respiratory manifestations between the primary and secondary syndrome. In the latter, the respiratory involvement is a reflection of the primary rheumatic disorders. In fact, pleural effusions are usually found in Sjögren's syndrome associated with other rheumatic disorders and not in the primary syndrome.

Gastrointestinal and hepatobiliary features

Patients with Sjögren's syndrome often complain of dysphagia, owing to dryness of the pharynx and oesophagus, or to abnormal oesophageal motility. Nausea and epigastric pain are also common complaints. Biopsies of gastric mucosa show chronic atrophic gastritis and lymphocytic infiltrates (Buchanan *et al*. 1966), similar to those described in minor salivary glands. In addition, patients with Sjögren's syndrome have hypopepsinogenaemia, an elevated serum gastrin, low serum vitamin B_{12}, and antibodies to parietal cells (Trevino *et al*. 1987).

Acute or chronic pancreatitis has been reported rarely. In contrast, subclinical pancreatic involvement is a rather common finding, as illustrated by the fact that hyperamylasaemia is found in one-quarter of patients with the syndrome (Tsianos *et al*. 1984).

The prevalence and nature of liver involvement was studied in 300 patients with Sjögren's syndrome (Skopouli *et al*. 1994). Seven per cent had antimitochondrial antibodies and 5 per cent had elevated liver enzymes. Patients with antimitochondrial antibodies had elevated liver enzymes and no evidence of hepatitis B and C viral infection. Eleven out of 17 patients with antimitochondrial antibodies underwent liver biopsy. The histopathological picture disclosed in seven specimens was an 'autoimmune cholangiitis', that is a chronic granulomatous cholangiitis affecting small and medium-sized bile ducts and a mild periportal inflammation, without, however, evidence of 'piecemeal' necrosis (Fig. 9). These histological features are similar with those observed in stage I of primary biliary cirrhosis.

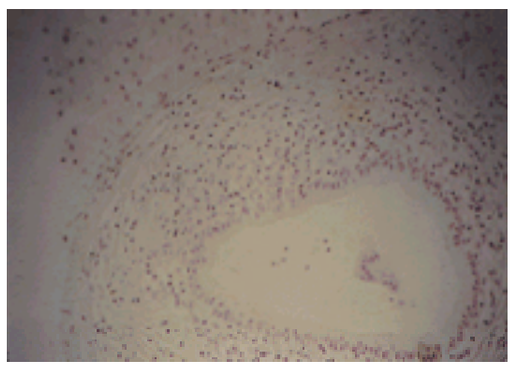

Fig. 9 Periportal inflammation in liver biopsy of a patient with Sjögren's syndrome.

There is also a high incidence of Sjögren's syndrome in patients with primary biliary cirrhosis: sicca manifestations have been described in approximately half of a group of patients with primary biliary cirrhosis; among these, 10 per cent had severe clinical features of dryness (Tsianos *et al*. 1990).

Renal involvement

Overt kidney disease is found in approximately 10 per cent of patients with Sjögren's syndrome (Kassan and Talal 1987), while approximately 35 per cent have an abnormal urine acidification test. Interstitial disease is the most common renal finding. Most of the patients present with hyposthenuria and hypokalaemic, hyperchloraemic distal tubular acidosis. Distal tubular acidosis can be silent or can present with recurrent renal colic and/or hypokalaemic muscular weakness. Untreated renal tubular acidosis leads to renal stones, nephrocalcinosis, and compromised renal function (Moutsopoulos *et al*. 1991) (Fig. 10). Less commonly, these patients have proximal tubular acidosis with Fanconi syndrome (Kassan and Talal 1987); renal biopsy reveals interstitial lymphocytic infiltration. Glomerunophritis in Sjögren's syndrome has been described in few patients (Moutsopoulos *et al*. 1978); the histological type may be membranous or membranoproliferative. In all cases a consistent serological finding was cryoglobulinaemia associated with hypocomplementaemia.

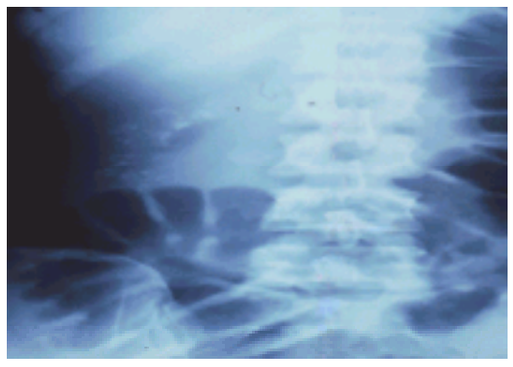

Fig. 10 Abdominal radiograph of a patient with Sjögren's syndrome reveals nephrocalcinosis of the right kidney.

Vasculitis

Vascular involvement is found in approximately 5 per cent of patients with Sjögren's syndrome. It affects small and medium-sized vessels. The most common manifestations are purpura (Fig. 11), recurrent urticaria, skin ulcerations, and mononeuritis multiplex. However, cases of systemic vasculitis with visceral involvement affecting kidney, lung, gastrointestinal tract, spleen, breast, and the reproductive tract have been described (Alexander 1987a; Tsokos *et al*. 1987). There are two histopathological types of vasculitis, according to the type of the infiltrating cell—the mononuclear and the neutrophil type. The latter is associated with hypergammaglobulinaemia, high titres of rheumatoid factor, antibodies to Ro(SSA) cellular antigen, and hypocomplementaemia (Alexander 1987a). In another classification of vascular involvement (Tsokos *et al*. 1987), the small-vessel vasculitis was of the hypersensitivity type, that is leucocytoclastic and lymphocytic, while the medium-vessel vasculitis was acute necrotizing and simulated polyarteritis nodosa but without the formation of aneurysms. Endarteritis obliterans was seen in patients with a long-standing history of vasculitis.

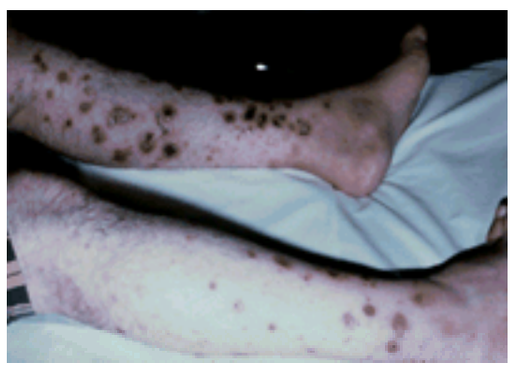

Fig. 11 The lower extremities of a patient with Sjögren's syndrome with hypergammaglobulinaemia and cryoglobulins show diffuse, palpable purpura.

Neuromuscular involvement

Neurological manifestations of Sjögren's syndrome include peripheral sensory or sensorimotor neuropathy as a consequence of vascular involvement. Cranial neuropathy, usually affecting single nerves such as the trigeminal or the optic, has been well documented. Involvement of the central nervous system in the syndrome is a matter of considerable controversy. Over the last decade some investigators have described a high proportion of such involvement, which before had been unrecognized internationally. They found that this disease was multifocal, recurrent, and progressive. The clinical signs included hemiparesis, hemisensory deficits, seizures, movement disorders, and transverse myelopathy. Some patients presented with diffuse brain injury expressed as encephalopathy, aseptic meningitis, and dementia (Alexander 1987b). On the other hand, others have failed to demonstrate severe central involvement in 55 patients with primary and 50 with secondary Sjögren's syndrome (Binder *et al*. 1988). Eighteen of these patients had mild neurological abnormalities confined to the secondary syndrome; all were characteristics of the underlying rheumatic disorders. A study of 63 consecutive patients with primary Sjögren's syndrome revealed that 17 had a mild sensory or sensorimotor neuropathy while one patient with past history of hypertension had had a mild episode (Andonopoulos *et al*. 1990a), suggesting that peripheral neuropathy is a rather common finding in Sjögren's syndrome whereas central nervous disease must be rare.

Many patients with the primary syndrome complain of myalgia, but muscle enzymes are usually normal or slightly elevated. Severe polymyositis with extensive necrosis of muscle fibres and invasion of macrophages into the affected muscle has been described in Sjögren's syndrome (Leroy *et al*. 1990). This kind of myositis seems to respond well to pulse cyclophosphamide therapy.

Other manifestations

Autoimmune thyroid disease has been described in some patients with primary Sjögren's syndrome. In a study by Karsh *et al*. (1980), half of the patients with Sjögren's syndrome presented with antithyroid antibodies and signs of altered thyroid function as evaluated by a basal thyroid-hormone stimulation test.

Sjögren's syndrome may also associated with interstitial cystitis (Van de Merwe *et al*. 1993), which is a non-bacterial disease of the bladder producing constant or intermittent, long-lasting symptoms, such frequent micturition, nocturia, and suprapubic or perineal pain. Bladder biopsy discloses intense inflammation in the mucosa and submucosa with lymphoid cells and mast cells. Lymphoid cell infiltrates contain CD4+ T cells as well as B-cell nodules with germinal centres. Detrusor fibrosis

can be seen in the later stages of the disease (Harrington *et al*. 1990).

Mild normochromic and normocytic anaemia is a common finding; leucopenia and thrombocytopenia are relatively rare features. An elevated erythrocyte sedimentation rate is found in approximately 70 per cent of patients (Moutsopoulos *et al*. 1980). In contrast, C-reactive protein is not detected in patients with primary Sjögren's syndrome but is found in those with Sjögren's syndrome and rheumatoid arthritis (Table 7) (Moutsopoulos *et al*. 1983b).

	n	%
Anaemia (Hb < 35)	27/130	21
Leucopenia (WBC < 3500 cells/mm³)	8/130	6
Thrombocytopenia (PLT < 10 000)	2/132	2
ESR (>25 mm/h)	76/125	61

Table 7 Laboratory findings in Greek patients with primary Sjögren's syndrome (data tabulated from 132 patients)

Lymphoproliferative disease

Patients with Sjögren's syndrome have a 44 times higher relative risk of developing lymphoma, compared with age-, sex-, and race-matched normal controls (Kassan *et al*. 1978). Immunohistological studies in biopsies of such patients with lymphoma show that these are primarily of B-cell origin, usually expressing IgM-k in their cytoplasm (Zulman *et al*. 1978). The lymphomas are of two major types, either of highly undifferentiated B cells or well-differentiated immunocytomas.

Lymphomas may differ by location and grading. In our patients, among eight lymphomas in patients with Sjögren's syndrome, six were low-grade immunocytomas and two intermediate-grade non-Hodgkin's lymphomas. Five of the immunocytomas were diagnosed from biopsies of minor salivary or lacrimal glands. Two of the patients with immunocytomas showed spontaneous regression, while the other two developed high-grade lymphoma 3 and 5 years later (Pavlidis *et al*. 1992). Therefore, the clinical picture of Sjögren's syndrome-associated lymphoma appears to be diverse, suggesting that the therapeutic approach should be guided by the stage and the grade of the disease.

Other organs that may be affected by the lymphomas are the reticuloendothelial system, lungs, kidneys, and the gastrointestinal tract.

The diagnostic interpretation of a tissue with lymphoproliferative infiltration is sometimes very difficult. The term pseudolymphoma describes lesions that show tumour-like clusters of lymphoid cells but do not meet criteria for malignancy. Despite the use of modern molecular techniques, such as immunogenotyping (Cleary *et al*. 1987), pseudolymphoma remains in ill-defined clinicopathological entity and lymphoma should always be suspected in a patient with lymphadenopathy, organomegaly, or enlargement of major salivary glands.

Secondary Sjögren's syndrome

The association of Sjögren's syndrome with rheumatoid arthritis was first described by Henrik Sjögren in 1939. During the following years it became evident that sicca manifestations can also be found in other autoimmune rheumatic diseases, such as systemic lupus erythematosus and progressive systemic sclerosis. In addition, manifestations of Sjögren's syndrome have been described in polymyositis, polyarteritis nodosa, and primary biliary cirrhosis (see Table 1) (Moutsopoulos *et al*. 1980).

The incidence of clinically overt Sjögren's syndrome in patients with rheumatoid arthritis is around 5 per cent. Using a special questionnaire, however, 20 per cent of patients with rheumatoid arthritis registered complaints of dry eyes and/or xerostomia (Andonopoulos *et al*. 1987). The diagnosis of rheumatoid arthritis usually preceded that of Sjögren's syndrome by many years. Patients with the arthritis and the syndrome usually present with keratoconjunctivitis sicca, while enlargement of the parotids or other major salivary glands is less common than in primary Sjögren's syndrome. In addition, extraglandular features of the primary syndrome, such as lymphadenopathy, renal involvement, and Raynaud's phenomenon, are uncommon in Sjögren's syndrome associated with rheumatoid arthritis. Such clear differences in the natural history and the clinical manifestations of the syndrome in the presence and absence of rheumatoid arthritis are not usually found in other autoimmune diseases associated with sicca manifestations. In fact, patients with primary Sjögren's syndrome and those with systemic lupus may have similar disease manifestations such as arthralgias, rash, peripheral neuropathy, and glomerulonephritis. These observations prompted Heaton (1959) to conclude that Sjögren's syndrome was a benign form of systemic lupus. The diagnosis is usually obtained histologically; approximately 20 per cent of patients with systemic lupus have lymphocytic infiltrates in biopsies from their minor salivary glands (Andonopoulos *et al*. 1990b).

Dry eyes and mouth are found in approximately 20 per cent of unselected patients with scleroderma (Medsger 1987). Subjective xerostomia could be due to fibrosis of the exocrine glands. In fact, in biopsies from minor salivary glands of 44 unselected patients with scleroderma, 38 per cent had fibrosis while only 22 per cent had lymphocytic infiltration compatible with Sjögren's syndrome (Andonopoulos *et al*. 1989).

Diagnosis and differential diagnosis

Since the initial definition and the proposed criteria of Sjögren's syndrome by Bloch *et al*. (1965), several sets of criteria have been used by different groups for the diagnosis of Sjögren's syndrome. As a result, patients with Sjögren's syndrome had often been missed at diagnosis, or classified incorrectly due both to the great variability at disease presentation and to the lack of well-defined and commonly accepted diagnostic criteria.

Recently, a prospective concerted action involving 26 centres in 12 European countries led to a study with the goal of obtaining validated criteria for the diagnosis of Sjögren's syndrome. The study resulted in: (i) the validation of a simple 6-item questionnaire for determination of dry eyes and mouth, useful in the initial screening for Sjögren's syndrome, and (ii) the definition of a new set of criteria for Sjögren's syndrome. The sensitivity and specificity of both questionnaire and diagnostic criteria were determined, exhibiting good discrimination between patients and controls. Hence, using this set of criteria, a general agreement can be reached on the diagnosis of Sjögren's syndrome (Vitali *et al*. 1992a).

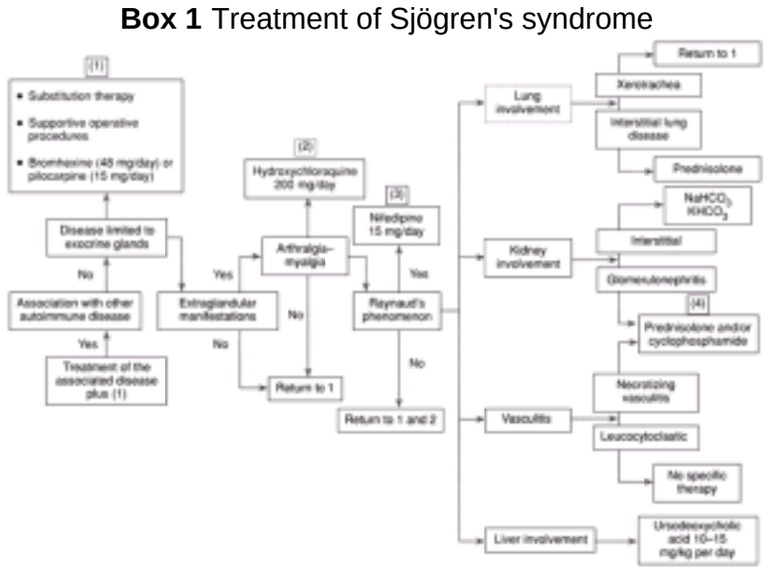
Differential diagnosis must be, of course, from other diseases responsible for dry eyes, xerostomia, and parotid enlargement. Sarcoidosis in one disease that can mimic the clinical picture of Sjögren's syndrome (Drosos *et al*. 1989). However, the biopsy of minor salivary glands reveals non-caseating granulomas in sarcoidosis, while there is a lack of autoantibodies to Ro(SSA) or La(SSB). Other medical conditions that can mimic the syndrome are lipoproteinaemias (types II, IV, and V), chronic graft-versus-host disease, amyloidosis, and, more recently, patients with human immunodeficiency virus (**HIV**) infection (Moutsopoulos and Talal 1989). In fact, sicca manifestations, with parotid enlargement, pulmonary involvement and lymphadenopathy, have been reported in 12 patients with HIV infection. These patients has an increased prevalence of HLA-DR5 alloantigen. The virus has been detected in lymphocytes from labial salivary glands in two of six patients with HIV infection, but the two diseases seem to be different, as patients with HIV infection have no autoantibodies to Ro(SSA) and La(SSB) autoantigens, and the lymphocytic infiltrates in their salivary glands are not as prominent as in Sjögren's syndrome and consist of CD8+ T cells (Youinou *et al*. 1990b).

Therapy—prognosis (Box 1)

Sjögren's syndrome is a chronic, multisystem disease. Therefore, patients with Sjögren's syndrome should be followed regularly for significant functional deterioration, signs of complications and significant changes in the course of the disease. The patient should be informed that regular outpatient visits, and close collaboration with

the outpatient clinics for rheumatology, ophthalmology, and oral medicine, give the most satisfactory results.

Box 1 Treatment of Sjögren's syndrome



Sicca manifestations are of unknown aetiology. Hence, treatment of Sjögren's syndrome is aimed at symptomatic relief and limiting the damaging local effects of chronic xerostomia and keratoconjunctivitis sicca by substitution of the missing secretions (Moutsopoulos and Vlachoyiannopoulos 1993).

Keratoconjunctivitis sicca is treated with fluid replacement supplied as often as necessary. To replace deficient tears, there are several readily available ophthalmic preparations (Tearisol; Liquifilm; 0.5 per cent methylcellulose; Hypo Tears). In severe cases, it may be necessary for patients to use these as often as every 30 min. If corneal ulceration is present, eye-patches and boric acid ointment are recommended. Certain drugs that may cause further deterioration of lacrimal and salivary function, such as diuretics, antihypertensive drugs and antidepressants, should be avoided. The low levels of humidity in air-conditioned environments, as well as windy or dry climates, must be avoided. Soft contact lenses may help to protect the cornea, especially in the presence of filaments. However, the lenses themselves require wetting and the patients must be followed very carefully due to the increased risk of infection.

Treatment of xerostomia is difficult. Stimulation of salivary flow by sugar-free, highly flavoured lozenges has been found to be rather helpful. Most patients carry water and use sugarless lemon drops or chewing-gum. These must be sugar free, because of the risk of rampant dental caries. Adequate oral hygiene after meals is essential for the prevention of dental disease. Topical oral treatment with fluoride enhances dental mineralization and retards damage to tooth surfaces. In rapidly progressive dental disease, fluoride can be directly applied to the teeth from plastic trays that are used at night. Propionic acid gels may be used to treat vaginal dryness. Bromhexine given orally at high doses (48 mg/day) has been suggested to improve sicca manifestations. However, frequent ingestion of fluids, particularly with meals, is often the best solution.

Pilocarpine hydrochloride (5 mg, three times daily) can also improve sicca manifestations, via its muscarinic, cholinergic activity (Fox 1992). Flushing and sweating are possible side-effects.

Patients with Sjögren's syndrome often complain of parotid gland swelling. If the gland becomes tender with permanent enlargement, infection should be ruled out and treatment with tetracycline orally should be recommended (500 mg, four times daily). Local moist heat and non-steroidal anti-inflammatory drugs are usually helpful in resolving this problem. If the gland remains tender, lymphoma should be ruled out by biopsy.

Preliminary studies showed that hydroxychloroquine, which is efficacious and safe in other autoimmune diseases, may be useful in treating Sjögren's patients. A dose of 200 mg/day partially corrects hypergammaglobulinaemia and decreases the titre of IgG antibodies to La/SSB antigen. Furthermore, hydroxychloroquine decreased the erythrocyte sedimentation rate and increased the haemoglobin (Fox *et al*. 1988).

Corticosteroids (prednisolone 0.5–1 mg/kg per day) or other immunosuppressive agents (i.e. cyclophosphamide) are indicated for the treatment of life-threatening extraglandular manifestations, particularly when renal or severe pulmonary involvement and systemic vasculitis are present.

In conclusion, Sjögren's syndrome remains an incurable disease without a single therapeutic approach that can change its natural course. The prognosis of the disease depends on the extension and type of the systemic features, and the appearance of a lymphoma. The treatment and prognosis of malignant lymphoma depends on the histological type, the location, and the extension. Decisions about chemotherapy and/or radiotherapy should be guided by experienced oncologists.

5.11.1 Classification of vasculitis

David G. I. Scott and Richard A. Watts

Introduction

Vasculitis means inflammation of blood vessels. Implicit in this definition is that the blood vessel is the primary site of inflammation. The blood vessel wall is thus infiltrated with inflammatory cells and perivascular cuffing does not equate with vasculitis. The consequence of such inflammation is often destruction of the vessel wall which is seen on histology as fibrinoid necrosis (Fig. 1). It is for this reason that many use the term 'necrotizing vasculitis'.

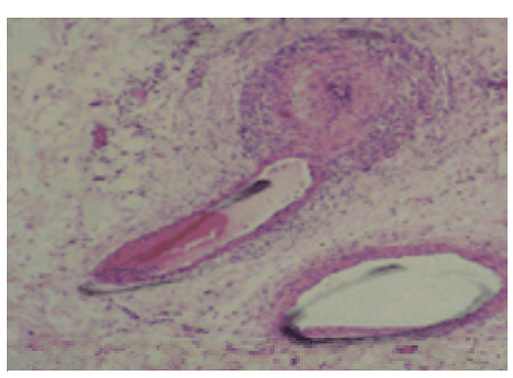

Fig. 1 Histology showing typical necrotizing vasculitis

The vasculitides are a heterogeneous group of relatively uncommon diseases which can arise *de novo* (e.g. polyarteritis nodosa, Wegener's granulomatosis) or as a secondary feature of an established clinical disease such as rheumatoid arthritis or systemic lupus erythematosus.

The consequences of such vascular inflammation depend upon the size, site, and the number of blood vessels involved. Vasculitis can occasionally be ocalized and clinically insignificant but more commonly is generalized and potentially life threatening, especially when small muscular arteries are involved. Muscular arteries may develop focal or segmental lesions. The former (affecting part of the vessel wall) may lead to aneurysm formation and possibly rupture; segmental lesions (affecting the whole circumference) are more common and lead to stenosis or occlusion with distal infarction. Haemorrhage or infarction of vital internal organs are the most serious problems of systemic vasculitis and explain the poor prognosis of untreated polyarteritis nodosa (Frohnert and Sheps 1967) or of arteritis complicating rheumatoid arthritis (Schmid *et al*. 1961; Bywaters and Scott 1963; Scott *et al*. 1981). Small vessel vasculitis, by contrast, most commonly affects the skin and rarely causes dysfunction of internal organs. Widespread small-vessel vasculitis may cause problems, especially in the kidney, when sufficient numbers of adjacent vessels are affected with significant release of inflammatory mediators or where overall perfusion is threatened.

Epidemiology

The epidemiology of the systemic vasculitides is documented poorly. Many studies have been from tertiary referral centres with the problems of referral bias and uncertainty of denominator population or have involved small populations. We have estimated the incidence of the major forms of systemic vasculitis in a stable, ethnically homogeneous population—the Norwich (United Kingdom) Health Authority (414 000 adults) over a 6-year period between 1988 and 1994 (Watts *et al*. 1995). The overall annual incidence of systemic vasculitis (excluding giant cell arteritis) was 38.6 per million (95 per cent confidence intervals 31.3 to 47.2). The commonest systemic vasculitides were systemic rheumatoid vasculitis—12.5 per million per year (95 per cent confidence intervals 8.5 to 17.7) and Wegener's granulomatosis—8.5 per million per year (95 per cent confidence intervals 5.2 to 12.9). Details of the incidence of this and the other commoner systemic vasculitides are shown in Table 1. These data suggest that the overall incidence of systemic vasculitis is significantly greater than previously thought (estimated at 10 per million per year). Whether this represents a genuine increased incidence with time or increased physician awareness, especially in association with the introduction of the antineutrophil cytoplasmic antibody (**ANCA**) test is uncertain.

	Number of patients	Annual incidence (per million; 95% confidence intervals)
Systemic rheumatoid vasculitis	31	12.5 (8.5–17.7)
Wegener's granulomatosis	21	8.5 (5.2–12.9)
Churg–Strauss syndrome	6	2.4 (0.9–5.3)
Microscopic polyangiitis	6	2.4 (0.9–5.3)
Henoch–Schönlein purpura	3	1.2 (0.3–3.5)
Systemic lupus erythematosus[a]	9	3.6 (1.7–6.9)
Miscellaneous[b]	8	
Unclassified	12	
Systemic vasculitis (overall)[c]	96	38.6 (31.3–47.2)

The adult population of the Norwich Health Authority is 414 000
[a]Arteritis diagnosed on clinical or histological evidence.
[b]Wegener, sarcoma, cryoglobulinaemia.
[c]Overall figure excludes giant cell arteritis and localized cutaneous vasculitis.

Table 1 Estimated annual incidence of the commoner vasculitides in the Norwich Health Authority, 1988 to 1994

Classification of vasculitis

Classification means distribution in classes or groups according to a method or system. Classification of vasculitis is confusing because of the considerable overlap between the different vasculitic syndromes and because the cause of the vasculitis is usually unknown.

Historical

Kussmaul and Maier (1866) are credited with the first description of 'periarteritis nodosa' in 1866 when they described a 'new disease' characterized by numerous nodules along the course of small muscular arteries. Earlier descriptions by Rokitansky (1852), Pelletan (1810), and possibly by Michaelis and Matani (1755) referenced by Lamb (1914), suggest that formal recording of the disease is at least 200 years old.

In the early part of the twentieth century there were large numbers of reports of vasculitis labelled as periarteritis nodosa, including patients with rheumatic fever (von Glahn and Pappenheimer 1926), hypersensitivity states in animals and man (Rich 1942; Rich and Gregory 1943), and most cases with histological evidence of vasculitis affecting any size of vessel, leading to considerable confusion.

In 1952, Zeek reviewed the literature relating to vasculitis and periarteritis nodosa and used the generic term 'necrotizing angiitis' to indicate the specific damage to the blood vessel wall rather than the presence of anti-inflammatory cells alone (see above); she classified these into five distinct entities: (i) hypersensitivity angiitis, (ii) allergic granulomatous angiitis, (iii) rheumatic arteritis, (iv) periarteritis nodosa, and (v) temporal arteritis. Almost all modern classifications are based on this system, which essentially combined histological changes and clinical features. Refinements included use of the term polyarteritis nodosa in the 1950s, the identification of patients with and without lung involvement (Rose and Spencer 1957), and the relationship between vasculitis and granuloma formation discussed by Alarcon-Segovia and Brown (1964) , who considered the vasculitides to represent 'a continuous spectrum of tissue changes ranging from pure necrosis and granuloma formation to pure angiitis'. Two notable omissions from Zeek's classification were Wegener's granulomatosis and Takayasu's arteritis; these were not fully described in the English literature until after 1953 (Lie 1988).

1970 to 1990

In the 1970s it was realized that there was a considerable overlap in the size of arteries involved (Gilliam and Smiley 1976). At this time Fauci advocated a classification scheme which, apart from including more conditions, also included Churg–Strauss syndrome in an overlapping group of systemic necrotizing vasculitides (Fauci *et al*. 1978).

During the 1980s, classification schemes developed based on the histopathological changes, in particular the size of the predominant vessel involved (e.g. Scott 1988; Lie 1988; Lie 1994). Lie also included a group of infectious vasculitides and vasculitis 'look-alikes'. The latter group includes atheroembolism which can present with clinical features very similar to polyarteritis nodosa. Furthermore he divided the vasculitides into primary and secondary vasculitis, that is vasculitis of unknown aetiology and that occurring secondary to either an infection or some other disease process, typically an autoimmune rheumatic disease.

Current classifications

In 1993 an international consensus conference was convened in Chapel Hill (**CHCC**) which developed definitions for the nomenclature of the systemic vasculitides based on clinical and laboratory features (Table 2) and a new classification scheme based on vessel size (Jeanette *et al*. 1994).

Table 2 Names and definitions of vasculitides adopted by the Chapel Hill Consensus Conference on the nomenclature of systemic vasculitis [a]

This and other current classification schemes have not addressed pathogenic mechanisms, in particular the relationship between ANCA and systemic vasculitis. Antibodies directed against proteinase 3 are associated strongly with Wegener's granulomatosis and those against myeloperoxidase with microscopic polyangiitis.

All previous studies required either histopathological or angiographic evidence of vasculitis. The increasing use of tests for ANCA, in particular, has resulted in some patients having a diagnosis of vasculitis made without biopsy or angiographic confirmation and this has resulted in changes in diagnostic emphasis. For example the increase in Wegener's granulomatosis seen in Leicester (United Kingdom) during the 1980s was attributed partly to increased diagnostic awareness following introduction of assays for ANCA (Andrews *et al*. 1990). If a classification system is to be useful then it should reflect aetiopathogenesis and/or approaches to treatment.

We feel that because of these developments the CHCC system is inadequate and we have developed a modification (Table 3) which reflects not only dominant vessel size but also ANCA (Scott and Watts 1994). Unlike the CHCC classification we have split Wegener's granulomatosis, Churg–Strauss syndrome, and microscopic polyangiitis from the rest because: (i) they often involve small arteries; (ii) they are diseases most commonly associated with ANCA; (iii) they are associated with a high risk of glomerulonephritis; and (iv) they are diseases which respond best to immunosuppresion with cyclophosphamide. The aetiology of these diseases is probably unrelated to immune complex formation, in contrast to pure small-vessel vasculitis such as Henoch–Schönlein purpura and essential mixed cryoglobulinaemia. Our classification also reflects broad therapeutic strategies (Table 4), with the medium and small vessel group responding best to immunosuppresion with cyclophosphamide in addition to corticosteroids, the large vessel group requiring moderate- to high-dose corticosteroids, usually alone, and the small vessel group only sometimes requiring corticosteroids at a low dose.

Dominant vessel involved	Primary	Secondary
Large arteries	Giant cell arteritis Takayasu's arteritis Isolated CNS angiitis	Arthritis associated with RA Infection (e.g. syphilis)
Medium arteries	Classical PAN Kawasaki disease	Infection (e.g. hepatitis B) Hairy cell leukaemia
Small vessels and medium arteries	Wegener's granulomatosis* Churg–Strauss syndrome* Microscopic polyangiitis*	Vasculitis 2° to RA, SLE, SS Drugs, malignancy Infection (e.g. HIV)
Small vessels (leucocytoclastic)	Henoch–Schönlein purpura Essential mixed cryoglobulinaemia Cutaneous leucocytoclastic angiitis	Drugs*, malignancy Infection (e.g. hepatitis B,C)

*Diseases most commonly associated with ANCA (antimyeloperoxidase and antiproteinase 3 antibodies), a significant risk of renal involvement, and which are most responsive to immunosuppression with cyclophosphamide.
†e.g. sulphonamides, penicillins, thiazide diuretics, and many others.
CNS, central nervous system; HIV, human immunodeficiency virus; PAN, polyarteritis nodosa; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SS, Sjögren's syndrome.
From Scott and Watts (1994).

Table 3 Classification of systemic vasculitis

Dominant vessel involved	Corticosteroids alone	Cyclophosphamide + corticosteroids	Others
Large arteries	+++	–	+
Medium arteries	+	++	++[a]
Small vessels and medium arteries	+	+++	–
Small vessels	+	–	++

[a]Includes plasmapheresis, antiviral therapy for hepatitis B associated vasculitis, and intravenous immunoglobulin for Kawasaki disease.
Reproduced from Scott and Watts (1994) with permission.

Table 4 Relationship between vessel size and response to treatment

Despite these developments in classification and definition of the vasculitides a number of problems still remain. There is still considerable overlap between the groups (Fig. 2). For example palpable purpura due to leucocytoclastic vasculitis of small vessels affects up to 20 per cent of patients with 'polyarteritis nodosa' as defined in studies by Cohan and Adu (Cohan *et al*. 1980; Adu *et al*. 1987), but the CHCC definition of polyarteritis nodosa specifically excludes such microscopic/small vessel involvement. Necrotizing arteritis can involve the temporal arteries, mimicking giant cell arteritis (Morgan and Harris 1978; Fraha and Abu-Haider 1979). Giant cell arteritis itself can affect smaller vessels in the breast (Potter *et al*. 1981) and mimic carcinoma, and also involve the posterior ciliary artery resulting in blindness. Classification should thus be based on dominant vessel size and not be over-restrictive. The CHCC classification has not received universal acceptance because of these problems (Lie 1994).

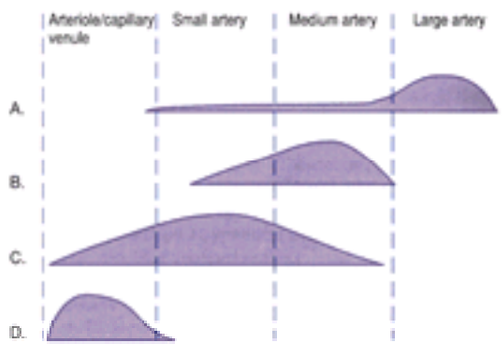

Fig. 2 Relationship between vessel size and classification.

Localized vasculitis produces particular problems in classification. It is important to exclude systemic symptoms and so confirm the benign nature of the vasculitis with long-term follow-up studies. Localized 'polyarteritis nodosa' has been described in a number of sites, including the gall bladder, uterus, and skin (Remigo and Zaino 1970; Borrie 1972; Diaz-Perez and Winkelmann 1974; Scott *et al*. 1982). Whether any of the described cases represents vasculitis truly localized to an individual vessel is debatable, but the lack of progression of cutaneous polyarteritis in long-term studies emphasizes that these cases should be classified and treated differently to their systemic counterparts.

The concept of localized giant-cell arteritis is more difficult. Most cases have arteritis restricted to the head and neck, but there are sporadic reports of giant cell arteritis at other sites, including the aorta, breast, and skin (Klein *et al*. 1975; Potter *et al*. 1981; Goldberg *et al*. 1987; Smith *et al*. 1988). The most convincing case of localized giant-cell arteritis was a mesenteric arteritis leading to bowel perforation; there was no evidence of giant cell arteritis at other sites and the patient remained well after surgery, requiring no drug therapy during an 18 month follow-up (Smith *et al*. 1988). Such cases stress the importance of the word 'systemic' in classification of arteritis, and the importance of detailed investigations, including histology, before embarking on potentially harmful drug treatment.

Rheumatoid vasculitis also causes problems with classification (see Table 3). A wide range of vessels may be involved, from digital capillaries to medium-sized arteries. Aortitis involving the aortic arch has been described in a few cases, so classification can involve all four groups. Aneurysms have been described rarely (indicating true involvement of medium-sized arteries) but we have seen arteritic changes on angiograms in four patients with severe systemic rheumatoid vasculitis.

Classification criteria for individual vasculitides

The American College of Rheumatology (**ACR**) has now published criteria for the classification of vasculitis (Fries *et al*. 1990). This series of papers describes 807 patients with seven different vasculitic diseases—polyarteritis nodosa, Wegener's granulomatosis, Churg–Strauss vasculitis, hypersensitivity vasculitis, Henoch–Schönlein purpura, giant cell arteritis and Takayasu's arteritis, seen in 48 medical centres in North America. These patients have been analysed to look for classification criteria for each specific disease; that is, those clinical findings that both identify the disease and separate it from others. The authors stress the classification criteria provide a standard way of evaluating and describing groups of patients in therapeutic, epidemiological, or other studies. A list of the proportion of patients in a group that fulfils the criteria gives considerable information about the clinical status of the patients included. The ACR criteria were presented in two forms: a traditional table and a tree format. The sensitivity and specificity rates varied considerably: 71.0 to 95.3 per cent for sensitivity and 78.7 to 99.7 per cent for specificity (Fries *et al*. 1990; Hunder *et al*. 1990). The most sensitive and specific criteria were found in Churg–Strauss syndrome, giant cell arteritis and Takayasu's arteritis; hypersensitivity vasculitis was the least well-defined condition. The criteria were not tested against the general population or against patients with other autoimmune rheumatic diseases or rheumatic conditions. These papers are important as for the first time they enable comparison of patients reported in an uniform manner—a problem which hitherto has bedevilled the study of vaculitis.

Polyarteritis nodosa and microscopic polyangiitis

Polyarteritis nodosa is a multisystem disease characterized by inflammation and necrosis of medium-sized muscular arteries leading to aneurysm formation and organ infarction (Kussmaul and Maier 1866). Davson in 1948 showed that in some patients who at autopsy had extrarenal vasculitis involving small and medium arteries, the

only detectable renal lesion was capillary inflammation (Davson *et al*. 1948). These patients have been said to have 'microscopic' polyarteritis. The main clinical feature in these patients is rapidly progressive renal failure. This is in contrast to patients in whom the dominant involvement is of medium-sized arteries, the condition now called 'classical' polyarteritis nodosa, with organ infarction as the main clinical feature (e.g. gut, nerve, or renal infarction). Microscopic polyarteritis is associated with ANCA, usually of myeloperoxidase specificity, unlike classical polyarteritis nodosa which is usually ANCA negative.

The ACR (1990) described criteria for classical polyarteritis nodosa but not for microscopic polyarteritis. The classification criteria for polyarteritis nodosa are given in Table 5 and have greater than 80 per cent specificity and sensitivity (Lightfoot *et al*. 1990). A classification tree was also constructed using the following six criteria: angiographic abnormality (Fig. 3), biopsy-proven granulocyte or mixed leucocyte infiltrate in arterial wall, neuropathy, sex, weight loss greater than 6.5 kg, and elevation of serum hepatic enzymes. This gave a sensitivity of 87.3 per cent and specificity of 89.3 per cent. These ACR criteria do not have an absolute requirement for a tissue diagnosis or arteriographic abnormality to make the diagnosis of polyarteritis nodosa.

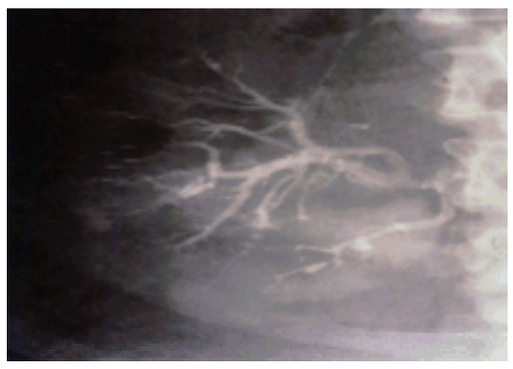

Fig. 3 Renal angiogram showing typical small aneurysms.

Criterion	Definition
1. Weight loss >4 kg	Loss of 4 kg or more of body weight since illness began, not due to dieting or other factors
2. Livedo reticularis	Mottled reticular pattern over the skin of portions of the extremities or torso
3. Testicular pain or tenderness	Pain or tenderness of the testicles, not due to infection, trauma, or other causes
4. Myalgias, weakness, or leg tenderness	Diffuse myalgias (excluding shoulder and hip girdle) or weakness of muscles or tenderness of leg muscles
5. Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy
6. Diastolic BP >90 mmHg	Development of hypertension with the diastolic BP higher than 90 mmHg
7. Elevated blood urea or creatinine	Elevation of BUN >40 mg/dl or creatinine >1.5 mg/dl, not due to dehydration or obstruction
8. Hepatitis B virus	Presence of hepatitis B surface antigen or antibody in serum
9. Arteriographic abnormality	Arteriogram showing aneurysms or occlusions of the visceral arteries, not due to atherosclerosis, fibromuscular dysplasia, or other non-inflammatory causes
10. Biopsy of small or medium-sized artery containing PMN	Histological changes showing the presence of granulocytes or granulocytes and mononuclear leucocytes in the artery wall

For classification purposes, a person shall be said to have polyarteritis nodosa if at least three of these ten criteria are present. The presence of any two or more criteria yields a sensitivity of 85.9%, and a specificity of 86.6%. BP, blood pressure; BUN, blood urea nitrogen; PMN, polymorphonuclear neutrophils.
Reproduced from Lightfoot *et al*. (1990) with permission.

Table 5 ACR 1990 criteria for the classification of polyarteritis nodosa (traditional format)

The CHCC specifically addressed the definition of both classical and microscopic polyarteritis (Table 2) (Jeanette *et al*. 1994). They defined classical polyarteritis nodosa as a disease of medium- and small-sized arterities without glomerulonephritis or vasculitis in arterioles, capillaries, or venules. This complete exclusion of small vessel disease has caused controversy because some patients show considerable overlap. A segmental necrotizing glomerulonephritis can occur in some patients with aneurysms of medium arteries. More commonly segmental necrotizing glomerulonephritis occurs without evidence of interlobar or interlobular arteritis and this explains why the concept of microscopic polyarteritis nodosa was introduced (Wainwright and Davson 1950). The glomerulonephritis in microscopic polyangiitis and Wegener's granulomatosis is similar to other vasculitic diseases, including systemic lupus erythematosus and Henoch–Schönlein purpura, except for the very low levels of immunoglobulin or complement deposition. The term 'pauci-immune' glomerulonephritis is sometimes used. The CHCC defined microscopic polyarteritis as a necrotizing vasculitis predominately affecting small vessels but small- and medium-sized arteries may be involved. They prefer, as we do, the term microscopic polyangiitis for this pattern of disease, emphasizing the difference between it and classical polyarteritis nodosa.

Polyarteritis nodosa has always been a rare disease with an estimated annual incidence of 2 to 10 per million (Sack *et al*. 1975; Scott *et al*. 1982; Kurland *et al*. 1984). Detailed analysis of the patients in these studies suggests that they included some patients with microscopic polyangiitis and Churg–Strauss syndrome, and hence that the annual incidence may be less than they reported. Using the CHCC definition of classical polyarteritis nodosa we have not seen a single case since 1988, suggesting that it has become a very rare disease. However, comparing the ACR criteria for polyarteritis nodosa with the CHCC definitions we have seen five patients with microscopic polyangiitis who fulfil the ACR criteria for polyarteritis nodosa and a further five with microscopic polyangiitis who do not. Seven of these ten patients with microscopic polyangiitis are ANCA positive.

The annual incidence of microscopic polyangiitis in Leicester (United Kingdom) increased from 0.5 to 3.3 per million following the introduction of the ANCA test in 1987 (Andrews *et al*. 1990). Data from our epidemiological studies in Norwich suggest that the annual incidence of microscopic polyangiitis is very similar at 2.4 per million (Watts *et al*. 1995) Whether these changes in incidence represent a true change or reflect changes in diagnostic patterns is uncertain.

Wegener's granulomatosis (see also Chapter 5.11.2)

Wegener first described this form of granulomatous necrotizing vasculitis in 1936 (Wegener 1936). The disease is characterized by necrotizing granulomata of the upper and lower respiratory tract, a necrotizing systemic vasculitis, and a focal glomerulonephritis (Godman and Churg 1954). A more limited form of the disease has been described with lesions restricted to the upper and lower respiratory tract (Carrington and Liebow 1966). This was thought to represent a more benign form of the disease because of the absence of overt renal disease, although 5 out of 16 patients died from non-renal disease within 1 year of diagnosis. Respiratory tract disease may precede systemic and renal vaculitis by many months or years. DeRemee classified Wegener's granulomatosis on the basis of the organs involved (ELK)—E standing for ear, nose, throat; L for lung involvement; and K for kidney involvement (DeRemee *et al*. 1976). This classification has proved useful in staging patients with the disease, but presupposes a progression from E–L–K, which does not always occur. Patients may present with pulmonary or renal involvement. More recently this progression has been viewed as a continous spectrum which may be entered at any point (Luqmani *et al*. 1994a).

The ACR 1990 classification criteria for the diagnosis of Wegener's granulomatosis are shown in traditional format in Table 6 (Leavitt *et al*. 1990). A classification tree was also constructed with five criteria: the same four criteria plus haemoptysis. This gave a sensitivity of 87.1 per cent and specificity of 93.6 per cent.

Criterion	Definition
1. Nasal or oral inflammation	Development of painful or painless oral ulcers, or purulent or bloody nasal discharge
2. Abnormal chest radiograph	Chest radiograph showing the presence of nodules, fixed infiltrates, or cavities
3. Urinary sediment	Microhaematuria (>5 red blood cells per high power field) or red cell casts in urine sediment
4. Granulomatous inflammation on biopsy	Histological changes showing granulomatous inflammation within the wall of an artery or in the perivascular or extravascular area (artery or arteriole)

For purposes of classification, a person shall be said to have Wegener's granulomatosis if at least two of these four criteria are present. The presence of any two or more criteria yields a sensitivity of 88.2% and a specificity of 92.0%.
Reproduced from Leavitt *et al*. (1990) with permission.

Table 6 ACR 1990 criteria for the classification of Wegener's granulomatosis (traditional format)

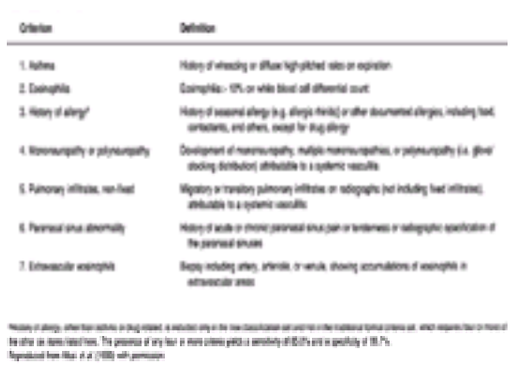
The CHCC definition restricts the term Wegener's granulomatosis to patients with necrotizing granulomatous inflammation (Table 2) (Jeanette *et al*. 1994). In the earlier stages of disease there may be overlap between Wegener's granulomatosis and microscopic polyangiitis, and subsequently the illness may evolve with development of new inflammatory lesions. Neither the CHCC nor the ACR classification scheme address the issue of limited disease.

The incidence of Wegener's granulomatosis appears to be increasing. In 1980 to 1986 in Leicester (United Kingdom) the annual incidence of Wegener's granulomatosis was estimated to be 0.7 per million, while in 1987 to 1989 the incidence was 2.8 per million (Andrews *et al*. 1990). In Norwich during the period 1988 to 1994 the estimated annual incidence was 8.5 per million (Carruthers *et al*. 1996). This does not appear to be due to changing diagnostic criteria as we have compared the clinical features of our patients to those seen at the National Institutes of Health (**NIH**, United States; 1962 to 1983) and Birmingham (United Kingdom; 1981 to 1991) and did not find any significant differences between the three groups. The Leicester group used the same diagnostic criteria as the NIH. It is, however, noteworthy that as the annual incidence of Wegener's granulomatosis has apparently increased that of classical polyarteritis nodosa has decreased, suggesting that some patients formerly labelled as polyarteritis nodosa may now be reclassified as Wegener's granulomatosis.

Churg–Strauss syndrome

In 1951, Churg and Strauss described the postmortem features of 13 patients who died following an illness characterized by asthma, eosinophilia, fever, and a systemic illness (Churg and Strauss 1951). Histologically there is a granulomatous necrotizing vasculitis. Chumbley, in 1977, reported a series of 30 patients with Churg–Strauss syndrome, and stressed the relative infrequent occurrence of renal involvement (Chumbley *et al*. 1977). Lanham, in 1984, provided a clinical definition of Churg–Strauss syndrome as a triad of asthma, eosinophilia (greater than 1×10^{9}/l), and a systemic vasculitis involving two or more extrapulmonary organs (Lanham *et al*. 1984). In their experience extravascular granulomata were not essential for the diagnosis of Churg–Strauss syndrome. They also noted a triphasic pattern of illness with allergic rhinitis, evolving into asthma; followed by peripheral blood eosinophilia and eosinophilic tissue infiltrates; and finally a systemic vasculitis phase. The granulomata may be localized and associated with a variety of systemic manifestations. Furthermore the necrotizing vasculitis may be indistinguishable from that found in classical polyarteritis nodosa and/or microscopic polyangiitis.

The ACR criteria for the diagnosis of Churg–Strauss syndrome are given in Table 7 (Masi *et al*. 1990). These criteria do not include some common clinical features of Churg–Strauss syndrome such as rash or cardiac involvement, as they gave poor discrimination. The combination of asthma and eosinophilia are both sensitive and highly specific for the diagnosis of Churg–Strauss syndrome. A classification tree was also constructed using three of six criteria that gave a sensitivity of 95 per cent and a specificity of 99.2 per cent.



Criterion	Definition
1. Asthma	History of wheezing or diffuse high-pitched rales on expiration
2. Eosinophilia	Eosinophils > 10% on white blood cell differential count
3. History of allergy[a]	History of seasonal allergy (e.g. allergic rhinitis) or other documented allergies, including food, corticosteroids, and others, except for drug allergy
4. Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy (i.e. glove/stocking distribution) attributable to a systemic vasculitis
5. Pulmonary infiltrates, non-fixed	Migratory or transitory pulmonary infiltrates on radiographs (not including fixed infiltrates) attributable to a systemic vasculitis
6. Paranasal sinus abnormality	History of acute or chronic paranasal sinus pain or tenderness or radiographic opacification of the paranasal sinuses
7. Extravascular eosinophils	Biopsy including artery, arteriole, or venule, showing accumulations of eosinophils in extravascular areas

[a]History of allergy, either from asthma, or drug-related, as instructed only on the new classification and used not in the traditional formal criteria set, which requires four or more of the criteria listed here. The presence of any four or more criteria yields a sensitivity of 85.07% and a specificity of 99.7%.
Reproduced from Hoffman *et al*. (1992) with permission

Table 7 ACR 1990 criteria for the classification of Churg–Strauss syndrome

The CHCC definition of Churg–Strauss syndrome (Table 2) includes the presence of asthma and eosinophilia (Jeanette *et al*. 1994). The presence of conspicious eosinophils in inflammatory infiltrates is not alone a discriminating feature as they can occur in other types of vasculitis including Wegener's granulomatosis and microscopic polyangiitis.

The annual incidence of Churg–Strauss syndrome has been estimated to be 2.4 per million (Watts *et al*. 1995).

Hypersensitivity vasculitis

Vasculitis occurring secondary to allergic or hypersensitivity mechanisms has been considered to be a distinct entity since the late 1940s (Zeek *et al*. 1948) and was included in Zeek's original classification (Zeek 1952). Distinguishing features were considered to be the prominent cutaneous involvement and frequent precipitation by serum or drugs. Pathologically the disease involves small vessels with leucocytoclasis. The lesions are all of the same age and can be induced experimentally. However, often there is no clear evidence of an inciting agent and a similar picture can be seen in vasculitis associated with connective tissue disease (rheumatoid arthritis, systemic lupus erythematosus, Sjögren's syndrome), malignancy, Henoch–Schönlein purpura, and cryoglobulinaemia.

The ACR 1990 criteria for the diagnosis of hypersensitivity vasculitis were relatively insensitive (71.0 per cent) and non-specific (78.5 per cent). This reflects the occurrence of a hypersensitivity-like picture in other conditions, particularly Henoch–Schönlein purpura and microscopic polyangiitis, and some authorities consider these conditions to represent different forms of hypersensitivity to foreign antigens (Heng 1985).

The CHCC did not use the term hypersensitivity vasculitis but considered that the 'categories of microscopic polyangiitis and cutaneous leucocytoclastic angiitis probably best equate with the most common usage of hypersensitivity vasculitis' (Jeanette *et al*. 1994).

Henoch–Schönlein purpura

Schönlein initially described acute purpura and arthritis occurring in children in 1837 (Schönlein 1837). Subsequently Henoch described the additional features of colicky abdominal pain and nephritis in 1874 (Henoch 1874). The classical presentation is with purpura, arthritis, haemorrhagic gastrointestinal involvement, and glomerulonephritis. It occurs most often in children, but rarely, adults of any age may be affected. Significant IgA deposition is usually seen in renal or skin biopsies. Henoch–Schönlein purpura is often considered to be a form of hypersensitivity vasculitis.

The ACR criteria readily distinguish Henoch–Schönlein purpura from other forms of vasculitis, although it was recognized that there were considerable similarities between Henoch– Schönlein purpura and hypertensitivity vasculitis, both in terms of clinical features and the classification criteria (Mills *et al*. 1990). Palpable purpura was a common criterion for both diseases. Also, although arthritis and nephritis are typical features of Henoch–Schönlein purpura, neither was sensitive for the diagnosis, and haematuria as a sign of nephritis was neither sensitive nor specific. A classification tree was also constructed with similar criteria and yielded a sensitivity of 89.4 per cent and a specificity of 88.1 per cent (Table 8).

Criterion	Definition
1. Palpable purpura	Slightly raised "palpable" haemorrhagic skin lesions, not related to thrombocytopenia
2. Age < 20 years	Patient 20 years or younger at onset of first symptom
3. Bowel angina	Diffuse abdominal pain, worse after meals, or the diagnosis of bowel ischaemia, usually including bloody diarrhoea
4. Mail granulocytes on biopsy	Histological changes showing granulocytes in the walls of arterioles or venules

For purposes of classification a patient shall be said to have Henoch–Schönlein purpura if at least two of these four criteria are present. The presence of any two or more criteria yields a sensitivity of 87.1% and a specificity of 87.7%.
Reproduced from Mills et al. (1990) with permission.

Table 8 ACR 1990 criteria for the classification of Henoch–Schonlein purpura (traditional format)

The CHCC definition of Henoch–Schönlein purpura is a small vessel vasculitis with IgA-dominant immune deposits (Table 2) (Jeanette *et al*. 1994). These deposits distinguish Henoch–Schönlein purpura from microscopic polyangiitis. The CHCC did not consider other types of immune-complex mediated disease apart from cryoglobulinaemic vasculitis.

The annual incidence of Henoch–Schönlein purpura in children is 135 per million (Stewart *et al*. 1988). Our data from Norwich suggest that the annual incidence in adults is 1.2 per million (Watts *et al*. 1995).

Takayasu's arteritis

Takayasu's arteritis is a chronic, granulomatous large-vessel arteritis which was described in 1908 by Takayasu (Takayasu 1908), but Savory had described the association between the absence of radial pulses and ocular abnormalities in 1856 (Savory 1856).

Ishikawa proposed diagnostic criteria for Takayasu's arteritis in 1988 and suggested that an age of less than 40 years should be an obligatory criterion for the diagnosis (Ishikawa 1986). In this study of 96 Japanese patients with Takayasu's arteritis two major criteria were proposed: arteriographic evidence of left or right mid-subclavian artery stenosis or occlusion. In addition minor diagnostic criteria were described: high erthrocyte sedimentation rate, carotid artery tenderness, hypertension, aortic regurgitation, or arteriographic evidence of lesions in other branches of the aorta. The presence of both major, or one major and two minor, or four or more minor criteria suggested a diagnosis of Takayasu's arteritis with a sensitivity of 84 per cent (Ishikawa 1986). These patients were, however, only compared with 12 patients having other aortic disease and not to patients with other forms of vasculitis.

The ACR classification criteria for the diagnosis of Takayasu's arteritis are given in Table 9 (Arend *et al*. 1990). Takayasu's arteritis is clearly distinguished from giant cell arteritis by age. A high erthrocyte sedimentation rate, carotid artery tenderness, and/or hypertension lack specificity and sensitivity to differentiate patients with Takayasu's arteritis from other forms of arteritis. A classification tree was also constructed with five of the same six criteria omitting claudication of a limb. This gave a sensitivity of 92.1 per cent and specificity of 97.0 per cent.

Criterion	Definition
1. Age at disease onset < 40 years	Development of symptoms or findings related to Takayasu's arteritis at age < 40 years
2. Claudication of extremities	Development and worsening of fatigue and discomfort in muscles of one or more extremity while in use, especially the upper extremities
3. Decreased brachial artery pulse	Decreased pulsation of one or both brachial arteries
4. BP difference > 10 mmHg	Difference of > 10 mmHg in systolic blood pressure between arms
5. Bruit over subclavian arteries or aorta	Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta
6. Arteriogram abnormality	Arteriographic narrowing or occlusion of the entire aorta, its proximal branches, or large arteries in the proximal upper or lower extremities, not due to arteriosclerosis, fibromuscular dysplasia, or similar causes; changes usually focal or segmental

For purposes of classification a patient shall be said to have Takayasu's arteritis if at least three of these six criteria are present. The presence of any three or more criteria yields a sensitivity of 90.5% and a specificity of 97.8%. BP: blood pressure.
Reproduced from Arend et al. (1990) with permission.

Table 9 ACR 1990 criteria for the classification of Takayasu's arteritis (traditional format)

The CHCC considered Takayasu's arteritis to be a granulomatous inflammation of the aorta and its branches 'usually' occurring in patients younger than 50 years (Table 2) (Jeanette *et al*. 1994). They recognized that age is a useful discriminator between Tayakasu's arteritis and giant cell arteritis.

Takayasu's arteritis is rare in the United States with an annual incidence of up to 2.6 per million (Hall *et al*. 1985), but much more common in Japan and the Far East. In the United Kingdom we have not seen a single case from the Norwich Health District in 7 years. However, 7 cases were seen in the West Midlands from a population of 6 million during an 8-year period in the 1990s, suggesting a much lower annual incidence (0.14 per million) (D.G.I. Scott, unpublished data).

Kawasaki disease

Kawasaki disease (mucocutaneous lymph node syndrome) is an acute vasculitis of unknown aetiology that primarily affects infants and young children, and was first described in Japan in 1967 (Kawasaki 1967). Coronary vasculitis is a major cause of morbidity and mortality.

There is no laboratory test for the diagnosis of Kawasaki disease and the diagnosis is therefore based on standard clinical criteria (Table 10) (Rauch and Hurwitz 1985). There are several problems with these criteria. Some patients who do not fulfil the criteria develop coronary artery disease; also the mucocutaneous features are very variable. Burns and colleagues compared 280 patients with acute Kawasaki disease with 42 patients evaluated for Kawasaki disease in whom other diagnoses were eventually made (Burns *et al*. 1991). They found considerable overlap between the two groups with 46 per cent of the control group satisfying the criteria for Kawasaki disease. The most common alternative diagnoses were measles and group A b-haemolytic streptococcal infection.

Fever of at least 5 days duration

Presence of at least four of the five following conditions

1. Bilateral non-exudative conjunctival injection
2. One of the following changes in oropharynx:
   injected or fissured lips, injected pharynx, or 'strawberry tongue'
3. One of the following extremity changes:
   erythema of the palms or soles, oedema of the hands or feet, or periungual desquamation
4. Rash, primarily polymorphous but not vesicular
5. Acute non-suppurative cervical lymphadenopathy

Illness not explained by an other known disease process

From Rauch and Hurwitz (1985).

Table 10 Diagnostic criteria for Kawasaki disease

The ACR did not develop criteria for Kawasaki disease. The CHCC considered Kawasaki disease and felt that the presence of mucocutaneous lymph node syndrome is the defining feature that separates Kawasaki disease from juvenile polyarteritis nodosa (Jeanette *et al*. 1994). The absence of involvement of vessels smaller than arteries in their view distinguishes Kawasaki disease from microscopic polyangiitis, this is however controversial as involvement of small vessels has been described (Lie 1994).

Other vasculitides

The CHCC also considered essential cryoglobulinaemic vasculitis, cutaneous leucocytoclastic vasculitis, and giant cell arteritis. Classification criteria for giant cell arteritis are considered elsewhere.

Cryoglobulins are plasma proteins which reversibly precipitate in the cold and have been classified on the basis of the type of immunoglobulin contained within the cryoprecipitate. Types II and III contain two types of immunoglobulin (mixed cryoglobulinaemia) and are associated with a small vessel vasculitis. They may occur in the absence of underlying disease (essential mixed cryoglobulinaemia).

Cutaneous leucocytoclastic vasculitis is confined to patients in whom there is no evidence of systemic involvement. These patients have a much better prognosis. Other systemic vasculitides must be excluded rigorously. Those patients with elevated levels of immune complexes are at greater risk of immune-complex mediated disease such as Henoch–Schönlein purpura and cryoglobulinaemic vasculitis, whilst those with ANCA are at risk of developing an ANCA-associated disease (e.g. Wegener's granulomatosis).

The development of the ACR criteria and the CHCC definitions have been important steps in improving the classification and definition of the systemic vasculitides. However, despite the use of these criteria a significant number of patients cannot be classified;. in our experience approximately 10 per cent. It is possible that some of these will evolve into typical forms of systemic vasculitis, but others may represent rarer forms which are currently poorly documented and understood.

Secondary vasculitis

Vasculitis occurring as a consequence of an autoimmune rheumatic disease is relatively common and is in our experience the commonest cause of systemic vasculitis, particularly secondary to rheumatoid arthritis and systemic lupus erythematosus (Table 1). It may also occur in dermatomyositis, scleroderma, overlap syndromes, Sjögren's syndrome, rheumatic fever, and relapsing polychondritis. Classification criteria are not well established except for vasculitis occurring secondary to rheumatoid arthritis.

Rheumatoid arthritis

Vasculitis complicating rheumtoid arthritis was first described in 1898, in a patient with involvement of the vasa nervorum (Bannatyne 1898). The association was clearly established in the 1940s and 1950s (Bywaters 1949; Bywaters 1957). The classical features are peripheral gangrene and mononeuritis multiplex (Hart *et al*. 1957; Pallis and Scott 1965). However, pericarditis, scleritis, nodules, and systemic disease occur frequently, and more recent series have described a wider spectrum of disease (Scott *et al*. 1981; Luqmani *et al*. 1994b). The size of vessel involved ranges from the aorta to capillaries. Small vessel vasculitis can occur in isolation as small nail-edge or nailfold lesions. These lesions are generally considered to be benign but can herald or coexist with major arterial disease (Bywaters 1957; Bywaters and Scott 1963). Systemic rheumatoid vasculitis occurs more commonly in males with longstanding rheumatoid arthritis who are strongly seropositive for rheumatoid factor (Scott *et al*. 1981; Luqmani *et al*. 1994b).

Scott and Bacon proposed criteria for the definition of systemic rheumatoid vasculitis (Table 11) (Scott and Bacon 1984). An obligatory criterion was the presence of established rheumatoid arthritis as defined by the ACR. This should prevent confusion with other forms of either primary or secondary vasculitis as such patients are unlikely to meet the ACR criteria for the diagnosis of rheumatoid arthritis. However, these criteria have not been validated formally.

The presence in a patient with rheumatoid arthritis of one or more of:

1. Mononeuritis multiplex or acute peripheral neuropathy
2. Peripheral gangrene
3. Biopsy evidence of acute necrotizing arteritis plus systemic illness (e.g. fever, weight loss)
4. Deep cutaneous ulcers or active extra-articular disease (e.g. pleurisy, pericarditis, scleritis) if associated with typical digital infarcts or biopsy evidence of vasculitis

Other causes of such lesions such as diabetes mellitus and atherosclerosis should be excluded. Patients with nailfold or digital infarcts alone are excluded.
From Scott and Bacon (1984).

Table 11 Classification criteria for systemic rheumatoid vasculitis

In our experience systemic rheumatoid vasculitis as defined by the Scott and Bacon criteria is amongst the commonest forms of systemic vasculitis with an annual incidence of 12.5 per million (Watts *et al*. 1994).

Aetiology

The 'best' classification system should involve the aetiological agent responsible for the vascular damage. This is unknown in the majority of cases of vasculitis, but even when it appears to be known there is still considerable confusion. For example, hepatitis B surface antigen has been associated with pure cutaneous vasculitis, cryoglobulinaemic vasculitis, glomerulonephritis, arthritis, and polyarteritis nodosa (Scott 1986). There is also one report of hepatitis B associated with giant cell arteritis (Bacon *et al*. 1975). A similar picture has now emerged with the vasculitis associated with human immunodeficiency virus infection, with descriptions of leucocytoclastic vasculitis, eosinophilic vasculitis, polyarteritis nodosa, granulomatous angiitis, and lymphomatoid granulomatosis (Siefert 1989).

The most frequently postulated pathogenetic mechanism for the production of vasculitis is the deposition of circulating immune complexes. This has been documented particularly in the small vessel vasculitides, though circulating immune complexes have been detected in almost all diseases associated with vasculitis. The activity of these complexes and their relation to pathogenesis is often doubtful; for example complement activation is rare in the group associated with systemic necrotizing arteritis, except in those cases associated with hepatitis B infection. Complement activation is seen much more frequently in small vessel vasculitis (cryoglobulinaemia, Henoch–Schönlein purpura) and vasculitis complicating rheumatoid arthritis and systemic lupus erythematosus.

Other proposed mechanisms include *in situ* formation of immune complexes, direct invasion of the vessel wall by antigen (including virus), antibodies to myelocyte lysosomal enzymes (see below), cytotoxic antibodies to endothelium, and cell-mediated immune reactions to cell-wall antigens. The importance of these mechanisms to classification is as yet undefined, with the possible exception of ANCA.

ANCA

Antineutrophil cytoplasmic antibodies were first described in 1985 as sensitive and specific markers for Wegener's granulomatosis (Van der Woude *et al*. 1985). Since then ANCA have been described in other types of systemic vasculitis (e.g. microscopic polyangiitis) and some non-vasculitic diseases (Gross *et al*. 1993a), and the disease associations and antigenic targets of ANCA have been defined more clearly. Two major staining patterns are seen on indirect immunofluorescence: cytoplasmic (cANCA) and perinuclear (pANCA). Proteinase 3 is the main target antigen of cANCA and is chiefly found in patients with Wegener's granulomatosis,

whilst myeloperoxidase is the predominant target antigen of pANCA and is found in microscopic polyangiitis (Falk and Jeanette 1988).

Disease associations of cANCA

cANCA are highly sensitive (81 per cent) and specific for Wegener's granulomatosis (97 per cent) and are directed against proteinase 3 (Gross *et al*. 1993b). The specificity of cANCA for biopsy-proven Wegener's granulomatosis is around 90 per cent (Gross *et al*. 1993b). In limited or initial-phase Wegener's granulomatosis (i.e. upper and lower airways disease only) 55 per cent of patients are cANCA positive, whereas in systemic disease 88 per cent of patients are cANCA positive (Gross *et al*. 1993b). cANCA can be found in types of vasculitis with close clinical and pathological relations to Wegener's granulomatosis, such as microscopic polyangiitis (15 per cent) and Churg–Strauss syndrome (25 per cent), but rarely in classical polyarteritis nodosa (2 per cent) (Hauschild *et al*. 1993). False-positive cANCA (i.e. occurring in non-vasculitic illnesses) are very rare (Gross *et al*. 1993).

Disease association of pANCA

Unlike cANCA, pANCA are not specific for a single disease but are seen in a wide spectrum of disease including: (i) systemic vasculitis, e.g. microscopic polyangiitis, Churg–Strauss syndrome, Wegener's granulomatosis; (ii) necrotizing glomerulonephritis; (iii) rheumatic disease, e.g. rheumatoid arthritis, Still's disease, Felty's syndrome; (iv) autoimmune rheumatic disease, e.g. systemic lupus erythematosus, Sjögren's syndrome; and (v) inflammatory bowel disease. pANCA is present in less than 3 per cent of patients with biopsy-proven Wegener's granulomatosis (Hauschild *et al*. 1993).

The major target autoantigen of pANCA is myeloperoxidase (therefore sometimes called myeloperoxidase-ANCA). Myeloperoxidase-ANCA are found in 70 per cent of patients with microscopic polyangiitis and up to 50 per cent of patients with Churg–Strauss syndrome. pANCA may, however, be targeted against other antigens such as lactoferrin, cathepsin G, human neutrophil elastase, and lysozyme. In these circumstances the immunofluorescence staining pattern may be slightly different from the characteristic pANCA, such a staining pattern is known as atypical or xANCA.

An association between ANCA and extra-articular manifestations of vasculitis in patients with rheumatoid arthritis or Felty's syndrome (Juby *et al*. 1992) has been reported, especially if antibodies to lactoferrin or elastase were present (Coremans *et al*. 1992). Antibodies to cathepsin G have been described in patients with ulcerative colitis (Kallenberg *et al*. 1992). xANCA are detected in sera from patients with an even broader range of diseases including infection and carcinoma (Peter 1993).

Role of ANCA in classification

A classical, cANCA staining pattern strongly suggests a diagnosis of Wegener's granulomatosis in a patient with appropriate clinical findings. However, the presence of ANCA detected by immunofluorescence alone has limited diagnostic value. Indirect immunofluorescence should be followed by antigen-specific assays for proteinase 3 and myeloperoxidase. Proteinase 3 antibodies are associated strongly with Wegener's granulomatosis, myeloperoxidase antibodies less strongly with microscopic polyangiitis. The diagnostic value of a positive ANCA by immunofluorescence which is not directed against proteinase 3 or myeloperoxidase is uncertain. A diagnosis of systemic vasculitis, including Wegener's granulomatosis and necrotizing glomerulonephritis, should not be based on the detection of specific ANCAs alone but should be considered in the correct clinical background. A tissue diagnosis is still frequently needed to confirm the diagnosis.

For broad classification purposes we have grouped Wegener's granulomatosis, microscopic polyangiitis, and Churg–Strauss syndrome together, as they share some clinical and pathological features and are the three diseases most commonly associated with ANCA (Table 3). Using CHCC definitions, other types of vasculitis are much less frequently associated, or have no association, with ANCA.

Prognosis

Twenty years ago, a precise characterization of the different types of vasculitis might have been considered of academic interest only, because of the lack of any specific, effective treatment. Immunosuppressive therapy, particularly with cyclophosphamide, has dramatically changed the outcome of many of the more severe forms of vasculitis, especially Wegener's granulomatosis, polyarteritis nodosa, and systemic rheumatoid vasculitis (Fauci *et al*. 1979; Fauci *et al*. 1983; Scott and Bacon 1984; Hoffman *et al*. 1992; Gordon *et al*. 1993). It is important to diagnose these diseases accurately, not only to instigate early appropriate treatment, but also to avoid using cytotoxic agents (with their potentially severe side-effects) in diseases where their use is unnecessary.

Despite recent therapeutic advances, the vasculitic diseases still have significant morbidity and mortality, reflecting the importance of accurate classification. Prognosis is affected particularly by the size of vessel involved and the presence (or absence) of renal involvement. Up to 40 per cent of patients with polyarteritis nodosa, 20 to 30 per cent with systemic rheumatoid vasculitis, and 10 to 20 per cent with Wegener's granulomatosis, die within a year of diagnosis. Although the terminal event is now more commonly sepsis than uncontrolled vasculitis, the importance of renal involvement in the mortality of systemic vasculitis is shown by comparing those whose serum creatinine is more than 500 mmol/l (47 per cent mortality) with those whose serum creatinine is less than 500 mmol/l (15 per cent mortality) at the time of diagnosis (Adu *et al*. 1987), stressing the danger of any delay in diagnosis. A similar picture is seen in Wegener's granulomatosis, where, in addition, there may be significant morbidity from nasal, laryngeal, or pulmonary involvement. Signifiant renal damage is rare in patients with systemic rheumatoid vasculitis. However, these patients also have a significant morbidity and mortality; the presence of arteritis, either clinically or on biopsy, is associated with a higher mortality (44 per cent) than small vessel disease (20 per cent), where cardiac disease (restrictive pericarditis, aortic regurgitation, etc.) is a common cause of death (Scott and Bacon 1987). All these figures stress the importance of accurate classification, particularly of those patients with vasculitis involving small- or medium-sized arteries.

By contrast the prognosis for small vessel vasculitis is much more favourable. Less than 10 per cent of patients with Henoch–Schönlein purpura develop significant renal involvement and of these only a few develop chronic renal disease. Some patients with essential mixed cryoglobulinaemia develop a polyarteritis-like picture years after presentation (Gorevic *et al*. 1980). Giant cell arteritis and Takayasu's arteritis are rarely fatal but may be associated with significant complications (e.g. blindness and ischaemia).

Conclusion

The systemic vasculitides are a group of important inflammatory conditions resulting in inflammation and necrosis of blood vessel walls. They are somewhat commoner than previously believed with an annual incidence approaching 40 per million. The most common forms of systemic vasculitis are systemic rheumatoid vasculitis (12.5 per million per year) and Wegener's granulomatosis (8.5 per million per year).

Classification criteria and disease definitions are now well established, which should lead to conformity between different centres. Particular problems still exist with the definition of classical polyarterits nodosa and microscopic angiitis, and it is important when these terms are employed that the classification criteria used for diagnosis are always given.

Classification systems are still evolving. Recent changes include the recognition of the importance of the dominant blood-vessel size, the distinction between primary and secondary vasculitis, and the incorporation of pathogenetic markers such as ANCA (Table 3).

5.11.2 Wegener's granulomatosis

Wolfgang L. Gross

Introduction

Wegener's granulomatosis has been recognized as a distinct clinicopathological entity for 60 years. Of unknown aetiology, it is a granulomatous disorder associated with systemic necrotizing vasculitis (for review, see Wegener 1990; Wegener 1990b). It involves predominantly the upper airways, the lungs, and the kidneys: 'classical' Wegener's granulomatosis represents a triad of upper airway (= **E**), lung (= **L**) and renal disease (= **K**) according to the **ELK** classification (DeRemee *et al*. 1976). However, since the disease may be confined to E or to E and L as a purely granulomatous process without clinical evidence of systemic vasculitis, these *formes frustes* of Wegener's granulomatosis have been designated 'limited disease' (without kidney involvement), 'limited forms' (E or E and L) or 'initial phase' (locoregional restricted granulomatous process without clinically apparent vasculitis) (Carrington and Liebow 1966; Gross 1989; Nölle *et al*. 1989; DeRemee 1993).

The 'classical' syndrome represents a generalized disease process that usually begins with an initial phase of variable duration characterized by symptoms limited mostly to the upper and/or lower respiratory tract (for review, see Wegener 1990; Wegener 1990b). Since more and more of these limited forms of Wegener's granulomatosis are being detected early, due partly to increased physicians' awareness and partly to more sophisticated diagnostic procedures, it has been learned that most of these 'initial phases' follow a rather subacute or chronic protracted course of unpredictable duration before transforming into the generalized (systemic) phase associated usually with high titres of antineutrophil cytoplasmic antibodies (**ANCA**). This is the well-recognized, full-blown disease characterized by systemic necrotizing vasculitis, usually with renal and pulmonary involvement. If untreated, it can turn into the fulminant form of the disease (e.g. renal–pulmonary syndrome), which carries a devastating prognosis (for review, see Gross 1989). Rheumatic complaints, and eye or peripheral nerve involvement, are frequently an ominous herald of the onset of the generalized vasculitic phase, which is usually also associated with constitutional symptoms such as malaise, weight loss, fever, and night sweats (Noritake *et al*. 1987; Gross 1989; Alcalay *et al*. 1990; Gross *et al*. 1991). In this phase, non-specific markers of inflammation, for example the erythrocyte sedimentation rate and C-reactive protein, are usually elevated. cANCA (proteinase 3 ANCA; **PR3-ANCA**), which has a 90 per cent specificity for Wegener's granulomatosis, is detectable in 95 per cent of sera from patients with generalized Wegener's granulomatosis, but in only about half of patients in the initial phase (Nölle *et al*. 1989).

Because of the potentially life-threatening course of many of the major necrotizing vasculitides, such as generalized Wegener's granulomatosis or microscopic polyangiitis, 'standard' treatment (United States National Institutes of Health standard therapy/Fauci's scheme) consisting of daily 'low-dose' (2–4 mg/day) cyclophosphamide plus glucocorticoids is generally considered to be of most benefit to the majority of patients (for review, see Hoffman 1990). This view has been challenged in recent years by data indicating (i) the variability of clinical course and aggressiveness in the same disease entity, (ii) continued morbidity despite therapy with cyclophosphamide plus glucocorticoids, (iii) a high incidence of relapse among patients thought to be 'cured', and (iv) the alarming range of toxic effects induced by the 'standard protocol' (Anderson *et al*. 1992; Frankel *et al*. 1992; Hoffman *et al*. 1992a).

Improved diagnostic procedures, including computed tomographic (**CT**) imaging of the lung and magnetic resonance imaging (**MRI**) of the head (Greenan *et al*. 1992; Muhle *et al*. 1993), immunodiagnostic methods such as ANCA assays, and the detection of cytokine/cytokine-receptor molecules such as the soluble interleukin-2 receptor, have enhanced diagnostic precision by clarifying the anatomical distribution of involvement and the clinical activity of the disease (Nölle *et al*. 1989; Salvarani *et al*. 1992; Schmitt *et al*. 1992; Stegemann *et al*. 1993). Consequently, it is now possible to design stage-adapted and disease-activity related therapeutic protocols instead of adhering to the rather rigid standard regimen developed 20 years ago.

Definition and classification

In spite of substantial efforts by many investigators, the nomenclature of the various subsets of Wegener's granulomatosis remains enigmatic (for review, see Gross 1996). A major problem is the lack of standardized terms and definitions. Thus different names are used (e.g. Wegener's granulomatosis; Wegener's vasculitis; microscopic polyarteritis of Wegener's type, etc.) for various forms of the same disease, and different interpretations of the same term (e.g. 'limited' Wegener's granulomatosis) can be found in the literature. In a first attempt to address this problem, an International Consensus Conference held in Chapel Hill in 1992 presented a proposal for both the nomenclature and definitions of vasculitides (see Table 2 of Chapter 5.11.1).

Usually, generalized ('full-blown', classical) Wegener's granulomatosis (Fig. 1) is described as a distinct clinicopathological entity characterized by lesions induced by necrotizing granulomatous inflammation in the upper (ear, nose, and throat) and the lower respiratory tract (including the lung), and by vasculitis (including kidney: glomerulonephritis) involving various additional organs (Wegener 1939). According to the original criteria of Godman and Churg (1954), Wegener's granulomatosis characteristically involves a triad of airway, lung, and renal disease.

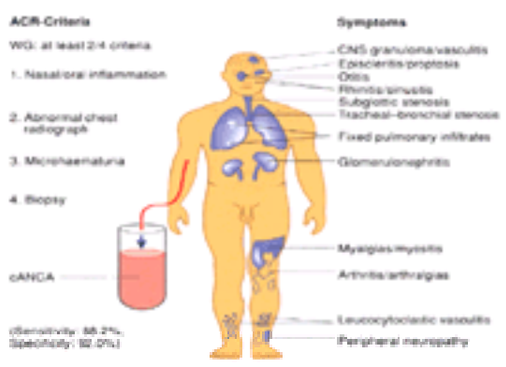

Fig. 1 Schematic representation of the characteristic clinical symptoms of Wegener's granulomatosis and the ACR 1990 classification criteria.

The 'ELK classification' proposed by DeRemee *et al*. (1976) has proved to be useful in clinical practice. Patients are classified according to the extent of the organ system involvement observed during the disease course (see Introduction; Fig. 2). The 'extended' ELK classification is now the basis for the 'Disease Extension Index' used in clinical studies (Nölle *et al*. 1989; Reinhold-Keller *et al*. 1994; Gross 1996) and, sometimes, in everyday practice.

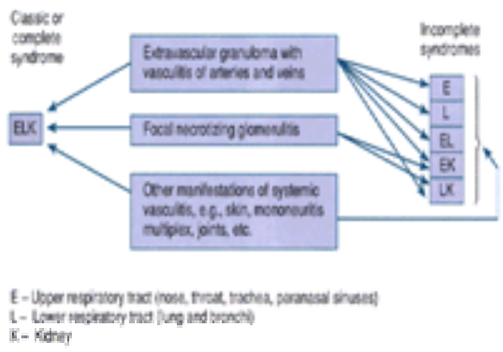

Fig. 2 Scheme for Wegener's granulomatosis in the ELK classification according to DeRemee *et al*. (1976) (with permission).

The American College of Rheumatology 1990 criteria for the classification of Wegener's granulomatosis (**ACR 1990** classification criteria) were developed by comparing 85 patients with Wegener's granulomatosis with 722 control patients with other forms of vasculitis (Leavitt *et al*. 1990). For the traditional format classification, four criteria were selected (Table 1). A classification tree was also constructed, based on the selection of five criteria. These criteria were the same as for the traditional format, plus haemoptysis. The classification tree had a sensitivity of 87.1 per cent and a specificity of 93.6 per cent.

Criteria	Definition
1. Nasal or oral inflammation	Development of painful or painless oral ulcers or purulent or bloody nasal discharge.
2. Abnormal chest radiograph	Radiograph of the chest showing the presence of nodules, fixed infiltrates, or cavities.
3. Urinary sediment	Microhaematuria (over 5 red blood cells/hpf) or red cell casts in the urine sediment.
4. Granulomatous inflammation on biopsy	Histological changes showing granulomatous inflammation within the wall of an artery or in the peri- or extravascular area (artery or arteriole)

Number of criteria present rule: For classification purposes, a patient should be said to have Wegener's granulomatosis if he/she has accumulated any two or more of these four criteria. This rule is associated with a sensitivity of 88.2 per cent and a specificity of 92.0 per cent.
From Leavitt *et al*. (1990) with permission

Table 1 ACR 1990 criteria for the classification of Wegener's granulomatosis

The Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis (**CHC 1992** definitions; Jennette *et al*. 1994) defined Wegener's granulomatosis as follows: granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels (e.g. capillaries, venules, arterioles, and arteries). Necrotizing glomerulonephritis is common. The disease is often associated with ANCA (see Table 2 of Chapter 5.11.1).

Neither the CHC definitions nor the ACR 1990 classification criteria addressed *formes frustes* of Wegener's granulomatosis. The criteria for definition and classification proposed for Wegener's granulomatosis (as part of the nomenclature for the vasculitides) require the presence of systemic vasculitis—but Wegener's granulomatosis may also occur as an inflammatory granulomatous process without apparent vasculitis! It must be borne in mind that neither the ACR 1990 nor the CHC 1992 constitute actual diagnostic criteria.

Epidemiology and natural history

Wegener's granulomatosis is a worldwide disease (Malaviya *et al*. 1990). New diagnostic tests (especially for ANCA) have led to an increased awareness of Wegener's granulomatosis (Andrews *et al*. 1990). Studies in the United States suggest an annual incidence of 4 per million population, while studies in England report an incidence of 8.5 per million (95 per cent confidence interval: 5.2–12.9), with an incidence for males of 10.8 and for females of 6.2 per million (Scott and Watts 1994). Wegener's granulomatosis has been observed in children and in elderly people; the peak incidence is in the fourth and fifth decades (Fauci *et al*. 1983; Hall *et al*. 1985; Weiner *et al*. 1986; McHugh *et al*. 1991; Rottem *et al*. 1993; Chakravarty *et al*. 1994).

Although, until the last decade, Wegener's granulomatosis was generally regarded as an invariably serious and fatal disease (Fauci *et al*. 1983), perceptions of it have since changed (Gross 1989; Hoffman *et al*. 1993a;). As with systemic lupus erythematosus, improved diagnostic procedures, including CT imaging of the lung and MRI of the head, as well as immunodiagnostic methods, such as ANCA assays, have enhanced diagnostic precision by identifying unclear clinical manifestations in the E or L region, and by clarifying the anatomical distribution of involvement (disease extension) and clinical disease activity (Luqmani *et al*. 1994; Reinhold-Keller *et al*. 1994). So, in addition to full-blown forms of Wegener's granulomatosis with possibly fatal outcome, indolent and/or less aggressive and life-threatening variants have been found to occur more frequently than once thought. In addition, the introduction of immunosuppressive drugs, dialysis, and renal transplantation have led to a dramatic improvement in survival rates in serious cases.

Prognosis

In their updated analysis of 158 patients with Wegener's granulomatosis, Hoffman *et al*. (1992a) emphasized the variability of the disease before diagnosis: the disease followed a confusing and indolent course in many cases (particularly in patients without renal manifestations) for up to 16 years before a definite diagnosis was established. The median and mean periods from onset of symptoms to diagnosis of Wegener's granulomatosis were 4.7 and 15 months, respectively. Diagnosis was made within 3 months after the onset of symptoms in only 42 per cent of patients; this is surprising because earlier studies had reported a median survival of only 5 months (Walton 1958). In Great Britain, 265 patients with Wegener's granulomatosis were observed between 1975 and 1985 (Anderson *et al*. 1992). The mean intervals from onset of symptoms to presentation and from presentation to diagnosis were both approximately 7 months; correct diagnosis was often missed for many years (range: less than 1–188 months). The mean survival of 4.2 years (shorter if renal disease was present) in patients receiving no drug treatment (10 per cent) indicates that these variants must have been very mild. Furthermore, it is striking that the median survival of 72 patients treated with glucocorticoids alone exceeded 12 years. Unfortunately, the investigators did not indicate the number of patients in the different treatment groups nor their disease activity and extent. Similar observations were published earlier and are reviewed elsewhere (Gross 1996).

Clinical features

Although Wegener's granulomatosis is a systemic disease with characteristic features reflected in the involvement of multiple organ systems (Table 2), it is essentially a true respiratory–renal syndrome. These two organ systems are largely responsible for the clinical course of the disease.

Organ or system	Patients			
	(number)		(%)	
	Group 1[a]	Group 2[b]	Group 1[a]	Group 2[b]
Lung	80	100	94	64
Paranasal sinuses	77	124	91	80
Kidney	72	104	85	67
Joints	57	120	67	77
Nose or nasopharynx	54	142	64	92
Ear	52	65	61	42
Eye	49	94	58	61
Skin	38	51	45	33
Nervous system	19	74	22	48
Heart	10	35	12	23

Table 2 Organ system involvement in Wegener's granulomatosis

Along with the well-known triad of necrotizing granulomas of the upper (E) and lower respiratory tract (L), plus glomerulonephritis (i.e. renal vasculitis; K), generalized Wegener's granulomatosis may also involve joints (A), skin (S), peripheral nerves (P), skeletal muscle (A), heart (H), brain (C) and eyes (EY), mostly via vasculitis of the small vessels (Fig. 1).

In Wegener's granulomatosis, involvement characteristically begins in the upper respiratory tract and precedes symptoms of generalized disease for a long period of time. These and pulmonary features may evolve over several months and even years, and can be followed by the overt presentation of systemic vasculitis, including glomerular disease. Because of the sometimes slow evolution, the diagnosis 'Wegener's granulomatosis' may not be made until some time after respiratory presentation.

On the other hand, Wegener's granulomatosis may sometimes start without obvious granulomatous lesions as a 'purely' small-vessel vasculitis (generalized phase). It is important to realize that there are overlapping features shared by Wegener's granulomatosis and microscopic polyangiitis, combined with the subsequent development over time of inflammatory lesions (for example, glomerulonephritis followed by skin vasculitis followed by pulmonary vasculitis—and, lastly, followed by obvious granulomatous lesions in the respiratory tract).

In any case, a strict diagnosis of Wegener's granulomatosis depends on (i) characteristic clinical symptoms, (ii) the demonstration of characteristic granulomas in biopsy material, and/or (iii) the detection of characteristic cANCA (PR3-ANCA) in the serum. It is noteworthy that each of these 'characteristics' can be observed in similar disorders, and that 'diagnosis' should not rely on any one of these variables alone.

Initial phase

['Initial stage'; E, L, EL according to the ELK classification, 'purely' granulomatous Wegener's granulomatosis; for review, see Gross (1989), DeRemee (1993), Boudes (1990).]

In most instances the ENT region (upper respiratory tract including the nose, sinuses, ears, and throat) is affected first. Characteristically, there are no clinical signs of systemic vasculitis. Patients with initial-phase Wegener's granulomatosis account for 10 per cent of those with vasculitis in a rheumatological unit.

The earliest nasal manifestations (E) usually include nasal obstruction (mucosal swelling), serosanguineous discharge, and epistaxis. Examination reveals granulation (Fig. 3), and there may be thick crusts that upon removal reveal friable mucosa or even septal perforation. In many patients the clinical diagnosis can be confirmed by the characteristic histological appearances obtained from nasal biopsy (Devaney *et al*. 1990; Del Bueno and Flint 1991). In addition to the symptoms described, facial pain, nosebleeds, nasal chondritis, saddling of the nose (Fig. 4), and involvement of paranasal sinuses (chronic sinusitis) typically occur.

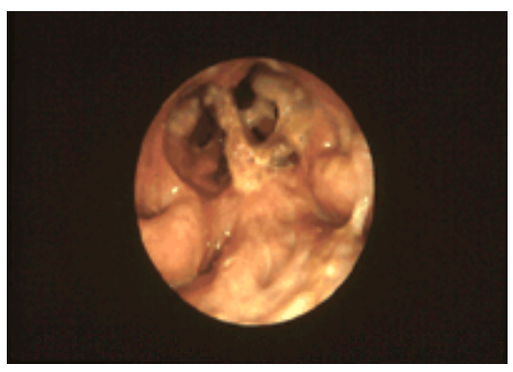

Fig. 3 Intranasal bilateral and septal mucosal disease with granulations and crusts leading to permanent serosanguinous discharge.

Fig. 4 Saddling of the nose due to destruction of the septal cartilage is a common finding in Wegener's granulomatosis.

In the oral cavity and oropharynx (E), gingival involvement can lead to ulcerative stomatitis, frank ulcerations (Fig. 5), or hyperplastic gingivitis (Fig. 6). Laryngeal symptoms such as hoarseness and/or increasing stridor are frequently due to reddish, friable, circumferential narrowing just below the cords and extending for 3 to 5 cm.

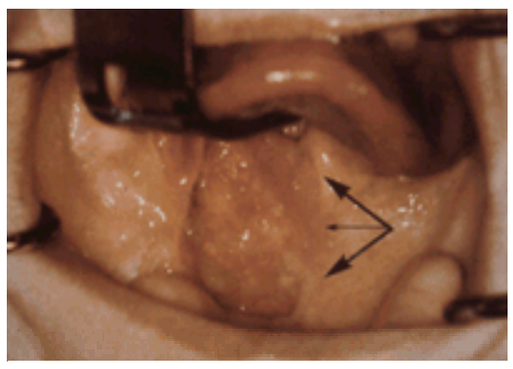

Fig. 5 Ulceration of the palate (an unusual site of manifestation for Wegener's granulomatosis) whose characteristic histological appearances led to the correct diagnosis in a patient with cavitating round nodules of the lung (see Fig. 11).

Fig. 6 Distinctive hyperplastic gingivitis originating in the interdental papilla area (biopsy-proven Wegener's granulomatosis).

Otological manifestations

The otological manifestations (E) of Wegener's granulomatosis include involvement of the external ear (chondritis, sometimes with secondary atrophy of the ear lobe), or middle ear (serous otitis media; suppurative otitis media, mastoiditis). Sometimes peripheral facial-nerve palsy occurs (D'Cruz *et al*. 1989; Murty 1990).

Eye symptoms

The eye symptoms (EY)—excluding those arising from small-vessel vasculitis seen only in generalized Wegener's granulomatosis, and which do lead to 'red eye'—derive from the granulomatous lesions (obstruction of the nasolacrimal duct) and masses developing retro-orbitally (protrusio bulbi; compression of the optic nerve; Fig. 7 and Fig. 8). Less frequently, orbital involvement may result from the spread of a purulent sinusitis, for example due to secondary bacterial infection (Charles *et al*. 1991; Satorre *et al*. 1991; Duncker *et al*. 1993).

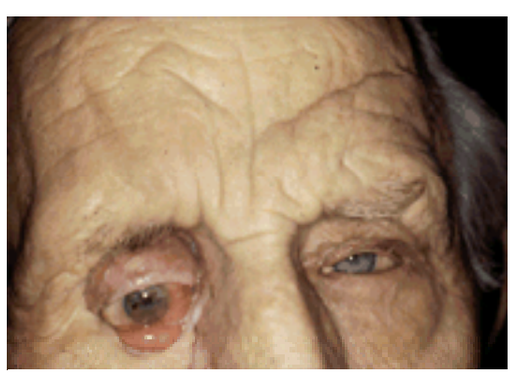

Fig. 7 Eye disease in Wegener's granulomatosis usually manifests itself in one of two ways: retro-orbital granuloma masses leading to proptosis (etc.), and small-vessel vasculitis leading to 'red eye' (see Fig. 18).

Fig. 8 Protrusio bulbi induced by retro-orbital granulomatous masses (CT scan).

Three types of involvement of the peripheral nervous system (P) have been described: disseminated vasculitis (see below: generalized Wegener's granulomatosis), contiguous granulomatous lesions, and disseminated, multicentric granulomatous lesions. The contiguous granulomatous lesion originates from the sinuses (Fig. 9) and middle ear, and spreads to the retropharyngeal area and base of the skull. This can lead to involvement of cranial nerves (I, II, III, VI, VII, VIII), and to proptosis (see above), or to diabetes insipidus, meningitis, etc. (Rosete *et al*. 1991; Greenan *et al*. 1992, Asmus *et al*. 1993; Nishino *et al*. 1993).

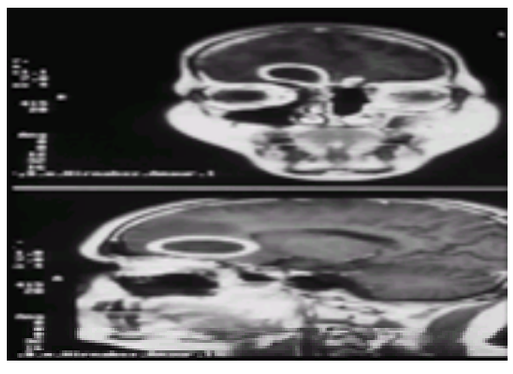

Fig. 9 Intracerebral spread of contiguous granulomatous lesion (frontal lobe) from the sinuses.

The tracheobronchial tree including the lung may also be involved in this locoregionally restricted and not yet generalized process of granulomatous inflammation: subglottic pseudotumour and/or stenosis leading to stridor and dyspnoea (Fig. 10); bronchial stenosis, which may cause atelectasis and/or obstructive pneumonia. Single or multiple nodules with or without cavitation (Fig. 11) are found incidentally in the lung of thus far asymptomatic persons (Specks and DeRemee 1990; Travis *et al*. 1991; Hoffman *et al*. 1992a).

Fig. 10 Laryngeal involvement: the circumferential narrowing just below the cords led to subglottic stenoses requiring tracheostomy (see also: saddle nose deformity).

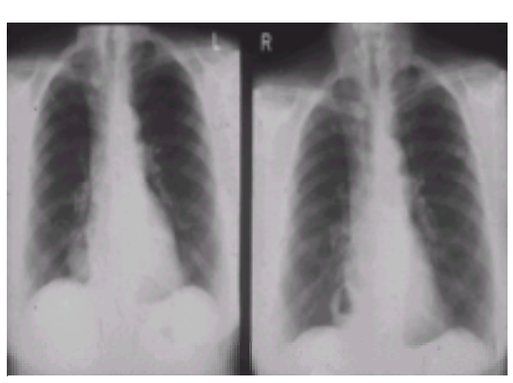

Fig. 11 Nodules in the lung usually consist of rounded lesions with well-defined margins (a); they tend to cavitate (b).

Because of the locoregionally restricted symptoms (mostly confined to the ENT region: E or lower respiratory tract including lung), the initial stage is puzzling to the diagnostician. It often takes years for Wegener's granulomatosis to be suspected and a histological diagnosis finally made. Fever can occur, perhaps caused by the underlying inflammatory disease, although it appears to be more commonly associated with secondary bacterial infection (mostly caused by *Staphylococcus aureus*) of the involved paranasal sinus (Fig. 12).

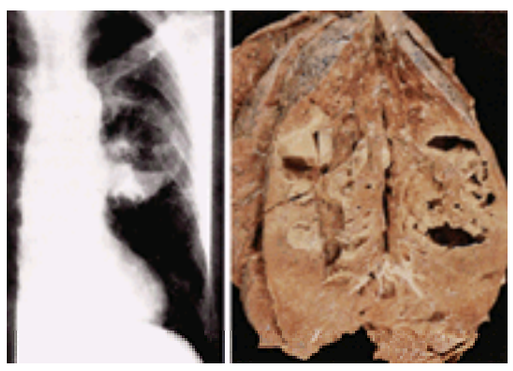

Fig. 12 Cavitary air-space consolidation initially thought to represent necrotizing bacterial pneumonia (radiographic findings and autopsy material).

Generalized Wegener's granulomatosis

P>['Systemic' Wegener's granulomatosis; E, L, K stage according to the ELK classification; for review, see Gross (1989), DeRemee (1993).]

The transition from the initial stage to the active generalized phase with its not infrequent fulminant course is heralded by the indirect symptoms of systemic vasculitis: weight loss, fever, night sweats (constitutional symptoms; similar to 'B-symptomatology' in Hodgkin's disease). Clinically, this combination of fatigue, malaise, and anorexia, together with uncharacteristic rheumatic complaints (polymyalgia, arthralgia; see below) and the striking laboratory abnormalities typical of this phase (erythrocyte sedimentation rate and C-reactive protein maximally elevated, leucocytosis, thrombocytosis), warrant close scrutiny to ensure early recognition of the imminent complications, which, if untreated, lead to the life-threatening conditions described below. Direct signs of the small-vessel vasculitis characteristically found in generalized Wegener's granulomatosis are 'red eye' (due to episcleritis, scleritis), palpable purpura of the lower extremities (due to leucocytoclastic vasculitis of the skin), peripheral neuropathy (due to the vasculitis of the vasa nervorum) and, most dangerous of all, renal involvement, which ranges from mild focal and segmental glomerulonephritis with minimal haematuria and little diminution of the glomerular filtration rate, to fulminant diffuse necrotizing and crescentic glomerulonephritis (rapidly progressive glomerulonephritis) with haematuria, pyuria, and red-cell casts, leading within several days or a few weeks to oligoanuria and dialysis. Additionally—or separately—pulmonary symptoms can arise, which may ultimately lead to pulmonary haemorrhage and severe respiratory insufficiency. In fulminant Wegener's granulomatosis, all of the symptoms described here can occur together (for example, in the form of a pulmonary–renal syndrome) or separately (alveolar

haemorrhage syndrome without glomerulonephritis; rapidly progressive glomerulonephritis without alveolar haemorrhage, etc.). In these, only rapid diagnosis and immediate immunosuppressive treatment can restrain this life-threatening condition and prevent endstage renal failure or death.

Most patients suffering from Wegener's granulomatosis, however, follow a clinical course lying between these extremes (initial-phase and fulminant generalized disease).

Otological manifestations in generalized Wegener's granulomatosis—in addition to those described for initial-phase Wegener's granulomatosis—characteristically include hearing loss due to sensorineural deafness, usually induced by the small-vessel vasculitis of the cochlear vessels and/or the vasa nervorum of the acoustic nerve. Vestibular impairment as manifested by vertigo can also occur. Similarly, peripheral facial nerve palsy can be induced by the otitis media (including mastoiditis) and the vasculitis (D'Cruz *et al*. 1989; Murty 1990).

Eye manifestations in the generalized stage of Wegener's granulomatosis are episcleritis ('red eye') (Fig. 13), vasculitis of the optic nerve, and occlusion of retinal arteries, all due to the now prominent vasculitic process, and in addition to the granulomatous lesions described above (Charles *et al*. 1991).

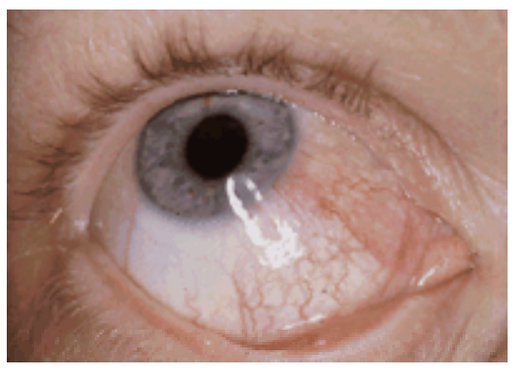

Fig. 13 Episcleritis as a characteristic clinical sign of disease activity in Wegener's granulomatosis.

The bronchial tree and lung (L) are involved usually in the systemic phase of Wegener's granulomatosis. In addition to the stenotic processes and nodules (this kind of pulmonary involvement itself is more typical of the initial phase of Wegener's granulomatosis and rather asymptomatic), localized or diffuse infiltrates should alert to the possibility of an alveolar haemorrhage resulting from the predominantly alveolar capillaritis. The three most consistent features for clinical recognition of alveolar haemorrhage are haemoptysis, infiltrates on the chest radiograph, and anaemia. The radiograph typically shows an alveolar or mixed alveolar–interstitial pattern. A distribution like that in pulmonary oedema is most common, but focal and sometimes migratory shadows are also observed (Fig. 14). However, the clinical and radiographic manifestations of immune alveolar haemorrhage are similar regardless of their aetiology. Such patients usually also have a rapidly progressive glomerulonephritis (Fig. 15) and thus typically present a pulmonary–renal vasculitic syndrome. Immunohistochemical tests on lung biopsies (e.g. via bronchoscopy) or kidney specimens reveal only a few or no immune deposits, thus excluding immune complex-mediated and antibasement membrane antibody-mediated pulmonary and pulmonary–renal vasculitic syndromes. Most patients with such 'pauci-immune' pulmonary–renal vasculitic syndromes have either cANCA (PR3-ANCA) or pANCA induced by myeloperoxidase antibodies (**myeloperoxidase-ANCA**) (Specks *et al*. 1989; Aberle *et al*. 1990; Cordier *et al*. 1990; Lombard *et al*. 1990; Dreisin 1993; Nishino *et al*. 1993).

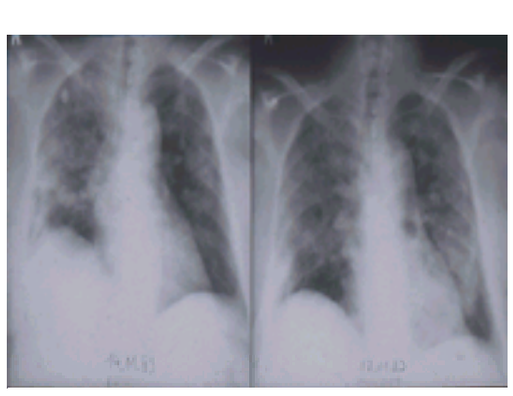

Fig. 14 Radiographic manifestation of alveolar haemorrhage in Wegener's granulomatosis.

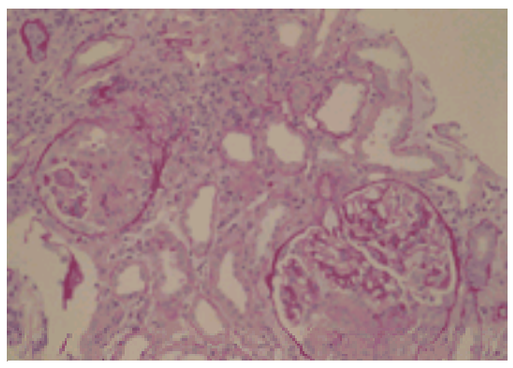

Fig. 15 Histopathology of a necrotizing and crescentic glomerulonephritis from a patient with rapidly progressive glomerulonephritis in Wegener's granulomatosis.

Abnormalities of pulmonary function include obstruction to airflow, reduced lung volumes, and abnormalities of diffusing capacity.

Kidney involvement (K) in generalized Wegener's granulomatosis shows considerable variation. At an extreme lies rapidly progressive glomerulonephritis, which is a major indicator of poor prognosis (see above). The most common manifestation of renal disease, however, is asymptomatic (micro-)haematuria with a nephritic urinary sediment and little if any renal functional impairment; this erythrocyturia is due to focal segmental glomerulonephritis. Immunohistologically, the glomeruli typically have no deposits of immunoglobulin; similarly, there is little ultrastructural evidence for immune-complex deposits. This has led to the term 'pauci-immune necrotizing and crescentic glomerulonephritis'. It is noteworthy that very similar lesions due to 'microscopic' vessel inflammation are seen in other 'ANCA-associated vasculitides' (e.g. microscopic polyangiitis) (Weiss and Crissman 1984; Wegener 1990; Falk and Jennette 1993; Jennette and Falk 1994a).

Clinical manifestations in the heart (**H** = heart involvement in the extended ELK classification) are not common in generalized Wegener's granulomatosis. However, asymptomatic pericardial effusions frequently occur and frank peri- (pan) carditis, severe granulomatous giant-cell myocarditis, and cardiomyopathy have been described (Weidhase *et al*. 1990).

Rheumatic complaints (**A** = arthralgia and/or myalgia, etc. in the extended ELK classification) ranging from mild myalgias and/or arthralgias to frank arthritis and/or myositis represent the second most frequent symptom complex (after ENT region symptoms) in generalized Wegener's granulomatosis. Musculoskeletal involvement,

particularly arthralgia and arthritis, was reported decades ago. More recently, these rheumatic manifestations were described in two-thirds of patients in a large series of cases of Wegener's granulomatosis. Twenty-eight per cent had non-erosive and non-deforming polyarthritis. Sacroiliitis was found in 3 of 50 and relapsing polychondritis in 2 of 50 patients with Wegener's granulomatosis. Rheumatoid factor was present in half of the patients with generalized Wegener's granulomatosis tested. In our own series of 186 patients with Wegener's granulomatosis (148 biopsy-proven), we found episodes of arthralgia, myalgia, or arthritis in two-thirds of cases as the presenting symptom and in three-quarters of all cases over time. Thus rheumatic complaints have been found to belong to the main symptom complex (Fig. 16). They are more frequent than symptoms of the eye, skin, or nervous system. The most common is myalgia (45 per cent), followed by frank arthritis (21 per cent), mainly in the larger joints (monoarthritis, 10 patients; oligoarthritis, 5; polyarthritis, 6). Approximately 90 per cent of patients with Wegener's granulomatosis suffering from rheumatic symptoms have a generalized form of the disease and the rheumatic symptoms usually occur together with the constitutional symptoms typically associated with active vasculitis (Noritake *et al*. 1987; Alcalay *et al*. 1990; Gross *et al*. 1991; Hoffman *et al*. 1992a) Wegener's granulomatosis can be associated with secondary relapsing polychondritis (Handrock and Gross 1993).

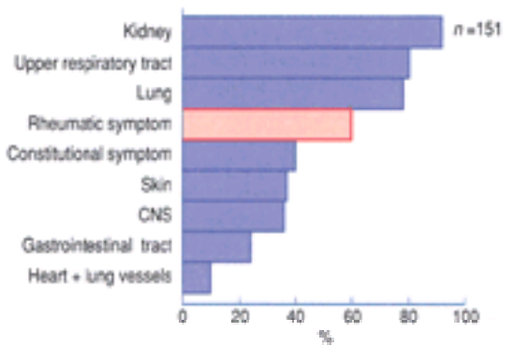

Fig. 16 Clinical symptoms in Wegener's granulomatosis.

Skin involvement (**S** = skin in the extended ELK classification) in systemic Wegener's granulomatosis usually occurs as palpable purpura due to leucocytoclastic vasculitis (Fig. 17). Less frequent are necrotic papules (Fig. 18) due to necrotizing vasculitis. Livedo reticularis and pyoderma gangrenosum are occasionally seen, sometimes as the presenting feature (Dreisin 1993; Frances *et al*. 1994).

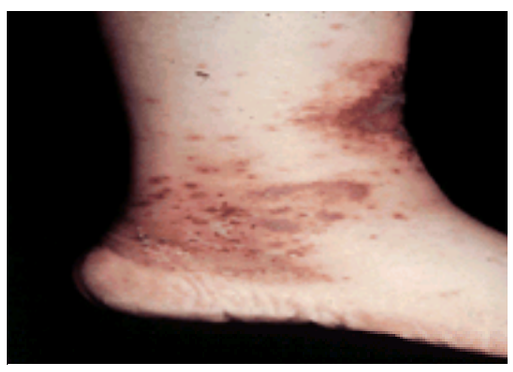

Fig. 17 Palpable purpura in a patient with fulminant Wegener's granulomatosis.

Fig. 18 Necrotic papules (and saddle-nose deformity) in Wegener's granulomatosis.

About one-third of patients with Wegener's granulomatosis have involvement of the nervous system (**C** = nervous system in the extended ELK classification). Peripheral neuropathy (excluding cranial neuropathy) occurs in about 30 per cent of patients; mononeuropathy multiplex and distal sensorimotor polyneuropathy are the leading lesions. Cerebrovascular events, seizures, and cerebritis are less frequent findings (Nishino *et al*. 1993).

In addition to this broad spectrum of symptoms, a wide variety of other manifestations, including involvement of the breast, ovaries, prostate, urethral duct, have been described, mostly in the form of case reports.

Laboratory investigations

Up to the mid-1980s, no disease-specific laboratory index for Wegener's granulomatosis existed. Disease activity was evaluated according to the clinical picture and general indices of inflammation (erythrocyte sedimentation rate, C-reactive protein) in the blood (Hoffman *et al*. 1992). In addition, the degree of normochromic normocytic anaemia, leucocytosis (usually with no or only moderate eosinophilia: less than 10 per cent), and thrombocytosis was correlated with the disease activity: all of these variables are only slightly elevated in the initial phase of Wegener's granulomatosis, and, by contrast, maximally elevated in the fulminant generalized stage, sometimes with 'leukaemoid' reactions (Gross 1996).

In contrast to the family of autoimmune rheumatic diseases (e.g. systemic lupus), generalized Wegener's granulomatosis is associated with no or only mild hypergammaglobulinaemia (minor elevations of all immunoglobulins in serum), no or only low-titre antinuclear antibody, no complement consumption (rather slight elevations), but with a rheumatic factor in up to 50 per cent of patients. In addition, cryoglobulins are characteristically absent. Indices for organ lesions, for example kidney involvement, have to be monitored by their typical tests, as for example by urine analysis (haematuria, seldom gross proteinuria), serum creatinine, etc.

Recently, cytokines, cytokine-receptor molecules, and adhesion molecules were shown to be associated with clinical disease activity when measured in serum and/or plasma (Schmitt *et al*. 1992; Stegemann *et al*. 1993; Mrowka and Sieberth 1994). Soluble interleukin-2 receptor (**sIL2-R**) is higher in patients with generalized and active disease than in those with limited and inactive disease. Surprisingly, amounts of sIL2-R are significantly elevated in patients with complete clinical remission. Further, high, amounts of sIL2-R are associated with a high probability of relapse in this group. Serum levels of soluble cell-adhesion molecules (**CAM**) (sICAM-1, sVCAM-1, sE-selectin) were found to be significantly higher in Wegener's granulomatosis than controls; in addition, sICAM-1 and sVCAM-1 decreased with clinical

remission. Surface-antigen expression of LAM-1 on granulocytes was decreased in patients with low disease activity (Riecken *et al*. 1994).

Markers of endothelial perturbation and damage (Blann *et al*. 1992; Pearson 1993; Ohdama *et al*. 1994) have been shown to be useful indicators of disease activity or progression. von Willebrand factor in plasma is secreted from endothelial cells and is widely used as one of the best markers for vasculitic disease activity. However, as with other markers (e.g. C-reactive protein), von Willebrand factor is transiently elevated during any acute-phase response to infection. Thrombomodulin, an endothelial cell-specific glycoprotein that is an important regulator of activated thrombin (converting thrombin from a procoagulant to an anticoagulant by altering its substrate specificity so that it no longer cleaves fibrinogen but activates protein C), has been found in the circulation of patients with vasculitis, including Wegener's granulomatosis. The levels of elevated soluble thrombomodulin correlate well with disease activity. In addition, autoantibodies recognizing endothelial-cell antigens are present in the serum of patients with Wegener's granulomatosis. However, they do not play a major part in the routine analysis of disease activity.

Antineutrophil cytoplasmic autoantibodies represent a class of antibodies directed not only against various constituents of neutrophil granules but even against monocytic and endothelial antigens (for review, see Jennette and Falk 1993; Gross and Csernok 1995; Kallenberg *et al*. 1994). ANCA are routinely detected by indirect immunofluorescence on ethanol-fixed neutrophils (Wiik *et al*. 1993). At least three different patterns of fluorescence can be distinguished: the (*c*lassic) cytoplasmic pattern (Fig. 19(a)) with accentuated fluorescence intensity in the area within the nuclear lobes (cANCA), the *p*erinuclear pattern (pANCA) (Fig. 19(b)), and a more diffuse cytoplasmic staining pattern (atypical ANCA). In vasculitis, cANCA is a seromarker for Wegener's granulomatosis and pANCA is a marker for microscopic polyangiitis; the cytoplasmic pattern associated with Wegener's granulomatosis is characteristically induced by PR3-ANCA, and the perinuclear pattern seen in microscopic polyangiitis is typically induced by myeloperoxidase-ANCA. However, the associations are not absolute and PR3-ANCA is sometimes seen in microscopic polyangiitis and myeloperoxidase-ANCA in Wegener's granulomatosis.

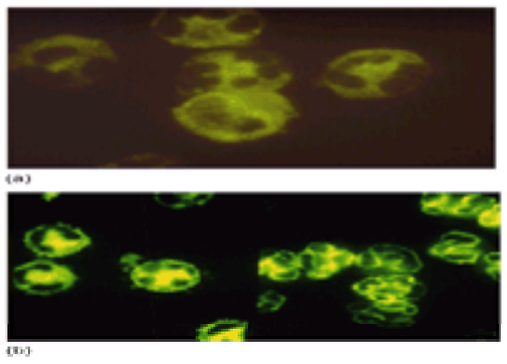

Fig. 19 Antineutrophil cytoplasmic autoantibodies: (a) cANCA and (b) pANCA fluorescence patterns.

Three major studies on cANCA comprising a total of more than 200 patients with Wegener's granulomatosis have found a 90 per cent sensitivity of the test for generalized (systemic) Wegener's granulomatosis and 75 per cent for limited Wegener's granulomatosis. It should be mentioned that these data concern patients with active disease only; during remission, cANCA were detected in a far lower percentage of the patients. However, few patients with active generalized Wegener's granulomatosis have been found to be cANCA-negative.

Various longitudinal studies have shown that titres of ANCA rise before a relapse of Wegener's granulomatosis. The rise proved to be a sensitive indicator for ensuing relapse and was detectable a mean of 49 days before the clinical manifestations. Moreover, rising titres may not only predict a relapse but can also help to differentiate relapses from the superinfections occurring not infrequently during immunosuppressive therapy. Since cANCA titres do not follow disease activity in a considerable number of patients, titres alone should not be used as a criterion for changing treatment protocols.

The specificity of cANCA for Wegener's granulomatosis has been found to be as high as 98 per cent. The application of cANCA screening to identify oligosymptomatic Wegener's granulomatosis (e.g. E, L, K, or EL, or K in the ELK classification) has led to a rise in the frequency of diagnosis of this disease. 'Initial phase' Wegener's granulomatosis can now be diagnosed using the ACR 1990 classification criteria, the definition developed by the Chapel Hill Conference in 1992, and ANCA serology. Detection of ANCA allows for the recognition (and treatment) of the underlying disease in cases presenting as Tolosa–Hunt syndrome, facial nerve paralysis, polyneuritis cranialis, peripheral neuropathy, secondary relapsing polychondritis, idiopathic necrotizing–crescentic glomerulonephritis, or renal failure of unknown origin requiring haemodialysis. It does not, however, enable recognition of acute renal failure following infectious vasculitis due to leptospirosis, as has been reported in the literature (see Gross and Csernok 1995 for review).

cANCA are found infrequently in vasculitides closely related to Wegener's granulomatosis, for example microscopic polyarteritis, Churg–Strauss syndrome, classical polyarteritis nodosa, and only exceptionally in giant-cell arteritides and Takayasu arteritis, Henoch–Schönlein purpura, cutaneous leucocytoclastic angiitis, and cryoglobulinaemic vasculitis.

A homogeneous 'cANCA' fluorescence pattern has been observed in symptomatic patients who are human immunodeficiency virus-positive and, more recently, in patients with amoebic liver abscess. In general, though, the findings of cANCA is rare in infectious disorders and one should always be aware of the possibility of a concomitant (secondary) vasculitis. Numerous recent studies, however, have shown that 'ANCA' are far from specific for Wegener's granulomatosis and have challenged the diagnostic potential of these autoantibodies. Therefore, a multinational group of experts sponsored by the European Community has attempted to work out a standardization of assays (Hagen *et al*. 1993a; Hagen *et al*. 1993b). Using their technique, one can be sure that the detection of cANCA (and/or PR3-ANCA) will help in diagnosing and evaluating disease activity in Wegener's granulomatosis.

Monitoring disease activity and disease extension

Because generalized Wegener's granulomatosis is a multisystem disease with a high rate of relapse (Hoffman *et al*. 1992a; Gordon *et al*. 1993), it is especially important that the clinical aspect of disease activity and disease extension be monitored on a regular and controlled basis by an interdisciplinary team of physicians, ear, nose, and throat surgeons, ophthalmologists, neurologists, and radiologists (Gross 1996).

At the biochemical level, the value of the erythrocyte sedimentation rate and C-reactive protein as—admittedly non-specific—indices of disease activity is accepted generally. In the initial phase of disease, both can be normal, although secondary and opportunistic infections can lead to elevated levels. cANCA titers seem to correlate with disease activity in most patients (Nölle *et al*. 1989). Consequently, changes in cANCA titre remain one of the most important laboratory markers for changes in disease activity, and the only one specific for Wegener's granulomatosis. In contrast to the erythrocyte sedimentation rate and C-reactive protein, the cANCA titre does not rise in a secondary infection. Greatly increased amounts of sIL-2R are found in patients with increased disease activity and may be an indicator of imminent relapse in those in complete clinical remission (Schmitt *et al*. 1992).

The value of MRI of the head in determining disease extension is now widely recognized (Greenan *et al*. 1992; Asmus *et al*. 1993; Muhle *et al*. 1993; Heller *et al*. 1995). MRI can demonstrate not only extensions of the granulomatous lesions within the upper respiratory tract not detectable by nasal endoscopy or conventional radiographs, but it can also disclose intracerebral granulomas (Fig. 9) and/or infarcts of grey and white matter following vasculitis.

In patients with obvious lung involvement or in those under immunosuppression who have suspected opportunistic infection, bronchoalveolar lavage can help in obtaining a histological diagnosis from transbronchial biopsy specimens (Lombard *et al*. 1990) and in demonstrating Wegener's granulomatosis-specific disease activity (marked increase in neutrophils) or *Pneumocystis carinii* (or cytomegalovirus etc.) infection (Hoffman *et al*. 1991; Sen *et al*. 1991; Barth *et al*. 1991; Jarrousse *et al*. 1993).

For patients in whom cytotoxic agents have been employed previously, continued surveillance must include the evaluation of signs and symptoms that suggest toxicity (haemorrhagic cystitis, bladder cancer, myelodysplasia, lymphoma, etc.). Because of the occurrence of 'silent' relapses, especially in the kidneys and lungs, urinalysis (sediment) and chest radiographs should be performed at close intervals if there are even minor clinical symptoms.

Pathology and pathogenesis

Wegener's granulomatosis is a clinicopathological entity closely associated with cANCA, particularly those induced by the PR3 antibodies, whose diagnosis requires the fulfilment of specific clinical and pathological criteria and/or the presence of ANCA (PR3-ANCA) in the serum.

Until fairly recently, autopsy pathology had provided most of the tissue for morphological investigations that led to the model of the classic pathological triad of granulomatous inflammation, necrosis, and vasculitis (Godman and Churg 1954). As a matter of fact, however, only tissue from open lung biopsies exhibits this triad. More commonly, only one or two elements of the triad are seen in biopsies not of the airway. Therefore, a pathological study was performed on 126 head-and-neck biopsies from 70 patients with Wegener's granulomatosis to work out criteria for the diagnosis of Wegener's granulomatosis based on such biopsies (Devaney *et al*. 1990). The following criteria were proposed:

1. If all three major pathological criteria are present, it may be considered diagnostic if there is clinical involvement of E, L, K or either L or K.
2. If two major pathological criteria are met, it may be considered diagnostic if there is typical clinical involvement of the lung and kidney as well (E, L, K); however, if only one of these sites is involved (E, L, or K), the diagnosis may be considered as probable and further biopsies should be performed.
3. If only one of the major pathological criteria is present, it may be considered as suggestive of Wegener's granulomatosis if the patient has typical clinical evidence of Wegener's granulomatosis (E, L, K) or as suspicious for Wegener's granulomatosis if the patient has only one additional site of disease (E and L or E and K).

The diagnostic value and limitations of orbital biopsy in Wegener's granulomatosis were recently delineated (Kalina *et al*. 1992).

Wegener's granulomatosis begins with granulomatous changes, as Fienberg's group was able to establish after decades of research (for review, see Wegener 1990). More recently, open lung biopsies have been studied to determine the histogenesis of pulmonary lesions and to identify early lesions (Mark *et al*. 1988). The earliest microscopic lesion is a small focus of necrosis of collagen. This is followed by an accumulation of histiocytes and their aggregation around the necrosis to form a palisading granuloma. Progression continues from micronecrosis (usually with neutrophils: 'microabscesses') to macronecrosis (wide-spread necrosis), and later to fibrosis.

Collagen in many structures of the lung was seen to have become necrotic. This included walls of blood vessels and conducting airways, alveolar walls and pleura. The primary process, therefore, is not restricted to blood vessels, although Wegener's granulomatosis is often described as a primary vasculitis.

In this study the major criteria for the histological diagnosis of Wegener's granulomatosis based on lung biopsies were outlined. The major discriminating features are palisading granulomas or palisading histiocytes in vascular walls and in extravascular tissue, microabscesses or fibrinoid necrosis in vascular walls, leucocytoclastic capillaritis, diffuse granulomatous tissue, and granulomatous bronchiolitis. Granulomatous inflammation must be found in any case.

Palisading granuloma should be distinguished from a compact, circumscribed, rounded granuloma of tuberculoid or sarcoid type. Palisading granuloma is virtually pathognomonic of Wegener's granulomatosis; by contrast, the observation of a granuloma of the tuberculoid or sarcoid type is strong evidence against Wegener's granulomatosis. Analogous to chronic granulomatous inflammation in response to a known cause (e.g. tuberculosis), palisading histiocytes and diffuse granulomatous tissue may constitute signs of a good host response in Wegener's granulomatosis. Fibrinoid necrosis of collagen within scars suggests active disease in the face of repair and preceding a host response.

From the morphological point of view, the second major feature of Wegener's granulomatosis, vasculitis, is even more polymorphic. Vasculitis generally originates in granulomas of the respiratory tract. In many cases, the anatomical picture is dominated by a necrotizing vasculitis similar to the microscopic form of polyarteritis. Vessels of many types can be affected in Wegener's granulomatosis, resulting in various clinical expressions. Less frequently, the histological picture resembles that seen in classic polyarteritis nodosa, giant-cell or Horton's arteritis, and other vasculitic disorders.

Characteristically, the acute vasculitis exhibits segmental necrotizing lesions in the walls of arteries, arterioles, capillaries, and venules. Commonly involved vessels include arteries and arterioles in skeletal and cardiac muscle as well as in liver and kidneys, postcapillary venules and arterioles in the skin, and capillaries in the pulmonary alveoli and renal glomeruli.

The third feature of the classical triad, involvement of the kidneys (for review, see Ritz *et al*. 1991; Jennette and Falk 1994b; Gross *et al*. 1995), is also characterized by a variety of clinical and anatomical pictures. As in other affected organs, the kidneys exhibit scattered granulomas in addition to variably disseminated vasculitic processes and often marked interstitial inflammatory infiltration. Glomerular involvement is frequent and is characterized histologically by segmental fibrinoid necrosis and crescent formation. No ultrastructural evidence of immune-complex localization can be found ('pauci-immune necrotizing and crescentic glomerulonephritis). Glomerular basement membranes and Bowman's capsule are often disrupted in areas of necrosis. Injury to the glomerular capillary wall is an important initiating event in the formation of glomerular crescents. Thus, the extent of renal capillaritis determines the number of crescents that ultimate lead to rapidly progressive glomerulonephritis.

Immunopathology

The aetiology of Wegener's granulomatosis is still completely unknown. In recent years, microbial infections, drugs, and tumours have been described as the 'triggering events'; in case reports viral infections (coxsackie B3, parvovirus B19) have appeared to precipitate Wegener's granulomatosis. Furthermore, an association between chronic nasal carriage of *S. aureus* and higher relapse rates in Wegener's granulomatosis has been reported (Stegemann *et al*. 1994). It has also been speculated that *S. aureus* may produce proteases with antigenic cross-reactivity with PR3 ('Wegener's autoantigen'). Sequencing of the genome of *S. aureus* will certainly be helpful in the search for possible candidates displaying molecular mimicry of PR3 and *S. aureus*.

Hydralazine, propylthiouracil, and a few other medications can induce side-effects similar to vasculitis. Both drugs have been reported to precipitate Wegener's granulomatosis (or microscopic polyarteritis). Transformation of these drugs into cytotoxic products by activated neutrophils has been described. Cytotoxicity may induce autoimmunity by exposing autoreactive lymphocytes to abnormal forms of self-material released during premature cell death (Jiang *et al*. 1994).

Recently, an association between Wegener's granulomatosis and malignancy was observed: 6.1 per cent (29/477) in a large series of patients with malignant disease. In 23 patients the tumour was diagnosed before or simultaneously with the Wegener's granulomatosis. Nearly one-third of these patients suffered from renal-cell carcinoma. Since PR3 has been found in a renal cancer cell line, autoimmunity could be induced via this pathway (for review, see Gross and Csernok 1995).

Predisposing factors are far less well accepted in Wegener's granulomatosis than in the group of collagen vascular diseases. Infrequently, Wegener's granulomatosis occurs in several members of one family (Muniain *et al*. 1986; Knudsen *et al*. 1988; Hay *et al*. 1991; Stoney *et al*. 1991; Rottem *et al*. 1993). The association between Wegener's granulomatosis and certain HLA antigens (B8, DR2) is weak. Interestingly, the persistence of ANCA in treated Wegener's granulomatosis is associated with HLA-DQw7 (Elkon *et al*. 1983; Murty *et al*. 1991). An association of severe and moderate deficiencies in protease inhibitor phenotypes with PR3-ANCA-associated vasculitis has been observed (Esnault *et al*. 1993; Elzouki *et al*. 1994). In addition, Fcg-receptor alleles may represent inheritable disease risk factors influencing the magnitude of this process, which is probably induced by neutrophil activation via ANCA (Porges *et al*. 1994).

Autoantibodies against PR3-ANCA are highly specific for Wegener's granulomatosis and since their titre often follows clinical disease activity it is believed that PR3-ANCA are of immunopathogenic relevance in this disorder. This has been extensively reviewed in recent years: for example Jennette and Falk (1992); Gross *et al*. (1993a); Gross *et al*. (1993b); Hagen *et al*. (1993); Wiik (1993); Jennette and Falk (1994a). It has been shown that the autoantibody interferes with the biological functions (e.g. by inhibition of elastinolytic activity), and with enzyme inhibitors (e.g. a $_1$-antitrypsin) of PR3. It can also activate neutrophils when PR3 is accessible on the cytoplasmic membrane by engaging the FcgRIIa receptors to produce reactive oxygen species and to degranulate. The latter event has led to the ANCA–cytokine sequence theory: As a unifying construct, it was proposed that priming doses of proinflammatory cytokines (such as those produced during infection) induce surface expression of ANCA target antigens. Binding of ANCA to these antigens leads to neutrophil degranulation and endothelial cell injury with subsequent vascular damage.

ANCA can activate primed [tumour necrosis factor-a-(**TNF-a**) pretreated] polymorphonuclear neutrophils to produce reactive oxygen species to release lysosomal enzymes (Falk *et al*. 1990) and to cause endothelial cell injury (Ewert *et al*. 1990; Savage *et al*. 1993). Proinflammatory cytokines and/or their receptors are found in serum (plasma) in active systemic vasculitis (Kekow *et al*. 1993; Roux-Lombard *et al*. 1994).

The activation pathway was once unrecognized, since PR3 (and myeloperoxidase) were thought to be located only within the azurophilic granules (Calafat *et al*. 1990). Then PR3 was detected on the plasma membrane of neutrophils using the monoclonal antibody WG M1 and electron microscopy (Csernok *et al*. 1990). Later, *in vitro* and *ex vivo* studies using flow cytometric analysis revealed that TNF-a and interleukin (**IL**) 8 act synergistically and induce a translocation of PR3 from the intragranular loci to the cell surface of neutrophils (Csernok *et al*. 1994). Apart from studies revealing upregulation of PR3 and the ability of ANCA-positive $F(ab)_2$ preparations to bind to the surface of neutrophils, to stimulate a respiratory burst, and to modulate neutrophil migration (Keogan *et al*. 1993), more recent investigations on the pathway of full neutrophil activation have shown that murine monoclonal ANCA IgG (but not IgM) binds to PR3 and stimulates the FcgRIIa ligand to activate human neutrophils via the receptor-mediated signal transduction system (Porges *et al*. 1994). Thus, ANCA-mediated neutrophil activation may occur mostly as a consequence of engagement of FcgRIIa by the Fc region of ANCA and, at least in part, via $F(ab)_2$ binding. The sum of *in vitro* and *in vivo* experimental findings supports the pathophysiological model of ANCA-mediated vasculitis depicted in Fig. 20.

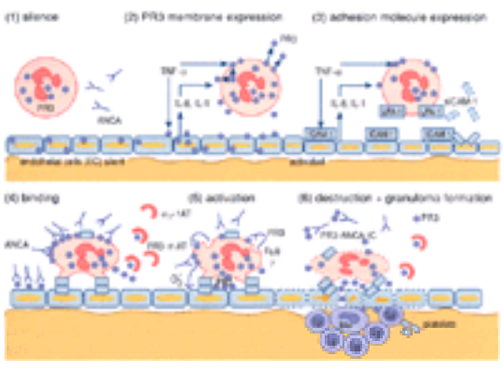

Fig. 20 Pathophysiological model of ANCA-mediated vasculitis (ANCA–cytokine sequence theory).

Mayet *et al*. (1993a) have added exciting observations to the sparse data on ANCA–endothelial cell interactions. They were able to show that TNF-a, IL-1a/b, and interferon-g lead to increased PR3 expression in the cytoplasm of endothelial cells, with translocation of PR3 to the cell membrane. Thus, PR3 located directly on the inner surface of the vessel wall becomes accessible for ANCA binding. Adhesion of polymorphonuclear neutrophils occurs via the induction of endothelial leucocyte adhesion molecule-1 (**ELAM-1**) expression on the endothelial cell surface (Mayet and Meyer zum Büschenfelde 1993). On the other hand, ANCA can bind to endothelial cells incubated with myeloperoxidase or PR3 via charge differences (cationic lysosomal proteins bind to anionic structures such as the surface of endothelial cells) and can, *in vitro*, induce complement-dependent endothelial cell lysis (Savage *et al*. 1993). Although these *in vitro* studies have demonstrated that ANCA can interact with endothelial cells, direct immunocytochemistry on lesional tissue has failed to demonstrate the binding of PR-ANCA to (Brouwer *et al*. 1994; Mrowka *et al*. 1995), or the deposition of IgG on, endothelial cells (Noronha *et al*. 1993), thus casting doubt on the immunopathological relevance of these *in vitro* findings.

PR3/myeloperoxidase deposits in tissue from ANCA-associated vasculitis have been studied by several groups (Brouwer *et al*. 1994; Mrowka *et al*. 1994; Gross *et al*. 1995). Cytokine-induced expression of adhesion molecules (e.g. LFA-1, ICAM-1, ELAM-1) facilitate close contact between neutrophils and endothelial cells, with subsequent shielding of these aggressive enzymes from their natural inhibitors (a_1 -antitrypsin, elafin, etc.; Fig. 20). Immunohistological studies of vasculitic tissue have demonstrated that both kinds of molecules are up-regulated: among the active (ANCA-associated) resident cells in glomerulonephritis, endothelial and infiltrating mononuclear cells express a variety of cytokines (IL-1, -2 and -3, TNF-a, interferon-g, platelet-derived growth factor, and transforming growth factor-b), cytokine and growth-factor receptors (**R**) (TNF-R, IL-1R type II, IL-2R, interferon-gR, and platelet-derived growth factorb-R) as well as the adhesion molecules described above (Waldherr *et al*. 1993). ICAM-1 was most abundantly present in renal lesions of Wegener's granulomatosis and the intensity of its expression correlated with the presence of glomerular crescents and the number of LFA-1 (CD11a) leucocytes. Serum levels of soluble adhesion molecules (e.g. sICAM-1) correlated with disease activity and renal functional impairment (Hauschild *et al*. 1992; Kekow *et al*. 1993; Brouwer *et al*. 1994; Mrowka and Sieberth 1994).

Activated neutrophils and the extracellular localization of lysosomal enzymes were recently observed in renal biopsies from Wegener's granulomatosis (Brouwer *et al*. 1994; Gross *et al*. 1995). Activation of neutrophils was assessed by measuring hydrogen peroxide production *in situ*; the number of activated cells in the biopsy correlated with the extent of renal functional impairment. Accordingly, PR3, myeloperoxidase, and human leucocyte elastase were localized extracellularly in renal tissue. Using a plastic embedding method, the binding of these enzymes to negatively charged structures such as endothelial cells and the glomerular basement membrane was well demonstrated, but the expression of PR3 was not found within endothelial cells. This observation was recently confirmed by Mrowka *et al*. (1995), who studied the distribution of PR3 and human leucocyte elastase in 120 renal biopsies from patients with glomerulonephritis and found these ANCA antigens expressed in ANCA-positive and -negative glomerulonephritis.

A growing body of evidence indicates that autoantibody activity in autoimmune diseases might be regulated by idiotype–anti-idiotype reactions. Observations on the clinical and *in vitro* effects of pooled human immunoglobulin and ANCA interactions (Jayne *et al*. 1993; Richter *et al*. 1993; Pall *et al*. 1994) suggest that a defect in the regulation of the idiotypic network could be involved in the production of these autoantibodies. Furthermore, network interactions can be used to develop important experimental and therapeutic agents. Our group recently generated a murine monoclonal antibody directed against a human monoclonal anti-PR3 antibody (Csernok and Gross 1993). This antibody (type Ab2b, designated 5/7) inhibits the anti-PR3 activity of cANCA in serum from patients with Wegener's granulomatosis. The anti-idiotype 5/7 is a powerful tool for studying the organization of the idiotypic network in Wegener's granulomatosis and can be used for therapeutic immunoabsorption. Furthermore, the binding of PR3-ANCA to cytokine-treated endothelial cells was blocked by the 5/7 idiotype (Mayet *et al*. 1993b). These data indicate that regulation of the idiotypic network may play an important apart in the interaction between ANCA and vascular endothelium.

Granuloma formation usually indicates a state of T-cell hyperactivity and immunohistological studies have revealed a predominance of CD4+ cells in renal biopsies of patients with Wegener's granulomatosis (Brouwer *et al*. 1991). In cellular crescents of rapidly progressive glomerulonephritis and in the peripheral blood of patients with Wegener's granulomatosis, the number of activated (CD25+) T cells is also increased. An increase in concentrations of serum cytokines (e.g. TNF-a, IL-6) during the acute phase of the disease is an indirect indicator of T-cell activation (for review, see Kekow *et al*. 1993). Elevated concentrations of sIL-2R have been detected in serum from patients with Wegener's granulomatosis, and were shown to correlate with disease activity. It has been demonstrated that even in complete remission, sIL-2R tends to be increased in Wegener's granulomatosis (Schmitt et al, 1992). However, T-cell responses to neutrophil extract did not differ between patients with vasculitis and controls: both showed only low levels of antigen-specific proliferation, and these could not be amplified by *in vitro* selection (Mathieson *et al*. 1992). In contrast to these findings, T cells from patients with Wegener's granulomatosis (PR3-ANCA positive) have been found to proliferate after exposure to highly purified PR3; however, 33 per cent of samples from healthy controls also reacted *in vitro* to PR3. In any case, the above noted extracellular localization of lysosomal proteins in renal biopsies (or elsewhere in tissue lesions in Wegener's granulomatosis) could induce the accumulation and activation of monocytes, and transform them to epithelioid and/or multinucleated giant cells characteristic of granulomas, as delineated in Fig. 20.

The IgG subclass distribution of cANCA shows a high prevalence of IgG4 antibody (Brouwer *et al*. 1991), together with increased total IgG4. This suggests repeated antigen stimulation in a T-cell response and contrasts with the IgG subclass distribution of, for example, antinuclear antibodies, which are mainly restricted to IgG1 and IgG3 (Kallenberg *et al*. 1991). Recently, a reduced CD4/CD8 T-cell ratio was reported, but this has not yet been confirmed by others (Ikeda *et al*. 1992).

Necrotizing vasculitis occurs in a number of experimental conditions involving animal models, but none of these closely resembles human systemic vasculitis (for review, see Mathieson *et al*. 1993). Brown Norway rats treated with HgCl develop a number of autoantibodies, including myeloperoxidase-ANCA, resulting in tissue injury in a number of organs, with necrotizing vasculitis especially prevalent in the gut (Mathieson *et al*. 1993). Despite similarities with human systemic vasculitis, the lack of nephritis in particular reveals the weakness of this model. The typical renal lesion of the ANCA-associated vasculitides is a pauci-immune glomerulonephritis that lacks any prominent deposition of immunoglobulin or complement, but often has extracapillary proliferation forming 'crescents' (Falk *et al*. 1990).

Brouwer *et al*. (1993) immunized Brown Norway rats with human myeloperoxidase. Five weeks after immunization the left kidney was perfused with various injurious agents, including hydrogen peroxidase plus myeloperoxidase or other products of activated neutrophils. The rats developed necrotizing crescentic glomerulonephritis and vasculitis. Since myeloperoxidase, IgG, and C3 could be detected along the glomerular basement membrane 24 h after perfusion, the 'pauci-immune' character of this vasculitis model is questionable, even when immune deposits were generally absent 4 and 10 days after perfusion. In addition, others have consistently found immune deposits along the glomerular basement membrane in both rat strains (Brown Norway and spontaneously hypertensive) used by Brouwer (Yang *et al*. 1993).

Inflammation of the vessel wall has been elicited by direct gene transfer of a foreign class I major histocompatibility complex gene, HLA-B7, to specific sites in porcine arteries. Transfer and expression of this recombinant gene was confirmed by polymerase chain reaction and immunohistochemistry, and cytolytic T cells specific for HLA-B7 were detected. This model demonstrates that vessel damage can be induced by cell-mediated immune injury (Nabel *et al*. 1992).

Treatment

Because of the possibly life-threatening course of generalized Wegener's granulomatosis there has been general agreement that the 'standard' treatment (Fauci *et al*. 1983) consisting of daily 'low-dose' (2–4 mg/day) cyclophosphamide plus glucocorticoids—undoubtedly an extremely effective therapy—is of most benefit to the majority of patients (Cupps 1990; Hoffman 1993b). This view has been challenged recently by data indicating (i) the variability of clinical course in Wegener's granulomatosis, (ii) continued morbidity despite treatment with cyclophosphamide plus glucocorticoids, (iii) a high incidence of relapse, and (iv) an alarming range of toxic effects induced by this protocol (for review, see Gross 1994).

Although the introduction of therapy with cyclophosphamide plus glucocorticoids 30 years ago improved the prognosis in Wegener's granulomatosis from a mean survival of 5 months (Walton 1958)) to a 93 per cent chance of remission (Fauci *et al*. 1983), an updated analysis (Hoffman *et al*. 1992a) now presents less favourable data on both the efficacy of the protocol (remission rate, 75 per cent) and its side-effects (serious infectious complications, 46 per cent; cyclophosphamide-induced haemorrhagic cystitis, 43 per cent; bladder cancer, 2.8 per cent; myelodysplasia, 2 per cent). These side-effects were noted earlier and are alarming because of their high rate of induced morbidity and mortality (Conn *et al*. 1988; Stillwell *et al*. 1988; Bradley *et al*. 1989; Ettinger *et al*. 1989; Anderson *et al*. 1992; Jarrousse *et al*. 1993). In addition, immediate hypersensitivity reactions to cyclophosphamide and mesna have also been observed (Knysak *et al*. 1994).

Glucocorticoids alone have failed to produce satisfactory results (Hoffman *et al*. 1992, Briedigkeit *et al*. 1993). On the other hand, high doses of glucocorticoids (in combination with daily cyclophosphamide; standard protocol in Wegener's granulomatosis) given over prolonged periods (several months) are accompanied by serious infectious complications: 50 per cent of all infections due to bacteria, pneumocystis, and fungi occurred during daily glucocorticoid therapy, 21 per cent during alternate-day therapy, 16 per cent under single-agent cytotoxic therapy, and 12 per cent during periods of no therapy (Hoffman *et al*. 1992). Such infections can contribute to vascular occlusion (Conn *et al*. 1988). Therefore glucocorticoids should be used only in conjunction with cyclophosphamide (or see below: methotrexate, azothioprine) and high initial doses of glucocorticoids should be tapered more vigorously (see Table 3) than recommended in the original report (Fauci *et al*. 1983).

The knowledge that Wegener's granulomatosis follows a two-phase course, together with the increasing identification of cases during the initial phase due to the diagnostic use of ANCA, provide a rationale for stage-adapted treatment (for review, see Hoffman 1993b; Gross and Rasmussen 1994; Gross 1996). The recognition of the toxicity and the newly discovered aspects of the disease course have led investigators to study other types of therapy for this disorder.

Trimethoprim–sulphamethoxazole

While trimethoprim–sulphamethoxazole may have the capacity to induce remission in the 'initial phase' of Wegener's granulomatosis (DeRemee *et al*. 1985; DeRemee *et al*. 1993; Reinhold-Keller *et al*. 1996), the possibility that it may actually prolong the initial phase is currently being investigated in double-blind, controlled studies. Recent experience does not indicate that trimethoprim–sulphamethoxazole can prevent relapse of generalized Wegener's granulomatosis in remission and thus it does not appear suited for treatment of classical Wegener's granulomatosis (Reinhold-Keller *et al*. 1996). Despite the lack of prospective, controlled studies, the available data on trimethoprim–sulphamethoxazole have led to its more widespread use (2 × 1 tablet, double strength) in patients in the initial stage of Wegener's granulomatosis, as described above.

Pulse cyclophosphamide

Inconsistent results were obtained in 12 patients with generalized Wegener's granulomatosis treated with pulse cyclophosphamide (Steppat and Gross 1989). Similarly, the National Institutes of Health reported only temporary benefit in 13 of 14 patients treated with the same pulse cyclophosphamide regimen; lack of response and failure to sustain improvement or tolerate continued treatment were noted in 79 per cent of patients (Hoffman *et al*. 1990). By contrast, two nephrological groups reported that the outcome after pulse cyclophosphamide therapy was similar to that following the 'standard protocol' (Falk *et al*. 1990; Haubitz *et al*. 1991). These differences may be ascribed to the fact that all of the nephrological patients had renal involvement, whereas only 50 per cent and 32 per cent of the patients investigated in the former studies showed signs of renal disease. In addition, the group studied in Chapel Hill (Falk *et al*. 1990) was mixed: only 19 of 37 patients with Wegener's granulomatosis had cANCA and a majority of the other patients had pANCA, suggesting that cases of microscopic polyangiitis had been included. Therefore, in order to determine for ourselves the clinical and/or immunological markers affecting response to pulse cyclophosphamide, we studied its efficacy in 43 patients with cANCA-positive and biopsy-proven Wegener's granulomatosis. Fifty-eight per cent of our patients did not respond to pulse cyclophosphamide treatment. Collectively, a poor response was seen in patients with generalized disease involving more than four organ systems (mainly the heart, nervous system, eyes, skin) and with constitutional symptoms and a high cANCA titre (Reinhold-Keller *et al*. 1994). We conclude, therefore, that pulse cyclophosphamide should be used in order to reduce the total amount of cyclophosphamide. Pulse cyclophosphamide can also be applied in generalized Wegener's granulomatosis with less extensive disease and a lower ANCA titre (according to the disease extension index) or in generalized Wegener's granulomatosis with formerly extensive and/or fulminant disease in partial remission (Table 3).

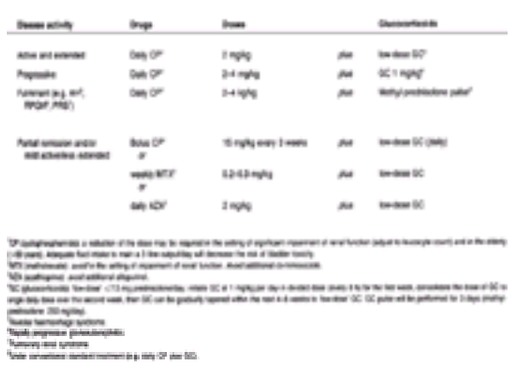

Table 3 Recommendations for drug usage in generalized Wegener's granulomatosis with respect to disease activity and extension

Methotrexate

Hoffman *et al*. (1992b) recently used 'low-dose' methotrexate (20–30 mg weekly) plus glucocorticoids in 29 patients with Wegener's granulomatosis without 'immediately life-threatening disease', although 12 (41 per cent) did have active glomerulonephritis. Treatment produced a marked improvement in 76 per cent and remission in 69 per cent. However, 3 of the 29 patients (10 per cent) suffered from *Pneumocystis carinii* pneumonia during the first month of treatment (including prednisone 60 mg/day). These data have been confirmed by Handrock *et al*. (1994). In conclusion, weekly low-dose methotrexate can be used to maintain (partial) remission in cases of Wegener's granulomatosis without renal function impairment.

Cyclosporin

Until now cyclosporin has been used only as a back-up treatment in Wegener's granulomatosis. In four patients with poor response to (oral) cyclophosphamide or with

intolerable side-effects, cyclosporin was able to control disease activity at dosages between 5 and 10 mg/kg per day (Schollmeyer *et al*. 1990). Recently, Allen *et al*. (1993) presented data on patients with active Wegener's granulomatosis undergoing combined therapy with cyclosporin and low-dose glucocorticoids. Cyclosporin was effective at initial doses of up to 5 mg/kg per day, but mild flare-ups occurred when this was lowered to 2 mg/kg per day.

Schmitt *et al*. (1993) reported on 20 patients who received renal transplants between 1982 and 1993. Treatment before transplant consisted of oral cyclophosphamide and glucocorticoids in 18 patients, and of pulse cyclophosphamide and glucocorticoids or azathioprine plus glucocorticoids in one patient each. At the time of transplant, 6 patients had symptoms of active disease. Nevertheless, 18 patients are still alive with functioning grafts (mean creatinine, 1.7 mg/per cent) and 16 are in complete remission. These results demonstrate that the rate of survival and graft function in patients with Wegener's granulomatosis is similar to that of other transplant recipients, so patients with active Wegener's granulomatosis need not be excluded from transplantation.

These data indicate that immunosuppressive therapy after transplantation must not necessarily include cyclophosphamide and that cyclosporin is effective under such circumstances.

High-dose intravenous immunoglobulin

The ability of intravenous immunoglobulin to diminish vasculitic features was described quite recently (Jayne *et al*. 1991; Tuso *et al*. 1992). Intravenous immunoglobulin was applied to 26 patients (14 with Wegener's granulomatosis, 11 with polyarteritis nodosa, 1 with rheumatoid vasculitis) requiring an intensification of therapy but mostly refractory or intolerant to glucocorticoids and cytotoxic drugs. They received a total dosage of 2 g/kg Sandoglobulin over 5 days. All patients appeared to improve after intravenous immunoglobulin, with 13/26 achieving full remission; the benefit was sustained in 18/26 at 12 months. Allowing for changes in other medications, 19/26 were in full remission after 1 year, six in partial remission, while one had died of septic complications.

In another study, intravenous immunoglobulin was given to nine patients with Wegener's granulomatosis and one with systemic pANCA-associated vasculitis, none of whom had attained complete remission under 'standard therapy' (Richter *et al*. 1995). The response was measured by blind interdisciplinary clinical assessment, cranial MRI, and immunodiagnostic analyses. All 15 patients were treated with Venimmune® (0.4 g/kg per day) for 5 days. Sixty per cent of the patients responded to therapy with improvement of single disease manifestations, but none experienced complete remission. In conclusion, intravenous immunoglobulin may play a part in Wegener's granulomatosis as an adjuvant to conventional therapy in patients with progressive disease.

Monoclonal-antibody therapy

This was introduced in 1990 for treatment of vasculitis (Mathieson *et al*. 1990). A case of severe vasculitis treated several times with an anti-CDw52 antibody (Campath 1H) responded with significant but only transient improvement. Remission lasted for more than 2 years, but this was achieved by following anti-CD52 with injection of an anti-CD4 antibody. The same group has since reported on four patients (two each with microscopic polyangiitis, Sjögren's syndrome, and Behçet's disease) who were unresponsive to immunosuppressive drugs but who received 'substantial and sustained benefit' from Campath 1H and hIgG1 anti-CD4 antibody (Lockwood *et al*. 1993). Similar results have been obtained in a few patients with systemic Wegener's granulomatosis (C. M. Lockwood, personal communication). Two other groups have reported on the successful treatment of two severe and intractable cases of relapsing polychondritis with vasculitis using a mouse and chimerical anti-CD4 monoclonal antibody (Choy *et al*. 1991; van der Lubbe *et al*. 1991).

In conclusion, preliminary studies have achieved encouraging results in patients with severe Wegener's granulomatosis refractory or intolerant to standard immunosuppressive therapy. Because such patients have a poor prognosis, these protocols appear suited as rescue regimens and should only be undertaken at experienced centres familiar with the side-effects or in trials already underway.

Azathioprine

Azathioprine has been used in the treatment of Wegener's granulomatosis and microscopic polyangiitis for many years. It has been found to be clearly less effective than cyclophosphamide for the induction of remission in generalized disease, but it seems to be valuable for maintenance of remission (Bouroncle *et al*. 1967; Fauci *et al*. 1983; Gaskin and Pusey 1992; Gordon *et al*. 1994).

Therapeutic recommendations

Recent long-term studies have revealed considerable variation in the clinical severity of Wegener's granulomatosis, while 'standard' therapy (e.g. daily cyclophosphamide plus glucocorticoids), as outlined above, is associated with considerable treatment-related morbidity, mortality, and a high incidence of relapses. On the other hand, less toxic therapeutic strategies (e.g. methotrexate) are being pursued with remarkable success. For the future, therefore, stage- and activity-dependent therapy protocols have to be developed and strategies for inducing remission must be differentiated from strategies for desperate situations (compassionate regimens). At present, many centres follow the procedures described below (see Table 3).

In initial-phase Wegener's granulomatosis, treatment can start with daily co-trimoxazole (2 × 1 double-strength tablet) if the patient can be followed easily.

In active and extended (generalized phase) Wegener's granulomatosis, most centres still begin treatment with the National Institutes of Health standard protocol (daily 2 mg/kg cyclophosphamide plus glucocorticoids). However, in contrast to the originally described concept (treatment should be continued for 1 year after the induction of remission), the therapeutic strategy is usually changed when partial remission is achieved (e.g. within the first year of treatment) to a less toxic protocol, such as pulse cyclophosphamide or weekly low-dose methotrexate (if there is no renal insufficiency) or to azathioprine (see Table 3). In addition, glucocorticoids should be tapered more vigorously (Table 3).

In the setting of (slowly) progressive Wegener's granulomatosis, by contrast, higher daily doses of cyclophosphamide (2–4 mg/kg) and glucocorticoids have to be used. The dose of cyclophosphamide will then be adjusted to maintain a total leucocyte count between 3000 and 4000/µl ('intensified' National Institutes of Health protocol) for several weeks in order to stop disease progression. In addition to an adequate fluid intake (3–4 l/day), mesna can be used to decrease the risk of cyclophosphamide-induced bladder toxicity.

In more rapidly progressive Wegener's granulomatosis (including fulminant disease), methylprednisolone pulses (250 mg/day for 3 days) are used in addition to the 'intensified' National Institutes of Health protocol. Plasmapheresis is recommended only if rapidly progressive glomerulonephritis could to lead to oligoanuria and dialysis.

In cases of generalized Wegener's granulomatosis without life- or organ-threatening disease activity, especially in the 'non-renal' variants, therapy can begin with milder protocols, for example pulse cyclophosphamide treatment every 3 weeks or weekly low-dose methotrexate, if the patient can be closely followed-up.

The adverse effects of cyclophosphamide therapy are significant (for review, see Cupps 1990). During the initial phase the leucocyte and platelet counts should be monitored at least 2 to 3 times per week. The dose of cyclophosphamide necessary to maintain a specific leucocyte count decreases as the total dose of glucocorticoids is reduced. The dose of both agents should be adapted to the age of the patient (complications arise in elderly people). The use of cyclic oestrogens may decrease the cyclophosphamide-associated toxicity in the ovary. Patients should be encouraged to maintain a fluid intake of about 3 l/day. The toxicity of glucocorticoids can be minimized by vigorous tapering (see above) and, in the event of pre-existing osteopenia, by supplementary vitamin D. A flow chart of recommended management is shown in Fig. 21.

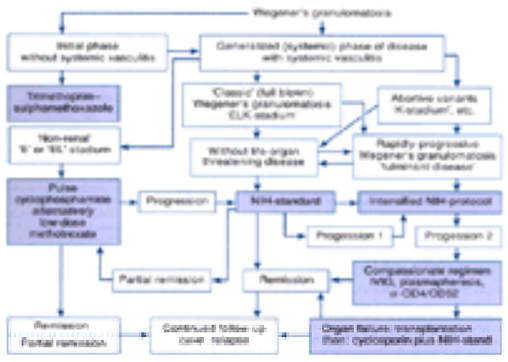

Fig. 21 Flow chart of recommended management.

It would be a grave error to assume that the available pharmacological options are enough to provide sufficient treatment. Wegener's granulomatosis obviously involves many organs and requires multidisciplinary care. Patients frequently need, for example, tympanostomies, drainage tubes for otitis media, subglottic and thoracic surgery for stenosis in the lower respiratory tract, ophthalmic surgery for obstruction of the nasolacrimal ducts, cytoscopy for cyclophosphamide-induced cystitis or bladder cancer, and renal transplantation. In addition, because of its relapsing nature, the physician treating Wegener's granulomatosis is obliged to maintain constant surveillance. This is especially true for those organs in which relapse may be asymptomatic (kidneys, lungs).

5.11.3 Classical polyarteritis nodosa, microscopic polyarteritis, and Churg–Strauss syndrome

D. Adu and Paul A. Bacon

Acknowledgement: We are grateful to Dr A.J. Howie for the photomicrographs used in Chapter 5.11.3.

Introduction and historical background

The aetiology and pathogenesis of most forms of systemic necrotizing vasculitis remain obscure. Few areas are more contentious than the classification of the necrotizing vasculitides. The difficulties are in part due to the clinical overlap within these disorders and in part because we know so little about their aetiology. Our levels of description are based on histopathology, clinical presentation, immunology, and behaviour either spontaneous or in response to treatment, and these are inexact tools for classification (see Chapter 5.11.1).

The simplest classification is into three groups of diseases based on vessel size—giant-cell arteritis of large arteries; necrotizing vasculitis of medium and small muscular arteries; and small vessel disease involving arterioles, capillaries, and venules. The necrotizing arteritis group contains both vasculitis as a complication of connective tissue disorders, such as rheumatoid arthritis, and idiopathic disease. The latter ranges from pure arteritis (classical polyarteritis nodosa) to granulomatous vasculitis (Wegener's).

In the 19th century, following Kussmaul and Maier's (1866) classical description onwards, periarteritis nodosa was considered as a rare distinct disease entity. It was characterized by visible nodular lesions at autopsy involving the muscular arteries. However, in the 20th century cases were described in which the diagnosis was made microscopically, with consequent changes in emphasis of disease descriptions. In her classic review Zeek (1952) divided the necrotizing vasculitides into five main groups. The first of these was hypersensitivity angiitis which typically involved capillaries, arterioles, and the small arteries as well as the venules and which she differentiated from periarteritis nodosa, allergic granulomatous angiitis, rheumatoid arteritis, and temporal arteritis. The organs involved were the kidney in particular, often with necrotizing glomerulonephritis, but the angiitis was usually widespread and pulmonary vessels were frequently involved. The term hypersensitivity angiitis is now used for clinical syndromes in which cutaneous manifestations predominate and in which visceral involvement is uncommon.

Pulmonary disease is a prominent feature of systemic vasculitis and studies in the 1930s separated off firstly Wegener's granulomatosis with predominant respiratory tract granuloma formation but also complicated by a vasculitis as an entity that was distinct from polyarteritis (Wegener 1936). In 1951, Churg and Strauss described the clinical syndrome of asthma, eosinophilia, and systemic vasculitis with extravascular granulomata that bears their name.

Renal lesions have been associated with polyarteritis since the comprehensive description by Kussmaul and Maier (1866). Most classic reviews have found an incidence of renal involvement in approximately 80 per cent. The morphological changes of polyarteritis nodosa—a term first used by Ferrari (1903)— were described in detail by Arkin (1930). He pointed out that in cases without aneurysms the vasculitis may only be seen microscopically, and referred to such cases as microscopic polyarteritis nodosa. This theme was taken up and expanded in a detailed clinicopathological study by Davson *et al*. (1948). They linked the presence of the primary systemic vasculitis with the occurrence of segmental necrotizing glomerulonephritis in a subgroup of patients. They again suggested that such patients had a microscopic form of polyarteritis, which they thought was distinct from the periarteritis (or polyarteritis) nodosa described by Kussmaul and Maier. They divided their patients into two groups, those with severe and widespread glomerular disease (9 out of 14) and those with minimal or no glomerular disease. Half of the first group had arterial (arcuate artery) involvement in addition to glomerular disease. These presented with a rather uniform clinical picture with pyrexia, leucocytosis, and uraemia in the presence of a normal blood pressure. The second group had variable clinical symptoms including elevated blood pressure, locomotor symptoms, abdominal pain, heart and lung involvement. Pathology here showed lesions typical of classical periarteritis and of malignant hypertension. Davson *et al*. concluded that the microscopic form of polyarteritis was different from the classical aneurysmal type. Importantly, they stated clearly that it was possible to separate microscopic polyarteritis from other forms of diffuse nephritis on both clinical and pathological grounds, establishing that the nephritis was not a coincidental or unrelated feature.

Definition of microscopic polyangiitis (polyarteritis)

It is now widely accepted on both sides of the Atlantic that the microscopic form of necrotizing angiitis with predominant involvement of the renal and pulmonary capillaries is a separate disease entity from the original descriptions of periarteritis or polyarteritis nodosa. The main question is that of nomenclature, and we favour that proposed by the Chapel Hill consensus conference (Jennette *et al*. 1994) (Table 1) but many would disagree (Lie 1994). The preferred name is now microscopic polyangiitis (microscopic polyarteritis) which has to be distinguished from classical polyarteritis nodosa. The most important distinguishing feature is the presence of vasculitis in small vessels (arterioles, venules, and capillaries) in microscopic polyangiitis and its absence in the latter. It has to be emphasized that some overlap of the size of vessel involved is seen. By definition microscopic polyangiitis must have involvement of microscopic vessels, but it is recognized that it can also involve small or medium-sized arteries. In contrast classical polyarteritis nodosa must have no involvement of microscopic vessels and therefore no glomerulonephritis. Microscopic polyangiitis and classical polyarteritis nodosa are thus differentiated by the presence or absence of small vessel involvement, rather than by the involvement of medium-sized arteries which can occur in either. The precise definitions and the question of whether involvement at all sites carry the same diagnostic weight, are still matters of discussion. For example the occurrence of small vessel involvement of the skin in classical polyarteritis nodosa with otherwise typical arterial involvement at all other sites would not change the diagnosis in our view. The definition of microscopic polyangiitis also requires few or no immune deposits in the blood vessels, in order to allow differentiation from those variants of small vessel vasculitis that do have well-defined immune complexes. This is particularly important to allow distinction from Henoch–Schönlein purpura and cryoglobulinaemic vasculitis, both with predominant cutaneous involvement. It also differentiates other forms of immune complex-mediated small vessel vasculitis such as that seen in systemic lupus erythematosus. The most frequent, clinically important aspect of microscopic polyangiitis is the glomerular lesion; similar small vessel lesions may occur in the lung. It is recognized that identical glomerular lesions may be seen in Wegener's granulomatosis but there are other important distinctions from that condition examined below.

Size of vessel	Syndrome	Granuloma	ANCA
Large	Takayasu's arteritis	+	+
	Temporal arteritis	+	–
Medium	Polyarteritis nodosa	–	+C
	Churg–Strauss syndrome	+	+P
	Kawasaki disease	–	–
Small	Wegener's granulomatosis	+	+C
	Microscopic polyangiitis	–	+P
	Leucocytoclastic vasculitis	–	–

From Jennette et al. 1994.

Table 1 Nomenclature of vasculitis proposed by the Chapel Hill consensus conference

Comparison with classical polyarteritis nodosa

The clinical distinction between the microscopic and the classical aneurysmal form of polyarteritis is not always easy. The overlapping vessel size which occurs in microscopic polyangiitis confuses interpretation of older series and makes the interrelationship of the two syndromes difficult to interpret. For example 25 per cent of renal patients in our series (Adu *et al*. 1987), all of whom had glomerulonephritis, also had renal arteritis. There is a similarity in the clinical symptoms. Even in the renal series, the majority of patients first present with non-renal symptoms. However, previous experience in a District General Hospital had emphasized the wide spectrum of severe organ involvement in classical polyarteritis nodosa (Scott *et al*. 1982). A comparison of several series of patients from renal units with those from general or overlapping departments confirmed that there are real differences (Adu *et al*. 1987). The general series, which contained many cases of classical polyarteritis nodosa, showed a higher incidence of fever, heart and lung, gastrointestinal, and peripheral nerve involvement. The difference in vessel size involved appears to dictate not just the clinical pattern of organ damage but also the prognosis. Thus visceral infarction or haemorrhage in classical polyarteritis nodosa contributes prominently to the overall outcome. The overt clinical symptoms often also contribute to an earlier diagnosis and thus institution of therapy in classical polyarteritis nodosa.

In microscopic polyangiitis there is an increase in both renal and lung disease. Pulmonary involvement in this disease has been noted in previous series and contributes to a poor prognosis (Savage *et al*. 1985; Adu *et al*. 1987). Patients may present with overt or even massive pulmonary haemorrhage in association with renal failure—so-called pulmonary renal syndrome—and these patients tend to fair badly. Less dramatic pulmonary involvement is even more frequent. The pathological lesion, a necrotizing vasculitis in small alveolar vessels, is essentially the same as in the kidney. The most striking difference between the two conditions in our series is the frequency of presentation. Eight microscopic polyangiitis cases have been seen for every classical polyarteritis nodosa case. This is not due to a biased collection from a renal centre, since the Birmingham Vasculitis Group collects cases from rheumatological as well as renal clinics and from general physician referrals. It reflects the widespread experience in Europe now that microscopic polyangiitis is common (and perhaps increasing in incidence) while classical polyarteritis nodosa is rare (and perhaps decreasing). There is also a difference in outcome. Relapse rates are high in vasculitis and this was seen in two-fifths of our classical polyarteritis nodosa cases, but only in a quarter of the microscopic polyangiitis group. However the overall prognosis is much worse in microscopic polyangiitis, which in our series showed a 40 per cent overall mortality over the decade, largely related to renal failure often associated with delayed referrals. In contrast classical polyarteritis nodosa responded well to therapy, with a 100 per cent survival in our hands despite the relapses (Gordon *et al*. 1993).

The advent of testing for antineutrophil cytoplasmic antibodies (**ANCA**) has provided another way to compare the two forms of angiitis (reviewed by Kallenberg *et al*. 1994). In microscopic polyangiitis the majority of patients (80 per cent) are ANCA positive. Specificity is directed predominantly towards myeloperoxidase and to a lesser extent against proteinase 3. In contrast, in our patients with classical polyarteritis nodosa a positive ANCA was found in 14 per cent. Others have also concluded that classical polyarteritis nodosa, without evidence of small vessel involvement, is usually ANCA negative (Cohen Tervaert *et al*. 1991; Guillevin *et al*. 1993).

Comparison with Wegener's granulomatosis

Although patients with Wegener's granulomatosis have, by definition, disease of the upper and lower respiratory tract and histological evidence of necrotizing granulomata often with an accompanying vasculitis, biopsies of lesions often show only a non-specific inflammation. A particular feature of respiratory disease in Wegener's granulomatosis is that even with treatment it is persistent and often relapsing and this helps to differentiate this disease from microscopic polyangiitis where the respiratory disease, for example pulmonary haemorrhage or epistaxis, is usually acute and transient. Wegener's granulomatosis is the classical disease which is ANCA positive, with an antibody specificity directed primarily to proteinase 3. An identical, pauci immune, necrotizing glomerulonephritis also occurs in this condition, but there is little to support the concept that microscopic polyangiitis represents a renal-limited form of Wegener's granulomatosis (Adu *et al*. 1987; Gordon *et al*. 1993).

Treatment

Therapy in these previously incurable disorders with a very high mortality has been revolutionized in the past two decades by the introduction of cytotoxic/immunosuppressive regimes. The dramatic effect of cyclophosphamide together with steroids in Wegener's granulomatosis was first established in 1971 (Novack and Pearson 1971) and these observations were later confirmed (Fauci and Wolff 1973) and extended to polyarteritis (Fauci *et al*. 1979). Recent controlled data support this beneficial effect.

Specific diseases

Classical polyarteritis

Classical polyarteritis nodosa is a systemic illness characterized by necrotizing inflammation of medium-sized arteries leading to aneurysm formation. It affects the viscera and other organs. The clinical presentation is dominated by organ infarction and haemorrhage, a neuropathy, and myalgia in the context of a systemic illness.(Frohnert and Sheps 1967; Sack *et al*. 1975; Leib *et al*. 1979; Cohen *et al*. 1980; Scott *et al*. 1982)

Age, sex, and race

In most studies there is a consistent predominance of males (male:female ratio, 1.9–2:1). The majority of patients have been Caucasian although the disease has been described in black and Asian groups. The age range is from 14 to 80 years with a peak frequency of onset in the 40s and 50s.

Clinical presentation

The clinical presentation in these patients is summarized in Fig. 1 and compared with those of patients with microscopic polyangiitis. Patients with classical polarteritis nodosa often present with systemic features comprising malaise, fever, and weight loss. About 60 per cent of patients have an arthralgia (or less commonly an arthritis) and 50 per cent of patients have a rash that is erythematous, purpuric, or vasculitic. Punched-out ulcers may occur, often around the ankles. A prominent feature in these patients is a peripheral neuropathy in 40 per cent of patients, often presenting as a mononeuritis multiplex. Gastrointestinal involvement is frequent, found in 45 per cent of our series, and carries a high morbidity and mortality. Presenting features include gut infarction, bleeding, pancreatitis, and infarction of the gallbladder, as well as non-specific abdominal pain. Renal disease in the form of an abnormal urinary sediment occurs in 55 per cent of patients, although only 24 per cent of patients have renal impairment and it is often mild. Myalgia is a prominent symptom and biopsy of affected muscles often shows a vasculitis. Rarely, testicular pain is a presenting feature of polyarteritis.

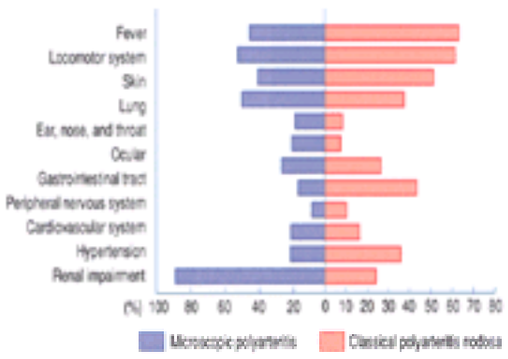

Fig. 1 Clinical features at presentation in classical polyarteritis nodosa (Frohnert and Sheps 1967; Sack *et al*. 1975; Leib *et al*. 1979; Cohen *et al*. 1980; Scott *et al*. 1982) and microscopic polyarteritis (Serra *et al*. 1984; Savage *et al*. 1985; Adu *et al*. 1987).

Hepatitis B and classical polyarteritis nodosa

Positive hepatitis B serology has been noted in between 5 and 40 per cent of different series of patients with classical polyarteritis nodosa (Frohnert and Sheps 1967; Sack *et al*. 1975; Leib *et al*. 1979; Cohen *et al*. 1980). Its prevalence appears to reflect the incidence of hepatitis B carriage in the population. It also suggests that polyarteritis nodosa is not a disease with a single aetiological agent or mechanism. In England less than 10 per cent of patients have positive hepatitis B serology (Scott *et al*. 1982) but this is considerably higher in studies from some parts of Europe (Guillevin *et al*. 1988). Clinically these patients appear more likely to have a nephrotic syndrome, which is otherwise rare in polyarteritis (Guillevin *et al*. 1988).

Localized polyarteritis

Isolated organ involvement in polyarteritis is rare. Involvement of the skin, testes, epididymis, breasts, uterus, appendix, and gallbladder have all been reported and we have seen arteritis localized to one kidney. It is not yet clear how these patients should be managed, especially if there are no systemic signs of vasculitis. The risk of progression to systemic disease in such cases is not known, although one study suggested that on long-term follow-up, the majority of patients progressed to systemic disease (Minkowitz *et al*. 1991). Close long-term follow-up is clearly important.

Microscopic polyangiitis

These patients have predominant involvement of glomerular capillaries but without granuloma formation, such as is seen in Wegener's granulomatosis. Unlike classical polyarteritis nodosa most patients with microscopic polyangiitis present with or develop severe renal disease, particularly if the diagnosis is delayed, and most studies of this disorder emanate from renal units (Serra *et al*. 1984; Savage *et al*. 1985; Coward *et al*. 1986; Adu *et al*. 1987). There may be little evidence of multisystem disease but diagnosis is aided by the detection of ANCA. In microscopic polyangiitis a perinuclear pattern of staining (**p-ANCA**) is usually seen, in contrast with the diffuse granular cytoplasmic staining (**c-ANCA**) seen in Wegener's granulomatosis (Falk and Jennette 1988; Lee *et al*. 1990). P-ANCA detects a much wider range of antigens than c-ANCA but in microscopic polyangiitis the frequent antigenic specificity is to myeloperoxidase.

Age, sex, and race

Most studies show a male predominance (male:female ratio, 1.2–1.8:1) and the overwhelming majority of patients reported are Caucasian, with only a few Negroid patients and Asians from the Indian subcontinent (Serra *et al*. 1984; Savage *et al*. 1985; Adu *et al*. 1987). The mean age at presentation is around 50 years.

Clinical features of microscopic polyangiitis

Much of the initial clinical presentation of microscopic polyangiitis is non-specific. The symptoms of microscopic polyangiitis are compared with those of classical polyarteritis nodosa in Fig. 1 (Serra *et al*. 1984; Savage *et al*. 1985; Adu *et al*. 1987). Systemic symptoms such as malaise, anorexia, fever, and weight loss predominate initially and these are accompanied by often asynchronous episodes of rash, arthralgia, myalgia, and conjunctivitis. These symptoms have often been present for months before there is a clinical suspicion of a multisystem disorder. A rash is present in approximately 40 per cent of cases, usually purpuric or vasculitic, and occurs most commonly on the limbs, in particular the hands and feet (Fig. 2). Skin ulceration is uncommon, being found in less than 5 per cent of patients, most commonly around the ankles (Fig. 2). Arthralgia or myalgia is present in about a half of patients and a quarter of these develop an asymmetric large joint arthritis.

Fig. 2 Vasculitic rash and 'punched-out' ulcer on the leg of a patient with microscopic polyangiitis.

Renal diseasex

The clinical presentation of renal disease is with microscopic haematuria (80 per cent of patients), frank haematuria (6 per cent of patients) and proteinuria (80 per cent of patients). Over 90 per cent of patients have renal impairment, and in most series no fewer than 30 per cent of patients were oliguric by the time the diagnosis was made. Hypertension is infrequent, being found in 21 per cent of patients, and usually mild.

Pulmonary disease

Symptoms of lung disease are found in about 50 per cent of patients and usually take the form of haemoptysis, pleurisy, and asthma. Frank pulmonary haemorrhage develops in 5 per cent of patients (Fig. 3) and this can be severe enough to require mechanical ventilation. The importance of diffuse pulmonary haemorrhage in both microscopic polyangiitis and Wegener's granulomatosis has been emphasized (Haworth *et al*. 1985).

Fig. 3 Diffuse reticulonodular pulmonary shadowing in the chest radiograph of a patient with microscopic polyangiitis and pulmonary haemorrhage.

Churg–Strauss syndrome

Clinical features

In 1951, Churg and Strauss described autopsy features in 13 patients who died following an illness characterized by asthma, eosinophilia, fever, and a systemic illness. All 13 patients had had asthma for up to 10 years prior to the onset of other symptoms. Fever was a universal finding, as was eosinophilia, although the levels varied considerably within individuals over time. Anaemia, weight loss, heart failure, recurrent pneumonia, and bloody diarrhoea were common. Hypertension was seen in patients with more long-standing disease. Skin lesions were usually present, varying from purpura to nodules (biopsy of which revealed granulomata). Central and peripheral nerve involvement were common, especially peripheral neuropathy (in 8 out of 13 cases). Significant renal involvement was unusual in their patients, although mild urinary sediment abnormalities were often seen.

The spectrum of clinical features of this disorder are summarized in Fig. 4. Lanham *et al*. (1984) provided a clinical definition of Churg–Strauss syndrome as a triad of asthma, eosinophilia (more than 1.5×10^9), and a systemic vasculitis involving two or more extra-pulmonary organs. From their experience and a review of the literature they concluded that extravascular granulomas were not essential for the diagnosis of Churg–Strauss syndrome. In their study, asthma or an allergic rhinitis often preceded by years the development of a peripheral blood eosinophilia and pulmonary shadowing resembling Löffler syndrome, and this in turn was followed by a systemic vasculitis. However, these manifestations may occur simultaneously (Chumbley *et al*. 1977). Although infrequently reported, renal involvement does occur and usually presents with microscopic haematuria plus proteinuria and less commonly with renal failure or a nephrotic syndrome (Clutterbuck *et al*. 1990).

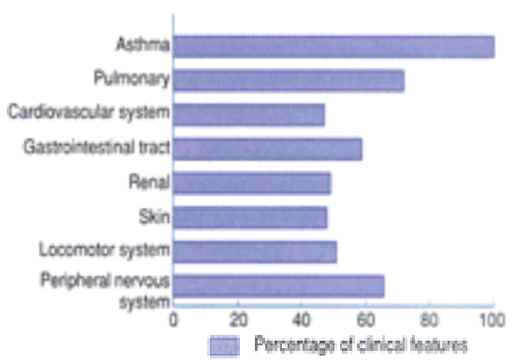

Fig. 4 Clinical features of Churg–Strauss syndrome (Lanham *et al*. 1984).

Differential diagnosis of Churg–Strauss syndrome

The prominence of asthma, an allergic rhinitis, and persistent elevation of the eosinophil count as well as the predominance of eosinophils in areas of inflammation help to differentiate Churg–Strauss syndrome from Wegener's granulomatosis, classical polyarteritis nodosa, and microscopic polyangiitis. Clinically this differentiation is not always easy (Guillevin *et al*. 1988) and the American College of Rheumatology had difficulty in classifying some of their patients with Wegener's granulomatosis, polyarteritis nodosa, and Churg–Strauss syndrome according to well-defined criteria (Masi *et al*. 1990).

Approach to the diagnosis of vasculitis

Difficulties in the classification of vasculitis often lead to delays in diagnosis. This delay is particularly marked in the elderly when it is often asociated with the rapid development of renal failure, which in turn carries a high mortality.

Clinical

The initial diagnosis is often clinical, and a high index of suspicion is required in patients with a multisystem disease, especially with a fever, skin, or renal involvement. A particular feature of systemic vasculitis is that the symptoms may be separated in time and also often fluctuate in severity. Thus for example an individual may have had an episode of arthritis followed by a uveitis and then renal disease before the possibility of a vasculitis is considered. The clinical suspicion should be pursued aggressively and with urgency in order to establish a diagnosis quickly. The overwhelming need at this stage to establish a diagnosis of a vasculitis which then requires therapy is greater than the need to establish a precise syndrome diagnosis. This may not be apparent at first presentation but subsequent progress often clarifies that. Usually there is an otherwise unexplained acute phase response with a high white blood-cell count, C-reactive protein, and erythrocyte sedimentation rate. A biopsy of clinically involved tissue is often helpful, for example skin, muscle, sural nerve, or kidney. Where there is no specific organ involvement, renal and coeliac axis angiograms should be considered.

Immunological investigations in microscopic polyangiitis, classical polyarteritis nodosa, and Churg–Strauss syndrome

Antineutrophil cytoplasmic antibodies (reviewed by Kallenberg *et al*. 1994; see also Chapter 5.11.2)

ANCA were first described by Davies *et al*. (1982) and Hall *et al*. (1984) in patients with a segmental necrotizing glomerulonephritis, some of whom had features consistent with a systemic vasculitis. The report of Van der Woude *et al*. (1985) showed that antineutrophil cytoplasmic antibodies were found commonly in the sera from patients with Wegener's granulomatosis. Subsequently these observations were extended to patients with microscopic polyangiitis (Savage *et al*. 1987). Two broad patterns of cytoplasmic staining have been recognized. In the first there is granular staining of the cytoplasm of ethanol-fixed neutrophils (c-ANCA). This pattern of staining is commonly seen in the sera of patients with Wegener's granulomatosis (Van der Woude *et al*. 1985). The target antigen for this antibody is almost entirely restricted to a 29 kDa serine proteinase, neutrophil serine proteinase 3 (Goldschmeding *et al*. 1989). The second pattern is of perinuclear staining (p-ANCA) which is seen in the sera of patients with microscopic polyangiitis and also idiopathic segmental necrotizing glomerulonephritis. A wider range of specificities is seen with p-ANCA, although the majority of these antibodies are directed against myeloperoxidase (Falk and Jennette 1988; Lee *et al*. 1990) and in a few cases against elastase and lactoferrin.

Approximately 80 per cent of patients with active, systemic Wegener's granulomatosis have c-ANCA antibodies in their sera (reviewed by Van der Woude *et al*. 1989; Specks and De Remee 1990). P-ANCA are found in the sera of approximately 80 per cent of patients with microscopic polyangiitis and about 75 per cent of patients

with Churg–Strauss syndrome (Cohen Tevaert *et al*. 1991; Guillevin *et al*. 1993). P-ANCA is less disease specific as well as less sensitive. Elevated titres are reported in Kawasaki's syndrome, rheumatoid vasculitis, and idiopathic segmental necrotizing glomerulonephritis. Between 14 and 20 per cent of patients with classical polyarteritis nodosa have a positive ANCA (Adu *et al*. 1993; Guillevin *et al*. 1993) and in patients with polyarteritis nodosa that is positive for hepatitis B, 11 per cent are reported to have a positive ANCA (Guillevin *et al*. 1993). It is important to recognize that ANCA have also been described in systemic lupus erythematosus (rarely), rheumatoid arthritis, inflammatory bowel disease, and in some infectious diseases (reviewed by Kallenberg *et al*. 1994).

ANCA in pathogenesis

The pathogenesis of vascular inflammation in systemic vasculitis is unknown. ANCA have recently been postulated to have a major role in this (reviewed by Kallenberg *et al*. 1994). Proinflammatory cytokines induce the surface expression of PR3 and MPO on neutrophils where they are accesible to react with ANCA (Falk *et al*. 1990a). Recent studies have shown that neutrophils primed with tumour necrosis factor-a are activated by ANCA to produce reactive oxygen products as well as to degranulate by the cross-linking of surface-expressed ANCA antigen with FcgR11 (Porges *et al*. 1994) and this can lead to bystander injury to endothelial cells (Ewert *et al*. 1992; Savage *et al*. 1992). MPO and PR3 bind to endothelial cells of cultured human umbilical vein by a charge mechanism and can then react with ANCA, with the potential for subsequent endothelial cell damage through complement activation or neutrophil adhesion and activation (Savage *et al*. 1992; Varagunam *et al*. 1992a). Further, it has been reported that ANCA can increase neutrophil adhesion to cultured endothelial cells, although the mechanism of this is unclear.

ANCA-negative vasculitis

The majority of patients with classical polyarteritis nodosa (more than 80 per cent) and a minority of patients with microscopic polyangiitis (20 per cent) have a negative ANCA. This means that whilst ANCA are a useful non-invasive test n the diagnosis for vasculitis they are not essential for diagnosis. Serial studies suggest that while rising ANCA titres may predict a later flare, this is not always the case (Jayne *et al*. 1995). Strictly ANCA appear to be neither necessary nor sufficient for either diagnosis or flares of vasculitis, emphasizing the complex interactions which lead to disease expression.

Antiendothelial cell antibodies

Several studies have reported the presence of antibodies to endothelial cells (**AECA**) in the sera of patients with both Wegener's granulomatosis and polyarteritis (Frampton *et al*. 1990; Varagunam *et al*. 1992b). It has been suggested that AECA are important in the pathogenesis of vasculitis and inferred that they might cause endothelial injury. Alternatively they may be a reaction to endothelial damage and thus useful in assesment. It is as yet unclear whether these antibodies are going to be useful in diagnosis or management of these disorders.

Renal and coeliac angiograms

The value of arteriography in the diagnosis of classical polyarteritis nodosa has been reviewed by Travers *et al*. (1979). The radiological findings include aneurysms and also segmental narrowing and variation in the calibre of arteries, together with pruning of the peripheral vascular tree. Interpretation of the significance of such findings requires a radiologist with special experience. Aneurysms are most found commonly in the hepatic and renal arterial tree (Fig. 5) but can also occur in cerebral and pulmonary arteries. In the kidneys, wedge-shaped areas of infarction may be seen. Angiography is helpful both for confirming the presence and for documenting the extent of a necrotizing vasculitis. It is less useful in establishing the precise disease label. Aneurysms may also occur infrequently in other vasculitic disorders such as Wegener's granulomatosis and systemic lupus erythematosus. Where there is a clinical suspicion of classical polyarteritis nodosa it is sensible to do renal and coeliac angiograms and only to proceed to a renal biopsy if no aneurysms are found.

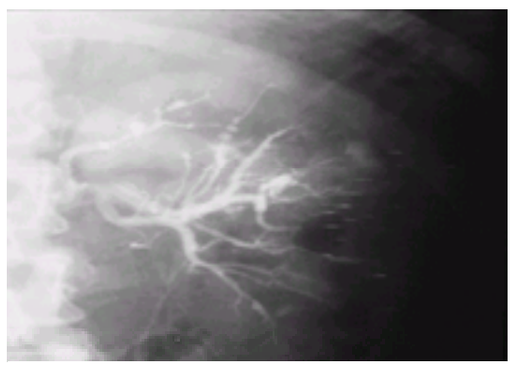

Fig. 5 Renal arteriogram in classical polyarteritis nodosa showing multiple aneurysms on renal vessels.

Pathology

Classical polyarteritis nodosa

Histology shows an arteritis with endothelial damage, fibrinoid necrosis affecting both intima and media (Fig. 6) and an inflammatory infiltrate of intima and media consisting predominantly of neutrophils but also of mononuclear cells. Often there is destruction of the internal elastic lamina. In some lesions the media and adventitia are surrounded by an infiltrate of mononuclear leukocytes and neutrophils. Immunofluorescent studies are in general negative for immunoglobulins and complement (Spargo *et al*. 1980; Cupps and Fauci 1981; Ronco *et al*. 1983).

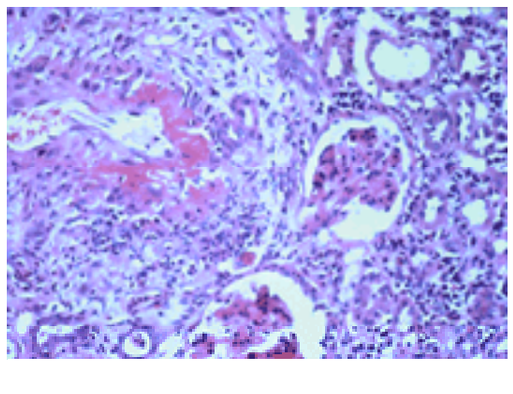

Fig. 6 Photomicrograph of a renal biopsy showing fibrinoid necrosis of an interlobular artery. Haematoxylin and eosin, original magnification × 25.

Microscopic polyangiitis—renal pathology

The characteristic renal lesion is a focal, segmental necrotizing glomerulonephritis with fibrinoid necrosis and thrombosis of segments of the glomerular tufts surrounded by neutrophils (Fig. 7) (Davson *et al*. 1948; Serra and Cameron 1985; D'Agati *et al*. 1986; Adu *et al*. 1987). Often there is rupture of the glomerular basement membrane with adjacent extracapillary proliferation. Between 15 and 20 per cent of biopsies show extensive extracapillary proliferation (crescent formation). Healed glomerular lesions are characterized by sharply defined segmental scars in which disrupted glomerular capillary loops can be seen. Glomerular immune deposits of immunoglobulin and complement are sparse and this is of value in differentiating the glomerular lesions of microscopic polyangiitis from those of

other vasculitic disorders such as systemic lupus erythematosus and Henoch–Schönlein purpura. In about 20 per cent of the patients there is an acute vasculitis affecting arterioles as well as arteries. This often takes the form of endothelial damage, with fibrinoid necrosis disrupting the internal elastic lamina, and an infiltrate of neutrophils plus mononuclear cells in the media, the adventitia, and surrounding the vessel.

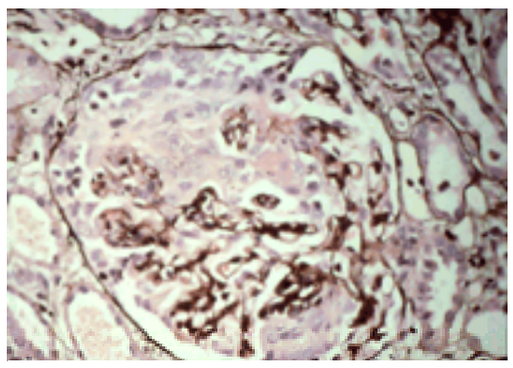

Fig. 7 Photomicrograph of a renal biopsy showing a segmental necrotizing glomerulonephritis with thrombosis and disruption of glomerular capillary loops and overlying extracapillary proliferation (crescents). Periodic acid–methenamine silver, original magnification × 100.

Most biopsies show a tubulointerstitial infiltrate with lymphocytes and eosinophils often around affected glomeruli. The severity of renal impairment correlates more closely with the severity of tubular damage than with the extent of glomerular disease.

Electron microscopy (D'Agati et al. 1986)

Electron microscopy of glomeruli and also of arteries and arterioles shows that the earliest changes are of endothelial swelling and degeneration with focal detachment of the endothelium and subendothelial deposits of fibrin. With more advanced lesions there is more widespread denudation of endothelium with intraluminal fibrin deposits and occasional thrombi. At this stage polymorphonuclear leucocytes and monocytes are found both in the vessel lumen and within and around the walls.

Leucocyte infiltrate

Studies of renal histology in patients with Wegener's granulomatosis and microscopic polyangiitis have shown infiltrating monocytes/macrophages and neutrophils within glomeruli and in crescents. CD3 and IL-2R positive T cells were also identified in crescents, in the periglomerular area, and in the interstitium (Noronha *et al*. 1993; Brouwer *et al*. 1994)

Cell adhesion molecules

Cell adhesion molecules (**CAMs**) play a critical role in the migration of leucocytes to sites of inflammation, in selecting the types of leucocytes that accumulate, and in modifying leucocyte function, thus providing a mechanism by which leucocytes accumulate in renal tissues leading to glomerular and interstitial inflammation. CAMs expressed by the human kidney include the glycoproteins, intercellular adhesion molecule-1 (ICAM-1, CD54), and vascular cell adhesion molecule-1 (**VCAM-1**), which belong to the immunoglobulin supergene family, and the selectin, E-Selectin. The glomerular endothelium in biopsies from patients with Wegener's granulomatosis and microscopic polyangiitis expresses VCAM-1, which was not seen in any of the normal biopsies studied (Bruijn and Dinklo 1993; Pall *et al*. 1996). VCAM-1 expression by the glomerular endothelium may be important in selectively recruiting monocytes/macrophages and T lymphocytes that express VLA-4 (CD49d/CD29). It is possible that this adhesion molecule is involved in the genesis of this type of glomerular inflammation.

Churg–Strauss syndrome

The histological lesions described by Churg and Strauss included extravascular necrotic lesions which were widespread but most commonly seen in the epicardium. Acute lesions showed a predominant eosinophilic infiltrate whilst more chronic lesions comprised of giant-cell granulomata. In addition there was often a necrotizing arteritis with an infiltrate comprising eosinophils and giant-cell granulomata. Subsequent studies by Chumbley *et al*. (1977) and Lanham *et al*. (1984) suggest that a granulomatous vasculitis and extravascular granulomata were not essential for the diagnosis of Churg–Strauss syndrome. As with microscopic polyangiitis, the predominant renal lesion found in 85 per cent of cases is a focal, segmental necrotizing glomerulonephritis, often with extracapillary proliferation. Eosinophil infiltration and granulomata in the renal interstitium and a necrotizing arteritis are uncommon and found in less than 10 per cent of cases (Clutterbuck *et al*. 1990).

Other investigations in patients with a vasculitis

These provide evidence of an acute phase response with anaemia, high white blood-cell count, erthrocyte sedimentation rate, C-reactive protein, platelets, and serum complement levels, and a low serum albumin (reviewed by Serra and Cameron 1985). Serum levels of factor VIII-related antigen are raised in patients with vasculitis (Woolf *et al*. 1987). An eosinophilia (more than 1.5×10^{9}/l) is a characteristic feature of Churg–Strauss syndrome, although lesser degrees of eosinophilia may be seen in patients with classical polyarteritis nodosa who usually also have pulmonary disease (Frohnert and Sheps 1967). Microscopic haematuria and proteinuria are common presenting abnormalities in patients with renal disease. Abnormal liver function tests with a raised serum alkaline phosphatase are found in approximately 50 per cent of patients with microscopic polyangiitis (Savage *et al*. 1985; Adu *et al*. 1987). Low titres of rheumatoid factor are found in both Wegener's granulomatosis (Fauci *et al*. 1983) and classical polyarteritis nodosa (Leib *et al*. 1979; Scott *et al*. 1982). Low titres of antinuclear antibodies are found in a minority of patients with classical polyarteritis nodosa (Cohen *et al*. 1980; Scott *et al*. 1982). Immune complexes, usually in low titre, have been reported in the sera of some patients with a vasculitis (Scott *et al*. 1982; Ronco *et al*. 1983; Serra *et al*. 1984) but their significance is uncertain.

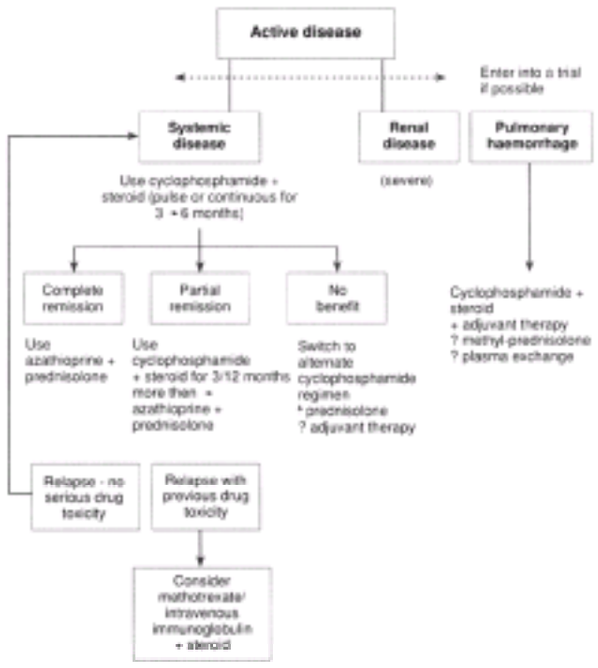
Therapy and prognosis of vasculitis

Overview of treatment

There is now a general consensus of opinion that the prognosis of idiopathic systemic necrotizing vasculitis (Wegener's granulomatosis, classical polyarteritis nodosa, and microscopic polyangiitis) has been greatly improved by the addition of cyclophosphamide to steroid treatment as originally reported by Fauci *et al*. 1979; (Fauci *et al*. 1983). The only controlled study in patients with classical polyarteritis nodosa confirmed this (Guillevin *et al*. 1991). Before the use of steroids and immunosuppressive therapy the 1-year survival rate in Wegener's granulomatosis was 20 per cent and the 2-year survival 7 per cent (Walton 1958). In classical polyarteritis nodosa the overall 5-year survival was less than 15 per cent (Frohnert and Sheps 1967; Leib *et al*. 1979). There are no historical data on the treatment of microscopic polyangiitis. Most published clinical series are relatively recent and include a large proportion of patients with renal failure. Recent studies show that over 80 per cent of patients with Wegener's granulomatosis and classical polyarteritis nodosa and over 70 per cent of patients with microscopic polyangiitis now survive for more than 5 years (reviewed by D'Amico and Sinico 1990).

Treatment of these vasculitides is essentially the same; the sole exception to this is antiviral treatment in polyarteritis nodosa induced by hepatitis B. The aims of treatment of systemic vasculitis are first to induce remission of active disease, thereby limiting the consequences of vascular injury so as to improve survival and limit disease-related morbidity. Second, to maintain remission thereby preventing organ damage from relapses. Third, to limit the consequences of the toxicity of treatment with cyclophosphamide and steroids. Now that most patients with a systemic vasculitis survive their acute illness this is an important additional aim. This makes choice of remission maintenance regimes a key issue (see Box 1).

Box 1 Algorithm for the treatment of systemic vasculitis



Treatment of classical polyarteritis nodosa and microscopic polyangiitis

There is still uncertainty as to how much cyclophosphamide and prednisolone should be given, whether they should be given continuously and orally, or as intermittent intravenous pulses, and for how long treatment should be given.

Continuous oral prednisolone and cyclophosphamide

This has been used in most studies (Fauci *et al*. 1979; Fauci *et al*. 1983; Adu *et al*. 1987). Prednisolone is used at an initial dose of 0.6 to 1 mg/kg per day and the dose tapered to around 0.15 mg/kg per day at 4 to 6 months. Cyclophosphamide is started at a dose of 1.5 to 2 mg/kg per day and the dose adjusted to avoid a leucocyte count of less than 4×10^{9}/l.

Intermittent bolus prednisolone and cyclophosphamide

Our current intermittent regime, initially intravenous and then switched to oral pulses, has been described in detail elsewhere (Bacon 1987; Bacon *et al*. 1992) and is summarized in the appendix. Following evidence of the benefits of this regime in rheumatoid vasculitis (Scott and Bacon 1984) and lupus nephritis (Austin *et al*. 1986), we have successfully used a similar regime in patients with Wegener's granulomatosis, classical polyarteritis nodosa, and microscopic polyangiitis (Bacon *et al*. 1992; Adu *et al*. 1993). Previous studies in lupus nephritis showed that pulse cyclophosphamide was as effective in improving and stabilizing renal function and was associated with a lower incidence of cyclophosphamide toxicity than the continuous oral regime (Austin *et al*. 1986). Haemorrhagic cystitis or malignancy was not seen in patients treated with pulse cyclophosphamide and amenorrhoea appeared to be less common in patients treated with pulse cyclophosphamide compared with those receiving continuous oral cyclophosphamide. Uncontrolled studies of pulse cyclophosphamide in systemic vasculitis have yielded contradictory findings. Falk *et al*. (1990b) showed that monthly intravenous cyclophosphamide plus continuous oral prednisolone for 6 months was as effective as continuous oral cyclophosphamide plus prednisolone in patients with ANCA-positive glomerulonephritis and systemic vasculitis in terms of renal improvement and patient survival. Likewise, Haubitz *et al*. (1991) found that all eight patients with Wegener's granulomatosis treated with monthly intravenous cyclophosphamide and oral prednisolone went into remission and that drug toxicity was less than in 15 patients treated with continuous oral cyclophosphamide and prednisolone. By contrast Hoffman *et al*. (1990) found that only 2 out of 11 (18 per cent) patients with Wegener's granulomatosis treated with monthly pulse cyclophosphamide and oral prednisolone achieved sustained remission. We use a pulse regime with only a 2-week gap between the initial three doses. In our ongoing controlled study, we found that pulse cyclophosphamide and steroids were equally as effective in inducing remission (Adu *et al*. 1993) and improving renal function as continuous cyclophosphamide and steroids. With both treatment regimes survival was comparable, with 90 per cent of patients with a systemic vasculitis surviving their first year of treatment. It is unlikely that this can be improved significantly. Relapses in the short term were comparable in the two treatment regimens.

Dose adjustments for renal failure and age

The metabolites of cyclophosphamide are excreted by the kidneys and accumulate in renal failure (Juma *et al*. 1981). In our experience this can lead to marrow suppression (Adu *et al*. 1987). The dose of cyclophosphamide must, therefore, be reduced in patients with renal impairment. A similar dose reduction is also advised in patients over the age of 70 years as they appear to be more sensitive than younger patients to marrow suppression with cyclophosphamide.

Duration of treatment

There is no agreed view on how long treatment should be continued. The duration of treatment is important as cyclophosphamide and steroids have substantial side-effects that have become more important as more patients survive their acute disease. On the one hand an inadequate duration of treatment might be accompanied by relapses, organ damage from vasculitis, and the consequences of this; and on the other hand overtreatment leads to a high drug toxicity. With the improved survival with current treatment, morbidity from haemorrhagic cystitis, bladder carcinoma, and lymphoma has become a major clinical problem. In Wegener's granulomatosis Fauci *et al*. (1983) recommended that treatment with cyclophosphamide should be continued for a year after remission is induced, after which the dose of cyclophosphamide and prednisolone should be tapered over several months. In patients on continuous oral prednisolone and cyclophosphamide we currently change from cyclophosphamide to azathioprine when remission is induced, usually after 4 to 6 months of treatment. Azathioprine and low-dose prednisolone is then continued with a low-dose alternative-day regime. Fuiano *et al*. (1988) also recommended keeping the patient on long-term prednisolone and azathioprine once cyclophosphamide has been discontinued. With the intermittent prednisolone and cyclophosphamide regime, cyclophosphamide is currently discontinued at 18 months and the patient changed to azathioprine and low-dose alternate-day prednisolone. The total dose of cyclophosphamide with the intermittent regime is considerably lower than with the continuous regime but we are currently studying shorter pulse regimes.

Intravenous methylprednisolone

This has been used in patients with active disease, especially when there is a crescentic glomerulonephritis. There is no compelling evidence that this confers any additional benefits when given in conjunction with continuous oral prednisolone and cyclophosphamide.

Plasmapheresis

Data from the Hammersmith Hospital suggest that plasma exchange may be of benefit in patients with a vasculitis who are also dialysis dependent (Hind *et al*. 1983; Pusey *et al*. 1991). We reserve the use of plasma exchange for patients with severe vasculitis, unresponsive to cytotoxics and steroids, or for patients with diffuse pulmonary haemorrhage or a diffuse crescentic glomerulonephritis.

Pooled, human intravenous immunoglobulin

Jayne *et al*. (1990) have suggested a beneficial effect of intravenous, pooled, normal human immunoglobulin in patients with ANCA-positive vasculitis. *In vitro* studies have shown that intravenous immunoglobulin contains anti-idiotypic antibodies to ANCA and AECA, capable of inhibiting the binding of these autoantibodies to their autoantigens. The possible mechanisms by which intravenous immunoglobulin works are still unclear. The treatment must be regarded as experimental until data from controlled studies are available.

Anti-T-lymphocyte antibodies

In a recent case report, Mathieson *et al*. (1990) successfully used a genetically engineered monoclonal antibody, Campath-1H (anti-CDw52) directed against

lymphoid cells and monocytes specifically, together with an anti-CD4 antibody against T-helper cells, to treat one patient with intractable systemic vasculitis that was ANCA negative. A subsequent study confirmed and extended these observations to four patients (Lockwood *et al*. 1993). This treatment may be of use in systemic vasculitis that is resistant to conventional treatment.

Other treatments

There are anecdotal reports that cyclosporin may be of benefit in patients with Wegener's granulomatosis resistant to cyclophosphamide (Borleffs *et al*. 1987; Gremmel *et al*. 1988) but these have not been confirmed. There appears to be no good reason at present for using this drug to treat patients with a vasculitis in preference to cyclophosphamide.

Treatment of Churg–Strauss syndrome

Lanham *et al*. (1984) found that steroids alone were beneficial, although 4 of their 16 cases were given cytotoxic agents, and 3 had additional plasma exchange. Chumbley *et al*. (1977) also found that steroids alone were useful, although the 5-year survival was only 62 per cent, suggesting that the long-term prognosis might have been improved by the addition of cytotoxic agents. In patients with renal involvement, additional cyclophosphamide has been reported to be of benefit (Clutterbuck *et al*. 1990). We and others (Guillevin *et al*. 1991) routinely add cyclophosphamide to steroids if renal or neurological disease occurs.

Side-effects of treatment

A prominent complication of treatment with steroids and cyclophosphamide is sepsis and in our earlier study this was a major cause of death (Adu *et al*. 1987). We routinely use prophylactic oral amphotericin to reduce the risk of oral candidiasis and an H_2-receptor antagonist to reduce peptic ulceration. Cystitis is a well-recognized complication of cyclophosphamide therapy with an incidence varying from 15 to 34 per cent (Stillwell and Benson 1988; Fauci *et al*. 1983). We have not seen this complication in patients on intermittent intravenous cyclophosphamide. We routinely give Mesna. By binding the acrolein metabolites of cyclophosphamide, Mesna reduces the urothelial toxicity of cyclophosphamide (Bryant *et al*. 1980). With prolonged treatment this toxicity can lead to the development of bladder tumours (Stillwell *et al*. 1988). Other malignancies associated with long-term use of cyclophosphamide include leukaemia and lymphoma (Green *et al*. 1986). Cyclophosphamide may also lead to the development of azoospermia (Fairley *et al*. 1972) and ovarian dysfunction (Miller *et al*. 1971) and, when indicated, storage of gametes may be advised. Rarely cyclophosphamide can lead to the development of an interstitial pulmonary fibrosis (Cooper *et al*. 1986).

Consequences of drug toxicity

In their follow-up report of patients with Wegener's granulomatosis treated with long-term cyclophosphamide, Hoffman *et al*. (1992) found that drug-related toxicity had become a major cause of morbidity, being found in 42 per cent of patients. On long-term follow-up, 43 per cent of their patients developed cyclophosphamide-induced haemorrhagic cystitis, 2.8 per cent a bladder cancer, 2 per cent lymphomas, 2 per cent myelodysplasia, and 57 per cent of the women ovarian failure. Overall there was a 2.4-fold increase in malignancies, a 33-fold excess risk of bladder cancer and an 11-fold excess risk of lymphoma compared with age-matched controls. Despite this very significant treatment toxicity from cyclophosphamide, the patients had active disease for 54 per cent of the total time of follow-up. A clear conclusion of these data and our own is that whilst cyclophosphamide is effective in inducing remission it appears to be relatively ineffective in maintaining remission. As more patients survive their acute illness this burden of serious drug-related toxicity becomes unacceptably high, prompting a search for safer and at least equally effective ways of maintaining remission. There are now real anxieties about the appropriateness of using long-term oral cyclophosphamide in patients with a systemic vasculitis.

Monitoring disease activity in systemic vasculitis

Clinical disease activity

Accurate assesment of disease activity makes it possible to differentiate disease activity from the effects of chronic damage with dysfunction and infection. This is important as a guide to increasing or reducing the doses of potentially toxic drugs. Several disease activity scores have been developed. These include the Kallenberg score (Kallenberg *et al*. 1990), the vasculitis activity index (Olsen *et al*. 1992), and the Birmingham vasculitis activity score (**BVAS**) (Luqmani *et al*. 1994). In our study there was reasonable correlation between these three scores. In clinical practice the BVAS score appeared to provide a precise assessment of organ involvement in vasculitis compared with a physician's global assessment (Luqmani *et al*. 1994). For longer-term follow-up, assessment of damage (accumulating, non-healing scars) and the patient's functional status are also important. In the European Community collaborative studies, a protocol combining all these aspects has been devised (Bacon *et al*. 1995).

ANCA and disease activity

There is now good evidence that ANCA titres correlate with disease activity, tending to fall in remission and rise with relapse (Cohen Tervaert *et al*. 1989; Nolle *et al*. 1989). Sequential titres of antibodies to proteinase 3 and myeloperoxidase are useful in monitoring disease activity and predicting relapses but do not always provide correct predictions (Jayne *et al*. 1995) and thus should be used with other markers of activity. The correlation with disease activity is not sufficiently close (Kerr *et al*. 1993) to justify an increase in immunosuppressant therapy with rises in ANCA titre as has been suggested (Cohen Tervaert *et al*. 1989). Some of our patients with a positive ANCA or a rise in ANCA titre have remained free of active disease for several years.

Non-specific markers of disease activity

C-reactive protein

C-reactive protein is an acute phase protein and several studies have reported that the serum levels correlate closely with disease activity in patients with Wegener's granulomatosis and microscopic polyangiitis (Hind *et al*. 1984). The serum levels of C-reactive protein rise with sepsis and both this and factor VIII-related antigen may be persistently elevated in infarction. This can limit its usefulness in monitoring disease activity in vasculitis. In addition they do not predict relapse.

Factor VIII-related antigen

Factor VIII-related antigen is a glycoprotein that is present in endothelial cells and megakaryocytes and synthesized by both cell types. It plays a role in platelet adhesion to the subendothelium, and serum levels are raised in endothelial injury. Recent studies have reported that serum levels of factor VIII-related antigen are raised in patients with vasculitis (Woolf *et al*. 1987). Our own observations are that the serum levels of this antigen rise after the onset of vascular injury and that this rise persists for several months after clinical improvement. This limits its usefulness as a marker of disease activity.

Circulating soluble adhesion molecules

Cell adhesion molecules circulate in a soluble form from proteolytic cleavage of the membrane-bound CAMs. Significantly raised serum levels of sICAM-1 and sE-selectin are found in patients with active Wegener's granulomatosis and microscopic polyangiitis and these probably reflect the extent of endothelial activation and injury (Pall *et al*. 1994). It is as yet unclear whether this is going to be useful in predicting disease activity.

Outcome

Short-term outcome

Survival has improved in all of the vasculitides and in excess of 80 per cent of patients now survive their acute illness. Although our current treatment regimes are effective in inducing remission, current strategies for maintaining remission are inadequate. We have not achieved disease- and treatment-free remission for our patients.

Relapses

With an increasing proportion of patients surviving their acute illness, it has become important to define the risks and consequences of relapses, and to balance this against the potential toxicity of continued treatment with cyclophosphamide and prednisolone. The study of Gordon *et al*. (1993) reported a high rate of relapses of up to 70 per cent over a 10-year period in patients with Wegener's granulomatosis, classical polyarteritis, and microscopic polyangiitis. In that study the tendency of the survival curves to flatten out with time (Fig. 8) contrasted markedly with the cumulative relapse rate with time (Fig. 9). Relapses occurred for up to 68 months and there was no suggestion from the actuarial curves that the rate at which relapses are occurring decreased with time. There have been suggestions that classical polyarteritis nodosa may be a self-limiting disease which tended not to recur once remission was induced. In the study of Fauci *et al*. (1979) no relapses occurred whilst patients were on cyclophosphamide and steroids. Leib *et al*. (1979), however, found that 12 per cent of patients ran a chronic course and Gordon *et al*. (1993) found that 42 per cent of patients with classical polyarteritis nodosa relapsed. Few series report on relapses in patients with microscopic polyangiitis. Savage *et al*. (1985) reported that 12 out of 33 patients with microscopic polyangiitis had 19 relapses. Serra *et al*. (1984) described 18 patients with microscopic polyangiitis who had a chronically active course which they described as a 'smouldering' vasculitis. These patients had a worse prognosis than long-term survivors with 'stable' inactive vasculitis. In the study of Gordon *et al*. (1993) relapses in microscopic polyangiitis occurred least frequently of all the vasculitides at a rate of 25.3 per cent and this compares with the rate of 36.4 per cent reported by Savage *et al*. (1985) 10 years earlier. The median time to relapse was shorter in microscopic polyangiitis (24 months) than in classical polyarteritis nodosa (33 months). A significant proportion of patients who relapsed, microscopic polyangiitis (33 per cent) and classical polyarteritis nodosa (40 per cent), did so once all treatment had been discontinued, although patients with microscopic polyangiitis had more relapses whilst on treatment albeit in a reducing dose.

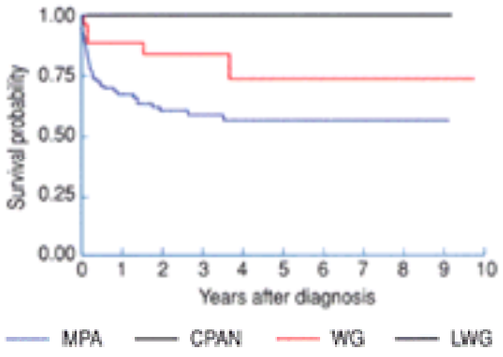


Fig. 8 Kaplan-Meier curve of the probability of survival of patients with microscopic polyangiitis (MPA), classical polyarteritis (CPAN), Wegener's granulomatosis (WG), and limited Wegener's granulomatosis (LWG). (From Gordon *et al*. 1993, with permission.)

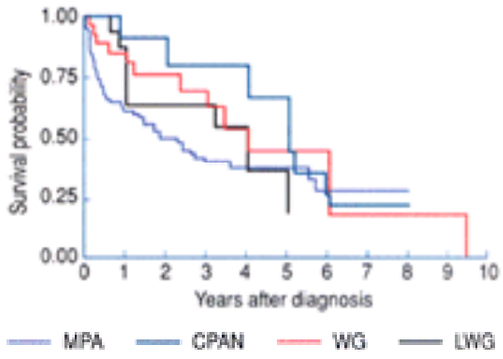

Fig. 9 Kaplan-Meier curve of the probability of surviving in terms of remaining free of relapse or of dying in patients with microscopic polyangiitis (MPA), classical polyarteritis (CPAN), Wegener's granulomatosis (WG), and limited Wegener's granulomatosis (LWG). (From Gordon *et al*. 1993, with permission.)

The clinical pattern of relapse does not necessarily mimic the original presentation, in that entirely new organs could be involved at relapse. The clinical features at relapse were in general less severe than at initial presentation in patients with microscopic polyangiitis who had significantly less systemic, renal, and pulmonary symptoms probably because they were under close supervision. Most patients at relapse had a rash and arthralgia. Patients with classical polyarteritis nodosa had more systemic symptoms at relapse. While relapse was generally a mild, non-systemic phenomenon, it may carry serious consequences including the development of renal failure and death. The vasculitides are not curable with our current treatment strategies. The implications of this are that these patients require long-term follow-up and possibly treatment.

One group of patients who had a low relapse rate were patients with microscopic polyangiitis who were on chronic dialysis and it seems either that patients with endstage renal failure have 'burned out' their disease or that renal failure is in itself immunosuppressive.

Whilst current drug treatments for inducing remission seem fairly successful it is clear that our regimes for maintaining remission are inadequate. The likelihood that relapse is a consequence of the way in which treatment modifies these diseases means that any future trial considering the efficacy of different treatments should measure not only survival as an endpoint, but also the rate of relapse and toxicity as a means of assessing the impact of treatment on patients with these diseases. There is clearly a need for prolonged follow-up in patients with a vasculitis as relapses can occur unpredictably after many years of remission.

Long-term prognosis (Fig. 8)

Overall the prognosis in patients with a vasculitis has improved over the past few years. Nevertheless, these disorders still carry a substantial mortality and morbidity.

Classical polyarteritis nodosa

The 5-year survival in classical polyarteritis nodosa ranges from 63 per cent (Guillevin *et al*. 1988) to 80 per cent (Leib *et al*. 1979) and in our own studies was 100 per cent (Gordon *et al*. 1993). Adverse prognostic factors include increasing age (Sack *et al*. 1975; Leib *et al*. 1979; Guillevin *et al*. 1988), renal failure, and gastrointestinal disease (Guillevin *et al*. 1988).

Microscopic polyangiitis

The overall prognosis in microscopic polyangiitis is much worse and in our series showed a 40 per cent mortality over a decade, largely related to renal failure often associated with delayed referrals. In other studies the 5-year survival in patients with microscopic polyangiitis ranges from 38 to 80 per cent (reviewed by D'Amico and Sinico 1990). Adverse prognostic factors include age (Adu *et al*. 1987; Fuiano *et al*. 1988) and the severity of renal failure before institution of therapy (Serra *et al*. 1984; Adu *et al*. 1987).

Churg–Strauss syndrome

The overall 5-year survival in Churg–Strauss syndrome is reported to be 62 per cent (Chumbley *et al*. 1977).

Conclusion

Progress in therapy will be linked to an increased understanding of the aetiology of disease and pathogenetic mechanisms, which probably vary from one syndrome to another despite almost identical histopathology of necrotizing vasculitis. Only when these have been defined will more specific, and hopefully less toxic, therapy be available. Nevertheless, the prognosis in vasculitis has improved enormously, so that aggressive therapy is rewarding. At present the main aim must be earlier diagnosis, since therapy is both more successful and less toxic before advanced renal impairment develops; together with the development of less-toxic long-term maintenance regimes.

Appendix

Protocol for the treatment of vasculitis with intermittent pulses of cyclophosphamide and prednisolone

Table 2 sets out the protocol for the treatment of vasculitis with intermittent pulses of cyclophosphamide and prednisolone, and should be used in conjunction with the following notes.

The induction regimen is used for up to 6 months. It can be shorter if clinical remission is achieved early but is continued for at least 3 months of treatment.

The remission regimen commences immediately after the end of the induction regimen, and is continued for up to 1 year from the start of induction.

The consolidation regimen is normally for a further 6 months, but may be continued for longer if disease activity is still apparent.

The maintenance phase is continued probably indefinitely.

In patients who are already being treated with immunosuppressive agents, the pulse therapy should not be started until 2 weeks has elapsed off cytotoxics to avoid severe marrow toxicity. All patients should be prescribed ordinary (not enteric coated) prednisolone in view of potential problems of variable absorption of active compound. During the pulse week, all patients are prescribed ranitidine, 150 mg at night, and amphotericin lozenges, 10 mg four times daily as prophylaxis. Further use is at the discretion of the physician. If patients develop infections during the course of treatment, then immunosuppression will be stopped until the infection has been adequately treated. If there is evidence of renal impairment or marrow suppression, or the patient is over the age of 70 years, the dose of cyclophosphamide and steroid will be adjusted accordingly (see dose adjustments below).

Phase	Time (week)	Pulse number	Route	Dose	
				Cyclophosphamide	Prednisolone
Induction	0, 2, 4,	1–3	IV	15 mg/kg × 1	10 mg/kg
	7, 10, 13, 17, 21, 25	4–9	Oral	5 mg/kg × 3	1.3 mg/kg × 3
Remission	30, 35, 40, 48, 52	10–14	Oral	5 mg/kg × 3	1.3 mg/kg × 3
Consolidation	58, 64, 70, 78	15–21	Oral	5 mg/kg × 3	1.3 mg/kg × 3
Maintenance	Oral prednisolone, 0.15 mg/kg alternate days				

Table 2 Protocol for the treatment of vasculitis

Tests before each pulse

Full blood count should be measured before each pulse is given, and the values should be in the normal range. If they are not, the pulse should be deferred until they are. Creatinine should be measured before each pulse, and if abnormal the dose of the pulse should be adjusted according to Table 3.

Serum creatinine	Cyclophosphamide dose	Prednisolone dose
< 150	15 mg/kg	10 mg/kg
150–250	10 mg/kg	10 mg/kg
251–500	7.5 mg/kg	10 mg/kg
> 500	5 mg/kg	7 mg/kg

Table 3 Bolus therapy

Escalation protocol

At any stage as decided by the clinician, the following may be given:

1. Additional bolus methylprednisolone intravenously, 1 g/day × 3 days;
2. Additional bolus cyclophosphamide intravenously, 5 mg/kg.day × 3 days;
3. Plasma exchange (optional).

Mesna is to be given in three oral doses totalling 75 per cent of the dose of cyclophosphamide for every dose of intravenous cyclophosphamide.

Dose adjustments are devised for the following reasons:

1. Maximum doses: the maximum bolus dose of cyclophosphamide, regardless of weight, will be 1000 mg. The maximum bolus dose of prednisolone regardless of weight will be 1000 mg.
2. Cytopenia prior to bolus therapy: delay bolus until count restored to above lower limit of normal (white cell count > 3.5 or neutrophil count > 2.0, platelets > 140). If cytopenia recurs, reduce cyclophosphamide bolus by 25 per cent.
3. Renal failure on bolus therapy: reduce as shown in Table 3.
4. Bolus therapy in the elderly (defined as over the age of 70 years): reduce the cyclophosphamide dose to 10 mg/kg, steroid dose unchanged.

5.11.4 Small vessel vasculitis

Clive E. H. Grattan and Victoria A. Jolliffe

Introduction

Small vessel vasculitis is characterized by inflammation centred on damaged capillaries and postcapillary venules. Muscular arteries are not usually involved although, confusingly, a recent international consensus on the classification of vasculitis (Jennette *et al*. 1994) includes patterns of vasculitis involving small and medium-sized arteries (Wegener's granulomatosis, Churg–Strauss syndrome, and microscopic polyangiitis) within the spectrum of small vessel vasculitis. It is however clear that there is a range of clinical and pathological features within defined diagnostic groups depending on the organ and size of vessel affected. The cutaneous lesions of Wegener's granulomatosis, for instance, may show the typical clinical and histological features of small vessel vasculitis as part of the wider spectrum of this systemic granulomatous disorder (Daoud *et al*. 1994; Francès *et al*. 1994). Small vessel vasculitis usually presents in the skin although the microvasculature of any tissue may be affected, especially the joints and kidneys. The most widely recognized clinicopathological patterns of small vessel vasculitis are listed in Table 1. Henoch–Schönlein purpura is regarded by many as a special form of allergic vasculitis. The division into leucocytoclastic and non-leucocytoclastic patterns of vasculitis is not absolute since skin biopsies may show a spectrum of pathological changes ranging from predominantly neutrophilic to predominantly mononuclear cell infiltrates in Sjögren's syndrome, drug-induced vasculitis, urticarial vasculitis, and nodular vasculitis. There is some evidence that cellular infiltrates may evolve from neutrophilic to mononuclear as lesions mature, but in many patients the pattern of inflammation remains unchanged throughout the course of their illness.

1. Leucocytoclastic vasculitis
   - Allergic vasculitis (synonym: hypersensitivity angiitis)
     - Drugs, infections, autoimmune diseases, inflammatory diseases, malignancy, idiopathic
     - Henoch–Schönlein purpura (synonym: anaphylactoid purpura)
   - Urticarial vasculitis (synonym: hypocomplementaemic vasculitis)
   - Cryoglobulinaemia
   - Hypergammaglobulinaemic purpura (of Waldenström)
   - Erythema elevatum diutinum and granuloma faciale
2. Non-leucocytoclastic vasculitis
   - Drug-related vasculitis
   - Nodular vasculitis
   - Livedo vasculitis
   - Pityriasis lichenoides acuta and chronica

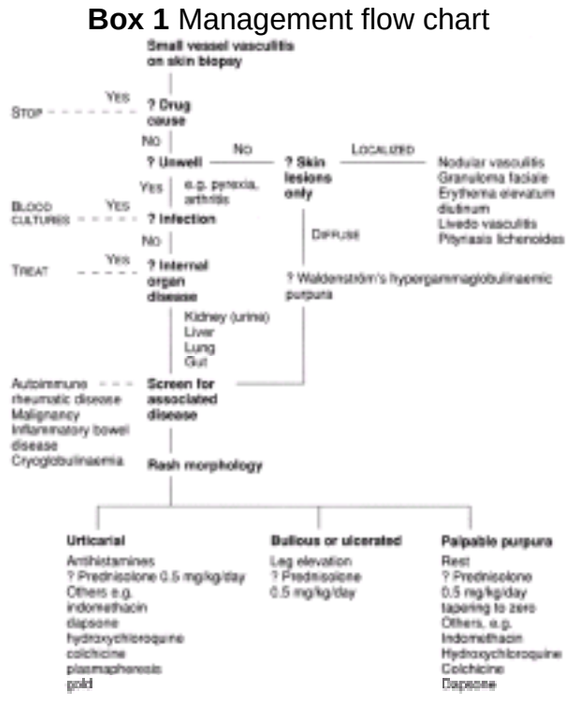
Table 1 Clinicopathological classification of small vessel vasculitis

The definition of small vessel vasculitis is open to different interpretations. Some authors restrict it to lesions with a clearly defined leucocytoclastic histology showing neutrophils within and around blood vessel walls, leucocytoclasis (fragmentation of neutrophils), fibrin in and around the damaged blood vessels, and swelling, hypertrophy, or necrosis of endothelial cells. Others will accept the presence of inflammatory cells within vessel walls and at least one of the above features as being sufficient for diagnosis. Evidence of vessel wall damage should be the key feature for diagnosis whether the predominant cell type is neutrophilic, eosinophilic, mononuclear, or mixed. Red cells may be seen in the surrounding tissue and intraluminal fibrin thrombi may form as a result of it. Of 98 cases of cutaneous vasculitis diagnosed on skin biopsy over a 5-year period in an adult population of around 400 000, 49 had definite leucocytoclastic vasculitis, 13 showed some features of it, and 12 had a predominantly lymphocytic vasculitis (unpublished data).

The clinical presentation of cutaneous leucocytoclastic vasculitis can vary considerably even though the underlying pathological changes may be indistinguishable. Conversely, the appearance of skin lesions may be similar even though the nature of the inflammatory infiltrate may differ. The full-blown picture of small vessel vasculitis with systemic features can be very similar to other patterns of vasculitis, including polyarteritis nodosa. This overlap may cause difficulty in distinguishing one form of vasculitis from another with complete certainty.

A management flow chart is given in Box 1. Although skin biopsy is essential to confirm the diagnosis of small vessel vasculitis, clinical decisions should not be delayed until the result is available in an unwell patient.

Box 1 Management flow chart



Leucocytoclastic vasculitis

Pathogenesis

Immune complex deposition appears to be important in the pathogenesis of most, if not all, forms of leucocytoclastic vasculitis. Experimental immune complex disease in animals is accompanied by leucocytoclastic vasculitis. Immune complex deposits were demonstrated by tissue immunofluorescence as early as 20 min after the onset of experimental Arthus reactions in guinea-pig skin and had disappeared by 18 h (Cream *et al*. 1971). Cochrane (1971) showed that soluble factors from sensitized rabbit basophils caused platelet clumping when reacted with antigen, this in turn caused release of vasoactive amines leading to permeability of the blood vessel and subsequent deposition of immune complexes. Immunofluoresence studies have demonstrated immunoglobulins and C3 within small blood vessels of lesional and adjacent normal skin in patients with leucocytoclastic vasculitis (Sams *et al*. 1975). Immune complexes can be demonstrated in a subendothelial location by electron microscopy and direct immunofluorescence of histamine-induced vasculitis lesions and clinically normal skin of patients with leucocytoclastic vasculitis (Braverman and Yen 1975; Gower *et al*. 1977). Serial biopsies of cold-induced urticaria in a patient with cold urticaria and vasculitis demonstrated C3 deposition within 5 min of ice application, preceding the deposition of fibrin, immunoglobulin, or obvious mast cell degranulation (Eady *et al*. 1981). An antibody raised against the terminal components of the complement pathway (C5b to C9) stained 13 of 15 lesional biopsies from patients with leucocytoclastic vasculitis (Boom *et al*. 1987) indicating that activation of the terminal complement components may contribute to local tissue damage. Antigens of candida, *Mycobacterium tuberculosis*, and streptococci have been identified in skin lesions of patients with neutrophilic vasculitis, together with IgG (Parish 1971), suggesting that bacterial antigen–antibody complexes formed *in vivo* may trigger the subsequent inflammatory events. In a series of 53 patients with cutaneous vasculitis 77 per cent showed two or more positive serological tests for circulating immune complexes (Andrews *et al*. 1979).

The following sequence of pathogenetic events may occur: (1) the endothelium of postcapillary venules becomes more permeable due to release of vasoactive factors, including histamine; (2) circulating immune complexes, formed in response to infections, foreign haptens, or self-antigens lodge beneath the endothelium; (3) local complement activation initiates adherence of neutrophils to endothelium through adhesion molecule expression; (4) they release lysosomal enzymes that damage the vessel wall and surrounding tissues; (5) newly generated C3a and C5a anaphylatoxins degranulate mast cells, releasing neutrophil and eosinophil chemotactic factors and vasoactive mediators, thereby amplifying the tissue reaction; (6) the acute response is followed by an influx of mononuclear cells and macrophages (Zax *et al*. 1990) which promote resolution of the reaction through recruitment of suppressor T lymphocytes and phagocytosis of the cellular debris.

Clinical

Clinical features, laboratory abnormalities, treatment, and prognosis are considered below.

Allergic vasculitis

Allergic vasculitis corresponds approximately to 'hypersensitivity angiitis' in Pearl Zeek's original classification of necrotizing vasculitis (Zeek 1952). The term allergic is a little contentious since it implies an immunological aetiology, which may be an oversimplification. Leucocytoclastic vasculitis is sometimes used synonymously as a clinicopathological term but this usage is better avoided because it may lead to confusion with the histological reaction pattern.

Allergic vasculitis is the commonest pattern of leucocytoclastic vasculitis in adults. It is characterized by purpuric or necrotic skin lesions, with or without systemic features. Men and women are affected equally. The onset may be from childhood to old age. Skin lesions tend to be distributed maximally over the lower legs. The buttocks, trunk, and upper extremities may also be affected. There is often a mixture of haemorrhagic papules that do not blanche on pressure (palpable purpura) (Fig. 1), erythematous or purpuric macules, urticarial plaques, vesicles, pustules, haemorrhagic bullae (Fig. 2), erosions, and ulcers. One or more systemic features occur in at least 50 per cent of patients. Arthralgia and arthritis, microscopic haematuria, abdominal symptoms (pain, nausea, diarrhoea, or bleeding), low-grade fever or malaise are the commonest. Pulmonary involvement (cough, dyspnoea, or haemoptysis) and neurological manifestations (peripheral neuropathy, benign intracranial hypertension, aseptic meningitis, and uveitis) have been reported.

Fig. 1 Palpable purpura on the lower leg of a patient with allergic vasculitis.

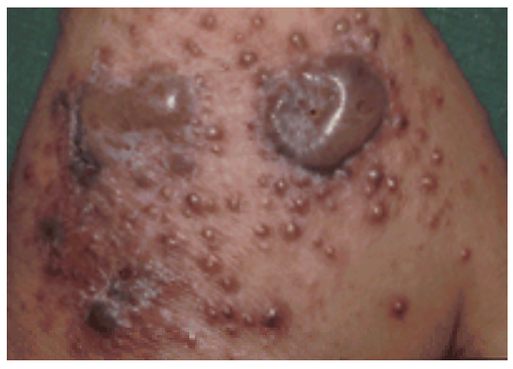


Fig. 2 Haemorrhagic blisters on the back of the hand of the same patient shown in Fig. 1.

The erythrocyte sedimentation rate (**ESR**) is usually raised, in the region of 50 mm/h, and there may be mild to moderate anaemia. Complement consumption and immune complex formation tend to reflect disease severity. Hypocomplementaemia was found in patients showing neutrophilic rather than predominantly mononuclear infiltrates in lesional skin biopsies (Soter *et al*. 1976). Non-organ-specific autoantibodies, including antinuclear antibody, rheumatoid factor, and extractable nuclear antigen antibodies may be detectable. It is important to perform frequent urinalysis. Renal function should be monitored carefully if persistant haematuria or proteinuria are found and a renal biopsy performed where indicated.

Some important precipitants and disease associations are summarized in Table 2. Allergic vasculitis has been reported with many classes of drugs including antibiotics, thiazide diuretics, non-steroidal anti-inflammatory drugs, and recombinant human granulocyte colony stimulating factor (Jain 1994). There have been case reports of many others, including additives in a drug formulation (Lowry *et al*. 1994). Human immunodeficiency virus (**HIV**) antigen has been found in lesional skin biopsies of symptomatic HIV-infected individuals with granular immune deposits in small vessel walls (Gherardi *et al*. 1993). Embolic lodging of bacteria and microthrombi in the skin microvasculature may account for the vasculitic lesions seen in infective endocarditis and septicaemia. Small vessel vasculitis may occur in autoimmune rheumatic disorders (rheumatoid arthritis, Sjögren's syndrome, and systemic lupus erythematosus). Rheumatoid arthritis was the commonest association in a series of 88 patients presenting with cutaneous leucocytoclastic vasculitis (Ekenstam and Callen 1984). The presence of antibodies to Ro and rheumatoid factor in Sjögren's syndrome was associated closely with skin lesions showing leucocytoclastic vasculitis on histology (Molina *et al*. 1985). Various other inflammatory disorders have been associated, including inflammatory bowel disease, chronic active hepatitis, and sarcoidosis (Aractingi *et al*. 1993). Greer *et al*. (1988) have

reviewed the association with malignancy. However, despite thorough clinical evaluation and laboratory investigation over 50 per cent of cases remain unexplained (idiopathic) in most reported series.

Precipitants
Drugs, e.g. sulphonamides, penicillins, thiazides, and many others
Infections
Viral, e.g. hepatitis B, human immunodeficiency virus
Bacterial, e.g. β-haemolytic streptococcus
Foreign protein, e.g. serum sickness
Associations
Autoimmune diseases, e.g. rheumatoid arthritis, Sjögren's syndrome (anti-Ro positive), systemic lupus erythematosus
Inflammatory diseases, e.g. chronic active hepatitis, ulcerative colitis, Crohn's disease, sarcoidosis
Malignancy, e.g. myelo- and lymphoproliferative disorders, solid tumours

Table 2 Causes of allergic vasculitis

The condition is often acute and self-limiting but may pursue a relapsing or chronic course. Occasionally death may occur from a number of causes, including renal failure, gastrointestinal haemorrhage, or perforation. In a review of lesional skin biopsies Hodge *et al*. (1987) found that the overall histological severity correlated with a clinical severity score based on cutaneous and visceral involvement but did not predict the presence or absence of systemic vasculitis. Deeper infiltrates were associated with a higher frequency of pulmonary involvement.

Identifiable causes should be removed or treated whenever possible. Bed rest seems to reduce the appearance of new skin lesions but probably does not alter the long-term outcome. The legs should be elevated and bandaged to reduce oedema. Analgesia may be required. Although encouraging responses have been claimed with indomethacin (Millns *et al*. 1980), hydroxychloroquine (Lopez *et al*. 1984), colchicine (Callen 1985), and dapsone (Fredenberg and Malkinson 1987) for control of the underlying disease, systemic steroids are often required and may have to be used at high doses, especially for progressive renal involvement. Immunosuppressive agents, such as azathioprine, may be appropriate for patients with refractory disease.

Henoch–Schönlein purpura

This tends to be regarded as a special form of allergic vasculitis. It is also known as 'anaphylactoid purpura'. The classical presentation is with purpura, arthritis, haemorrhagic gastrointestinal involvement, and glomerulonephritis. It occurs most often in children but adults of any age may be affected. IgA is usually detectable in biopsies of skin, gut, and kidney. Complement appears to be activated by the alternative rather than the classical pathway. It is not clear whether the cases originally described as peliosis rheumatica by Schönlein (1837) and those of Henoch (1874) would have fitted the current concept of a predominantly IgA-associated small vessel vasculitis, because immunological investigations, including direct immunofluorescence, were not available at the time. The paediatric aspects of Henoch–Schönlein purpura are discussed in Chapter 5.11.8.

The skin lesions are often indistinguishable from those seen in allergic vasculitis. The appearance of palpable purpuric plaques on the lower legs with multifocal areas of haemorrhage or necrosis and reticulated borders has been emphasized as a distinctive sign of Henoch–Schönlein purpura in adults (Piette and Stone 1989). Systemic involvement is common but not invariable. Cream *et al*. (1970) found evidence of renal involvement in 50 per cent of 77 adults, presenting with urinary abnormalities alone, acute nephritis, or as slowly progressive renal failure without an initial acute nephritic syndrome. Gastrointestinal involvement (abdominal pain, melaena stool, haematemesis, diarrhoea, or constipation) occurred in 44 per cent, arthralgia or arthritis in 56 per cent, and oedema of legs and ankles in 57 per cent of their series.

Corticosteroids given during the acute illness appear to relieve abdominal pain and arthralgia but there is little convincing evidence that they prevent progression of renal disease or influence the eventual prognosis (Roth *et al*. 1985).

Urticarial vasculitis

Urticarial skin lesions and arthritis are the commonest presentation of this systemic disorder. Females outnumber males in most reported series by over 2:1. Patients are usually middle-aged. Morphologically, the urticarial wheals resemble those of chronic (ordinary) urticaria (Fig. 3) but may also show central purpura or rarely resemble erythema multiforme. They can occur at sites of pressure and be associated with facial and laryngeal angio-oedema. As a general rule, the wheals of urticarial vasculitis last from 24 to 72 h and tend to have a burning or painful quality, whereas those of chronic urticaria are pruritic and last less than 24 h. The commonest systemic features are musculoskeletal. Malaise and low-grade fever may accompany the attacks of urticaria. Renal damage (evidenced by haematuria, proteinuria), gastrointestinal symptoms (abdominal pain, nausea, vomiting, diarrhoea), and pulmonary disease (cough, dyspnoea, haemoptysis) may occur. Other less common manifestations include lymphadenopathy, uveitis, and benign intracranial hypertension.

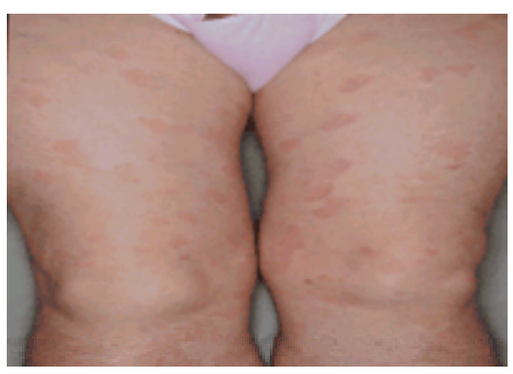

Fig. 3 The wheals of urticarial vasculitis resemble those of chronic urticaria but last longer and may show bruising.

A rare variant of urticarial vasculitis (Schnitzler's syndrome) is characterized by chronic urticaria-like lesions, arthralgia, lymphadenopathy, bone pain, intermittent fever, high ESR, leucocytoclastic vasculitis, and IgM macroglobulinaemia (Schnitzler *et al*. 1974). Interleukin-a antibodies found in some of these patients may play a part in its pathogenesis (Saurat *et al*. 1991).

The term 'hypocomplementaemic vasculitis' has been used for urticarial vasculitis because some early reports described cases in which the early components of complement were reduced (McDuffie *et al*. 1973), but complement abnormalities are by no means invariable and many cases are normocomplementaemic. Hypocomplementaemia and circulating immune complexes were detected in just under half the patients studied in one large series (Sanchez *et al*. 1982). Reduced levels of C1q have been linked with the presence of immunoglobulin G C1q precipitins in some patients (Zeiss *et al*. 1980) but they are not specific for urticarial vasculitis. The most consistent laboratory abnormality is an elevated ESR (Soter *et al*. 1974). Non-organ-specific antibodies are uncommon. Lesional skin biopsies show a range of histological changes from typical leucocytoclastic vasculitis to dense or sparse mixed perivascular infiltrates (Russell Jones *et al*. 1983). Interstitial dermal neutrophilic infiltrates were found in addition to perivascular infiltrates in patients with hypocomplementaemic urticarial vasculitis (Mehregan *et al*. 1992).

Patients with hypocomplementaemia tend to have more systemic manifestations than those with normocomplementaemia. However, the majority of patients with urticarial vasculitis, including those with systemic involvement, follow a chronic but benign course. Glomerulonephritis and chronic obstructive airways disease are

potentially the most serious complications. The relationship between urticarial vasculitis and systemic lupus erythematosus is not entirely clear as urticarial lesions showing histological leucocytoclastic vasculitis have been reported in 7 per cent of patients with systemic lupus erythematosus (Provost *et al*. 1980). Progression of urticarial vasculitis to systemic lupus erythematosus appears to be rare but has been described (Bisaccia *et al*. 1988).

The treatment of urticarial vasculitis has been reviewed by Berg *et al*. (1988). Systemic antihistamines are used widely but tend to be disappointing. Indomethacin, hydroxychloroquine, dapsone, colchicine, plasmapheresis, and gold (Handfield-Jones and Greaves 1991) have been reported to be helpful in small series or anecdotal reports. Systemic steroids often have to be given in high doses to achieve control and tapered to the lowest maintenance level to prevent relapse.

Cryoglobulinaemia

Cryoglobulins are immunoglobulins which precipitate when cold. They have been divided into three types: in type I the cryoglobulin fraction is a single monoclonal immunoglobulin; type II has mixed monoclonal and polyclonal components, usually consisting of IgM rheumatoid-like factor combined with polyclonal IgG; type III has exclusively mixed polyclonal components. Mixed cryoglobulins are associated with autoimmune rheumatic diseases, lymphoproliferative disorders, and infections. The prefix 'essential' is used if no underlying disorder can be found. Hepatitis B virus infection should always be excluded as the virus or its antibody were found in a high proportion of patients previously thought to have essential mixed cryoglobulinaemia when cryoprecipitates were examined as well as sera (Levo *et al*. 1977).

Mixed cryoglobulinaemia presents with purpuric skin lesions showing leucocytoclastic vasculitis on biopsy, polyarthralgia, weakness, and progressive renal disease. It is uncommon. Women are affected about twice as frequently as men, usually in their sixth decade. Gorevic *et al*. (1980) have summarized an 18-year experience of 40 patients with mixed cryoglobulinaemia and reviewed the literature: recurrent palpable purpura were present in all their patients, polyarthralgias in 72 per cent, and renal disease in 55 per cent. Hepatic involvement (hepatomegally, abnormal liver function tests, or mild to severe inflammation on biopsy) was present in 70 per cent of their series. Oedema, hypertension, leg ulcers, Raynaud's phenomenon, abdominal pain, and susceptibility to bacterial pneumonia also occurred in descending order of frequency. A more recent report describes similar skin changes with type I cryoglobulinaemia (Cohen *et al*. 1991). Peripheral neuropathy may occur. Accompanying laboratory abnormalities include reductions in the early components of complement, a raised ESR, and anaemia.

The prognosis is much worse in patients with renal disease. The main causes of death are renal failure, systemic vasculitis, and infection. Necropsy findings showed widespread arteritis in some patients (Gorevic *et al*. 1980) indicating that the vasculitis is not always confined to small vessels.

Treatment of symptomatic mixed cryoglobulinaemia is generally unsatisfactory. High-dose steroids, chemotherapy, plasmapheresis, or a combination of all three (Geltner *et al*. 1981) may bring about limited improvement in renal function, leg ulcers, and purpura. Anecdotal success has been reported with high-dose intravenous gammaglobulin (Boom *et al*. 1988).

Hypergammaglobulinaemic purpura

Waldenström (1943) described three female patients with hyperglobulinaemia, long-standing purpura, and an elevated ESR. This benign disorder should not be confused with Waldenström's macroglobulinaemia which is a lymphoma characterized by a monoclonal IgM paraproteinaemia. Histology of the purpuric skin lesions shows a leucocytoclastic vasculitis. The similarity between hypergammaglobulinaemic purpura and the cutaneous features of some patients with Sjögren's syndrome has been emphasized (Alexander and Provost 1983).

Erythema elevatum diutinum and granuloma faciale

Erythema elevatum diutinum and granuloma faciale are rare but distinctive forms of localized chronic cutaneous leucocytoclastic vasculitis. There is no systemic involvement. The aetiology of these disorders is unknown but erythema elevatum diutinum has been associated with myeloma.

Erythema elevatum diutinum is characterized by slowly enlarging oedematous purplish-brown plaques over the backs of hands, elbows, or knees which heal slowly over months or years with fibrosis. Early lesions may blister (Fig. 4). The clinical and laboratory features have been reviewed by Gibson and Su (1990).

Fig. 4 An early lesion of erythema elevatum diutinum on the back of the hand showing bullous changes.

Granuloma faciale presents with single or multiple pink to brown, well-defined smooth papules and plaques on the face (Fig. 5) which persist for years. It is distinguished histologically from erythema elevatum diutinum by the presence of numerous eosinophils and a zone of normal collagen beneath the epidermis.

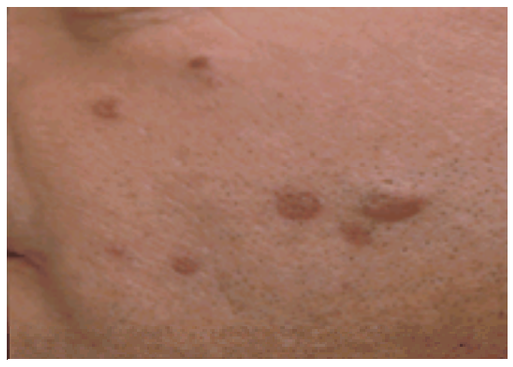

Fig. 5 Reddish-brown papules on the cheek typical of granuloma faciale.

The chronicity of both erythema elevatum diutinum and granuloma faciale is surprising in view of the histology which would suggest an acute pattern of inflammation. Erythema elevatum diutinum may respond well to dapsone. Intralesional steroids can help granuloma faciale.

Non-leucocytoclastic vasculitis

Drug-related vasculitis

Cutaneous and systemic vasculitis showing mononuclear infiltrates and eosinophils in vessel walls without fibrin deposition or necrosis, have been attributed to a variety of drugs, including penicillins and thiazides (Mullick *et al*. 1979).

Nodular vasculitis

The differential diagnosis of nodular forms of cutaneous vasculitis embraces a wide range of disorders, including erythema nodosum and other inflammatory diseases of the subcutaneous fat (Ryan 1992).

Nodular vasculitis is regarded as a distinct subgroup characterized by recurrent subcutaneous nodules usually occurring on the legs of young or middle-aged women. Patients are otherwise healthy. The histological changes range from perivascular lymphocytic infiltrates and granulomatous changes to leucocytoclastic vasculitis with fibrinoid necrosis. The aetiology is uncertain. Associated streptococcal infection may occasionally be found and should be treated. Tuberculosis does not appear to be associated, as with erythema induratum (Bazin's disease). The condition tends to resolve spontaneously but may persist for many years. Individual lesions may respond to intralesional triamcinolone. High doses of potassium iodide have been reported to be beneficial (Schulz and Whiting 1976).

Livedo vasculitis

Ischaemic damage may result from vascular occlusion rather than primary vessel wall inflammation. Livedo vasculitis (segmental hyalinizing vasculitis) is characterized histologically by endothelial proliferation and intraluminal thrombosis. Elevated fibrinopeptide levels, normal complement, and absence of immune complexes on serological studies favour a thrombogenic vasculopathy (McCalmont *et al*. 1992).

Clinically there is a livedo-like pattern of purpura, ulcers, and white atrophic scars known as *atrophie blanche* (Bard and Winkelmann 1967) (Fig. 6). The relevance of antiphospholipid antibodies to the pathogenesis of this disorder and others characterized by vaso-occlusion, including Degos' disease, has been reviewed (Grattan and Burton 1991).

Fig. 6 Acute lesions of livedo vasculitis heal with pigmentation and ' *atrophie blanche*' scarring.

Pityriasis lichenoides

The acute form of this relatively uncommon skin disorder is characterized by crops of oedematous pink papules which enlarge rapidly, and may become haemorrhagic before developing necrotic centres which heal over several weeks with scarring (Fig. 7). Although the eruption may be accompanied by mild constitutional symptoms, such as fever and arthralgia, there are no systemic complications and the disorder is usually self-limiting. Histology shows a lymphocytic perivascular infiltrate. While the endothelial cells are often blurred or swollen, fibrinoid necrosis is seen very rarely and some authorities believe that the changes do not amount to true vasculitis. However, the presence of IgM and C3 deposition in the walls of superficial blood vessels of fresh lesions in both acute and chronic forms of the disease support an immune complex aetiology (Clayton and Haffenden 1978).

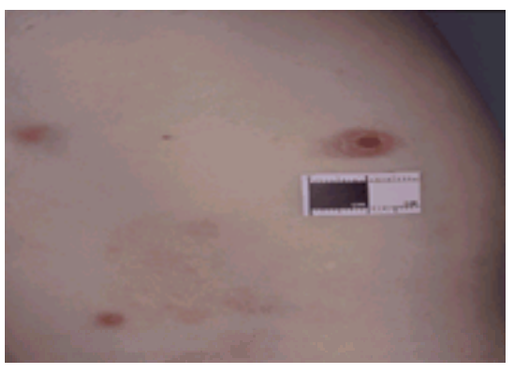

Fig. 7 Oedematous papules on the upper arm of a patient with pityriasis lichenoides acuta showing early central necrosis which will heal with scarring.

Pityriasis lichenoides chronica may succeed the acute form or arise *de novo*. The early pink lesions mature into reddish-brown papules with adherent scale which usually heal without scars. Successive crops of lesions may erupt consecutively for months or years. Treatment with ultraviolet B irradiation is often helpful.

5.11.5 Polymyalgia rheumatica

G. S. Panayi

Definitions

Polymyalgia rheumatica

Since both polymyalgia rheumatica and giant cell arteritis are clinical syndromes it is important that agreed definitions of the conditions are employed not only for uniformity of diagnosis but also for epidemiological and investigational studies. The criteria of Jones and Hazleman (Table 1) are succinct and easily applied in practice for the diagnosis of polymyalgia rheumatica. Some comments are necessary. There may be apparent weakness on testing the shoulder and pelvic girdle muscles but this is due to pain rather than intrinsic muscle weakness. Investigations to exclude inflammatory arthritis, malignant disease, or muscle diseases should be carried out objectively but with restraint as discussed under 'diagnosis' below.

1. Shoulder and pelvic girdle pain which is primarily muscular in the absence of true muscle weakness
2. Morning stiffness
3. Duration of at least 2 months unless treated
4. ESR over 30 mm/h or C-reactive protein over 6 μg/ml
5. Absence of rheumatoid or inflammatory arthritis or malignant disease
6. Absence of objective signs of muscle disease
7. Prompt and dramatic response to systemic corticosteroids

From Jones and Hazleman (1981).

Table 1 The diagnostic criteria for polymyalgia rheumatica

Giant cell arteritis

The criteria for diagnosis of giant cell arteritis according to Jones and Hazleman (1981) are shown in Table 2, whilst those by Ellis and Ralston (1983) are shown in Table 3. The advantages of the criteria of Ellis and Ralston (1983) are that they do not include the erythrocyte sedimentation rate (**ESR**) and have a more inclusive description of the clinical features of giant cell arteritis compared with the criteria of Jones and Hazleman (1981). However, the diagnostic criteria of the latter have the advantage of brevity. It should be remembered that although up to one-quarter of patients can present with normal ESR, before being treated with corticosteroids, they are still liable to serious complications including visual loss. This can happen even during treatment when there is a normal ESR. The biopsy is classifically taken from the temporal artery but other sites have included practically all vessels arising from the arch of the aorta.

1. Positive temporal artery biopsy or cranial artery tenderness noted by a physician
2. One or more of the following: visual disturbance, headache, jaw pain, cerebrovascular insufficiency
3. ESR over 30 mm/h or C-reactive protein over 6 μg/ml
4. Response to systemic corticosteroids

Table 2 The Jones and Hazleman (1981) diagnostic criteria for giant cell arteritis

1. Age greater than 55 years
2. Positive response within 48 h to corticosteroid therapy
3. Length of history greater than 2 weeks
4. Positive temporal artery biopsy
5. Proximal, symmetrical girdle, or upper arm muscle pain+ stiffness+tenderness
6. Jaw claudication
7. Clinical abnormality of the temporal artery (tenderness, thickening, redness)
8. Systemic symptoms or signs (malaise, anorexia, weight loss, anaemia, pyrexia)
9. Temporal headache
10. Visual disturbance (loss, diplopia, blurring)

Positive diagnosis present if criteria 1 to 3 present plus any three of criteria 5 to 10 or criterion 4.

Table 3 The Ellis and Ralston (1983) diagnostic criteria for giant cell arteritis

The American College of Rheumatology (**ACR**) has developed criteria for the classification of giant cell arteritis by comparing a group of 214 patients with the condition and 593 controls with other forms of vasculitis (Hunder *et al*. 1990) (Table 4). In the traditional format a patient shall be said to have giant cell arteritis if at least three out of five criteria listed in the Table are present. The presence of three or more criteria yielded a sensitivity of 93.5 per cent and a specificity of 91.2 per cent. A classification tree was also constructed using six criteria. Elevated ESR was excluded in the tree format due to low specificity (48 per cent) and claudication of jaw and/or tongue on deglutition was included. In the classification tree the presence of temporal artery tenderness of decreased pulsation separated cases from controls better than any other criteria. The tree classification defines giant cell arteritis in fairly simple terms as a vasculitis with onset above 50 years of age, abnormal temporal arteries, or claudification of jaw and/or tongue upon deglutition, and arterial biopsy showing vasculitis with predominantly mononuclear cells or granulomatous inflammation. One hundred and ninety-six of 214 patients with giant cell arteritis had biopsies showing arteritis and 18 lacked biopsy proof. Fifteen out of 18 had negative biopsies and in three biopsy was not performed.

1. Age at disease onset ⩾50 years
2. New headache
3. Temporal artery tenderness or decreased pulsation
4. Elevation of ESR ⩾50 mm/h
5. Abnormal artery biopsies showing necrotizing arteritis with mononuclear infiltrate or granulomatous inflammation usually with multinucleated giant cells

Diagnosis of giant cell arteritis, if three of five criteria are present.

Table 4 ACR 1990 criteria for the classification of giant cell arteritis (traditional format)

It should be noted that several controls with other types of vasculitis, such as Wegener's granulomatosis and polyarteritis nodosa, had biopsies of lung or other tissues showing chronic granulomatous arteritis together with enough additional criteria to misclassify them as giant cell arteritis. Biopsies of a temporal artery was not specified because few controls had this procedure. If temporal artery biopsy was specified, few controls would have been misclassified.

The ACR criteria are easy to apply and do not require exclusions other than the presence of a autoimmune rheumatic disease. In the tree classification the use of scalp tenderness and headache as surrogates for temporal artery abnormality and positive biopsy provide flexibility when some clinical data are not available.

Relationship between polymyalgia rheumatica and giant cell arteritis

Patients with features of both polymyalgia and giant cell arteritis are seen and this raises the question of the relationship between the two. Polymyalgia rheumatica is a more common condition than giant cell arteritis. One-half of the patients with giant cell arteritis have polymyalgic symptoms and 15 to 22 per cent of patients with polymyalgia rheumatica have been shown to have giant cell arteritis by either temporal artery biopsy or clinical symptoms (Huston *et al*. 1978; Chuang *et al*. 1982). In other studies the proportion of patients with a myalgic presentation who have positive arterial biopsies but no clinical features of giant cell arteritis varies from 6 per cent (Hunder and Allen 1973), to 40 per cent (Fauchald *et al*. 1972), to 50 per cent, which is the highest recorded (Malmvall and Bengston 1978). It used to be thought that polymyalgia rheumatica was always a manifestation of giant cell arteritis but most patients with the former, even if followed for many years, do not develop clinical or biopsy-proven giant cell arteritis. This was true even in the days before the use of systemic corticosteroids. There are, undoubtedly, patients with polymyalgia rheumatica who have a positive biopsy for giant cell arteritis but whose clinical picture is identical to patients with polymyalgia rheumatica without the lesions of giant cell arteritis (Fauchald *et al*. 1972). Conversely, there are patients with giant cell arteritis who also have clinical evidence of polymyalgia rheumatica. Thus, polymyalgia rheumatica and giant cell arteritis may be considered as components of a single syndrome, the expression of which depends on unknown factors; genetic factors may be the most important of these.

Genetic and epidemiological studies

Genetic studies

A genetic basis for polymyalgia rheumatica/giant cell arteritis has long been suspected because of the occurrence of the disease within families and in sib pairs (Moss and Soukop 1988). However, their mode of inheritance remained unknown until studies on possible HLA associations were undertaken. The study of Hansen *et al*. (1985) has been the only one to show an association with a class I major histocompatibility antigen, HLA Cw3. The increased occurrence of HLA A31, HLA B40 and, of greater importance, HLA DR4 was ascribed as being secondary and due to their linkage disequilibria with HLA Cw3. Armstrong *et al*. (1983) showed a link between polymyalgia rheumatica and giant cell arteritis and HLA Cw6 with a relative risk of 9.0. This is the only reported association with a C locus antigen. However, most studies agree that the true link is with HLA DR4. Richardson *et al*. (1987) found an association between polymyalgia rheumatica or polymyalgia rheumatica plus giant cell arteritis with HLA DR4, whilst giant cell arteritis alone did not show this association. By contrast, Ninet *et al*. (1987) found that it was giant cell arteritis, whether alone or associated with polymyalgia rheumatica, which was linked to HLA DR4. Whether this discrepancy can be accounted for by the racial differences in the two studies, Anglo-Saxon in the former and French in the latter, is not known, but it should be emphasized that Armstrong *et al*. (1983) found a link with polymyalgia rheumatica or giant cell arteritis while Cid *et al*. (1988), in a Spanish population, found a link of HLA DR4 with polymyalgia rheumatica alone. It may be that differences in the population of patients being studied may account for some of the discrepancies. The studies by Sakkas *et al*. (1990) have used restriction fragment length polymorphism (**RFLP**) with DRb, DQa, and DQb probes and appropriate restriction endonucleases in order to investigate the class II MHC association at the molecular level. In this study the link between polymyalgia rheumatica and HLA DR4 was confirmed whilst the DQ specifities DQw7 and DQw8 (previously DQ3.1 and DQ3.2 respectively) were found in similar frequency to the controls. Rheumatoid arthritis is linked to the third hypervariable region of HLA DR4. Whilst polymyalgia rheumatica and giant cell arteritis are also linked to HLA DR4, molecular analysis has shown that this is with the second hypervariable region of the HLA DRB1 gene (Weyand *et al*. 1994a). Two conclusions can be drawn from these findings. First, the reported association of rheumatoid arthritis with polymyalgia rheumatica/giant cell arteritis is probably due to chance or to misdiagnosis. Second, HLA-DRB1 alleles are not predictive for progression of polymyalgia rheumatica to giant cell arteritis.

Demaine *et al*. (1983) have reported that the immunoglobulin allotypic marker G1m(2) was significantly increased in patients with giant cell arteritis but not with polymyalgia rheumatica. The increase in G1m(2) in the group with giant cell arteritis was not accompanied by a corresponding rise in the number of patients homozygous for G1m(2), i.e. all the increase could be attributed to patients with the G1m(1, 2, 3): G3M (5, 10, 21) phenotype. Using a DNA probe for the switch region of Igμ and a1 heavy chain genes and RFLP analysis, Sakkas *et al*. (1990) were unable to pinpoint these Gm polymorphisms further. However, these findings suggest that genes outside the MHC and probably residing in the region of the immunoglobulin heavy chain on chromosome 14q are also involved in the genetics of polymyalgia rheumatica/giant cell arteritis. It is these additional genetic factors which may modify the clinical expression of disease.

The T-cell receptor genes are highly polymorphic and intimately involved in the genetics of the immune response. No RFLP association was found with T-cell receptor a, b, or g genes (Sakkas *et al*. 1990).

Epidemiological studies

The prevalence of giant cell arteritis/polymyalgia rheumatica has strikingly different rates in different racial groups with Scandinavians having the highest and black and Hispanic races the lowest (Gonzalez *et al*. 1989). Furthermore, only 12 to 25 per cent of black patients with giant cell arteritis have polymyalgia rheumatica compared with 40 to 60 per cent in white patients (Love *et al*. 1986) and this may be related to the low frequency of HLA DR4 in the black population. There may be geographical variation in the expression of clinical features as a Japanese study has reported a higher frequency of fever and involvement of the pelvic girdle than the

Western reports (Nishioka *et al*. 1986).

Ninety-six patients with polymyalgia rheumatica were identified in a 10-year survey (1970 to 1979) at the Olmstead County Hospital, Minnesota (Chuang *et al*. 1982) leading to an average annual incidence of 11.1/100 000 persons (53.7/100 000 in persons over 50 years of age). Polymyalgia rheumatica is more common in older age groups with age-specific incidence increasing from 19.8/100 000 in persons aged 50 to 59 years to 112.2/100 000 in those aged 70 to 79 years. Giant cell arteritis was found in 15 out of 96, i.e. 18 per cent of those surveyed. Bengtsson and Malmvall (1982) surveyed the incidence of polymyalgia rheumatica over 3 years at Goteborg, Sweden which has a population of 400 000. The annual incidence was lower with an incidence rate of 6.7/100 000 persons or 20.4/100 000 in those 50 years or older. In the Swedish study the incidence of giant cell arteritis was 41 out of 90 patients with polymyalgia rheumatica, i.e. 46 per cent. The differences in data between the two studies may be partly due to the difference in diagnostic criteria and methods of data collection. A 9-year study of polymyalgia rheumatica/giant cell arteritis in Reggio Emilia, Italy, from 1980 to 1988 revealed an annual incidence of 6.9/100 000 in persons over 50 years of age (Salvarani *et al*. 1991).

The incidence of polymyalgia rheumatica/giant cell arteritis, at least amongst the white races in the northern hemisphere, lies between 1.7 and 7.7 per 1000 of the elderly population. However, it is obvious that these figures derive from studies using different diagnostic criteria, prospective or retrospective design, and different catchment populations. Properly controlled, large, and prospective studies in different racial groups from different parts of the world are urgently required. Such data may enhance our understanding of the genetic and environmental factors contributing to the development and expression of polymyalgia rheumatica/giant cell arteritis.

The frequent acute influenza-like onset has stimulated interest in the search for an environmental agent in polymyalgia rheumatica/giant cell arteritis. Polymyalgia rheumatica has been reported as being preceded by viral infection, vaccination for influenza or typhoid fever, and by *Yersinia enterocolitica* infection. The finding of antibodies to hepatitis B antigen (Bacon *et al*. 1975) has not been verified (Bridgeford *et al*. 1980). The higher prevalence and titre of antibodies to adenovirus and respiratory syncytial virus in patients with polymyalgia rheumatica compared with controls is intriguing (Cimmino *et al*. 1993). Case reports of polymyalgia rheumatica and giant cell arteritis in conjugal pairs also suggest as environmental agent (Kyle *et al*. 1984). Antibodies to intermediate filaments have been described in high concentrations in polymyalgia rheumatica/giant cell arteritis (Dasgupta *et al*. 1987). These antibodies are typically found in viral infections and may suggest a viral aetiology. Polymyalgia rheumatica has been reported following a tick bite in an 84-year-old woman with serological evidence of *Borrelia burgdorferi* injection. Sixty-three per cent of patients (12 of 19) with polymyalgia rheumatica/giant cell arteritis were found to have elevated or borderline IgG antibody titres (Vaith *et al*. 1988) to this pathogen.

Arterial biopsy

In diagnosis

The histological proof of granulomatous change in the temporal artery or in an artery arising from the aorta or in the aorta itself is generally considered diagnostic proof of giant cell arteritis even if the symptoms are those of incomplete giant cell arteritis or even polymyalgia rheumatica alone (Table 5). An adequate biopsy requires a segment of artery 2- to 3-cm long. Many centres recommend biopsy of the opposite artery if histology is negative in the selected artery. Granulomatous giant cell arteritis is seen in approximately 50 per cent of positive biopsies, showing panarteritis with a mixed cellular infiltrate that is predominantly lymphomononuclear (Lie *et al*. 1990) (Fig. 1). Occasionally a circumferential band of fibrinoid necrosis may also be seen. There is no correlation between histological and clinical features in individual patients (Lie 1987). Pretreatment biopsies give the most successful diagnostic rate (80 per cent) which falls to 60 per cent after 1 week of treatment and becomes much lower after longer periods of treatment (Lie 1987), although others have found that up to 14 days of glucocorticoid treatment does not alter the biopsy positivity rate (Achkar *et al*. 1994).

Disease	Artery	Positive biopsy (%)	Year	Author
GCA	Temporal	30/88 (31)	1992	Chmielewski et al.
PMR/GCA	Temporal	14/75 (14)	1989	Stuart
PMR/GCA	Temporal	21/81 (25.9)	1988	Robb-Nicholson et al.
GCA	Temporal	28/107 (27.1)	1988	Fernandez-Herlihy
GCA	Temporal	42/200 (21)	1988	Pongo et al.
GCA	Temporal	5/45 (11.1)	1988	Weyman et al.
GCA	Temporal	43/102 (43.7)	1987	Villaseca et al.

Table 5 Recent studies on the value of temporal artery biopsy in the diagnosis of polymyalgia rheumatica (PMR)/giant cell arteritis (GCA)

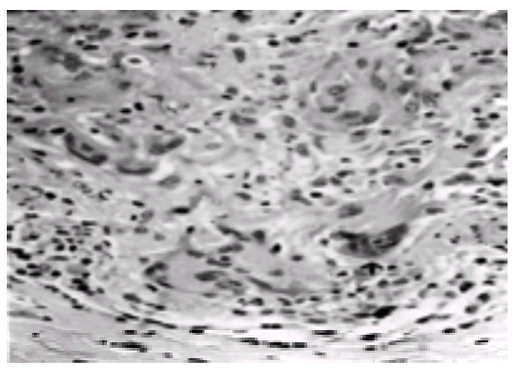

Fig. 1 Typical arterial histology from a patient with giant cell arteritis showing granulomatous inflammation with giant cells (arrow points to a giant cell).

The presence of skip lesions and of differential involvement means that histological proof of giant cell arteritis can vary from 11 to 44 per cent of temporal artery biopsies depending on various selection factors. Efforts have been made to improve the positive biopsy rate by means of arteriographic or Doppler ultrasound examination of the temporal artery but to no avail. There can be large artery involvement with a variety of symptoms including intermittent claudication of an extremity, paraesthesia, Raynaud's phenomenon, and aortic rupture. Clinical examination may reveal absent or decreased pulsation of large arteries with bruits over them. The angiographic findings are characteristic and help to distinguish it from atheromatous stenosis (Klein *et al*. 1975). Angiography reveals (1) long segments of smooth arterial stenoses alternating with those of normal or an increased calibre, (2) smoothly tapered occlusions of affected large arteries, (3) absence of irregular plaques and ulceration, which is characteristic of atheromatous involvement, and (4) anatomic distribution with major involvement of subclavian, axillary, or brachial arteries.

For understanding the pathogenesis

The pathogenesis of polymyalgia rheumatica/giant cell arteritis is not known. Since there is obvious vascular involvement in giant cell arteritis and since giant cell arteritis and polymyalgia rheumatica frequently coexist, it has been assumed that polymyalgia rheumatica also has a vascular basis but direct proof of this supposition is difficult to find. Although evidence of endothelial damage or activation can be found in elevated levels of circulating von Willebrand factor and factor VIII, this observation is common to many inflammatory conditions. Immune complexes have been conspicuous by their absence. Antineutrophil cytoplasmic antibodies (**ANCA**), which are elevated in many forms of macroscopic and microscopic vasculitides, are not found in polymyalgia rheumatica/giant cell arteritis, although Cats and colleagues have found high titres of ANCA, but of unknown specificity, in the serum of patients with giant cell arteritis (Cats *et al*. 1993). Antibodies to intermediate filaments may reflect underlying disease activity (Monteagudo *et al*. 1994).

However, patients with of polymyalgia rheumatica/giant cell arteritis have low numbers of circulating CD8 T cells which are activated, as shown by their high positivity for HLA-DR antigen, which is normally absent from the surface of resting T cells. The relationship of these findings to the pathogenesis of polymyalgia rheumatica/giant cell arteritis is not known but they are similar to those found in the blood of children with Kawasaki's syndrome in which arterial damage is very prominent. Activated CD8 T cells can be cytotoxic and also produce a variety of proteolytic enzymes, especially granzymes, which have cytotoxic and inflammatory potential. A temporal artery with positive histological appearance shows infiltration of mononuclear cells, T cells, and macrophages, and disruption of the elastic lamina of the artery. The lesion may contain deposits of IgG, IgM, IgA, complement, and fibrinogen and the use of immunofluorescence to detect these deposits may be more sensitive and specific than light microscopy alone, although this has not been adopted for routine clinical use (Wells *et al*. 1989). There is also a marked accumulation of fibronectin, fibrin, fibrinogen, and their degradation products, as well as factor VIII, but none of these findings is characteristic (Chemnitz *et al*. 1987).

The T cells infiltrating the temporal artery in giant cell arteritis are CD4+: these are activated as shown by their positivity for HLA DR and the interleukin-2 receptor but, interestingly, show little or no surface expression of the transferrin receptor which is another T-cell activation marker (Andersson *et al*. 1987; Cid 1989). The reason for this discrepancy is unknown but it is worth remarking that although CD4+ T cells in the rheumatoid synovium are HLA-DR positive, few of them express the interleukin-2 receptor. Thus T-cell activation in different chronic inflammatory foci may be at different stages. The elevated serum levels of soluble interleukin-2 receptor provide systemic evidence for T-cell activation but are not useful for disease monitoring (Salvarani *et al*. 1992). Analysis of the T-cell receptor genes used by CD4 T cells expanded from the temporal artery biopsies suggests that they are of limited heterogeneity. This implies that locally present antigen may be driving the granulomatous reaction (Schaufelberger *et al*. 1993; Weyand *et al*. 1994b).

CD8+ T cells form the minority T-cell population and there are few or no B cells and no natural killer cells. The paucity of B cells in the lesions correlates with the lack of a systemic hypergammaglobulinaemia. Although corticosteroids do not influence the cellular distribution within the lesion, a finding similar to that in the rheumatoid synovium, they nevertheless induce functional changes in T cells since within 4 days of starting corticosteroid therapy there is a dramatic fall in the number of T cells positive for interleukin-2 receptors from 87.5 to 14 per cent (Cid 1989).

Macrophages are found in increased numbers in all lesions and are activated as shown by their high expression of HLA DR and transferrin receptor (Andersson *et al*. 1987). Macrophages in the arterial biopsies have been shown to produce interleukin 6, interleukin 1b, and a 72-kDa type IV collagenase. Monocytes from the peripheral blood of patients with giant cell arteritis or polymyalgia rheumatica express interleukins 6 and 1b. These findings suggest that these diseases have local as well as systemic inflammation (Wagner *et al*. 1994). Studying the bone marrow might be rewarding. Macrophages could also act as antigen-presenting cells. The additional cells present are interdigitating cells, which are a form of antigen-presenting cell, found in 41 per cent of temporal artery biopsies; these patients have a significantly shorter disease duration before presentation (mean 1.5 months compared with 3.8 months) (Cid 1989). Arterial smooth muscles are HLA-DR negative so it is unlikely that they are serving as antigen-presenting cells (Andersson *et al*. 1988).

Clinical features

Polymyalgia rheumatica and giant cell arteritis are rare in patients less than 50 years old and the mean age at onset is approximately 70 years. Women are affected more than men (ratio 2:1). The onset is frequently abrupt with pain and stiffness in the neck and shoulder girdle. Hips and thighs are involved less often. Prolonged and severe morning stiffness is a characteristic feature. There may be asymmetry at onset although symptoms become quickly bilateral. Systematic symptoms such as malaise, anorexia, weight loss, low-grade fever, and depression are present frequently. Active joint mobility is often restricted by pain and stiffness whereas passive movements are full. There is no objective muscle weakness although severe muscle pain and stiffness may give this misleading impression

Arthralgia and even synovitis is not uncommon (Chou and Schumacher 1984). Synovitis of the knees and sternoclavicular joints may be evident clinically. Shoulder and hip joint involvement may be more difficult to detect due to the overlying muscles. Synovial fluid examination, arthroscopic synovial biopsies, and joint scintiscanning (O'Duffy *et al*. 1976) have confirmed joint inflammation. Indeed, it has even been proposed that the prominence of shoulder and pelvic girdle symptoms is due to axial synovitis involving the glenohumoral and hip joints (Koski 1992). Arthroscopic synovial biopsies have revealed a lymphocytic inflammatory infiltrate. However, florid synovitis is uncommon in true polymyalgia rheumatica and a clinically significant, chronic, erosive arthropathy suggests an alternative diagnosis of rheumatoid arthritis as this may have a polymyalgic onset in the elderly.

There are case reports of polymyalgia rheumatica associated with underlying malignancy, although it is unclear whether the incidence of neoplasm is increased truly compared with age and sex-matched controls. A retrospective study of case notes reported a high incidence of hypothyroidism in polymyalgia rheumatica/giant cell arteritis (Wiseman *et al*. 1989) but a subsequent study failed to confirm these findings (Dasgupta *et al*. 1990).

Giant cell arteritis

Presenting symptoms may vary widely but headache is the most common initial symptom, being present in two-thirds of patients. The pain is often severe and usually localized to arteries of the scalp (superficial, temporal, and occipital) though it may be more diffuse. The artery involved may be tender or exhibit reduced pulsations. Frequently there is diffuse scalp tenderness.

Visual symptoms are said to occur in 25 to 50 per cent of cases and include diplopia, ptosis (transient or permanent), and partial or total blindness. The symptoms are caused by ischaemia of the optic nerve secondary to involvement of branches of the ophthalmic or posterior ciliary arteries. Recent reports suggest that visual complications may be less frequent than previously reported in pure polymyalgia rheumatica (Myles *et al*. 1992). Unfortunately there are no predicative features for when these may occur and such complications have occurred in patients with quiescent disease and normal erythrocyte sedimentation rates.

Laboratory features

A marked acute-phase response is characteristic of both polymyalgia rheumatica and giant cell arteritis. There is a mild to moderate normochromic anaemia, thrombocytosis is common, and the white cell count is usually normal. The erythrocyte sedimentation rate (ESR) is elevated and frequently much raised, over 100 mm/h, although in occasional cases it may be completely normal. C-reactive protein is often raised and some studies have claimed it is more sensitive than ESR. Long-term studies have shown that ESR is as good an indication of the acute-phase response (Kyle and Hazleman 1989). There may be a decrease in albumin concentration and increase in a_2-globulins, fibrinogen, and other acute-phase reactants.

Serum immunoglobulins are usually normal although they may be raised in severe cases. Complement levels are normal. Tests for autoantibodies and rheumatoid factor are negative. Antibodies to intermediate filaments and to neutrophil cytoplasmic antigens have been described (see above).

Increases in alkaline phosphatase can occur and less frequently there is increase in transaminases with prolonged prothrombin time. Liver biopsies are generally normal although granulomatous hepatitis has been described. Muscle enzymes and electromyography are normal. Muscle histology is normal, although ultrastructural studies of muscle have shown crystalline inclusions in the mitochondria. Thyroid function tests are usually normal although they may reflect changes due to non-thyroidal illness. Synovial fluid analysis is compatible with an inflammatory state with poor mucin clot and leucocyte counts ranging from 1000 to 20 000/mm^3 with a majority of polymorphonuclear leucocytes. Biopsies have shown a lymphocytic synovitis.

Levels of factor VIII/von Willebrand factor have been found to be elevated in polymyalgia rheumatica/giant cell arteritis. Values are highest in giant cell arteritis but do not closely parallel the ESR and may reflect endothelial damage. Nordberg *et al*. (1991) studied 53 patients with giant cell arteritis by serial analysis of von Willebrand factor antigen and plasminogen activator inhibitor. The concentration of von Willebrand factor slowly decreased and reached control range 18 months after diagnosis. However, levels failed to correlate with clinical features and results of temporal biopsy, and failed to predict flare-up of disease and vascular complications. The activity of plasminogen activator inhibitor was no different from levels in age-matched controls. Von Willebrand factor antigen is present along the lamina elastica of the arterial wall in giant cell arteritis but absent from arterial biopsy in pure polymyalgia rheumatica (Olsson *et al*. 1990). Fibrinolysis has also been described in these conditions (Grau *et al*. 1984). Plasma fibronectin was not significantly different from controls in a study by Puccetti *et al*. (1987).

Interleukin 6 (**IL-6**) is a multifunctional cytokine responsible for secretion of acute-phase proteins by hepatocytes. The level of serum IL-6 was raised in 15 patients with untreated polymyalgia rheumatica/giant cell arteritis and declined following therapy (Dasgupta *et al*. 1990; Roche *et al*. 1993). However, in seven patients it remained elevated above baseline at 6 months despite optimum treatment and remission of symptoms. This suggests ongoing disease activity despite suppression of acute-phase response and symptoms. As stimulated endothelial cells are a potent source of IL-6, elevated IL-6 levels may reflect endothelial damage. However, immunohistochemistry and in situ hybridization have shown that IL-6 is produced predominantly by macrophages and some fibroblasts in the media of the inflamed

artery and by endothelial cells (Emilie *et al*. 1994). Paradoxically, the very effectiveness of glucocorticoids in returning the acute-phase response to normal pose a problem in deciding how quickly and by how much steroids should be decreased. Serial estimation of a $_1$-antichymotrypsin may be helpful as it does not return to normal until some 18 months after institution of glucocorticoid therapy (Pountain *et al*. 1994).

A study of T-cell subsets in peripheral blood showed selective depletion of CD8+ cells, which remained depressed after 1 year of treatment and only becomes normal after 2 years of treatment (Dasgupta *et al*. 1989).

Blood flow has been studied in temporal arteries (Brunholz and Mullen 1988) and in the central retinal, short posterior ciliary, and ophthalmic arteries (Ho *et al*. 1994) by Doppler ultrasonography. Abnormal flow (reduced, reversed, or alternating flow) was seen. This procedure may be useful in diagnosis and management as some of the waveforms were not seen in non-arteritic optic neuropathy.

Diagnosis

The diagnosis of polymyalgia rheumatica is based essentially on clinical symptoms and signs and it is significant that on follow-up in two large series the diagnosis was revised in 20 to 25 per cent of cases. Thus, even after the diagnosis has been made and treatment started, the possibility of other diseases should be kept in mind. Table 6 lists the conditions which can present with polymyalgic symptoms. The following conditions cause greatest difficulty.

1. Rheumatic disease in the elderly
   Rheumatoid arthritis
   Systemic lupus erythematosus
2. Inflammatory myopathies
3. Endocrinopathy
   Hypothyroidism
   Hyperthyroidism
4. Neoplasia
   Carcinoma
   Multiple myeloma
5. Occult sepsis
6. Bilateral shoulder capsulitis especially with diabetes
7. Osteoarthritis
8. Depressive illness
9. Parkinsonism

Table 6 Conditions that can present with polymyalgic symptoms

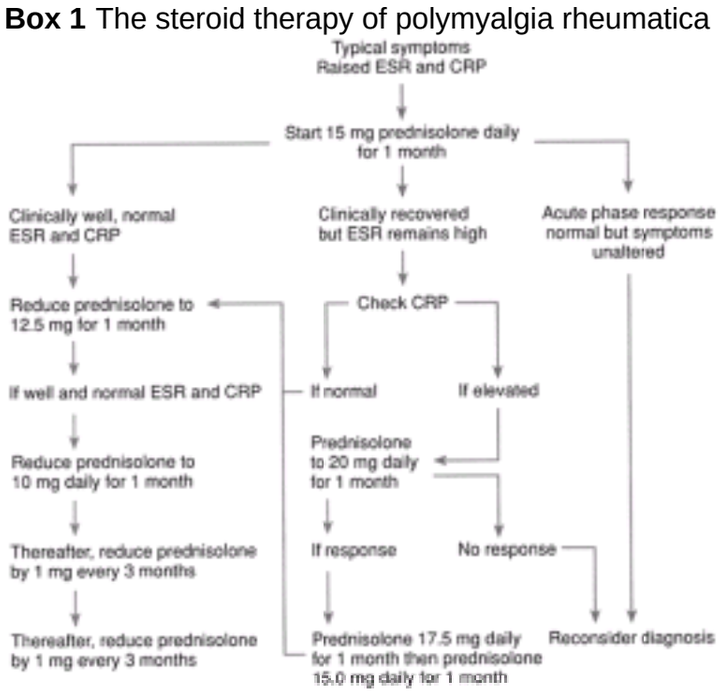
1. Rheumatoid arthritis. It may be impossible to distinguish polymyalgic onset of rheumatoid arthritis from true polymyalgia rheumatica. High titres of rheumatoid factor, prominent articular symptoms, and partial response to low-dose steroids may distinguish the former, while polymyalgia rheumatica is associated with low-grade synovitis and low titre or, more commonly, absent rheumatoid factor.
2. Neoplasia. Although it is still debatable whether there is true association of neoplasia with polymyalgia rheumatica, it is important not to mistake the generalized musculoskeletal aching, systemic symptoms, weight loss, and raised ESR of occult cancer for polymyalgia rheumatica. A thorough physical examination is mandatory and although it is not necessary to embark on detailed investigation, tests such as a protein electrophoretic strip and a chest radiograph should be carried out.
3. Inflammatory myopathies may present with muscle pains. However, in polymyalgia rheumatica there should be no objective muscle weakness. In addition creatine kinase levels and electromyography are normal.
4. Chronic sepsis may simulate polymyalgia rheumatica especially if associated with low-grade pyrexia. Blood cultures should be obtained if fever is present.
5. Hypothyroidism and less frequently hyperthyroidism may present with muscle pain and generalized stiffness. Thyroid function should be checked although abnormalities may merely reflect changes from a non-thyroidal illness.
6. Parkinsonian rigidity can occasionally mislead the unwary, although the condition is easily distinguished once it is considered and sought.
7. Bilateral capsulitis of shoulders, such as is seen in diabetes, can mimic polymyalgia rheumatica but should easily be differentiated by the restriction of passive movements. Similarly, osteoarthritis of hips and shoulders can cause difficulty but can be excluded by radiographs.
8. Depressive illnesses can frequently present with myalgic symptoms and should therefore be considered.

The limitations to the diagnosis of polymyalgia rheumatica are that there are no specific clinical features or any specific laboratory tests for this disease. The acute-phase response and its response to steroids is helpful but should be interpreted with caution as a raised ESR, whatever the cause, is likely to decrease with high-dose steroids (e.g. 20 mg or more daily). What distinguishes polymyalgia rheumatica is a complete and quick response (within 4 days) to low-dose steroids (e.g. 10 to 15 mg daily).

CD8+ lymphocytes in the peripheral blood may help in providing a marker of disease activity that is independent of the acute-phase response. We have found that even after a year CD8 cell numbers were low, probably reflecting disease activity. Most other conditions with similar presentations are accompanied by normal levels of CD8 so this test may help in distinguishing the condition, although further comparative studies are required to establish the specificity and sensitivity. A study of CD8 levels in 108 patients undergoing temporal artery biopsies suggests a positive predictive value of 85 per cent for either biopsy-positive giant cell arteritis or polymyalgia rheumatica while the likelihood of absence of giant cell arteritis or giant cell arteritis syndrome with normal CD8+ values was 60 per cent (Elling *et al*. 1990).

Treatment (Box 1,Box 2)

Box 1 The steroid therapy of polymyalgia rheumatica



Box 2 Summary

Elevated ESR in the face of a normal CRP suggests that inflammation is controlled

Give calcium and vitamin D supplements to prevent osteoporosis

Only some 50% of patients have ceased prednisolone by 2 years

Follow same schedule for giant cell arteritis but start therapy at 30 mg prednisolone daily

Polymyalgia rheumatic and giant cell arteritis are indications for corticosteroid treatment. Dramatic symptomatic response usually occurs within 48 h of introducing steroids. Despite this early gratifying response, continuing skilled supervision is necessary for several reasons, including the need to monitor for disease complications and the complications of steroid therapy. Correct assessment of disease activity is paramount in preventing steroid-related morbidity.

Polymyalgia rheumatica responds to low-dose steroids and treatment should be started with prednisolone at 15 mg daily as a single morning dose. There are no universal guidelines to tapering steroid dosage although, according to a recent report, prednisolone at 10 mg/day is required in the second month to prevent an unacceptable relapse rate (Kyle and Hazleman 1990). Further reductions below 10 mg are recommended in 1 mg decrements every 4 to 6 weeks.

Behn *et al*. (1983) in a prospective study of 176 patients reported that 10 mg of prednisolone is sufficient for control of symptoms of polymyalgia rheumatica. Others (Healey and Wilske 1977; Spiera and Davison 1978) have concurred but Kyle and Hazleman (1989), in a controlled prospective study, found that 13 of 20 patients with polymyalgia rheumatica relapsed on an initial dose of 10 mg/day, and 15 to 20 mg of prednisolone was required for adequate disease control.

The rationale for a lower dose of steroids than used hitherto in polymyalgia rheumatica/giant cell arteritis is based on several studies showing that major and minor steroid side-effects are quite common and their occurrence is related to initial dose, treatment duration, and, most critically, to cumulative dose. It is important to use the lowest satisfactory dose which contains symptoms and not merely be guided by the ESR. It is wrong to use the ESR as a chief guide to therapy since active disease may exist with a normal ESR and, on the other hand, it may be impossible to attain a normal ESR without an excessively high steroid dosage. Laboratory measures independent of the acute-phase response, such as the percentage of circulating CD8+ T cells and serum a $_1$-antichymotrypsin, may be helpful in long-term disease monitoring.

Other routes of steroid therapy may also be useful in polymyalgia rheumatica. In a pilot study, 120 mg of intramuscular methylprednisolone acetate administered initially for 3 weeks and then monthly at reducing doses was successful in induction and maintenance of disease remission (Dasgupta *et al*. 1991). Cumulative steroid dosage was 40 to 60 per cent lower than in a conventional regimen. This route has the advantage of ensuring compliance, and may not suppress the hypothalamic–pituitary axis. Further controlled studies are needed to compare the efficacy of this steroid regimen with that of oral prednisolone, as well as incidence of steroid side-effects with particular emphasis on bone mineral density.

Other agents such as dapsone, azathioprine, and d-penicillamine have been used in polymyalgia rheumatica/giant cell arteritis. Use of dapsone has been associated with very serious haematological complications such as agranulocytosis and haemolytic anaemia. Azathioprine has been anecdotally reported to have been of benefit and a controlled study showed a small but significant response (De Silva 1986).

Non-steroidal anti-inflammatory drugs have been used in polymyalgia rheumatica but should not be the first choice unless there is a major contraindication to steroid therapy.

5.11.6 Large vessel vasculitis

Richard A. Watts and David G. I. Scott

Introduction

Systemic vasculitis may be classified by the size of the predominant vessel involved and presumed aetiology (Scott and Watts 1994). Large vessels may be defined as the aorta and its largest branches to the major body regions—subclavian, carotid, and femoral arteries (Jeanette *et al*. 1994). The primary vasculitides are those in which there is no known precipitating cause, whereas the secondary vasculitides occur in a setting of infection or pre-existing autoimmune disease such as rheumatoid arthritis. The classification of large vessel vasculitis is given in Table 1. The major causes of primary large vessel vasculitis—Takayasu's arteritis and giant cell arteritis involve predominately large vessels, occasionally medium-sized vessels (i.e. renal, hepatic, coronary, mesenteric arteries), but almost never involve vessels smaller than arteries. Similarly medium and small vessel diseases such as Wegener's granulomatosis rarely involve large vessels (Davenport *et al*. 1994) By contrast some causes of secondary large vessel vasculitis such as rheumatoid arthritis have a broader spectrum of vessel involvement and frequently involve medium and small vessels.

Primary	Secondary
Takayasu's arteritis	Infection
Giant cell arteritis	Bacterial
Buerger's disease	Fungal
Cogan's syndrome	Mycobacterial
Wegener's granulomatosis	Spirochaetal
Isolated CNS angiitis	Rheumatoid arthritis
	Seronegative spondylarthropathy
	Systemic lupus erythematosus
	Juvenile chronic arthritis
	Kawasaki disease
	Sarcoidosis
	Rheumatic fever
	Relapsing polychondritis

CNS=central nervous system

Table 1 Causes of large vessel vasculitis

Giant cell arteritis is probably the most common of the primary systemic vasculitides in North America and Western Europe (Churg 1993). The estimated annual incidence in the United Kingdom is 13 per million adults and 42 per million individuals over the age of 60 (Jonasson *et al*. 1979). In Sweden, the annual incidence of giant cell arteritis proved by biopsy is 55 per million adults and 168 per million adults aged over 50 years (Bengtsson and Malmvall 1981), whilst in Iceland the annual incidence in individuals aged over 50 years is 270 per million (Baldursson *et al*. 1994). Takayasu's arteritis is much less common with an estimated annual incidence in Sweden of 0.8 per million (Waern *et al*. 1983). Systemic rheumatoid vasculitis which can involve large vessels has an annual incidence in the United Kingdom of 12.6 per million adults (Watts *et al*. 1994). However, large vessel involvement is uncommon occurring in less than 5 per cent of cases (Luqmani *et al*. 1994). There is no data on the incidence of other types of large vessel vasculitis. Data from the Norwich Vasculitis Register suggests that in the United Kingdom large vessel arteritis is rare. Over a six-year period (1988 to 1994) only 6 cases of large vessel vasculitis have been registered out of a total of 200 cases of systemic vasculitis (Scott and Watts, unpublished data). These 6 cases comprise 3 with arteritis complicating giant cell arteritis, 2 with brachial arteritis and one with infective aortitis.

The aorta is of mesenchymal origin, any injury to the aorta, whether of infectious, toxic, traumatic or immunological aetiology, results in similar morphological appearances (Lande and Berkman 1976). In the acute phase of most types of aortitis, inflammation is restricted to the media and adventitia without involvement of the intima. During the healing or chronic phase of aortitis, the cellular infiltrate resolves and is replaced by collagen, which retracts resulting in a 'wrinkled' or characteristic 'tree-bark' appearance of the aorta. Fibrosis leads to smooth tapering stenosis or even occlusion of the lumen. Sites of inflammation and intimal damage act as focal points for the development of accelerated atherosclerosis.

P>In Takayasu's arteritis the large elastic arteries are primarily involved, whilst in giant cell arteritis the changes are seen most often in the medium-sized muscular arteries which possess well developed internal and external elastic laminae (e.g. temporal artery). In 10 to 15 per cent of cases of giant cell arteritis there is involvement of the large elastic arteries (Hunder 1986).

The clinical features of large vessel arteritis are protean. Arch aortitis (e.g. Takayasu's arteritis) presents with diminished or absent peripheral pulses, claudication, bruits, hypertension and heart failure, often in the presence of a systemic illness and acute phase response. Occlusion or stenosis of the carotid or vertebral arteries leads to transient or permanent neurological deficits. Infective arteritis by contrast usually presents with aneurysm formation rather than stenosis.

The differential diagnosis of aortitis includes atherosclerosis, inflammatory aneurysms of the abdominal aorta, and aortic dissection. These conditions occur predominantly in the elderly and are not associated with an acute phase response. In younger patients abdominal aneurysms may be inflammatory and associated with a raised erythrocyte sedimentation rate. They are often only recognized at surgery (Rijbroek *et al*. 1994). Inflammatory abdominal aortic aneurysms occur in the infrarenal aorta and are associated with atherosclerosis. There is no evidence of infection or other inflammatory process. In peripheral arteries the differential

diagnosis includes atherosclerosis, fibromuscular dysplasia and thromboangiitis obliterans (Buerger's disease). Fibromuscular dysplasia affects typically the renal arteries, although other muscular arteries can be involved. Buerger's disease attacks middle and small arteries of the extremities leading to peripheral gangrene. It occurs in smokers. Inflammatory or infective angiitis must be considered in patients with clinical evidence of arteritis and an acute phase response. Histology of resected arteries will show evidence of arteritis or infection. Resected specimens should be cultured whenever an infective aetiology is considered.

The assessment of patients with suspected large vessel arteritis should include: assessment of acute phase response, disease extent and aetiology (Table 2). Total aortography is essential to establish the extent of disease in the aorta and major vessels. Increasingly, magnetic resonance imaging is being substituted for conventional arteriography. Temporal artery biopsy is useful in older patients with a large vessel arteritis, even if there is no clinical evidence of temporal arteritis.

Non-specific	
	Full blood count
	Acute phase response (erythrocyte sedimentation rate, plasma viscosity, C-reactive protein)
Disease extent	
	Chest radiograph
	Aortography (including major branches)
	Magnetic resonance imaging
	Echocardiography
Organ involvement	
	Creatinine
	Urinalysis
Aetiology	
	Blood cultures
	VDRL test
	Temporal artery biopsy
	Rheumatoid factor
	Antinuclear antibody
	Antineutrophil cytoplasmic antibody
	Anticardiolipin antibody

Table 2 Assessment of patients with suspected large vessel arteritis

Antineutrophil cytoplasmic antibodies (ANCA) are associated with systemic vasculitis—in particular Wegener's granulomatosis and microscopic polyangiitis. They are not associated with large vessels vasculitis of either inflammatory or infective origin (Churg 1993).

Treatment of inflammatory large vessel arteritis is with corticosteroids and in resistant cases immunosuppressive agents. Infectious arteritis should be treated with appropriate antibiotics. Surgical resection of aneurysms or bypass of stenotic lesions may be required.

Takayasu's arteritis

Takayasu's arteritis is a chronic granulomatous panarteritis affecting large elastic arteries such as the aorta and its major branches, and less frequently the pulmonary arteries.

In 1908 Takayasu presented to a clinical meeting the case of a 21-year-old woman with an unusual arteriovenous malformation in the retina associated with blindness due to cataract formation (Takayasu 1908). Colleagues pointed out the association between ocular abnormalities and the absence of radial pulses. Earlier descriptions include those by Savory in 1856 and Morgagni in 1761 (DiGiacomo 1984). Morgagni described a 40-year-old woman with a 6-year history of absent radial pulses who died in pulmonary oedema with an ectatic proximal aorta, lower thoracic aortic stenosis, and cardiac hypertrophy secondary to aortic incompetence.

There are a number of synonyms that have previously been widely used to describe patients presenting with evidence of aortitis. These include: aortic arch syndrome, pulseless disease, idiopathic aortitis, stenosing aortitis, aortoarteritis and occlusive thromboarteriopathy.

Epidemiology

The epidemiology of Takayasu's arteritis is poorly documented. In the United States (Olmstead County) three cases were seen in the period 1971 to 1983, equivalent to an annual incidence of 2.6 per million (Hall *et al*. 1985). The annual incidence was estimated in Sweden (1969 to 1975) to be 0.8 per million (Waern *et al*. 1983). In Birmingham (United Kingdom) during a 6 year period the annual incidence was estimated to be 0.15 per million (Scott unpublished ata), whilst in the Norwich (United Kingdom) epidemiological study of systemic vasculitis no cases were seen in the period 1988 to 1994 (Watts *et al*. 1995). The prevalence is, however, higher in the Far East, Central and South America and the India subcontinent, but the annual incidence is unknown.

Takayasu's arteritis predominately affects woman (up to 90 per cent of cases; Lupi-Herrera *et al*. 1977; Ishikawa 1988; Kerr *et al*. 1994). The age of onset is in the second to third decade (Lupi-Herrera *et al*. 1977; Ishikawa 1988; Kerr *et al*. 1994). European series have reported a higher median age of onset (41 years) (Waern *et al*. 1983). Takayasu's arteritis does occur in children (Sharma *et al*. 1991) and in the recent American series they accounted for one third of cases (Kerr *et al*. 1994).

In rare cases Takayasu's arteritis has been associated with rheumatoid arthritis (Rush *et al*. 1986), seronegative spondylarthropathy (Magaro *et al*. 1988), systemic lupus erythematosus (Saxe and Altman 1992), juvenile chronic arthritis (Hall and Nelson 1986), adult Still's disease (Wilson *et al*. 1979) and inflammatory bowel disease (Achar and Al-Nahib 1986); whether these are true associations or chance occurrences is unknown.

Definition

Ishigawa proposed diagnostic criteria for Takayasu's arteritis in 1988 and suggested that an age of less than 40 years should be an obligatory criterion for the diagnosis (Ishikawa 1986). The diagnosis of the disease was based on one obligatory criterion (age of less than 40 years), two major criteria (left and right mid-subclavian artery lesions) and nine minor criteria (high erythrocyte sedimentation rate, common carotid tenderness, hypertension, aortic regurgitation or annuloaortic ectasia, and lesions of the pulmonary artery, left mid-carotid artery, distal brachiocephalic trunk, thoracic aorta and abdominal aorta). In addition to the obligatory criterion, the presence of two major or one major plus two or more minor criteria gave a high probability of Takayasu's arteritis. In a study of 96 patients with the disease, there was 84 per cent sensitivity. None of 12 patients with other aortic diseases met these criteria for the diagnosis of Takayasu's arteritis.

The American College of Rheumatology 1990 classification criteria for the diagnosis of Takayasu's arteritis are given in Table 3 (Arend *et al*. 1990). The disease is clearly distinguished from giant cell arteritis by age of onset. In this study, 63 patients with Takayasu's arteritis were compared with 744 patients with other forms of systemic vasculitis. A high erythrocyte sedimentation rate, carotid artery tenderness and/or hypertension lacked the specificity and sensitivity to differentiate accurately patients with Takayasu's arteritis from other forms of arteritis. The sensitivity of the criteria in the traditional table format (Table 3) was 90.5 per cent with a specificity of 97.8 per cent. A classification tree was also constructed with five of the same six criteria omitting limb claudication. This gave a sensitivity of 92.1 per cent and a specificity of 97.0 per cent.

Criterion	Definition
1. Age at disease onset	Development of symptoms or findings related to Takayasu's arteritis at age < 40 years
2. Claudication of extremities	Development and worsening of fatigue and discomfort in muscles of one or more extremity while in use, especially the upper extremities
3. Decreased brachial artery pulse	Decreased pulsation of one or both brachial arteries
4. BP difference	Difference of > 10 mmHg in systolic blood pressure between arms
5. Bruit over subclavian arteries or aorta	Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta
6. Arteriogram abnormality	Arteriographic narrowing or occlusion of the entire aorta, its proximal branches, or large arteries in the proximal upper or lower extremities, not due to atherosclerosis, fibromuscular dysplasia, or similar causes; changes usually focal or segmental

Reproduced from Arend *et al*. (1990) with permission.
For purposes of classification, a patient shall be said to have Takayasu arteritis if at least three of these six criteria are present. The presence of any three or more criteria yields a sensitivity of 90.5 per cent and a specificity of 97.8 per cent. BP = blood pressure.

Table 3 American College of Rheumatology 1990 criteria for the classification of Takayasu's arteritis (traditional format)

The definition of Takayasu's arteritis was considered by the Chapel Hill Consensus conference on the nomenclature of the systemic vasculitides (Jeanette *et al*. 1994). It was defined as a 'granulomatous inflammation of the aorta and its major branches, usually occuring in patients aged less than 50 years'. They recognized that age is a useful discriminator between Takayasu's arteritis and giant cell arteritis.

Clinical features

The clinical features of Takayasu's arteritis have been reviewed recently in a series of patients from the United States (Table 4) and are broadly similar to previous series (Lupi-Herrera *et al*. 1977). The spectrum of presentation, disease severity, and pace of progression can often lead to a delay in diagnosis. The classic description of Takayasu's arteritis is of a triphasic illness characterized by pre-pulseless inflammation, followed by painful ischaemic vessels, and ending in 'burnt out disease' (Lupi-Herrera *et al*. 1977; Hall *et al*. 1985). More recent studies suggest that 20 per cent of patients have a monophasic illness not requiring therapy and that 57 per cent of patients never have constitutional symptoms (Kerr *et al*. 1994).

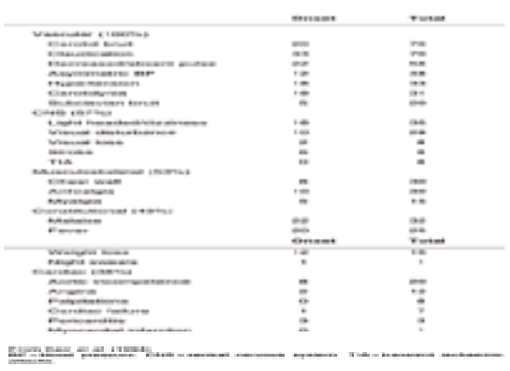

Table 4 Clinical features of Takayasu's arteritis

The hallmark of the disease is vascular ischaemic symptoms with bruit, claudication, or diminished pulses. Disease is often extensive involving the aorta and its branches. The most common vascular abnormality (more than 90 per cent of cases) is a bruit occurring most frequently in the carotid vessels (70 per cent) and in multiple sites in a third of cases. Claudication and a diminished or absent pulse is more common in the arms than legs. Carotidynia occurs in a third of patients and a similar proportion complain of lightheadedness or dizzyness. Hypertension occurs in 30 to 70 per cent of patients as a consequence of renal artery stenosis, which may be either unilateral or bilateral (Lupi-Herrera *et al*. 1977; Ishikawa 1988; Kerr *et al*. 1994).

Musculoskeletal symptoms occur in half of patients, with arthralgias in one third to one half of patients. Peripheral synovitis is less common occurring in 18 per cent of patients. Myalgia is found infrequently but can be severe.

Cardiac lesions occur in 40 per cent with aortic incompetence (20 per cent) resulting from aortitis, which may also involve the proximal coronary arteries. Congestive cardiac failure may result from aortic incompetence or systemic hypertension and accounts for the majority of fatal outcomes. Hypertension contributes to left ventricular hypertrophy and myocardial failure, but coronary arteritis results in myocardial infarction and fibrosis. Pulmonary artery involvement is common (50 per cent) with lesions localized to large and medium pulmonary vessels (Lupi-Herrera *et al*. 1977).

Cutaneous manifestations include erythema nodosum (8 per cent) which responds to treatment of the disease and probably reflects vasculitis rather than panniculitis. Leg ulcers, hypocomplementaemic vasculitis and pyoderma gangrenosum have all been described occurring in association with Takayasu's arteritis.

Neurological features occur in all stages of the disease and reflect carotid artery involvement. Non-specific symptoms such as headache and vertigo are seen in up to 90 per cent of cases (Churg 1993), but sensory loss and aphasia occur infrequently. Strokes are an important contributor to mortality. Visual disturbance occurs in 30 per cent of patients with either blurring of vision, which may be posturally dependent, diplopia or amaurosis fugax. Retinal disease with arteriovenous anastomosis occurs late in the disease. Visual disturbances are often related to systemic hypertension and 40 per cent of cases have fundal changes consistent with hypertension. Cataracts and neovascularization as described by Takayasu is now uncommon (Hall *et al*. 1985; Kerr *et al*. 1994).

Takayasu's arteritis may develop during childhood. In Eastern countries presentation is often with cardiac failure and hypertension in association with renal artery stenosis. Comparison of paediatric with adult onset patients in the United States suggests that systemic features are more common, whilst claudication is less common in childhood cases (Kerr *et al*. 1994).

Takayasu's arteritis should be considered in any young patient with limb or organ ischaemia, hypertension, or systemic illness. These patients should be investigated with full angiography (see below).

Assessment

Objective assessment of disease activity in systemic vasculitis is difficult and differentiation must be made between new lesions and scars from previous active disease. Generic assessment schemes such as the Birmingham Vasculitis Assessment Score (BVAS) may be utilized (Luqmani *et al*. 1994). Active disease was defined by Kerr and colleagues as new or worsening of two or more characteristic features. (Kerr *et al*. 1994). Complete resolution of all clinical features or their stabilization, in the setting of fixed vascular lesions, was indicative of remission. Clinical assessment of involved vessels may be difficult as symptoms of ischaemia will depend on the degree of stenosis and the adequacy of any collateral circulation. Measurement of blood pressure may be difficult in patients with diminished or absent pulses in several limbs.

Laboratory investigation

The erythrocyte sedimentation rate is often elevated in active disease. Serial measurements may correlate with disease activity, but not with histological extent (Kerr et al., 1994). Other surrogate measures such as von Willebrand factor and endothelin-1 have been reported to reflect disease activity, but have not been established as reliable markers (Woolf *et al*. 1987). Antineutrophil cytoplasmic antibodies are not associated with Takayasu's arteritis (Churg 1993). Levels of soluble adhesion molecules such as soluble intracellular adhesion molecule-1 (sICAM-1), soluble vascular adhesion molecule-1 (sVCAM-1), and soluble E-selectin may reflect endothelial activation and damage, and hence be used as markers of vascular damage. Levels of sICAM-1, sVCAM-1 and sELAM are elevated in other forms of systemic vasculitis (e.g. Wegener's granulomatosis and giant cell arteritis) (Carson *et al*. 1993) but there have not yet been any systematic studies in Takayasu's arteritis.

The diagnosis of Takayasu's arteritis has depended on arteriography to demonstrate the characteristic changes in the aorta and its major branches; long stenotic lesions occur in almost all patients (Fig. 1 and Fig. 2). Total arteriography is essential for angiographic diagnosis of the extent of the disease. Irregularity of the vessel wall occurs in one-third and aneurysms in 27 per cent of patients (Kerr *et al*. 1994). The distribution of lesions has been classified to reflect disease above and below the diaphragm—type I disease is localized to the aortic arch and its branches; type II involves the thoracic descending aorta and abdominal aorta but not the aortic arch; type III is a mixture of types I and II; type IV features aspects of types I, II, or III together with involvement of the pulmonary artery (Lupi-Herrera *et al*. 1977).

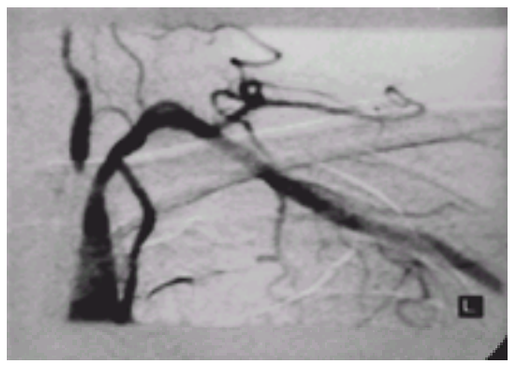

Fig. 1 Arch aortogram from a patient with aortic arch syndrome showing a long tapering stenosis of the left subclavian artery.

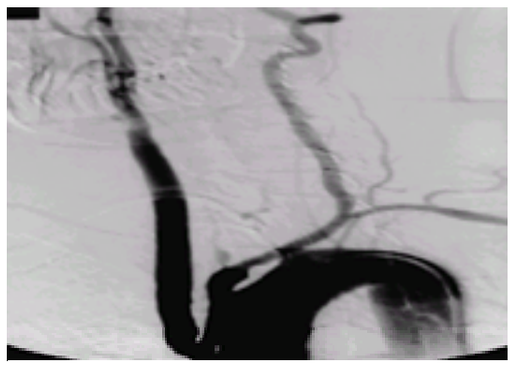

Fig. 2 Arch aortogram from a patient with Takayasu's arteritis. This shows (i) occlusion of the left subclavian at its origin, (ii) absence of the left common carotid artery, (iii) grafts *in situ* between the origin of the left common carotid and the left subclavian/vertebral artery and also between the aortic arch and right common carotid artery.

High resolution B-mode ultrasonography is more sensitive in detecting carotid lesions than angiography and correlates with the presence of bruits (Maeda *et al*. 1991). The ultrasonographic hallmark of Takayasu's arteritis is a diffuse thickening of the intima–media complex, the 'Macaroni sign'. Ultrasonography is limited by its inability to image the thoracic aorta and pulmonary arteries.

The role of magnetic resonance angiography (MRA) is still being evaluated. MRA is able to image the aorta and its major branches and demonstrate aortic wall thickening, stenosis and aneurysms. Improving resolution and newer scanning techniques are improving rapidly the ability of MRA to evaluate blood vessels and it is likely that it will become the technique of choice, replacing conventional contrast angiography (Link *et al*. 1993).

Aetiology and immunopathogenesis

The aetiopathogenesis of Takayasu's arteritis is not well understood. The association with mycobacterial infection has not been confirmed (Lupi-Herrera *et al*. 1977). Occasional examples of multicase families have been published, suggesting a common genetic or environmental factor. Immunopathological findings include hypergammaglobulinaemia, the presence of rheumatoid factors, anti-aorta antibodies, immune complexes (Lupi-Herrera *et al*. 1977) and anti-endothelial cell antibodies in peripheral blood (Sima *et al*. 1994). Antineutrophil cytoplasmic antibodies are not present. Elevated numbers of CD4+ T cells in peripheral blood, together with a decrease in CD8+ T cells and B cells have been reported but the significance of this finding is uncertain (Sagar *et al*. 1992). The inflammatory infiltrate conversely has an excess of CD8+ T cells, which are cytotoxic to endothelial cells in vitro (Scott *et al*. 1986).

In Japanese patients there is an association with the HLA haplotypes Bw52, Dw12, DR2, and DQW 1 (Dong *et al*. 1992; Kasuya *et al*. 1992) but this association has not been found in American patients (Hall *et al*. 1992). HLA-Bw52 positive Japanese patients have an association with heart disease and a worse prognosis with a higher incidence of aortic incompetence and left ventricular perfusion abnormalities (Kasuya *et al*. 1992)

A single case of Takayasu's arteritis following hepatitis B vaccination has been reported (Castrenasa-Isla *et al*. 1993). The patient developed erythema nodosum, arthralgia and upper limb claudication after receiving plasma-derived hepatitis B vaccine. Hepatitis B infection has not otherwise been associated with Takayasu's arteritis, unlike the well recognized association with polyarteritis nodosa.

Management

Medical treatment

Initial medical treatment for patients with active Takayasu's arteritis is with corticosteroids (prednisolone, 60 to 80 mg/day) and response rates of 20 to 100 per cent have been reported, with subsequent resolution of symptoms and stabilization of vascular abnormalities (Sen *et al*. 1963; Fraga *et al*. 1972; Lupi-Herrera *et al*. 1977; Kerr *et al*. 1994). However, 40 per cent of patients require additional cytotoxic agents, and 23 per cent have chronic unremitting disease (Kerr *et al*. 1994). The median time to remission in this study was 22 months (Kerr *et al*. 1994). Our experience of 7 patients confirms this data, with 3 patients requiring cytotoxic therapy in addition to corticosteroids (2, cyclophosphamide; 1, azathioprine). Continuous oral cyclophosphamide has been shown to induce remission in patients with corticosteroid-resistant disease in 4 of 6 patients treated (Shelhamer *et al*. 1985). The toxicity of cyclophosphamide in the treatment of systemic vasculitis can be reduced with the use of pulse intravenous regimens. There is little experience in the use of pulse cyclophosphamide in Takayasu's arteritis, although we have used such a regimen with good results in a small number of patients. Methotrexate is being used increasingly as a steroid sparing agent in the vasculitides. Hoffman and colleagues recently reported their experience of low-dose oral methotrexate in 18 patients with Takayasu's arteritis (Hoffman *et al*. 1994). Sixteen patients were followed up for an average of 2.8 years. The mean dose of methotrexate was 17.1 mg per week, which together with corticosteroids, resulted in remission in 13 patients; however, 7 patients relapsed on reduction of corticosteroid dose. Reintroduction of methotrexate resulted in a further remission. Sustained remissions of 4 to 34 months have been observed. Methotrexate is an effective method of inducing disease remission, permits reduction in the total corticosteroid dose and is therefore an alternative to cyclophosphamide in patients with disease that is difficult to control with corticosteroids alone. A flow diagram illustrating the managment of Takayasu's arteritis is given in Fig. 3.

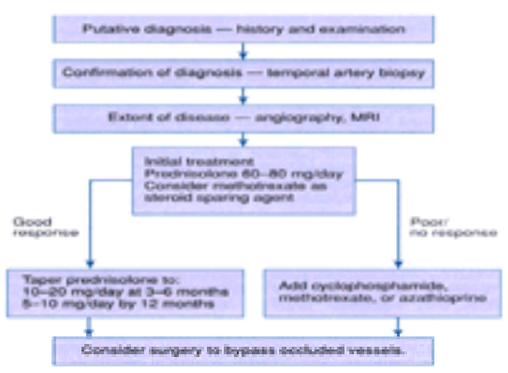

Fig. 3 Flow diagram illustrating the immunosuppresive treatment of large vessel involvement in Takayasu's arteritis and giant cell arteritis.

Hypertension can be difficult to manage in patients with Takayasu's arteritis, particularly in those individuals with involvement of subclavian and femoral arteries, making measurement of blood pressure difficult. Wherever possible hypertension should be controlled by angioplasty or surgery. Medical control of hypertension must be cautious because of the risk to organs perfused by stenosed arteries from a fall in blood pressure. Angiotensin converting enzyme (ACE) inhibitors must be used with caution in patients with renal artery stenosis, because such patients have elevated renin levels and may be especially sensitive to the first dose of an ACE inhibitor. Beta-blockers may be used as an alternative. Vasodilators are potentially dangerous in the presence of fixed stenotic lesions (Ito 1992).

Anticoagulation is not currently recommended for Takayasu's arteritis. The role of anticoagulation and/or antiplatelet drugs in patients with no evidence of a hypercoagulable state has not been evaluated, but low dose aspirin may be sensible.

Surgical treatment

Surgery has an important adjunctive role in the management of patients with Takayasu's arteritis. Hypertension secondary to renal artery stenosis is a common mode of presentation, particularly in South-East Asia. Percutaneous transluminal angioplasty has been reported to restore patency in up to 80 per cent of cases (Sharma *et al*. 1992), but restenosis can occur within 1 to 2 years (Kumar *et al*. 1990). This can be managed with repeated angioplasty but formal bypass surgery may be necessary.

Elective bypass procedures are best performed during the inactive phase of the disease. Operative procedures include bypass of stenosed segments of arteries, resection of aneurysms and replacement of aortic valves (Ohtecki *et al*. 1992; Robbs *et al*. 1994). Anastomotic sites should be chosen in areas unaffected by inflammation, and autologous grafts perform better than synthetic grafts (Kerr *et al*. 1994). Overall operative mortality is 3 to 4 per cent and is associated with surgery for aneurysm rupture (Robbs *et al*. 1994).

Prognosis

The majority of patients (74 per cent) have some impairment of activities of daily living, and 47 per cent are permanently disabled (Kerr *et al*. 1994). Mortality is, however, low and 5- and 10-year survival rates of 80 to 90 per cent have been reported (Hall *et al*. 1985; Ishikawa 1988; Subramayan *et al*. 1989). Hypertension, cardiac involvement, aortic or arterial aneurysms, and severe functional disability predict greater morbidity and mortality in these studies. Ishikawa recently reported the long-term outcome in 120 patients followed for a median of 13 years (Ishikawa and Maetani 1994). The survival rate at 15 years was 82.9 per cent. The major determinants of outcome were the presence of complications (retinopathy, hypertension, aortic regurgitation and aneurysm) and the pattern of previous disease.

Pregnancy does not appear to exacerbate the inflammatory process, but if pregnancy is considered then it may be safer in a quiescent phase (Kerr *et al*. 1994). Hypertension, aneurysms and extent of disease are associated with an increased risk of maternal or fetal death (Wong *et al*. 1983). The increases in intravascular volume during pregnancy may exacerbate hypertension, aortic regurgitation and congestive cardiac failure. Moderate doses of corticosteroids have not had a detrimental effect on the fetus. Normal vaginal delivery is possible and caesarean section should be considered on obstetric merits and not because of coexistence of Takayasu's arteritis (Kerr *et al*. 1994).

Giant cell arteritis

Giant cell arteritis is a granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery (Jeanette *et al*. 1994). The main features of the disease and its relation to polymyalgia rheumatica (PMR) are described elsewhere (Chapter 5.11.5). This section will review large vessel involvement in giant cell arteritis.

The inflammatory process of giant cell arteritis may involve the aorta and its major branches; this involvement may be minimal and clinically silent, however, extensive inflammation may lead to aortic incompetence, aneurysm formation, aortic rupture and death. Postmortem studies have demonstrated the extensive nature of the inflammatory process in giant cell arteritis, but many lesions are clinically silent (Cooke *et al*. 1946; Wilkinson and Russell 1972; Ostberg 1973). In a prospective study of 889 postmortem cases in which the temporal arteries and two transverse sections of the aorta were examined, giant cell arteritis was found in 1.7 per cent (Ostberg 1973).

Hamrin found that the aortic arch syndrome was present in 14 out of 93 cases of giant cell arteritis (Hamrin *et al*. 1972), whilst Klein and colleagues reviewed 248 patients with this disease and found that 34 (13.7 per cent) had definite or possible clinical evidence of involvement of the aorta and its major branches (Klein *et al*. 1975). At presentation of giant cell arteritis, 5 per cent of patients have large vessel involvement (Klein *et al*. 1975). Upper limb involvement is present in 6.3 per cent of patients with giant cell arteritis/polymyalgia rheumatica (Ninet *et al*. 1990). Our experience suggests that large vessel involvment in giant cell arteritis is less common. We have seen 3 cases over a 6 year period compared with approximately 100 cases of uncomplicated giant cell arteritis/polymyalgia rheumatica.

Clinical features

Systemic manifestations are present in a majority of patients with large vessel involvement, with malaise, fever, anorexia, sweats and weight loss. There is no difference in the frequency of polymyalgic symptoms and permanent visual loss between patients with large artery involvement and those without (Klein *et al*. 1975).

Intermittent claudication is the most common symptom occurring in 75 per cent of patients (Table 5) (Hunder 1990). Raynaud's phenomenon occurs in 20 per cent and may be unilateral. Physical examination reveals bruits over large arteries and/or decreased pulses. Bruits may be audible over long sections of artery. The arms alone were involved in 50 per cent of cases, legs alone in 12 per cent and arms and legs in 24 per cent (Klein *et al*. 1975). The remaining 12 per cent were either asymptomatic or had symptoms related to the chest or abdomen. Lie reviewed 72 cases with histologically proven extracranial giant cell arteritis: the ascending and aortic arch were most frequently involved (39 per cent), subclavian and axillary arteries (26 per cent), and femoropopliteal arteries (18 per cent) (Lie 1995). Evans and colleagues from the Mayo clinic identified 41 patients with giant cell arteritis and thoracic aortic aneurysms seen between 1950 and 1991 (Evans *et al*. 1994). During this period 1330 cases of biopsy-proven giant cell arteritis were seen. Laboratory investigations were similar in patients with and without aortic involvement. In 8 patients thoracic aorta involvement was diagnosed before or simultaneously with giant cell arteritis. The median interval in the remaining 33 patients was 7 years (3 months to 20 years). In only half of the patients was there evidence of active or recurrent giant cell arteritis at the time of development of thoracic involvement.

Symptom/sign	%
Intermittent claudication	74
Upper limb	40
Lower limb	13
Both	22
Raynaud's phenomenon	22
Paraesthesia	9
Decreased/absent pulses	91
Upper limb	61
Lower limb	17
Both	13

From Hunder (1990).

Table 5 Clinical features of large vessel arteritis occurring in giant cell arteritis

Large vessel involvement can become clinically apparent at any stage of the disease, either at initial presentation, when corticosteroid dose is being reduced or after corticosteroids have been withdrawn (Hunder 1990). Development of intermittent claudication of the arms may be the first manifestation of giant cell arteritis in a patient without symptoms suggestive of either polymyalgia rheumatica or temporal artery tenderness.

Diagnosis of large vessel involvement requires careful examination of arteries for tenderness, decreased pulses and bruits. Angiography is necessary to demonstrate the extent of arterial disease.

The differential diagnosis of patients with large vessel involvement due to giant cell arteritis includes Takayasu's arteritis and atherosclerosis. Takayasu's arteritis involves a younger age group (less than 50 years), different ethnic communities (giant cell arteritis is rare in non-Caucasians, whilst Takayasu's arteritis is common in Asians), the disease is usually more extensive and temporal artery biopsy is negative. Atherosclerosis, like giant cell arteritis, affects the population over 60 years of age, but is a more common cause of claudication than giant cell arteritis; however, the presence of claudication with evidence of a systemic illness (fever, malaise, weight loss, raised erythrocyte sedimentation rate) should suggest the possibility of an underlying vasculitic process. The diagnosis can be confirmed by angiography or temporal artery biopsy.

Laboratory investigations

The erythrocyte sedimentation rate is usually elevated at the time of diagnosis of large vessel involvement, but cases have been reported of large vessel disease developing at a time of apparent disease quiescence. The diagnosis should be considered in patients with an elevated erythrocyte sedimentation rate and limb, especially upper limb, ischaemia. In these patients temporal artery biopsy should be performed even if the temporal arteries are clinically normal.

Histology of large arteries is similar to that seen in the temporal artery with disruption of the elastic lamina, mononuclear cell infiltrate, giant cells and granulomata. Fibrosis occurs in longstanding lesions and results in luminal narrowing.

The demonstration of the extent of large vessel involvement in giant cell arteritis is dependent on imaging of the vessels involved. Doppler ultrasonography will demonstrate diminution of blood flow in an extremity and allow localization of lesions. Angiography has been the key to diagnosis of large vessel involvement (Fig. 4). The angiographic features most suggestive of arteritis are: (i) long segments of smooth arterial stenosis alternating with areas of normal or increased calibre, (ii) smooth tapered occlusions of affected large arteries, (iii) absence of irregular plaques and ulceration, and (iv) anatomical distribution of these changes with major involvement of subclavian, axillary and brachial arteries (Klein *et al*. 1975). The role of magnetic resonance imaging is uncertain at present, but as with Takayasu's arteritis will undoubtedly become more important.

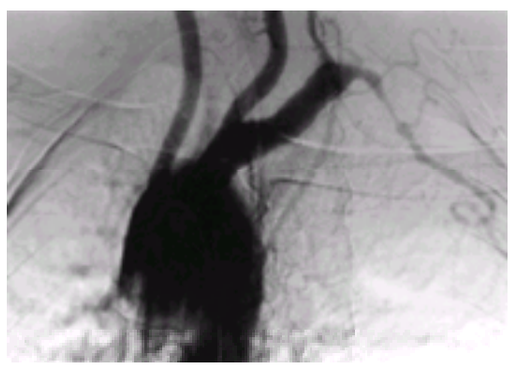

Fig. 4 Arch aortogram from a patient with giant cell arteritis showing dilatation of the right subclavian artery terminating in a long stricture distal to the origin of the vertebral artery (from Watts *et al*. 1989 with permission).

Treatment and prognosis

Improvement in blood flow through extremities rapidly occurs following treatment with high-dose corticosteroids (45 to 60 mg/day), rendering reconstructive surgery unnecessary. Evolution of arterial stenosis can be serially monitored using Doppler ultrasonography. Vessels that are occluded on the angiogram rarely recanalize and in these cases clinical improvement is due to collateral formation. Surgery should be considered in patients with persistent limb ischaemia. This should be after the inflammatory phase has subsided to prevent early thrombosis of the graft (Ninet *et al*. 1990).

Large vessel involvement in giant cell arteritis is potentially fatal following rupture of an inflammatory aortic aneurysm, stroke or myocardial infarction (Säve-Söderburgh *et al*. 1986). All patients with giant cell arteritis should be assessed carefully for large artery lesions.

Cytotoxic agents (methotrexate or cyclophosphamide) should be considered for those patients with persistent disease activity.

The vasculitides in general, although well recognized as a cause of coronary ischaemia, are rarely considered in the assessment of patients with ischaemic heart disease.

Infection-related arteritis

Infection-related aortitis was first described by Ambrose Paré in the sixteenth century, who associated syphilis with aortic aneurysms. During the nineteenth century, syphilis was recognized as the most common cause of aortitis, but pyogenic organisms and tuberculosis were increasingly recorded. A wide variety of organisms have since been recognized as causing a large vessel arteritis, including bacteria, fungi and spirochaetes (Table 6). Viral infections are not known to be associated with a large vessel arteritis.

Bacterial	*Staphylococcus* *Streptococcus* *Pneumococcus* *Klebsiella* *Pseudomonas* *Brucella* *Salmonella* *Haemophilus* *Serratia*
Mycobacterial	*Mycobacterium tuberculosis*
Fungal	*Candida* *Cryptococcus* *Aspergillus* *Coccidioides* *Histoplasma* *Mucor* *Blastomyces*
Spirochaetal	Syphilis

Table 6 Causes of infective large vessel arteritis

The vascular reaction to direct infection depends on the organism and the site of infection. Two mechanisms for infection-related vasculitis have been proposed: first, direct microbial toxicity either by endothelial invasion or the effect of microbial toxins on endothelium; or second, immune-mediated either via immune complexes or

cellular responses. Large vessel vasculitis secondary to infection occurs as a result of direct microbial endothelial invasion and leads to an erosive arteritis with mycotic aneurysm formation (Fig. 5).

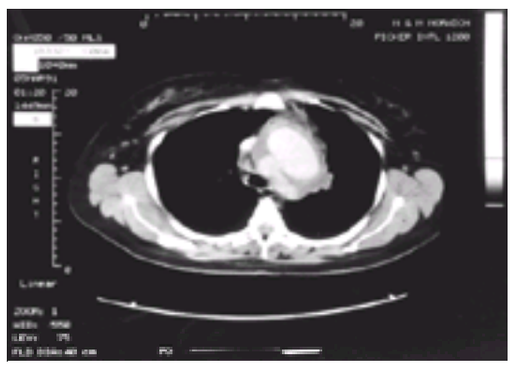

Fig. 5 Thoracic CT scan showing an aneurysm of the descending aorta. *Pneumococcus pneumoniae* was cultured from the resected vessel (from Chakravarty and Scott 1992 with permission).

Bacterial infective arteritis

Infective arteritis occurring as a result of direct endothelial invasion by bacteria or fungi results in formation of a mycotic aneurysm. Such aneurysms may develop in several ways, by septic embolization from a focus of infection such as a cardiac valve, by direct extension from a neighbouring abscess or by haematogenous spread of organisms from a portal of entry. Previously damaged or atherosclerotic vessel walls are very susceptible to bacterial seeding. Predisposing factors for development of a mycotic aneurysm include immunodeficiency, malignancy, diabetes mellitus, intravenous drug abuse and malignancy.

A wide variety of bacteria have been reported as causing infective large vessel arteritis including *Staphylococcus*, *Streptococcus*, *Klebsiella*, *Pneumococcus*, and *Pseudomonas* spp. (Table 6). Recently vasculitis has been described in association with more unusual organisms: *Salmonella* (Oskoui *et al*. 1993), *Haemophilus* (Chakravarty and Scott 1992) and *Brucella* (Aguado *et al*. 1987). *Staphylococcus* and *Salmonella* were the most frequently identified organisms in a 10-year study of 21 patients (Oz *et al*. 1989).

Aortic mycotic aneurysms may be clinically silent until they reach a massive size and rupture, with fatal haemorrhage occurring before a clinical diagnosis is made. Clinical symptoms are usually related to the systemic manifestations of infection (fever, leucocytosis), and if the aneurysm is large enough it may cause pressure effects—cough, chest pain, hoarseness and dysphagia with thoracic aneurysms, and epigastric or lumbar pain and a palpable mass with abdominal aneurysms. In the limbs mycotic aneurysms usually present with pain, tenderness and fever associated with a pulsatile mass, which may be palpable when present in the extremities. They are associated with a high mortality from sepsis and haemorrhage. The source of the infection is often from infected heart valves (80 per cent), though rarely it may be the result of direct microbial arteritis. Transient bacteraemia occurs frequently in intravenous drug abusers and results in direct vessel wall infection. *Salmonella*, *Staphylococcus*, and *E. coli* are the usual organisms. The presentation may be insidious and diagnosis delayed until haemorrhage occurs.

Diagnosis is based on a high level of suspicion particularly in patients with fever, leucocytosis, abdominal pain and positive blood cultures. The aorta may appear normal on plain radiographs and a CT scan may be required to demonstrate aortic infection

The mortality of bacterial aortitis is still high. In a series of 21 cases seen over 10 years, there were 8 disease-related deaths, but no graft infections were seen in the survivors (Oz *et al*. 1989).

Spirochaetal infection

Treponema pallidum is a well recognized cause of aortitis, with aneurysm formation and development of aortic incompetence. The primary histological changes are in the vasa vasorum with endarteritis, and perivascular infiltration with lymphocytes and plasma cells. Infection occurs early in the disease and organisms lie dormant in the aortic wall. Spirochaetes can, however, only rarely be detected in tissue. Symptomatic aortic disease occurs as a feature of tertiary disease. The majority of syphilitic aneurysms are located in the thoracic aorta with the following distribution: sinus of Valsalva less than 1 per cent, ascending aorta 36 per cent, aortic arch 24 per cent, descending aorta 24 per cent, and multiple locations 4 per cent (Berkman 1986). Presentation is with aortic incompetence (60 per cent of cases) or coronary ostial stenosis. Coronary arteritis may occur independently of aortitis. Diagnosis is based on the radiographic appearances and serological tests. Treatment is with antibiotics and surgical resection. The differential diagnosis of syphilitic aortitis includes Takayasu's arteritis, extracranial giant cell arteritis, and the aortitis of rheumatic diseases.

Borrelia burgdorferi infection causes a small vessel vasculitis which does not involve large vessels.

Fungal infections

Fungal infections of the endothelium are rare. *Candida*, *Aspergillus*, and *Histoplasma* are the most common organisms; however, *Blastomyces*, *Coccidioides*, *Cryptococcus*, and *Mucor* have been described rarely (Berkman 1986; Leavitt and Kauffman 1988). Infection results in formation of a mycotic aneurysm, similar to that seen with bacterial arterial infections. Direct infection is rare. Most cases of fungal aortitis occur in patients who are already severely immunocompromised from other diseases, those who have received multiple courses of intravenous antibiotics, or intravenous drug abusers. These patients have a high mortality (70 per cent) and require aggressive antifungal therapy.

Mycobacterial infection

Mycobacterial infection may involve blood vessels of any size, with veins being more vulnerable than arteries. Large vessel tuberculous arteritis is uncommon, with an equal division between thoracic and abdominal aneurysms (Silbergleit *et al*. 1965; Berkman 1986). The aorta may be infected by the tubercle bacillus by haematogenous dissemination in miliary disease, lymphangitic spread and direct extension from contiguous structures. Aneurysm formation occurs in half of the cases. Clinical presentation is non-specific with fever, chest pain, haemoptysis, dysphagia, abdominal pain and a palpable mass. Tuberculous vasculitis results in granuloma formation and a panarteritis. Acid-fast bacilli may be detectable in macrophages of the inflammatory infiltrate. Treatment is with antituberculous drugs, combined with surgical resection.

Mycobacterium leprae may cause vasculitis but this typically involves small arteries. Other atypical mycobacteria have not been described as causing a large vessel aortitis.

Rheumatoid arthritis

Systemic rheumatoid vasculitis was first described by Bywaters in 1949 and the clinical features delineated over the next decade (Bywaters 1957). The annual incidence of this disease is 12.6 per million, making it one of the most common forms of systemic vasculitis (Watts *et al*. 1994). All sizes of vessel from large arteries to capillaries may be involved. Large vessel involvement with aortitis or aortic regurgitation is rare in patients with rheumatoid arthritis and was only first clearly described by Zvaifler and Weintraub (1963) . In a large comparative series seen between 1970 and 1994 from three centres in the United Kingdom comprising nearly 150 cases of systemic rheumatoid vasculitis, large vessel involvement was seen in 5 per cent (Luqmani *et al*. 1995). Aortitis was identified in 10 cases in a series of 180 postmortems performed on patients with rheumatoid vasculitis (Gravallese *et al*. 1989). As with other forms of systemic rheumatoid vasculitis, the typical patient with large vessel disease has long-standing seropositive erosive rheumatoid vasculitis. In most cases there is multiorgan involvement (Gravallese *et al*. 1989) including a coronary arteritis. Aortitis is rarely diagnosed antemortem, but may be the cause of death, particularly in cases with associated coronary arteritis. Aortitis

and aortic incompetence may result in haemodynamic compromise with congestive cardiac failure.

Histological features of rheumatoid aortitis include necrosis of medial smooth muscle and elastica, with an inflammatory infiltrate comprising lymphocytes and plasma cells. A panmural aortitis can occur. Rheumatoid granulomata are seen in half of the cases (Gravallese *et al*. 1989).

Systemic rheumatoid vasculitis responds well to corticosteroids and cyclophosphamide (Luqmani *et al*. 1995). There is however no data on the response of rheumatoid aortitis or aortic incompetence to immunosuppressive therapy, however this treatment should be considered in patients presenting with active aortitis since prevention or delay in the necessity for surgery may be achieved.

Spondylarthopathies

Aortitis may complicate the seronegative spondylarthropathies in particular ankylosing spondylitis (Buckley and Roberts 1973) and Reiter's syndrome (Morgan *et al*. 1986). The aortic ring and ascending aorta are the typical sites of involvement but distal aortitis has been described (Morgan *et al*. 1984). Aortic incompetence occurs in up to 5 per cent of cases of ankylosing spondylitis, 2.5 per cent of cases of Reiter's syndrome and probably less frequently in the other seronegative spondylarthropathies (Townend *et al*. 1991).

The seronegative spondylarthropathies are associated with the HLA-B27 haplotype. Inflammatory diseases associated with this haplotype have been found in 15 to 20 per cent of patients with lone aortic regurgitation, suggesting that lone aortic regurgitation may reflect an inflammatory valvulitis or aortitis (Bergfeldt *et al*. 1988)

Echocardiography shows thickening of the aortic leaflets, subaortic echodense bumps and aortic root densities (Labresh *et al*. 1985). Histologically there is thickening of the aortic valve cusps and aorta, together with lymphocytic infiltration in the aortic wall and fibrosis of the aortic root (Buckley and Roberts 1973). These changes can be difficult to distinguish from lesions occurring in syphilitic aortitis.

Treatment of the inflammatory process with immunosuppressive agents has been suggested, but no controlled data exists as to their benefit in this situation, in particular whether the need for aortic valve replacement can be delayed or prevented (Townend *et al*. 1991).

Systemic lupus erythematosus

The typical vascular lesion of systemic lupus erythematosus involves small vessels, large vessels are rarely involved. Saxe and Altman reviewed 19 reported cases of Takayasu's arteritis associated with systemic lupus erythematosus, and pointed out that the diseases have a similar age of onset and female preponderance (Saxe and Altman 1992). However, the absence of specific markers for systemic lupus erythematosus in patients with Takayasu's arteritis who subsequently develop systemic lupus erythematosus suggests that the coexistence of these two conditions may be coincidental. Some of these cases are incompletely reported and would not be considered necessarily to be either of the diseases using current diagnostic criteria. Patients with systemic lupus erythematosus who develop large vessel thrombosis as part of the antiphospholipid antibody syndrome, may mimic the obstructive vasculopathy seen in Takayasu's arteritis.

Relapsing polychondritis

Relapsing polychondritis is a systemic disease of unknown aetiology with inflammation of cartilaginous structures. Vasculitis occurs in 11 to 56 per cent of cases with involvement of large and medium-sized vessels (Michet 1990). Large artery involvement is uncommon (less than 15 per cent of cases) and present as an aortic arch syndrome, thoracic or abdominal aortic aneurysm with rupture, or aortic regurgitation. Small vessel vasculitis and a segmental necrotizing glomerulonephritis may occur simultaneously. The vasculitis may present at the same time as other manifestations of relapsing polychondritis or many years afterwards. The aortitis of relapsing polychondritis results in loss of glycosaminoglycans from the aortic wall, particularly in the media with loss of elastic tissue.

Treatment is with corticosteroids, and the role of cytotoxic agents is uncertain. Surgical repair is required for valvular and artery occlusions.

Behçet's syndrome

Behçet's syndrome is a chronic relapsing condition characterized by a triad of aphthous stomatitis, genital ulceration, and uveitis. A large vessel arteritis is well described (Little and Zarins 1982; Lakhanpal *et al*. 1985). Major arterial occlusions were present in 36 per cent and there was evidence of vasculitis in 18 per cent of cases at autopsy (Lakhanpal *et al*. 1985). Shimizu and colleagues described 81 patients with Behçet's disease in whom occlusion of large arteries was present in 17 and aneurysms in 24 patients (Shimizu *et al*. 1979). Aortitis is uncommon and is represented histologically by inflammation in the media and adventitia, particularly around the vasa vasorum. Multiple pulmonary aneurysms occur which may communicate with the bronchi and present as massive haemoptysis.

Cogan's syndrome

Cogan's syndrome is a rare condition characterized by recurrent episodes of acute sensorineural hearing loss and non-syphilitic keratitis (Cogan 1945). Systemic features occur and vascular involvement is common (Vollertsen *et al*. 1986).

Vasculitis occurs early in the disease, within the first year in two-thirds of patients, but can occur up to 8 years after onset (Vollertsen *et al*. 1986). The clinical manifestations will depend on the vessel involved.

Cardiac involvement occurs in 15 to 25 per cent of patients (Cheson *et al*. 1976; Vollertsen *et al*. 1986), manifesting mainly as aortic regurgitation which may be rapidly progressive over a period of months. It is associated with either a valvulitis or an aortitis. Aortic regurgitation may occur at diagnosis or up to 12 years after diagnosis (Vollertsen *et al*. 1986). Aortitis may lead to narrowing of the coronary ostia and arteries arising from the aortic arch; a distal coronary arteritis may also occur.

Angiography demonstrates arterial occlusion of large and medium vessels with scattered stenosis, and a diffuse irregular narrowing can also be seen (Vollertsen *et al*. 1986).

Histological examination of the aorta reveals neutrophils, mononuclear cells, giant cells, destruction of the elastic lamina, neovascularization, necrosis, scarring and fibrotic hypertrophy (Cheson *et al*. 1976). Similar findings are observed in other vessels.

Treatment of Cogan's syndrome is with corticosteroids, and clinical improvement occurs in most cases. The role of cytotoxic drugs in undetermined. Treatment of aortic regurgitation is by valve replacement (Cochrane and Tatoulis 1991). Arterial bypass grafting may be required.

Kawasaki disease

Kawasaki disease is a inflammatory vascular disease of childhood which typically results in the formation of coronary artery aneurysms. Systemic artery aneurysms occur in 4 per cent of patients with Kawasaki disease, the most common site being the axillary and iliac arteries (Inioue *et al*. 1988). Aortitis and consequent aneurysm formation is rare. Fibrosis and arterial luminal stenosis is a late sequelae of acute Kawasaki disease. Treatment of acute disease is with aspirin and intravenous immunoglobulin.

Wegener's granulomatosis

Wegener's granulomatosis is a disease of predominately small and medium vessels. The clinical features and management of Wegener's granulomatosis is described in Chapter 5.11.2. Coronary and large artery involvement has only rarely been described in patients with Wegener's granulomatosis (Davenport *et al*. 1994; Logar *et al*. 1994). Two patients had clinically significant aortic valve incompetence. Histology of the resected valve showed myxoid degeneration due to previous vasculitis affecting the vessels of the aortic wall, together with valvular necrosis (Davenport *et al*. 1994). Carotid arteritis has been described in a patient with ANCA-positive

crescentic glomerulonephritis (Logar *et al*. 1994).

Rheumatic fever

Rheumatic fever occurs as part of the immune response to Group A streptococci. During acute rheumatic fever arteritis can develop in different sized arteries, and Aschoff bodies may develop in the adventitia of the aorta and other large arteries. An acute vasculitis may involve the vasa vasorum, with endothelial cell swelling, luminal leucocytes, and a perivascular infiltrate of lymphocytes, macrophages, and leucocytes (Virmani and McAllister 1986).

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease of unknown aetiology. Cardiac involvement is well recognized in patients who die suddenly. Sarcoid granulomata have been described rarely in the aorta and its large branches. The granulomata are found in the adventitia (Virmani and McAllister 1986).

Central nervous system angiitis

Primary angiitis of the central nervous system is a rare disease of unknown aetiology, occasionally it involves large vessels but more typically medium or small arteries (Calabrese and Mallek 1988; Abu-Shakra *et al*. 1994). The clinical features are non-specific and entirely neurological. Presentation may be acute with severe headache, stroke, neurocognitive defect, or seizure. There may be evidence of systemic illness with elevation of acute phase proteins. The diagnosis is made by the presence of characteristic histological findings, with a granulomatous vasculitis in the leptomeninges or cortex. Angiography demonstrates beading or ectasia alternating with stenosis. These changes are typically distal to the termination of the carotid arteries. Treatment is with corticosteroids with or without cyclophosphamide.

5.11.7 Behçet's syndrome

Hasan Yazici and Sebahattin Yurdakul and Vedat Hamuryudan

Introduction

Behçet's syndrome is a systemic vasculitis (Lie 1992) of unknown aetiology with a definite and peculiar geographic distribution. Most cases are clustered around the countries of the Mediterranean basin, the Middle East, and the Far East. Its most dreaded complication, eye disease, is one of the leading causes of blindness in these areas.

Beginning with Hippocrates many have written about patients with disorders that today are considered elements of Behçet's syndrome. In 1937 Hulusi Behçet, professor of dermatovenereology in Istanbul, described in detail three patients with oral and genital ulceration and hypopyon uveitis, and proposed that this was a distinct entity. Subsequently it was realized that many other clinical manifestations were part of this syndrome (Shimizu *et al*. 1979). Table 1 gives the most important of these manifestations.

Lesion	Prevalence (%)
Aphthous ulcerations	97–100
Genital lesions	80–90
Skin lesions	80
Eye lesions	50
Arthritis	40–50
Thrombophlebitis	25
Neurological involvement	1–15
Gastrointestinal involvement	0–25

Table 1 Clinical findings in Behçet's syndrome

Epidemiology

The usual onset of the syndrome is in the third or fourth decade. The onset is rare in children and after the age of 45. Recently there has been an increased awareness of childhood cases (Özdoğan 1994).

The male:female ratio is approximately equal but the syndrome has a more severe course in men. Large scale epidemiological studies are lacking. Based on case registries, the prevalence is about 1:300 000 in Northern Europe and 1:10 000 in Japan. The prevalence may be higher in Mediterranean countries. In Turkey, based on two spot surveys among the adult population, the prevalence rates were 8 and 38:10 000 (Yurdakul *et al*. 1988). For unexplained reasons, few cases are reported from the United States and Australia.

Genetics

The syndrome is associated with HLA B5, specifically with HLA B51 (Ohno *et al*. 1982), however there is geographical variation. Patients from the Mediterranean countries and Japan show this association whereas those from the United States and United Kingdom, perhaps with the exception of those with eye disease, do not (Yazici *et al*. 1980). The association with HLA B5 is primarily with those patients attending hospital and therefore with more severe disease (Yurdakul *et al*. 1988).

In a syndrome associated with an HLA allele, one would expect a more pronounced familial occurrence than one ordinarily sees in Behçet's syndrome. In general there is no consistent inheritance pattern (Bird Stewart 1986). We have seen two monozygotic brothers concordant for the syndrome (Hamuryudan *et al*. 1991a). There is also an increased prevalence of lymphocytotoxic antibodies among the healthy children of patients with Behçet's yndrome (Günaydin *et al*. 1992).

Clinical features

Skin and mucosal involvement

Oral aphthae (Fig. 1)

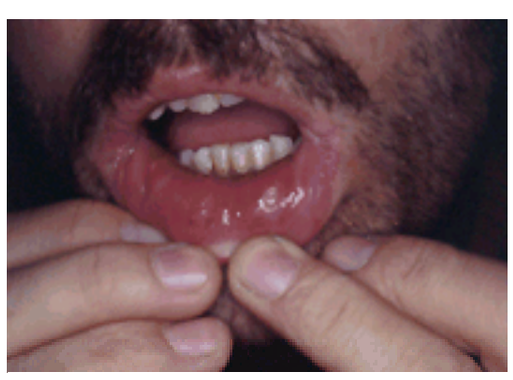

Fig. 1 Oral aphthae.

These are almost always present. However, 1 to 3 per cent of patients can have several of the other features of the syndrome without ever having aphthae. Aphthae are frequently the first manifestation of the syndrome. It is not uncommon for some patients to have only aphthae for many years before other features appear. The majority of oral ulcers in Behçet's syndrome are indistinguishable from those seen in recurrent oral ulceration, but tend to be multiple and occur more frequently. Large (major) ulcers are less frequent and herpetiform ulcers are rare. Major ulcers, however, can be very troublesome because they heal with scarring, which can even occlude the oropharynx. The minor ulcers do not as a rule leave scars. The histology reveals non-specific ulceration with necrotic material. There is evidence of vasculitis with an increase in mast cells.

Genital ulceration (Fig. 2)

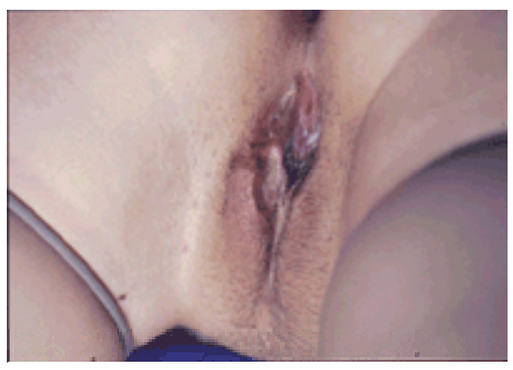

Fig. 2 Fresh genital ulceration.

In the male, 90 per cent of the genital ulcers occur on the scrotum and almost always leave scars. They are less frequent on the shaft and on the glans penis. Urethritis is not observed unless there is an associated meatal ulcer.

In the female the labia (major and minor) are affected commonly. Ulcers are less frequent in the more proximal part of the genital tract and cervical lesions are rarely seen. Histologically, they are indistinguishable from oral aphthae.

Skin lesions (Fig. 3)

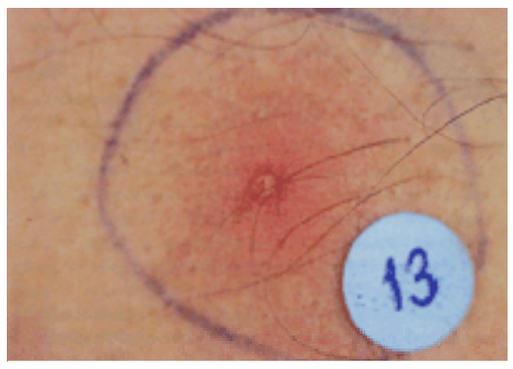

Fig. 3 The pathergy reaction in the form of a pustule.

The skin lesions of Behçet's syndrome can be divided into three main types: (i) nodular lesions resembling erythema nodosum, (ii) papulopustular lesions also called acneiform or simply acne, (iii) others (palpable purpura, ulcerations, Sweet's syndrome, etc.) all representing various forms of vasculitis. The lesions resembling erythema nodosum are similar to idiopathic erythema nodosum and those due to other conditions (e.g. sarcoidosis). Their tendency to leave a pigmented area after the acute period is a somewhat distinguishing feature, and one which is explained by the erythrodiapedesis observed histologically. Sometimes superficial thrombophlebitis can be clinically indistinguishable from erythema nodosum. The papulopustular lesions, when present in intertrigenous areas like axillae and the inguinal folds, tend to erode and ulcerate. Most papulopustular lesions are histologically very similar to ordinary acne. However, they differ from the latter in their propensity to occur also in the extremities. The other forms of skin lesions are leucocytoclastic vasculitis, necrotizing arteritis of the small and medium arteries, superficial thrombophlebitis, and unclassifiable papules and pustules (Azizlerli *et al*. 1992). Painful papules, which histologically show a neutrophilic infiltration of the skin without fibrinoid necrosis (Sweet's syndrome) are also seen (Lakhanpal *et al*. 1988).

The pathergy reaction (Fig. 3), a curious hyperreactivity of the skin to a needle prick, is peculiar to this syndrome (Gilhar *et al*. 1989). The only other condition in which it is known to be positive with any consistency is pyoderma gangrenosum. After a skin puncture with a needle a papule or a pustule forms in 24 to 48 h.

There is some debate as to the true prevalence of this reaction. It is seldom found among patients in Northern Europe or the United States. In patients from Japan and Turkey it is positive in around 60 to 70 per cent when tested repetitively. It is, however, possible that its prevalence may be decreasing in recent years (DilŠen *et al*. 1993). Whether this is a matter of patient selection, the recent use of disposable needles, or a true decline in prevalence is a matter of debate.

The mechanism of the pathergy reaction is still obscure. Surgical cleaning of the skin considerably dampens this reaction (Fresko *et al*. 1993), which suggests that more than disrupting the integrity of the epidermis and dermis is required.

The reaction shows an initial accumulation of neutrophils followed by mast cells and mononuclear cells. The pathergy phenomenon in Behçet's syndrome is not confined to the skin: various tissues are known to be hyperreactive to surgical trauma, and it is not uncommon to have attacks of uveitis after eye surgery and synovitis after an arthrocentesis.

The propensity for inflammation in Behçet's syndrome can also be observed in the response these patients have to intradermal injections of sodium monourate crystals (Çakir *et al*. 1991). Patients with Behçet's syndrome have an augmented response to these crystals and it is interesting to note that British patients show a similar heightened response even though they are, as noted above, generally pathergy negative.

Eye involvement (Fig. 4)

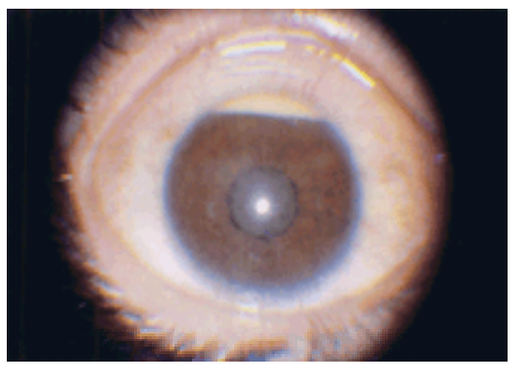

Fig. 4 Hypopyon uveitis.

This is one of the most serious manifestations. Males and those with younger age of onset, i.e. less than 25 years of age, have an increased prevalence. While the overall prevalence is about 50 per cent, in the younger male it is approximately 70 per cent. Females are affected less severely. Disease is bilateral in 90 per cent of the patients with ocular involvement. The onset of eye disease is usually within 2 to 3 years of the development of the syndrome.

Eye disease in Behçet's syndrome consists of a chronic relapsing posterior and anterior uveitis. Isolated anterior uveitis is found in only 10 per cent of those with ocular involvement. Conjunctivitis is rare. Occasionally episcleritis and conjunctival ulceration are seen.

Hypopyon uveitis (Fig. 4) is very typical of Behçet's syndrome, although occasionally it can be observed in Reiter's syndrome. It is an accumulation of white cells and debris in the anterior chamber that precipitates to form a layer due to gravity. Hypopyon is seen in 20 per cent of patients with eye disease and as rule is almost always associated with severe retinal disease.

The basic retinal lesion is a vasculitis, which can lead to exudates, haemorrhages, venous thrombosis, papilloedema, and macular disease that frequently results in a hole. The pars plana is also involved. During an acute flare there is a marked influx of fibrin, inflammatory cells, and cellular debris into the vitreous. After each flare there is usually some residual structural damage in the form of retinal changes, vitreal opacities, posterior synechiae, and cataracts. Secondary glaucoma frequently develops. The extent of these structural changes determinates the cours e of eye disease in Behçet's syndrome.

Musculoskeletal system

Behçet himself, as early as 1938, described 'rheumatoid' involvement in Behçet's syndrome. It can occasionally be the initial manifestation. Involvement of the joints (Table 2) is seen in about one-half of the patients in the form of arthritis or arthralgia (Yurdakul *et al*. 1983). It is mono- or oligoarticular but can be symmetrical. It is quite common to have symmetrical disease of the wrist or elbow, which can be confused with rheumatoid arthritis. Usually lasting a few weeks it seldom leads to deformity. Erythema of the overlying skin is not seen. Erosions are uncommon. Chronic synovitis lasting months to years with deformity and erosions are seen, but rare. The synovial fluid is inflammatory (see below). The histological changes are non-specific.

Seen in 50 per cent of the patients either as arthritis or arthralgia
Non-deforming and short lasting (few weeks)
Knees, ankles, wrists, and elbows are involved most commonly
Sacroiliac joint involvement is not prevalent in controlled studies
Usually mono- or oligoarticular but can be symmetrical with a potential for confusion with rheumatoid arthritis
Synovial fluid is commonly inflammatory but a good mucin clot is usual
Synovial histology is non-diagnostic; paucity of plasma cells and superficial-layer ulceration are the most outstanding features
Aseptic necrosis of the bone not related to steroid use can be seen

Table 2 Features of arthritis in Behçet's syndrome

Knees are the most commonly affected joints, followed in frequency by ankles, wrists, and elbows. There has been much debate about the involvement of the sacroiliac joints in Behçet's syndrome, but an increased prevalence has not been found in controlled studies. Furthermore there is considerable interobserver variation in interpretation of the sacroiliac joint on a plain radiograph of the pelvis (Yazici *et al*. 1987a). Regardless of the presence or absence of involvement of this joint, back pain is quite rare in Behçet's syndrome. The main debate about sacroiliac involvement centres around the erroneous inclusion of Behçet's syndrome among the seronegative spondylarthropathies (Moll *et al*. 1974). Other reasons why Behçet's syndrome is not a spondylarthritis include the lack of familial association with the spectrum of spondylarthritides, the association with HLA B51 and, most importantly, the presence of widespread vasculitis. In addition, the nature of the 'shared' clinical features in Behçet's syndrome is very different from that in this group of diseases. The genital ulceration is usually scrotal, urogenital infection is absent, nail changes are not seen, and the nature and course of eye involvement are totally different (Yazici 1987).

Myositis is occasionally found in Behçet's syndrome. It is usually local but generalized forms can also be seen. The muscle enzymes are not raised in the local forms and the histological features are indistinguishable from those of polymyositis.

Another musculoskletal manifestation associated with Behçet's syndrome is aseptic necrosis of the bone. This is possibly related to vasculitis and not necessarily to steroid use.

Neurological involvement (Fig. 5)

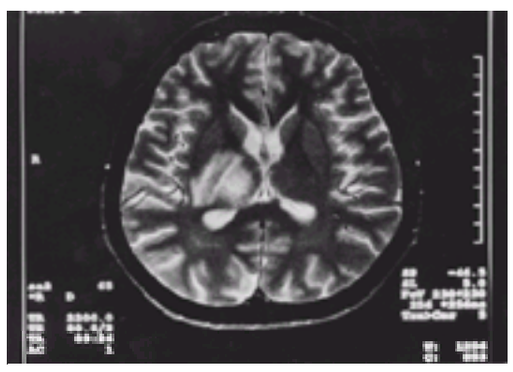

Fig. 5 Involvement of the central nervous system (T_2 -weighted MRI showing a hyperintense lesion in the right thalamus, capsula interna, and nucleus lentiformis in a 28-year-old male patient).

There is much variation in the reported prevalence rates of neurological involvement. In a prospective survey a prevalence rate of 5 per cent was found (Serdaroğlu *et al*. 1989). Pyramidal signs are the most common, followed by cerebellar and sensory symptoms and signs. Symptoms of increased intracranial pressure and meningeal irritation are also observed. Dementia can develop in an occasional patient. In the majority of the cases, headaches can be related to the basic pathology only if there are other associated signs and symptoms in the central nervous system. Papilloedema usually indicates occlusion of a venous sinus (Wechsler *et al*. 1992). As is true with eye involvement, the most severe forms of central nervous involvement are seen in the male.

The findings in cerebrospinal fluid are non-specific. Opening pressures and protein content are usually increased. Pleocytosis is present. Glucose can be low. Computed tomographic scans are of limited value unless localizing symptoms are present. Magnetic resonance imaging may prove to be more sensitive and specific.

The most common site of involvement is the brainstem. Hemispheric, meningeal, and spinal cord lesions are also seen. In contrast to the other vasculitides, peripheral nerve disease is unusual.

The histological appearances of the central nervous lesions in Behçet's syndrome are non-specific. There are inflammatory and degenerative changes. Frank vasculitis is not seen. The usual vascular change is a perivascular infiltration, sometimes with perivascular lamellar fibrosis. Microabscesses can also be observed.

Some patients develop psychiatric problems. Reliable prevalence rates are lacking. As in systemic lupus some of the psychiatric problems in Behçet's syndrome may be the result of a situational response to a chronic disease and occasionally of steroid use.

Cardiovascular and pulmonary involvement

Cardiac involvement

Endocarditis, myocarditis, and pericarditis can all occur but are rare. Cases with coronary vasculitis and ventricular aneurysms have also been documented. In a prospective controlled survey among 64 patients we failed to find an increased prevalence of cardiac disease (Özkan *et al*. 1992).

Venous lesions

Involvement of the veins is one of the main manifestations of Behçet's syndrome. In fact, Behçet's syndrome, together with systemic lupus and Buerger's disease, is one of the few vasculitides that can involve the venous side of the circulatory system together with the arterial side. Furthermore, in contrast to the other two, it can involve the vena cavae.

Thrombophlebitis occurs in 25 per cent of all patients. More frequent in the calf, it is also seen in veins of the upper extremity. There is a propensity to develop venous thromboses after venepunctures. A frequent outcome of thrombosis in the lower extremities is dermatitis of chronic stasis associated with recurring skin ulcers. Thrombosis of the iliac veins and both vena cavae is less frequent and seen almost only in male patients. This is usually less associated with the formation of collateral vessels. Occlusion of the suprahepatic veins can cause a Budd–Chiari syndrome, which carries a high mortality.

In the common variety of thrombophlebitis, for example of the pelvic veins in the postoperative state, only a short segment of the vessel wall is diseased. The thrombus is adherent to the wall at this site and has a long, non-adherent tail. This is not so in Behçet's syndrome. Here large segments of the vessel wall are diseased and consequently the thrombus formed is adherent to the wall at all places. Sometimes the entire length of the inferior vena cava is thus affected. This explains, we believe, why pulmonary embolism is rare in Behçet's syndrome even though thrombophlebitis is seen in one-quarter of the patients.

Arterial lesions (Fig. 6 and Fig. 7)

Fig. 6 Carotid artery aneurysm.

Fig. 7 Pulmonary artery aneurysms.

Starting with the aorta, all the arterial tree can be afflicted (Hamza 1987; Koç *et al*. 1992). Aneurysms of the abdominal aorta, carotid, femoral, popliteal, and less commonly coronary arteries can be seen (Fig. 6). The rupture of these aneurysms is frequently fatal. The basic pathology is thought to be a vasculitis of the vasa vasorum. There is a high recurrence rate after reconstructive surgery of the aneurysms of the peripheral vessels. This complication is thought to be related to the pathergy phenomenon.

The basic pulmonary pathology in Behçet's syndrome is also related to vasculitis. Pulmonary vascular changes in the form of arterial aneurysms, arterial and venous thromboses, and pulmonary infarcts are found (Efthimiou *et al*. 1986; Hamuryudan *et al*. 1994a). The classic radiographic finding is the non-cavitating mass lesion (Fig. 7). Computed tomographic scans are usually adequate for diagnosis.

Pulmonary arterial aneurysms in Behçet's syndrome carry a grave prognosis. Among our patients the mortality was 50 per cent despite treatment, the terminal event usually being the rupture of an aneurysm into a bronchus.

Pleural effusions are seldom in Behçet's syndrome. They may be associated with the pulmonary vascular disease or may be present independently.

Gastrointestinal involvement

While gastrointestinal involvement is seen in about one-third of patients from Japan (Shimizu *et al*. 1979), it is quite rare among patients reported from the Mediterranean basin. The basic pathology is that of mucosal ulceration. This is seen most commonly in the ileum, followed by the caecum and other parts of the colon. Occasionally oesophageal ulceration can occur. Histologically the ulcers are indistinguishable from those found in ulcerative colitis. Intestinal lymphangiectasia have also been reported. The course of intestinal Behçet's syndrome is that of exacerbations and remissions. The usual symptoms are abdominal pain and melaena. A mass is often palpable in the abdomen. The ileocaecal ulcers have the worst prognosis, with a distinct tendency to perforate.

Hepatic problems are not common in Behçet's syndrome except when an associated Budd–Chiari syndrome is present. A slightly enlarged spleen is noticed in 20 per cent of the male patients (Soysal *et al*. 1990), not necessarily related to portal hypertension secondary to venous thrombosis.

Other clinical features

Renal involvement is seen much less frequently than one would expect in a systemic vasculitis. There are occasional reports of glomerulonephritis (Hamuryudan *et al*. 1991b). Epididymitis is seen around 5 per cent of the patients.

Amyloidosis is seen sporadically and when present usually presents with a nephrotic syndrome. It is of the AA type and carries a grave prognosis. In a rectal biopsy survey of non-symptomatic patients without any proteinuria, no cases of silent amyloidosis could be identified (Yurdakul *et al*. 1990).

Diagnosis

The full-blown syndrome is easy to identify; the so-called incomplete forms sometimes cause problems. Reiter's and Stevens–Johnson syndromes can also be problems in differential diagnosis for the uninitiated. However, an occasional patient with inflammatory bowel disease associated with oral ulcers, skin lesions, and episcleritis may be impossible to differentiate from Behçet's syndrome. Another difficult aspect is a patient with multiple sclerosis with one or two features of Behçet's syndrome.

Many criteria have been proposed to diagnose Behçet's syndrome. Recently a set of classification criteria have been proposed by a computer analysis of clinical features of 914 cases collected around the globe (International Study Group for Behçet's Disease 1990). Diseased controls with features that may be confused with Behçet's syndrome were also included in the analysis. Using the presence of recurrent aphthous ulceration as mandatory, together with proper exclusions, these criteria require involvement of two other organ systems. In this scheme a positive pathergy test can replace involvement of an organ system.

Laboratory investigations

There are no laboratory findings specific for Behçet's syndrome. A moderate anaemia of chronic disease and leucocytosis are seen in 15 per cent of the patients. Neither reflects the clinical activity. The erythrocyte sedimentation rate is only mildly elevated, as is the C-reactive protein. Again neither correlates well with disease activity (Müftüoğlu *et al*. 1986).

The synovial fluid is usually inflammatory. The cell count is between 5 000 and 50 000/mm ^{3} with neutrophils predominating. Despite this high cell count the mucin clot is usually good (Yurdakul *et al*. 1983).

Serum immunoglobulins are sometimes elevated, while autoantibodies are absent. Complement levels may be high. Despite the pauci-immune nature of the basic disease process, antineutrophilic antibodies are not a feature of Behçet's syndrome.

Pathogenesis

The prevailing opinion is that Behçet's syndrome is caused by a defect in immunoregulation and this defect in turn is triggered by an infectious agent(s) (Lehner *et al*. 1991). Among the candidates for the infectious agents are herpes simplex type 1 (Denman *et al*. 1980; Eglin *et al*. 1982) and some strains of streptococcus (Mizushima *et al*. 1988). Microbial and human heat shock proteins (**HSP**) show marked amino acid homology. Behçet's syndrome patients have both lymphocytes and antibodies which recognize certain synthetic peptides derived from mycobacterial HSP. Likewise a similar recognition exists to human mitochondrial HSP peptides that are homologous to mycobacterium HSP peptides. Finally these peptides are uveitogenic in rats (Stanford *et al*. 1994). These observations indicate that multiple agents, through molecular mimicry of their HSP peptides to the human tissues, can initiate an immune response and organ disease in Behçet's syndrome.

The evidence for immunological aberration is abundant (Arbesfeld and Kurban 1988). Antibodies to oral mucosa, circulating immune complexes, lymphocytotoxins in serum, a decrease in the OKT4:OKT8 ratio and in natural killer cells during disease exacerbations are among these. Increased levels of soluble interleukin-2 receptors, a common finding in autoimmune disease, also occur in Behçet's syndrome (Hamzoui and Ayed 1989). There is also an increased *in vivo* accumulation of activated lymphocytes expressing g T-cell receptors at the sites of inflammation (Hamzoui *et al*. 1994).

In contrast, the lack of autoantibodies, the rarity of associated Sjögren's syndrome (Günaydin *et al*. 1994), the lack of association with other autoimmune diseases both among the patients and their relatives, the rather poor response to steroids, and finally the more severe disease expression among males are points against an autoimmune mechanism in Behçet's syndrome (Yazici 1987).

The heightened inflammatory response, best manifested by the pathergy reaction (Tüzün *et al*. 1979), prompted research into leucocyte activity. Polymorphonuclear leucocyte activity is certainly increased (Matsumura and Mizushima 1975). A transgenic mice model has also been developed which attempts to provide an explanation for this heightened inflammatory activity (Takeno *et al*. 1995).

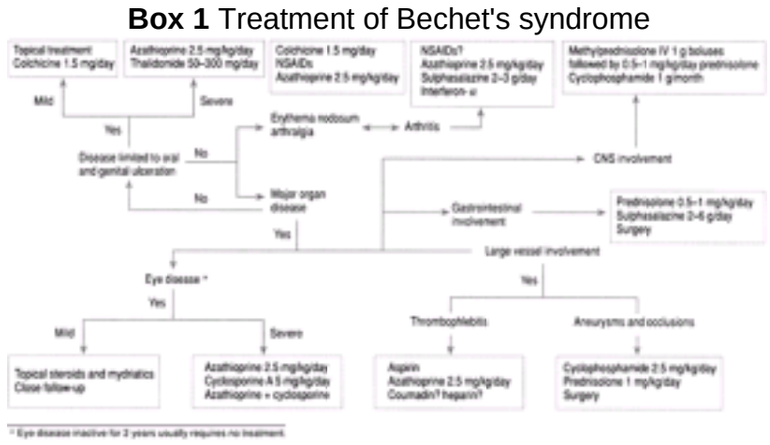
The widespread vascular disease in Behçet's syndrome has justifiably turned attention to endothelial pathology, and the increase in thromboses to problems with coagulation. Increased levels of factor VIII-related antigen are found only in patients with major (i.e. pulmonary artery and its branches; vena cavae) involvement of vessels (Yazici *et al*. 1987b). There is also a defect in prostacyclin production from the vessel wall (Kansu *et al*. 1986). Two other stigmas of endothelial injury in this syndrome are the presence of the antiendothelial cell antibodies (Aydintuğ *et al*. 1993) and increased serum levels of endothelin (Koç *et al*. 1993). Both observations might obviously be secondary events. Fibrinolytic activity is defective in Behçet's syndrome (Hampton *et al*. 1991). However, no single abnormality has been shown to account for this. The initial reports of increased levels of antiphospholipid antibodies have not been confirmed in subsequent studies.

Any theory that tries to explain the pathogenesis of Behçet's syndrome should also take into consideration the reasons for the more severe disease seen in the male and the young (Yazici *et al*. 1984). The pathergy reaction is also more strongly positive in the male (Yazici *et al*. 1985). This brings sex hormones into consideration. Serum concentrations of the major sex hormones are normal among the patients; however, this does not negate a possible influence of hormonal effects via metabolic products or alterations of end-organ responsiveness. In this respect the so-called acneiform skin lesion of Behçet's syndrome is clinically and histologically indistinguishable from ordinary acne, an androgen-dependent lesion.

Management (Yazici *et al*. 1995)

There are several important features of Behçet's syndrome that have to be taken into consideration when planning the management: (i) the usual course of the syndrome in any organ system is that of exacerbations and remissions with the overall activity generally abating with the passage of time; thus the principal aim is to prevent irreversible structural damage, which is the outcome of the early stormy course; (ii) being young and male are separate and additive negative prognostic factors; (iii) eye disease usually occurs, if at all, either initially or within the first few years; (iv) the syndrome can be fatal, especially in the young male; and (v) there are many patients with Behçet's syndrome who do not need any treatment but reassurance. Box 1 contains a scheme for the treatment of Behçet's syndrome.

Box 1 Treatment of Bechet's syndrome



Immunosuppressive drugs are the main line of treatment for eye involvement. Although corticosteroids have been used for a long time, there is no formal evidence that they are effective. In fact there is suspicion that they may be harmful. Their short-term use over a few months, however, may shorten the duration of an attack. Large centres treating Behçet's syndrome are now using steroids less frequently.

In the only controlled, double-blind study of cytotoxic immunosuppressive agents, azathioprine at 2.5 mg/kg per day was shown to be superior to placebo in maintaining visual acuity and perhaps more importantly in preventing the emergence of new eye disease (Yazici *et al*. 1990). It was not useful in restoring the already compromised vision. It would be unrealistic to expect restoration of impaired visual acuity when this is due to structural changes like synechiae. Thus it is important that treatment is begun well before these changes appear. Other cytotoxic, immunosuppressive agents such as chlorambucil and cyclophosphamide are also used, and extrapolating from the controlled experience with azathioprine their use is justified (O'Duffy 1990).

Cyclosporin is an effective and rapidly acting drug in the uveitis of Behçet's syndrome (Masuda *et al*. 1989). Problems with cyclosporin are the potential nephrotoxicity, especially at doses greater than 5 mg/kg per day, and the very frequent relapses after cessation of therapy. The high cost is another problem. Eye disease in remission for 2 years or more needs no further treatment. Young males usually need to be treated more vigorously. Once initiated, the usual course for cytotoxic or cyclosporin therapy is a minimum of 2 years, after which attempts at discontinuation are made. In some patients, after a course for 6 to 8 months of combined azathioprine and cyclosporin, treatment is continued with azathioprine only. In more resistant cases azathioprine is used in combination with cyclosporin (both at conventional doses) for extended periods of time. Our uncontrolled experience with this mode of therapy in severe eye disease is quite favourable.

Structural damage to the eye can be managed surgically (i.e. vitrectomy) at specialized centres. However, the results are not uniformly satisfactory. There is always the problem of new attacks of inflammation in surgically handled tissue in Behçet's syndrome. Also the already established disease in the retina can not be helped by surgery. Local mydriatics should be used in the acute stage to prevent synechiae.

The oral and genital ulcers are usually well controlled by immunosuppressives and steroids. However, these should be reserved for more severe cases. Most of the time, a local steroid preparation that adheres to fresh ulceration (such as triamcinolone acetonide oral paste) is all that is required. Thalidomide in doses ranging from 50 mg on 3 nights a week to 300 mg daily seems to be highly effective in the treatment of the orogenital ulcers of Behçet's syndrome. Limitations for its use are teratogenicity and peripheral neuropathy. The incidence and relationship of the neuropathy to the dose used is a matter of debate (Denman *et al*. 1993).

Colchicine has been claimed to be beneficial for almost every manifestation of Behçet's syndrome, but without any formal trials. The rationale for its use is the increased chemotaxis of the polymorphonuclear leucocytes found in this syndrome. In the only controlled study with colchicine it was superior to placebo only in the treatment of erythema nodosum and arthralgias (Aktulga *et al*. 1980). When started the usual practice is to use the colchicine for several years.

Cyclophosphamide, either 2 to 2.5 mg/kg per day orally or 500 to 1500 mg weekly or monthly intravenous boluses, is required to treat those patients with severe cutaneous, arterial, or pulmonary vasculitis or those with arterial aneurysms or vena caval involvement. There is no formal experience with any therapy for central nervous disease; however, steroids and immunosuppressives are again used. Steroids are usually employed in the form of pulsed intravenous methylprednisolone at a dosage of 1 g for 3 to 7 days followed by oral prednisolone at 0.5 to 1 mg/kg per day for a few months.

Gastrointestinal involvement is initially managed by sulphasalazine at a dosage of 2 to 6 g/day. Sometimes surgery is required, with resection of large segments of bowel. Usually a good portion of uninvolved area should also be removed to prevent recurrences. Surgery is also mandatory for aneurysms of peripheral vessels.

Controlled studies have not shown either the viral agent acyclovir, or transfer factor to be effective. In an open, self-controlled study a-interferon was shown to be effective in controlling some of the extraocular manifestations, especially the arthritis, of the syndrome (Hamuryudan *et al*. 1994b).

There is debate whether to use heparin or oral anticoagulants for the thrombophlebitis of Behçet's syndrome. Pulmonary embolism is seldom observed, as explained above. In this setting antiplatelet drugs (i.e. aspirin) are probably sufficient. We also use azathioprine in thrombophlebitis of Behçet's syndrome as an agent to suppress the disease activity in general.

Prognosis

We had in the past thought that Behçet's syndrome caused significant morbidity but not appreciable mortality. Our recent experience shows otherwise. Mention has already been made of those patients with pulmonary arterial aneurysms. We have also now assessed the 10-year mortality of 152 patients registered in our clinic in 1982. With 81 per cent follow-up information the minimum mortality was 6.5 per cent among our male patients. This was statistically more than expected for the 15 to 24 age bracket when compared with standard mortality statistics. In contrast, there was no observed mortality among the females (Yazici *et al*. 1996).

Apart from the bleeding pulmonary arterial aneurysms, the other causes of mortality in Behçet's syndrome are ruptured peripheral aneurysms, severe central nervous system disease, Budd–Chiari syndrome, and finally intestinal ulceration and perforation especially prominent among the Japanese.

5.11.8 Primary vasculitis in children

Michael J. Dillon

Vasculitis occurs in many different diseases and syndromes in childhood (Hicks 1988). It is the predominant manifestation of the disorder in some but in others may be one aspect of a more widespread autoimmune rheumatic disease (Ansell 1980; Cassidy and Petty 1995). As a result classification is difficult and is not entirely satisfactory (Dillon 1989). A classification that has proved useful, based on that of Fink (1986), is outlined in Table 1. There are other classifications including those of the American College of Rheumatology Subcommittee on Classification of Vasculitis (Hunder *et al*. 1990) and the Chapel Hill Conference on the Nomenclature of Systemic Vasculitis (Jennette *et al*. 1994). The latter is reproduced in Chapter 5.11.1. However, for the purposes of this chapter the classification shown in Table 1 will be utilized.

Polyarteritis
Macroscopic
Microscopic
Kawasaki disease
Mucocutaneous lymph node syndrome
Granulomatous vasculitis
Wegener's granulomatosis
Churg–Strauss syndrome
Leucocytoclastic vasculitis
Henoch–Schönlein purpura
Hypersensitivity angiitis
Cutaneous polyarteritis
Vasculitis associated with connective tissue disease
Systemic lupus erythematosus
Juvenile chronic arthritis
Mixed connective tissue disease
Dermatomyositis
Scleroderma
Giant cell arteritis
Takayasu disease
Miscellaneous vasculitides

Table 1 Childhood vasculitis

Polyarteritis (macroscopic and microscopic)

The classic form of polyarteritis, usually referred to as polyarteritis nodosa, is a necrotizing vasculitis associated with aneurysmal nodules along the walls of medium-sized muscular arteries and is akin to that described initially by Kussmaul and Maier (1866). Although there is some overlap with smaller vessel disease, polyarteritis nodosa appears to be a distinct entity and despite being rare can and does occur in childhood (Blau *et al*. 1977; Magilavy *et al*. 1977; Reimold *et al*. 1977). It is of interest that this type of vasculitis is less common in adults in whom microscopic polyangiopathy and Wegener's granulomatosis predominate.

The average age of patients with polyarteritis at the Hospital for Sick Children in London, was 7.5 years (ranging from 17 days to 15 years) with a male:female ratio of 1.6:1 (Dillon 1989; Dillon 1990). Many children on presentation were initially misdiagnosed with infections, autoimmune rheumatic disorders and malignant diseases often considered before the correct diagnosis was established. Although in the majority of cases reported genetic factors do not play a part, the occasional familial case has been described (Mason *et al*. 1994).

Microscopic polyarteritis differs from classic polyarteritis nodosa by the presence of extensive glomerular involvement and is defined as small vessel vasculitis with focal segmental glomerulonephritis, but without granulomatous disease of the respiratory tract (Savage *et al*. 1985). It can be difficult to distinguish it from Wegener's granulomatosis, especially if the latter presents atypically and often presents as idiopathic crescentic glomerulonephritis which is considered currently to be a manifestation of this form of polyarteritis (Jardim *et al*. 1992).

Clinical manifestations

The main clinical features of the macroscopic disease are malaise, fever, skin rash, abdominal pain and arthropathy (Reimold *et al*. 1977; Dillon 1989; Dillon 1990; Cassidy and Petty 1995). In addition myalgia, ischaemic heart and testicular pain, renal manifestations such as haematuria and hypertension, neurological features such as focal deficits, hemiplegia, visual loss, mononeuritis multiplex and organic psychosis can occur. Skin lesions are variable and may masquerade as those of Henoch–Schönlein purpura or multiform erythema, but can also be necrotic and associated with peripheral gangrene (Fig. 1). System involvement in the Hospital for Sick Children patients was as follows: renal 63 per cent; cardiac 26 per cent; neurological 26 per cent; respiratory 21 per cent; and gut 15 per cent (although a much higher percentage of patients with abdominal pain implied that gut disease was more common) (Dillon 1990). This spectrum of disease activity and distribution in the referred patients to the above hospital is not dissimilar to other published data, even to the extent of renal involvement, which is reported in 50 to 60 per cent of children with polyarteritis nodosa (Blau *et al*. 1977; Magilavy *et al*. 1977; Reimold *et al*. 1977; Cassidy and Petty 1995). Similar features may also be seen occasionally in the microscopic variety since extra renal manifestations are reported (Gaskin and Pusey 1992). However, the predominant presentation in this type of vasculitis is renal impairment with proteinuria, haematuria and hypertension (Coward *et al*. 1986; Adu *et al*. 1987).

Fig. 1 Necrotic skin lesions in polyarteritis nodosa

Laboratory and radiological investigations

Investigation usually demonstrates anaemia, polymorphonuclear leucocytosis, thrombocytosis, an increased erythrocyte sedimentation rate and C reactive protein (Blau *et al*. 1977; Magilavy *et al*. 1977; Reimold *et al*. 1977; Dillon 1989; Cassidy and Petty 1995). Platelets are hyperaggregable and there are circulating immune complexes in plasma (Levin *et al*. 1985). The plasma of some patients with active disease has a greenish colour due to a caeruloplasmin-like acute reactant that can be diagnostically helpful. Antineutrophil cytoplasmic antibodies (ANCA) have been detected in certain forms of polyarteritis (Jennette and Falk 1990; Dillon and Tizard 1991) and the indirect immunofluorescence appearance, the immunoglobulin class and the antigen to which the antibody is raised all have important bearings on the diagnositic value of the observations. In macroscopic polyarteritis nodosa ANCA have been considered to be absent but recently, in adults, both cytoplasmic and perinuclear patterns of ANCA staining by indirect immunofluorescence have been reported (Gross *et al*. 1991) and this has been confirmed in children (Wong *et al*. 1992). In microscopic polyarteritis ANCA findings are heterogeneous, with predominantly a perinuclear pattern of antibody staining using the indirect immunofluorescence technique and evidence that myeloperoxidase is the antigen involved (Jennette and Falk 1990; Dillon and Tizard 1991; Wong *et al*. 1992).

Biopsy material may prove to be diagnostically important, especially if an affected area or lesion in skin, muscle or other tissue is available. It is worth emphasizing, however, that the characteristic histopathological changes may not be present in sections examined and this would not necessarily exclude the diagnosis, since vasculitis is very variable in terms of the extent that tissues are affected. Renal biopsy is more valuable in diagnosing microscopic polyarteritis when features of crescentic glomerulonephritis may be revealed (Coward *et al*. 1986). Macroscopic vasculitis affecting the renal vessels may be suggested by patchy areas of decreased isotope uptake on technetium-99 DMSA (dimercaptosuccinic acid) scanning (Dillon 1990). However, the most valuable investigative procedure for macroscopic disease is renal and hepatic angiography (Fig. 2(a and b)) (McLain *et al*. 1972; Yousefzadeh *et al*. 1981; Dillon 1989; Dillon 1990).

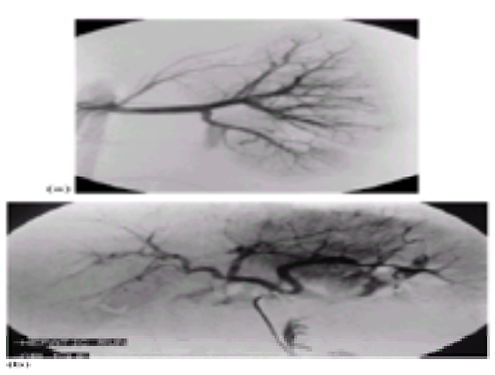

Fig. 2 (a) Renal angiogram showing small peripheral aneurysms in polyarteritis nodosa. (b) Coeliac angiogram showing abnormal hepatic vessels with aneurysms in polyarteritis nodosa.

Treatment and prognosis

Treatment for macroscopic and microscopic polyarteritis includes the use of steroids and oral cyclophosphamide, although pulsed intravenous injections of the latter are advocated by some. There is also a case for administering some antiplatelet therapy such as dipyridamole, but aspirin is usually contraindicated since the patients initially are on high-dose steroids and there may be a risk of gastrointestinal bleeding. Plasma exchange (Tizard and Dillon 1991) and intravenous prostacyclin have roles in life-threatening situations. Recently high-dose intravenous gammaglobulin has been introduced with some success (Jayne *et al*. 1991). Azathioprine and cyclosporin appear to have a role in maintaining remission but are not that helpful in inducing remission. A number of reviews deal with the therapy of childhood vasculitis (Cameron 1988; Larsson and Baum 1988; Dillon 1990; Roberti *et al*. 1993).

Prognosis is variable and mortality is at times over 20 per cent in spite of aggressive therapy (Fink 1977; Dillon 1989; Dillon 1990). However, in some series of childhood polyarteritis the outcome has been substantially better, at times with steroid alone, raising the question as to the precise diagnosis in and the severity of the disease in the affected children (Blau *et al*. 1977; Magilavy *et al*. 1977; Reimold *et al*. 1977).

Kawasaki disease (mucocutaneous lymph node syndrome)

This systemic childhood vasculitis was first described by Tomisaku Kawasaki in Japan in 1967 (Kawasaki 1967). Over 80 000 cases have subsequently been reported from that country alone, but the disease is of worldwide distribution and mainly affects infants and young children under 5 years of age. There is a male preponderance, an ethnic bias towards oriental or Afro-Caribbean children, some seasonality, and occasional epidemics (Hicks and Mellish 1986; Rowley *et al*. 1988; Kawasaki 1989; Shulman 1987). The incidence in Japan is 150 per 100 000 children under 5 years of age per year, but elsewhere it is substantially less: 10.3 in the United States, 2.9 in Germany and 3.4 in the United Kingdom (Shulman 1987; Kawasaki 1989; Dhillon *et al*. 1993).

Clinical features

The principal symptoms are outlined in Table 2 (Japan Kawasaki Disease Research Committee 1984), and illustrated in Fig. 3 and Fig. 4. For the diagnosis to be made at least five of the six items should be satisfied. Patients with four items can be diagnosed if coronary artery aneurysms are seen on two-dimensional echocardiography or coronary angiography. The incidence of cardiovascular complications can be up to 35 per cent if transient coronary artery dilatation, pericardial effusion, ECG abnormalities, pericarditis, myocardial infarction, ventricular aneurysms, mitral incompetence and cardiac failure are included (Table 3) (Rowley *et al*. 1988; Susuki *et al*. 1990; Tizard *et al*. 1991b). The incidence of coronary artery aneurysms (Fig. 5) ranges from 20 to 30 per cent. Cases of incomplete Kawasaki disease, however, are being recognized and the criteria may need to be reviewed in the future. Other significant symptoms or findings in Kawasaki disease are shown in Table 3 (Japan Kawasaki Disease Research Committee 1984).

Fever persisting for 5 days or more
Changes in the peripheral extremities (reddening of palms and soles, indurative oedema in initial stage, and membranous desquamation of the skin of the hands and feet in the convalescent phase)
Polymorphous exanthema
Bilateral conjunctival injection
Changes of lips and oral cavity (reddening of lips, strawberry tongue, diffuse injection of oral and pharyngeal mucosa)
Acute non-purulent cervical lymphadenopathy

Table 2 Principal symptoms of Kawaski disease

Fig. 3 Kawasaki disease showing characteristic rash, redness of the sole and oedema of the dorsum of the foot.

Fig. 4 Kawasaki disease showing membranous desquamation of skin of the foot in convalascent phase.

The cardiovascular system: heart murmurs, gallop rhythm, ECG changes, cardiomegaly, two-dimensional echo findings of pericardial effusion, coronary artery aneurysms, aneurysms of peripheral arteries, angina pectoris and myocardial infarction
The gastro-intestinal tract: diarrhoea, vomiting, abdominal pain, hydrops of the gallbladder, ileus and jaundice
The blood: leucocytosis, thrombocytosis, increased erythrocyte sedimentation rate, increased C reactive protein, hypo-albuminaemia, and anaemia
The urine: proteinuria, increased leucocytes in sediment
The skin: transverse furrows of finger nails
The respiratory tract: cough and rhinorrhoea
The joints: pain and swelling
The neurological system: pleocytosis in cerebrospinal fluid, convulsions and facial palsy

Table 3 Other significant symptoms and findings in Kawasaki disease

Fig. 5 Two-dimensional echocardiogram (parasternal short-axis view) showing medium-sized aneurysm (6.8 mm) of right coronary artery and smaller aneurysms of left main and left arterior descending coronary arteries (arrows) in child with Kawasaki disease.

Laboratory investigations

In patients with Kawasaki disease a polymorphonuclear leucocytosis and thrombocytosis is seen and circulating platelet-aggregating factors and immune complexes are demonstrable (Levin *et al*. 1985). Both ANCA and anti-endothelial cell antibodies (AECA) have also been determined in acute sera from patients (Leung *et al*. 1986; Savage *et al*. 1989; Tizard *et al*. 1991c; Kaneko *et al*. 1994). The ANCA findings on immunofluorescence were thought to be characteristic with a diffuse cytoplasmic staining and possibly distinct antigens involved (Kaneko *et al*. 1993). However, the diagnostic value of ANCA and AECA in Kawasaki disease has recently been questioned (Guzman *et al*. 1994; Nash *et al*. 1995) in studies showing that these antibodies did not differentiate early Kawasaki disease from other childhood illnesses.

Aetiology

Most workers agree that Kawasaki disease is likely to have an infective basis but the nature of the infective agent and the mechanisms involved remain in doubt. A number of organisms have been considered including *Streptococcus sanguis*, *Propionibacterium acnes*, Epstein–Barr virus, human herpes virus 6, chlamydia, rickettsia and retroviruses (Shulman 1987; Kawasaki 1989; Takahashi and Taubert 1993). Presently there has been considerable interest in the possibility that the condition is caused by new clones of staphylococci that cause toxic shock syndrome or streptococci that produce pyrogenic exotoxin (Leung *et al*. 1993).

Treatment and prognosis

Therapeutically aspirin and high-dose intravenous gammaglobulin, either as four or five daily doses of 400 mg/kg per day (Newburger *et al*. 1986) or one dose of 2 g/kg (Newburger *et al*. 1991), are recommended. Dipyridamole has also been used by some groups in addition to aspirin. When giant coronary artery aneurysms are present, especially with evidence of ischaemia, intravenous prostacyclin has been utilized (Tizard *et al*. 1991b) and intra-arterial or intravenous urokinase has been advocated in circumstances of coronary artery occlusion with thrombus (Terai *et al*. 1985). Revascularization surgery of the coronary arteries may be indicated for stenotic lesions after the acute phase of the illness is over (Susuki *et al*. 1985). The use of steroids remains controversial. There has been a policy contraindicating their use because of increased risks of coronary artery complications compared with aspirin, but this may need to be reconsidered since they certainly have been of value, given with antiplatelet therapy, in children with severe disease who do not respond to gammaglobulin treatment at The Hospital for Sick Children in London.

The overall outlook for children with Kawasaki disease is good. A 1 to 2 per cent acute mortality rate from myocardial infarction has been reduced further in many countries by alertness of clinicians to the diagnosis and early use of gammaglobulin with antiplatelet therapy. Nonetheless, there is a late morbidity and occasional mortality caused by stenotic lesions of coronary arteries in later life and it has been postulated that adult atheromatous coronary disease in some cases may have its origins in childhood and be due to covert or overt Kawasaki disease (Brecker *et al*. 1988).

Wegener's granulomatosis

Wegener's granulomatosis (Wegener 1936) is a necrotizing granulomatous vasculitis of the upper and lower respiratory tract, associated with glomerulonephritis and variable degrees of small vessel vasculitis elsewhere. It can be a generalized disorder or present in a limited local form, involving, initially at least, the respiratory tract. It is rare in childhood but has been reported (Moorthy *et al*. 1977; Baliga *et al*. 1978; Orlowski *et al*. 1978; Halstead *et al*. 1986; Dillon 1990; Singer *et al*. 1990; Rottem *et al*. 1993) and the association with ANCA showing a cytoplasmic immunofluorescence appearance has created another means of diagnosis as well as a method of monitoring disease activity (Van der Woude *et al*. 1985; Savage *et al*. 1987).

Clinical and laboratory findings

Clinical manifestations are similar to those reported in polyarteritis nodosa. There are, however, particular features that might lead clinicians to the diagnosis including subglottic stenosis due to granulomatous involvement of the trachea (Fig. 6), at times requiring tracheostomy (Halstead *et al*. 1986; Dillon 1990; Tizard *et al*. 1991a; Rottem *et al*. 1993), and other upper airway findings such as sinus opacity, nasal septum disease and lower respiratory tract features frequently masquerading as infection (Fig. 7). Some of these findings are also seen in relapsing polychondritis, an even rarer condition of childhood, which can cause diagnostic confusion (Blau 1976). Glomerulonephritis, at times taking the form of an aggressive crescentic glomerulonephritis, is seen but is not a prerequisite for the diagnosis. A proportion of children have disease that is limited to the upper and lower respiratory tract (Hall *et al*. 1985b; Rottem *et al*. 1993). Patients' serum usually contains circulating ANCA with the characteristic granular cytoplasmic distribution (C-ANCA) on indirect immunofluorescence and an antibody directed against proteinase 3 (Jennette and Falk 1990; Dillon and Tizard 1991; Gross *et al*. 1991; Wong *et al*. 1992).

Fig. 6 Subglottic stenosis due to granulomatous involvement of the trachea in Wegener's granulomatosis. Note tracheostomy tube.

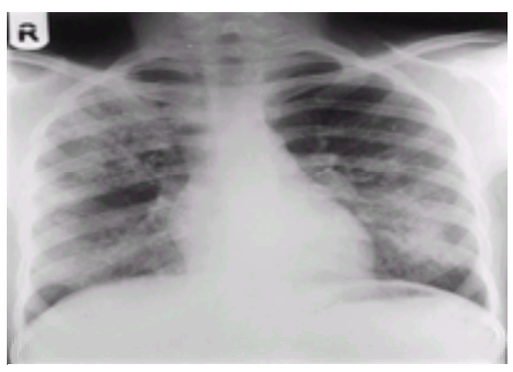

Fig. 7 Pulmonary involvement in Wegener's granulomatosis.

Treatment and prognosis

Steroids and cyclophosphamide (orally or by pulsed intravenous injection) are the mainstays of treatment, but additionally some use antiplatelet medication and antimicrobials such as cotrimoxazole and, in life-threatening situations, plasma exchange (Gaskin and Pusey 1992; Roberti *et al*. 1993; Rottem *et al*. 1993). Response to therapy is variable but the majority of patients need to remain on long-term steroid and immunosuppressive agents. Once remission has been induced, it can be maintained in many children on a combination of steroid and azathioprine or cyclosporin (Dillon 1990; Gaskin and Pusey 1992). Mortality rate amongst The Hospital for Sick Children patients has been of the order of 15 per cent (Tizard *et al*. 1991a).

Churg–Strauss syndrome

Churg–Strauss syndrome or allergic granulomatosis is extremely rare in childhood (Churg and Straus 1951; Frayha 1982). The clinical picture consists of variable vasculitic features with asthma, eosinophilia, infiltrates on chest radiographs, and extravascular granulomata on biopsy (Chumbley *et al*. 1977). ANCA may be present with perinuclear or cytoplasmic staining on indirect immunofluorescence. Steroids are the mainstay of therapy but cytotoxic agents such as cyclophosphamide may need to be introduced to control disease activity (Chumbley *et al*. 1977; Roberti *et al*. 1993).

Henoch–Schönlein purpura (anaphylactoid purpura)

Henoch–Schönlein purpura is the most common form of systemic vasculitis of childhood and comes into the general category of leucocytoclastic vasculitides, involving small vessels especially in the skin (Gairdner 1948; Allen *et al*. 1960). Within this general group of conditions there is often an identifiable initiating factor such as a drug or a microorganism, hence the alternative descriptive terms of allergic or hypersensitivity vasculitis. Henoch–Schönlein purpura is chiefly a disease of childhood, more common in males, often preceded by an upper respiratory infection and more common in the winter months (Meadow *et al*. 1972; Levy *et al*. 1976).

Clinical characteristics

The salient features are a non-thrombocytopenic palpable purpura, arthritis or arthralgia, abdominal pain, gastrointestinal haemorrhage and glomerulonephritis. The palpable purpura is prominent on dependent and pressure-bearing areas such as the lower limbs and buttocks, but in young children facial involvement and subcutaneous oedema are features. Glomerulonephritis occurs in 50 per cent of patients and in 10 per cent of these it is serious (Kobayashi *et al*. 1977; Koskimies *et al*. 1974). The spectrum of renal disease varies from isolated microscopic haematuria to a nephritic/nephrotic syndrome with renal failure.

Laboratory investigations

The majority of affected children have a moderate leucocytosis and thrombocytosis. Thrombocytopenia would raise serious doubts about the diagnosis. Serum IgA and IgM are increased in 50 per cent of patients and a proportion have circulating IgA containing immune complexes and cryoglobulins (Trygstad and Stiehm 1971; Levinsky and Barratt 1979; Knight 1990). In some patients IgA ANCA have been demonstrated (Van den Wall Bake *et al*. 1987). Haematuria and proteinuria are found frequently. Renal function impairment, with or without hypertension in the presence of nephrotic range proteinuria, would be an indication for a renal biopsy. Histological examination of biopsy material may reveal proliferative glomerulonephritis of variable severity from focal segmental lesions to extensive crescentic glomerulonephritis. Immunofluorescence will often demonstrate mesangial IgA deposits and in some cases C3, fibrin, and IgM.

Treatment and prognosis

Treatment is supportive. Corticosteroids given over a few weeks may help severe gut disease but are not thought to benefit the renal disease except in the context of aggressive rapidly progressive glomerulonephritis when steroid, immunosuppressive and antiplatelet therapy have a therapeutic role. If renal function is rapidly deteriorating pulsed methyl prednisolone and/or plasmapheresis appear to have some beneficial effects.

The prognosis is usually good, but there is some morbidity and occasional mortality associated with gut and kidney disease (Allen *et al*. 1960). Amongst patients who present with a nephritic, nephrotic or nephritic/nephrotic syndrome, 44 per cent have hypertension or impaired renal function on long-term follow-up, whereas 82 per cent who present with haematuria (with or without proteinuria) are normal (Goldstein *et al*. 1992). Overall, 2 to 5 per cent of children with Henoch–Schönlein purpura progress to endstage renal failure accounting for approximately 10 per cent of renal failure in childhood (Kobayashi *et al*. 1977; Koskimies *et al*. 1981). Renal transplantation is possible and successful in such patients and recurrence in the graft rare.

Hypersensitivity angiitis

The commonest small vessel vasculitis other than Henoch–Schönlein purpura is hypersensitivity vasculitis. This is usually a drug-induced condition but can be associated with other antigens including infectious agents (Kunnamo *et al*. 1986). The predominant clinical manifestations involve the skin, with palpable nodules or purpura (Fig. 8), although other organs can be affected and it is important to realise that the condition can with time evolve into one of the systemic necrotizing vasculitides (Fauci *et al*. 1978). Removal of the precipitating agent is usually followed by resolution, but sometimes non-steroidal anti-inflammatory drugs, and steroids may be indicated.

Fig. 8 Palpable purpuric nodules in skin of patient with hypersensitivity vasculitis.

Cutaneous polyarteritis

This is another syndrome with some similarities to Henoch–Schönlein purpura with crops of painful skin nodules and livido reticularis often with a story of preceding upper respiratory tract infection (Diaz-Perez and Winklemann 1980; Fink 1991; David *et al*. 1993). The condition responds to penicillin, non-steroidal anti-inflammatory drugs and steroids. However, the concern is that the condition may be a manifestation of a systemic necrotizing vasculitis. Should this be the case, additional immunosuppressive therapy will be necessary. David *et al*. (1993) reported that all their patients had an erythematous, nodular, painful rash, often on the medial aspect of the feet, plus an evanescent arthritis affecting the knees and ankles. More than 50 per cent of patients also had brawny oedema of muscles and periorbital oedema. Two of their 12 patients went on to develop angiographically-confirmed polyarteritis nodosa (David *et al*. 1993). Cutaneous vasculitis usually runs a benign course, but relapses, particularly in association with recurrent streptococcal infection, are seen in up to 25 per cent of cases. Clinicians seeing this condition usually advise continuing penicillin prophylaxis throughout childhood to prevent relapses since it is amongst the relapsing group that systemic vasculitis tends to occur.

Vasculitis associated with autoimmune rheumatic disorders

Vasculitis is seen at times in systemic lupus erythematosus, juvenile chronic arthritis, mixed connective tissue disease, dermatomyositis and scleroderma and the concept that some of these disorders may be forms of systemic vasculitis has a degree of support. This is particularly relevant to juvenile dermatomyositis in which necrotizing vasculitis in arterioles, capillaries and venules of striated muscle, skin, subcutaneous tissue and gastrointestinal tract has been identified (Banker and Victor 1966; Dillon and Ansell 1995). Crowe *et al*. (1982) reported a group of children with dermatomyositis in which there was muscle infarction, lymphocytic vasculitis and a non-inflammatory vasculopathy associated with extensive erythematous and ulcerative cutaneous disease and who tended to develop calcinosis. Clinically, within this group of patients, periungual erythema and telangiectasia of the nail beds are characteristic, as is telangiectasia along the eyelids which may be accompanied by oedema. Occlusive endarteropathy is likely to be responsible for the cutaneous lesions with ulceration and this, at times, occurs in a livido reticular pattern. Infarction of the palate is associated with weakening of palatal movement and retinal exudates can occur as a result of retinal vascular involvement. Vasculitis can cause acute gastrointestinal ulceration with bleeding or perforation and occasionally there can also be myocardial involvement. Therapeutically, bolus intravenous methylprednisolone is recommended for severe gastrointestinal involvement or vasculitic ulcers. Intravenous gammaglobulin may also have a role and plasma exchange has been utilized. Persistence of widespread ulceration in spite of therapy with severe changes in the capillary loops would be an indication for additional immunosuppressive therapy. Methotrexate in recalcitrant dermatomyositis has been generally accepted (Miller *et al*. 1992); however, there is relatively little information as to how effective it is in vasculitis. As with other vasculitides cyclophosphamide may prove effective when other regimens have failed.

Giant cell arteritis (Takayasu disease)

Giant cell arteritis (Takayasu disease) is a segmental inflammatory vasculitis causing stenosis and aneurysm formation in large arteries, especially the aorta and its major branches (Hall *et al*. 1985a). After Henoch–Schönlein purpura and Kawasaki disease it is the third commonest form of childhood vasculitis if considered worldwide (Lee *et al*. 1967; Wiggelinkhuizen and Cremin 1978). Its aetiology is unclear but genetic and infective factors, for example, tuberculosis, may play a part (Wiggelinkhuizen and Cremin 1978).

Clinical features and management

Early disease manifestations include fever, night sweats, anorexia, weight loss, and arthritis (Lupi-Herrera *et al*. 1977). Subsequently features of hypertension, heart failure and pulse deficits become apparent (Lee *et al*. 1967; Wiggelinkhuizen and Cremin 1978 ; Hall *et al*. 1985a). Leg length inequality can also occur as a result of the aortic pathology compromising lower limb blood supply (Morales *et al*. 1991). The erythrocyte sedimentation rate is increased as are other acute-phase reactants and there may be widening and calcification of the aorta on a plain abdominal radiograph. Doppler ultrasonography, plus magnetic resonance or standard angiography are usually required to establish the diagnosis (Southwood *et al*. 1988). Corticosteroids, plus other immunosuppressives, have been utilized therapeutically in the acute phase (Sunamori *et al*. 1976; Lupi-Herrera *et al*. 1977). A positive tuberculin test may justify antituberculous therapy and hypotensive agents and antiplatelet therapy also have a place. Reconstructive surgery and transluminal angioplasty have been undertaken in older children with inactive disease (Shelhamer *et al*. 1985).

Miscellaneous vasculitides

A number of other conditions in which there is a vasculitic component exist that are too numerous to deal with individually in this chapter. However, there are three that deserve special mention: Behçet's syndrome, familial Mediterranean fever, and Cogan's syndrome.

Behçet's syndrome, first reported by Behçet in 1937, consists of the triad of aphthous stomatitis, genital ulceration, and iritis. It is relatively rare in childhood, but can and does occur and it is well recognised that a vasculitic component is an important feature (Hamza 1993; Koné-Paut and Bernard 1993; Shafaie *et al*. 1993; Özdagan 1994). Systemic therapy is usually necessary for patients with severe cutaneous, systemic or pulmonary vasculitis or those with arterial aneurysms or vena caval involvement. Agents that have been used include steroids and cytotoxic drugs, such as azathioprine or cyclophosphamide, but other medications for treating various aspects of childhood Behçet's syndrome, such as colchicine, levamizole, cyclosporin, and thalidomide may have roles. The prognosis is variable, as in adults, but vascular involvement is related to a poor outcome (Özdagan 1994).

Familial Mediterranean fever often manifests itself for the first time in childhood (Sohar *et al*. 1967; Pras *et al*. 1994). Although not normally considered to be associated with vasculitis there are now a number of reports describing both polyarteritis nodosa and Henoch–Schönlein purpura in affected patients (Flatau *et al*. 1982; Schlesinger *et al*. 1985; Sachs *et al*. 1987; Glikson *et al*. 1989; Pras *et al*. 1994). It is therefore important to consider the possibility of an associated vasculitis in patients with familial Mediterranean fever that may need treating in its own right. Patients with Henoch–Schönlein purpura symptomatically appear to respond to systemic steroid treatment (Pras *et al*. 1994) and those with polyarteritis nodosa with steroid and cyclophosphamide (Sachs *et al*. 1987; Glikson *et al*. 1989).

Non-syphilitic interstitial keratitis with vestibuloauditory dysfunction was first described by Cogan (1945). Although rare and usually affecting young adults it has been reported in children (Cheson *et al*. 1976; Kundell and Ochs 1980) and in addition to the main features there can be evidence of a widespread vasculitis that may require treatment with corticosteroids (Kundell and Ochs 1980; Cassidy and Petty 1995)

Conclusion

As can be seen there is a wide spectrum of vasculitic disease affecting children. The distinction from other conditions, especially those associated with infection, is often difficult, but it is usually possible to categorize the disorders into clinicopathological entities even though there is a substantial degree of overlap. The current range of investigative tools usually allows the correct diagnosis to be established and modern therapeutic approaches have made a major impact in achieving control of disease activity, but in spite of this the level of morbidity and mortality is not inconsequential.

5.12 Overlap syndromes in adults and children

Enrique Roberto Soriano and Neil John McHugh

Introduction

Autoimmune rheumatic diseases (connective tissue diseases) are an overlapping group of disorders of unknown aetiology. Their classification depends on identifying clusters of clinical and laboratory features. At least three problems arise when attempting to classify individual patients into one of the defined autoimmune rheumatic diseases early on in their disease or when they present with clinical overlaps: (1) most of the clinical or laboratory features are not exclusive to one disease; (2) many of the symptoms and signs that define the autoimmune rheumatic diseases do not occur concurrently, but rather occur sequentially; (3) as many as 25 per cent of patients with autoimmune rheumatic disease present with an overlap syndrome with typical features of more than one disorder.

The terms undifferentiated connective tissue disease, overlap syndrome, and even mixed connective tissue disease (**MCTD**), have been used for patients who are not comfortably placed within any one of the defined autoimmune rheumatic diseases. These terms are not interchangeable, but unfortunately are often applied loosely. This chapter will describe some of the more common overlap conditions, and what is known concerning environmental triggers. Mixed connective tissue disease is discussed at some length reflecting the large proportion of studies in this area, although there is debate as to whether this disease is a distinct entity or a disease in evolution. Mention will be made of attempts to define more homogeneous subsets of autoimmune rheumatic disease by knowledge of immunogenetic and serological profiles.

Undifferentiated connective tissue disease

The diagnosis of undifferentiated connective tissue disease is best applied to those patients with features strongly suggestive of an autoimmune rheumatic disease but who do not fulfil criteria for any one disorder. The features usually include Raynaud's phenomenon, polyarthritis, rash, and myalgia (Alarcon *et al*. 1991). Undifferentiated connective tissue disease may develop into a well defined autoimmune rheumatic disease, may persist unchanged over time, or the symptoms may even disappear. Outcomes from large multicentre prospective studies are awaited (Alarcon *et al*. 1991). Raynaud's phenomenon is probably the most frequent clinical feature of undifferentiated connective tissue disease. Other factors that may be predictive of the development of later autoimmune rheumatic disease are listed in Table 1.

Scleroderma-like nailfold capillary abnormalities
Positive antinuclear antibody (titre > 1/100)
Anticentromere or antitopoisomerase 1 (Scl-70) antibody
Digital pitting scars
Abnormal erythrocyte sedimentation rate

Adapted from LeRoy and Medsger (1992).

Table 1 Possible prognostic factors in Raynaud's phenomenon

Overlap syndrome

The term overlap syndrome has been used when two or more autoimmune rheumatic diseases, or some of their unique manifestations, occur in the same individual simultaneously. Features that are characteristic of certain defined autoimmune rheumatic diseases are given in Table 2. The overlap may consist of full expression of the features of two or more conditions, or more commonly may be limited to one or more manifestations of each disease. In the latter case, the diagnosis of undifferentiated connective tissue disease may equally apply.

Systemic lupus erythematosus	Systemic sclerosis	Polydermatomyositis	Rheumatoid arthritis
Malar rash	Sclerodermа	Myositis	Erosive arthritis
Photosensitivity	Oesophageal hypomotility	Heliotrope rash	Subcutaneous nodules
Glomerulonephritis		Gottron's papules	Rheumatoid factor
Central nervous system disease	Telangiectasia	Antisynthetase antibodies	
Anti-Sm antibodies		Anti-Mi-2 antibodies	
Anti-double-stranded DNA	Antitopoisomerase I antibodies		

Table 2 Features usually restricted to one connective tissue disease, and less common in others

Serological subsets

A characteristic feature of autoimmune rheumatic diseases is the presence of autoantibodies. As autoantibodies are associated with particular clinical features, knowledge of the autoantibody profile may help in diagnosis and prognosis. The best known example is the association of anti-U1RNP antibodies with mixed connective tissue disease which will be further discussed. Other examples include the association of anti-Ro (SS-A) and anti-La (SS-B) antibodies with Sjögren's syndrome, antiphospholipid antibodies with the antiphospholipid syndrome, and antibodies to tRNA synthetases with the antisynthetase syndrome. There are less common autoantibodies such as anti-Pm-Scl (Fig. 1) which may identify patients with other overlap features. Also, in most cases there are strong associations between autoantibody-defined subsets of disease and HLA genes that may explain the genetic basis for disease susceptibility (Table 3).

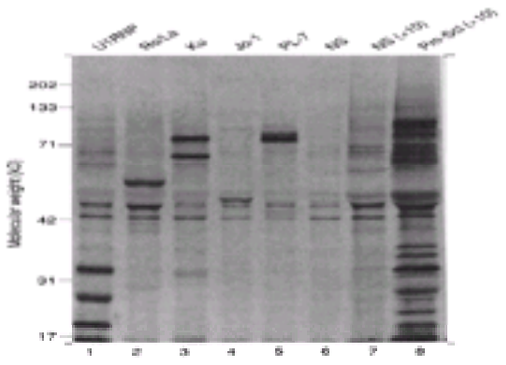

Fig. 1 Proteins immunoprecipitated using sera containing autoantibodies that are associated with overlap syndromes; anti-U1RNP with MCTD, anti-Ro/La antibodies with systemic lupus erythematosus (**SLE**)/Sjögren's syndrome, anti-Ku with systemic lupus erythematosus or scleroderma, anti-Jo-1 (histidyl-tRNA synthetase) and anti-PL-7 (threonyl- tRNA synthetase) with the antisynthetase syndrome, and anti-Pm-Scl with polymyositis/scleroderma/arthritis. NS, normal serum.

Overlap syndrome	Autoantibody specificity	HLA class II allele
Mixed connective tissue disease	U1RNP	HLA-DR4 (DRB1*0401) HLA-DQ3 (DQB1*0301) (Kawano, et al. 1995)
Polymyositis, interstitial lung disease, Raynaud's, arthritis	Jo-1 (histidyl-tRNA synthetase) and less often other tRNA synthetases	HLA-DR3, DR52 (Goldstein et al. 1992)
Systemic sclerosis, polymyositis	PM-Scl Ku U2-RNP	HLA-DR3 (Marguerie et al. 1992)

Table 3 Recognized clusters of clinical overlaps, autoantibodies, and HLA class II alleles

Mixed connective tissue disease

Definition

Mixed connective tissue disease was first described by Sharp and co-workers (Sharp *et al*. 1971; Sharp *et al*. 1972) as an 'apparently distinct rheumatic disease syndrome' in which the clinical characteristics included a combination of features similar to those of systemic lupus erythematosus, scleroderma, and polymyositis. The spectrum has been broadened by some to include features of rheumatoid arthritis (Hench *et al*. 1975; Sullivan *et al*. 1984). Mixed connective tissue disease was considered unique as it was associated with autoantibodies to a ribonuclease-sensitive component of extractable nuclear antigen, now known as U1RNP.

There remains debate as to whether mixed connective tissue disease is a distinct disease, a disease in evolution, or a subset of another autoimmune rheumatic disease such as systemic lupus erythematosus (LeRoy *et al*. 1980; Lazaro *et al*. 1989; McHugh *et al*. 1990; Black and Isenberg 1992). Diagnosis that is dependent on a single serological finding may suffer from ascertainment bias. Many patients with the clinical features 'characteristic' of mixed connective tissue disease do not have anti-U1RNP antibodies (Ginsburg *et al*. 1983; Lazaro *et al*. 1989), and conversely anti-U1RNP antibodies may appear in other conditions (McHugh *et al*. 1990). None the less, mixed connective tissue disease is considered by some to be a syndrome that has a core of manifestations associated with a serological marker (Alarcon-Segovia 1994). Three substantially revised and distinct sets of diagnostic criteria have been proposed (Table 4).

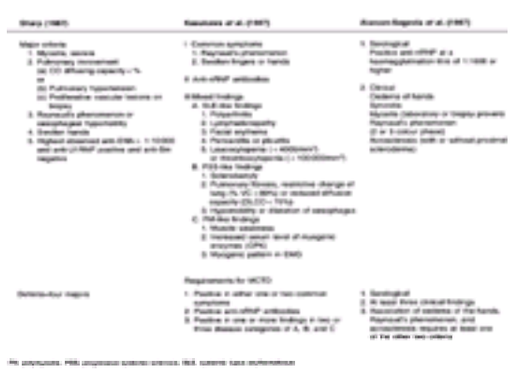

Table 4 Diagnostic criteria for mixed connective tissue disease (MCTD)

Epidemiology

Mixed connective tissue disease is a disease of the second to fourth decades of life with a mean age of onset of 35 years in adults (Sharp *et al*. 1972; Prakash *et al*. 1985), and 10 years in children (Singsen *et al*. 1977; Savouret *et al*. 1983). Women are affected more often than men at all ages, and represent around 80 per cent of patients. The incidence of mixed connective tissue disease in adults remains unknown. A hospital-based retrospective study of children under 15 in Sweden, reported an incidence of 0.13/100 000 per year, compared with an incidence of 0.43/100 000 per year for systemic lupus erythematosus and 0.28/100 00 per year for polymyositis/dermatomyositis (Magnusson 1993). In a nationwide, prospective, hospital-based study for 4 years in Finland in children aged 0 to 15 years, the annual incidence rate for mixed connective tissue disease (diagnosed according to Sharp's criteria) was 0.10/100 000 compared with 0.37 for systemic lupus erythematosus, 0.30 for polymyositis/dermatomyositis, and 0.05 for scleroderma (Pelkonen *et al*. 1994).

Clinical features (Table 5)

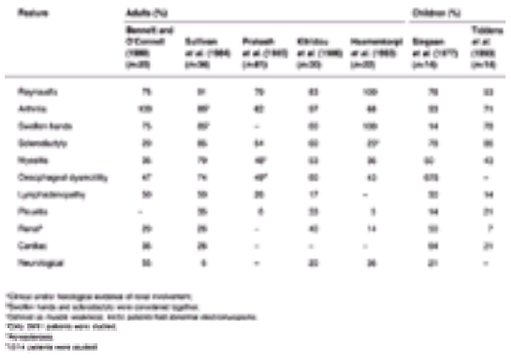

Table 5 Frequent clinical features in adults and children with mixed connective tissue disease

General symptoms

The typical patient is a 20- to 30-year-old female presenting with Raynaud's phenomenon, arthralgias/arthritis, swollen hands and/or puffy fingers, in association with a high titre, speckled pattern, antinuclear antibody (**ANA**) (Fig. 2). Other presenting symptoms may include fatigue, fever, serositis, mild myositis, aseptic meningitis or unexplained lymphadenopathy.

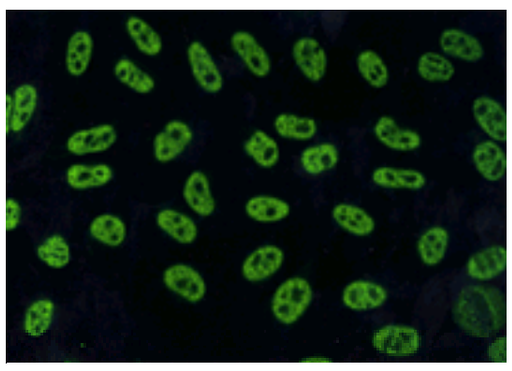

Fig. 2 Typical coarse speckled pattern of ANA detected by indirect immunofluorescence in serum from a patient with mixed connective tissue disease. Note the relative sparing of staining of the nucleolus within the cell nucleus.

Vascular involvement

Raynaud's phenomenon is present in 75 to 100 per cent of adults and children (Table 5), and is often the first symptom to appear. Ischaemic necrosis and ulcerations of the fingertips are rare but may occur (Sharp *et al*. 1972; Gilliam and Prystowsky 1977; Peller *et al*. 1985). Nailfold capillaroscopy shows capillary dilatation and capillary loss (avascular areas) in 50 to 90 per cent of patients with mixed connective tissue disease (Maricq *et al*. 1980; Peller *et al*. 1985; Granier *et al*. 1986) and may be associated with pulmonary disease (Sullivan *et al*. 1984; Pallis *et al*. 1991). Dystrophic, branched 'bushy' capillaries may be especially characteristic for mixed connective tissue disease (Granier *et al*. 1986). Angiographic studies have shown evidence of vasculopathy of both small and medium-sized vessels in the hands (Peller *et al*. 1985).

Skin

Swelling of the hands, particularly of the fingers leading to a sausage appearance (Fig. 3), occurs more frequently in adults than in children. The skin of the hands may be taut and thick and histologically resembles scleroderma. Scleroderma extending more proximally is not usually a feature of mixed connective tissue disease. Other less frequent cutaneous manifestations are alopecia, depigmentation, telangiectasia, erythema nodosum, and chronic discoid lesions. A malar rash, suggestive of systemic lupus erythematosus, and dermatomyositis-like skin are more frequent in children than in adults.

Fig. 3 Typical 'sausage-shaped' swollen fingers of a patient with mixed connective tissue disease.

Joints

Polyarthralgia is an early symptom and occurs in most patients. A symmetrical polyarthritis most often involving hands and wrists may mimic rheumatoid arthritis but is less deforming and erosive. None the less ulnar deviation, swan neck changes, and flexion contractures are not rare and atlantoaxial subluxation has been reported (Stuart and Maddison 1991). Erosions are found in about 60 per cent of the patients (Udoff *et al*. 1977; Bennett and O'Connell 1980; Catoggio *et al*. 1983), and are usually small, punched-out, and asymetrically distributed (O'Connell and Bennett 1977). Prominent periarticular calcification is not uncommon (Fig. 4) and arthritis induced by hydroxyapatite crystal has been reported (Hutton *et al*. 1988). Avascular necrosis of bone may occur in children (Tiddens *et al*. 1993) and adults (O'Connell and Bennett 1977). Minute, multiple peritendinous nodules may be found adjacent to the flexor tendons of the forearms and the extensor tendons of the hands (Babini *et al*. 1985). Arthritis may be more frequent and destructive in children in whom the initial diagnosis may be juvenile chronic arthritis.

Fig. 4 Prominent periarticular calcification in a patient with mixed connective tissue disease.

Muscle

Myalgias are common and about two-thirds of patients develop an inflammatory myopathy that is identical clinically and histologically to polymyositis (Sharp *et al*. 1972; Bennett and O'Connell 1980). Very often myositis may occur acutely in a patient who has other mild features (Bennett and O'Connell 1980; Lundberg *et al*. 1992a), and prompts the diagnosis of mixed connective tissue disease. The prognosis seems more favourable than in polymyositis/dermatomyositis with less corticosteroid treatment needed (Nimelstein *et al*. 1980; Lundberg *et al*. 1992a). In children, vasculitis and inflammatory infiltration of skeletal muscle has been reported at autopsy, without clinical or laboratory evidence of muscle disease (Singsen *et al*. 1977).

Gastrointestinal tract

Gastrointestinal involvement is similar to that in systemic sclerosis, with heartburn and dysphagia the most common symptoms (Table 6). Oesophageal manometry is abnormal in up to 85 per cent of patients (Marshall *et al*. 1990; Doria *et al*. 1991). Corticosteroid treatment may improve oesophageal dysfunction (Marshall *et al*. 1990) but is needed rarely. Extensive gastrointestinal tract involvement with malabsorption (Norman and Fleischmann 1978), colonic and small bowel perforations due to vasculitis, acute pancreatitis (Marshall *et al*. 1990), duodenal haemorrhage (Hirose *et al*. 1993), pneumatosis intestinalis and pneumoperitoneum (Bennett and O'Connell 1980; Pun *et al*. 1991), haemobilia due to vasculitis of the gallbladder (Kuipers *et al*. 1991), protein-losing enteropathy (Furuya *et al*. 1992), and secretory diarrhoea (Thiele and Krejs 1985) have all been reported. Hepatomegaly and splenomegaly are found in about 25 per cent of patients but major liver involvement is uncommon. The spectrum of gastrointestinal involvement is similar in children with mixed connective tissue disease.

Symptom	Number of patients	Frequency
Asymptomatic	16	26
Heartburn or regurgitation	29	48
Dysphagia	23	38
Dyspepsia	12	20
Diarrhoea	2	8
Constipation	3	5
Vomiting	2	3

Adapted from Marshall *et al*. (1990).

Table 6 Gastrointestinal symptoms in 61 patients with mixed connective tissue disease

Keratoconjunctivitis sicca

Sicca symptoms are not uncommon in adults and children with mixed connective tissue disease, depending on the bias of patients selected for study. Sialectasia was found in 82 per cent of 39 adults with mixed connective tissue disease studied by parotid sialography (Ohtsuka *et al*. 1992), although 50 per cent of these patients also fulfilled criteria for Sjögren's syndrome.

Neurological involvement

Trigeminal sensory neuropathy may occur in up to 10 per cent of patients and may be an early manifestation of the disease (Bennett *et al*. 1978; Searles *et al*. 1978; Sullivan *et al*. 1984; Hagen *et al*. 1990). Involvement of the central nervous system is rare in adults although an aseptic meningitis-like syndrome has been reported (Bennett and O'Connell 1980). Other occasional findings are headaches, seizures, peripheral neuropathy (Bennett *et al*. 1978), spinal cord involvement (Kappes and Bennett 1982), transverse myelitis (Weiss *et al*. 1978), hypertrophic cranial pachymeningitis (Fujimoto *et al*. 1993), and demyelination (Nitsche *et al*. 1991). Three of the 14 children reported by Singsen *et al*. had cerebral involvement (Singsen *et al*. 1977).

Heart

Major cardiovascular abnormalities are uncommon (Table 7). Pericarditis may occur in up to 20 per cent of patients and pericardial tamponade has been reported (Bennett and O'Connell 1980; Langley and Treadwell 1994). Electrocardiogram abnormalities are more common (Alpert *et al*. 1983; Oetgen *et al*. 1983), and cardiac conduction defects have been described (Emlen 1979; Rakovec *et al*. 1982). Echocardiographic changes including pericardial effusions, mitral valve prolapse, and right ventricle enlargement have been found in 38 to 60 per cent of patients (Alpert *et al*. 1983; Oetgen *et al*. 1983). Abnormal left ventricular diastolic filling has been documented by Doppler studies in the absence of myocardial disease (Leung *et al*. 1990). Intimal hyperplasia of coronary arteries and inflammatory cell infiltrates of the myocardium may be found in both adults and children (Singsen *et al*. 1977; Alpert *et al*. 1983).

Symptom	Alpert *et al.* (1983) (n=38) (%)	Cetgen *et al.* (1983) (n=16) (%)	Prakash *et al.* (1985) (n=81) (%)
Dyspnoea	63[a]	38[a]	16
Pericardial chest pain	6	19	7[b]
Angina pectoris	8	19	7[b]
Palpitations	16	25	–

[a]Dyspnoea could be attributed to pulmonary origin in all but one patient in each series.
[b]Cause of chest pain not stated.

Table 7 Cardiac involvement in adults with mixed connective tissue disease

Lungs

Pleuropulmonary involvement is common and may be clinically inapparent. The most common clinical findings are dyspnoea, pleuritic pain, and bibasilar rales (Table 8). Children may present with reduced exercise tolerance. Chest radiograph abnormalities include basal interstitial fibrosis, pleural effusion, pneumonic infiltrates, and pleural thickening (Sullivan *et al*. 1984; Prakash *et al*. 1985). Abnormalities of pulmonary function test are very common and may include a restrictive pattern, small airway involvement and respiratory muscle weakness (Izumiyama *et al*. 1993; Lazaro *et al*. 1993). Interstitial lung disease usually responds to corticosteroids but rapidly progressive cases have been reported (Weiner-Kronish *et al*. 1981).

Feature	Sullivan *et al.* (1984) (n=34) (%)	Prakash *et al.* (1985) (n=81) (%)
Asymptomatic	33	75
Dyspnoea	58	16
Pleuritic pain	40	7
Bibasilar rales	42	–
Cough	24	5
Abnormal chest radiograph	30	21
Restrictive pulmonary function tests	41	69
Decreased diffusing capacity	72	69

Table 8 Pulmonary involvement in adults with mixed connective tissue disease

Pulmonary hypertension is frequent in mixed connective tissue disease, may be difficult to detect and is a major cause of death (Table 9). The presence of scleroderma-type capillary changes on nailfold capillary microscopy may be predictive of the development of pulmonary hypertension (Sullivan *et al*. 1984). Anticardiolipin antibodies and/or a lupus anticoagulant may be more frequent in this group of patients (Hainaut *et al*. 1986; Miyata *et al*. 1992). Histological findings show proliferative vascular abnormalities resembling those found in the **CREST** (**c**alcinosis, **R**aynaud's phenomenon, (o)**e**sophageal dysmotility, **s**clerodactly, **t**elangiectasia) syndrome. Patients with post-sternal pain, pulmonary diastolic murmur, right ventricular hypertrophy on ECG, and higher mean pulmonary artery pressure have a poor prognosis (Kasukawa *et al*. 1990). Pulmonary hypertension seems less frequent in children.

Presumed cause of death	Death (n=31)	Frequency (%)
Pulmonary hypertension	11	35
Septicaemia	3	10
Sudden death	3	10
Myocardial infarction	2	6
Pulmonary embolus	1	3
Pulmonary vasculitis	1	3
Scleroderma-like renal crisis	1	3
Others, possibly unrelated	8	26
Unknown	2	6

Data taken from Bennett and O'Connell 1980, Nimelstein *et al*. 1980, Grant *et al*. 1981, Sullivan *et al*. 1984, Prakash *et al*. 1985, and Kitridou *et al*. 1986.

Table 9 Reported causes of death in mixed connective tissue disease

Kidney

In their initial report Sharp *et al*. (1972) stressed the paucity of renal involvement but later reports have found a prevalence of up to 50 per cent in adults and children (Table 5, and Hench *et al*. 1975; Bennett and Spargo 1977; Grant *et al*. 1981). Nephrotic syndrome associated with membranous nephropathy is the most common presentation and may respond to high-dose corticosteroid therapy (Kitridou *et al*. 1986). The characteristic renal lesion is an immune- deposit nephritis. Renal crisis is a rare manifestation but should be suspected in a patient with accelerated hypertension as the treatment with angiotensin-converting enzyme inhibitor may be effective (Satoh *et al*. 1994). Glomerular and vascular deposition of amyloid material have been reported (Piirainen 1989; Kessler *et al*. 1992). As in systemic lupus erythematosus, renal lesions may be found in adults and children without clinically evident renal disease (Bennett and Spargo 1977; Singsen *et al*. 1977; Singsen *et al*. 1980).

Laboratory findings

The most common laboratory features in adults and children are listed in Table 10. A moderate anaemia of chronic inflammation is usually present. Frank haemolytic anaemia and severe thrombocytopenia requiring splenectomy may occur but are rare complications. Thrombocytopenia may be associated with anticardiolipin antibodies (Doria *et al*. 1992a). Hypergammaglobulinaemia is more frequent than in systemic lupus erythematosus. Hypocomplementaemia and cryoglobulins are present in about a third of patients but neither seem specifically associated with renal or other organ involvement. An elevated creatine phosphokinase may be associated with aseptic meningitis and trigeminal neuropathy in addition to myositis (Bennett and O'Connell 1980).

Feature	Adults (%)			Children (%)	
	Bennett and O'Connell (1993) (*n*=22)	Sullivan *et al.* (1994) (*n*=34)	Prahash *et al.* (1992) (*n*=81)	Singsen *et al.* (1977) (*n*=14)	Tolaino *et al.* (1992) (*n*=14)

Table 10 Laboratory features in adults and children with mixed connective tissue disease

Autoantibodies

The presence of autoantibodies to the ribonuclease-sensitive component of extractable nuclear antigen (**ENA**) by a haemagglutination test is a characteristic serological feature of mixed connective tissue disease. The autoantibodies are now termed anti-U1RNP antibodies. The presence of these autoantibodies is suggested by a high titre, coarse speckled, nuclear pattern on an indirect immunofluorescence screen for antinuclear antibodies (Fig. 2). Immunodiffusion tests are now more commonly used than haemagglutination to confirm the presence of anti-U1RNP antibodies. The ribonuclease-resistant component of ENA is recognized by anti-Sm antibodies which frequently coexist with anti-U1RNP antibodies. The absence of anti-Sm antibodies and anti-DNA antibodies in sera positive for anti-U1RNP is also felt to be an important discriminatory finding (Table 4) as anti-Sm and anti-DNA antibodies are more specific for systemic lupus erythematosus.

Anti-U1RNP and anti-Sm antibodies recognize polypeptides on small ribonucleoproteins which participate in the formation of spliceosomes and process RNA. Anti-U1RNP antibodies selectively immunoprecipitate the U1RNA by recognition of 70 kDa, A and C polypeptides which are unique to the U1RNP particle, whereas anti-Sm antibodies immunoprecipitate the abundant uridine-rich small RNAs U1, U2, U5, and U4/U6 by recognition of core polypeptides found on all these RNAs. These core proteins common to each snRNP are B' (29 kDa), B (28 kDa), D1 to D3 (16 kDa), E (12 kDa), F (10 kDa) and G (9 kDa), of which B'/B and D are the major targets for anti-Sm antibodies. Precise characterization of the autoantibody specificity may be obtained by the technique of western blotting (Fig. 5). Although there is no clear-cut association between the titre of anti-U1RNP antibodies and activity of disease, the profile of autoantibody recognition to the U1RNP particle may change over time, and in some cases has been related to changes in features of the disease (Fisher *et al*. 1985).

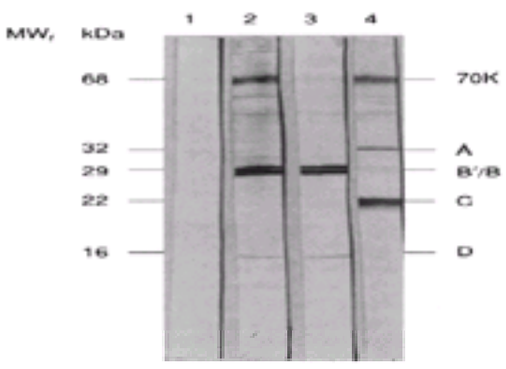

Fig. 5 Immunoblot showing the U1RNP and Sm antigenic peptides. Lane 1, normal serum; Lane 2, anti-U1RNP and anti-Sm serum; Lane 3, anti-Sm serum; Lane 4, anti-U1 RNP and anti-Sm serum.

Pathogenesis

It is likely that environmental factors trigger mixed connective tissue disease in genetically susceptible individuals. Various environmental agents have been reported including drugs such as procainamide, toxins such as polyvinyl chloride (Kahn *et al*. 1989), and silicone implants (Kumagai *et al*. 1984). Familial cases are rare but autoimmune conditions including mixed connective tissue disease may cluster in families, suggesting the inheritance of a common autoimmune diathesis. There appears to be a link with MHC class II genes (Table 3).

Histopathology

Proliferative vascular changes may be widespread and involve organs not clinically affected (Singsen *et al*. 1980). The vascular changes are similar to systemic sclerosis but accompanied by less fibrosis. There is a predilection for intimal thickening of large arteries including coronary, pulmonary, renal, and aortic arteries (Singsen *et al*. 1980; Alpert *et al*. 1983; Sullivan *et al*. 1984). Skin biopsies show dermal thickening with hypertrophy of collagen bundles, thickening of blood vessel walls and a perivascular mononuclear cell infiltration. Immunofluorescence studies of non-involved skin have shown a particulate epidermal nuclear staining pattern and granular dermo–epidermal junction deposits of immunoglobulin (Gilliam and Prystowsky 1977; Reimer *et al*. 1983). High levels of circulating anti-endothelial antibodies (Bodolay *et al*. 1989), factor VIII-related antigen (James *et al*. 1990) and ristomycin-cofactor activity (Udvardy *et al*. 1991) point to endothelial cell injury and alteration of platelet function.

Immunoregulatory abnormalities

B-cell hyperactivity is evident by polyclonal hypergammaglobulinaemia, and spontaneous *in vitro* production of immunoglobulins (Kallenberg *et al*. 1988). However the autoantibody response to the U1RNP particle appears antigen-driven rather than as a result of non-specific polyclonal activation. Recognition of one protein on the snRNP particle may allow processing and presentation of other proteins on the same complex by B cells (Fatenjad *et al*. 1993). Under conditions in which T cell tolerance to snRNPs is overcome, such a mechanism may lead to affinity maturation of a high-titre autoantibody response to the U1RNP particle. The initial autoantibody response may be initiated by molecular mimicry. Indeed, there are several regions of homology between U1RNP proteins and infectious agents such as human retroviral proteins (Query and Keene 1987). Antibodies to native HIV-1 and HTLV-I have been reported in mixed connective tissue disease (Ranki *et al*. 1992), although retroviral genomic material was not isolated in these patients.

T cells reactive to snRNPs have been isolated from patients with mixed connective tissue disease as well as healthy individuals (Hoffman *et al*. 1993). T-cell clones reactive to the snRNP A protein show restricted usage of TCR-b chain genes (Okubo *et al*. 1994). Therefore, snRNP-reactive oligoclonal T cells may accumulate in patients with mixed connective tissue disease. Rapidly dividing cells randomly accumulate gene mutations including mutations in the hypoxanthine-guanine phosphoribosyl transferase (**HPRT**) gene. An increased frequency of mutations in the HPRT gene in T cells isolated from patients with mixed connective tissue disease has been found, which may suggest a role for activated T cells in pathogenesis (Holyst *et al*. 1994). Prolonged survival of autoreactive cells by defects in apoptosis accounts for accelerated autoimmunity including the generation of autoantibodies to snRNPs in certain inbred strains of mice (Watanabe-Fukunaga *et al*. 1992). The role of molecules which regulate apoptosis such as Fas receptor and Fas ligand in human autoimmune disease is currently unknown.

Diagnosis

The presence of anti-U1RNP antibodies is a major criteria for diagnosis (Table 4), but should not be used alone to make the diagnosis. Only the criteria proposed by Sharp (1987) (Table 4) allow for the diagnosis of mixed connective tissue disease without the presence of anti-U1RNP antibodies. All sets of criteria had similar sensitivity when applied to a large population with autoimmune rheumatic disease (Alarcon-Segovia and Cardiel 1989), and although the criteria of Alarcon-Segovia

(Alarcon-Segovia and Villarreal 1987) appeared more specific, the findings need validation in a less selected series of patients. An advantage of Alarcon-Segovia's criteria is their simplicity, but a disadvantage is the need for a haemagglutination test which is now seldom used in clinical practice. The Japanese diagnostic criteria for mixed connective tissue disease (Kasukawa *et al*. 1987) was highly specific and sensitive in a group of Italian patients (Doria *et al*. 1991), and seems useful in children (Tiddens *et al*. 1993).

Longitudinal studies in mixed connective tissue disease

Long-term follow-up studies have shown that after many years of disease, features of only one autoimmune rheumatic disease (mainly scleroderma or systemic lupus erythematosus) predominate over the 'overlap' features present earlier in the course of the disease, which has cast doubt on mixed connective tissue disease being a separate entity. However, many of the patients that fulfil carefully selected criteria for mixed connective tissue disease at the time of diagnosis, will still fulfil them at long-term follow-up. Most of the patients originally described by Sharp *et al*. (1972) developed either systemic sclerosis or systemic lupus erythematosus of variable severity on long-term follow-up, although 5 of 25 patients were virtually asymptomatic (Nimelstein *et al*. 1980). In a series of 14 children with mixed connective tissue disease followed for nearly 10 years, features of systemic lupus erythematosus and polymyositis became less prominent, but scleroderma-like symptoms and joint abnormalities persisted (Tiddens *et al*. 1993).

Scleroderma-like skin abnormalities in adults and children are less responsive to treatment than initially thought and in most cases will persist, or may develop in patients who are initially diagnosed as having seronegative rheumatoid arthritis (Bennett and O'Connell 1980; Catoggio *et al*. 1993). Therefore the clinical features of mixed connective tissue disease do appear to evolve with time; skin and pulmonary lesions persist in adults whereas skin and joint involvement are prominent in children. The differentiation of mixed connective tissue disease into systemic lupus erythematosus or systemic sclerosis may be determined by the immunogenetic background (Gendi *et al*. 1995).

Studies in patients with anti-U1RNP antibodies

About 50 per cent of patients with anti-U1RNP antibodies do not have mixed connective tissue disease, even with extended follow-up (Table 11), although sometimes long periods of time are needed for the development of overlap manifestations (Lemmer *et al*. 1982). High titres of anti-U1RNP antibodies are associated more strongly with the development of mixed connective tissue disease than low titres (Lundberg and Hedfors 1991). Virtually all patients with mixed connective tissue disease will fulfil criteria for another autoimmune rheumatic disease at some stage in their illness. In our experience, patients with anti-U1RNP antibodies who fulfil criteria for mixed connective tissue disease without fulfilling criteria for systemic lupus erythematosus or systemic sclerosis are extremely rare (McHugh *et al*. 1990). None the less, studies that exclude mixed connective tissue disease once another autoimmune rheumatic disease is diagnosed (Calderon *et al*. 1984; Van Den Hoogen *et al*. 1994) may be misleading, as such patients may still be said to have the former disease. In the context of systemic lupus erythematosus, the presence of anti-U1RNP antibodies is associated with Raynaud's phenomenon, swollen fingers, myositis, pulmonary involvement, and less renal disease (Reichlin and Mattioli 1972; Maddison *et al*. 1978; McHugh *et al*. 1990). In patients with an overlap syndrome, the presence of anti-U1RNP antibodies may be associated with Raynaud's phenomenon and pulmonary hypertension (Ginsburg *et al*. 1983; Lazaro *et al*. 1989).

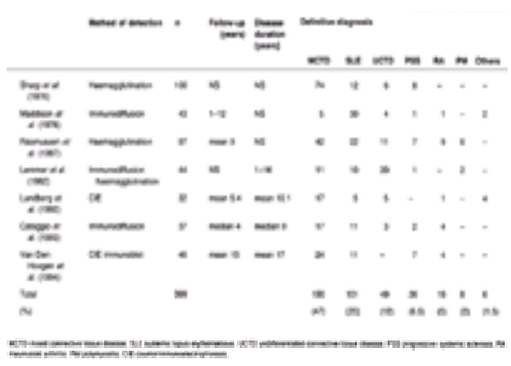

Table 11 Outcome in patients with anti-U1RNP antibodies

Prognosis

The prognosis is not as favourable as originally reported. The major cause of mortality appears to be pulmonary hypertension (Table 9). One-third of the 34 patients followed by Sullivan *et al*. (1984) had very severe disease requiring repeated courses or sustained high doses of corticosteroids, and 4 patients died. The mortality rate in some of the larger series is shown in Table 12. The 5- and 10-year survival rate was 90.5 per cent and 82.1 per cent in a Japanese series of patients, which was similar to that for systemic lupus erythematosus (Miyawaki and Onodera 1987). In children the presence of reactivity to the Sm D polypeptide is associated with a poorer prognosis (Hoffman *et al*. 1993).

	Number of patients	Follow-up (years)	Disease duration (years)	Number of deaths (%)
Bennett and O'Connell (1980)	20	4	–	4 (20)
Nimelstein *et al.* (1980)	22	3.75	12	8 (36)
Grant *et al.* (1981)	23	–	–	5 (22)
Sullivan *et al.* (1984)	34	6.26	11	4 (12)
Prakash *et al.* (1985)	81	5	–	6 (7)
Kitridou *et al.* (1986)	30	9.4	13	4 (13)
Total	210			31 (15)

Table 12 Reported mortality in mixed connective tissue disease

Management

Management of mixed connective tissue disease depends on manifestations of the disease. A suggested approach to management is outlined in Fig. 6. The scleroderma-like features are not as responsive to corticosteroids as originally reported. Raynaud's phenomenon is managed as in scleroderma, with emphasis on the patient keeping warm, avoiding trauma to the fingers, and discouragement of cigarette smoking. Vasodilators such as calcium channel blockers, angiotensin-converting enzymes, pentoxifylline and ketanserin are effective in some patients. Intravenous prostacyclin may be used for acute ischaemic digital lesions.

Fig. 6 Management of overlap syndrome.

Oesophageal involvement may respond to corticosteroids, although such treatment is rarely justified. More often, antacids, H_2-antagonists and omeprazole are required. Fatigue, fever, lymphadenopathy, arthralgia, and myalgia may respond to non-steroidal anti-inflammatory drugs in conventional doses. The addition of antimalarial agents early in the course of the disease is becoming a more widespread practice. Low-dose corticosteroids (less than 20 mg of prednisolone per day) may be needed if general symptoms do not respond to other measures. The development of an erosive polyarthritis may warrant the introduction of methotrexate or azathioprine. Myositis in mixed connective tissue disease may respond to lower doses of corticosteroids than polymyositis (Lundberg *et al*. 1992).

The management of renal disease remains controversial, although knowledge of histology may help in the decision. High-dose corticosteroids were effective for nephrotic syndrome and proteinuria in about two-thirds of patients described by Kitridou *et al*. (1986). However, cytotoxic drugs are probably indicated for those patients with more proliferative lesions, or those patients that require large corticosteroid doses for long periods of time.

Antiphospholipid antibodies should be sought in patients with pulmonary hypertension, and anticoagulation therapy considered when these antibodies are present (Ueda *et al*. 1991). Corticosteroids and cytotoxic drugs should be considered at an early phase because of the poor prognosis associated with pulmonary hypertension in mixed connective tissue disease and its usually rapid progression (Weiner-Kronish *et al*. 1981; Alpert *et al*. 1992). There are reports of patients responding to chlorambucil (Weiner-Kronish *et al*. 1981), cyclophosphamide (Friedman *et al*. 1992), and cyclophosphamide and cyclosporin A (Dahl *et al*. 1992). Recurrent episodes of pulmonary vasoconstriction may contribute to the development of pulmonary hypertension in patients with diffuse systemic sclerosis, the CREST syndrome and mixed connective tissue disease (Alpert *et al*. 1992). Nifedipine, hydralazine, prazosin, phenotolamine, ketanserin, prostacyclin, and captopril are all capable of acute and sustained reduction of pulmonary vascular resistance in such patients and therefore may be of additional therapeutic value.

Polymyositis overlap syndromes

Anti-tRNA synthetases syndrome

Autoantibodies are found in the majority of patients with polymyositis and dermatomyositis (Reichlin and Arnett 1984). The most frequent autoantibody is anti-Jo-1 which is directed against histidyl-tRNA synthetase, one of the 20 different enzymes that attaches the tRNA with its specific amino acid (Mathews and Bernstein 1983; Wasicek *et al*. 1984). Antibodies to five of these synthetases have been identified in patients with inflammatory myopathy (Targoff 1992). Anti-Jo-1 is found in 15 to 20 per cent of all myositis patients, and is found very rarely in dermatomyositis (Nishikai and Reichlin 1980).

A characteristic group of clinical features is associated with this group of autoantibodies. The 'antisynthetase syndrome' is characterized by myositis (100 per cent), interstitial lung disease (50 to 75 per cent), arthritis (60 to 100 per cent), and Raynaud's phenomenon (60 per cent) (Targoff 1992). A particular cutaneous feature is the presence of hyperkeratosis and fissuring along the lateral aspects of the fingers, so-called 'mechanic's (or machinist's) fingers' (Fig. 7).

Fig. 7 Mechanic's finger.

Interstitial lung disease is one of the characteristic findings in the antisynthetase syndrome. Interstitial lung disease is found in 50 to 75 per cent of myositis patients with anti-Jo-1, compared with only 10 to 20 per cent of myositis overall (Bernstein *et al*. 1984; Hochberg *et al*. 1984; Love *et al*. 1991; Targoff 1992). The interstitial lung disease is indistinguishable from idiopathic interstitial lung disease, and it may persist despite response of the myositis to treatment and become a greater clinical problem than the myositis itself (Targoff and Arnett 1990). Arthritis is more frequent in patients with anti-Jo-1 antibodies (Bernstein *et al*. 1984; Plotz *et al*. 1989; Oddis *et al*. 1990; Targoff 1992). It is usually non-erosive, but deforming arthritis may be seen in one-third of patients. The wrist and finger joints are the most commonly involved joints.

Almost all patients with anti-Jo-1 antibodies have myositis at some stage in the course of their disease. However, antisynthetase antibodies may be found in patients with 'idiopathic' lung disease without clinical myositis (Bernstein *et al*. 1984; Targoff and Arnett 1990). Subclinical or absent myositis is more common with other non-Jo-1 antisynthetase antibodies (Targoff 1992). The myositis is indistinguishable from that of patients without antisynthetase antibodies, although patients with the autoantibodies may develop myositis at a younger age and have a more rapid form of onset (Plotz *et al*. 1989).

Rhupus

The existence of patients with a clinical picture resembling both rheumatoid arthritis and systemic lupus erythematosus has long been recognized. The description of lupus erythematosus cells by Hargraves in 1948 allowed a more precise segregation of patients with systemic lupus erythematosus, although a number of patients with 'true' rheumatoid arthritis, usually with more severe disease and extra-articular manifestations, were positive for lupus erythematosus cells. Conversely, there are patients with systemic lupus erythematosus who have a prominent synovitis associated with rheumatoid factor.

The appearance of nodules or an erosive arthropathy in patients with systemic lupus erythematosus (Cohen and Webb 1987) suggests a genuine overlap between the two conditions. The term 'rhupus' has been used to describe such patients (Panush *et al*. 1988). Although numerous case reports have appeared documenting a true coexistence of diffuse glomerulonephritis with nodules or erosive polyarthritis, 'rhupus' does not seem to occur more frequently than expected than the chance concurrence of systemic lupus erythematosus and rheumatoid arthritis (Panush *et al*. 1988). Some of the patients described in these earlier studies had overlap features and if serological techniques had been available for detecting anti-U1RNP antibodies, they may have fulfilled criteria for mixed connective tissue disease. Immunogenetic factors may determine which clinical features become most prominent (Brand *et al*. 1992).

Scleroderma overlap syndromes

Scleroderma and primary biliary cirrhosis

The association between systemic sclerosis and primary biliary cirrhosis is well recognized (Murray-Lyon *et al*. 1970; Reynolds *et al*. 1971). Scleroderma occurs in 4 to 17 per cent of patients with primary biliary cirrhosis according to large series (Clarke *et al*. 1978). Scleroderma in primary biliary cirrhosis is usually the CREST syndrome, now better referred to as limited cutaneous systemic sclerosis. Conversely, up to 5 per cent of patients with scleroderma have clinical evidence of primary biliary cirrhosis (Reimer 1990).

Antimitochondrial antibodies, the serological hallmark of primary biliary cirrhosis, are found in 15 to 25 per cent of sera from patients with systemic sclerosis, with a minority of the latter patients having overt evidence of primary biliary cirrhosis (Reimer 1990). Anticentromere antibodies, the serological hallmark of the CREST syndrome, are found in up to 30 per cent of sera from patients with primary biliary cirrhosis (Reynolds *et al*. 1971; Bernstein *et al*. 1982), and more than half of these patients have at least some features of CREST (Bernstein *et al*. 1982). The serological overlap between primary biliary cirrhosis and systemic sclerosis is more prevalent than the clinical overlap, although subclinical hepatic involvement may not be evident without liver biopsy. The serological overlap is not because of cross-reactivity between mitochondrial and centromere-associated antigens, which are independent antigenic targets (Whyte *et al*. 1994).

Patients with primary biliary cirrhosis also have a high prevalence of Sjögren's syndrome or keratoconjunctivitis sicca (Culp 1985). While evaluating 17 patients with primary biliary cirrhosis keratoconjunctivitis sicca was found in 76 per cent and a positive lip biopsy compatible with Sjögren's in 62 per cent of patients (Soriano *et al*. unpublished data)

Scleroderma–polymyositis overlap

Muscle involvement was recognized early in the description of the systemic sclerosis. Two different types of myopathy may occur. The more common myopathy is characterized by mild or no proximal muscle weakness, mild elevation of muscle enzymes, polyphasic motor unit potentials of normal amplitude and duration on electromyograms, and interstitial fibrosis and variation in diameter of muscle fibres without active inflammation on biopsy. This form has been classified as 'simple myopathy' (Clements *et al*. 1978) and does not appear to change significantly over long periods of time. A less frequent form resembles polymyositis with more proximal muscle weakness, very high muscle enzyme concentrations, inflammatory changes on biopsy, and polyphasic motor unit potentials of short duration and small amplitude on electromyography. The latter form requires active therapy and has been labelled inflammatory myopathy or 'complicated myopathy' (Clements *et al*. 1978).

In the series of patients with polymyositis reported by Bohan and co-workers (Bohan *et al*. 1977), 21 per cent of 153 patients had another autoimmune rheumatic disorder and were classified as type V polymyositis. The most frequently associated autoimmune rheumatic disease was scleroderma (36 per cent). The diagnosis of mixed connective tissue disease was not considered, especially as detailed serological investigation was not available. However, anti-U1RNP antibodies were present in 25 to 33 per cent of a later series of similar patients (Hochberg *et al*. 1986; Love *et al*. 1991). Of 34 patients studied in Argentina with polymyositis/dermatomyositis, 14 (41 per cent) had type V polymyositis. Anti-U1RNP was present in 67 per cent of cases, and one- half fulfilled Alarcon Segovia's criteria for mixed connective tissue disease (Imamura *et al*. 1993).

Other autoantibody specificities may also be associated with the scleroderma–polymyositis overlaps. Anti-Ku antibodies are associated with polymyositis–scleroderma overlap syndrome in Japan, but are less frequent in the United States; conversely anti-Pm-Scl antibodies are more frequent in polymyositis–scleroderma overlap in the United States but not in Japan (Targoff 1992). In general anti-Pm-Scl antibodies are found in 8 per cent of myositis patients and 3 per cent of scleroderma patients (Targoff 1992). Among 22 patients with anti-Pm-Scl antibodies, polymyositis/dermatomyositis alone was present in 55 per cent, scleroderma without polymyositis/dermatomyositis in 5 per cent, and myositis–scleroderma overlap in 41 per cent (Reichlin *et al*. 1984).

The prognosis of patients with type V polymyositis is no different from that in polymyositis alone (Bohan *et al*. 1977). It is possible that lower doses of corticosteroids may be sufficient to control myositis in association with mixed connective tissue disease (Lundberg *et al*. 1992).

Eosinophilia–myalgia syndrome, toxic oil syndrome, eosinophilic fasciitis

The eosinophilia–myalgia syndrome was first defined in 1989 (Centers for Disease Control 1989) as a new epidemic in association with the ingestion of L-tryptophan preparations (Belongia *et al*. 1990; Eidson *et al*. 1990), traced to a single Japanese manufacturer. (Belongia *et al*. 1990; Carr *et al*. 1994). The clinical picture and the pathological features, strongly resemble those of the Spanish toxic oil syndrome. Toxic oil syndrome was another epidemic that occurred in Spain in 1981 and was associated with the ingestion of adulterated rapeseed cooking oil. The presence of eosinophilia and fasciitis, link these two epidemics with eosinophilic fasciitis. However, no toxin has been associated with eosinophilic fasciitis.

Eosinophilia–myalgia syndrome and toxic oil syndrome

Epidemiology

The use of L-tryptophan was widespread in the United States in 1989 for the treatment of insomnia, premenstrual syndrome, and depression. Tryptophan was available to consumers without a prescription; thus a very large section of the population were at risk. As of 1 August 1992, the Centers for Disease Control had received a total of 1511 reports, including 38 deaths (Nightingale 1992). The surveillance case definition of eosinophilia–myalgia syndrome was as follows: eosinophil count greater than 1000/mm^3, incapacitating myalgia, and exclusion of other infectious or neoplastic illnesses that could account for the other two findings (Kilbourne *et al*. 1990). However, the actual number of individuals in whom some type of eosinophilia–myalgia syndrome had developed was estimated to be several times higher (Nightingale 1992).

National surveillance data from the United States in 1990 showed that 84 per cent of affected patients were female, 97 per cent were non-Hispanic white, and 87 were aged 35 years or older (median: 48; range: 4 to 85) (Swygert *et al*. 1990). The female preponderance is more likely due to ingestion patterns rather than gender susceptibility (Silver 1993). The usual daily dose ranged from 10 to 15 000 mg (median: 1500), and the median time between beginning use of tryptophan and the onset of symptoms was 127 days (range: 1 to 3668). Twenty-two per cent of those affected with eosinophilia–myalgia syndrome had taken tryptophan for more than 1 year before becoming ill, and 12 per cent had discontinued tryptophan a median of 15 days (range: 1 to 2858) before onset of symptoms (Swygert *et al*. 1990). Two risk factors for developing eosinophilia–myalgia syndrome were older age and the quantity of tryptophan consumed. The latter risk factor was not associated with the syndrome in a recent epidemiological study in Germany (Carr *et al*. 1994), possibly because of batch variations of quantities of the contaminants in the L-tryptophan (Mayeno and Gleich 1994). The occurrence rate of eosinophilia–myalgia syndrome in Germany was estimated as 40 per 100 000 users of the implicated source (Carr *et al*. 1994).

Toxic oil syndrome occurred in Spain in 1981 affecting more than 20 000 individuals with about 500 deaths (Mayeno and Gleich 1994). Epidemiological investigations implicated the use of aniline-denatured rapeseed oil that was sold and reprocessed illegally (Kilbourne *et al*. 1988).

Clinical features and histology

Symptoms at presentation

The more common clinical and laboratory manifestations of eosinophilia–myalgia syndrome and toxic oil syndrome are summarized in Table 13. The majority of patients with eosinophilia–myalgia syndrome presented with a flu-like syndrome characterized by myalgia and arthralgia, associated with profound weakness and fatigue (Kaufman *et al*. 1990). By definition all patients had severe myalgia with an elevated peripheral eosinophil count. Myalgia was generally diffuse, although could be localized, and accompanied by severe episodic muscle cramps (Kaufman *et al*. 1990; Hedberg *et al*. 1992). By contrast, patients with toxic oil syndrome presented as an atypical pneumonia, with non-productive cough, pleuritic chest pain, headache, fever, and bilateral pulmonary infiltrates. Gastrointestinal findings and striking eosinophilia became prominent within the first month.

Feature	EMS (Berygger et al. 1990) n=1075 (%)	TOS (Milesuma et al. 1983) n=181 (%)
Myalgia	100	95.5
Arthralgia	73	8.4
Rash	60	64.7
Peripheral oedema	59	64.7
Cough	59*	68.1
Dyspnoea	59*	42
Fever	36	68.1
Scleroderma like skin	32	–
Alopecia	28	5
Neuropathy	28	30.5
Hepatomegaly	5	37
Leucocytosis	65	71.1
Eosinophilia (> 500 cmm^3)	100*	77.7
Elevated ESR	33	38.6
Elevated aldolase	46	55.4
Elevated creatine kinase	10	–
Abnormal chest radiograph	21	87.6
Abnormal liver function test	49	41.3

*By definition all patients had eosinophilia and myalgia and eosinophil count at most recent visit > 10^3 cells (Berygger et al. 1990).
†Cough and dyspnoea taken together (Berygger et al. 1990).

Table 13 Prevalence of selected clinical and laboratory findings in eosinophilia–myalgia syndrome (EMS) and toxic oil syndrome (TOS)

Neuromuscular involvement

The clinical and pathological manifestations of neuromuscular involvement were qualitatively similar in both diseases, although more severe in toxic oil syndrome (Hertzman and Abaitua Borda 1993). In the acute and intermediate phases myalgia, muscle cramps, weakness, arthralgia, paraesthesia, and dysaesthesia were reported (Table 13). Late severe sensorimotor polyradiculopathy, with progressive weakness and occasional respiratory muscle involvement, and neuropathic contractures of the hands and wrist more commonly occurred in patients with toxic oil syndrome (30 per cent compared with less than 5 per cent) (Hertzman and Abaitua Borda 1993; Bolster and Silver 1994). In toxic oil syndrome the presence of severe initial systemic findings was associated with progression to neuromuscular illness (Kilbourne *et al*. 1983).

The most prominent histological feature in both conditions was a perimysial and epimysial inflammatory infiltrate consisting of mononuclear cells, histiocytes, and eosinophils (Kaufman *et al*. 1990; Varga *et al*. 1993; Lin *et al*. 1992). The degree of inflammatory infiltrate appeared to correlate with the extent of clinical symptoms (Kaufman *et al*. 1990). Myofibril atrophy, regeneration, and necrosis were almost absent in all biopsies, despite the severe and incapacitating myalgia (Lin *et al*. 1992). Later in the course of the disease, muscle fibre atrophy consistent with denervation was observed in both conditions (Hertzman and Abaitua Borda 1993).

Lungs

Pulmonary involvement was a major feature in both conditions. Toxic oil syndrome was characterized by an acute onset of cough and dyspnoea. Radiographic and pathological changes in toxic oil syndrome were consistent with a non-inflammatory non-cardiogenic pulmonary oedema, and 250 deaths occurred from this complication (Hertzman and Abaitua Borda 1993). Acute respiratory involvement in eosinophilia–myalgia syndrome occurred less frequently and was characterized by an interstitial pneumonitis that resolved spontaneously or was highly responsive to corticosteroids (Hertzman and Abaitua Borda 1993). Dyspnoea in eosinophilia–myalgia syndrome was related to parenchymal involvement of the lungs and to respiratory muscle weakness (Read *et al*. 1992).

Pulmonary hypertension developed in the intermediate stage of both conditions (1 to 12 months) in 8 per cent of patients with toxic oil syndrome (Cheg 1993) and in 5 per cent of patients with eosinophilia–myalgia syndrome (Martin *et al*. 1990). Cardiac involvement was rare and usually occurred as a result of pulmonary hypertension. However, primary involvement of the heart and coronary arteries has been reported in eosinophilia–myalgia syndrome (Berger *et al*. 1994) and in toxic oil syndrome (James *et al*. 1991).

Skin

The most frequent cutaneous manifestations in the acute phase of eosinophilia–myalgia syndrome and toxic oil syndrome were diffuse erythematous macules over the trunk and extremities. Oedema associated with cutaneous induration in the arms and legs was found in 28 to 60 per cent of patients with eosinophilia–myalgia syndrome (Kaufman *et al*. 1990; Swygert *et al*. 1990), and in 90 per cent of those with toxic oil syndrome. The oedema was due to fascial inflammation and was often accompanied by venous furrowing and the 'peau d'orange' induration characteristic of eosinophilic fasciitis (Kaufman *et al*. 1990). Histologically the changes could not be distinguished from eosinophilic fasciitis, with an inflammatory infiltrate of the fascial layers, a chronic perivascular infiltrate in the dermis in early cases, and thickening and homogenization of collagen bundles in later cases (Lin *et al*. 1992). Active skin lesions had disappeared in biopsy specimens at late follow-up (Hertzman and Abaitua Borda 1993), with oedema replaced by scleroderma-like changes. Non-necrotizing vascular lesions were more common in toxic oil syndrome than in eosinophilia–myalgia syndrome (Bolster and Silver 1994).

Gastrointestinal tract

Hepatomegaly, abdominal pain, nausea, diarrhoea, odynophagia, and dysphagia were particularly prominent during the first month in patients with toxic oil syndrome. Gastrointestinal symptoms have been reported in 64 per cent of patients who died of causes related to eosinophilia–myalgia syndrome (Swygert *et al*. 1993). Clinical evidence of pancreatic disease was rare in both entities, but 30 per cent of autopsies on patients with toxic oil syndrome showed marked atrophy of the pancreas (Hertzman and Abaitua Borda 1993).

Central nervous system

Cognitive symptoms and significant impairments of verbal and visual memory, conceptual reasoning, and motor speed were reported in 62 per cent of patients with eosinophilia–myalgia syndrome (Krupp *et al*. 1993) and 20 to 30 per cent of patients with toxic oil syndrome (Hertzman and Abaitua Borda 1993). Most patients with eosinophilia–myalgia syndrome were taking L-tryptophan because of insomnia and depression, and the use of antidepressive drugs may have contributed to some of these features. (Krupp *et al*. 1993). Electroencephalograms, computed tomography scans, and magnetic resonance imaging studies were normal (Hertzman and Abaitua Borda 1993; Krupp *et al*. 1993).

Laboratory findings

The laboratory findings are shown in Table 13. The most characteristic finding was the presence of eosinophilia in peripheral blood, usually within the first week. The eosinophilia was responsive to corticosteroid treatment and in eosinophilia–myalgia syndrome to discontinuation of L-tryptophan. The serum IgE levels were characteristically normal in eosinophilia–myalgia syndrome but were elevated in nearly half of patients with toxic oil syndrome (Belongia *et al*. 1990). Antinuclear antibodies were found in 40 per cent of patients with eosinophilia–myalgia syndrome and in a minority of patients with toxic oil syndrome. Normal creatine kinase levels were seen in almost all patients, although isolated elevation of serum aldolase was reported in 58 per cent of patients with eosinophilia–myalgia syndrome (Kaufman *et al*. 1990)

Aetiology and pathogenesis

Eosinophilia–myalgia syndrome

The epidemic nature of eosinophilia–myalgia syndrome, and its association with batches of L-tryptophan originating from a single manufacturer, suggested a contaminant (Varga *et al*. 1993). High-performance liquid chromatography analysis of L-tryptophan revealed more than 60 contaminants (Belongia *et al*. 1990). A single absorbance peak labelled 'peak E', or peak 97, and later identified as 1,1'-ethylidene bis[tryptophan] (**EBT**), was found consistently in L-tryptophan lots associated with eosinophilia–myalgia syndrome (Belongia *et al*. 1990). Lewis rats treated with EBT and/or case-associated L-tryptophan for 6 weeks developed significant increases in the thickness of the myofascia, compared with animals treated with vehicle or L-tryptophan not associated with the case. However, only animals treated with case-associated L-tryptophan (and not those receiving EBT) showed evidence of immune activation. Although these results demonstrated the pathological effect of EBT, they did not rule out the possibility that other impurities in the L-tryptophan associated with eosinophilia–myalgia syndrome may have contributed to some of the features of the syndrome (Love *et al*. 1993). Another murine model of eosinophilia–myalgia syndrome induced by intraperitoneal

administration of EBT was reported recently (Silver *et al*. 1994). A second contaminant (peak UV-5) has been identified as 3-(phenylamino)alanine (**PAA**) and related to L-tryptophan associated with cases of eosinophilia–myalgia syndrome (Mayeno *et al*. 1992). Of interest, PAA is chemically similar to 3-phenylamino-1,2-propanediol, an aniline derivative implicated in the development of toxic oil syndrome. The fact that many patients had ingested tryptophan for long periods (10 years or more) before becoming ill makes the existence of an inborn error of tryptophan metabolism an unlikely cause of eosinophilia–myalgia syndrome (Carr *et al*. 1994; Mayeno and Gleich 1994). However, several studies have found abnormal tryptophan metabolism in patients with eosinophilia–myalgia syndrome and toxic oil syndrome, with a shunting of L-tryptophan metabolism to the kynurenine pathway (Silver *et al*. 1992; Varga *et al*. 1993; Bolster and Silver 1994). These abnormalities could play a role in the pathogenesis of eosinophilia–myalgia syndrome, but more probably are a consequence of inflammation (Varga *et al*. 1993).

Both cellular and humoral autoimmune mechanisms have been implicated in the pathogenesis of eosinophilia–myalgia syndrome (Varga *et al*. 1993). A hypothetical model is that the initial trigger (tryptophan contaminant or metabolite) activates inflammatory cells, which are induced to secrete cytokines (IL-5, GM-CSF, transforming growth factor-b) that cause activation of eosinophils, and fibroblasts. Activated eosinophils may release cytokines and toxic granule proteins (including major basic protein), that may contribute to tissue injury. Activated fibroblasts produce increased amounts of collagen and other extracellular matrix components resulting in the characteristic fibrosis (Varga *et al*. 1993).

Toxic oil syndrome

Fatty acid anilides have been proposed as the aetiological agents in toxic oil syndrome. Fatty acid anilides may alter arachidonic acid metabolism or impair fibrinolytic activity in endothelial cells leading to the early intimal lesions seen in these patients (Bolster and Silver 1994).

Prognosis

The disease-related mortality rate for the first year was 2.7 per cent for eosinophilia–myalgia syndrome and 1.5 to 3.6 per cent for toxic oil syndrome (Alonso-Ruiz *et al*. 1993; Kaufman 1993; Swygert *et al*. 1993). It is likely that the incidence rate of eosinophilia–myalgia syndrome was underestimated, and toxic oil syndrome was more severe than eosinophilia–myalgia syndrome in its acute stages (Kaufman 1993). Progressive polyneuropathy and myopathy accounted for 67 per cent of deaths in patients with eosinophilia–myalgia syndrome. Older age and involvement of more than one organ system, in particular neuromuscular, pulmonary, and cardiovascular sequelae, suggested a poor prognosis (Swygert *et al*. 1993).

Long-term morbidity was frequent in both syndromes. Persistent symptoms such as myalgia (50 to 94 per cent), muscle cramping (43 to 90 per cent), and neuropathy (30 to 91 per cent) were reported up to 36 months after the onset of eosinophilia–myalgia syndrome (Kaufman 1993). The consumption of multivitamin supplements before the appearance of eosinophilia–myalgia syndrome was associated with reduced severity of subacute symptoms (Hatch and Goldman 1993). In an 8-year follow-up study of 332 patients with toxic oil syndrome, only 9 per cent achieved full remission (Alonso-Ruiz *et al*. 1993). The severity of the chronic manifestations was variable, but was mild in most of the cases (Alonso-Ruiz *et al*. 1993). Muscle cramps and chronic musculoskeletal pain were the most common symptoms.

Management

A variety of medical regimens, mainly non-steroidal anti-inflammatory agents and corticosteroids, have been used to treat patients with eosinophilia–myalgia syndrome and toxic oil syndrome. Although acute symptoms such as oedema, acute pulmonary disease, and eosinophilia responded to corticosteroid treatment, such treatment was not associated with long-term improvement in symptoms. Corticosteroids may have been life saving in cases of acute respiratory failure due to non-cardiogenic pulmonary oedema in toxic oil syndrome.

Eosinophilia–myalgia syndrome in children

Eosinophilia–myalgia syndrome occasionally has been identified among children, including a neonate with persistent eosinophilia whose mother ingested tryptophan during pregnancy (Hatch *et al*. 1991). More recently a case of eosinophilia–myalgia syndrome was reported in a child with phenylketonuria who developed the syndrome after ingesting a specialized infant formula containing contaminated tryptophan (Springer *et al*. 1992).

Eosinophilic fasciitis

Eosinophilic fasciitis is a relatively uncommon idiopathic disease, first described by Shulman (1974), and characterized by fasciitis and peripheral blood eosinophilia. It shares similar clinical and histological features with eosinophilia–myalgia syndrome and toxic oil syndrome, but significant internal organ involvement is uncommon. Also, there are differences that distinguish eosinophilic fasciitis from systemic sclerosis: the absence of Raynaud's phenomenon, normal nailfold capillaries, sparing of the dermis, infrequent visceral involvement, absence of the serological features characteristic of systemic sclerosis, and the development of haematological complications, such as aplastic anaemia and thrombocytopenia, seldom reported in typical systemic sclerosis (Michet *et al*. 1981; Maddison 1991). The age of onset is 30 to 40 years (mean: 47; range: 11 to 72), and in half of the patients a history of recent strenuous exertion can be recalled (Lakhampal *et al*. 1988).

Cutaneous manifestations are the most common presenting feature and usually evolve through three stages: pitting oedema, 'peau d'orange', and induration. These stages are often present simultaneously in different areas of the body (Maddison 1991). The arms and legs are affected most commonly and simultaneous involvement of hands and feet is not uncommon. Localized morphoea may occur in other areas, especially in children (Miller 1992). Synovitis is not uncommon and may be the presenting feature. Low-grade myositis may be present, although serum creatine kinase levels are usually normal.

Eosinophilic fasciitis has been associated with malignancy and may present as a paraneoplastic syndrome (Naschitz *et al*. 1994), which remits with successful cancer surgery. Haematological malignancies are overrepresented, and aplastic anaemia in particular has a high associated mortality (Hoffman *et al*. 1982). Eosinophilic fasciitis associated with malignancy has a female predominance and usually fails to respond to corticosteroids (Naschitz *et al*. 1994).

Peripheral eosinophilia, sometimes impressive, is the most striking laboratory feature. Eosinophilia may be transient and the diagnosis should not be dismissed because of its absence. Diagnosis is confirmed by a cutaneous biopsy to include tissue extending from the epidermis to skeletal muscle and the deep fascia. Characteristic histological findings are a widespread inflammatory infiltrate involving the deep fascia and septae of the subdermal fat as well as the dermal layer and a normal epidermis.

The cause of eosinophilic fasciitis is unknown. Of interest is the association with strenuous exertion, especially in men. After the description of eosinophilia–myalgia syndrome associated with L-tryptophan, some retrospective studies have found an association of eosinophilic fasciitis with the consumption of L-tryptophan (Freundlich *et al*. 1990; Martin *et al*. 1991), while others have not (Varga *et al*. 1991). Recently two cases of diffuse fasciitis with peripheral eosinophilia were described in which *Borrelia burgdoferi* was identified on biopsy specimens. The term borrelial fasciitis was used to describe such lesions (Granter *et al*. 1994).

More than half of patients with eosinophilic fasciitis respond to corticosteroids, although complete remission is achieved in only 15 per cent. There may be spontaneous remissions. Other agents such as cimetidine, hydroxychloroquine, colchicine, D-penicillamine, and cyclosporin (Laneuville 1992) have been used with variable results. In children, two-thirds of patients developed cutaneous fibrosis (Farrington *et al*. 1993).

5.13.1 Amyloidosis

Gunnar Husby

Definition of amyloid and amyloidosis

The term amyloidosis relates to a heterogeneous group of disorders (rather than a single disease entity) characterized by extracellular deposition of a proteinaceous, fibrillar material—amyloid—in various tissues and organs (Glenner 1980; Husby and Sletten 1986; Husby 1992). The unique amyloid fibril is the principal component of all amyloids irrespective of the clinical expression, tissues, or species involved, or whether they arise spontaneously or are induced in experimental animals.

Amyloid fibrils as seen in the electron microscope are rigid and non-branching with a diameter of 10 to 15 nm, of indefinite length, and consist of polypeptide chains arranged in a twisted b-pleated sheet (Glenner 1980). This specific structure of the fibril proteins determines the tinctorial and optical properties of amyloid, i.e. the affinity for Congo red and the typical green/yellow birefringence seen when amyloid stained with Congo red is viewed in a polarizing microscope (Cooper 1974). The low solubility and relative resistance to proteolytic digestion of the amyloid fibrils contribute to the irreversible and often progressive course of amyloidosis, in many cases leading to death within months or a few years of diagnosis (Husby 1985).

Benditt and Eriksen (1964) observed that in spite of the morphological similarities between amyloids in different clinical settings, amyloid is heterogeneous also with respect to the nature of the amyloid fibrils. Subsequent studies of amyloid extracted from different affected tissues (Pras *et al*. 1968) have revealed that they may be composed of a variety of different protein subunits (Husby and Sletten 1986).

In addition, an extrafibrillar protein called the amyloid-P component or protein **AP**, derived from a normal plasma glycoprotein, termed **SAP**, is invariably present in amyloid, regardless of the type of fibril protein (Pepys 1988). A carbohydrate moiety in the form of glycosaminoglycans and proteoglycans has also been demonstrated in all amyloids deposits so far examined (Kisilevski 1987; Magnus *et al*. 1989; Husby *et al*. 1994b; Stenstad *et al*. 1994).

Amyloid fibril proteins

The chief component of amyloid fibrils is a distinct protein subunit with a relatively small molecular mass—3000 to 30 000 Da in different fibril preparations (Glenner 1980; Husby and Sletten, 1986). Several, apparently non-related proteins can constitute this amyloid fibril subunit in different cases of amyloidosis, a common feature being the ability to assume the b-pleated sheet typical of amyloid (Glenner 1980). A steadily increasing number of such proteins (17 at the present time) have been characterized by their amino acid sequence (Table 1), and in many cases complementary DNA has also been established. The different amyloid proteins are often related to distinct clinical forms of amyloidosis. Indeed, many types of amyloid disease can now be defined and classified by structural analysis of the fibril proteins and/or the genes coding for them (Benditt and Eriksen 1971; Glenner 1980; Husby and Sletten 1986; Husby 1994).

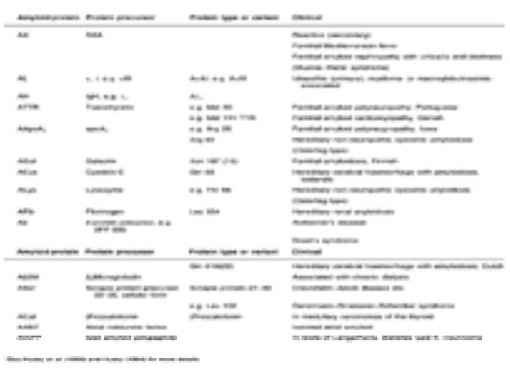

Table 1 Nomenclature and classification of human amyloid and amyloidosis [a]

Certain serum proteins are precursors of the different fibril proteins in the various systemic forms of amyloidosis (Glenner 1980; Husby and Sletten 1986). Two important types of fibril protein related to systemic amyloidosis are the amyloid-L (**AL**) and amyloid-A (**AA**) proteins (Table 1). Protein AL, which consists of homogeneous (monoclonal) immunoglobulin light chains or their aminoterminal fragments is seen in idiopathic and myeloma-associated amyloidosis (AL amyloidosis) (Glenner 1980; Husby 1983). Protein AA (Table 2), which is derived from the serum amyloid-A protein (Husebekk *et al*. 1985), is associated with reactive amyloidosis, familial Mediterranean fever, familial nephropathic amyloidosis with febrile urticaria—the Muckle–Wells syndrome (Muckle 1979; Linke *et al*. 1983)—and spontaneous or experimental amyloidosis in animals (Glenner 1980; Husby and Sletten 1986). These forms of amyloidosis could therefore also be called AA. Serum amyloid A (**SAA**), an apolipoprotein present on high-density lipoprotein in serum, is one of the most sensitive acute-phase proteins described (Marhaug *et al*. 1986). However, its function is largely unknown except for its association with AA amyloidosis and an active role in the metabolism and transport of cholesterol (Meek *et al*. 1994). An extensive review of the histology of SAA/AA proteins and genes and their relation to AA amyloidosis has recently been published (Husby *et al*. 1994a).

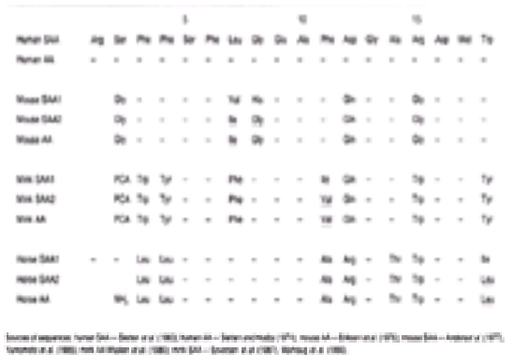

Table 2 Partial aminoterminal amino acid sequence of serum amyloid-A (SAA) and amyloid-A (AA) proteins from man, mouse, mink, and horse, numbered according to human SAA. Alignment is done to maximize homology. Only the amino acid residues that differ from those of human SAA and AA are shown for mouse, mink, and horse. Those amino acid residues that specify amyloidogenic SAA molecules are underlined

Different genetic variants of transthyretin (Table 1), previously termed prealbumin (Husby *et al*. 1990), are associated with the autosomal-dominant familial amyloid polyneuropathies and cardiomyopathies (Nordlie *et al*. 1988; Benson and Wallace 1989). Normal transthyretin makes up systemic senile amyloid (Westermark *et al*. 1986).

Three other serum proteins are also associated with hereditary amyloidosis (Table 1). A variant of apolipoprotein **AI** represents the fibril protein in familial amyloid polyneuropathy from Iowa (Nichols *et al*. 1988), whereas a variant gelsolin, an actin-modulating protein, plays the same role in familial amyloid polyneuropathy of Finnish origin (Maury 1990a). Recently a molecular variant of fibrinogen (Uemichi *et al*. 1994) was found to be associated with hereditary renal amyloidosis, the first form of inherited amyloidosis to be described by Ostertag (1932). A variant of the bacteriolytic enzyme, lysozyme (a product of macrophages and polymorphs normally present in various body secretions), is the amyloid fibril protein found in cases of systemic amyloidosis with predominant renal effects (Pepys *et al*. 1993).

A variant of cystatin C, an enzyme inhibitor, is the fibril protein precursor in inherited cerebral haemorrhage with amyloidosis, Icelandic type (Ghiso *et al*. 1986). The cerebral vessels of members of a Dutch family with a similar clinical picture are affected by amyloid made up by the amyloid b-protein, a 42-amino acid fragment of a variant b-protein precursor (Levy *et al*. 1990). Amyloid b-protein derived from normal b-protein precursor (a cell membrane protein) makes up the cerebral amyloid in Alzheimer's disease and Down's syndrome (Glenner and Murphy 1989).

b_2-Microglobulin, which represents a part of class I histocompatibility molecules, makes up the fibrils in amyloidosis associated with long-term dialysis treatment for renal failure (Gejyo *et al*. 1985). b_2-Microglobulin-derived amyloid affects mainly structures of the locomotor system, like the carpal tunnel, joints, and bone, but systemic distribution is also seen (Kay 1993).

Several hormones are known to form amyloid. The first to be demonstrated was a calcitonin-like molecule in amyloid deposited locally in medullary carcinomas of the thyroid and their metastases (Sletten *et al*. 1976). Atrial natriuretic factor makes up amyloid in isolated atrial amyloidosis of the heart (Johansson *et al*. 1987), and islet amyloid polypeptide plays the same role in amyloid localized to the islets of Langerhans in association with diabetes type II and insulinomas (Westermark *et al*. 1986).

It is thus clear that amyloidosis is heterogeneous not only with respect to clinical expression and protein composition, but also to the functional aspect of the various amyloid precursors.

Pathogenesis

The mechanisms by which the various soluble precursor proteins are converted to insoluble protein aggregates with the unique morphology of amyloid fibrils, and are then deposited in the different target tissues, are not clarified. Also, the predilection of certain amyloid fibrils for particular tissues or organs, often distant from the cells actually producing the fibril protein precursor, remains a mystery.

It is generally accepted that the aetiology and pathogenesis of amyloidosis are multifactorial. Furthermore, the relative importance of the various amyloid-promoting factors may differ in the different types of amyloidosis. Best studied are the pathogenetic mechanisms in the reactive AA type of amyloidosis, as this type is readily induced in experimental animals, and spontaneous AA amyloidosis has been demonstrated in a variety of warm-blooded species, ranging from birds to primates (Husby 1989; Husby 1992).

Amyloidosis may be caused by amyloidogenic precursor protein present in excess amounts, either as a consequence of increased production or decreased clearance. AA amyloid is prevalent in those of the chronic inflammatory diseases that are known to stimulate the acute phase response and thereby production of serum amyloid-A protein (e.g. rheumatoid arthritis), but not in those that are not (e.g. scleroderma). However, AA amyloidosis affects only a minority of patients with rheumatoid arthritis, although most such patients have raised serum amyloid A (Husby 1992). Additional pathogenetic factors are obviously required. Serum amyloid A is polymorphic, which means that more than one gene codes for the protein. There is convincing experimental evidence that serum amyloid-A molecules (Table 2) genetically determined to have particular amyloidogenic structures are important in AA amyloidosis (Meek *et al*. 1986; Husby *et al*. 1994b). The same is probably the case in the inherited amyloidoses related to genetic variants of transthyretin, apo-AI, gelsolin, and b-protein precursor (Table 1).

In most instances, the different amyloid proteins comprise a smaller or larger fragment of their precursors, pointing to an incomplete degradation (Glenner 1980). Defective proteolysis may therefore be implicated in amyloidosis (Fuks and Zucker-Franklin 1985; Husby *et al*. 1994a; Husby *et al*. 1994b).

Amyloid-enhancing factor, a poorly defined material probably consisting of both protein and carbohydrate, is produced by reticuloendothelial cells during persistent inflammation (Hol *et al*. 1986; Kisilevski and Young 1994). This factor precedes the occurrence of amyloid in affected organs in experimental amyloidosis (Kisilevski and Young 1994) and has been shown to shorten the induction time of experimental amyloidosis from weeks to between 24 and 48 h.

Glycosaminoclycans occur in the tissues in close temporal and morphological relationship to amyloid deposition (Snow *et al*. 1987; Stenstad *et al*. 1994) and have been proposed to account for the carbohydrate moiety in amyloid-enhancing factor (Snow *et al*. 1987). The large negative charge of the glycosaminoglycans indicates an effect on the folding of precursor proteins to form fibrils (Snow *et al*. 1987). Glycosaminoglycans may also protect amyloid proteins or their precursors against proteolysis and stabilize the structure of the fibrils in the extracellular milieu. (Husby *et al*. 1994b).

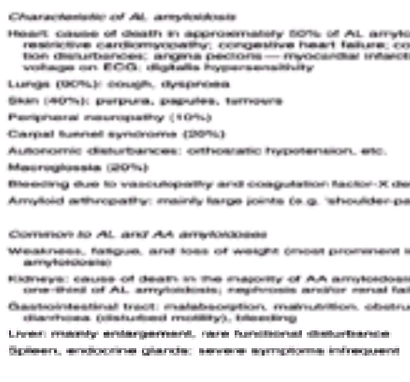
Protein AP, of which SAP is the precursor, is also invariably present in amyloid deposits as an extrafibrillar constituent (Pepys 1988). AP has also been thought to protect amyloid proteins against proteolysis (Husby *et al*. 1994b). A DNA polymorphic site, 5' to the SAP gene, was significantly associated with AA amyloidosis in juvenile rheumatoid arthritis, suggesting an active role in amyloidogenesis (Woo *et al*. 1987). Experiments in our laboratory (Husby *et al*. 1994b) strongly suggest a close interaction between the fibril proteins, glycosaminoglycans, and AP *in vivo*, often mediated by calcium-dependent bindings. Chemical manipulation of this may prove to have therapeutical implications in amyloidosis.

Clinical amyloidosis syndromes

A large number of partly overlapping amyloidosis syndromes have been described, and they have been difficult to classify by their clinical expression, although many attempts at this have been made during the last 150 years (Glenner 1980; Kyle 1982; Husby and Sletten 1986; Pepys 1988). The classification of amyloid and amyloidosis based on the nature of the fibril proteins (Table 1) is therefore of great help for clinical practice as well as scientific work (Husby 1994). Under the following headings, the most important amyloidosis syndromes are described in relation to their protein correlates.

Idiopathic and myeloma-associated AL amyloidosis

The mean age at diagnosis of AL amyloidosis is approximately 60 years. The organ distribution of amyloid is similar in idiopathic and myeloma-associated amyloidoses (Kyle 1982; Kyle *et al*. 1986). The most severe clinical features of AL amyloidosis are caused by accumulation of amyloid in the heart and kidneys (Kyle 1982; Janssen *et al*. 1986; Kyle *et al*. 1986; Stone 1990). Interstitial and vascular amyloidosis of the heart leads to congestive heart failure, conduction disturbances or angina pectoris, sometimes myocardial infarction, and causes about one-half of the deaths associated with this condition (Table 3). Decreased voltage on ECG is common. The patients are hypersensitive to digitalis, which, when given, may cause fatal arrhythmias. The extent of cardiac involvement is the most important predictor for survival in AL amyloidosis (Kyle *et al*. 1986).



Characteristic of AL amyloidosis
Heart: cause of death in approximately 50% of AL amyloidosis; restrictive cardiomyopathy; congestive heart failure; conduction disturbances; angina pectoris — myocardial infarction; low voltage on ECG; digitalis hypersensitivity
Lungs (90%): cough, dyspnoea
Skin (40%): purpura, papules, tumours
Peripheral neuropathy (10%)
Carpal tunnel syndrome (20%)
Autonomic disturbances: orthostatic hypotension, etc.
Macroglossia (20%)
Bleeding due to vasculopathy and coagulation factor-X deficiency
Amyloid arthropathy: mainly large joints (e.g. 'shoulder-pad sign')

Common to AL and AA amyloidoses
Weakness, fatigue, and loss of weight (most prominent in AL amyloidosis)
Kidneys: cause of death in the majority of AA amyloidosis and in one-third of AL amyloidosis; nephrosis and/or renal failure
Gastrointestinal tract: malabsorption, malnutrition, obstruction, diarrhoea (disturbed motility), bleeding
Liver: mostly enlargement, rare functional disturbances
Spleen, endocrine glands: severe symptoms infrequent

Table 3 Clinical features of AL and AA amyloidoses

Glomerular and vascular amyloidosis of the kidneys with consequent nephrosis and/or renal failure causes one-third of the deaths. Pulmonary amyloidosis with cough and dyspnoea is common. Amyloidosis of the skin with purpura, amyloid papules, or tumours is seen in nearly one-half of the patients. Some patients develop peripheral neuropathy (10 per cent) and carpal tunnel syndrome (20 per cent) in addition to autonomic disturbances, for example orthostatic hypotension (Kyle 1982).

Characteristic, but not so common features of AL amyloidosis are macroglossia, seen in 20 per cent of the patients, and amyloid arthropathy affecting mainly large joints. The 'shoulder pad sign' due to amyloid infiltration of the shoulder joint (Fig. 1) is almost pathognomonic. Purpura is a frequent and characteristic finding (Fig. 1). The coagulation factor-X deficiency seen in AL amyloidosis appears to be due to the high affinity of AL-type fibrils for factor X, which may therefore be trapped in the amyloid substance (Furie *et al*. 1981). Together with increased fibrinolysis and amyloid infiltration of the blood vessels, the factor-X deficiency may lead to severe haemorrhages (Kyle 1982).

Fig. 1 (a) Amyloidosis with purpura around the eyelids, lips, and anterior thorax. Macroglossia with inability to close the mouth and amyloid arthropathy with bilateral shoulder pad sign are also present. (Reprinted from the Revised Clinical Collection on the Rheumatic Diseases 1981; used by permission of the American College of Rheumatology). (b) A 14-year-old girl suffering from severe, seropositive juvenile chronic arthritis with onset at 5 years of age, complicated by AA amyloidosis verified by rectal biopsy 6 years later. The clinical picture is dominated by malabsorption and gastrointestinal bleeds with severe weight loss, anaemia, renal failure, hepatosplenomegaly, hormonal disturbances with dwarfism/infantilism, and severe polyarthritis. These manifestations are caused by the underlying arthritic disorder, its treatment with corticosterioids and cytotoxic drugs, and the systemic AA amyloidosis.

Gastrointestinal amyloidosis may be associated with malabsorption, malnutrition, obstruction, diarrhoea (disturbed motility), and bleeding. Amyloidosis of the liver causes enlargement rather than functional disturbances. Amyloid is often present in the spleen, lymph nodes, and endocrine glands but severe symptoms are infrequent.

Localized, so-called tumour-forming, AL has been reported to be present in various organs, of which the respiratory and genitourinary tracts and the skin are most frequent (Husby 1992).

The patients with idiopathic AL amyloidosis regularly have increased numbers of plasma cells in the bone marrow; M components in serum and Bence-Jones proteinuria are also frequent findings, illustrating that this disorder belongs to the immunocyte dyscrasias with the same basic pathogenetic mechanisms as myelomatosis. The major difference between them is that the osteolytic lesions of myelomatosis are not present in idiopathic AL amyloidosis. Another difference is that the k to l ratio, which is approximately 2:1 in myelomatosis, is reversed (1:2) in AL amyloidosis, thus reflecting the greater amyloidogenic potential of l-light chains (Husby and Sletten 1986).

Reactive AA amyloidosis

Reactive AA amyloidosis is mainly associated with long-standing infectious or non-infectious inflammation, and less frequently with cancer, mainly renal cell carcinoma or Hodgkin's disease (Husby 1992). In areas where the incidence of chronic infections like tuberculosis and leprosy has declined, reactive amyloidosis is mostly caused by chronic rheumatic diseases, mainly adult rheumatoid arthritis and juvenile chronic arthritis, and ankylosing spondylitis, with frequencies in living patients of about 3 to 10 per cent, and by occasional cases of Reiter's disease and psoriatic arthropathy (Husby 1985). AA amyloidosis is also seen in some cases of Crohn's disease. Interestingly, this form of amyloidosis is extremely rare in systemic autoimmune rheumatic diseases like systemic lupus erythematosus, dermatomyositis, systemic sclerosis, and Sjögren's syndrome, and these diseases are associated with minimal acute-phase protein responses and hence low concentrations of serum amyloid A.

A marked geographic difference in the prevalence of AA amyloidosis in juvenile chronic arthritis, high (5 to 10 per cent) in European countries and low (0.1 per cent) in the United States, has been attributed to a more frequent occurrence of urinary tract infections caused by *Escherichia coli* in Europe (Filipowicz-Sosnowska *et al*. 1978). *E. coli* endotoxin is a highly potent inducer of the acute phase response as well as of experimental amyloidosis.

Arthritic patients with highly systemic disease are more prone to develop amyloidosis than those with milder disease; however, it is hard to predict individual cases at risk (Husby 1985). HLA studies have failed to disclosed markers for reactive amyloidosis.

Amyloid of the AA type has a tendency to localize in small vessels and parenchymal organs (Table 3). Renal disease (Fig. 2), often with the nephrotic syndrome and/or renal failure, is the chief manifestation and the major cause of death. In a series of 189 patients with rheumatoid arthritis and AA amyloidosis reported by

Wegelius *et al*. (1980) only seven (3.7 per cent) lacked demonstrable clinical signs of renal involvement, and all patients with juvenile chronic arthritis in a series of 51 who developed amyloidosis had proteinuria at the time of diagnosis (Schnitzer and Ansell 1977). Proteinuria in rheumatoid arthritis should always be associated with possible amyloidosis until its cause is eventually disclosed. Haematuria occurs, but less often. Hypertension is uncommon in adult-onset rheumatoid arthritis with amyloidosis, but is found in about half of the patients with amyloidosis associated with juvenile chronic arthritis (Schnitzer and Ansell 1977; Woo 1994). Renal vein thrombosis is frequently found at autopsy.

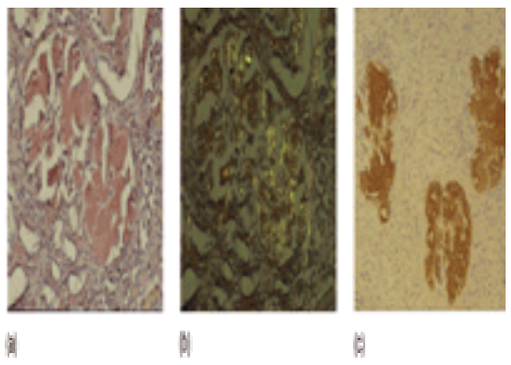


Fig. 2 Renal AA amyloidosis: (a)light microscopy of Congo red-stained glomerular amyloid (original magnification, × 160); (b) polarization microscopy of the same view field revealing the typical green/yellow birefringence of amyloid (× 160); (c) glomerular AA amyloid stained with peroxidase-labelled antiserum to protein AA and examined by light microscopy—no staining was obtained with antisera to other amyloid proteins (× 160).

Infiltration of blood vessels by amyloid, particularly in the gastrointestinal tract, can result in severe bleeding, sometimes life threatening, and malabsorption. AA amyloidosis of the liver is frequent and causes organ enlargement rather than functional disturbance. This type of amyloid may also affect the spleen, endocrine glands, and heart, but without causing severe symptoms. Interestingly, amyloid arthropathy and carpal tunnel syndrome are not features of AA amyloidosis, but are characteristic of both AL and b_2-microglobulin-associated amyloidoses.

No routine laboratory test (except biopsy) can distinguish between arthritic patients with and without AA amyloidosis. The high affinity of protein SAP for amyloid fibrils has recently been utilized in the diagnosis of AS and other systemic amyloidoses for research purposes. Radiolabelled SAP injected intravenously produces scintigraphic images quite accurately demonstrating the distrbution of amyloid *in vivo* (Hawkins 1994). So far, this procedure has been used for research purposes.

Familial Mediterranean fever with AA amyloidosis (see Chapter 5.13.2)

Amyloidosis associated with familial Mediterranean fever is the only form of systemic amyloidosis known to be inherited largely as a recessive trait (Pras 1986). Like other forms of AA amyloidosis, nephropathy is the most important feature and a significant cause of death. Familial Mediterranean fever itself is characterized by attacks of fever, peritonitis, pleuritis, and synovitis with onset during childhood, affecting mainly Sephardic Jews, Anatolian Turks, and Armenians with origin in the Mediterranean area. The prevalence as well as the disease course of amyloidosis in Mediterranean fever are highly heterogeneous in the different ethnic groups (Pras 1986). It appears that the febrile attacks and amyloidosis are inherited independently, and marked heterogeneity with regard to the serum amyloid-A genes has also been observed among patients with this fever syndrome (Sack 1988). A substitution of threonine for phenylalanine at position 69 of amyloid protein A involving all three bases of the codon has been observed in one case of amyloidosis in familial Mediterranean fever (Levin *et al*. 1972), but not confirmed in others.

The causal gene for familial Mediterranean fever has been located to the short arm of chromosome 16 (Pras *et al*. 1992), apparently not related to the human SAA gene family on chromosome 11 (Husby *et al*. 1990), and there is no link between this gene locus and that coding for human SAA present on chromosome 11 (Husby *et al*. 1994b)

Inherited autosomal-dominant amyloidosis

Point mutations causing single amino-acid substitutions in various amyloid protein precursors are associated with a heterogeneous group of familial amyloidoses inherited as autosomal dominants (Table 1) (Benson and Wallace 1989; Glenner and Murphy 1989). The majority of cases are related to different genetic variants of transthyretin. Neuropathy, cardiopathy, nephropathy, and vitreous opacities are the most important clinical problems and occur in a variety of combinations, but also as more or less single clinical entities. Amyloid made up by genetic variants of other proteins (Table 1) may show similar clinical characteristics in addition to causing cerebral amyloid angiopathy and lattice corneal dystrophy. Some examples of inherited, autosomal-dominant amyloidoses, the geographic origin, and protein correlations are listed next (the syndromes are described in more detail by Glenner and Murphy (1989) and Benson (1991)):

1. familial amyloid polyneuropathy related to transthyretin–methionine 30—Portuguese, Swedish, Japanese, and others (Andrade 1952);
2. familial amyloid polyneuropathy, transthyretin–serine 84—Indiana/Swiss, Maryland/German (Benson and Wallace 1989);
3. familial amyloid polyneuropathy, transthyretin–histidine 58—Maryland/German (Nichols *et al*. 1989);
4. familial amyloid cardiomyopathy and neuropathy, transthyretin–alanine 60—Appalachian Indians, (Benson and Wallace 1989);
5. familial amyloid cardiomyopathy (Fig. 3), transthyretin–methionine 111—Danish (Frederiksen *et al*. 1962; Nordlie *et al*. 1988; Nordvåg *et al*. 1992);

Fig. 3 Cardiac amyloidosis. Polarization microscopy of amyloid-laden myocardium stained with Congo red from a patient with transthyretin–methionine 111 familial amyloid cardiomyopathy of Danish origin; massive infiltration of green birefringent amyloid displacing muscle cells is seen (× 250).

6. familial amyloid polyneuropathy, apolipoprotein AI–arginine 26—Iowa (Nichols *et al*. 1988);
7. familial amyloidosis with lattice corneal dystrophy, gelsoline–aspartic acid 187—Finnish (Meretoja 1969; Maury 1990a);
8. hereditary cerebral haemorrhage with amyloidosis, cystatin C–glutamic acid 58—Icelandic (Ghiso *et al*. 1986) and amyloid b-protein–glutamic acid 618—Dutch (Levy *et al*. 1990);
9. the Muckle–Well's syndrome (nephropathy, nerve deafness, and urticaria) related to amyloid protein A (Muckle 1979; Linke *et al*. 1983);
10. hereditary, non-neuropathic systemic amyloidosis with predominant renal involvement (Ostertag 1932) is related to various substitutions in apolipoprotein A1 (Soutar *et al*. 1992), lysozyme (Pepys *et al*. 1993), or the a-chain of fibrinogen (Table 1)—south or north America, the latter being of Irish or Scandinavian descent (Uemichi *et al*. 1994).

Alzheimer's disease

The presenile dementia described by Alzheimer is probably the most common form of amyloidosis (Glenner and Murphy 1989). Amyloid is deposited extracellularly as

Alzheimer's plaques and in the wall of cerebral vessels; even the intraneuronal neurofibrillary tangles are made up by paired helical filaments with the typical b-pleated sheet characteristic of amyloid. The amyloid b-protein in Alzheimer's disease derives from the b-protein precursor whose gene resides on chromosome 21.

The same manifestations of cerebral amyloid composed of the amyloid b-protein is seen in people with Down's syndrome over 40 years of age (Glenner and Murphy 1989). Down's syndrome is associated with trisomy of chromosome 21, and it is conceivable that this leads to an overproduction of b-protein precursor. Altered processing of the amyloid b-protein precursor has been proposed as a pathogenetic factor, and genetic variants of the protein are associated with familial occurrence of Alzheimer's disease. Another risk factor is the type 4 allele of apolipoprotein E (Corder *et al*. 1993). The same type of amyloid is occasionally seen in senile dementia (Glenner and Murphy 1989).

Organ manifestations

Heart

Cardiac amyloidosis manifesting mainly as cardiomyopathy, but also with conduction disturbances and coronary heart disease (Table 3), is a particularly severe manifestation of AL (Kyle 1982; Husby 1983; Janssen *et al*. 1986) and certain forms of inherited amyloidosis (Benson and Wallace 1989). Among the last, the Danish transthyretin–methionine 111 (Nordlie *et al*. 1988) and the Appalachian transthyretin–alanine 60 (Benson and Wallace 1989) are the most important forms (Fig. 3). Cardiac amyloidosis is also a major manifestation of senile systemic amyloidosis related to normal transthyretin (Westermark *et al*. 1990), and senile isolated atrial amyloidosis related to the polypeptide-hormone atrial natriuretic factor (Johansson *et al*. 1987). In general the senile cardiac amyloidoses are benign. AA amyloidosis of the heart localizes mainly to the vasculature without causing major problems.

The respiratory tract

Amyloid may be deposited in any part of the respiratory system, from the nasal cavity to the pulmonary parenchyma and hilar glands. The clinical consequences are most severe in AL amyloidosis (Kyle 1982). Localized (nodular) AL amyloidosis is quite frequent and has a much more favourable prognosis, but may sometimes require surgical removal (Glenner 1980; Husby 1983).

Kidney and urinary tract

The most severe manifestation is renal amyloidosis, the major cause of death in AA amyloidosis (Glenner 1980; Husby 1985; Woo 1994), and frequently also in AL and hereditary amyloidoses related to variants of transthyretin and apo-AI (Glenner 1980; Kyle 1982; Glenner and Murphy 1989). Affected patients present with proteinuria and/or nephrotic syndrome, and frequently develop fatal renal failure. Hypertension and haematuria are less common. Renal biopsy reveals deposition of amyloid in glomeruli, in addition to its peritubular, vascular, and interstitial localization (Fig. 2).

The gastrointestinal tract

The entire gastrointestinal tract is a common target of amyloid deposition, making it an accepted site for diagnosis biopsy (Fig. 4). Intestinal amyloid causes motility disturbances with diarrhoea or constipation, malabsorption, bleeds, and perforation (Table 3) (Glenner 1980; Kyle 1982; Husby 1992). Nutritional disturbance due to macroglossia in AL amyloidosis (Fig. 1) or altered intestinal motility in the inherited neuropathies are quite common causes of death. Fatal gastrointestinal bleeds due to AA amyloidosis has been observed in several patients with rheumatic disease (Husby 1985).

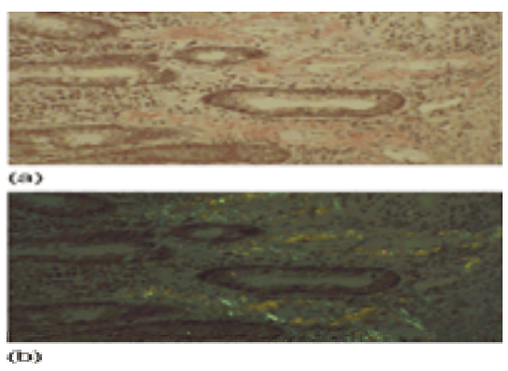

Fig. 4 Light (a) and polarization (b) microscopy of a Congo red-stained section from a rectal biopsy containing vascular and interstitial amyloid in the submucosal layer (× 160). (Photomicrographs kindly provided by Dr Michael Kearney, Tromsø, Norway.)

The endocrine system

Fibrils made up by hormone-related or -derived polypeptides are seen locally in some endocrine tumours. Calcitonin-related amyloid in medullary carcinoma of the thyroid and islet amyloid polypeptide in diabetes type II and insulinomas are best known (Table 1). Endocrine glands are also affected by systemic AA and AL amyloidoses (Husby 1992).

Skin

Amyloid deposits are generally present in subcutaneous fat in both AL and AA, as well as inherited systemic amyloidoses, and thin-needle aspirates of abdominal fat (Fig. 5) have become a useful material for histological diagnosis (Westermark and Stenkvist 1973). In addition, cutaneous amyloid is a common feature of AL amyloidosis in the form of papules, nodules, or purpura (Kyle 1982). The skin is also the site of localized amyloid, e.g. lichen amyloidosus (Black 1976).

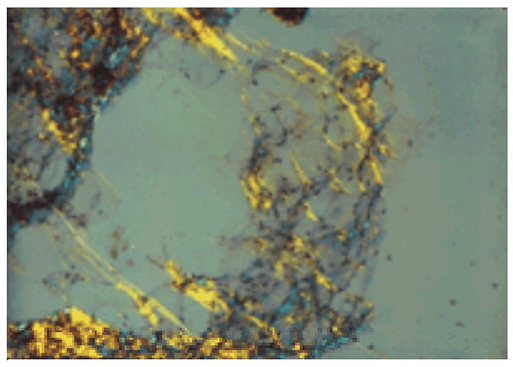

Fig. 5 Polarization microscopy of a subcutaneous, abdominal fat stained with Congo red showing marked deposition of amyloid compatible with the diagnosis of systemic amyloidosis. (Photomicrograph kindly provided by Professor Per Westermark, Linköping, Sweden.)

The locomotor system

The deposition of amyloid in the locomotor system is perhaps most common in b_2-microglobulin-related amyloidosis affecting patients on long-term dialysis for renal failure, who develop carpal tunnel syndrome, arthropathy, and cystic bone lesions, sometimes with pathological fractures, particularly when dialysed for more than 8 years. Ordinary haemodialysis is not able to remove b_2-microglobulin from plasma. Patients with this form of amyloidosis reportedly have abnormally glycosylated b_2-microglobulin capable of inducing inflammation with expression of cytokines and collagenase, which may contribute to destruction of bone and connective tissue (Miyata *et al*. 1994). Although b_2-microglobulin related amyloidosis is undoubtedly of systemic nature, structures of the locomotor system are of marked predilection for amyloid deposition in these patients (Maury 1990b; Kay 1993).

Characteristic of AL amyloidosis, though not so frequent, are the carpal tunnel syndrome (20 per cent), peripheral neuropathy (10 per cent), arthropathy (Fig. 1), or myopathy (less than 5 per cent) (Kyle 1982; Husby 1983). Another infrequent complaint is jaw claudication, which should be considered in the differential diagnosis of temporal arthritis/polymyalgia rheumatica (Gertz *et al*. 1986).

Erosive arthritis occurs in some patients with hereditary amyloidosis, i.e. of the Indiana and Iowa kindreds (Benson and Wallace 1989).

As amyloid arthropathy often has an inflammatory appearance, it may mistakenly be diagnosed as a rheumatic disorder. However, the joint fluid is generally non-inflammatory, sometimes with amyloid-containing synovial debris (Husby 1983).

Localized 'microdeposits' of amyloid in structures of the locomotor system occur with increasing frequency in aged people, mostly in menisci of the knee, joint capsules, and intervertebral discs, sometimes associated with the deposition of calcium pyrophosphate or with osteoarthrosis. The clinical significance of such amyloids, which possibly originate from local tissue proteins, is not clear (Husby and Sletten 1986).

Inclusion body myositis is a subset of chronic polymyositis characterized by muscle fibres with inclusion bodies containing amyloid fibrils. Very interestingly, the same b_2-amyloid protein as that seen in Alzheimer's disease and its precursor have recently been demonstrated to be constituents of these intramuscular amyloid deposits. This shows that b-amyloid can accumulate also outside the central nervous system. (For review see Askanas and Engel 1993)

Diagnosis

The diagnosis of amyloidosis is based on the demonstration of tissue deposits of amyloid. An absolute prerequisite for diagnosis is therefore that the clinician suspects amyloidosis in relevant clinical states. It is a regrettable fact, however, that the diagnosis of amyloidosis is far too often missed during life and is not evident until autopsy. The clinician should realize that AL amyloidosis may occur without an underlying predisposing disorder or in association with monoclonal gammopathies; that rheumatic disorders, long-standing or recurrent infections, and certain malignancies predispose for reactive, AA amyloidosis; and that a family history of amyloidosis may point to inherited disease. Unexplained manifestations that should alert the clinician to consider amyloidosis are: loss of weight (Fig. 1(a) and (b)), fatigue, proteinuria with or without renal failure, restrictive cardiomyopathy, gastrointestinal or respiratory problems, hepatomegaly, cutaneous conditions including purpura, and neuropathy/carpal tunnel syndrome.

It is established that rectal tissue (Fig. 4) which includes the submucosal vessels is a highly representative biopsy in systemic amyloidosis (Husby 1985). There may be bleeding after this procedure, but severe blood loss is infrequent.

In recent years, needle aspirates of abdominal subcutaneous fat (Fig. 5), which are less invasive than rectal biopsy, have increasingly been used for diagnosis (Westermark and Stenkvist 1973). Affected or suspected organs or tissues in the actual case under examination, such as kidneys (Fig. 2), liver, spleen, peripheral nerves, or skin, may be appropriate sites of biopsy but the risk of complications must be considered.

The amyloid carpal tunnel syndrome may be the initial finding in systemic amyloidoses. All tissues removed at surgery for carpal tunnel syndrome should therefore be examined for the presence of amyloid.

Examination of alkaline Congo red-stained tissue sections or aspirated fat smears in a polarizing microscope revealing the apple-green/yellow birefringence characteristic of amyloid deposits is the histochemical method of choice (see Fig. 2,Fig. 3,Fig. 4, and Fig. 5) (Glenner 1980; Kyle 1982; Hawkins 1994). Immunohistochemical methods with specific antisera to classify the various amyloid fibril proteins (Fig. 2) are increasingly used, but are not available for routine diagnostic purposes. Electron microscopy may confirm the diagnosis.

The strong calcium-dependent affinity of protein AP/SAP for amyloid fibrils of any protein type can be utilized diagnostically (Hawkins 1994). Radiolabelled SAP injected intravenously will rapidly and specifically localize to the amyloid deposits to yield high resolution scintigraphic images. This technique is currently at the experimental stage in humans, but is a highly promising diagnostic measure in clinical practice.

Other laboratory tests include analysis of DNA or its protein product to detect genetic variants of proteins known to make up amyloid in the hereditary amyloidoses (Benson and Wallace 1989; Nordvåg *et al*. 1992). Indeed, the use of restriction fragment-length polymorphism combined with *in vitro* amplification of genes using polymerase chain reaction is an extremely sensitive tool for detecting gene carriers and thereby individuals at risk—even before birth (Nichols *et al*. 1989; Nordvåg *et al*. 1992).

Radionuclide imaging using calcium-seeking isotopes, for example $^{99}Tc^{m}$, echocardiography, bone marrow examination, and demonstration of monoclonal immunoglobulins in serum or urine are examples of laboratory methods used in the clinical work-up of patients with amyloidosis (Hazenberg and van Rijswijk 1994).

Therapeutic aspects

In general, amyloidosis is a progressive disease for which there is no cure. As the aetiology and pathogenesis are multifactorial, there are problems with therapy. Prospective, controlled studies of intervention are sparse. The marked prognostic heterogeneity of patients with hereditary amyloidosis makes genetic counselling difficult (Sequeiros and Saraiva 1987). With these problems in mind, the following therapeutic approaches are suggested:

1. reduce the availability of precursor protein to prevent or slow down amyloid formation;
2. attempts at dissolving amyloid deposits *in vivo*;
3. treatment directed towards affected organs.

These are now considered in more detail.

Reduction of amyloid precursor

In reactive AA amyloidosis the synthesis of the precursor serum amyloid A can be reduced by turning down the stimulated hepatic production of acute phase proteins (Husby 1992). This is achieved by effective treatment of the underlying inflammatory or neoplastic disorder, whenever possible. In the face of the poor prognosis of amyloidosis, rather drastic therapeutic intervention may be considered. Cytotoxic drugs have convincingly been shown to improve the prognosis of amyloidosis associated with both adult rheumatoid arthritis (Ahlmen *et al*. 1987; Berglund *et al*. 1993) and juvenile chronic arthritis (Fig. 6) (Woo 1994). Any use of cytotoxic drugs must, however, be weighed against the risk of potentially hazardous adverse effects such as leukaemia. Treatment of familial Mediterranean fever with colchicine prevents the occurrence of febrile attacks as well as AA amyloidosis, and is also effective in the treatment of established amyloidosis in such patients (Zemer *et al*. 1986). A recent review of the literature (Livneh *et al*. 1993) also concluded that colchicine may be added to any therapeutic regimen of AL or AA amyloidosis.

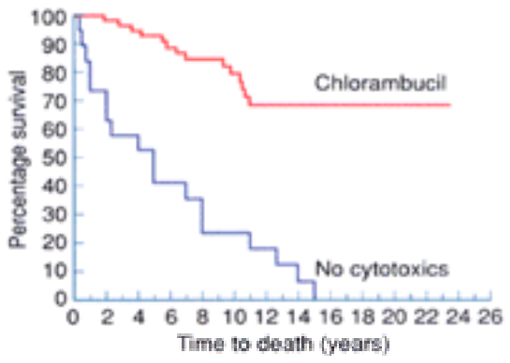

Fig. 6 Survival of juvenile chronic arthritis with amyloidosis with and without treatment using the cytotoxic drug chlorambucil. Although historical controls are used, the markedly improved survival strongly indicates that this can be attributed to treatment. (From Woo (1990) with kind permission from author, editors, and publisher.)

In controlled trials, treatment with the cytotoxic drug melphalan in combination with corticosteroids has been shown (Kyle *et al*. 1990) to improve the symptoms and signs, and possibly also survival, in AL amyloidosis. Studies using historical controls shows that colchicine may exert some additional effect on AL amyloidosis when combined with melphalan and prednisolone (Cohen *et al*. 1987; Kyle *et al*. 1990; Gertz *et al*. 1991). These treatments are thought to work by reducing the number of cells producing the monoclonal immunoglobulin light-chain precursor of amyloid, or to hamper their protein production or secretion. High-dose cytotoxic drugs in combination with stem cell transfusion appears promising (Majolino *et al*. 1993).

A diet where the only source of fat was fish oil high in w-3 polyunsaturated fatty acids has been shown to retard the progression of azocasein-induced AA amyloidoses in mice (Cathcart *et al*. 1987). As fish-oil diets may also suppress the activity of chronic inflammation, a prophylactic or retardant effect on human AA amyloidosis associated with arthritis is an interesting possibility.

Plasmapheresis has been tried in those amyloidoses related to genetic variants of transthyretin, but without documented effect. Of more interest are the recently performed liver transplantations in such patients, which remove the site of production of the variant transthyretin and replace it by a liver harbouring only normal transthyretin genes (Holmgren *et al*. 1993).

Renal transplantation improves the articular complaints and retards the development of amyloid bone cysts in b $_2$-microglobulin-associated amyloidosis (Jadoul *et al*. 1989). A restoration of the normal clearance of b$_2$-microglobulin may explain the therapeutic effect.

***Dissolution of amyloid deposits* in vivo**

Dimethyl sulphoxide partially dissolves amyloid fibrils *in vitro*, and treatment of amyloidotic mice with this compound reduces the amount of amyloid (Isobe and Osserman 1976). It has therefore been tried in the treatment of human AA, AL, and transthyretin-related amyloidoses. A beneficial effect has been reported in occasional patients (Hazenberg and van Rijswijk 1994), but there are no reports of controlled studies. Many patients refuse to take dimethyl sulphoxide because it gives a bad body odour.

Organ-directed therapy

Renal transplantation is increasingly used in amyloid nephropathy, particularly of AA background (Stone 1990). A series of patients had increased survival as well as improvement of quality of life (Hartmann *et al*. 1992). Although the results of renal transplantation are not as good as in non-amyloid nephropathies, more patients should probably be given the chance to receive renal transplant also in AL, transthyretin, and b $_2$-microglobulin-associated amyloidoses (Kay 1993).

The effect of heart transplantation for amyloidosis have been reported in a few patients, most of them with AL type (see Stone 1990); five of six such patients were reportedly alive 21 plus or minus 12 months after transplantation.

Other therapeutic considerations

Patients with cardiac amyloid may have increased sensitivity to digitalis, and calcium-channel blocking agents may aggravate heart failure in such patients. Amyloid appears to bind such agents *in vitro* and possibly also *in vivo* (Stone 1990), and they should be used with caution in amyloidosis patients.

Comprehensive reviews of the clinical and therapeutic aspects of adult (Hazenberg and van Rijswijk 1994) and childhood amyloidoses (Woo 1994) of particular interest in rheumatology have recently been published.

Prognosis

The prognosis of amyloidosis depends on the localization and progress of the tissue deposition of amyloid. Survival time is largely dependent on the time of diagnosis, which varies significantly. It is clear, however, that systemic amyloidosis must be regarded as a severe condition with a high risk of death. AA amyloidosis has been estimated to be the cause of up to 47 per cent of deaths in European patients with juvenile chronic arthritis (Baum and Gutowska 1977). A Finnish report concluded that amyloidosis was the cause of death in 8 per cent of patients with adult rheumatoid arthritis coming to autopsy (Koota *et al*. 1975). On the other hand, the outcome of reactive AA amyloidosis is more favourable than many physicians have previously thought. Reports from Finland and the United States indicate that survival time after diagnosis of amyloidosis associated with rheumatoid arthritis is 4 to 5 years (Wegelius *et al*. 1980; Kyle 1982). In juvenile chronic arthritis with amyloidosis, survival may be even better when treated with cytotoxic drugs for 8 to 9 years (Baum and Gutowska 1977; Schnitzer and Ansell 1977) or longer (Fig. 6) (Woo 1990). There is a large individual variation in survival time for AA amyloidosis, in one report (Tribe *et al*. 1980) ranging from a few weeks up to 20 years.

The prognosis of AL amyloidosis is less favourable. Reported survival rates are less than 2 years for idiopathic type, and 7 months or even less in AL amyloidosis with myeloma (Janssen *et al*. 1986; Kyle 1990). Again, there is a wide range in survival time of individual patients, from weeks up to 5 years or more (Kyle *et al*. 1986). Cardiac amyloid is the most common cause of death and the major determinant of prognosis among patients with AL (Kyle 1990). Urinary excretion of monoclonal l-light chains is associated with inferior survival in AL amyloidosis compared with monoclonal k-chains or no monoclonal protein (Gertz and Kyle 1990)

In the hereditary amyloid polyneuropathies and cardiomyopathies related to variants of transthyretin, there are also wide variations in the course and prognosis among the different affected families as well as between individual gene carriers in the same families. Some patients may die with cachexia before the age of 40 years, whereas others may be in good health at 90 years (Sequeiros and Saraiva 1987).

5.13.2 Familial Mediterranean fever

Pnina Langevitz and Avi Livneh and Deborah Zemer and Mordechai Pras

History

A genetic disease with a gene frequency as high as that of familial Mediterranean fever in Sephardi Jews must have existed for hundreds or thousands of years. Nevertheless, in the first half of the twentieth century only a few isolated characteristic cases could be traced in medical publications (Janeway and Mosenthal 1908; Alt and Barker 1930). The reason why a disease with such dramatic manifestations has only recently been recognized may be connected with the geographical distribution of its sufferers, who resided mainly in areas where modern medical facilities were not available at the time. This changed in the 1940s and 1950s when the population affected became exposed to advanced medical facilities and research, partly due to migrations.

Siegal (1945) was the first to describe the abdominal attacks as a separate disease entity. Later, many typical cases were included in the heterogeneous case collection termed 'periodic disease'1 by Reimann (1949). French physicians described many typical cases of familial Mediterranean fever in Jewish patients deriving from North Africa (Mamou and Cattan 1952; Siguier *et al*. 1953; Benhamou *et al*. 1954). They were the first to perceive the familial nature and the fatal renal lesion of the disease.

Tel Hashomer Hospital in Israel served in the early 1950s as a referral centre for the new immigrants who came mainly from Mediterranean countries. Enigmatic cases who appeared on the wards with recurrent, short-lived episodes of fever accompanied by peritoneal, pleural, or arthritic inflammation caught the attention of the group led by Professor Harry Heller. In a series of publications (Heller *et al*. 1958; Heller *et al*. 1961a; Heller *et al*. 1961b; Sohar *et al*. 1961; Sohar *et al*. 1967) they defined the clinical features of the disease and its diagnostic criteria, established its genetic nature, mode of transmission, and ethnic distribution, emphasized the role of amyloidosis, and coined the name 'familial Mediterranean fever'.

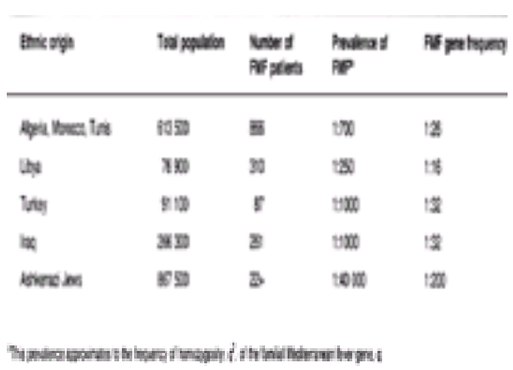
Diagnostic criteria

Despite many attempts at elucidation in the last 35 years the mechanisms leading to the clinical manifestations of the disease are still unknown, as is the underlying basic error of metabolism and the location of the gene. There is no specific diagnostic laboratory test. The diagnostic criteria are based on clinical manifestations.

1. Short attacks of fever recurring at irregular intervals. In most cases the temperature rises to 39–40°C.
2. Painful inflammatory manifestations in the abdomen, chest, joints, or skin, associated with the fever.
3. Nephropathic amyloidosis leading to terminal renal failure early in life.
4. Autosomal-recessive inheritance.
5. Virtual ethnic restriction to Mediterranean stock (Sephardi Jews, Armenians, Anatolian Turks, Arabs, and Ashkenazi Jews).
6. Dramatic response to continuous colchicine treatment in abolishing or reducing febrile attacks.

The inheritance of familial Mediterranean fever

The disease may become manifest as early as during the first year of life, although in most cases onset is later. In two-thirds of our patients the first manifestations appeared during the first decade of life; by the end of the second decade 90 per cent are affected. Only rarely is the onset delayed beyond the age of 40 (Sohar *et al*. 1967). Among our 4000 patients there are only about 100 Ashkenazi Jews and the disease is rare in other Jewish ethnic groups (Yemenite and Iranian). Table 1 shows the prevalence and gene frequency of familial Mediterranean fever, calculated by the number of patients and the size of the total population in each ethnic subgroup.



Ethnic origin	Total population	Number of FMF patients	Prevalence of FMF*	FMF gene frequency
Algeria, Morocco, Tunis	613 500	888	1:700	1:26
Libya	78 900	310	1:250	1:16
Turkey	91 100	87	1:1000	1:32
Iraq	266 300	261	1:1000	1:32
Ashkenazi Jews	867 500	25+	1:40 000	1:200

*The prevalence approximates to the frequency of homozygosity (q^2) of the familial Mediterranean fever gene, q.

Table 1 Prevalence and gene frequency of familial Mediterranean fever (FMF)

The peculiar ethnic restriction and the familial aggregation in familial Mediterranean fever suggests a genetic aetiology. Analysis of 229 of our families led us to conclude that the disease is due to a single, recessive autosomal gene (Sohar *et al*. 1967).

In about 90 affected families, out of several hundreds, the disease occurred in more than one generation. Although in most of these families the inheritance could be considered to be autosomal-recessive, in two the transmission could not be explained by recessive inheritance and must be assumed to be dominant (Yuval *et al*. 1995).

The clinical picture

Attacks

The febrile, painful attacks that are the hallmark of the disease are characterized by marked elevation of body temperature, acute inflammation of the peritoneum, synovia, or pleura, a duration of 12 to 48 h, and complete health between attacks (Sohar *et al*. 1967).

Repeated attacks at irregular intervals and in an unpredictable sequence are typical of the disease: periods of one febrile attack a week can vary with remissions of

weeks, months, or even years, with no apparent cause. During the illness a patient will probably encounter several forms of attacks, but the recurrence of one type over many years is not uncommon.

The most frequent manifestation is the abdominal attack, experienced by 90 per cent of patients; in 68 per cent of these it is the presenting sign. As the most dramatic manifestation, these attacks attract attention and extensive diagnostic efforts (Sohar *et al*. 1967). They are marked by the sudden onset of fever (often with chills) and pain spreading over the entire abdomen from variable points of origin. As the attack gains in intensity, guarding, rebound tenderness, board-like rigidity, distension, and absence of peristalsis appear. Multiple, small fluid levels in the small bowel on radiography combine to suggest an acute abdominal catastrophe. After 6 to 12 h the signs and symptoms recede, and within 24 to 48 h the attack is usually over, leaving the patient as well as before.

Organization of the exudate may result in fibrous adhesions, which in rare cases may give rise to mechanical ileus (Michaeli *et al*. 1966). This may be responsible for chronic subileus in some patients and ascites in others (Zemer *et al*. 1977). It is probably the cause of sterility in some affected women (Ismachovich *et al*. 1973).

The pleural attack has been experienced by 45 per cent of our patients, and in 5 per cent it was the presenting sign (Sohar *et al*. 1967). It assumes the picture of an acute febrile pleuritis, resembling the peritoneal attacks in its abrupt onset, rapid resolution, and unpredictable recurrence. The pleuritic attack may be limited to the chest or may shift to the abdomen. Breathing is painful and breath sounds are diminished on the affected side. There may be radiological evidence of a small exudate in the costophrenic angle, which is difficult to aspirate and which resolves within 48 h. No sequelae of clinical significance have been noted.

Pericarditis is a rare feature of familial Mediterranean fever. We observed clinical attacks of pericarditis in 20 of our patients (A. Livneh, unpublished data). On M-mode echocardiography, pericardial involvement was reported to be more common than in the general population (Dabestani *et al*. 1982). No permanent sequelae have been reported.

The articular attack is the second most common form of attack. It was experienced by 75 per cent of the patients in our series, and was the presenting symptom in 16 per cent of them. Arthritic attacks may recur for years as the only feature of the disease, before other forms appear (Sohar *et al*. 1967).

As a rule, large joints are involved, particularly those of the lower extremities. Arthritic attacks of familial Mediterranean fever may present in two forms: acute, or chronic and protracted. In the acute form the onset is abrupt, fever ranges from 38 to 40°C, and the affected single joint is tender, swollen, and held immobile because of the severe pain. Redness and local heat are frequently less marked than would be expected in so acute a process. The signs and symptoms usually peak in 1 to 2 days and then gradually subside, leaving no residue. The attacks can sometimes be precipitated by minor trauma or effort, such as prolonged walking. Synovial effusion is often demonstrable. The synovial fluid is sterile and varies in appearance from cloudy to purulent, depending upon the acuteness and severity of the synovitis. Resolution of a short attack can occur in as soon as 2 to 3 days, but more commonly takes a week and sometimes nearly a month.

About 5 per cent of patients experience protracted attacks, which persist for more than a month. Usually the hip or knee are involved (Sohar *et al*. 1967; Sneh *et al*. 1977), but episodes in other joints, such as the ankle and, rarely, the temporomandibular or the sternoclavicular, may also assume a protracted course. Rather than recovering after several days, the joint remains markedly swollen and painful, presenting a picture of chronic monoarthritis or in rare cases, chronic oligoarthritis. The affected knee joint, in extreme cases, resembles a fluid bag from which up to 200 ml can be drained (Fig. 1). After several weeks or months, sometimes even after a year or more, the pain subsides spontaneously. During such protracted attacks in a joint, short attacks involving other joints, the abdomen, or chest may occur (Sohar *et al*. 1967).

Fig. 1 Protracted arthritis of right knee, which lasted 11 months, in a 15-year-old patient (before colchicine was introduced for treatment).

In some protracted cases, especially in the hips, damage to the joints can be so severe as to cause permanent deformity, which ultimately may require joint replacement (Fig. 2). In 27 of our patients, there was residual incapacity in the affected joint (21 in the hips). Seven hips showed radiologically typical aseptic necrosis of the femoral head, and in 14 sclerosis and narrowing of the joint space was observed. Most of these hips eventually required total prosthetic replacement (Sneh *et al*. 1977). In a summary of 22 total hip replacements performed in 18 patients with familial Mediterranean fever between 1971 and 1985 a relatively high percentage of aseptic loosening of the cemented hip prosthesis was noted. This finding led us to recommend cementless hip prostheses in such patients (Salai *et al*. 1993).

Fig. 2 Results of protracted arthritis of both hips in a 17-year-old girl. State following hip arthroplasty of left hip. Narrowing of the joint space, sclerosis, and aseptic necrosis of the lateral aspect can be seen in the right hip.

Among 160 patients with protracted arthritis we found a small group of 11 in whom the HLA-B27 was negative, who fulfilled the criteria for seronegative spondylarthropathy. Most of these patients responded to therapy with non-steroidal anti-inflammatory drugs, but some of them required the addition of disease-modifying antirheumatic drugs (Langevitz *et al*. 1994a).

Muscle pains occur in about 20 per cent of patients with familial Mediterranean fever. Usually the pain is not severe, appears in the lower extremities after physical exertion, lasts from a few hours to 1 to 2 days, and subsides with rest or non-steroidal anti-inflammatory drugs. In 12 per cent of patients with familial Mediterranean fever a syndrome of protracted febrile myalgia developed, characterized by severe, debilitating myalgia accompanied by fever, abdominal pain, a high erythrocyte sedimentation rate, leucocytosis, and hyperglobulinaemia. In a few patients a mild, short-lasting, vasculitic, non-thrombocytopenic purpura with a deposition of IgA was noted. In patients that were treated by non-steroidal anti-inflammatory drugs the attacks lasted 6 to 8 weeks, but they subsided promptly after a high dose of prednisone (Langevitz *et al*. 1994b). Since colchicine is known to induce neuropathy and myopathy in rare cases, especially in transplanted patients treated with cyclosporin (Yussim *et al*. 1994), it is important to differentiate colchicine-induced myopathy from an attack of protracted febrile myalgia.

Erysipelas-like erythema is one of the most characteristic manifestations of familial Mediterranean fever. It was reported in 11 per cent of affected children, usually combined with arthritis. Rather sharply bordered red patches, hot, tender, and swollen, and 10 to 35 cm^2 in area, appear on the skin of the lower extremities. They are usually located between the knee and ankle, or on the dorsum of the foot or ankle region, and are also accompanied by abrupt elevation of body temperature and last about 24 to 48 h (Sohar *et al*. 1967).

Orchitis (an acute, unilateral, painful swelling and redness of the testis due to inflammation of the tunica vaginalis) has been recognized as a form of attack in children or young adults; it subsides spontaneously after 12 to 24 h, without anatomical residue (Eshel *et al*. 1988).

Elevation of body temperature, sometimes to 40°C for a few hours, occurs frequently, especially in children, as the only expression of an attack (Sohar *et al*. 1967). This phenomenon is often falsely attributed to viral infection, pharyngitis, or tonsillitis.

One-third of our patients complained of pain in the heels or soles of the feet related to mild exertion such as walking or prolonged standing, which subsides after night rest. There are no objective signs of inflammation or elevation of temperature.

Mild splenomegaly of 1 to 4 cm, unrelated to amyloidosis, was found in many patients. In some patients the liver was also palpable. None showed clinical or laboratory malfunction of these organs.

Haematuria, sometimes only microscopic, has been observed in several patients during and between attacks. Mild anaemia with a low serum iron is common. Low levels of haemoglobin (7–10 g per cent) were found in some patients.

Allied conditions

Henoch–Schönlein purpura occurred in over 40 of our patients admitted to our hospital. Most of the patients were children and young adults, and in most of them the disease was characterized by a prolonged and severe course that required steroid therapy in many cases.

Polyarteritis nodosa has been reported in 15 cases of familial Mediterranean fever (Sachs *et al*. 1987; Glikson *et al*. 1989). All 15 were young patients, while polyarteritis nodosa generally occurs in the fifth or six decade of life. Polyarteritis nodosa is a rare disease with an incidence of 5 to 6 per million and the 15 cases recorded in about approximately 10 000 cases of familial Mediterranean fever are more than would be expected by chance (Pras *et al*. 1996).

A relatively high incidence of fibromyalgia (30 per cent) was found in patients with familial Mediterranean fever, especially in those who suffers from back and leg/foot pain (Langevitz *et al*. 1994c).

Various types of glomerulonephritis were reported in few patients with familial Mediterranean fever, including post-streptococcal glomerulonephritis, diffuse mesangial proliferative glomerulonephritis with IgA and IgM deposits and also rapidly progressive glomerulonephritis (Said *et al*. 1992).

Amyloidosis

A genetically determined, AA-type amyloidosis, clinically manifested as nephropathy (Sohar *et al*. 1967; Levine *et al*. 1972) is the fatal lesion in patients with familial Mediterranean fever.

The role of amyloidosis in the natural history of the disease was studied in an untreated group of 470 patients and revealed some typical features. Its clinical presentation occurs at an early age; 90 per cent of the patients who died from amyloidosis were under 40 and six were under 10 (Sohar *et al*. 1967). Subsequent evaluation showed a lower incidence of amyloidosis in some Jewish ethnic groups (Pras *et al*. 1982) and in Armenians (Schwabe and Peters 1974). The onset of the clinical signs of amyloidosis does not correlate with the frequency or intensity of the febrile attacks.

Recent studies showed that pregnancy may have possible deleterious effect on amyloid nephropathy in patients with more advanced renal failure at conception (Livneh *et al*. 1993).

Clinically, the amyloid nephropathy passes through several stages. There is a preclinical stage but since it can only be diagnosed by repeated rectal and renal biopsies or is inadvertently found in an occasional Congo red-stained appendectomy specimen, no attempt was made to determine its duration. Persistent proteinuria in an otherwise healthy patient with familial Mediterranean fever has proved to be a certain indication of renal amyloidosis.

Clinical evidence of extrarenal amyloidosis was scant when patients died from renal failure before chronic dialysis was introduced as a routine treatment for chronic renal failure. Adrenal insufficiency is not apparent despite the severe involvement observed at autopsy (Sohar *et al*. 1967). Some patients show clinical and laboratory evidence of intestinal malabsorbtion (Ravid and Sohar 1974). Following prolongation of life by chronic dialysis and renal transplantation, amyloid deposition in other organs has become more pronounced. In recent years we have observed extrarenal amyloid deposition that interfered with the normal function of certain organs (Table 2). The deposition of amyloid in the small bowel is a particularly grave consequence that caused the death of six patients.

Amyloid cardiomyopathy

Giant hepatomegaly

Amyloid goitre

Addison's disease

Fatal malabsorption

Table 2 Extrarenal amyloidosis in familial Mediterranean fever

The amyloidosis of familial Mediterranean fever is not directly related to the recurrent inflammatory attacks. In some patients it occurs before the appearance of the febrile attacks and in a few it is the only manifestation of the disease (Blum *et al*. 1962). Thirteen per cent of our patients who succumbed to amyloidosis were below 15 years of age, and the youngest died at 5 years after amyloidosis had been manifest for 3 years (Sohar *et al*. 1967; Gafni *et al*. 1968).

Amyloidosis is prevalent mainly in Jewish patients of North African origin. Before the time of colchicine treatment only 11 patients of 418 of North African origin (2.5 per cent) survived and reached 40 years of age without demonstrating clinical signs of amyloidosis (Pras *et al*. 1982). The incidence of amyloidosis in untreated patients is very much higher than in the inflammatory and infectious diseases that predispose to reactive ('secondary') amyloidosis.

Laboratory tests

Laboratory findings are meagre and non-specific. The erythrocyte sedimentation rate is accelerated and acute-phase proteins such as a_2-globulin and fibrinogen are increased, especially during attacks, but also in between (Sohar *et al*. 1967). The special attention accorded to serum amyloid A is due to the fact that its N-terminal fragment is AA protein, which is part of the AA amyloid fibril. Serum amyloid A is raised considerably in amyloidotic patients with familial Mediterranean fever. During attacks, very high concentrations of serum amyloid A are observed, which decrease gradually in the days following an attack. However, even during remissions the

serum amyloid A in patients with familial Mediterranean fever is usually two or three times normal (Knecht *et al*. 1985). Since serum amyloid A is a universal acute-phase protein it is found to be elevated in other inflammatory febrile diseases and cannot therefore be used as a diagnostic measure for familial Mediterranean fever. The absence of LE cells, antinuclear factor, and rheumatoid factor, or the elevation of antistreptolysin-O titres, are relevant in patients with joint involvement.

It has recently been found that the familial Mediterranean fever (*FMF*) gene in our Sephardi families is located on the short arm of chromosome 16 (Pras *et al*. 1992a; Pras *et al*. 1992b). Cloning of the *FMF* gene will elucidate the abnormal biochemical product and the pathogenesis of the febrile inflammatory episodes of this disease.

Treatment (Table 3)

Clinical characteristics	Colchicine	Additional therapies
To control febrile attacks and prevention of amyloidosis	Continuous 1–2 mg daily	
Amyloid nephropathy:		
Normal blood creatinine	2 mg daily	
Abnormal creatinine	1 mg daily	
Acute arthritis	Increase the usual dose by 0.5 mg	NSAIDs for 1–2 weeks
Protracted arthritis	1.5–2 mg	NSAIDs for months, intra-articular corticosteroids
Seronegative spondylarthropathy	1.5–2 mg	NSAIDs, DMARDs
Protracted febrile myalgia	1.5–2 mg	Corticosteroids 1 mg/kg per day

Table 3 Approach to the management of familial Mediterranean fever

Until 1973 therapeutic measures were restricted to alleviating pain. Daily prophylactic treatment with colchicine was suggested by Goldfinger (1972) and assessed by double-blind studies (Zemer *et al*. 1974). The dose required to prevent attacks is not body weight-dependent. Treatment is started with 1 mg colchicine/day, regardless of age or severity of attacks. This dose is increased if necessary to 1.5 to 2 mg, until remission from attacks is achieved. Doses larger than 1 mg must be divided in two. Our experience has shown that if doses of 2 mg/day do not produce remission, further elevation of the dose not improve responsiveness. Omission of a daily dose may be followed promptly by an attack.

Sixty-five per cent of patients enjoy complete remission of attacks if they adhere to their daily dose of colchicine. Partial remission, defined as either a significant decrease in the frequency and severity of all forms of attacks or the remission of one form (usually abdominal) but not of another (usually arthritic), is experienced by an additional 30 per cent. In 5 per cent of treated patients the attack rate remains unchanged. They are maintained on 2 mg/day to prevent amyloidosis.

Our experience showed that continuous prophylactic treatment with colchicine in patients inhibits the development of nephropathic amyloidosis (Zemer *et al*. 1986). Colchicine even reversed the nephrotic syndrome in some patients with amyloidosis (Zemer *et al*. 1992). None of the patients who started treatment without proteinuria has developed amyloidosis during the follow-up period of 21 years, while a control group of non-compliant patients showed the same rate of amyloidosis as would be expected in the natural history of the disease.

Side-effects of colchicine are generally mild. Diarrhoea and nausea are the most common, and usually prove transient and easily controllable.

In 1973, when prophylactic colchicine treatment in familial Mediterranean fever was introduced, we were worried about its possible effects on children, because of its well-known antimitotic action. It is now clear, after hundreds of children have been taking the drug daily for more than 18 years, that in none of the treated patients, including children in their first decade of life, has colchicine caused any deviation from normal in physical examination, routine laboratory tests, linear growth, or sexual development (Zemer *et al*. 1991). The data on the effect of colchicine on fertility in patients with familial Mediterranean fever are controversial (Ehrenfeld *et al*. 1986; Ehrenfeld *et al*. 1987). It is known that a high temperature may cause transient azoospermia. In many of our patients who had suffered from frequent febrile attacks, colchicine treatment improved spermatogenesis by preventing the inflammatory febrile attacks. Fertility is sometimes apparently impaired in women with familial Mediterranean fever, probably due to the induction of early miscarriages or to pelvic adhesions that develop after frequent abdominal attacks. Colchicine, by preventing the abdominal attacks, may lessen the rate of early miscarriages and the development of pelvic adhesions. Four pregnancies producing infants with Down syndrome were reported in colchicine-treated patients (Ravia *et al*. 1991; Rabinovitch *et al*. 1992; and our unpublished data). So, routine amniocentesis to exclude chromosomal aberrations in colchicine-treated patients is recommended.

A daily dose of 1.5 to 2.0 mg colchicine appears to protect the renal graft from amyloidosis (Livneh *et al*. 1992). Although several live kidney transplantations have been successfully performed in some of our patients, cadaver kidney transplant is the treatment of choice in the endstage disease of familial Mediterranean fever.

5.13.3 Panniculitis

Jeffrey P. Callen

Panniculitis refers to inflammation within the subcutaneous fat (Patterson 1983). Panniculitis is probably a dynamic process that progresses through inflammation with neutrophils to lymphocytes to histiocytes and ends with fibrosis (Thiers 1988). The panniculitis can become granulomatous when in the histiocytic phase. The exact nature of the infiltrate perhaps depends upon when the biopsy is taken in relation to the age of the lesion being sampled. The panniculitides have been divided into four categories based on histopathological criteria: (i) septal panniculitis, (ii) lobular panniculitis, (iii) mixed with septal and lobular components, and (iv) panniculitis with vasculitis. Table 1 presents one of the currently accepted classifications for the panniculitides. Frequently the panniculitides are associated with systemic disease. Often the separation of one syndrome from another is possible only after a period of observation.

Table 1 Classification of the panniculitides

Clinical features

The prototypic septal panniculitis is erythema nodosum (Soderstrom 1982). A relatively common process, erythema nodosum is usually acute and self-limited. Erythema nodosum occurs most commonly in young adult women, but any age or sex can be affected. The typical clinical presentation is the sudden onset of one or more tender, erythematous nodules on the anterior tibial surface (Fig. 1). The nodules are deep and are better palpated than visualized. As the lesions age they may soften and develop an ecchymotic appearance. Over a 4- to 6-week period, the lesions eventually heal without scar formation. Ulceration of the primary process is extremely rare. While other symptoms may be present, they are usually those of an associated condition.

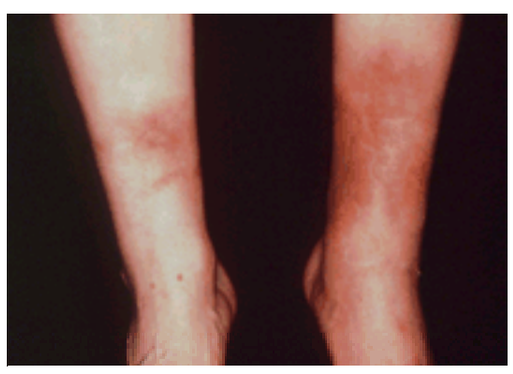

Fig. 1 Erythema nodosum—multiple tender subcutaneous erythematous nodules.

Although erythema nodosum is usually an acute process, many patients with chronic or recurrent disease have been described. Terms such as chronic erythema nodosum, erythema nodosum migrans, subacute nodular migratory panniculitis (Vilanova's disease), or septal granulomatous panniculitis have been used to characterize these patients (Prestes *et al*. 1990). The patient with erythema nodosum migrans tends to be a middle-aged (mean 45 to 50 years) woman. The disease is often present for several years, and is most common on the legs. As with acute erythema nodosum, accompanying symptoms may be present, but are usually a result of the associated condition.

Causative or associated conditions are present in about 50 per cent of patients with acute, recurrent, or chronic variants of erythema nodosum. The associated conditions can be broken into three broad categories: infectious diseases, therapeutic agents, or systemic diseases (usually inflammatory). Some of the known associations are listed in Table 2.

Infections:	
Streptococcal pharyngitis	
Tuberculosis	
Valley fever (coccidioidomycosis)	
Blastomycosis	
Histoplasmosis	
Psittacosis	
Yersinia colitis	
Salmonella gastroenteritis	
Cat scratch fever	
Leprosy	
Drugs:	
Antibiotics — penicillins, sulphonamides	
Birth control pills	
Systemic processes or diseases:	
Pregnancy	
Sarcoidosis	
Inflammatory bowel disease	
Collagen-vascular disorders — dermatomyositis, lupus erythematosus, scleroderma	
Malignancy (rare)	
Sweet's syndrome	
Idiopathic	

Table 2 Some aetiological causes of or associations with erythema nodosum

The infectious agents associated with erythema nodosum primarily tend to affect the respiratory or gastrointestinal tracts and are most often bacterial or fungal in origin. The most common drugs linked with the disease are antibiotics and oral contraceptives. Pregnancy, particularly in its second trimester, is a known association; and erythema nodosum will recur with subsequent pregnancies or with oral contraceptive use. A specific variant of sarcoidosis is associated with erythema nodosum, known as Löfgren's syndrome. This is an acute, often self-resolving variant in which erythema nodosum occurs in association with asymptomatic bilateral hilar lymphadenopathy, arthritis, and anterior uveitis. Crohn's disease (granulomatous colitis and regional enteritis) and ulcerative colitis have been associated with erythema nodosum. Patients with these inflammatory bowel diseases develop erythema nodosum that parallels the activity of the bowel disease. Panniculitis can occur with the collagen-vascular diseases (Winkelmann 1983), but it may not be best to classify the process as erythema nodosum (see below).

Weber-Christian disease

This is characterized by multiple recurrent subcutaneous nodules (Fig. 2), with accompanying fever (Panush *et al*. 1985). Histopathologically, the disease is characterized by a lobular panniculitis with an early neutrophilic infiltrate, fat degeneration, foamy histiocytes, and giant-cell formation. Eventually fibrosis occurs, and this, in addition to the destruction of fat, results in the clinical finding of an atrophic scar. Other clinical features that commonly occur are arthralgias and myalgias. Some patients also have recurrent abdominal pain. In addition to the skin lesions, any area of the body containing fat can be affected by Weber-Christian disease. Several cases of mesenteric panniculitis have been reported, as has involvement of the heart, lungs, liver, and/or kidneys (Lemley *et al*. 1991). The disease is chronic, but can result in death in 10 to 15 per cent of cases. Some of the patients with Weber-Christian disease have had multiple surgical procedures because of an acute inflammatory lesion in the presence of fever.

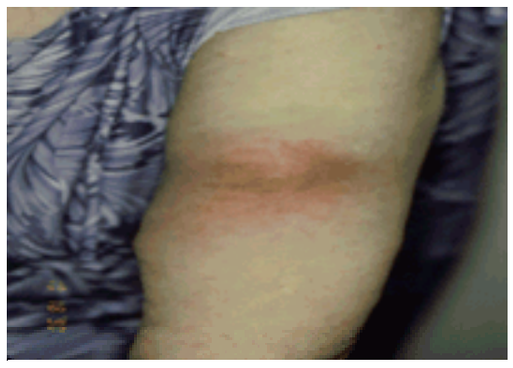

Fig. 2 Weber-Christian disease—this patient developed multiple recurrent subcutaneous lesions with accompanying fever and arthritis.

The laboratory abnormalities associated with Weber-Christian disease include an elevated sedimentation rate, anaemia, leucopenia or leucocytosis, depression of complement components, and evidence of circulating immune complexes. There have been several reports of a $_1$-antitrypsin deficiency in patients with Weber-Christian disease (Breit *et al*. 1983), however, the meaning of this finding is not clear. In addition, patients who have lupus erythematosus or pancreatic disease have been diagnosed with this form of panniculitis; however, their accompanying laboratory abnormalities would be those associated with the primary process.

Panniculitis associated with a$_1$-antitrypsin deficiency

Several groups of patients with a lobular or septal panniculitis have been ound to have a deficiency of a $_1$-antitrypsin (Smith *et al*. 1987). In a study of 96 patients with panniculitis, Smith *et al*. (1989) found 15 patients with a$_1$-antitrypsin deficiency. There were differences in the clinical and histopathological manifestations, but very little difference in the associated conditions present in either group. Specifically, the group with a $_1$-antitrypsin deficiency was more likely to have ulceration and drainage, and correspondingly had greater amounts of fat necrosis and destruction of elastic tissue. Geller and Su (1994) have suggested that the finding of splaying of neutrophils between collagen bundles is highly suggestive of this form of panniculitis. Furthermore, Smith *et al*. (1987) believed that induction of lesions by trauma was more likely in the enzyme deficient group. The recognition of these patients may be important on several grounds. First, debridement of the lesion should be avoided; second, in patients felt to have factitial panniculitis, a $_1$-antitrypsin deficiency should be considered; third, these patient should be evaluated for pulmonary disease and should be counselled to avoid smoking; and fourth, therapy with a $_1$-proteinase inhibitor concentrate may be helpful. A recent report documented the effectiveness of doxycycline and postulated that its effects were mediated through anticollagenase properties (Humbert *et al*. 1991).

Pancreatic panniculitis

Some patients with pancreatic diseases develop subcutaneous fat necrosis (lobular panniculitis) (Fig. 3), with accompanying polyarthritis and osseous intramedullary fat necrosis (Wilson *et al*. 1983). A variety of changes have been implicated in the development of this process including pancreatitis, pancreatic carcinoma (acinar cell), pancreatitis secondary to cholelithiasis, post-traumatic lesions, pancreatic ischaemia, pancreatic pseudocyst (Zimmerman-Gorska *et al*. 1986), and a pancreatic difusum (a congenital pancreatic abnormality) (Huber and Asaad 1986). It is not clear whether the elevated lipase in the circulation is primarily involved in the pathogenesis of the fat necrosis, or whether its presence follows the fat necrosis (Simkin *et al*. 1983). Histopathologically there is extensive fat necrosis with a basophilic alteration of lipocytes. Ghost cells with absent nuclei are also common. Treatment centres on non-specific measures for control of the panniculitis (see below) and reduction of the pancreatic inflammation or removal of a pancreatic tumour.

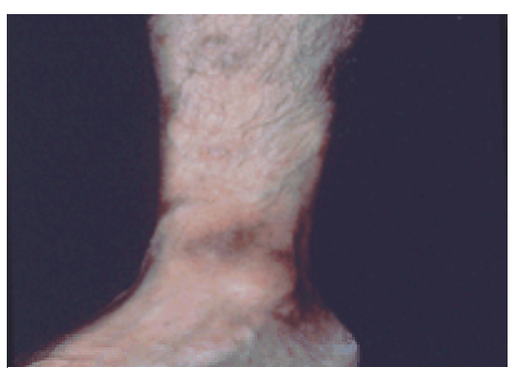

Fig. 3 Pancreatic panniculitis. Tender, erythematous subcutaneous nodules in a patient with pancreatitis (by courtesy of Robert Schosser, MD of Lexington, KY, USA).

Calcifying panniculitis of renal failure

Patients with renal failure often have abnormal calcium–phosphorus metabolism. Rarely, these patients develop acute, erythematous, tender indurated nodules as a manifestation of calciphylaxis (Lugo-Somolinos *et al*. 1990; Ivker *et al*. 1995). The panniculitic lesions can progress to necrosis and ulceration (Fig. 4). Laboratory evaluation reveals a normal calcium level and hyperphosphataemia with an elevated calcium–phosphorus product. This condition must be differentiated from metastatic calcification and pancreatic panniculitis. The prognosis is poor, and treatment is aimed at a correction of the calcium–phosphorus imbalance. Parathyroidectomy may at times be helpful.

Fig. 4 Calcifying panniculitis (calcifylaxis) in this patient with renal failure. The reaction has resulted in necrosis and ulceration of the nodular lesions on the lower extremity.

Post-steroid panniculitis

Panniculitis following withdrawal of corticosteroid therapy is a rare entity that seems to be limited to children (Roenigk *et al*. 1964). Patients reported have been treated with corticosteroids for a wide array of problems including leukaemia, nephrotic syndrome, rheumatic carditis, and encephalopathy. Interestingly, the panniculitis may clear upon readministration of the corticosteroids. The pathogenesis of this rare complication is not understood.

Lipoatrophic panniculitis

Several conditions have been described in children that often result in lipoatrophy following the inflammatory reaction. There exists a spectrum which perhaps includes Rothman-Makai syndrome (lipogranulomatosis subcutanea), lipoatrophic panniculitis, lipophagic panniculitis of childhood (Winkelmann *et al*. 1989), and localized lipoatrophy (atrophic connective tissue disease panniculitis) (Peters and Winkelmann 1980). These children tend to have multiple erythematous lesions, most commonly on the extremities, which resolve with subcutaneous atrophy (Fig. 5) (Roth *et al*. 1989). The patients often are febrile. They may have associated 'autoimmune' phenomena such as juvenile chronic arthritis, Hashimoto's thyroiditis, or diabetes mellitus (Billings *et al*. 1987). There is no known effective therapy, but some patients have responded to oral corticosteroids, oral antimalarials, or oral dapsone.

Fig. 5 Lipoatrophy following an active panniculitis of unknown cause in this child.

Histiocytic cytophagic panniculitis

Histiocytic cytophagic panniculitis was described by Crotty and Winkelmann (1981) as a chronic histiocytic disease of the subcutaneous fat, with accompanying inflammatory panniculitis, fever, serositis, and 'reticuloendotheliomegaly'. This is an extremely rare entity, having been reported in a small number of patients. The process may be a primary skin disorder of unknown cause, but has also been linked to neoplastic processes such as lymphoma and malignant histiocytosis (Barron *et al*. 1985). Histopathologically, the fat contains both T cells and histiocytes (Perniciaro *et al*. 1994). Haemorrhagic complications, perhaps due to thrombocytopenia, have occurred in half of the patients (Crotty and Winkelmann 1981). Alegre and Winkelmann (1989) have suggested that aggressive therapy with cytotoxic agents be used early in this process.

Factitial panniculitis

Factitial panniculitis from external trauma or from the injection of foreign substances is not uncommon, and should be considered in any patient with panniculitis and unusual clinical or histopathological features (Fig. 6). In traumatic lesions an organizing haematoma is often demonstrated histopathologically; whereas with the injection of foreign material, refractile bodies, or a 'Swiss cheese' effect are encountered. Occasionally spectroscopic and/or chromatographic techniques are necessary to identify the causative injected material.

Fig. 6 Factitial panniculitis—this patient developed multiple lesions, which were surgically drained or excised; only after careful inspection of several specimens by polarized microscopy was refractile material found.

Lupus erythematosus panniculitis (lupus profundus)

This is a rare manifestation of chronic cutaneous lupus erythematosus occurring in less than 3 per cent of cases of systemic lupus erythematosus, and less than 1 per cent of cases with cutaneous lupus erythematosus (Izumi 1985). The lesions are tender, red-blue, subcutaneous nodules (Fig. 7) that may eventually ulcerate or atrophy. Calcification may occur in late lesions (Fig. 8) The lesions tend to occur on the face, upper arms, and/or buttocks. The lesions may underlie a typical lesion of discoid lupus erythematosus. Trauma may initiate or worsen these lesions. Facial lesions are common, and in a recent report, lupus panniculitis accounted for periparotid swelling and was confused clinically with a possible neoplastic process (White *et al*. 1993). Histopathological changes include a panniculitis which is both lobular and septal. The overlying epidermis and dermis often demonstrate changes of lupus erythematosus, in which case the diagnosis of lupus erythematosus panniculitis can be histopathologically confirmed. Although one-half of the patients have four or more of the criteria for systemic lupus erythematosus, the activity of the panniculitic lesion does not seem to follow the course of the systemic disease (Tuffanelli 1982).

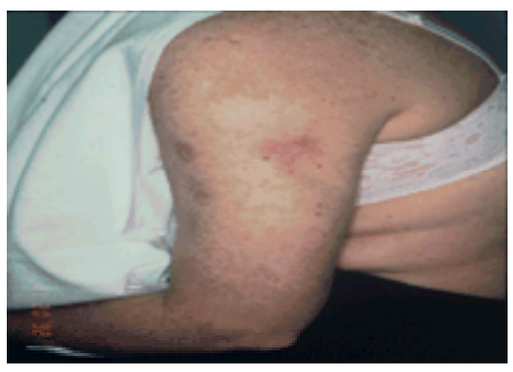

Fig. 7 Lupus erythematosus panniculitis. Erythematous to violaceous nodules with resultant atrophy of the subcutaneous tissue.

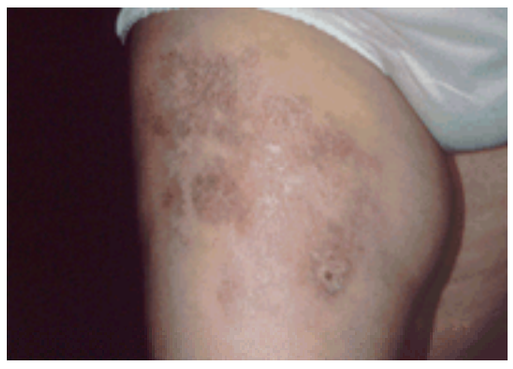

Fig. 8 Calcified subcutaneous nodules of lupus erythematosus.

Sclerosing panniculitis

Jorizzo *et al*. (1991) coined the term sclerosing panniculitis to describe a group of patients with well-circumscribed, indurated, inflammatory plaques of the lower extremity (Fig. 9). These lesions most frequently occur in women and are often accompanied by signs of venous insufficiency. There may be a history of prior thrombophlebitis (Alegre *et al*. 1988). Histopathologically this disorder is characterized by fat necrosis, sclerosis, and a lobular panniculitis. Fat microcysts with foci of membranous fat necrosis are also commonly observed in the later stages of the disease. Sclerosing panniculitis is probably a manifestation of venous insufficiency and thus therapy should include support stockings, elevation, and rest. Measures for the prevention of phlebitis are also warranted. Low-dose aspirin or other non-steroidal anti-inflammatory drugs may be helpful. Intralesional injection of triamcinolone acetonide may also be helpful.

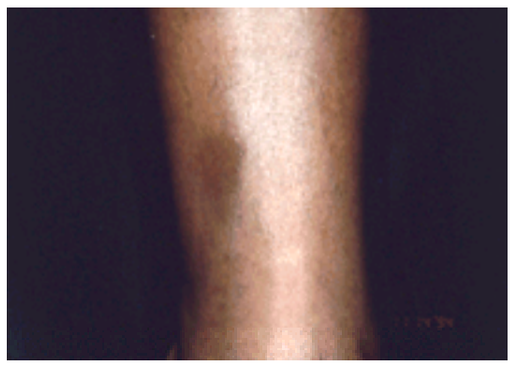

Fig. 9 Sclerosing panniculitis. Tender, subcutaneous nodule in a patient with peripheral oedema.

Panniculitis with vasculitis

Nodular vasculitis, polyarteritis nodosa (both cutaneous and systemic varieties), and small vessel vasculitis may involve subcutaneous vessels and result in

inflammatory or ischaemic changes in the subcutaneous fat. Erythema induratum is a form of nodular vasculitis thought to be due to tuberculosis.

Evaluation

The evaluation of the patient with panniculitis should include a careful history, physical examination, and a deep incisional biopsy. Findings from this examination will usually allow appropriate classification. Patients with erythema nodosum should be screened for the possibility of infection of the upper respiratory tract, and a throat swab for a rapid streptococcal screen, a skin test with PPD (purified protein derivative), and a chest radiograph should be obtained. Inflammatory bowel disease or infectious enteritis are usually symptomatic and thus it is rarely necessary to perform endoscopic or radiographic procedures in these patients. In patients in whom Weber-Christian disease or pancreatic panniculitis are being considered, tests for enzymatic abnormalities such as amylase, lipase, or a $_1$-antitrypsin deficiency should be ordered. In all patients the possibility of a coexistent collagen vascular disease should be considered.

Differential diagnosis

The differential diagnosis of erythema nodosum involves distinguishing it from (i) other forms of panniculitis (all of which may present with tender subcutaneous nodules), (ii) insect bites, (iii) thrombophlebitis, or (iv) cellulitis (Black 1988). Insect bites may be tender, red, infiltrated lesions. The distribution is dependent upon the type of bite, and in general the patient lacks associated symptomatology. Often there is a puncture site within the lesion. Cellulitis rarely manifests as subcutaneous nodules. The lesion of cellulitis may be tender and erythematous, but often there is an accompanying fever and a lymphangitic streak ascending from the primary area of involvement. When the diagnosis is in question, a wedge biopsy or deep punch biopsy which includes subcutaneous fat will be helpful.

The differential diagnosis of Weber-Christian disease includes other lobular panniculitides, erythema nodosum, and lupus erythematosus panniculitis (lupus profundus). Erythema nodosum can be separated on clinical and histopathological grounds. Lupus profundus occurs in conjunction with typical skin lesions of lupus erythematosus or in patients with systemic lupus erythematosus. This latter group may be difficult to distinguish from Weber-Christian disease, particularly in view of the reports of Weber-Christian disease in some patients with systemic lupus erythematosus. Perhaps the diagnosis of Weber-Christian disease should be made only in the absence of associated disorders such as lupus erythematosus, scleroderma, dermatomyositis, malignancy, pancreatic disease, sarcoidosis, or factitial panniculitis (Diesk and Panush 1981).

Treatment

The treatment of erythema nodosum and other panniculitides first involves assessment of a causative disease and its treatment. In the absence of a treatable disorder, therapy is symptomatic (Callen 1985). Acute erythema nodosum is often self-limited, thus non-toxic therapies are advised. Bed rest and leg elevation are very helpful in controlling symptomatology. In patients who need to continue to be ambulatory, support stockings or tights may be helpful (Lehman 1980). Aspirin or other non-steroidal anti-inflammatory agents may be helpful. My experience with aspirin has not produced results prior to toxicity and therefore my choice is to use oral indomethacin at a dosage of 25 to 75 mg per day (Barr and Robinson 1981).

In patients with chronic erythema nodosum or frequent recurrences, oral potassium iodide at a dosage of 300 to 900 mg per day has been useful in open clinical trials. My experience with 15 patients with erythema nodosum treated with oral potassium iodide has yielded control of the disease in 10 patients (unpublished observation). Furthermore, in some of the responding patients, when the drug is stopped or the dosage is lowered, the disease has relapsed, only to respond again with reinstitution of therapy. Other therapies which may be considered include oral corticosteroids, colchicine (Lupton *et al*. 1988), or an immunosuppressive agent. Systemic corticosteroids which are almost always effective, are often complicated by iatrogenic Cushing's syndrome. Colchicine has not been effective in any of the patients that I have treated. Azathioprine and cyclosporin have been used successfully in some patents. One adjunctive therapy that can be helpful is intralesionally injected triamcinolone acetonide (3 to 5 mg/ml).

There is no specific therapy for Weber-Christian disease. Reports have centred on the use of anti-inflammatory agents including aspirin, non-steroidal anti-inflammatory drugs, oral corticosteroids, antimalarials, and immunosuppressives including cyclophosphamide and cyclosporin (Usuki *et al*. 1988). In addition, colchicine, dapsone, and potassium iodide may be effective in individual cases.

Patients with lupus erythematosus panniculitis may respond to antimalarials or to intralesional injections of triamcinolone. Corticosteroids and/or immunosuppressives are rarely necessary for lupus erythematosus panniculitis.

Conclusion

Panniculitides form a wide array of syndromes that perhaps can be separated on the basis of clinical features, associated disorders, and/or histopathological features. Unfortunately, several of the syndromes have overlapping features, the pathogenesis is not understood for most, and therapeutic options are similar for all. The differential diagnosis often depends on an adequate specimen for histopathological investigation. Thus a deep, fusiform, incisional biopsy or a wedge biopsy, often including fascia, should be performed. Furthermore, a biopsy of the youngest lesion should be taken. Sections should be serially cut to identify the pattern of the panniculitis: lobular, septal, vasculitis, or mixed. The patient should be tested for underlying processes including ingestants, infections, malignancy, and autoimmune disorders. Treatment, in the absence of an underlying disease, is aimed at control of the inflammatory reaction with agents such as non-steroidal anti-inflammatory drugs, corticosteroids, dapsone, potassium iodide, antimalarials, colchicine, or immunosuppressive agents.

5.13.4 Neutrophilic dermatoses

Jeffrey P. Callen

The neutrophilic dermatoses are a group of non-infectious disorders characterized by the presence of an angiocentric, vessel-based, primary neutrophilic inflammatory cell infiltrate (Table 1) (Jorizzo 1988). These disorders can be further divided into those which lead to destruction of vessel walls (vasculitis) and those that do not destroy the vessels. The disorders to be discussed in this chapter will be those in which the vessel wall is not destroyed. For a full discussion of Behçet's disease see Chapter 5.11.7, the vasculitides see Chapter 5.11.1,Chapter 5.11.2,Chapter 5.11.3,Chapter 5.11.4,Chapter 5.11.5,Chapter 5.11.6,Chapter 5.11.7 and Chapter 5.11.8, and familial Mediterranean fever see Chapter 5.13.2. The remaining disorders are linked by the presence of similar associated processes, massive cutaneous neutrophilic infiltrates, occasionally overlapping clinical features, and similar approaches to therapy.

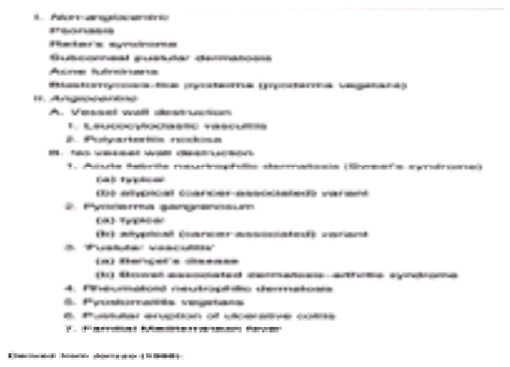

Table 1 Non-infectious neutrophilic dermatoses

Sweet's syndrome (acute febrile neutrophilic dermatosis)

In 1964, R.D. Sweet described a group of patients with one or more attacks of painful, erythematous plaques, accompanied by fever, arthralgias, and leucocytosis (Sweet 1964). The histopathological correlate was a massive neutrophilic infiltration of the dermis in the absence of vessel wall destruction or demonstrable infection. Sweet termed the process acute febrile neutrophilic dermatosis, but it has become known as Sweet's syndrome. Since Sweet's original description, more than 500 cases have been reported (von den Driesch *et al*. 1994).

This syndrome is more frequent in women (female:male, 3.7:1) between the ages of 30 and 70 years (mean age 52.6 years). Children with Sweet's syndrome have also been reported (Boatman *et al*. 1994). The disease may be preceded by symptoms suggestive of an upper respiratory tract infection. The skin lesions are felt to be distinctive, but may simulate several other processes. The characteristic lesion is a well defined, erythematous plaque with a mamillated surface, which may give the clinical impression of microvesiculation (Fig. 1). There is rarely any accompanying epidermal change or ulceration, and the lesions usually heal without scar formation. Pustules may stud the surface or may be a major feature of the process. A relatively common clinical variant is a tender, erythematous nodule which clinically resembles erythema nodosum (Cohen *et al*. 1992). Genital lesions have been reported, but are rare (Banet *et al*. 1994). The lesions occur in crops, and may be initiated by a variety of traumatic injuries (pathergy) such as a needle stick, wound debridement, or burn (Fig. 2). The lesions are accompanied by fever and malaise in most patients, and myalgias and/or arthralgias in about half. Headache, nausea, vomiting, diarrhoea, and/or conjunctivitis may also occur in some patients. Untreated lesions resolve over 6 to 8 weeks, however, many patients continue to produce new lesions chronically or recurrently.

Fig. 1 Sweet's syndrome. This patient developed erythematous plaques with a central mamillated 'microvesicular' surface.

Fig. 2 This patient's pustular lesion on an erythematous base was initiated after a kitchen accident in which boiling water splattered on her hand.

The laboratory findings include a leucocytosis which is composed of mature neutrophils. White blood cell counts generally range from 10 to 20 000 cells/mm ^{3}. The remainder of the blood count is within normal limits, except in patients who have leukaemia-associated Sweet's syndrome. The erythrocyte sedimentation rate is

frequently elevated. On rare occasions a patient may have proteinuria. Histopathologically there is a dense dermal infiltrate composed of mature polymorphonuclear leucocytes. The infiltrate may be more pronounced in perivascular areas, and leucocytoclasia is frequent, but the vessel walls are spared. Oedema in the papillary dermis may be intense coinciding with the microvesicular lesions observed clinically. Immunofluorescence microscopy has been negative in a small number of cases in which it has been reported.

Sweet's syndrome has been reported with a variety of diseases. Von den Driesch *et al*. (1994) has suggested that Sweet's syndrome can be subdivided into four groups: (i) classic or idiopathic, (ii) parainflammatory, (iii) paraneoplastic, and (iv) pregnancy associated (Cohen *et al*. 1993). While idiopathic cases are the most frequent, paraneoplastic Sweet's syndrome is the most frequently identified association and myelogenous leukaemia or preleukaemia account for most of the paraneoplastic conditions (Cooper *et al*. 1983; Cohen *et al*. 1988) Sweet's syndrome is not clinically or histopathologically different among the four groups; however, in the presence of leukaemia, the patients more frequently tend to be anaemic or thrombocytopenic and may have haemorrhagic lesions (Fig. 3). Other associated processes in paraneoplastic Sweet's syndrome include benign monoclonal gammopathy, lymphoma, myelodysplastic disorders, and various solid tumours (including breast, stomach, genitourinary, and colon most commonly) (Cohen *et al*. 1993). Parainflammatory Sweet's syndrome has also been reported in conjunction with lupus erythematosus, rheumatoid arthritis (Trentham *et al*. 1976; Harary 1983), Sjögren's syndrome (Prystowsky *et al*. 1978), inflammatory bowel disease (Crohn's disease and ulcerative colitis), Behçet's disease, thyroiditis, various infections (including HIV, hepatitis, mycobacteria, cytomegalovirus, salmonella), and drug hypersensitivity (Johnson and Grimwood 1994; Piette *et al*. 1994). It is not known how frequently paraneoplastic Sweet's syndrome occurs, but most authorities quote a figure ranging from 10 to 20 per cent, with about 40 to 50 per cent of these patients having a haematological malignancy.

Fig. 3 Sweet's syndrome in a patient with acute myelogenous leukaemia. The purpura is due to bleeding into the lesions associated with thrombocytopenia.

The pathogenesis of Sweet's syndrome is not known. Tests for circulating immune complexes, tissue-bound immunoglobulins, or complement have generally been negative. Kemmett and Hunter (1990) reported perinuclear antineutrophil cytoplasmic antibodies (**p-ANCA**) in 6 patients with Sweet's syndrome, but believed this to be an epiphenomenon. Von den Driesch (1994) was unable to demonstrate p- or c-ANCA in any of his 10 patients who were tested. Studies of neutrophil function have not shown a consistent abnormality. Furthermore, abnormalities of T cells and proinflammatory cytokines such as g-interferon or interleukin 8 have not been reproducibly reported.

Sweet's syndrome is usually an acute, steroid-responsive, self-limited disease. In general, a 2-week tapering course of oral prednisone (40 to 60 mg/day) is effective. One or more exacerbations requiring brief reinstitution of corticosteroids are common. From Sweet's initial report and the many later ones, it appears that the process can follow a chronic course, and the use of steroid-sparing agents should be considered. In reports of individual or small groups of patients, dapsone, potassium iodide, indomethacin, doxycycline, clofazimine, colchicine, metronidazole, isotretinoin, methotrexate, chlorambucil, cyclosporin, and pulse dosage of methylprednisolone have been successfully used (Hoffman 1977; Horio *et al*. 1980; Subhisa *et al*. 1983; Aram 1984; Case *et al*. 1989; Banet *et al*. 1994; von den Driesch 1994)

Pyoderma gangrenosum

Pyoderma gangrenosum is an uncommon, ulcerative, cutaneous condition with distinctive clinical characteristics (Callen 1990). Frequently there is an associated systemic disease. The diagnosis is made by exclusion of other processes that may cause cutaneous ulcers. Like patients with Sweet's syndrome, patients with pyoderma gangrenosum are often pathergic, with lesions sometimes developing after minor trauma.

The ulcerations of classical pyoderma gangrenosum are frequently clinically characteristic. The border is well defined with a deep erythematous to violaceous colour (Fig. 4). The lesion extends peripherally and often the border overhangs the ulceration (undermined) as the inflammatory process spreads within the dermis, only secondarily causing necrosis of the epidermis. The lesions may be single, or may occur in crops, often beginning as a discrete pustule with a surrounding inflammatory erythema. The lesions may occur on any surface, but are most common on the legs. Pain is a prominent feature and is sometimes so severe that narcotics are required for symptomatic relief. As the lesion heals, scar formation occurs and the resulting scar is often described as cribiform (Fig. 5).

Fig. 4 Pyoderma gangrenosum. Typical large ulceration with an undermined violaceous border.

Fig. 5 Healed lesion of pyoderma gangrenosum.

Several variants of pyoderma gangrenosum have been described. The pustular eruption of ulcerative colitis was first reported by O'Loughlin and Perry (1978). In this process the patient is acutely ill with fever and develops multiple sterile pustules (Fig. 6) (Fenske *et al*. 1983; Callen and Woo 1985). The lesions may regress without scarring, or some may progress into a typical lesion of pyoderma gangrenosum. Biopsy of the early lesion reveals sheets of mature polymorphonuclear leucocytes.

Fig. 6 Vesiculopustular eruption of ulcerative colitis.

Peristomal pyoderma gangrenosum is a recently recognized variant that occurs in patients with ulcerative colitis or Crohn's disease who have had abdominal surgery and have an ileostomy or colostomy (Keltz *et al*. 1993). The ulceration (Fig. 7) may occur as an early or late phenomenon. Perhaps irritation from the ileostomy or colostomy appliance is involved in the induction of this process (pathergy). These ulcerations must be differentiated from infections, dermatitis, or extension of the underlying bowel disease (Crohn's only).

Fig. 7 Peristomal pyoderma gangrenosum in a patient with an ileostomy after bowel surgery for ulcerative colitis.

Vulvar pyoderma gangrenosum is another recently recognized variant (McCalmont *et al*. 1991). Except for its location, the ulceration is otherwise typical of pyoderma gangrenosum (Fig. 8). This variant should be differentiated from Behçet's disease.

Fig. 8 Vulvar pyoderma gangrenosum.

Another variant is pyostomatitis vegetans. This process is one in which chronic, pustular, eventually vegetative erosions develop on the mucous membranes (Fig. 9), most notably in the oral cavity (Van Hale *et al*. 1985). Most of these patients have had inflammatory bowel disease, and some have had ulcerative skin lesions similar to pyoderma gangrenosum (Storwick *et al*. 1994).

Fig. 9 Pyostomatitis vegetans. This vegetative ulceration occurred in a patient with ulcerative colitis.

A condition known as malignant pyoderma is distinguished from pyoderma gangrenosum by three features: (i) lesions predominantly on the head and neck (atypical for pyoderma gangrenosum), (ii) lack of associated systemic diseases, and (iii) the absence of undermined borders and surrounding erythema (Perry *et al*. 1968). The distinctiveness of this variant has been questioned (Wernikoff *et al*. 1987; Newman and Frank 1993).

Lastly, there is a variant known as atypical or bullous pyoderma gangrenosum. In this the ulceration is more superficial, there is often a bullous, blue-grey margin (Fig. 10), and the upper extremities and face are more commonly affected (Perry and Winkelmann 1972; Romano and Safai 1979). This variant has been reported with

haematological disease, specifically preleukaemic conditions such as myeloid metaplasia (Callen *et al*. 1976), or acute myelogenous leukaemia. At times the separation of atypical pyoderma gangrenosum from leukaemia-associated Sweet's syndrome is difficult.

Fig. 10 Atypical pyoderma gangrenosum in a patient with a preleukaemic state. The lesion is a shallow ulcer with a bullous, blue-grey border.

The histopathological features of pyoderma gangrenosum are not specific, but are useful in ruling out other causes of cutaneous ulceration. There is controversy over what is the initial histopathological change, with some classifying the process as a neutrophilic dermatosis (Jorizzo 1988), and others believing that the initial changes involve lymphocytic infiltrate, endothelial cell swelling, and fibrinoid necrosis of the vessel wall (a lymphocytic vasculitis) (Su *et al*. 1986). Regardless, the lesion does not involve a leucocytoclastic vasculitis, nor is granuloma formation compatible with a diagnosis of pyoderma gangrenosum.

P>The aetiology and pathogenesis of pyoderma gangrenosum are not understood, but a variety of abnormalities of the immune system have been described. Although associated conditions are common (Table 2), perhaps a quarter to a half of the patients have 'idiopathic' disease. The most common associated conditions are inflammatory bowel disease, arthritis, paraproteinaemia, and haematological malignancy.

Table 2 Diseases associated with pyoderma gangrenosum

Initial reports of pyoderma gangrenosum emphasized the association with ulcerative colitis (Perry 1959). Eventually, it has become recognized that regional enteritis and Crohn's disease (granulomatous colitis) are found with pyoderma gangrenosum as often as ulcerative colitis (Powell *et al*. 1985; Prystowsky *et al*. 1989). In the most recent accounts, inflammatory bowel disease has constituted about 15 to 20 per cent of the associated phenomena. In addition, early reports stressed the relationship of pyoderma gangrenosum to the activity of the bowel disease, and even suggested that some patients' pyoderma gangrenosum lesions may benefit from surgical resection of the inflamed bowel (ulcerative colitis only). Callen *et al*. (1989) have reported pyoderma gangrenosum in association with inactive terminal ileitis, and Talansky *et al*. (1983) also have reported lack of effect of bowel resection in some patients with pyoderma gangrenosum and ulcerative colitis.

Arthritis is a frequent finding with pyoderma gangrenosum. In some of the later reports, arthritis has been the most frequent associated condition (Powell *et al*. 1985; Prystowsky *et al*. 1989). Five of the nine patients with arthritis reported by *Prystowsky et al*. (1989) had inflammatory bowel disease associated arthritis. In general, the arthritis associated with pyoderma gangrenosum is a symmetrical polyarthritis which may be seronegative or seropositive. Spondylitis, although it may occur in conjunction with inflammatory bowel disease associated with pyoderma gangrenosum, has not been reported independently with pyoderma gangrenosum.

A variety of malignancies have been reported with pyoderma gangrenosum, most commonly myelogenous leukaemia or preleukaemia. This association may be more common with the atypical variants of pyoderma gangrenosum. Although a variety of solid tumours have been reported, their presence is probably coincidental.

Paraproteinaemia, in general a benign variety, has been reported with pyoderma gangrenosum. With newer techniques of protein separation, it appears that 15 per cent of patients with pyoderma gangrenosum may have a benign monoclonal gammopathy, most often of IgA variety (Murray 1983; Prystowsky *et al*. 1989). The development of myeloma in these patients with pyoderma gangrenosum appears to be very rare.

The diagnostic evaluation (Table 3) of the patient presumed to have pyoderma gangrenosum has two objectives: (i) to rule out other causes of cutaneous ulceration, and (ii) to determine whether there is a treatable, systemic, associated disorder. There is not a specific laboratory or histopathological test that is diagnostic. Moreover, some of the associated disease processes may be clinically silent.

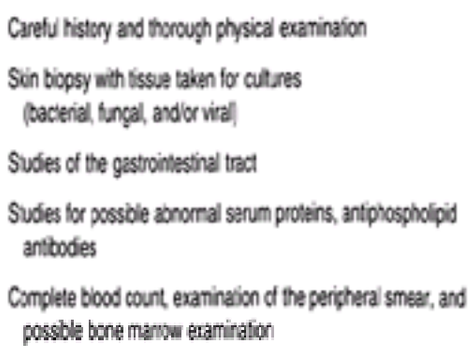

Table 3 Diagnostic evaluation of the patient with pyoderma gangrenosum

The differential diagnoses of ulcerative cutaneous lesions include: (i) infectious diseases, (ii) halogenodermas, (iii) vasculitis, (iv) insect bites, (v) venous or arterial insufficiency (including occlusive disease associated with antiphospolipid antibodies), and (vi) factitial ulcerations. Cultures should be taken from both exudate and tissues.

To test for the presence of an associated disorder, another series of examinations should be made. A thorough historical evaluation and examination of the gastrointestinal tract should be undertaken in conjunction with a gastroenterologist. Radiographic procedures may include an upper gastrointestinal series and a barium enema. Flexible sigmoidoscopy or colonoscopy, or both, may also be done, with appropriate biopsies being taken. A complete blood count, careful evaluation

of the peripheral smear, and possibly a bone marrow aspirate or biopsy will help rule out the presence of an associated haematological malignant process. Serum protein electrophoresis, serum immunodiffusion studies, and possibly, serum and urine immunoelectrophoresis will help to eliminate a diagnosis of an associated monoclonal gammopathy or myeloma. Multiple reports of pyoderma gangrenosum-like leg ulcers in patients with antiphospholipid antibodies have appeared and tests such as VDRL, anticardiolipin antibody, and partial thromboplastin time are now standard in the evaluation of a patient with pyoderma gangrenosum (Babe *et al*. 1992).

There is not a specific, uniformly effective treatment for pyoderma gangrenosum. Although systemic treatment may affect the underlying disease process in some patients with chronic ulcerative colitis (Mir-Madjlessi 1985), it sometimes becomes necessary to consider colectomy. Some patients' skin lesions will respond to bowel resection, but there are patients in whom total colectomy, including removal of the rectosigmoid colon, does not lead to a remission (Talansky *et al*. 1983). In one report a patient developed pyoderma gangrenosum 10 years after total colectomy (Cox *et al*. 1986). In mild cases, local measures, such as dressings, elevation, rest, topical agents, or intralesional injections may be sufficient to control the disease process. Compresses, wet to dry dressings, or the newer bio-occlusive semipermeable dressings may be useful. Cleansing or therapy with antibacterial agents such as hydrogen peroxide or benzoyl peroxide have been reported to be beneficial in an occasional patient. Hyperbaric oxygen has also been reported, in a small number of cases, to be effective. Superpotent topical corticosteroids and intralesional injections of corticosteroids (Gardner and Archer 1972) may be beneficial in some patients. Care must be taken to avoid introducing an infection and to limit the potential systemic effects of corticosteroids that arise from injecting large doses intralesionally. In general, the periphery of the lesions are injected, but the ulcer base may also be injected. Other topical approaches include the use of sodium cromoglycate, nitrogen mustard, and 5-aminosalicyclic acid (DeCock and Thorne 1980; Tsele *et al*. 1992).

In patients who do not respond to topical or local therapies, or whose severe, rapid course warrants the use of a systemic agent, sulphonamides, sulphones, or corticosteroids have been the most commonly used agents. Perry (1959) reported that oral sulphasalazine is effective in patients both with and without inflammatory bowel disease. Dapsone in doses of up to 400 mg per day has often been used as a monotherapy, or as an adjunctive steroid-sparing agent. Usually the drug is administered in lower doses (100 to 150 mg per day), and the usual precautions and pretherapy evaluation are necessary. The mechanism of action of the sulphanomides and sulphones in this process is not understood, but effects on the polymorphonuclear leucocyte may be a factor. Another antileprosy agent, clofazimine, has also been reported to be successful in some patients with pyoderma gangrenosum. Finally, several other antibiotics have been used successfully in individual cases; these include minocycline and rifampicin.

Systemic corticosteroids have been used extensively in patients with pyoderma gangrenosum and its variants and are generally believed to be very effective. Usually, large doses (40 to 120 mg per day) are necessary in order to induce a remission of the disease. These doses, used over the long term, will frequently result in steroid-related side-effects. In the studies by *Holt et al*. (1980), 6 of their 12 patients treated with corticosteroids developed serious steroid complications, and 4 of these 6 died as a result of the therapy. To avoid the complications of long-term steroid use, Johnson and Lazarus (1982), and subsequently others, have used pulse therapy with 1 g of methylprednisolone given intravenously each day for a period of 5 days. Maintenance of the remission was accomplished with oral corticosteroids every other day. Prystowsky *et al*. (1989) have reported the experience of Lazarus with a further eight patients. They found that remissions occurred in five of the patients, and that they were usually able to remove oral corticosteroid therapy and often lower the dose of other therapies. Pulse therapy is not without side-effects, which include sudden death. In the hands of Prystowsky *et al*., and my experience with three patients, this therapy has primarily resulted in transient hyperglycaemia; however, it should only be used with great caution and proper monitoring.

Immunosuppressive agents have been suggested for use in patients who fail to respond to other therapies, particularly systemic corticosteroids, or who develop steroid-related side-effects. Individual reports using oral azathioprine, cyclophosphamide (Newell and Malkinson 1983), chlorambucil (Burruss *et al*. 1994), cyclosporin (Matis *et al*. 1992), tacrolimus (FK 506) (Abu-Elmagd *et al*. 1993), or methotrexate (Teitel 1993) have suggested that, at least in some patients, these agents may be successful. Intravenous pulses of cyclophosphamide (Zonana-Nacach *et al*. 1994) or immunoglobulin (Gupta *et al*. 1995) have also been successful in individual patients. The mode of action of the immunosuppressive agents is not understood.

Rheumatoid neutrophilic dermatitis

Ackerman (1978) described a neutrophilic dermatosis in patients with rheumatoid arthritis. This is apparently a rare manifestation of rheumatoid arthritis, and has only been reported in a small number of patients (Scherbenske *et al*. 1989; Sanchez and Cruz 1990; Lowe *et al*. 1992). The patients are described as having symmetric, erythematous nodules and plaques on the extensor surfaces of the joints (Fig. 11). There is an apparent predilection for the dorsa of the hands and arms. It is not clear whether this condition is clinically or histopathologically distinct, specifically, whether it can be differentiated from Sweet's syndrome. An effective therapy has not been described.

Fig. 11 Rheumatoid neutrophilic dermatosis. This patient developed multiple vesiculopustular plaques on the dorsum of his hands.

Bowel-associated dermatosis–arthritis syndrome

Patients who had undergone bowel bypass surgery for morbid obesity have occasionally developed scattered pustular lesions (Fig. 12) and arthritis. This became known as the bowel bypass syndrome, and was felt to be an immune-complex disease caused by bacterial overgrowth in the blind loop. Treatment with antibiotics was often effective in clearing the cutaneous lesions and improving the joint symptoms. Later, Jorizzo *et al*. (1983) coined the term 'bowel-bypass syndrome without bowel bypass' or 'bowel-associated dermatosis–arthritis syndrome'. They reported on four patients with this syndrome of whom two had blind loops due to Billroth II procedures, one had ulcerative colitis, and one had Crohn's disease. Dicken (1984) reported two similar patients who had had Roux-en-Y procedures with resultant blind loops. Clinically, these patients present with a widespread eruption characterized by pustules on an erythematous or necrotic base. The lesions may be few in number, or may be extensive. Ulceration is rare. The appearance of the lesions is often accompanied by fever, arthralgias or a true inflammatory arthropathy, and myalgias. The arthritis accompanying this process is generally symmetrical, non-deforming, and most frequently involves the small joints such as the wrists, ankles, metacarpophalangeal, proximal interphalangeal, and metatarsophalangeal joints. Histopathologically, the disease resembles Sweet's syndrome. In fact, only after the report by Jorizzo *et al*. (1983) did we recognize that a patient reported by our group (Bechtel and Callen 1981) probably would have been more correctly diagnosed as having the bowel-associated dermatosis–arthritis syndrome (Fig. 13) rather than Sweet's syndrome, because of his prior Billroth II procedure. This disease is presumed to be due to immune complexes (Jorizzo *et al*. 1984) and while anti-inflammatory therapy is at times helpful, antibiotics frequently control the process, or bowel surgery (to remove 'blind' loops) will reverse it.

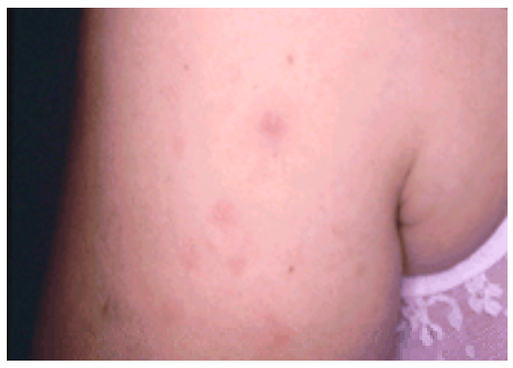

Fig. 12 Scattered pustules on an erythematous base in a patient with a bowel bypass for morbid obesity.

Fig. 13 Vesiculopustular eruption in a patient with previous ulcer surgery (Billroth II) and a blind loop—the so-called 'bowel bypass syndrome without a bowel bypass'.

5.13.5 Sarcoidosis

Barry Bresnihan

Sarcoidosis is a multisystem disease of unknown aetiology characterized by the presence of multiple, non-caseating granulomas in involved tissues. Symptoms and signs depend on the severity of disease in the affected organ systems. Tissues that may be involved include joints, bones and muscles.

Aetiology

Environmental factors are important in the aetiology of sarcoidosis. Firstly, the acute form of sarcoidosis presents more frequently during spring months (Poukkula *et al*. 1986), suggesting that an environmental agent with a higher prevalence during the spring may be causative. A number of localized outbreaks of sarcoidosis have suggested the possibility of an infectious agent (Veale and FitzGerald 1990). Others have suggested a relation between sarcoidosis and occupation (Edmondstone 1988).

Genetic factors also appear to be important. There is an increased incidence of sarcoidosis within families. The British Thoracic and Tuberculosis Association (1973) reported 121 patients among 59 families. In one series of 114 patients there was a 9.6 per cent frequency of sarcoidosis in the siblings of index cases (Brennan *et al*. 1984).

A number of studies have examined associations between HLA alleles and sarcoidosis, but no linkages with disease susceptibility have yet been identified (Mehra and Bovornkitti 1988). However, some investigators have suggested associations between HLA-B8 and sarcoid arthropathy (Brewerton *et al*. 1977), and more recently an association between HLA-B8, -DR3 and acute sarcoidosis with arthritis has been demonstrated (Kremer 1986).

Pathology

The characteristic histological feature of sarcoidosis found in all affected tissues is a well-defined, round or oval granuloma composed of compact, radially arranged epithelioid cells, a few multinucleate giant cells and a rim of lymphocytes (Fig. 1). Caseation is absent. A small area of fibrinoid necrosis may be present. Sarcoid granuloma may be divided into early, intermediate, and late stages. The epithelioid cells are derived from circulating monocytes. Giant cells are formed from fusion of epithelioid cells. Their size varies between 150 and 300 µm. Most giant cells are of foreign-body or Langhans type and may contain inclusion bodies, which represent metabolic end-products. The lymphocytes are derived from peripheral blood and consist predominantly of CD4+, T-helper cells (Hunninghake and Crystal 1981). There is evidence to support the suggestion that the accumulation of CD4+ lymphocytes may result from increased production of interleukin 2 (**IL-2**) (Semenzato *et al*. 1993). Soluble IL-2 receptor has been demonstrated in active sarcoidosis (Ina *et al*. 1992). Increased expression of the IL-2 receptor on mononuclear cells and alveolar macrophages correlated positively with serum concentrations of angiotensin-converting enzyme (Pforte *et al*. 1993). Studies of T-cell receptors have suggested that T cells accumulate in sarcoid lesions in response to persistent stimulation by a specific but unidentified antigen (Du Bois *et al*. 1992; Forrester *et al*. 1993).

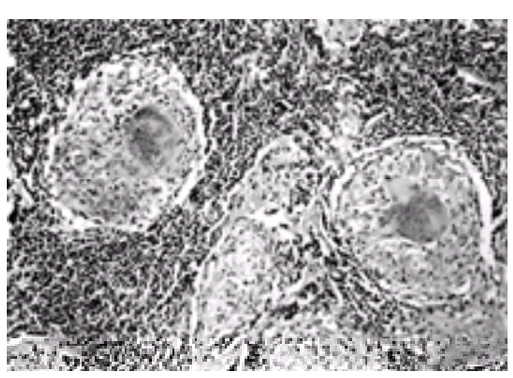

Fig. 1 Sarcoid granuloma. Two, well-formed, non-caseating granulomas are demonstrated in lymph-node tissue. Central multinucleated giant cells are present, surrounded by epithelioid cells and some lymphocytes. (By courtesy of Dr Mary McCabe, St. Vincent's Hospital, Dublin.)

A number of recent studies have suggested a role for several cytokines, including tumour necrosis factor-a, IL-1b, and IL-6, in disease pathogenesis and granuloma formation (Shakoor and Hamblin 1992; Pueringer *et al*. 1993; Steffen *et al*. 1993).

Epidemiology

Sarcoidosis occurs worldwide, but prevalence, clinical manifestations and outcome vary widely in different areas (Tierstein and Lesser 1983). Sarcoidosis is recognized more often in developed than in underdeveloped countries, in Western rather than in Far Eastern countries, and in Northern rather than Southern Europe. Moreover, the prevalence within a given region may vary. For example, Sweden and Denmark have prevalence rates of approx. 60 per 100 000 population, while Finland has a prevalence of 7.5 per 100 000. The overall prevalence rate in the United Kingdom has been estimated as 20 per 100 000, and in Ireland as 30 per 100 000. The highest reported prevalence in the United Kingdom (of up to 200 per 100 000) was observed in Irish immigrant women of child-bearing age living in London. In the United States, sarcoidosis is 10 to 17 times more prevalent among black than white individuals.

General clinical features

Sarcoidosis may involve almost any tissue in the body. Approximately half of patients with sarcoidosis will present with pulmonary symptoms such as dyspnoea, cough or chest pain (Sharma 1984a). A further 20 per cent approximately will present with an abnormal routine chest radiograph and minimal or no symptoms. Approximately 1 in 4 patients will present with non-specific constitutional symptoms including fever, weight loss and anorexia. Less than 10 per cent of patients will present with features confined to extrapulmonary systems such as the musculoskeletal system.

Acute sarcoidosis

Acute or subacute sarcoidosis may present as an illness of explosive onset, usually characterized by fever, erythema nodosum, and hilar lymphadenopathy. The association of hilar lymphadenopathy and erythema nodosum is often referred to as Lofgren syndrome (Lofgren 1953). Erythema nodosum appears to be more common among Swedish, Irish, Puerto Rican, and Mexican women of child-bearing age. This form of sarcoidosis has a high prevalence of spontaneous remission and a good prognosis. The chest radiograph clears within 1 year of presentation in more than 60 per cent of patients with acute sarcoidosis.

Chronic sarcoidosis

Chronic sarcoidosis is less common than acute sarcoidosis and has a subtle onset with an insidious progressive and highly variable clinical course. Chest radiographs demonstrate extensive parenchymal infiltration in more than 90 per cent of patients with chronic sarcoidosis. Pulmonary function tests confirm a restrictive lung defect. Other manifestations are listed in Table 1.

Lung: parenchymal disease
Skin: lupus pernio; skin plaques or nodules
Eye: uveitis; conjunctivitis; keratoconjunctivitis sicca
Lymphatic system: peripheral lymphadenopathy; splenomegaly
Bone marrow infiltration
Liver: hepatic granulomata; portal hypertension; hepatic failure
Kidney: nephrocalcinosis; renal calculi; granulomatous infiltration; glomerular disease; renal arteritis
Heart: cardiomyopathy; conduction abnormalities
Nervous system: cranial and peripheral neuropathy; papilloedema; intracerebral lesions; meningitis; seizures; spinal cord involvement; psychiatric disorders
Endocrine: pituitary; hypothalamus; thyroid; parathyroid; adrenal
Reproductive organs: ovaries; testes
Gastrointestinal tract and pancreas
Salivary and lacrimal glands
Nose, tonsils, larynx

Table 1 Clinical manifestations in chronic sarcoidosis

Laboratory investigations

Routine investigations

Most reports are that anaemia is uncommon in sarcoidosis (Sharma 1984b), occurring in approx. 5 per cent of patients. Haemolytic anaemia has been reported, but is rare. Leucopenia occurs in approximately one-third of patients, sometimes in the absence of splenomegaly and may reflect granulomatous infiltration of the bone marrow. Neutrophilia and polycythaemia are rare. There is eosinophilia in approximately one-quarter of patients. Thrombocytopenia has long been recognized as a relatively common complication of sarcoidosis. An elevated erythrocyte sedimentation rate occurs during acute disease episodes, particularly in association with erythema nodosum.

Reports of hypercalcaemia in sarcoidosis vary widely between 2 and 63 per cent. The reasons for such wide variation are unclear. The frequency tends to be higher in North American series. In a worldwide review of more than 3 000 patients, James *et al*. (1976) reported a frequency of 11 per cent. The serum calcium fluctuates during the course of the disease and may be raised during acute or subacute phases.

Mild elevation of serum bilirubin and alkaline phosphatase are common (Sharma 1984c). Severe jaundice and disturbance of liver function is uncommon, even in the presence of extensive liver involvement.

Urinary hydroxyproline concentrations are considerably increased in acute sarcoidosis, returning to normal as disease manifestations resolve. Hydroxyproline excretion is normal in chronic sarcoidosis. Hypercalcinuria occurs more frequently than hypercalcaemia, and has been reported in 49 per cent of one series where only 13 per cent had hypercalcaemia. Significant proteinuria has been reported in approximately one-third of patients.

Angiotensin-converting enzyme

Angiotensin-converting enzyme catalyses the conversion of angiotensin I to vasoactive angiotensin II and inactivates bradykinin. Increased concentrations of serum angiotensin-converting enzyme were first observed in 83 per cent of patients with active sarcoidosis. The incidence has varied in subsequent series. In one international study of almost 2000 patients, 57 per cent had elevated serum concentrations of this enzyme (Studdy and James 1983). Angiotensin-converting enzyme is produced mainly by the epithelioid cells in the granulomas and enzyme activity reflects the total granulomatous 'load' in the body. Serial measurements of this enzyme are useful when monitoring the course of the disease.

Kveim test

The intracutaneous injection of a saline suspension of previously validated human sarcoid spleen or lymph node will give rise to a non-caseating granulomatous reaction after 2 to 6 weeks in approximately three-quarters of patients with sarcoidosis (Kataria *et al*. 1980) The Kveim test is generally regarded as specific for sarcoid, but has a number of disadvantages, including variability of results with different antigen sources, the 2- to 6-week delay and the inability to treat with corticosteroids during the wait, the need for punch biopsy, and variability in histological interpretation. Newer diagnostic procedures yield diagnostic material more rapidly.

Diagnostic imaging

The chest radiograph may be normal, or demonstrate hilar lymphadenopathy with or without pulmonary infiltration, pulmonary infiltration without adenopathy or advanced and irreversible fibrosis. Computed tomography may demonstrate adenopathy or early granulomatous infiltration that is undetectable on plain radiographs.

Beaumont *et al*. (1982) described [^{67}Ga]citrate scanning of the lungs as a very sensitive method for detecting granuloma formation in sarcoidosis. Several studies have demonstrated that ^{67}Ga scanning of the lungs reflects disease activity and response to therapy (Lawrence *et al*. 1983; Baughmann *et al*. 1984). Lung uptake of ^{67}Ga is greatest in patients with acute disease and high serum concentrations of angiotensin-converting enzyme. Uptake of ^{67}Ga does not correlate with quantitative pulmonary function nor with the clinical course and outcome. It is uncertain why ^{67}Ga accumulates at sites of granulomatous inflammation.

Histology

Sarcoidosis may resemble other diseases such as lymphoma and tuberculosis. Many institutions have a policy of obtaining histological confirmation of the diagnosis in all cases. Transbronchial lung biopsy has become the most widely used biopsy technique and is both highly sensitive and selective (Tierstein 1983). Open lung biopsy and mediastinal lymph-node biopsy are also highly sensitive and selective options, but, being more invasive, have some disadvantages. Other tissues likely to yield positive histological findings include scalene node, liver, skin, muscle, conjunctiva, lacrimal and minor salivary glands, and spleen.

Bronchoalveolar lavage

Bronchoalveolar lavage provides samples of the alveolar secretions for analysis. Lavage fluids may be studied for cellular content and inflammatory mediators. Analysis of bronchoalveolar fluids is a useful aid in the differential diagnosis of some interstitial lung diseases (Hunninghake *et al*. 1979). Patients with acute pulmonary sarcoidosis generally have high lymphocyte counts and high T helper-/T suppressor-cell ratios in bronchoalveolar fluids. Serial analysis of these lavage fluids may provide valuable information on the response to therapy.

Musculoskeletal manifestations

Joint disease

Distinctive patterns of arthropathy are associated with both acute and chronic sarcoidosis (James *et al*. 1976). In acute sarcoidosis, transient flitting arthralgias may precede the emergence of fever, erythema nodosum (Fig. 2), and hilar adenopathy (Fig. 3) (Gumpel *et al*. 1967; Siltzbach and Duberstein 1968; Spilberg *et al*. 1969). The joints most frequently presenting with arthritis after the development of erythema nodosum are the ankles and knees, although others may be involved occasionally. Approximately 65 per cent of patients presenting with acute sarcoidosis will have articular features. Prominent signs of inflammation are present, with marked erythema and tenderness of involved joints causing pain and limited motion. The arthritis is usually symmetrical and migratory, and persists for periods of between 3 to 4 days and 3 to 4 months. It may be difficult on occasion to distinguish features of erythema nodosum from articular and periarticular inflammation of the ankle joints. Ultrasonographic examination may be helpful in this context. In one study, joint effusions were demonstrated in 6 of 24 consecutive patients examined and tenosynovitis was identified in 8 (Kellner *et al*. 1992). Joint effusions in other joints are usually not detectable. When an effusion is present it is usually only mildly inflammatory, with less than 1000 leucocytes/mm^3, predominantly lymphocytes and large mononuclear cells. Occasionally an inflammatory effusion is aspirated, with leucocyte counts of greater than 40 000/mm^3, predominantly neutrophils. Needle biopsy specimens of synovial membrane in acute sarcoid arthropathy show mild, non-specific synovitis consistent with the clinical impression that much of the inflammation is periarticular. After recovery, acute sarcoidosis only occasionally recurs.

Fig. 2 Erythema nodosum is characteristic of acute sarcoidosis. Tender, red swellings appear on the shins, thighs, and upper limbs. Resolving erythema nodosum resembles painful bruises. Erythema nodosum usually resolves fully within 3 to 6 weeks.

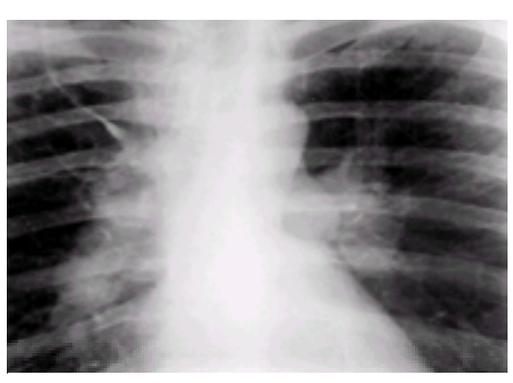

Fig. 3 Bilateral hilar lymphadenopathy due to sarcoidosis may be discovered on routine chest radiographs in asymptomatic individuals. It also frequently presents in acute sarcoidosis with fever, erythema nodosum, and arthritis.

Chronic arthritis is relatively uncommon in sarcoidosis (Gumpel *et al*. 1967; Siltzbach and Duberstein 1968; Spilberg *et al*. 1969; Grigor and Hughes 1976). It usually involves several joints and may appear either early or late in the course of the disease. Chronic monoarticular arthritis is rare. Large joints such as knees and ankles, elbows and wrists are most frequently involved. Hips and shoulders may also be affected. Involvement of spinal and temporomandibular joints has also been reported. Chronic arthritis involving the small joints of hands and feet is rare, except when secondary to osseous disease involving the phalanges (see below). Chronic polyarthritis is more frequently observed in women than men with sarcoidosis. A history of erythema nodosum is unusual in patients with chronic arthritis. Acute exacerbations may occur over a period of years, especially during periods of generalized disease activity. Chronic sarcoid arthritis is characterized by synovial thickening and effusions. Histological examination of synovial membrane may reveal typical non-caseating granulomas (Fig. 4). However, in some patients with chronic arthritis the histological features in synovial membrane are non-specific (Palmer and Schumacher 1984). Chronic arthritis may progress to joint deformity and destruction.

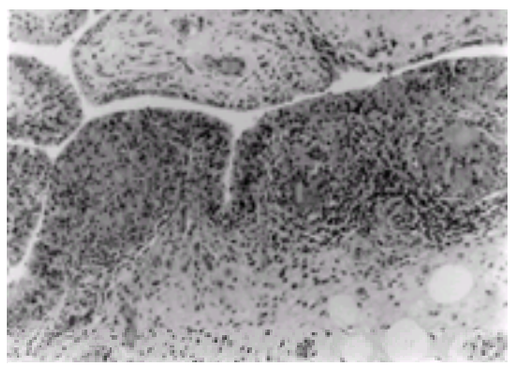

Fig. 4 Chronic arthritis in sarcoidosis showing thickening of the synovial lining layer, mononuclear cell infiltration, and non-caseating granulomas.

Bone disease

Bone involvement occurs in approx. 5 per cent of all patients with sarcoidosis. Bone cysts containing characteristic granulomas are most frequently observed in the phalanges of the hands and feet (Gumpel *et al*. 1967; James *et al*. 1976). Bone cysts are occasionally observed in long bones, pelvis, vertebrae, and the bones of the skull. Bone lesions are most frequently found in patients with persistent disease and are particularly frequent in those with lupus pernio (Fig. 5) and other chronic skin

lesions (Fig. 6). However, sarcoidosis limited to osseous disease of fingers and toes has been described (Schriber and Firooznia 1975). Bone lesions may be asymptomatic; frequently they are identified fortuitously after routine radiographic examination. Bone scanning techniques may be more sensitive than routine radiography in detecting early osseous sarcoidosis. Pain may be absent, even when obvious bone swelling is present.

Fig. 5 Lupus pernio, presenting as a bluish-red or violaceous swelling of the nose extending on to the cheek, is a characteristic of chronic sarcoidosis and is frequently associated with bone lesions.

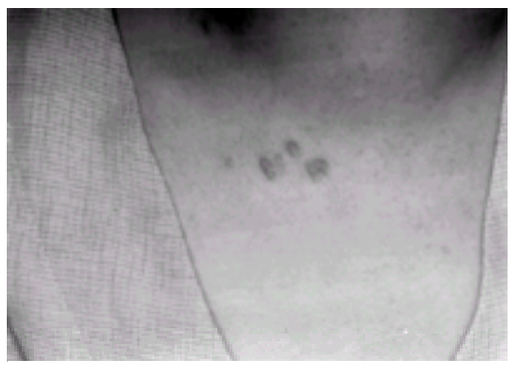

Fig. 6 Chronic cutaneous sarcoidosis, which may accompany bone involvement.

The most characteristic presentation of osseous sarcoidosis is of swollen, sausage-like digits resulting from cyst formation in the phalanges (Fig. 7). Single or multiple digits may be involved. Radiographic examination will demonstrate lytic lesions of various sizes ranging from minute cortical defects to intraosseous cysts causing diffusely expanded phalanges or cysts in phalangeal or metatarsal heads (Fig. 8 and Fig. 9). Less frequent radiographic changes include thickening of cortical bone with a fine reticular alteration of the trabecular pattern, acrosclerosis of distal phalanges or, rarely, gross bone destruction. Osseous sarcoidosis may cause secondary articular changes in the joints of the hands and feet.

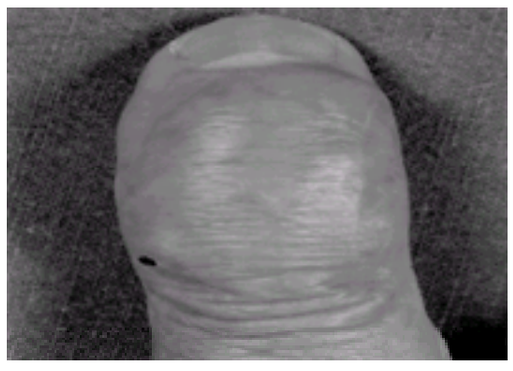

Fig. 7 Sarcoid dactylitis caused by granuloma formation in phalanges and surrounding soft tissue.

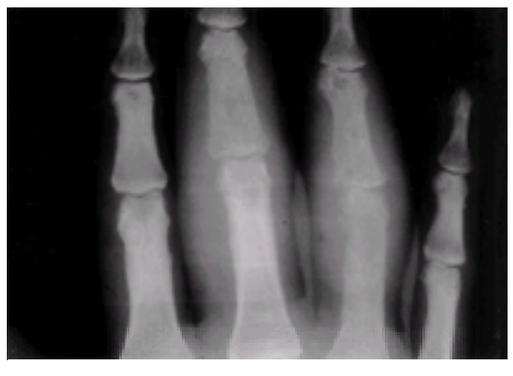

Fig. 8 Bone sarcoidosis presenting as dactylitis of the third and fourth fingers. The radiological changes are relatively early. Note the lacy, reticular pattern in the third middle and the fourth middle and proximal phalanges, associated with prominent soft-tissue swelling.

Fig. 9 Bone sarcoidosis involving four digits sparing the middle finger. Soft-tissue swelling, bone cysts and joint-space narrowing are prominent. There is expansion of

the second proximal phalanx.

Vertebral sarcoidosis may present with back pain or with neurological impairment resulting from cord compression. Radiographic examination of the spine will demonstrate extensive lytic or sclerotic changes in one or more vertebrae at any level. Pathological fracture has been reported as a complication of long-bone involvement. Skull involvement may appear as multiple lytic defects associated with overlying soft tissue swellings containing granulomas.

Muscle disease

Sarcoidosis of skeletal muscle is usually asymptomatic. In the early acute stages, especially in the presence of erythema nodosum, asymptomatic granulomatous muscle involvement is common, with a prevalence rate ranging between 50 and 80 per cent. Random muscle biopsy may, therefore, be a useful diagnostic procedure in patients presenting with erythema nodosum. Investigators have emphasized the need for generous sampling and examination of multiple tissue sections.

Muscle sarcoidosis has two clinical types: nodular and myopathic (Hinterbuchner and Hinterbuchner 1964). The nodular type often involves extremities and causes solitary or multiple nodules. The myopathic type involves muscles symmetrically and diffusely without causing an intramuscular mass. Slowly progressive myalgia, weakness and atrophy usually occur. Symptomatic muscular sarcoidosis may accompany the acute disease onset and is characterized by fever and severe pain and tenderness, usually involving the proximal muscles of the upper and lower limb girdles (Douglas *et al*. 1973). The histological appearances in acute symptomatic muscular sarcoidosis are identical to those in asymptomatic patients and consist of characteristic granulomatous lesions located between apparently normal muscle fibres. The electromyographic features are those of idiopathic polymyositis. A number of reports have described patients with isolated sarcoid muscle disease without apparent involvement of other organ systems. It is possible that these patients have granulomas in other tissues without their causing clinical manifestations. In patients who appear to have isolated muscle sarcoidosis, systematic clinical, radiological, and histological evaluation will usually reveal evidence of multisystem disease.

^{67}Ga scintigraphy is a useful diagnostic method for demonstrating myopathic disease, whereas abnormalities detected by magnetic resonance imaging may define the nodular type of muscular sarcoidosis (Otake 1994). Computed tomography, ultrasonography, and angiography were less useful in identifying sarcoid muscle disease.

Childhood sarcoidosis

Sarcoidosis is rare in childhood. Chronic arthritis and tenosynovitis have been described (Rosenberg *et al*. 1983). Arthritis usually affects knees and ankles, and is characterized by boggy thickening of synovia or tendon sheaths and effusion, causing minimal pain and limitation (Fig. 10). Arthritis usually occurs in children with onset of sarcoidosis before the age of 5 years, and is frequently associated with ocular and cutaneous manifestations. Sarcoid arthritis in children usually follows an indolent clinical course, with minimal or absent constitutional symptoms.

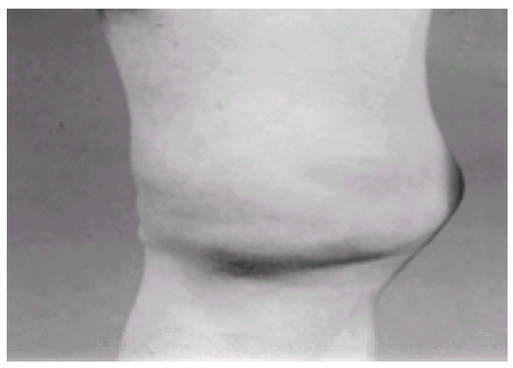

Fig. 10 Chronic sarcoid arthritis with boggy synovial thickening of the knee presenting in a 5-year-old boy who also had uveitis and elevated serum angiotensin-converting enzyme.

Treatment

Acute sarcoidosis with erythema nodosum and hilar lymphadenopathy is usually a self-limiting illness. The arthralgias and arthritis are transient. Symptoms are usually relieved by rest and non-steroidal anti-inflammatory drugs. Occasionally, a short course of corticosteroid therapy may be justified to relieve very acute symptoms. Exacerbations of chronic arthritis are usually associated with active multisystem disease, so that therapeutic decisions usually depend on the severity of the non-articular features. Thus, most patients with chronic arthritis will require corticosteroids for control of systemic disease.

In osseous sarcoidosis, therapy is not indicated for asymptomatic patients. Corticosteroid agents are usually prescribed for symptomatic osseous sarcoidosis, and healing of lytic and destructive lesions has been documented. Similarly, no therapy is required for asymptomatic muscle disease. Corticosteroids are usually recommended for symptomatic patients, although some uncertainties remain about the efficacy of corticosteroid therapy, particularly in chronic sarcoid myopathy.

5.13.6 The chronic, infantile, neurological, cutaneous, and articular syndrome (CINCA)

Anne-Marie Prieur

With increasing knowledge in paediatric rheumatology, new inflammatory entities have been more accurately defined. Closer scrutiny of particular sites of joint involvement and long-term follow-up now distinguish certain syndromes from systemic-onset juvenile chronic arthritis. The heterogeneity of so-called systemic-onset juvenile arthritis occurring during the first year of life was stressed several years ago by Prieur and Griscelli (1983). The children in question all had high fever, skin rash, and polyarthritis, but careful analysis of the symptoms allowed us to distinguish various entities. Among these, a group of patients displayed a chronic syndrome that also involved the central nervous system, including the eye and other sensory organs. The autonomy of this syndrome, which in Europe is designated as chronic, infantile, neurological, cutaneous, and articular syndrome (**CINCA**), is now accepted, although its cause remains a mystery.

Clinical presentation

Background

In definitive descriptions of CINCA, the first symptoms occur in early infancy and are often present at birth. The course of the disease is chronic, with intermittent flares associated with fever, and enlargement of lymph nodes and spleen. There have been individual case reports of a disease with these characteristics (Campbell and Clifton 1950; Lorber 1973; Ansell *et al*. 1975, Lampert *et al*. 1975; Fajardo *et al*. 1982), mostly preceding our suggestion that this could be a specific syndrome (Prieur and Griscelli 1981), and others have since confirmed its autonomy (Hassink and Goldsmith 1983; Yarom *et al*. 1985; Kaufman and Lovell 1986). A comprehensive description of the disease is given in Prieur *et al*. (1987). The syndrome is now more easily identified and more fully documented (Torbiak *et al*. 1989).

We have recognized five new cases, in particular a family in which father and daughter, and probably grandmother and great-grandfather, had the disease. The CINCA syndrome tends to be sporadic, but three families where more than one member is affected are known (see also Campbell and Clifton 1950; Ansell *et al*. 1975).

Perinatal events

The frequency of perinatal events is an important feature of this syndrome. These have been identified in half of the neonates in whom details of the perinatal period are known. After generally uneventful pregnancies (except for minor viral infections in a few cases), half of the babies are premature. The average birth weight is 2600 g (range 1700 to 4700 g) after a 38-week pregnancy (range 33 to 42 weeks). Five instances of anomaly in the umbilical cord have been found (umphaloceles or umphalitis). In one case, a histological study of the placenta showed thickened vessel walls with thrombosis and microcalcifications, and infiltration of the umbilical cord by polymorphonuclear cells. There was no evidence of infection in any of the infants, despite the occurrence of respiratory distress in three and icterus in five.

Signs and symptoms

In all cases, the association of skin rash, joint involvement, and central nervous manifestations is present.

Rash

The rash is present at birth in three-quarters of the children or occurs within the first 6 months after birth in the others. In a few patients, it has been noticed later or information on this period of life is lacking. The clinical expression is similar in all patients, although variable in intensity. It resembles the rash of Still's disease but is more intense, often having the appearance of a non-pruritic urticaria (Fig. 1). The rash is exacerbated during flare-ups of other symptoms of the disease. Skin biopsy shows a normal epidermis, mild inflammation in the dermis, and perivascular aggregation of polymorphonuclear cells with some eosinophils. No immunoglobulin or complement deposits have been found by immunofluorescence.

Fig. 1 The skin rash and patella overgrowth with knee deformity. (Reproduced from Prieur *et al*. 1987, with permission.)

Central nervous and sensory anomalies

These are important manifestations of this syndrome. They are usually discovered at the onset of symptoms that could be related to a chronic meningeal irritation, such as headaches, vomiting, seizures, or transitory episodes of hemiplegia. A chronic meningitis has been identified in 23 of 25 patients investigated; these patients had a mild leucocytosis with polymorphs (and sometimes eosinophils), and/or increased protein concentrations in the cerebrospinal fluid. Anomalies in the cerebrospinal fluid may vary at follow-up. Extensive attempts to demonstrate chronic infection, including electron microscopy of cells in the cerebrospinal fluid, have been negative. Clinical follow-up of the central nervous involvement often shows an increase in the meningeal irritation, with headaches and sometimes seizures. Spasticity of the legs is not uncommon, but to date no persistent neurological defect has been observed. A low IQ has been noticed in several patients.

The skull has an increased cranial volume and there is delay in the closure of the anterior fontanelle. In some patients, there are calcifications of the falx and dura (Fig. 2). Computed tomography (**CT**) often reveals a mild ventricular dilatation (Fig. 3).

Fig. 2 Calcifications on the falx and dura in a 12-year-old patient. (Reproduced from Prieur *et al*. 1987, with permission.)

Fig. 3 CT scan: enlargement of ventricles with an area of cerebral change of probable vascular origin. (Reproduced from Prieur *et al*. 1987, with permission.)

Sensory anomalies are progressive. Varying degrees of perceptive deafness are present in older children, often requiring the use of a hearing aid. Eye involvement can be severe: optic atrophy, papillitis, conjunctivitis, keratitis, uveitis, and chorioretinitis have been observed and can lead to a progressive visual defect (Fig. 4). Hoarseness is frequent.

Fig. 4 Papillitis.

Joint involvement

The severity of joint involvement varies among patients. The knees are most frequently affected (see Fig. 1), then elbows, wrists, ankles, and small joints of the hand. In some patients, the joint symptoms are mild, and manifest as transitory inflammation during flare-ups. In this group, the first articular manifestations are generally observed after the age of 2 years. In other patients, the arthropathy may present as early as 10 days of age (Hassink and Goldsmith 1983). The main finding is an overgrowth of the epiphyseal plate of the bone, resulting in hard bony enlargement. The synovial fluid exudate may show a non-specific inflammatory reaction. Progressive contractures and limitation of motion due to patellar and/or epiphyseal overgrowth occur (see Fig. 1).

The radiographic anomalies of affected joints are progressively more characteristic with increasing age in half of the patients. The first finding is swelling of periarticular soft tissues, sometimes with early periosteal reaction of the diaphysis (Kaufman and Lovell 1986). The most characteristic modifications are in the metaphysis and epiphysis of long bones, giving an irregular ossification with abnormal trabeculae. These anomalies may involve growth cartilage plates (Fig. 5); one biopsy showed an irregular metachromasia and completely disorganized columns of cartilaginous cells (Fig. 6). Surprisingly, no inflammatory cells were found in the abnormal cartilage (Fig. 6).

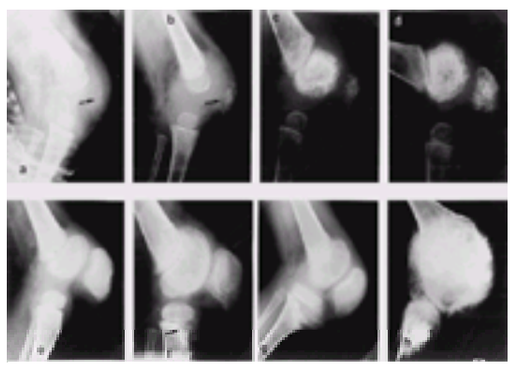

Fig. 5 Follow-up of radiographic anomalies in the knee at various ages: (a) 1 year; (b) 1 year and 6 months; (c) 2 years and 6 months; (d) 3 years and 9 months; (e) 5 years; (f) 6 years (arrow: late modification of tibial growth cartilage); (g) 8 years; (h) 33 years (another patient). (Reproduced from Prieur *et al*. 1987, with permission.)

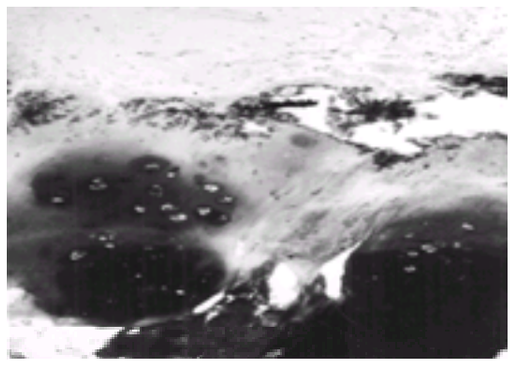

Fig. 6 Biopsy of growth-cartilage overgrowth: irregular metachromasia and disappearance of the normal columns of cartilaginous cells. Note the absence of inflammatory cells in this abnormal cartilaginous tissue. (By courtesy of Giulia Coumot-Witmer.)

Morphological changes

These patients have morphological changes in common. A progressive growth retardation with height below the third percentile is very frequent, but no defect in growth hormone has been found. The heads of these patients have a similar appearance, with enlargement (often with frontal bossing) and blond hair making these unrelated children look like siblings (Fig. 7(a and b)). The adults also resemble each other, as shown in Fig. 7(c and d). A saddle-back nose is frequent and the patient shown in Fig. 7(c) looks surprisingly like one of the patients in the first published descriptions in 1950 (Campbell and Clifton 1950). There is also clubbing of the fingers and toes (Fig. 8). Hands and feet appear short and thick. In some patients, the palms and soles have a wrinkled appearance.

Fig. 7 Morphological aspects of two unrelated children (a) and (b) and two unrelated adults (c) and (d). Patients (b) and (d) are daughter and father.

Fig. 8 Clubbing of finger in a 20-year-old girl.

Adult features

These children may reach adulthood, although eight deaths have been reported in children with this syndrome. The causes of death in five of the children were: secondary amyloidosis (Prieur *et al*. 1987); sepsis (Fajardo *et al*. 1982); leukaemia, possibly related to chlorambucil therapy (Prieur and Griscelli 1981); and subacute necrotizing leucoencephalopathy after head injury (Lampert 1986). An adult died of gangrene of the foot (Warin 1977).

Follow-up

Long-term follow-up reveals a slow worsening of most symptoms despite various therapeutic trials. Non-steroidal anti-inflammatory drugs induce pain relief. Steroids are partially effective for fever and pain, but not for skin lesions or joint disease. Immunosuppressive drugs have no dramatic effect; disease-modifying drugs are ineffective. Physiotherapy improves the functional status in patients with severe arthropathy.

Pathogenesis

The pathophysiology of this syndrome is unknown. There are indications of a non-specific inflammation: hypochromic anaemia, leucocytosis with a predominance of polymorphonuclear neutrophils and eosinophils, high platelet counts, and an increase in erythrocyte sedimentation rate and other acute-phase reactants. A polyclonal stimulation of immunoglobulin synthesis has been found in all patients. Surprisingly, no circulating immune complexes have been detected; no autoantibodies or immunodeficiency have been found. The microscopic architecture of the lymph nodes is preserved except for features of chronic inflammation, with an infiltration of the subcortical T-cell region by polymorphonuclear cells and often eosinophils. Extensive investigations for an infectious agent have been unsuccessful. Evidence of a retroviral infection was sought in leucocytes and cells from cerebrospinal fluid in a recently diagnosed patient, but the outcome was negative (C. Rouzioux, unpublished data).

This disorder is an unremitting inflammatory process that begins at birth. Most of the organs or tissues involved, except cartilage, show chronic inflammation. Cartilage may be the target organ in this syndrome, with the clustering of growth retardation, anomalies of ossification of skull and epiphyses, saddle-back nose, hoarseness suggesting laryngeal localization, and progressive deafness. Indeed, some indications of such a mechanism were suggested by the presence of a toxic effect of the serum from these patients on normal human cartilage cells in culture (Prieur *et al*. 1988). However, the origin of this disease remains unknown, even though one may speculate on an initiating event that takes place before birth. It represents an original and new disorder that must be distinguished from previously described rheumatic diseases of childhood.

5.13.7 Multicentric reticulohistiocytosis

P. J. Maddison

Multicentric reticulohistiocytosis is a rare systemic disease that is recognized clinically by the combination of typical papular and nodular skin lesions and a severe and destructive polyarthritis, although virtually any organ system of the body can be involved. The term 'multicentric reticulohistiocytosis' was introduced by Goltz and Layman (1954) to distinguish the disorder from solitary cutaneous nodules, termed reticulohistiocytomas, which have identical histological appearances but are not associated with systemic disease. There are a number of synonyms, which include lipoid dermatoarthritis, reticulohistiocytosis, giant-cell reticulohistiocytosis, and normocholesterolaemic xanthomatosis. At one time it was thought to be a lipid-storage disease but no consistent abnormality of serum or intracellular lipids has been identified. It is thought generally that the histiocytes and giant cells that characterize the lesions contain a non-specific accumulation of glycoprotein and lipids, and that this disease is a histiocytic granulomatous reaction to an unknown stimulus (Campbell and Edwards 1991). However, in one case, type VI collagen inclusions usually found in lymphohistiocytic neoplasms were demonstrated, supporting the concept of a proliferative rather than an inflammatory background for this condition (Fortier-Beaulieu *et al*. 1993).

Clinical features

Multicentric reticulohistiocytosis is primarily a disorder of adults, being slightly more common in women (Barrow and Holubar 1969), with a mean age of onset in the fifth decade. About 85 per cent of reported cases are caucasoid, but it can also occur in other ethnic groups (Lesher and Allen 1984). Typical cases have been reported in adolescence (Raphael *et al*. 1989), but in most instances the childhood form differs from that in adults in having a familial component, a marked tendency to involve the eye (glaucoma, uveitis, and cataracts), and a lack of giant cells in tissue sections, the last feature being considered an essential feature of multicentric reticulohistiocytosis (Zayid and Farraj 1973).

Skin nodules and a destructive polyarthritis are the most common features (Barrow and Holubar 1969; Chevrant-Breton 1977; Rapini, 1993). Arthritis is frequently the presenting feature. It has a similar distribution to rheumatoid arthritis, including the temporomandibular joints and atlantoaxial involvement (Gold *et al*. 1975), but also affects the distal interphalangeal joints. Commonly involved sites are the hands (75 per cent), knees (70 per cent), shoulders (65 per cent), wrists (65 per cent), hips (60 per cent), ankles (60 per cent), elbows (60 per cent), feet (60 per cent), and spine (50 per cent) Often it has a persistent course with progressive joint destruction, sometimes leading to the picture of arthritis mutilans with 'opera glass' deformities of the hand developing in approximately 20 per cent (Barrow and Holubar 1969). Radiographs of the joints show symmetrical erosions resembling rheumatoid arthritis. However, osteoporosis is not marked (Maki *et al*. 1995) and there is often prominent involvement of the distal interphalangeal joints, and the spread of erosions from the periphery of the joint produces apparent widening of the joint space (Fig. 1). Analysis of joint fluid shows low to moderate cell counts, mostly with a preponderance of mononuclear cells but sometimes of neutrophils. Synovial biopsy shows the presence of lipid-laden giant cells and histiocytes, as found in the involved skin.

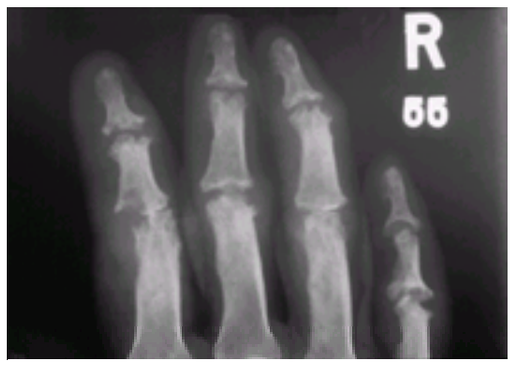

Fig. 1 Radiograph of the hand in multicentric reticulohistiocytosis.

Mucocutaneous involvement is apparent in approximately 90 per cent of patients at the time of presentation but may occur in the months following the development of arthritis. Occasionally it is the first feature. Skin lesions consist of numerous, usually non-pruritic, skin-coloured, yellowish or red-brown nodules, ranging from a few millimetres to several centimetres in diameter. Occasionally, however, pruritus is a feature, and can be severe and precede the overt lesions. The nodules mostly involve the hands in a periungual distribution, together with nodules scattered on the fingers and on the face, where lesions develop on the ears, at the corners of the mouth, and the side of the nose adjacent to the alae (Fig. 2 and Fig. 3). Extensive involvement of the face produces a leonine facies. Lesions can also occur on the forehead, chest, back, and over the olecranon process and knees. Xanthelasma develops in approximately 25 per cent. The oral mucous membranes are involved in approximately half, with, for example, numerous flesh-coloured papules on the buccal mucosa, sides of the tongue, surface of the palate, and gingiva. Occasionally the pharynx and larynx are affected (Katz and Anderson 1988). To date there have been no reports of vaginal or perianal involvement.

Fig. 2 Multicentric reticulohistiocytosis: nodules involving the hands.

Fig. 3 Multicentric reticulohistiocytosis: involvement of the face.

Although multicentric reticulohistiocytosis usually affects the skin and joints, a large variety of systemic features can occur, reflecting the potential involvement of most tissues and organs of the body. There are also reported associations with various types of malignancy. Constitutional manifestations occur in about one-third of patients, and include fever and weight loss; cases have been reported with pericarditis, pulmonary involvement, and myositis (Anderson *et al*. 1968; Fast 1976; Lesher and Allen 1984; Widman *et al*. 1988; Gao *et al*. 1990). There have also been case reports of lymph node enlargement, splenomegaly, marrow infiltration resulting in pancytopenia, salivary gland involvement, thyroid infiltration leading to hypothyroidism, and carpal tunnel syndrome (Warin *et al*. 1957; Orkin *et al*. 1964; Ehrlich *et al*. 1972; Furey *et al*. 1983; Finelli *et al*. 1986; Rene *et al*. 1990).

Laboratory abnormalities occur, but are inconsistent, and include a raised erythrocyte sedimentation rate, abnormal liver function tests, and elevated creatine phosphokinase. Paraproteinaemia of g heavy-chain type has been encountered but serological tests for such as rheumatoid factor are otherwise usually normal. Gallium scintiscans have been used to evaluate multicentric reticulohistiocytosis but the abnormalities are non-specific (Widman *et al*. 1988).

Approximately 25 per cent of patients with multicentric reticulohistiocytosis have been reported to have malignant disease (Catterall and White 1978). Associations have mostly been with internal carcinomas of the colon, breast, bronchus, cervix, ovary, and stomach. Cases have also been associated with sarcomas and lymphomas. Patients with malignant melanoma and pleural mesothelioma have also been reported (Coupe *et al*. 1987; Gibson *et al*. 1995). In one review of the literature (Nunnick *et al*. 1985), the onset of both diseases occurred in several patients within 1 year. The onset of multicentric reticulohistiocytosis in adulthood necessitates, therefore, a thorough clinical examination, including a chest radiograph, to look for signs of malignant disease. It is not necessary, however, to embark on invasive procedures to look for occult neoplasms. It should be borne in mind that there may be a bias towards reporting cases with underlying malignancy, especially previously unreported tumours, and some of the associations may be purely coincidental.

Pathology

Histologically, the nodular infiltrates, which have a granular or ground-glass appearance, consist of multinucleate (up to 20 nuclei) giant cells of the foreign-body type and histiocytes of the monocyte–macrophage lineage (Heathcote *et al*. 1985) admixed with small numbers of CD4+ lymphocytes and B cells. Histochemically, the cytoplasm of the giant cells contains diastase-resistant, periodic acid–Schiff-positive material thought to be glycoprotein, neutral fats, phospholipids, and iron (Barrow and Holubar 1969). Ultrastructural studies show the presence of pleomorphic cytoplasmic inclusions (Degas *et al*. 1975; Caputo *et al*. 1981). The giant cells and mononuclear histiocytes express the surface markers of the monocyte–macrophage lineage (Salisbury *et al*. 1990; Zegler *et al*. 1994), and cytokines and enzyme products of activated macrophages have been detected (Lotti *et al*. 1988; Zagala *et al*. 1988). Negative staining with markers such as CD1 and the absence of Birbeck granules helps to confirm that the cells are not derived from Langerhans cells, in contrast to histiocytosis X (Salisbury *et al*. 1990).

Diagnosis

The diagnosis is confirmed by skin or synovial biopsy. Solitary reticulohistiocytomas have identical histological findings but there is no evidence of systemic disease (Zegler *et al*. 1994).

Diseases that may possibly be confused with multicentric reticulohistiocytosis on the basis of clinical or histological findings are:

1. rheumatoid or psoriatic arthritis;
2. sarcoid dactylitis—associated with discrete tubercles that lack foam cells or giant cells typical of multicentric reticulohistiocytosis;
3. xanthomas;
4. fibroxanthoma;
5. histiocytosis X—usually presents in childhood and proliferating cells are epidermotropic Langerhans cells rather than of true monocyte–macrophage lineage;
6. generalized eruptive histiocytoma—not associated with arthritis and lesions do not exhibit the typical multinucleate giant cells;
7. tendon sheath giant-cell tumours—solitary, well-circumscribed nodules in the hands;
8. Farber's disease—lipogranulomatosis, usually fatal in infancy.

Treatment and course

The disease often runs a waxing and waning course and sometimes it stabilizes. It is difficult to predict the course in the individual case but as a rule the disease 'burns out' after 5 to 8 years, with regression of the cutaneous nodules (Lyell and Carr 1959; Albert *et al*. 1960), leaving the patient with severe joint deformities. Occasionally, systemic involvement can be severe enough to be life threatening (Barrow and Holubar 1969) but otherwise the prognosis is dominated by whether or not there is an associated malignancy.

Various drug treatments have been proposed to suppress the condition, including corticosteroids, adrenocorticotrophic hormone, salicylates, antimalarials, and cytotoxic agents. There are no controlled trials, as the condition is so rare, and therefore reports of efficacy should be interpreted with caution (Table 1).

Drug	Comments
Prednisolone	
Taylor (1977)	Single case history with improvement in pruritis and slow resolution of skin lesions
Zoale *et al*. (1980)	High-dose prednisolone effective in one patient
Cytotoxic drugs	
Hanauer (1973)	Remission on cyclophosphamide (one case)
Ehrlich *et al*. (1972)	Response in one patient to combination of azathioprine and prednisolone
Krey *et al*. (1974)	No response to azathioprine (one patient)
Gold *et al*. (1975)	Cyclophosphamide improved skin and joint disease (one case)
Brandt *et al*. (1982)	Improvement on cyclophosphamide with reduction in erosions on hand radiograph (one case); previous improvement of skin lesions with topical nitrogen mustard
Hanser *et al*. (1983)	Good response to chlorambucil before patient died from breast carcinoma
Doherty *et al*. (1984)	Good response first to cyclophosphamide, then to chlorambucil (one case)
Coupe *et al*. (1987)	Skin and joint manifestations responded well to cyclophosphamide until the patient died from associated mesothelioma
Grinberg *et al*. (1988)	Five patients treated with cyclophosphamide, one with chlorambucil, all improved, five went into remission, one relapsed after treatment stopped
Kurtz *et al*. (1988)	Response to cyclophosphamide until the patient died of recurrent melanoma
Other agents	
Davies *et al*. (1968)	Improvement in two patients on combination of hydroxychloroquine and prednisolone
Gold *et al*. (1977)	Improvement on rifampicin plus ethambutol in a patient with coexistent tuberculosis
Doherty *et al*. (1984)	No response to penicillamine (one case)
Kaur (1988)	No response to methotrexate (one case)
Gaumetou *et al*. (1991)	Good response to methotrexate resulting in prolonged remission (one case)

Table 1 Drug treatments for multicentric reticulohistiocytosis

Corticosteroids are of limited use. Skin infiltration does not usually respond, although there may be relief of troublesome pruritus (Taylor 1977). Joint symptoms

sometimes improve (Davies *et al*. 1968).

There is a consensus that alkylating agents are the treatment of choice and there are several reports of improvement in skin, joint, and systemic disease with cyclophosphamide in particular (Ginsburg *et al*. 1989). Patients with long-lasting remission after therapy with cyclophosphamide or chlorambucil have been reported (Hanauer 1972; Brandt *et al*. 1982; Coupe *et al*. 1987; Ginsburg *et al*. 1989; Kenik *et al*. 1990), but some do relapse when treatment is stopped (Ginsburg *et al*. 1989). Methotrexate is also reportedly successful (Gourmelen *et al*. 1991), but not in all cases (Giam 1988).

5.13.8 Hyperlipidaemias

Keng Hong Leong, J. Reckless and Neil John McHugh

Introduction

The relationship of lipid disorders to rheumatic diseases is multifaceted. For instance several abnormalities in the lipid and lipoprotein profile (or dyslipidaemia) have been documented in various forms of chronic arthritis. The dyslipidaemia may depend on the type or activity of the joint disease or may be influenced by other factors such as treatment or systemic complications of the disease. Whenever the dyslipidaemia is present, its severity will be influenced by diet and lifestyle factors, and also by the underlying genetic predisposition. Renal involvement in systemic lupus erythematosus is an example where the disease, treatment of the disease, or complications of the disease such as nephrotic syndrome may each have a separate influence on lipid metabolism. The dyslipidaemia may potentially influence disease outcome itself by accelerating atheroma, although the relative contribution of dyslipidaemia to the increased mortality from vascular disease observed in several rheumatic disorders is uncertain.

Musculoskeletal symptoms may be a manifestation of an underlying hyperlipidaemia and will be described in more detail. There is some evidence that potentially toxic lipid particles, such as oxidized low density lipoprotein (**LDL**), may accumulate within joints (Winyard *et al*. 1993), as well as having more recognized proinflammatory effects on other tissues. Oxidized LDL may be a target for potentially pathogenic autoantibodies that cross-react with phospholipids (Vaarala *et al*. 1993). Conversely, dietary modification of lipid intake may have beneficial effects on inflammatory disease. Dietary supplementation with polyunsaturated fatty acids of the omega 3 and omega 6 series may be effective therapy for certain rheumatic diseases as it is in animal models of inflammatory arthritis. This chapter will cover some of the above relationships between lipids and rheumatic disease and give an outline of appropriate management where relevant.

Lipid metabolism

A comprehensive review of lipid metabolism would not be appropriate but a brief reminder of certain aspects relevant to rheumatology is given here.

Lipid composition

Lipoproteins are complex particles that transport lipids such as triglycerides and cholesterol through the plasma. The composition of a typical lipoprotein particle is shown in Fig. 1. Each particle is composed of a non-polar core containing variable proportions of hydrophobic lipids (triglycerides and cholesterol ester) surrounded by a polar coat of phospholipids and free cholesterol, within which there are various apolipoproteins. This outer coat allows the particle to be soluble in aqueous plasma. The apolipoproteins have both structural roles in the lipoproteins and functional roles as enzyme activators or as ligands with high affinity for specific tissue-cell receptors. There are five main types of lipoprotein, defined by their relative density, that differ in their composition of lipid and the type of apolipoprotein (Table 1). Apolipoprotein A (**apoA**) is the major apolipoprotein in high density lipoprotein (**HDL**) and apolipoprotein B (**apoB**) is the major structural apolipoprotein of the other lipoproteins, chylomicrons, very low dense lipoprotein (**VLDL**), intermediate density lipoprotein (**IDL**), and LDL. The full apoB (apoB100) is found in VLDL, IDL, and LDL, having structural and functional components, but a truncated form, apoB48, having only the structural role, is present in chylomicrons made by gut cells. The main cholesterol-carrying lipoproteins are LDL and HDL while the main triglyceride-carrying lipoproteins are chylomicrons and VLDL. As VLDL is catabolized, remnants are formed known as IDL which are normally rapidly removed from the liver or converted to LDL.

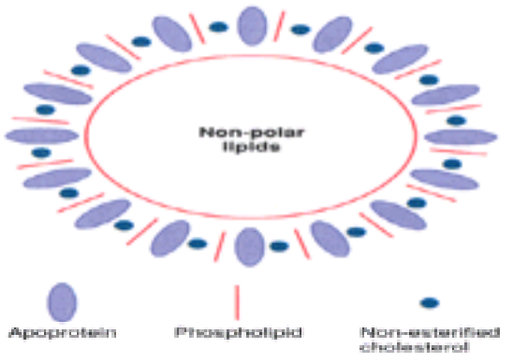

Fig. 1 Composition of typical lipoprotein particle.

Lipoprotein	Major lipids	Major lipoproteins
Chylomicrons and remnarts	Dietary triglycerides	AI, AII, B48, CI, CII, CIII, E
VLDL	Endogenous triglycerides	B48, CI, CII, CIII, E
IDL	Cholesteryl esters, triglycerides	B100, CIII, E
LDL	Cholesteryl esters	B100
HDL	Cholesteryl esters	AI, AII

Table 1 The major classes of lipoproteins

Lipid subclasses

The major lipoproteins are heterogeneous and subclasses can be detected by methods such as precipitation or ultracentrifugation. HDL can be separated into two main fractions—HDL2 and HDL3. HDL3 accepts cholesterol from cholesterol-replete tissues, converts to larger HDL2, which in turn delivers cholesterol to the liver or other lipoproteins. LDL exists in three main subclasses—LDL1, LDL2, and LDL3—which can be separated by cumulative flotation ultracentrifugtion. The normal LDL pattern is predominantly LDL2 with some LDL1 and less LDL3, but under certain circumstances this pattern can shift towards smaller particles with a predominance of small, dense LDL3 which is cholesterol depleted and relatively triglyceride rich. LDL3 is less readily recognized by normal LDL receptors and is more readily recognized (and much more likely to be taken up) by macrophages in the arterial subintimal space which form the foam cells of the fatty streak of early atheroma (Campos *et al*. 1992). VLDL can be separated into three main fractions—VLDL1, VLDL2, and VLDL3. The larger, more buoyant, triglyceride-rich VLDL1 particles, formed especially when there is increased hepatic triglyceride synthesis, are more likely to be precursors for LDL3, while small VLDL particles favour generation of the larger (more normal) LDL subclasses. Changes in the proportion of lipoprotein subclasses will not be apparent on basic lipid screening, yet this has an important bearing on the risk of atherosclerosis and may be influenced by metabolic and systemic alterations that accompany chronic rheumatic disorders. For example triglyceride lipases that have important roles in determining lipoprotein composition are influenced by cytokines that are upregulated in inflammatory conditions (as discussed below).

Exogenous pathway of lipid transport

Chylomicrons carry dietary triglycerides and cholesterol from the intestine to adipose tissue and skeletal muscle. Lipoprotein lipase liberates free fatty acid and monoglycerides which cross the endothelium to the peripheral tissue for further metabolism. The chylomicron remnant is removed by the liver.

Endogenous pathway of lipid transport

Triglycerides are synthesized in the liver and incorporated into VLDL particles. VLDL is a substrate for lipoprotein lipase in peripheral tissue where triglycerides are hydrolysed. VLDL becomes IDL which is either taken back up by the liver or loses further triglyceride and apolipoproteins apart from apoB and becomes cholesterol-rich LDL. Both the liver and extrahepatic tissues that utilize cholesterol recognize LDL via receptor-mediated pathways. Otherwise a variable amount of LDL is scavenged by the reticuloendothelial system and particularly by macrophages. HDL can accept cholesterol from cholesterol-replete tissues. Cholesterol is esterified on the surface of HDL by the enzyme lecithin:cholesterol acyltransferase to become a HDL core cholesterol ester. Subsequently, cholesterol ester in HDL can be exchanged with VLDL and LDL through the action of cholesterol ester transfer protein, or HDL cholesterol can be returned to the liver.

Lipoprotein (a)

ApoA is a complex protein with a protease domain and multiple repeats, called kringles, which have considerable homology with plasminogen. It is linked by a single disulphide bridge to the apoB of a LDL molecule to give lipoprotein (a). The apo (a) gene is highly polymorphic and lipoprotein (a) levels are mainly genetically determined. Interest in lipoprotein (a) stems from its reported association with the presence, severity, and progression of coronary heart disease (Terres *et al*. 1995). However, the risk of atherosclerosis may be most when high levels of lipoprotein (a) are associated with concomitant elevation in LDL–cholesterol levels (Maher and Brown 1995). High lipoprotein (a) levels are linked to premature macrovascular disease, but may not be as good a predictor of atheroma in the long term. Recent work in transgenic mice suggests that lipoprotein (a) acts to inhibit plasminogen activation, leading to reduced activation of transforming growth factor-b which has several adverse effects on vessel wall function (Grainger *et al*. 1994).

Lipids and inflammation

Essential fatty acids and inflammatory mediators

In addition to being core components of complex lipids, fatty acids are either incorporated into cell membranes or serve as precursors for biologically active metabolites, such as prostaglandins and leukotrienes. Essential fatty acids such as linoleic acid cannot be synthesized by mammals and are required in the diet. Polyunsaturated fatty acids contain at least two double bonds in their carbon backbone. Arachidonic acid is the commonest dietary polyunsaturated fatty acids and is a precursor for the potent proinflammatory 2-series prostanoids, via the action of cyclo-oxygenase, and for the 5-series leukotrienes, via the action of 5-lipoxygenase. Metabolites of arachidonic acid are also intimately involved in the early events controlling coagulation and vascular homeostasis. Platelet-derived thromboxane-A_2 is a powerful vasoconstrictor and causes platelet aggregation, whereas endothelial-derived prostacyclin, or PGI_2, causes vasodilatation and opposes platelet aggregation.

Omega-3 fatty acids are essential polyunsaturated fatty acids found in fish oils and include eicosapentaenoic acid. They are precursors of the 3-series prostanoids and the 5-series leukotrienes which competitively inhibit formation of proinflammatory eicosanoids derived from arachidonic acid. Another natural source of essential fatty acids is evening primrose oil which contains predominately gammalinoleic acid. This is a precursor of prostaglandin E_1 and of 15-OH-dihomo-gammalinoleic acid. Prostaglandin E_1 has anti-inflammatory effects and 15-OH-dihomo-gammalinoleic acid inhibits both 5- and 12-lipoxygenases, which generate proinflammatory eicosanoids.

Lipid peroxidation and antioxidants

Polyunsaturated fatty acids are the main target for lipoperoxidative injury by oxygen free radicals. In particular, polyunsaturated fatty acids and their attached phospholipid in plasma LDL can be oxidized by endothelial cells and macrophages. Oxidized LDL may exert several proinflammatory effects by virtue of its chemotactic, cytotoxic, and, possibly, immunogenic properties. LDL is modified by close contact with endothelial cells and becomes a much more ready substrate for scavenger uptake by subintimal macrophages. Hence, endothelially minimally-modified LDL is taken up by receptors on scavenger cells which become lipid-laden foam cells, representing an early event in atheroma formation. LDL3 in particular is more likely to be oxidized, to be immunogenic, to be poorly recognized by the LDL receptor, and more readily taken up by the scavenger pathway. Therefore, the generation of oxidized LDL may be an important factor in atherosclerosis, in addition to contributing to proinflammatory mechanisms in rheumatological disorders.

Certain micronutrients, such as selenium and vitamins A and E, act as antioxidants by preventing the accumulation of oxygen free radicals (Fox 1996). Levels of antioxidants may also have relevance to the susceptibility of LDL to oxidation. As the fat-soluble, antioxidant vitamins are carried on lipoproteins such as LDL, the antioxidant levels may be reflected in the delay time before oxidation propagation occurs in LDL.

Types of hyperlipidaemia

Various patterns of elevated lipoproteins have been recognized (Table 2). However, most patterns can be caused by several different genetic disorders or they may be secondary to other metabolic disturbances. Many hyperlipidaemias are the result of environmental factors exacerbating an underlying monogenic or, more usually,

polygenic hyperlipidaemic tendency or background. Nonetheless it is worth considering a framework to classify the primary inherited hyperlipidaemias, as shown in Table 3, together with what is known about their genetic basis. The pattern of secondary hyperlipidaemia associated with several rheumatic disorders will be discussed.

Lipoprotein pattern	Lipoprotein	Lipid
Type 1	Chylomicrons	Triglycerides
Type 2a	LDL	Cholesterol
Type 2b	LDL and some VLDL	Cholesterol and triglycerides
Type 3	Chylomicron remnants and IDL	Triglycerides and cholesterol
Type 4	VLDL	Triglycerides
Type 5	VLDL and chylomicrons	Triglycerides (and some cholesterol)

Table 2 Patterns of dyslipidaemia

Genetic disorder	Biochemical defect	Lipoproteins elevated (pattern)	Clinical findings
Lipoprotein lipase deficiency	Lipoprotein lipase deficiency	Chylomicrons (1)	Pancreatitis, eruptive xanthomata
Apoprotein CII deficiency	Apoprotein CII deficiency	Chylomicrons and VLDL (1 or 5)	Pancreatitis
Familial type 4 hyperlipoproteinaemia	Abnormal apoprotein E	Chylomicron remnants and IDL (3)	Palmar and tuberous xanthomata, premature atherosclerosis
Familial hypercholesterolaemia	LDL receptor deficiency	LDL (2A)	Tendon xanthomata, premature atherosclerosis
Familial hypertriglyceridaemia	Unknown	VLDL (4)	Eruptive xanthomata
Familial combined hyperlipidaemia	Unknown	LDL and VLDL (2a, 2b, 4)	

Table 3 Primary hyperlipidaemias

It is worth mentioning here that several drugs used in the treatment of hyperlipidaemia are known to give rise to rheumatic complaints, although this is extremely rare. Myopathy has been described in patients treated with statins, fibrates, or nicotinic acid (Zuckner 1990; Goldman *et al*. 1989; Ross Peirce *et al*. 1990). Rhabdomyolysis is also possible, although rare (Hino *et al*. 1996). However, early reports included patients on cyclosporin following heart transplantation, where cyclosporin impaired renal clearance of statins. Recently, the Committee on the Safety of Medicines have calculated that the statin or the fibrate use risk of serious myositis is less than one per 100 000 patient years exposure. Use of statin and fibrate together may increase the risk and milder cases of myositis may be missed. There are case reports of drug-induced lupus caused by lovostatin and clofibrate (Ahmad 1991; Howard and Brown 1973).

Musculoskeletal manifestations of primary hyperlipidaemia

Musculoskeletal symptoms or signs may be the first manifestation of a hyperlipidaemia. A transient polyarthritis is especially common in patients with familial hypercholesterolaemia. Larger rather than smaller peripheral joints tend to be affected. In 1968, Khadchadurian studied 14 families from whom 18 homozygotes with type 2 hyperlipoproteinaemia were identified (Khadchadurian 1968). Ten of these patients experienced a migratory polyarthritis resembling rheumatic fever. A monoarthritis or oligoarthritis may also occur in heterozygotes, commonly affecting the knee or occasionally the first metatarsophalangeal joint. Oligoarthritis and periarticular hyperaesthesia have been described in patients with type 4 hyperlipidaemia (Goldman *et al*. 1972; Buckingham *et al*. 1975). Articular manifestations have not been reported for type 1 or type 3 hyperlipidaemia.

Recurrent tendinitis is a common problem in patients with familial hypercholesterolaemia. Tendinous, tuberous, or periosteal xanthomata may also be present. Common sites for tendon xanthomata are the tendo-Achillis, patellar tendons and extensor tendons of the hands and feet. Sometimes, tenosynovitis may occur without obvious xanthomata. Tendinitis may occur during the early weeks of statin use, usually in patients with very high cholesterol levels. These episodes may result from the mobilization of deposited tissue cholesterol as blood levels fall with treatment, rather analogous to the acute gout that accompanies urate mobilization in the initial weeks of allopurinol treatment. Palmar xanthomata are typically seen in type III, remnant lipidaemia (familial dysbetalipoproteinaemia). Type I, V, and severe IV hyperlipoproteinaemias may be associated with eruptive xanthomatas over the knees, buttocks, shoulders, and back.

In addition to diet and change of lifestyle, for primary hypercholesterolaemia requiring drug therapy, statins (3-hydroxy-3-methylglutaryl coenzyme A, HMG Co-A, reductase inhibitors) are the agents of choice, with or without resins (bile acid sequestrants) where tolerated. For mixed lipidaemia fibrate drugs (fenofibrate, ciprofibrate, bezafibrate, or gemfibrozil) are first choice.

In a recent study of 80 patients with hyperlipidaemia, tendon xanthomatas, particularly of the tendo-Achillis, were found in about 50 per cent of patients with either adult familial hypercholesterolaemia or with mixed hyperlipidaemia (increased cholesterol and triglycerides), often with an associated tendinitis (Klemp *et al*. 1993). Oligoarthritis was seen only in patients with mixed hyperlipidaemia. The manifestations improved with lipid-lowering therapy.

Most cases of acute arthropathy associated with hyperlipidaemia resolve spontaneously. The synovial fluid is usually non-inflammatory. Positively birefringent suspected lipid crystals have been aspirated from a bursitis in a patient with hypercholesterolaemia (Schumaker and Michaels 1989). Subcutaneous cholesterol nodules mimicking rheumatoid nodules and gouty tophi have been described in patients with an apparently normal lipid profile (Szachnowski and Bridges 1994).

Lipids in joints

Lipid microspherules have been found in the joints of patients with rheumatoid arthritis. The mean levels of apoAI, apoB, and cholesterol levels were significantly higher in the synovial fluid of 12 patients with untreated rheumatoid arthritis than in eight patients with degenerative joint disease (Ananth *et al*. 1993). A likely explanation is the increased permeability for these lipoprotein constituents across inflamed synovial membranes. Lazarevic *et al*. did not find concomitant systemic lipid abnormalities nor the presence of antilipoprotein antibodies in such patients (Lazarevic *et al*. 1993a).

Whether synovial lipoproteins are involved in the pathogenesis of rheumatoid arthritis is unclear. Winyard *et al*. have reported positive immunostaining for oxidized LDL in synovial membranes from six patients with rheumatoid arthritis (Winyard *et al*. 1993). The staining was confined to foamy macrophages in the region of synovial blood vessels. The authors point out that inflamed synovial tissue has all the appropriate requirements for enhanced lipid peroxidation, such as macrophage enrichment, extensive iron deposits, and reduced concentrations of antioxidants such as vitamin E. Also, peroxidation products, such as 4-hydroxynonenal, have been detected in synovial fluid (Selley *et al*. 1992). Fairburn *et al*. found reduced levels of the lipid soluble antioxidant a-tocopherol, which terminates the process of lipid peroxidation, suggesting depleted levels may point to increased oxidative activity (Fairburn *et al*. 1992).

The pattern of dyslipidaemia in rheumatic disorders

Low levels of HDL have been found in several chronic inflammatory disorders and seem related to disease activity. Ilowite *et al*. identified such a pattern in a set of paediatric systemic lupus erythematosus patients studied longitudinally (Ilowite *et al*. 1988). The mean HDL–cholesterol and apoA1 were markedly lower in untreated

and clinically active systemic lupus erythematosus patients compared to controls. Levels of HDL–cholesterol and apoA1 returned to normal as the systemic lupus erythematosus became less active. In our own patients in Bath, low levels of HDL were found with systemic lupus erythematosus (Leong *et al*. 1995) and psoriatic arthritis (Jones *et al*. 1994) which was most noticeable in those patients with active disease. In rheumatoid arthritis, low levels of HDL–cholesterol have been found, which return to normal with treatment of the arthritis (Lazarevic *et al*. 1992; Svenson *et al*. 1987a; Svenson *et al*. 1987b).

Low levels of HDL are normally associated with high triglycerides epidemiologically. However, there are conflicting results for levels of other lipoprotein components apart from HDL in rheumatic disorders, which may be explained by confounding influences such as corticosteroid treatment, renal disease, and possibly altered catabolic states associated with chronic inflammation. Ilowite *et al*. (Ilowite *et al*. 1988) found an increase in total triglycerides and VLDL–cholesterol in children with systemic lupus erythematosus. Our systemic lupus erythematosus patients selected for absence of renal disease or corticosteroid treatment had lower levels of total cholesterol, triglycerides, and total LDL (although LDL-3 was increased) but VLDL was unchanged (Leong *et al*. 1995). A similar pattern was seen in patients with psoriatic arthritis where only LDL-3 was increased (Jones *et al*. 1994). Svenson *et al*. studied 48 patients with untreated rheumatoid arthritis and 21 with seronegative spondylarthropathy. Compared to healthy controls, the patients with active rheumatic disease had lower levels of VLDL–cholesterol and VLDL–triglyceride, as well as lower HDL–triglyceride and HDL–cholesterol (Svenson *et al*. 1987a). Lazarevic *et al*. also found low levels of LDL–cholesterol in patients with active rheumatoid arthritis or psoriatic arthritis (Lazarevic *et al*. 1992).

In individuals without rheumatic disorders, the usual effect of endogenous steroids (Cushing's syndrome) or of exogenous steroid therapy is predominantly to increase serum cholesterol, due to increased LDL–cholesterol and often VLDL–cholesterol. There is often increased triglycerides but this is less obvious unless there are additional reasons for hypertriglyceridaemia, such as diabetes (Havel *et al*. 1980) or underlying polygenic mixed hyperlipidaemia. HDL–cholesterol may rise with prednisolone treatment (Zimmerman *et al*. 1984).

The use of corticosteroids or nephrotic syndrome contributes to a type 2b hyperlipidaemia (raised cholesterol with moderately raised triglycerides). Ettinger *et al*. compared 46 systemic lupus erythematosus patients with 30 controls and found that systemic lupus erythematosus patients on corticosteroids had higher levels of total cholesterol, total triglyceride, and LDL–cholesterol (Ettinger *et al*. 1987; Ettinger and Hazzard 1988). Those who were not on steroids had levels similar to controls, apart from a lower HDL–cholesterol. Similar results were found in a study of 100 Singaporean Chinese patients with systemic lupus erythematosus (Leong *et al*. 1994). In the latter study, the type 2b pattern was associated with renal involvement and the use of corticosteroids. MacGregor *et al*. found raised concentrations of triglyceride and apoB in systemic lupus erythematosus patients treated with corticosteroids (MacGregor *et al*. 1992).

Evidence for increased mortality from atherosclerosis in rheumatic disorders

Rheumatoid arthritis is associated with an increased mortality. Mortality is higher in those with more severe disease (Wolfe *et al*. 1994). Prior *et al*. studied 489 consecutive patients with classical rheumatoid arthritis followed-up for a mean of 11.2 years and found a three-fold increase in overall mortality compared with age and gender-specific rates in the general population (Prior *et al*. 1984). Cardiovascular deaths were 2.5 times higher than expected values compared to age and gender-matched population figures. Rasker and Cosh followed a cohort of 100 patients for 18 years (Rasker and Cosh 1981). Of the 43 patients who died, 16 deaths were related to rheumatoid arthritis and 27 were unrelated. In the latter group, 14 were cardiac deaths and 8 were cerebrovascular events. However, results from other studies recording causes of death in 2262 rheumatoid arthritis patients from 13 centres, suggests that cardiovascular disease accounts for 40 per cent of deaths in rheumatoid arthritis which was no different from the general population (Pincus and Callahan 1986).

Urowitz *et al*. recognized a bimodal pattern of mortality in systemic lupus erythematosus with early deaths due to active disease or infections and late events related to atherosclerotic complications (Urowitz *et al*. 1976). Further analysis of 665 patients from the same centre largely confirmed the earlier findings, with about a five-fold overall excess death rate in systemic lupus erythematosus (Abu-Shakra *et al*. 1995). The authors concluded that atherosclerosis is a major cause of death and morbidity in patients with systemic lupus erythematosus. It is not clear whether the late cardiovascular disease is related primarily to corticosteroid treatment or to other manifestations of the disease. Petri *et al*. studied prospectively the risk factors for coronary artery disease in 229 systemic lupus erythematosus patients (Petri *et al*. 1992). Nineteen patients (8.3 per cent) had coronary artery disease which was associated with age at systemic lupus erythematosus diagnosis, duration of corticosteroid use, requirement for antihypertensive treatment, maximum cholesterol level, and obesity.

Many studies, including autopsy studies, have shown premature coronary atherosclerosis and myocardial infarction in relatively young patients with systemic lupus erythematosus. Bulkley and Roberts compared necroscopy findings of 36 systemic lupus erythematosus patients on corticosteroids with findings in patients not on corticosteroids (Buckley and Roberts 1975). Subepicardial and myocardial fat was increased in all the former group. In 42 per cent of the 18 patients who received corticosteroids for more than 1 year, the lumen of at least one of the three major coronary arteries was narrowed by more than 50 per cent by atherosclerotic plaques. In contrast, none of the 17 patients who received corticosteroids for less than 1 year, and who were on average 5 years older, had such findings. Systemic hypertension was twice as common in patients who received corticosteroids for longer than 1 year.

A number of other chronic rheumatic disorders are associated with a shortened life expectancy (Callahan and Pincus 1995). Patients with renal involvement and scleroderma, vasculitis, or systemic lupus erythematosus generally have the poorest prognosis. However, conditions thought to have a better outlook, such as ankylosing spondylitis, may also have an excess death rate (Radford *et al*. 1977; Rigby 1991). Current data suggests that there is a tendency for premature death in patients with rheumatic diseases. One significant contributor is the presence of cardiovascular or cerebrovascular disease. Longer-term, prospective studies with appropriate population controls will help clarify risk factors. As our ability to manage patients improves due to our increasing knowledge, survival of patients will be prolonged, as has already happened with systemic lupus erythematosus. Awareness of potential problems from premature atherosclerosis will become increasingly important.

Mechanisms for dyslipidaemia

Several mechanisms may account for the dyslipidaemia associated with chronic inflammatory disorders. Lipoprotein lipase is a membrane-bound enzyme responsible for liberation of fatty acids from VLDL resulting in formation of LDL. Reduced mass or inhibition of activity of lipoprotein lipase is an attractive hypothesis as it would account for reduced clearance of VLDL–triglyceride and an associated rise in plasma triglycerides. Normal or slightly low LDL–cholesterol would be expected as a result of lower precursor input into LDL—and LDL concentrations in plasma would tend to fall. HDL levels would also tend to fall because there would be a slower reduction in VLDL size, and therefore less VLDL surface coat given up to provide HDL.

Lipoprotein lipase activity is inhibited by several regulatory cytokines such as tumour necrosis factor-a (Fried and Zechner 1989), interleukin-1, and g-interferon (Querfeld *et al*. 1990), that are upregulated in inflammation. Furthermore, 24-h infusion of recombinant human tumour necrosis factor-a is associated with a decrease in serum cholesterol and HDL levels (Spriggs *et al*. 1988). However, tumour necrosis factor-a and other cytokines may also stimulate hepatic lipid secretion and increase *de novo* fatty acid synthesis (Feingold and Grunfeld 1992). Lipoprotein lipase is also an insulin-dependent enzyme and its synthesis in adipose and muscle is increased by insulin treatment. Whether the dyslipidaemia in active rheumatic disease may be due to a form of insulin resistance is not known. Hypertriglyceridaemia, low HDL, small dense LDL3, and insulin resistance (known as the atherogenic lipid profile) is often accompanied by glucose intolerance or diabetes, hypertension, hyperuricaemia, or gout, and procoagulant changes with high PA1–1 and fibrinogen.

Alternatively, an increased production of acute phase proteins by the liver in inflammation may occur at the expense of lipoprotein production. Also, acute phase reactants may interfere with HDL metabolism. Kumon *et al*. showed that in patients with rheumatic disease, total HDL cholesterol, apoA-I, and apoA-II were lower than in normal subjects and were inversely correlated with plasma concentrations of serum amyloid A protein (Kumon *et al*. 1993). It was suggested that serum amyloid A protein may displace apoA-I and apoA-II on HDL particles, and especially on HDL3.

Corticosteroids cause increased hepatic production of VLDL resulting in elevated plasma cholesterol, plasma triglyceride, HDL-C, VLDL-C, and LDL-C. Proteinuria leads to increased generalized hepatic protein synthesis, and hence lipoprotein synthesis which may also be driven by urinary loss of apoA of HDL. Conversely, control of hyperlipidaemia may retard the development of glomerulosclerosis (Kasiske *et al*. 1988).

Antibody-mediated mechanisms may also be important. Lazarevic *et al*. found antilipoprotein antibodies against VLDL and LDL in one-third of patients with active rheumatoid arthritis, but not in patients with osteoarthritis, psoriatic arthritis, or healthy blood donors (Lazarevic *et al*. 1993b). Autoantibodies against LDL have been demonstrated in diabetes mellitus. More recently anti-apoA1 antibodies have been described in systemic lupus erythematosus (Merrill *et al*. 1995). Rarely, antibodies against apoC-II may be associated with severe hypertriglyceridaemia, due to myeloma and clonal production of the antibody.

Rheumatic disorders

Systemic lupus erythematosus

Mechanisms accounting for vasculopathy

Factors to account for the increase in vascular disease in systemic lupus erythematosus include corticosteroid treatment, renal disease, dyslipidaemia, an underlying coagulopathy, vasculitis, and, possibly, antibody or immune-complex mediated injury. In support of the latter, Kabakov *et al*. demonstrated that in the presence of lupus sera, lipid accumulation in cultured smooth muscle cells is increased up to six fold compared to cells cultured with normal human sera from healthy donors (Kabakov *et al*. 1992). Incubation of the smooth muscle cells with circulating immune complexes isolated from lupus sera caused a three to four-fold increase in intracellular cholesterol level. The atherogenic effect was thought to be due to LDL-containing immune complexes.

Lipoprotein (a)

There are conflicting findings concerning the levels of lipoprotein (a) in systemic lupus erythematosus and the risk of thrombosis. Takegoshi reported a case of an 18-year-old systemic lupus erythematosus patient who had severe elevations of lipoprotein (a) associated with myocardial infarction and cerebral infarction (Takegoshi *et al*. 1990). Elevated levels of lipoprotein (a) levels have been reported in a few studies of patients with systemic lupus erythematosus (Matsuda *et al*. 1994; Borba *et al*. 1994) but not in association with thrombosis, which is in accordance with our own unpublished results. However, one recent study found increased lipoprotein (a) levels in systemic lupus erythematosus patients with myocardial and cerebral infarction (Kawai *et al*. 1995).

Lipids and antiphospholipid antibodies

The interplay between lipid abnormalities and antiphospholipid antibodies may be complex. A plasma cofactor which forms part of the antigenic complex recognized by antiphospholipid antibodies has been identified as b $_2$-glycoprotein I or apoH. Whether lipoproteins other than b $_2$-glycoprotein I are involved in the pathogenesis of the antiphospholipid syndrome is unknown. There may be an additive risk of thrombotic clinical events if both antiphospholipid antibodies and hyperlipidaemia are present together (Garrido *et al*. 1994). Lahita *et al*. found an association between anticardiolipin antibodies and low levels of HDL and apoAI, although cholesterol levels were also low in these patients (Lahita *et al*. 1993).

Antibodies to oxidized LDL have been described in patients with systemic lupus erythematosus (Vaarala *et al*. 1993). Monoclonal antibodies to cardiolipin have been derived from a mouse model of the antiphospholipid syndrome that have reactivity against b $_2$-glycoprotein and cross-react with oxidized LDL (Mizutani *et al*. 1995). In a prospective study of middle-aged dyslipidaemic men, there was a correlation between anticardiolipin levels and antibodies to oxidized LDL and the presence of both had an additive risk for myocardial infarction (Vaarala *et al*. 1995).

Rheumatoid arthritis

Most studies have shown that patients with rheumatoid arthritis have a lipid profile that increases the risk of atherosclerosis, especially when samples are studied during active phases of the disease (Lazarevic *et al*. 1992; Svenson 1987a; Svenson 1987b; Rantapää-Dahlqvist *et al*. 1991). The most consistent abnormality is a reduction in HDL. Magaro *et al*. reported lower levels of apoA1 compared with controls, although apoB was also reduced (Magaro *et al*. 1991). Lipoprotein (a) levels may also be increased (Rantapää-Dahlqvist *et al*. 1991). Therefore, dyslipidaemia associated with active rheumatoid arthritis needs to be considered as a contributing factor to the excess death rate observed in mortality studies.

Psoriatic arthritis

Patients with psoriatic arthritis have a similar pattern of dyslipidaemia to that occurring in rheumatoid arthritis (Lazarevic *et al*. 1992). Jones *et al*. found an atherogenic profile with low total HDL and HDL3, and elevated LDL3 and lipoprotein (a) levels (Jones *et al*. 1994). Elevated LDL3 may be particulary important as this small, dense subclass of LDL is much more likely to be taken up by macrophages in the arterial subintimal space, possibly explaining its association with coronary artery disease (Campos *et al*. 1992).

There may also be an imbalance in fatty acids and antioxidants either contributing to disease pathogenesis or as a secondary metabolic consequence of chronic inflammation. Azzini *et al*. found abnormalities in red blood cell fatty acid composition with increased total fatty acids and decreased w-6 polyunsaturated fatty acids (Azzini *et al*. 1995). Reduced levels of the antioxidant selenium and increased plasma concentrations of copper were also found (Azzini *et al*. 1995).

Systemic sclerosis

Vascular impairment secondary to reperfusion injury and the formation of free radicals are postulated as disease mechanisms in scleroderma. Bruckdorfer *et al*. reported that LDL in patients with systemic sclerosis are more susceptible to oxidation (Bruckdorfer *et al*. 1995). In addition to its toxic effects on endothelium, oxidized LDL may potentially contribute to the increased matrix synthesis seen in systemic sclerosis by upregulating certain adhesion molecules and growth factors such as platelet-derived growth factor.

Gout

There is a clear association between gout and type 4 hyperlipidaemia. Decreased HDL–cholesterol and increased VLDL levels have been reported (Ulreich *et al*. 1985; Matsubara *et al*. 1989). The association is unlikely to be causal as patients with gout often have other predisposing factors for hyperlipidaemia, such as obesity, increased alcohol consumption, and altered nutritional habit. Furthermore, in the disorder of insulin resistance the syndrome complex includes hyperuricaemia with or without gout, hypertension, mixed dyslipidaemia, glucose intolerance or diabetes mellitus, central obesity, hyperfibrinogenaemia, high PAI-1, and associated coronary heart disease and peripheral vascular disease.

Hyperlipidaemia may also be more directly associated with decreased renal excretion of uric acid. Renal excretion of urate is lower in hyperuricaemic–hyperlipidaemic patients than in hyperuricaemic–normolipidaemic patients. Tinahones *et al*. reported increased VLDL levels, diminished fractional excretion of uric acid, and increased apoCIII/CII ratios in patients with hyperuricaemia and hypertriglyceridaemia (Tinahones *et al*. 1995). ApoCIII inhibits the hydrolysis of triglycerides by lipoprotein and hepatic lipase, whereas apoCII is an activator of lipoprotein lipase. An altered apoCIII/CII ratio would lengthen the time VLDL remains in the plasma. The mechanism is unknown whereby lipids are directly or indirectly associated with altered renal handling of urate.

Management

The use of essential fatty acids in the treatment of rheumatic diseases

The use of essential fatty acids to treat inflammation has a supportive in vivo and biochemical basis, although the clinical efficacy and cost-effectiveness of such treatment in man remains uncertain. In animal models, marine oils have been effective in suppressing inflammation. Eicosapentaenoic acid supplementation prevented renal disease from developing in NZB/NZW mice (Prickett *et al*. 1981). A fish oil diet had a beneficial effect on the severity of collagen-induced arthritis (Cathcart and Gonnerman 1991) and on lupus-like features in MRL-*lpr* mice (Robinson *et al*. 1986).

Prostaglandins are synthesized from essential fatty acids (see above). The addition of omega 3 or omega 6 polyunsaturated fatty acids to the diet may shift the balance of prostaglandin metabolism towards substances that have less of a proinflammatory action. The two most extensively studied therapies have been fish oils and evening primrose oil. The former contains high levels of polyunsaturated fatty acids of the omega-3 series (such as eicosapentaenoic acid and docosahexaenoic acid) and the latter predominantly gammalinoleic acid.

P>Several studies in rheumatoid arthritis have shown some beneficial effects of diets containing essential fatty acids in fish oils, such as a reduced requirement for non-steroidal anti-inflammatory drugs (Lau *et al*. 1993). In a study of 66 patients randomized to fish oil or corn oil, Kremer *et al*. reported a decreased number of

tender joints, morning stiffness, and global arthritis activity and pain in the fish oil group (Kremer *et al*. 1995). Geusens *et al*. studied 90 patients on various dosage regimes of fish versus olive oil and found an improvement in the patients' global evaluation and physicians' assessment of pain in those patients taking the higher dose of fish oil (2.6 g/day) (Geusens *et al*. 1994). It is worth mentioning that olive oil may also have some active beneficial effects as it contains mainly unsaturated fats. Gammalinoleic acid at a dose of 1.4 g/day was better than placebo in improving joint tenderness and swelling in patients with rheumatoid arthritis (Leventhal *et al*. 1993).

There is some evidence that fish oils may be beneficial in other conditions such as psoriasis and systemic lupus erythematosus. Bittiner reported decreased pruritus, erythema, and scaling of skin psoriasis in 28 patients treated with fish oil compared to a placebo (Bittiner *et al*. 1988). A number of studies have reported an improvement in skin lesions with eicosapentaenoic acid. However, a preparation containing eicosapentaenoic acid, gammalinoleic acid, and decosahexaenoic acid (Efamol) had no significant beneficial effect in patients with psoriatic arthritis despite a fall in leukotriene B4 (Veale *et al*. 1994). It is possible that an insufficient dose of icosapentaenoic acid was used in the latter study. In a study of 27 patients with active systemic lupus erythematosus, symptoms were favourably affected by an eicosapentaenoic acid enriched diet in 14 patients compared to placebo (Walton *et al*. 1991). Another benefit of a fish oil diet is an alteration of the thromboxane/prostacyclin ratio towards substantially less thrombotic thromboxane and a substantially more antithrombotic prostacyclin.

It is important to note that the amount of essential fatty acids needed to produce clinical effects are often in excess of the dose available in commercial preparation. Also, it may be difficult to achieve such doses by ingestion of natural food substances. Fahrer *et al*. found that 7.5 g of fish oil, the therapeutic dose in many studies, is the equivalent of 700 g of fish (Fahrer *et al*. 1991) and carries a 70 calorie load. This means that four to six meals of fish per week are required in order to induce a potentially useful anti-inflammatory effect.

Longer-term studies with larger numbers of patients are required to help clarify the therapeutic role of essential fatty acids. It is possible that essential fatty acid supplementation may be a reasonable treatment alternative to non-steroidal anti-inflammatory agents, especially when the latter are contraindicated. Fish oils can improve moderate to marked hypertriglyceridaemia in some individuals, but do not alter LDL-cholesterol much—a dose of 10 g of fish oil (as Maxepa) being needed, equivalent to 90 calories daily.

Rationale for lipid-lowering treatment

Rheumatic diseases may well carry an increased risk of morbidity and mortality from premature atherosclerosis, although more evidence is needed. Abnormalities in the LDL subfraction are clearly present in patients on long-term corticosteroid treatment (Ettinger *et al*. 1987; Ettinger and Hazzard 1988; MacGregor *et al*. 1992). Many studies have shown the relationship between hypercholesterolaemia and the risk of coronary artery disease. The Framingham study showed that the risk of myocardial infarction was associated with higher levels of LDL-cholesterol and inversely associated with HDL levels (Castelli *et al*. 1986), as did the study of 362 262 American men screened from the Multiple Risk Factor Intervention Trial (Neaton *et al*. 1992). Therefore the dyslipidaemia present in chronic rheumatic diseases would appear to increase the risk of atheroma.

There is good evidence that the treatment of lipid abnormalities influences outcome, with reduced coronary heart disease deaths and events. In older studies, this was shown for cholesterol lowering with cholestyramine (Lipid Research Clinics Program 1984) or with gemfibrozil where triglyceride was also lowered and HDL cholesterol raised (Frick *et al*. 1987). More recently, the more potent statins have shown reduction in coronary heart disease deaths and events, in coronary artery surgery requirements, and in total mortality, both in primary (West of Scotland Coronary Prevention Study) (Shepherd *et al*. 1995) and in secondary (Scandinavian Simvastatin Survival Study) (Scandinavian Simvastatin Survival Study 1994) prevention studies. Many studies (e.g. Blankenhorn *et al*. 1987) have shown slowing of progression, and some regression, of atheroma in patients actively treated for hyperlipidaemia after coronary artery graft surgery.

Approach to treatment

Risk factors for hyperlipidaemia need to be assessed for the individual patient. A basic fasting lipid profile may be appropriate on any patient with a chronic inflammatory rheumatic disease, although subtle changes in lipid subfraction composition may be missed. Other associated risk factors, such as hypertension, diabetes, and smoking, are important and need to be fully discussed with the patient and managed.

Dietary intervention plays a major role in the management of hyperlipidaemia. While dietary change may produce only modest change in lipid levels, dietary modification may be all that is necessary in moderate hyperlipidaemia. Target levels for treatment of dyslipidaemia have been set in national and international guidelines (National Cholesterol Education Program 1994 ; Pyorala *et al*. 1994). In systemic lupus erythematosus, benefit of dietary change at 6 months has been shown in patients receiving corticosteroids (Hearth-Holmes *et al*. 1995). In adolescents with systemic lupus erythematosus, dietary modification with fish oil supplementation improved the lipid profile (Ilowite *et al*. 1995). However, a significant number of systemic lupus erythematosus patients might require further pharmacological therapy for persistent dyslipidaemia, with statins, fibrates, or other agents.

The role of hydroxychloroquine

Hydroxychloroquine is often used in the treatment of mild systemic lupus erythematosus and rheumatoid arthritis. Besides its immunomodulatory properties, hydroxychloroquine may have a protective role against hyperlipidaemia induced by corticosteroids. In a case–control study, patients with systemic lupus erythematosus on hydroxychloroquine had 35 to 45 per cent lower levels of total triglyceride, VLDL-triglyceride, LDL-triglyceride, and apoCIII than patients not on treatment (Hodis *et al*. 1993). Wallace *et al*. found that hydroxychloroquine was strongly associated with low levels of cholesterol, triglycerides, and LDL-cholesterol regardless of concomitant corticosteroid use (Wallace *et al*. 1990). In a cohort longitudinal study involving 264 patients with systemic lupus erythematosus (Petri *et al*. 1994) using a regression model for steroid use, a change in prednisolone dose of 10 mg was associated with a change in cholesterol level of 7.5 mg (+/– 1.46 SD) and a weight gain of 2.5 kg (+/– 0.6 SD). On the other hand, hydroxychloroquine at 200 mg or 400 mg/day were both associated with lower serum cholesterol. However, no prospective randomized study of hydroxychloroquine on lipoprotein and lipid levels has been carried out.

Conclusions

There is sufficient evidence to suggest that lipid metabolism is altered in chronic rheumatic diseases in a manner which may promote accelerated atherosclerosis. Further long-term studies are needed to determine the risk more precisely and that contributed by treatments such as corticosteroids. Dietary intervention would seem a sensible first treatment step, and lipid lowering agents may be required, appropriate target levels being cholesterol less than 5.0 mmol/l, triglyceride less than 2 mmol/l, and LDL–cholesterol less than 3.5 mmol/l. A prudent, low-fat diet, partly supplemented by mono- and polyunsaturated fatty acids, with high fibre should be encouraged. Whether dietary supplementaion with marine oils has a place in reducing requirements for anti-inflammatory agents is uncertain, although the dose of fat supplement may be unacceptable.

Lipid peroxidation products such as oxidized LDL may play an important role in promoting endothelial and synovial injury in addition to atheroma and, together with the possible protective role of antioxidants, warrant further study. Where patients have risk factors for coronary heart disease in addition to those from the rheumatic disease itself, for example in patients with systemic lupus erythematosus and hypertension, attention to all possible risk factors may be necessary to help prevent coronary heart disease. Treatment of risk factors is essential in patients who have manifested macrovascular disease, where there is adequate further life expectancy.

5.14 Soft-tissue rheumatism

Brian Hazleman

Introduction

Soft-tissue injuries, although commonly overlooked in the planning and provision of health care, are of major and increasing importance. Fortunately there has been an increase in interest in these lesions concomitant with an increase in our understanding of the associated disorders.

When rheumatology first developed as a medical subspeciality its basis was in the articular diseases, a concept that was soon found inadequate as it became apparent that other synovial structures, such as bursal and tendon sheaths, were equally affected by the same conditions. Later, the term 'abarticular rheumatism' was used to distinguish the extra-articular rheumatic complaints from the better-defined articular rheumatism. Because joints are hard and bony, and abarticular rheumatism by definition does not affect joints, the all-embracing term for this group of complaints, now in international usage, is soft-tissue rheumatism. The heterogeneity of soft-tissue rheumatism poses considerable problems in arriving at sensible treatment protocols and systems of management.

Lesions of tendons and their sheaths, fascias, bursae, joint capsules, and the tenoperiosteal junction (the enthesis) cause much illness and loss of productivity. They constitute a significant proportion of the workload of general medical practices and of hospital accident, orthopaedic, and rheumatology departments. As biopsy and surgery are rarely employed in their diagnosis and treatment, histological data are scanty and their pathological backgrounds poorly understood. While there are adequate anatomical and clinical features to allow identification of individual conditions, diagnosis is often imprecise and management remains largely empirical.

Any or all of these lesions may occur in association with overt systemic disease, as, for example, in inflammatory arthritis or infection, but a large proportion occur in its absence. In these circumstances local causes, such as chronic, repetitive, low-grade trauma, excessive and unaccustomed use, either at work or at play, may be responsible. These factors may also cause partial interruption of the blood supply, resulting in incomplete attempts at healing and degeneration, which render the extra-articular structures more vulnerable in the middle-aged and elderly people in whom these lesions predominate.

One feature common to all soft-tissue syndromes is a tendency to spontaneous remission. Many of the lesions take only weeks to improve and few persist with significant symptoms beyond 6 months. Therefore, a clear diagnosis allows the doctor to reassure the patient that arthritis is not present and that the prognosis is good. Failure to resolve is often due to further injury. Few of the lesions require complete rest, but most respond to selective rest of the region involved.

An accurate diagnosis of soft-tissue rheumatism can be made by taking a careful history, considering possible trauma or overuse, and carrying out a systematic examination. For most local lesions, further investigation is unnecessary and radiographs that reveal the expected, age-related degenerative changes can often confuse. It is usually apparent if there is a more generalized condition that requires appropriate investigation.

Classification

Disorders can be classified by clinicopathological process (tendinitis), by anatomical region (shoulder pain), or by aetiology (repetitive strain injury). There is no universally accepted classification. The following is practical and problem-orientated, and divides the conditions into (i) generalized and (ii) localized. The generalized forms may be further divided into those associated or not with inflammation (Table 1). Those that are localized may be regional, involving a few sclerotomes, or affecting a specific site (Table 1).

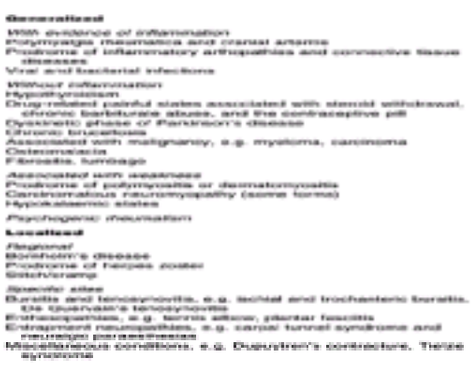

Table 1 Classification of soft-tissue rheumatism

Fibromyalgia or the 'fibrositis syndrome' is a particular variant of soft-tissue rheumatism. It is characterized by widespread aching and multiple tender sites. The tender sites are central to the definition and our understanding of this condition.

Generalized soft-tissue lesions

These may result from underlying disease, and most of the primary conditions can be diagnosed by careful clinical and laboratory assessment. These conditions will

not be discussed here, and polymyalgia rheumatica has been considered elsewhere (Chapter 5.11.5).

The diagnosis of 'psychogenic rheumatism' must be made with caution and after the exclusion of other diseases. Chronic pain may produce psychological overtones. There are several features that will suggest a psychological illness, since overt psychiatric symptoms are not usually present in rheumatic disorders but are common in patients who are unhappy at work or at home. Suggestive features include written lists of symptoms, inconsistent or negative physical findings on repeated examinations, and inappropriate concern with serious future disability.

Localized soft-tissue lesions

The major structures involved and associated lesions are listed in Table 2. Examination should permit accurate localization of the anatomical structure involved. The conditions frequently encountered in clinical practice are listed in Table 3.

Structure	Lesion
Tendons, tendon sheaths	Rupture, degeneration tendinitis, peritendinitis, tenosynovitis, ganglia
Tenoperiosteal junction	Enthesopathies, apophysitis
Bursae	Bursitis—acute or chronic
Fascias	Fasciitis, Dupuytren's contracture
Ligaments	Sprain, strain, tear

Table 2 Localized soft-tissue lesions

Site	Lesion
Shoulder	Rotator-cuff lesions Capsulitis of glenohumeral joint
Elbow	Lateral epicondylitis Medial epicondylitis Olecranon bursitis
Wrist and hand	Carpal tunnel syndrome Dupuytren's contracture De Quervain's tenosynovitis
Trunk	Non-specific neck and low back pain Trapezius muscle spasm 'Costochondritis'
Hip	Ischial and trochanteric bursitis Meralgia paresthetica
Knee	Bursitis Ligamentous sprains
Ankle and foot	Achilles tendinitis/peritendinitis Plantar fasciitis

Table 3 Common soft-tissue lesions and sites

Economic effects and burden on health-care services

Soft-tissue rheumatism is the most commonly encountered rheumatic cause of sickness absences from work, accounting for 44 per cent of medically certified rheumatic spells and 6 per cent of all incapacity spells. As is known from their natural history, however, the amount of time lost from work is comparatively less impressive. Thus the average duration of an incapacity spell for soft-issue rheumatism (21 days), when aggregated, amounts to 2.5 per cent of rheumatic days or 3.5 per cent of all days lost from work. These figures include absences on industrial injury benefit as well as sickness benefit, the former making up about one-fifth of the total. There is an age association in days lost. Traumatic disorders show no very marked trend, but the non-traumatic complaints are associated with an increase in days lost that is progressive with age; the rate is at least six times greater in the oldest as compared with the youngest quinquennium. This pattern reflects the fact that the average duration of incapacity spells grows longer with age, those occurring in the oldest group being more than twice as long as those in younger people. The overall pattern of spells is generally similar in most of the diagnostic categories, but muscle tendon and fascial lesions are unusual for the undue length of some of their incapacity spells.

In the United Kingdom alone the resultant loss of working days from soft-tissue lesions is likely to cost the country almost a billion pounds a year in lost productivity, apart from the value of social security payments, lost tax revenue, and health and social services applied to this problem. Behind these huge sums is a great deal of pain and misery, and much disruption to family life and work arrangements. The economic effects, loss of time from work, and the load that such patients present to both general practitioners and hospital doctors, are clearly immense. Greater attention needs to be focused on these diseases.

Epidemiology

Studies on the incidence of soft-tissue injuries are sadly inadequate as epidemiological studies have hitherto only infrequently been performed. Indeed, Dixon (1979) has described soft-tissue rheumatism as 'the great outback of rheumatology, a vast frontier land, ill-defined and little explained, its features poorly categorised and far from internationally agreed'. The fact that any or all of these soft-tissue lesions may be associated with overt systemic disease makes the classification and interpretation of data difficult. The lack of universally acceptable, defined criteria for these injuries has been a major obstacle to conducting epidemiological studies.

The absence of specific diagnostic tests for the soft-tissue syndromes highlights the importance of developing diagnostic criteria, based on combinations of the predominant clinical features, that are sensitive enough to exclude those without the syndrome. Most of these syndromes will be covered by the inclusion criteria of pain at a specific site or sites, local tenderness, limitation of movement, and pain on specific resisted movement or movements. There is a need for rigorous diagnostic criteria that take account of the lack of a 'gold standard' reference test, the continuous distribution pattern of the symptoms and signs, the variation in disease expression at differnt times, and the inter- and intraobserver variation in eliciting the specific clinical signs. Diagnostic criteria are required for defining occurrence, measuring outcome, and assessing the effect of intervention, for example in recruitment to clinical trials.

A population survey by the Swedish National Central Bureau of Statistics indicates a prevalence of all forms of soft-tissue rheumatism of 1.6 per cent in men and 3.6 per cent in women (Bjelle *et al*. 1990). Chronic complaints attributed to non-articular rheumatism as well as miscellaneous back disorders were estimated to occur in about 3 per cent of the adult (18–70 years) population of the United States in the 1976 National Health Interview Survey. In comparison, about 3 per cent of symptoms were attributable to rheumatoid arthritis and 8 per cent to degenerative joint disease. Together, soft-tissue lesions comprise one-third of all rheumatic diseases seen by family physicians and 3 to 4 per cent of all ambulatory medical-care visits (Wood *et al*. 1979).

There is considerable confusion in diagnostic terminology and a wide variation in reported incidence between countries, probably reflecting the contrasting, as well as legal, attitudes to these conditions. In general the increased incidence of these disorders appears to be due to new technology leading to advanced automation and mechanization. Occupational disorders are of interest because, theoretically at least, it should be possible to devise methods of working that would prevent their development. Ergonomic and behavioural studies have much to offer. Certainly sufferers are at present at considerable hazard of repeated attendance, as indicated by the reported rates of recrudescence for 'beat' knee (12 per cent), 'beat' elbow (7 per cent), and tenosynovitis of the wrist (6 per cent) (Wood *et al*. 1979). It would be of interest to learn why only some individuals exposed to particular methods of working develop soft-tissue injuries. Automation and mechanization have led to the need for repetitive movements that may produce repetitive strain injuries and associated overuse syndromes; this aspect will be discussed later.

Crude differences in age patterns may be discerned between traumatic and non-traumatic forms of soft-tissue rheumatism. The frequency of spells of strains and

sprains tends to reduce after the thirties, whereas non-traumatic conditions show a less marked decline and this does not appear until after the forties. Rates in women tend in general to be less than in men.
