Peroxisomes also have very important roles in plants. Two very different types have been studied extensively. One type is present in leaves, where it catalyzes the oxidation of a side product of the crucial reaction that fixes CO_2 in carbohydrate (Figure 12-28A). This process is called *photorespiration* because it uses up O_2 and liberates CO_2. The other type of peroxisome is present in germinating seeds, where it plays an essential role in converting the fatty acids stored in seed lipids into the sugars needed for the growth of the young plant. Because this conversion of fats to sugars is accomplished by a series of reactions known as the *glyoxylate cycle,* these peroxisomes are also called *glyoxysomes* (Figure 12-28B). In the glyoxylate cycle two molecules of acetyl CoA produced by fatty acid breakdown in the peroxisome are used to make succinic acid, which leaves the peroxisome and is converted into glucose. The glyoxylate cycle does not occur in animal cells, and animals are thus unable to convert the fatty acids in fats into carbohydrates.

A Short Signal Sequence Directs the Import of Proteins into Peroxisomes [22]

A specific sequence of three amino acids located near the carboxyl terminus of many peroxisomal proteins functions as an import signal (see Table12-3); if this sequence is experimentally attached to a cytosolic protein, the protein is imported into peroxisomes. The importance of this import process and of peroxisomes is dramatically demonstrated by the inherited human disease *Zellweger syndrome*, in which a defect in importing proteins into peroxisomes leads to a severe peroxisomal deficiency. These individuals, whose cells contain "empty" peroxisomes, have severe abnormalities in their brain, liver, and kidneys, and they die soon after birth. One form of this disease has been shown to be due to a mutation in the gene encoding a peroxisomal integral membrane protein called peroxisome assembly factor-1.

Peroxisomes presumably have at least one unique protein exposed on their cytosolic surface to act as a receptor that recognizes the signal on the proteins to be imported. At one time it was thought that the membrane of the peroxisome forms by budding from the ER, while the content is imported from the cytosol. There is now evidence, however, suggesting that new peroxisomes

arise only from preexisting ones, by organelle growth and fission, as described elsewhere for mitochondria and plastids and for the ER itself (Figure 12-29).

Summary

Peroxisomes are specialized for carrying out oxidative reactions using molecular oxygen. They generate hydrogen peroxide, which they also use for oxidative purposes - destroying the excess by means of the catalase they contain. Like mitochondria and plastids, peroxisomes are self-replicating organelles. Because they contain no DNA or ribosomes, they have to import all of their proteins from the cytosol. A specific three amino acid sequence near the carboxyl terminus of many of these proteins functions as a peroxisomal import signal.

Figure 12-28. Electron micrographs of two types of peroxisomes found in plant cells. (A) A leaf peroxisome with a paracrystalline core in a tobacco leaf mesophyll cell. Its close association with chloroplasts is thought to facilitate the exchange of materials between these organelles during photorespiration. (B) Peroxisomes in a fat-storing cotyledon cell of a tomato seed 4 days after germination. Here the peroxisomes (*glyoxysomes*) are associated with the lipid bodies where fat is stored, reflecting their central role in fat mobilization and gluconeogenesis during seed germination. (A, courtesy of P.J. Gruber and E.H. Newcomb; B, courtesy of S.E. Frederick and E.H. Newcomb.)
Figure 12-29. A model for how peroxisomes are assembled. The peroxisome membrane contains specific import receptor proteins. All peroxisomal proteins, including new copies of the import receptor, are synthesized by cytosolic ribosomes and then imported into the organelle. Thus peroxisomes form only from preexisting peroxisomes by a process of growth and fission. Presumably, the lipids required to make new peroxisome membrane are also imported. We discuss later how lipids made in the ER can be transported through the cytosol to other organelles.

The Endoplasmic Reticulum 23
Introduction

All eucaryotic cells have an endoplasmic reticulum (ER). Its membrane typically constitutes more than half of the total membrane of an average animal cell (see Table 12-2). It is organized into a netlike labyrinth of branching tubules and flattened sacs extending throughout the cytosol (Fi gure 12-30). The tubules and sacs are all thought to interconnect, so that the ER membrane forms a continuous sheet enclosing a single internal space. This highly convoluted space is called the ER lumen or the *ER cisternal space,* and it often occupies more than 10% of the total cell volume (see Table 12-1). The ER membrane separates the ER lumen from the cytosol, and it mediates the selective transfer of molecules between these two compartments.

The ER plays a central part in lipid and protein biosynthesis. Its membrane is the site of production of all the transmembrane proteins and lipids for most of the cell's organelles, including the ER itself, the Golgi apparatus, lysosomes, endosomes, secretory vesicles, and the plasma membrane. The ER membrane also makes a major contribution to mitochondrial and peroxisomal membranes by producing most of their lipids. In addition, almost all of the proteins that will be secreted to the cell exterior - as well as those destined for the lumen of the ER, Golgi apparatus, or lysosomes - are initially delivered to the ER lumen.

Membrane-bound Ribosomes Define the Rough ER 24

The ER captures selected proteins from the cytosol as they are being synthesized. These proteins are of two types: (1) transmembrane proteins, which are only partly translocated across the ER membrane and become embedded in it, and (2) water-soluble proteins, which are fully translocated across the ER membrane and are released into the ER lumen. Some of the transmembrane proteins will remain in the ER, but many are destined to reside in the plasma membrane or the membrane of another organelle; the water-soluble proteins are destined either for the lumen of an organelle or for secretion. All of these proteins, regardless of their subsequent fate, are directed to the ER membrane by the same kind of signal peptide and are translocated across it by the same mechanism.

In mammalian cells the import of proteins into the ER begins before the polypeptide chain is completely synthesized - that is, it occurs co-translationally. This distinguishes the process from the import of proteins into mitochondria, chloroplasts, nuclei, and peroxisomes, which is posttranslational and requires different signal peptides. Since one end of the protein is usually translocated into the ER as the rest of the polypeptide chain is being made, the protein is never released into the cytosol and therefore is never in danger of folding up before reaching the translocator in the membrane. In contrast to the posttranslational import of proteins into the mitochondria and chloroplasts, cytosolic chaperonins are therefore not required to keep the protein unfolded. The ribosome that is synthesizing the protein is directly attached to the ER membrane. These membrane-bound ribosomes coat the surface of the ER, creating regions termed rough endoplasmic reticulum (Figure 12-31).

There are, therefore, two spatially separate populations of ribosomes in the cytosol. Membrane-bound ribosomes, attached to the cytosolic side of the ER membrane, are engaged in the synthesis of proteins that are being concurrently translocated into the ER. Free ribosomes, unattached to any membrane, make all other proteins encoded by the nuclear genome. Membrane-bound and free ribosomes are structurally and functionally identical. They differ only in the proteins they are making at any given time. When a ribosome happens to be making a protein with an ER signal peptide, the signal directs the ribosome to the ER membrane. Since many ribosomes can bind to a single mRNA molecule, a polyribosome is usually formed, which becomes attached to the ER membrane via the signal peptides on multiple growing polypeptide chains (Figure 12-32). The individual ribosomes associated with such an mRNA molecule can return to the cytosol when they finish translation near the 3' end of the mRNA molecule. The mRNA itself, however, tends to remain attached to the ER membrane by a changing population of ribosomes that are also held at the membrane by a ribosome receptor that helps to bind it there. In contrast, if an mRNA molecule encodes a protein that lacks an ER signal peptide, the polyribosome that forms remains free in the cytosol and its protein product is discharged there. Therefore, only those mRNA molecules that encode proteins with an ER signal peptide bind to rough ER membranes; those mRNA molecules that encode all other proteins remain free in the cytosol. The individual ribosomal subunits are thought to move randomly between these two segregated populations of mRNA molecules (Figure 12-33).

Smooth ER Is Abundant in Some Specialized Cells 25

Regions of ER that lack bound ribosomes are called smooth endoplasmic reticulum, or smooth ER. In the great majority of cells such regions are scanty, and there is only a small region of the ER that is partly smooth and partly rough. This region is said to consist of transitional elements because it is from here that transport vesicles carrying newly synthesized proteins and lipids bud off for transport to the Golgi apparatus. In certain specialized cells, however, the smooth ER is abundant and has additional functions. In particular, it is usually prominent in cells that specialize in lipid metabolism: cells that synthesize steroid hormones from cholesterol, for example, have an expanded smooth ER compartment to accommodate the enzymes needed to make cholesterol and to modify it to form the hormones (Figure 12-34).

The main cell type in the liver, the *hepatocyte,* provides another example. It is the principal site of the production of lipoprotein particles; these particles carry lipids via the bloodstream to other sites in the body. The enzymes that synthesize the lipid components of lipoproteins are located in the membrane of the smooth ER, which also contains enzymes that catalyze a series of reactions to detoxify both lipid-soluble drugs and various harmful compounds produced by metabolism. The most extensively studied of the *detoxification reactions* are catalyzed by the *cytochrome P450* family of enzymes, which catalyze a series of reactions whereby water-insoluble drugs or metabolites that would otherwise accumulate to toxic levels in cell membranes are rendered sufficiently water-soluble to leave the cell and be excreted in the urine. Because the rough ER alone cannot house enough of these and other necessary enzymes, a major portion of the membrane in a hepatocyte normally consists of smooth ER (Figure 12-35 and see Table 12-2).

When large quantities of certain compounds, such as the drug phenobarbital, enter the circulation, detoxification enzymes are

synthesized in the liver in unusually large amounts, and the smooth ER doubles in surface area within a few days. Once the drug disappears, the excess smooth ER membrane is specifically and rapidly removed by a lysosome-dependent process called *autophagocytosis* (discussed in Chapter 13). How these dramatic changes are regulated is not known.

Another function of the ER in most eucaryotic cells is to sequester Ca^{2+} from the cytosol. The release of Ca^{2+} into the cytosol from the ER, and its subsequent reuptake, mediate many rapid responses to extracellular signals, as discussed in Chapter 15. The storage of Ca^{2+} in the ER lumen is facilitated by the high concentrations of Ca^{2+}-binding proteins there. In some cell types, and perhaps in most, specific regions of the ER are specialized for Ca^{2+} storage. Muscle cells, for example, have an abundant specialized smooth ER, called the *sarcoplasmic reticulum*, which sequesters Ca^{2+} from the cytosol by means of a Ca^{2+}-ATPase that pumps in Ca^{2+}; the release and reuptake of Ca^{2+} by the sarcoplasmic reticulum mediates the contraction and relaxation of the myofibrils during each round of muscle contraction (discussed in Chapter 16).

We shall now return to the two major roles of the ER: the synthesis and modification of proteins and the synthesis of lipids.

Rough and Smooth Regions of ER Can Be Separated by Centrifugation [26]

In order to study the functions and biochemistry of the ER, it is necessary to isolate the ER membrane. At first sight this seems a hopeless task since the ER is intricately interleaved with other components of the cytosol. Fortunately, when tissues or cells are disrupted by homogenization, the ER is fragmented and reseals into many small (~100 nm in diameter) closed vesicles called microsomes, which are relatively easy to purify. Microsomes derived from rough ER are studded with ribosomes and are called *rough microsomes*. The ribosomes are always found on the *outside* surface, so that the interior of the microsome is biochemically equivalent to the luminal space of the ER (Figure 12-36). Because they can be readily purified in functional form, rough microsomes are especially useful for studying the many processes carried out by the rough ER. To the biochemist they represent small authentic versions of the rough ER, still capable of protein synthesis, protein glycosylation, and lipid synthesis.

Many vesicles of a size similar to that of rough microsomes but lacking attached ribosomes are also found in these homogenates. Such *smooth microsomes* are derived in part from smooth portions of the ER and in part from vesiculated fragments of plasma membrane, Golgi apparatus, endosomes, and mitochondria (the ratio depending on the tissue). Thus, whereas rough microsomes can be equated with rough portions of ER, the origins of smooth microsomes cannot be so easily assigned. The microsomes of the liver are an exception. Because of the unusually large quantities of smooth ER in the hepatocyte, most of the smooth microsomes in liver homogenates are derived from smooth ER.

The ribosomes attached to them make rough microsomes more dense than smooth microsomes. As a result, the rough and smooth microsomes can be separated from each other by equilibrium centrifugation (Figure 12-37). When the separated rough and smooth microsomes of liver are compared with respect to such properties as enzyme activity or polypeptide composition, they are very similar, although not identical: apparently most of the components of the ER membrane can diffuse freely between the rough and smooth regions, as would be expected for a continuous fluid membrane. The rough microsomes, however, contain more than 20 proteins that are not present in smooth microsomes, showing that some restraining mechanism must exist for a subset of ER membrane proteins. Some of the proteins in this subset help bind ribosomes to the rough ER, while others presumably produce the flattened shape of this part of the ER (see Figure 12-35). It is not clear whether these membrane proteins are retained by forming large two-dimensional aggregates in the lipid bilayer or whether they are instead held in place by interactions with a network of structural proteins on one or the other face of the ER membrane.

Signal Peptides Were First Discovered in Proteins Imported into the Rough ER [27]

Signal peptides (and the signal peptide strategy of protein import) were first discovered in the early 1970s in secreted proteins that are translocated across the ER membrane as a first step toward their eventual discharge from the cell. In the key experiment the mRNA encoding a secreted protein was translated by ribosomes *in vitro*. When microsomes were omitted from this cell-free system, the protein synthesized was slightly larger than the normal secreted protein, the extra length being due to the presence of an amino-terminal *leader peptide*. In the presence of microsomes derived from the rough endoplasmic reticulum, however, a protein of the correct size was produced. These results were explained by the signal hypothesis, which postulated that the leader serves as a *signal peptide* that directs the secreted protein to the ER membrane and is then cleaved off by a signal peptidase in the ER membrane before the polypeptide chain is completed (Figure 12-38).

According to the signal hypothesis, the secreted protein should be extruded into the lumen of the microsome during its *in vitro* synthesis. This can be demonstrated with protease treatment: a newly synthesized protein made in the absence of microsomes is degraded when protease is added to the medium, whereas the same protein made in the presence of microsomes remains intact because it is protected by the microsomal membrane. When proteins without ER signal peptides are similarly synthesized *in vitro,* they are not imported into microsomes and therefore are degraded by protease treatment.

The signal hypothesis has been thoroughly tested by genetic and biochemical experiments and is found to apply to both plant and animal cells, as well as to protein translocation across the bacterial plasma membrane and, as we have seen, the membranes of mitochondria, chloroplasts, and peroxisomes. Amino-terminal ER signal peptides guide not only secreted proteins but also the precursors of all proteins made in the ER, including soluble proteins and membrane proteins. The signaling function of these peptides has been demonstrated directly by using recombinant DNA techniques to attach signal sequences to proteins that do not normally have them; the resulting fusion proteins are directed to the ER.

Cell-free systems in which proteins are imported into microsomes have provided powerful assay procedures for identifying, purifying, and studying the various components of the molecular machinery responsible for the ER import process.

A Signal-Recognition Particle (SRP) Directs ER Signal Peptides to a Specific Receptor in the Rough ER Membrane 28

The ER signal peptide is guided to the ER membrane by at least two components: a signal-recognition particle (SRP), which cycles between the ER membrane and the cytosol and binds to the signal peptide, and an *SRP receptor,* also known as a *docking protein*, in the ER membrane. The SRP was discovered when it was found that washing microsomes with salt eliminated their ability to import secreted proteins. Import could be restored by adding back the supernatant containing the salt extract. The "translocation factor" in the salt extract was then purified and found to be a complex particle consisting of six different polypeptide chains bound to a single small RNA molecule (Figure 12-39). SRP and SRP receptor are present in all eucaryotic cells and probably in procaryotic cells as well.

The SRP binds to the ER signal peptide as soon as the peptide emerges from the ribosome. This causes a pause in protein synthesis, which presumably gives the ribosome enough time to bind to the ER membrane before the synthesis of the polypeptide chain is completed, thereby ensuring that the protein is not released into the cytosol. This may provide a safety mechanism as many secreted proteins and lysosomal proteins are hydrolases that could wreak havoc in the cytosol. Cells that secrete large amounts of hydrolases take the added precaution of having high concentrations of hydrolase inhibitors in their cytosol.

Once formed, the SRP ribosome complex binds to the SRP receptor, which is an integral membrane protein exposed on the cytosolic surface of the rough ER membrane. The SRP is then released, and a poorly characterized translocation apparatus transfers the growing polypeptide chain across the membrane (Figure 12-40). Because one of the SRP proteins and both chains of the SRP receptor contain GTP-binding domains, it is thought that conformational changes that occur during cycles of GTP binding and hydrolysis (discussed in Chapter 5) ensure that SRP release occurs only after the ribosome has become properly engaged with the translocation apparatus in the ER membrane.

Translocation Across the ER Membrane Does Not Always Require Ongoing Polypeptide Chain Elongation 29

As we have seen, translocation of proteins into mitochondria, chloroplasts, and peroxisomes occurs *posttranslationally,* after the protein is completed and released into the cytosol, whereas translocation across the ER membrane usually occurs during translation (*co-translationally*). This explains why ribosomes are bound to the ER but usually not to other organelles. A ribosome attached to the rough ER may utilize the energy of protein synthesis to force its growing polypeptide chain through a channel formed by a translocator in the ER membrane. Recent studies *in vitro*, however, have shown that a small minority of protein precursors can be imported into the ER after their synthesis has been completed, thus demonstrating that translocation does not always require ongoing translation. Posttranslational protein translocation may occur even more commonly across the ER membrane in yeast cells and across the bacterial plasma membrane (which is thought to be evolutionarily related to the ER; see Figure 12-5). In both cases the translocation requires ATP hydrolysis, and in bacteria an electrochemical gradient is needed as well. A translocation apparatus has been reconstituted from purified bacterial components, one of which is an ATPase that is thought to help thread the protein through the membrane (Figure 12-41). Since the proteins that use a posttranslational translocation pathway are first released into the cytosol, they are prevented from folding up by binding to cytosolic chaperone proteins, just as we have seen for the posttranslational import into mitochondria and chloroplasts.

The Polypeptide Chain Passes Through an Aqueous Pore in the Translocation Apparatus <u>30</u>

It has long been debated whether polypeptide chains are transferred across the ER membrane in direct contact with the lipid bilayer or through a pore in a protein translocator. There is now strong evidence for a protein translocator. Normally, the pore in the translocator is plugged with the growing polypeptide chain that is in transit across the membrane; when the nascent chains are experimentally released from the ribosomes with the drug puromycin, however, the pores can be detected by the ion currents that flow through them. Although the pore is large enough to allow the passage of an unfolded polypeptide chain, it closes when the ribosome is removed from the membrane (<u>Figure 12-42</u>). Thus the pore seems to be a dynamic structure, opening when a ribosome with a growing polypeptide chain attaches to the membrane and closing when the ribosome detaches after the synthesis of the protein is completed.

The ER Signal Peptide Is Removed from Most Soluble Proteins After Translocation <u>31</u>

We have seen that in chloroplasts and mitochondria the signal peptides are cleaved from the precursor proteins once they have crossed the membrane. Similarly, amino-terminal ER signal peptides are removed by a signal peptidase on the luminal side of the ER membrane. The peptide by itself, however, is not sufficient to signal cleavage by the peptidase; this requires an adjacent cleavage site that is specifically recognized by the peptidase. We shall see below that ER signal peptides that are contained within the polypeptide chain rather than at the amino terminus do not have these recognition sites and are never cleaved; instead, they can serve to retain transmembrane proteins in the lipid bilayer after the translocation process has been completed.

The amino-terminal ER signal peptide of a soluble protein itself has two signaling functions: in addition to directing the protein to the ER membrane, it is thought to serve as a start-transfer signal, which remains bound to the translocation apparatus while the rest of the protein is threaded continuously through the membrane as a large loop. Once the carboxyl terminus of the protein has passed through the membrane, the signal peptide is released from the translocator pore, cleaved off by the signal peptidase, and rapidly degraded to amino acids by other proteases in the ER while the protein is released into the ER lumen (<u>Figure 12-43</u>).

In Single-Pass Transmembrane Proteins a Single Internal ER Signal Peptide Remains in the Lipid Bilayer as a Membrane-spanning alpha Helix <u>32</u>

The translocation process for proteins destined to remain in the membrane is more complex than it is for soluble proteins, as some parts of the polypeptide chain are translocated across the lipid bilayer whereas others are not. Nevertheless, all modes of insertion of membrane proteins can be considered as variants of the sequence of events just described for transferring a soluble protein into the lumen of the ER. We begin by describing the three ways in which single-pass transmembrane proteins (see <u>Figure 10-13</u>) become inserted into the ER.

In the simplest case an amino-terminal signal peptide initiates translocation, just as for a soluble protein, but an additional hydrophobic segment in the polypeptide chain stops the transfer process before the entire polypeptide chain is translocated. This stop-transfer peptide anchors the protein in the membrane after the ER signal (start-transfer) peptide is released from the translocator and is cleaved off (<u>Figure 12-44</u>). The stop-transfer peptide forms a single alpha-helical membrane-spanning segment, with the amino terminus of the protein on the luminal side of the membrane and the carboxyl terminus on the cytosolic side.

In the other two cases the signal peptide is internal, rather than at the amino-terminal end of the protein. Like the amino-terminal ER signal peptides, the internal signal peptide is recognized by SRP, which brings the ribosome making the protein to the ER membrane and serves as a start-transfer signal that initiates the translocation of the protein. After release from the translocator, the internal start-transfer peptide remains in the lipid bilayer as a single membrane-spanning alpha helix. Internal start-transfer peptides, however, can bind to the translocation apparatus in either of two orientations, and the orientation of the inserted start-transfer peptide, in turn, determines which protein segment (the one preceding or the one following the start-transfer peptide) is moved across the membrane into the ER lumen. In one case the resulting membrane protein has its carboxyl terminus on the luminal side (<u>Figure 12-45A</u>), while in the other it has its amino terminus on the luminal side (<u>Figure 12-45B</u>). The orientation of the start-transfer peptide depends on the distribution of nearby charged amino acids, as described in the figure legend.

Combinations of Start- and Stop-Transfer Signals Determine the Topology of Multipass Transmembrane Proteins <u>33</u>

In multipass transmembrane proteins the polypeptide chain passes back and forth repeatedly across the lipid bilayer (see <u>Figure</u>

). It is thought that an internal signal peptide serves as a start-transfer signal in these proteins to initiate translocation, which continues until a stop-transfer peptide is reached. In double-pass transmembrane proteins, for example, the polypeptide is released into the bilayer at this point (Figure 12-46). In more complex multipass proteins, in which many hydrophobic alpha helices span the bilayer, a second start-transfer peptide reinitiates translocation further down the polypeptide chain until the next stop-transfer peptide causes polypeptide release, and so on for subsequent start-transfer and stop-transfer peptides (Figure 12-47).

Whether a given hydrophobic signal sequence will function as a start-transfer or stop-transfer peptide must depend on its location in a polypeptide chain, since its function can be switched by changing its location in the protein using recombinant DNA techniques. Thus the distinction between start-transfer and stop-transfer peptides results mostly from their relative order in the growing polypeptide chain. It seems that the SRP begins scanning an unfolded polypeptide chain for hydrophobic segments at its amino terminus and proceeds toward the carboxyl terminus, in the direction that the protein is synthesized. By recognizing the first appropriate hydrophobic segment to emerge from the ribosome, the SRP sets the "reading frame": if translocation is initiated, the next appropriate hydrophobic segment will be recognized as a stop-transfer peptide, causing the region of the polypeptide chain in between to be threaded across the membrane. A similar scanning process continues until all of the hydrophobic regions in the protein have been inserted into the membrane.

Because membrane proteins are always inserted from the cytosolic side of the ER in this programmed manner, all copies of the same polypeptide chain will have the same orientation in the lipid bilayer. This generates an asymmetrical ER membrane in which the protein domains exposed on one side are different from those domains exposed on the other. This asymmetry is maintained during the many membrane budding and fusion events that transport the proteins made in the ER to other cell membranes (discussed in Chapter 13). Thus the way in which a newly synthesized protein is inserted into the ER membrane determines the orientation of the protein in the other membranes as well.

When proteins are dissociated from a membrane and reconstituted in artificial lipid vesicles, a random mixture of right-side-out and inside-out protein orientations usually results. Thus the protein asymmetry observed in cell membranes seems not to be an inherent property of the protein but to result solely from the process by which proteins are inserted into the ER membrane from the cytosol.

Translocated Polypeptide Chains Fold and Assemble in the Lumen of the Rough ER 34

Many of the proteins in the lumen of the ER are in transit, *en route* to other destinations; others, however, are normally resident there and are present at high concentrations. These ER resident proteins contain an ER retention signal of four amino acids at their carboxyl terminus that is responsible for retaining the protein in the ER (see Table 12-3). Some of these proteins function as catalysts that help the many proteins that are translocated into the ER to fold and assemble correctly. One such ER resident protein is *protein disulfide isomerase (PDI),* which catalyzes the oxidation of free sulfhydryl (SH) groups to form disulfide (S - S) bonds. Almost all cysteine residues in protein domains exposed to either the extracellular space or the lumen of organelles in the secretory and endocytic pathways are disulfide bonded; disulfide bonds do not form, however, in domains exposed to the cytosol because of the reducing environment there.

Another ER resident protein is a chaperone protein known as binding protein (BiP), which is structurally related to the hsp70 proteins and, like them, recognizes incorrectly folded proteins, as well as protein subunits that have not yet assembled into their final oligomeric complexes. BiP, like other chaperone proteins, is thought to bind to exposed amino acid sequences that would normally be buried in the interior of correctly folded or assembled polypeptide chains. The bound BiP both prevents the proteins from aggregating and helps to keep them in the ER (and thus out of the Golgi apparatus and later parts of the secretory pathway); it may also help them to fold normally. Like the hsp70 family of proteins, which bind unfolded proteins in the cytosol and facilitate their import into mitochondria and chloroplasts, BiP hydrolyzes ATP to provide the energy for its role in protein folding.

As we have seen earlier for mitochondrial hsp70 (see Figure 12-24), the binding of BiP to an unfolded protein chain emerging in the ER lumen may help pull the protein into the ER. This pulling process may be particularly important for proteins that enter the ER posttranslationally because in this case there is no ribosome attached to the membrane to help push the nascent protein through the translocator during the protein's synthesis.

Most Proteins Synthesized in the Rough ER Are Glycosylated by the Addition of a Common *N*-linked Oligosaccharide 35

The covalent addition of sugars to proteins is one of the major biosynthetic functions of the ER. Most of the soluble and membrane-bound proteins that are made in the ER, including those destined for transport to the Golgi apparatus, lysosomes, plasma membrane, or extracellular space are glycoproteins. In contrast, very few proteins in the cytosol are glycosylated, and those that are carry a much simpler sugar modification in which a single *N*-acetylglucosamine group is added to a serine or threonine residue of the protein.

An important advance in understanding the process of protein glycosylation was the discovery that a preformed oligosaccharide (composed of *N*-acetylglucosamine, mannose, and glucose and containing a total of 14 sugar residues) is transferred *en bloc* to proteins in the ER. Because this oligosaccharide is transferred to the side-chain NH_2 group of an asparagine amino acid in the protein, it is said to be *N-linked* or *asparagine-linked* (Figure 12-48). The transfer is catalyzed by a membrane-bound enzyme, an *oligosaccharyl transferase*, which has its active site exposed on the luminal side of the ER membrane; this explains why cytosolic proteins are not glycosylated in this way. The precursor oligosaccharide is held in the ER membrane by a special lipid molecule called dolichol, and it is transferred to the target asparagine in a single enzymatic step immediately after that amino acid emerges in the ER lumen during protein translocation (Figure 12-49). Since most proteins are co-translationally imported into the ER, *N*-linked oligosaccharides are almost always added during protein synthesis.

The lipid-linked precursor oligosaccharide is linked to the dolichol by a high-energy pyrophosphate bond, which provides the activation energy that drives the glycosylation reaction illustrated in Figure 12-49. The entire oligosaccharide is built up sugar by sugar on this membrane-bound lipid molecule prior to its transfer to a protein. The sugars are first activated in the cytosol by the formation of *nucleotide-sugar intermediates,* which then donate their sugar (directly or indirectly) to the lipid in an orderly sequence. Partway through this process, the lipid-linked oligosaccharide is flipped from the cytosolic to the luminal side of the ER membrane (Figure 12-50).

All of the diversity of the *N*-linked oligosaccharide structures on mature glycoproteins results from later modification of the original precursor structure. While still in the ER, three glucose residues (see Figure 12-48) and one mannose residue are quickly removed from the oligosaccharides of most glycoproteins. This oligosaccharide "trimming" or "processing" continues in the Golgi apparatus and is discussed in Chapter 13.

The *N*-linked oligosaccharides are by far the most common ones found on glycoproteins. Less frequently, oligosaccharides are linked to the hydroxyl group on the side chain of a serine, threonine, or hydroxylysine amino acid. These *O-linked oligosaccharides* are formed in the Golgi apparatus by pathways that are not yet fully understood (discussed in Chapter 13).

Some Membrane Proteins Exchange a Carboxyl-Terminal Transmembrane Tail for a Covalently Attached Glycosylphosphatidylinositol (GPI) Anchor After Entry into the ER 36

As discussed in Chapter 10, several cytosolic enzymes catalyze the covalent addition of a single fatty acid chain or prenyl group to selected proteins to help direct these proteins to cell membranes. A related process is catalyzed by enzymes in the rough ER: the carboxyl terminus of some membrane proteins destined for the plasma membrane is covalently attached to a sugar residue of a glycolipid. This linkage forms in the lumen of the ER by the mechanism illustrated in Figure 12-51, and it adds a glycosylphosphatidylinositol (GPI) anchor, which contains two fatty acids, to the protein. At the same time the transmembrane segment of the protein is cleaved off. An increasing number of plasma membrane proteins have been shown to be modified in this way. Since these proteins are attached to the exterior of the plasma membrane only by their GPI anchors, in principle they can be released from cells in soluble form in response to signals that activate a specific phospholipase in the plasma membrane. Trypanosome parasites, for example, use this mechanism to shed their coat of GPI-anchored surface proteins if attacked by the immune system.

Most Membrane Lipid Bilayers Are Assembled in the ER 37

The ER membrane produces nearly all of the lipids required for the elaboration of new cell membranes, including both phospholipids and cholesterol. The major phospholipid made is *phosphatidylcholine* (also called lecithin), which can be formed in three steps from choline, two fatty acids, and glycerol phosphate. Each step is catalyzed by enzymes in the ER membrane that have their active sites facing the cytosol, where all of the required metabolites are found. Thus phospholipid synthesis occurs exclusively in the cytosolic half of the ER bilayer. In the first step acyl transferases successively add two fatty acids to glycerol phosphate to produce phosphatidic acid, a compound sufficiently water-insoluble to remain in the lipid bilayer after it has been

synthesized. It is this step that enlarges the lipid bilayer; the later steps determine the head group of a newly formed lipid molecule, and therefore the chemical nature of the bilayer, but do not result in net membrane growth (Figure 12-52). The two other major membrane phospholipidsphosphatidylethanolamine (PE) and phosphatidylserine (PS) - as well as the minor phospholipid phosphatidylinositol (PI), are all synthesized in this way.

As phospholipid synthesis takes place in the cytosolic half of the ER bilayer, there needs to be a mechanism that transfers some of the newly formed phospholipid molecules to the other half of the bilayer. In synthetic lipid bilayers, lipids do not "flip-flop" in this way. In the ER, however, phospholipids equilibrate across the membrane within minutes, which is almost 100,000 times faster than can be accounted for by spontaneous "flip-flop." This rapid transbilayer movement is thought to be mediated by phospholipid translocators that are head-group-specific. In particular, the ER membrane seems to contain a translocator (a "*flippase*") that transfers choline-containing phospholipids - but not ethanolamine-, serine-, or inositol-containing phospholipids - between cytosolic and luminal faces. This means that phosphatidylcholine reaches the luminal face much more readily than the other phospholipids. In this way the translocator is responsible for the asymmetric distribution of the lipids in the bilayer (Figure 12-53).

The ER also produces cholesterol and ceramide. *Ceramide* is made by condensing the amino acid serine with a fatty acid to form the amino alcohol *sphingosine;* a second fatty acid is then added to form ceramide. The ceramide is exported to the Golgi apparatus, where it serves as the precursor for the synthesis of two types of lipids: oligosaccharide chains are added to form *glycosphingolipids* (glycolipids), and phosphocholine head groups are transferred from phosphatidylcholine to other ceramide molecules to form *sphingomyelin*. Thus both glycolipids and sphingomyelin are produced relatively late in the process of membrane synthesis. Because they are produced by enzymes exposed to the Golgi lumen, they are found exclusively in the noncytosolic half of the lipid bilayers that contain them.

Phospholipid Exchange Proteins Help Transport Phospholipids from the ER to Mitochondria and Peroxisomes [38]

As discussed in Chapter 13, the plasma membrane and the membranes of the Golgi apparatus, lysosomes, and endosomes all form part of a membrane system that communicates with the ER by means of transport vesicles that transfer both proteins and lipids. Mitochondria, plastids, and peroxisomes do not belong to this system, and they require different mechanisms for the import of proteins and lipids for growth. We have already seen that most (for mitochondria and plastids) or all (for peroxisomes) of the proteins in these organelles are imported from the cytosol. Although mitochondria modify some of the lipids they import, they do not synthesize lipids *de novo;* instead, their lipids have to be imported from the ER, either directly, or indirectly by way of other cellular membranes. In either case, special mechanisms are required for the transfer.

Water-soluble carrier proteins - called phospholipid exchange proteins (or *phospholipid transfer proteins*) - have been shown in *in vitro* experiments to have the ability to transfer individual phospholipid molecules between membranes. Each exchange protein recognizes only specific types of phospholipids. It functions by "extracting" a molecule of the appropriate phospholipid from a membrane and diffusing away with the lipid buried within its binding site. When it encounters another membrane, the exchange protein tends to discharge the bound phospholipid molecule into the new lipid bilayer (Figure 12-54). It has been proposed that phosphatidylserine is imported into mitochondria in this way and then decarboxylated to yield phosphatidylethanolamine, while phosphatidylcholine is imported intact.

Exchange proteins act to distribute phospholipids at random among all membranes present. In principle, such a random exchange process can result in a net transport of lipids from a lipid-rich to a lipid-poor membrane, allowing phosphatidylcholine and phosphatidylserine molecules, for example, to be transferred from the ER, where they are synthesized, to a mitochondrial or peroxisomal membrane. It might be that mitochondria and peroxisomes are the only "lipid-poor" organelles in the cytosol and that such an exchange process is sufficient, although other, more specific mechanisms probably also exist for transporting phospholipids to these organelles.

Summary

The extensive ER network serves as a factory for the production of almost all of the cell's lipids. In addition, a major portion of the cell's protein synthesis occurs on the cytosolic surface of the ER: all proteins destined for secretion and all proteins destined for the ER itself, the Golgi apparatus, the lysosomes, the endosomes, and the plasma membrane are first imported into the ER from the cytosol. In the ER lumen, the proteins fold and oligomerize, disulfide bonds are formed, and N-linked oligosaccharides are added.

Only proteins that carry a special hydrophobic signal peptide are imported into the ER. The ER signal peptide is recognized by a signal recognition particle (SRP), which binds both the growing polypeptide chain and the ribosome and directs them to a receptor protein on the cytosolic surface of the rough ER membrane. This binding to the membrane initiates the translocation process that threads a loop of polypeptide chain across the ER membrane through a hydrophilic pore in a protein translocator.

Soluble proteins destined for the ER lumen, for secretion, or for transfer to the lumen of other organelles pass completely into the ER lumen. Transmembrane proteins destined for the ER or for other cell membranes are translocated across the ER membrane but are not released into the lumen; instead, they remain anchored in the lipid bilayer by one or more membrane-spanning alpha-helical regions in their polypeptide chain. These hydrophobic portions of the protein can act either as start-transfer or stop-transfer signals during the translocation process. When a polypeptide contains multiple alternating start-transfer and stop-transfer signals, it will pass back and forth across the bilayer multiple times.

The asymmetry of lipid synthesis, protein insertion, and glycosylation in the ER establishes the polarity of the membranes of all of the other organelles that the ER supplies with lipids and membrane proteins.
Figure 12-30. The endoplasmic reticulum. Fluorescence micrograph of a cultured mammalian cell stained with an antibody that binds to a protein retained in the ER. The ER extends as a network throughout the entire cytosol, so that all regions of the cytosol are close to some portion of the ER membrane. (Courtesy of Hugh Pelham.)
Figure 12-31. The rough ER. Electron micrograph of the rough ER, which receives its name from the many ribosomes on its cytosolic surface. (Courtesy of L. Orci.)

Figure 12-32. Polyribosomes. Thin-section electron micrograph of polyribosomes attached to the ER membrane. The plane of section in some places cuts through the ER roughly parallel to the membrane, giving a face-on view of the rosettelike pattern of the polyribosomes. (Courtesy of George Palade.)
Figure 12-33. Free and membrane-bound ribosomes. A common pool of ribosomes is used to synthesize both the proteins that stay in the cytosol and those that are transported into the ER. It is the ER signal peptide on a newly formed polypeptide chain that directs the engaged ribosome to the ER membrane. The mRNA molecule may remain permanently bound to the ER as part of a polyribosome, while the ribosomes that move along it are recycled; at the end of each round of protein synthesis, the ribosomal subunits are released and rejoin the common pool in the cytosol.
Figure 12-34. Abundant smooth ER in a steroid-hormone-secreting cell. This electron micrograph is of a testosterone-secreting Leydig cell in the human testis.
Figure 12-35. Three-dimensional reconstruction of a region of the smooth and rough ER in a liver cell. The rough ER forms oriented stacks of flattened cisternae, each having a luminal space 20 to 30 nm wide. The smooth ER membrane is connected to these cisternae and forms a fine network of tubules 30 to 60 nm in diameter. (After R.V. Krstić Ultrastructure of the Mammalian Cell. New York: Springer-Verlag, 1979.)
Figure 12-36. Electron micrographs of microsomes. When cells are disrupted by homogenization, the cisternae of rough ER (A) break up into small closed vesicles called *rough microsomes* (B). Similarly, the smooth ER breaks up into small vesicles that lack ribosomes and are called *smooth microsomes*. (A, courtesy of Daniel S. Friend; B, courtesy of George Palade.)
Figure 12-37. The isolation procedure used to purify rough and smooth microsomes from the ER. When sedimented to equilibrium through a gradient of sucrose, the two types of microsomes separate from each other on the basis of their different densities.
Figure 12-38. The original signal hypothesis. A simplified view of protein translocation across the ER membrane, as originally proposed. When the signal peptide emerges from the ribosome, it directs the ribosome to a receptor protein on the ER membrane. As it is synthesized, the polypeptide is postulated to be translocated across the ER membrane through a protein pore associated with the receptor. The signal peptide is clipped off during translation by a signal peptidase, and the mature protein is released into the lumen of the ER immediately after being synthesized. We now know that the hypothesis is correct in outline but that additional components besides those shown in this figure are required. The signal peptidase, for example, is a complex of five different membrane-bound polypeptide chains, with one complex apparently associated with every translocation pore.

Figure 12-40. How ER signal peptides and SRP direct ribosomes to the ER membrane. The SRP and the SRP receptor are thought to act in concert. The SRP binds to the exposed ER signal peptide and to the ribosome, thereby inducing a pause in translation. The SRP receptor in the ER membrane, which is composed of two different polypeptide chains, binds the SRP ribosome complex. In a poorly understood reaction that involves multiple GTP-binding proteins, the SRP is released, leaving the ribosome on the ER membrane. A multisubunit protein translocation apparatus in the ER membrane then inserts the polypeptide chain into the membrane and transfers it across the lipid bilayer.

Figure 12-41. Translocation of a protein across the bacterial plasma membrane. In this schematic model, after a receptor in the translocation complex has bound the amino-terminal signal peptide, an energy-driven protein translocator threads the protein through the membrane, unfolding the polypeptide chain in the process. The energy is provided both by ATP hydrolysis and an electrochemical gradient across the membrane.
Figure 12-42. The demonstration of protein-translocating aqueous pores in the ER membrane. The experimental set-up is similar to that shown in Figure 10-5, with an artificial lipid bilayer separating two aqueous compartments. When rough microsomes are added to one of the compartments, they occasionally fuse with the lipid bilayer, incorporating a portion of ER membrane (with its bound ribosomes) into the bilayer. When the drug puromycin (*dark blue*) is added to the same compartment, it couples covalently to the carboxyl terminus of the growing polypeptide chain and releases it from the ribosome; pores of uniform size can now be detected as discrete increases in the electrical conductance across the membrane (the ion flow responsible for the increased electrical conductance is indicated by the *yellow arrow*). If the ribosomes are removed from the membrane with a high-salt wash, pores are no longer detected, indicating that ribosome binding is required to open (or assemble) the pore (not shown).
Figure 12-43. The translocation of a soluble protein across the ER membrane. In this hypothetical model the protein translocator in the membrane is postulated to exist in two alternative states - active or inactive. On binding an ER signal peptide (which acts as a start-transfer signal), the translocator adopts an active state and begins to transfer the polypeptide chain across the lipid bilayer as a loop. In this state it forms an aqueous pore across the membrane that can be detected electrophysiologically

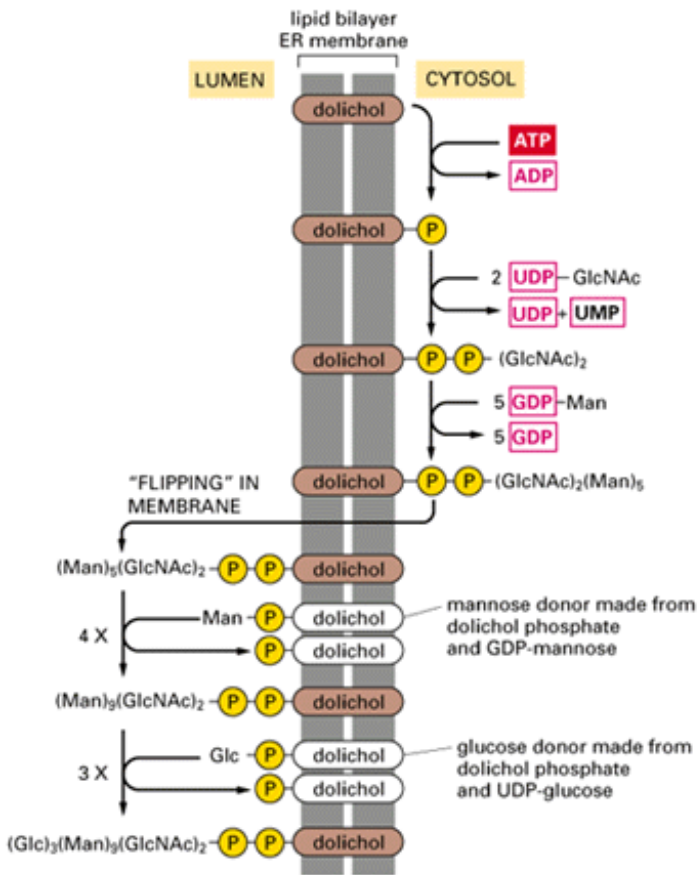
if the polypeptide chain is released (see Figure 12-42). After the protein has been completely translocated, the translocator reverts to an inactive conformation, which can no longer conduct ions across the membrane but is open to the lipid bilayer, allowing the hydrophobic signal peptide to diffuse out into the bilayer, where it is rapidly degraded. In this and the following two figures the ribosomes have been omitted for clarity.
Figure 12-44. How a single-pass transmembrane protein with a cleaved ER signal peptide is integrated into the ER membrane. In this hypothetical model the co-translational translocation process is initiated by an amino-terminal ER signal peptide (*red*) that functions as a start-transfer signal as in Figure 12-43. In addition to the start-transfer peptide, however, the protein also contains a stop-transfer peptide (*orange*). When the stop-transfer peptide enters the translocator and interacts with a binding site, the translocator flips into its inactive state and discharges the protein laterally into the lipid bilayer.
Figure 12-45. How a single-pass membrane protein with an internal signal peptide is integrated into the ER membrane. In this hypothetical model an internal ER signal peptide that functions as a start-transfer signal will bind to the translocator in such a way that its more positively charged end remains in the cytosol. If there are more positively charged amino acids immediately preceding the hydrophobic core of the start transfer peptide than there are following it on its carboxyl-terminal end, the start-transfer peptide will be inserted into the translocator in the orientation shown in (A), and the arm of the inserted loop carboxyl-terminal to the start-transfer sequence will be passed across the membrane. If, however, there are more positively charged amino acids immediately following the hydrophobic core of the start-transfer peptide than there are preceding it on its amino-terminal end, the start-transfer peptide will be inserted into the translocator in the orientation shown in (B), and the arm of the inserted loop amino-terminal to the start-transfer peptide will be passed across the membrane. Because translocation cannot start before a start-transfer sequence appears outside the ribosome, translocation of the amino-terminal portion of the protein shown in (B) can occur only after this portion has been fully synthesized. Note that there are two ways to insert a single-pass membrane-spanning protein whose amino terminus is located in the ER lumen: that shown in Figure 12-44 and that shown in (B) here.
Figure 12-46. How a double-pass membrane protein with an internal signal sequence is integrated into the ER membrane. In this hypothetical model an internal ER signal peptide acts as a start-transfer signal (as in Figure 12-45) and initiates the transfer of the carboxyl terminal arm of the polypeptide chain. When a stop-transfer peptide enters the translocator, it discharges the protein laterally into the membrane.
Figure 12-47. The insertion of the multipass membrane protein rhodopsin into the ER membrane. Rhodopsin is the light-sensitive protein in rod photoreceptor cells in the mammalian retina. (A) A hydrophobicity plot identifies seven short hydrophobic regions in rhodopsin. (B) The most amino-terminal region serves as a start-transfer peptide that causes the preceding amino-terminal portion of the protein to be passed across the ER membrane. Subsequent hydrophobic peptides will function in alternation as start-transfer and stop-transfer peptides. (C) The final integrated rhodopsin has its amino terminus located in the ER lumen and its carboxyl terminus located in the cytosol. The *blue hexagons* represent covalently attached oligosaccharides.
Figure 12-48. The asparagine-linked (*N*-linked) oligosaccharide that is added to most proteins in the rough ER membrane. The five sugar residues in the *gray box* form the "core region" of this oligosaccharide. For many glycoproteins only the core sugars survive the extensive oligosaccharide trimming process that takes place in the Golgi apparatus. Only asparagines in the sequences *Asn-X-Ser* or *Asn-X-Thr* (where X is any amino acid except proline) become glycosylated. These two sequences occur much less frequently in glycoproteins than in nonglycosylated cytosolic proteins; evidently there has been selective pressure against these sequences during protein evolution, presumably because glycosylation at too many sites would interfere with protein folding.
Figure 12-49. Protein glycosylation in the rough ER. Almost as soon as a polypeptide chain enters the ER lumen, it is glycosylated on target asparagine amino acids. The oligosaccharide shown in Figure 12-48 is transferred to the asparagine as an intact unit in a reaction catalyzed by a membrane-bound *oligosaccharyl transferase* enzyme. There is one copy of this enzyme associated with each protein translocator in the ER membrane.


Figure 12-50. Synthesis of the lipid-linked precursor oligosaccharide in the rough ER membrane. The oligosaccharide is assembled sugar by sugar onto the carrier lipid dolichol (a polyisoprenoid -- see Panel 2-4). Dolichol is long and very hydrophobic: its 22 five-carbon units can span the thickness of a lipid bilayer more than three times, so that the attached oligosaccharide is firmly anchored in the membrane. The first sugar group is linked to dolichol by a pyrophosphate bridge. This high-energy bond activates the oligosaccharide for its transfer from the lipid to an asparagine side chain of a nascent polypeptide on the luminal side of the rough ER. The synthesis of the oligosaccharide starts on the cytosolic side of the ER membrane and continues on the luminal face after the (Man) $_5$(GlcNAc) $_2$ lipid intermediate is flipped across the bilayer. All of the subsequent glycosyl transfer reactions on the luminal side of the ER involve transfers from dolichol-P-glucose and dolichol-P-mannose; these activated, lipid-linked monosaccharides are synthesized from dolichol phosphate and UDP-glucose or GDP-mannose (as appropriate) on the cytosolic side of the ER and are then thought to be flipped across the ER membrane. GlcNAc = N-acetylglucosamine; Man = mannose; Glc = glucose.
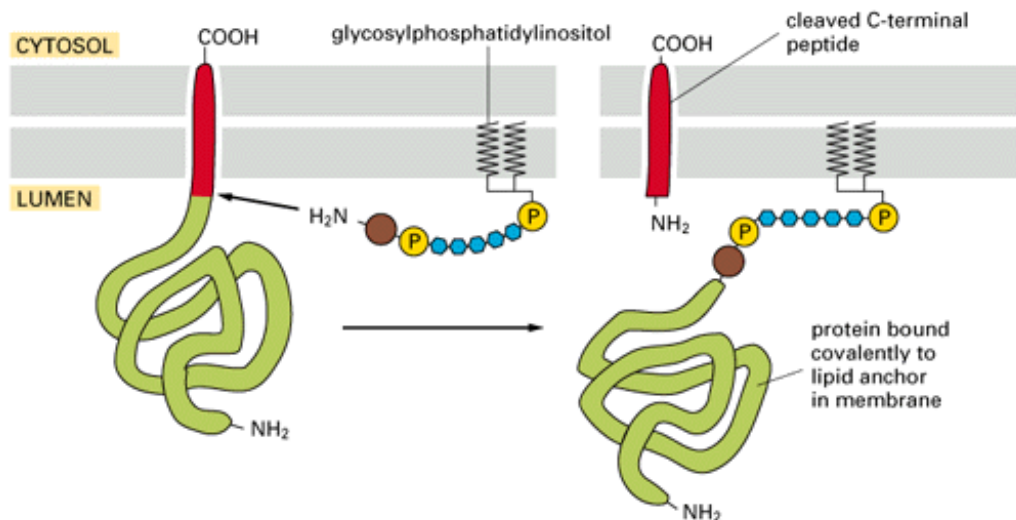

Figure 12-51. The attachment of a glycosylphosphatidylinositol anchor. Immediately after the completion of protein

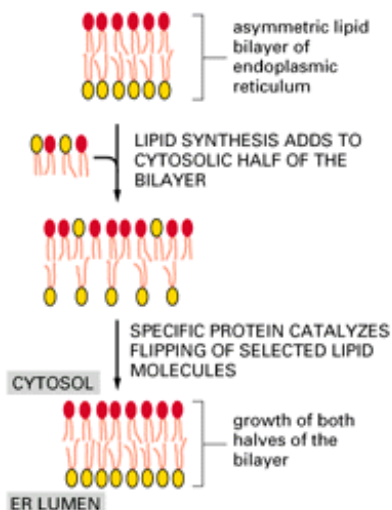
synthesis, the precursor protein remains anchored in the ER membrane by a hydrophobic carboxyl-terminal sequence of 15 to 20 amino acids, with the rest of the protein in the ER lumen. Within less than a minute, an enzyme in the ER cuts the protein free from its membrane-bound carboxyl terminus and simultaneously attaches the new carboxyl terminus to an amino group on a preassembled glycosylphosphatidylinositol intermediate. The signal that specifies this modification is contained within the hydrophobic carboxyl-terminal sequence and a few amino acids adjacent to it on the luminal side of the ER membrane; if this signal is added to other proteins, they too become modified in this way. Because of the covalently linked lipid anchor, the protein remains membrane-bound with all of its amino acids exposed initially on the luminal side of the ER and eventually on the cell exterior.
Figure 12-52. The synthesis of phosphatidylcholine. This phospholipid is synthesized from fatty acyl-coenzyme A (fatty acyl CoA), glycerol 3-phosphate, and cytidine-bisphosphocholine (CDP-choline).


Figure 12-53. The role of phospholipid translocators in lipid bilayer synthesis. Since new lipid molecules are added only to the cytosolic half of the bilayer and lipid molecules do not flip spontaneously from one monolayer to the other, membrane-bound phospholipid translocator proteins ("flippases") are required to transfer selected lipid molecules from the cytosolic half to

the luminal half so that the membrane grows as a bilayer. Because the flippase in the ER membrane preferentially recognizes and transfers choline-containing head groups, an asymmetric bilayer is generated, with the luminal monolayer (which produces the outer half of the plasma membrane bilayer) highly enriched for phosphatidylcholine.
Figure 12-54. Phospholipid exchange proteins. Because phospholipids are insoluble in water, their passage between membranes requires a carrier protein. Phospholipid exchange proteins are water-soluble proteins that carry a single molecule of phospholipid at a time; they can pick up a lipid molecule from one membrane and release it at another and thereby redistribute phospholipids between membrane-bounded compartments. The transfer of phosphatidylcholine (PC) from ER to mitochondria can occur without the input of additional energy because the concentration of PC is high in the ER membrane (where it is made) and low in the mitochondrial outer membrane. One would predict that there must be a flippase in the outer mitochondrial membrane to equilibrate the lipids between the two leaflets of the bilayer, and there must be a mechanism to transfer lipids between the outer and inner mitochondrial membrane. These postulated pathways, however, remain to be discovered.

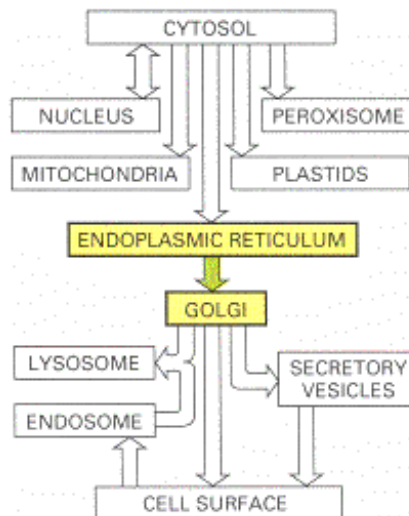
13. Vesicular Traffic in the Secretory and Endocytic Pathways

Introduction

Every cell must communicate with its environment. In a procaryotic cell all of this communication takes place across the plasma membrane: digestive enzymes, for example, are secreted to the cell exterior, and the small metabolites generated by digestion are then taken up by transport proteins in the plasma membrane. Eucaryotic cells, by contrast, have evolved an elaborate internal membrane system that allows them to take up macromolecules by a process called *endocytosis* and deliver them to digestive enzymes that are stored intracellularly in lysosomes; as a consequence, metabolites generated by digestion are delivered from the lysosomes directly to the cytosol as they are produced. Besides providing for regulated digestion of macromolecules by the *endocytic pathway,* the internal membrane system provides a means whereby eucaryotic cells can regulate the delivery of newly synthesized proteins and carbohydrates to the exterior. Because each molecule that travels along this *biosynthetic-secretory pathway* passes through multiple compartments, the cell can modify the molecule in a series of controlled steps, store it until needed, and then deliver it to a specific cell-surface domain by a process called *exocytosis.* The endocytic and biosynthetic-secretory pathways are shown in color in Figure 13-1.

The lumen of each compartment along the biosynthetic-secretory and endocytic pathways is topologically equivalent to the exterior of the cell, and the compartments are all in constant communication with one another, at least partly by means of numerous transport vesicles, which continually bud off from one membrane and fuse with another (Figure 13-2). The traffic is highly organized: the biosynthetic-secretory pathway leads outward from the ER toward the Golgi apparatus and cell surface, with a side route leading to lysosomes, while the endocytic pathway leads inward toward endosomes and lysosomes from the plasma membrane (Figure 13-3).

To perform its function, each transport vesicle that buds from a compartment must take up only the appropriate proteins and must fuse only with the appropriate target membrane. A vesicle carrying cargo from the Golgi apparatus to the plasma membrane, for example, must exclude proteins that are to stay in the Golgi apparatus, and it must fuse only with the plasma membrane and not with any other organelle. While participating in this constant flow of membrane components, each organelle must maintain its own distinct identity. In this chapter we consider the function of the Golgi apparatus, lysosomes, secretory vesicles, and endosomes, and we trace the pathways by which these organelles are interconnected. In the final section we consider the molecular mechanisms of budding and fusion that underlie all vesicular transport, and we discuss the fundamental problem of how, in the face of this transport, the differences between the compartments are maintained.
Figure 13-1. The secretory and endocytic pathways. In this "road map" of biosynthetic protein traffic, which was introduced in Chapter 12, both the secretory and endocytic pathways are colored.
Figure 13-2. Vesicular transport. Transport vesicles bud off from one compartment and fuse with another.
Figure 13-3. The intracellular compartments of the eucaryotic cell involved in the biosynthetic-secretory and endocytic pathways. Each compartment encloses a space that is topologically equivalent to the outside of the cell, and they all communicate with one another by means of transport vesicles. In the biosynthetic-secretory pathway (*red arrows*) protein molecules are transported from the ER to the plasma membrane or (via late endosomes) to lysosomes. In the endocytic pathway (*green arrows*) molecules are ingested in vesicles derived from the plasma membrane and delivered to early endosomes and then (via late endosomes) to lysosomes. Many endocytosed molecules are retrieved from early endosomes and returned to the cell surface for reuse; similarly, some molecules are retrieved from the late endosome and returned to the Golgi apparatus, and some are retrieved from the Golgi apparatus and returned to the ER. All of these retrieval pathways are shown with *blue arrows*.

Transport from the ER Through the Golgi Apparatus <u>1</u>


Introduction

As discussed in <u>Chapter 12</u>, newly synthesized proteins enter the biosynthetic-secretory pathway in the ER by crossing the ER membrane from the cytosol. Subsequent transport, from the ER to the Golgi apparatus and from the Golgi apparatus to the cell surface and elsewhere, is mediated by transport vesicles, which transfer proteins from membrane to membrane or from lumen to lumen (or to extracellular space) by cycles of vesicle budding and fusion (see <u>Figure 12-7</u>). The pathway from the ER via the Golgi apparatus to the cell surface is often referred to as the *default pathway* because proteins seem not to require special signals

to follow it: any protein that enters the ER (and folds and assembles properly) will automatically be transported through the Golgi apparatus to the cell surface unless it contains signals that either detain it in an earlier compartment en route or divert it, via the Golgi apparatus, to lysosomes or secretory vesicles.

In this section we focus mainly on the Golgi apparatus (also called the *Golgi complex*), which is a major site of carbohydrate synthesis as well as a sorting and dispatching station for the products of the ER. Many of the cell's polysaccharides are made in the Golgi apparatus, including the pectin and hemicellulose of the plant cell wall and most of the glycosaminoglycans of the extracellular matrix in animals (discussed in Chapter 19). But the Golgi apparatus also lies on the exit route from the ER, and a large proportion of the carbohydrates it makes are attached as oligosaccharide side chains to the proteins and lipids that the ER sends to it. Certain oligosaccharide groups serve as tags to direct specific proteins into vesicles that will transport them to lysosomes; other proteins and lipids, once they have acquired their appropriate oligosaccharides in the Golgi apparatus, are dispatched in transport vesicles to other destinations.

The Golgi Apparatus Consists of an Ordered Series of Compartments 2

The Golgi apparatus is usually located near the cell nucleus, and in animal cells it is often close to the *centrosome,* or *cell center.* It consists of a collection of flattened, membrane-bounded *cisternae* and thus resembles a stack of plates. Each of these Golgi stacks usually consists of four to six cisternae (Figure 13-4). The number of Golgi stacks per cell varies greatly depending on the cell type: some animal cells contain one large stack, while certain plant cells contain hundreds of small ones.

Swarms of small vesicles are associated with the Golgi stacks, clustered on the side abutting the ER and along the dilated rims of each cisterna (see Figure 13-4). These *Golgi vesicles* are thought to transport proteins and lipids both to and from the Golgi apparatus and between the Golgi cisternae. During their passage through the Golgi apparatus, the transported molecules undergo an ordered series of covalent modifications.

Each Golgi stack has two distinct faces: a *cis* face (or entry face) and a *trans* face (or exit face). Both the *cis* and *trans* faces are closely connected to special compartments, which are composed of a network of interconnected tubular and cisternal structures. These are the *cis* Golgi network (also called the *intermediary* or *salvage compartment*) and the *trans* Golgi network, respectively. Proteins and lipids enter the *cis* Golgi network in transport vesicles from the ER and exit from the *trans* Golgi network in transport vesicles destined for the cell surface or another compartment. Both networks are thought to be important for protein sorting: proteins entering the *cis* Golgi network can either move onward in the Golgi apparatus or be returned to the ER; proteins exiting the *trans* Golgi network are sorted according to whether they are destined for lysosomes, secretory vesicles, or the cell surface.

The Golgi apparatus is especially prominent in cells that are specialized for secretion, such as the goblet cells of the intestinal epithelium, which secrete large amounts of polysaccharide-rich mucus into the gut. In such cells unusually large vesicles are found on the *trans* side of the Golgi apparatus, which faces the plasma membrane domain where secretion occurs (Figure 13-5).

ER-Resident Proteins Are Selectively Retrieved from the *Cis* Golgi Network 3

Vesicles destined for the Golgi apparatus bud from a specialized region of the ER called the transitional elements, whose membrane lacks bound ribosomes and is often located between the rough ER and the Golgi apparatus (Figure 13-6). Vesicles budding from the transitional elements of the ER are thought to be nonselective. They will transport any protein in the ER to the Golgi apparatus, although it remains possible that there are signals which accelerate the process. There is one strict requirement, however, for the exit of a protein from the ER: it must be correctly folded and assembled. Proteins that are misfolded or incompletely assembled into their protein complexes are retained in the ER, either bound to the special binding protein BiP (discussed in Chapter 12) or in aggregates that cannot be packaged, and are eventually degraded within the ER. Thus exit from the ER can be regarded as a quality checkpoint: unless folding and subunit assembly are successfully completed, the protein is discarded. In fact, the ER seems to be one of the main sites in the cell where proteins are degraded (the other being lysosomes, as we discuss later, and the cytosol, as we discuss in Chapter 5).

Correctly folded proteins do not need a special signal to be transported out of the ER, but those, such as BiP, that are resident in the ER lumen do need such a signal to be retained there. Retention of soluble ER-resident proteins is mediated by a short, four-amino acid sorting signal, identified as KDEL (Lys-Asp-Glu-Leu) or a similar sequence (see Table 12-3). If this *ER retention signal* is removed from BiP, for example, by genetic engineering, the protein is secreted from the cell; and if the signal is transferred to a protein that is normally secreted, the protein is now retained in the ER. The retention signal works not by

anchoring resident proteins in the lumen of the ER but by the selective retrieval of ER-resident proteins after they have escaped in transport vesicles and been delivered to the *cis* Golgi network. In the *cis* Golgi network a specific membrane-bound receptor protein binds to the ER retention signal and packages any proteins displaying the signal into special transport vesicles that return the proteins to the ER. Thus for these resident proteins the ER is like an open prison: there is nothing to stop them leaving, but if they leave, they are brought back (Figure 13-7).

Golgi Proteins Return to the ER When Cells Are Treated with the Drug Brefeldin A [4]

The continuous retrieval of ER-resident proteins from the *cis* Golgi network means that transport between these two organelles occurs in both directions. As mentioned in the legend to Figure 13-7, receptors for the ER retention signal are also found in the later Golgi compartments, suggesting that a return pathway from these compartments to the ER exists. The importance of the return pathway from Golgi to ER is dramatically illustrated by studies using the drug brefeldin A, which blocks protein secretion by disrupting the Golgi apparatus. In brefeldin-A-treated cells the Golgi apparatus largely disappears and the Golgi proteins end up in the ER, where they intermix with ER proteins. When the drug is removed, the normal Golgi apparatus reforms and the Golgi proteins return to their proper Golgi compartments (Figure 13-8).

To explain these observations, it has been proposed that brefeldin A blocks the forward transport from the ER through the Golgi apparatus without affecting the return transport from the Golgi to the ER (Figure 13-9). In this way the drug would cause the Golgi apparatus to empty into the ER via the return pathway, and when the drug is removed, forward traffic would resume and deliver the Golgi proteins back to their proper compartment.

Oligosaccharide Chains Are Processed in the Golgi Apparatus [5]

As described in Chapter 12, a single species of *N*-linked oligosaccharide is attached *en bloc* to many proteins in the ER, and this oligosaccharide is then trimmed while the protein is still in the ER. Further modifications and additions occur in the Golgi apparatus, depending on the protein. The outcome is that two broad classes of *N*-linked oligosaccharides, the *complex oligosaccharides* and the *high-mannose oligosaccharides,* are found attached to mammalian glycoproteins. Sometimes both types are attached (in different places) to the same polypeptide chain. High-mannose oligosaccharides have no new sugars added to them in the Golgi apparatus. They contain just two *N*-acetylglucosamines and many mannose residues, often approaching the number originally present in the lipid-linked oligosaccharide precursor added in the ER. Complex oligosaccharides, by contrast, can contain more than the original two *N*-acetylglucosamines as well as a variable number of galactose and sialic acid residues and, in some cases, fucose. Sialic acid is of special importance because it is the only sugar in glycoproteins that bears a net negative charge (Figure 13-10).

The complex oligosaccharides are generated by a combination of trimming the original oligosaccharide added in the ER and the addition of further sugars. Whether a given oligosaccharide remains high-mannose or is processed is determined largely by its configuration on the protein. If the oligosaccharide is accessible to the processing enzymes in the Golgi apparatus, it is likely to be converted to a complex form; if it is inaccessible, it is likely to remain in a high-mannose form. The processing that generates complex oligosaccharide chains follows the highly ordered pathway shown in Figures 13-11 and 13-12.

The Golgi Cisternae Are Organized as a Series of Processing Compartments [6]

Proteins exported from the ER enter the first of the Golgi processing compartments (the *cis* compartment), which is thought to be continuous with the *cis*Golgi network; they then move to the next compartment (the *medial* compartment, consisting of the central cisternae of the stack) and finally to the *trans* compartment, where glycosylation is completed. The lumen of the *trans* compartment is thought to be continuous with the *trans*Golgi network, where proteins are segregated into different transport vesicles and dispatched to their final destinations - the plasma membrane, lysosomes, or secretory vesicles.

These oligosaccharide processing pathways occur in a correspondingly organized sequence in the Golgi stack, with each cisterna containing its own set of processing enzymes. Proteins are modified in successive stages as they move from cisterna to cisterna across the stack, so that the stack forms a multistage processing unit. This compartmentalization might seem unnecessary, since each oligosaccharide processing enzyme can accept a glycoprotein as a substrate only after it has been properly processed by the preceding enzyme. Nonetheless, it is clear that processing occurs in a spatial as well as a biochemical sequence: enzymes catalyzing early processing steps are localized in cisternae toward the *cis* face of the Golgi stack, whereas enzymes catalyzing later processing steps are localized in cisternae toward the *trans* face.

The transport of proteins between the different Golgi cisternae is thought to be mediated by transport vesicles, which bud from one cisterna and fuse with the next. Like the transport vesicles that shuttle from the ER to the Golgi apparatus, the vesicles shuttling between the Golgi cisternae are also thought to be nonselective for their cargo: any soluble or membrane protein that is not otherwise attached as a permanent resident to Golgi membranes can enter the transport vesicles and be moved forward in the biosynthetic-secretory pathway from the *cis* to the *medial* to the *trans* Golgi cisternae. Indeed, much of what we know about the molecular mechanism of vesicular transport was originally described using *in vitro* systems designed to measure protein transport between the Golgi cisternae (see Panel 13-1, pp. 638-639). Electron microscopists have seen small membrane tubules that seem to interconnect some Golgi stacks, and it is possible that some transfer of material from one cisterna to the next may also occur through these structures.

The functional differences among the *cis, medial,* and *trans* subdivisions of the Golgi apparatus were discovered by localizing the enzymes involved in processing *N*-linked oligosaccharides in distinct regions of the organelle, both by physical fractionation of the organelle and by labeling the enzymes in electron-microscope sections with antibodies. The removal of mannose residues and the addition of *N*-acetylglucosamine, for example, were shown to occur in the *medial* compartment, while the addition of galactose and sialic acid was found to occur in the *trans* compartment and the *trans* Golgi network (Figure 13-13). The functional compartmentalization of the Golgi apparatus is summarized in Figure 13-14.

Proteoglycans Are Assembled in the Golgi Apparatus 7

It is not only the *N*-linked oligosaccharide chains on proteins that are altered as the proteins pass through the Golgi cisternae en route from the ER to their final destinations; many proteins are also modified in other ways. Some have sugars added to the OH groups of selected serine or threonine side chains, for example. This *O*-linked glycosylation, like the extension of *N*-linked oligosaccharide chains, is catalyzed by a series of glycosyl transferase enzymes that use the sugar nucleotides in the lumen of the Golgi apparatus to add sugar residues to a protein one at a time. Usually, *N*-acetylgalactosamine is added first, followed by a variable number of additional sugar residues, ranging from just a few to 10 or more.

The Golgi apparatus confers the heaviest glycosylation of all on *proteoglycan core proteins,* which it modifies to produce proteoglycans. As discussed in Chapter 19, this process involves the polymerization of one or more *glycosaminoglycan chains* (long unbranched polymers composed of repeating disaccharide units) via a xylose link onto serines on the core protein. Many proteoglycans are secreted and become components of the extracellular matrix while others remain anchored to the plasma membrane. Still others form a major component of slimy materials such as the mucus that is secreted to form a protective coating over many epithelia.

The sugars incorporated into glycosaminoglycans are heavily sulfated in the Golgi apparatus immediately after these polymers are made, and this helps to give proteoglycans their large negative charge. Some tyrosine residues in proteins also become sulfated at this stage. In both cases the sulfation depends on a sulfate donor (3'-phosphoadenosine-5'-phosphosulfate, or PAPS) that is transported from the cytosol into the lumen of the *trans* Golgi network.

The Carbohydrate in Cell Membranes Faces the Side of the Membrane That Is Topologically Equivalent to the Outside of the Cell 8

Because all oligosaccharide chains are added on the luminal side of the ER and Golgi apparatus, the distribution of carbohydrate on membrane proteins and lipids is asymmetrical. As with the asymmetry of the lipid bilayer itself, the asymmetric orientation of these glycosylated molecules is maintained during their transport to the plasma membrane, secretory vesicles, or lysosomes. As a result, the oligosaccharides of all of the glycoproteins and glycolipids in the corresponding intracellular membranes face the lumen, while those in the plasma membrane face the outside of the cell (Figure 13-15).

What Is the Purpose of Glycosylation? 9

There is an important difference between the construction of an oligosaccharide and the synthesis of other macromolecules such as DNA, RNA, and protein. Whereas nucleic acids and proteins are copied from a template in a repeated series of identical steps using the same enzyme(s), complex carbohydrates require a different enzyme at each step, each product being recognized as the exclusive substrate for the next enzyme in the series. Given the complicated pathways that have evolved to synthesize them, it seems likely that the oligosaccharides on glycolipids and glycoproteins have important functions, but for the most part these functions are not known.

N-linked glycosylation, for example, is prevalent in all eucaryotes, including yeasts, but is absent from procaryotes. Because one or more *N*-linked oligosaccharides are present on most proteins transported through the ER and Golgi apparatus - a pathway that is unique to eucaryotic cells - it was once thought that their function was to aid this transport process. Drugs that block steps in glycosylation, however, do not generally interfere with transport (with the important exception of transport to lysosomes, which is discussed below), and mutant cells in culture that are blocked in various glycosylation steps in the Golgi apparatus, nevertheless, are viable and transport proteins normally. Although some proteins do not fold correctly without their normal oligosaccharide and therefore precipitate in the ER and fail to be transported, most proteins retain their normal activities in the absence of glycosylation.

Because chains of sugars have limited flexibility, even a small *N*-linked oligosaccharide protrudes from the surface of a glycoprotein (Figure 13-16) and can thus limit the approach of other macromolecules to the surface of the glycoprotein. In this way, for example, the presence of oligosaccharides tends to make a glycoprotein relatively resistant to protease digestion. It may be that the oligosaccharides on cell-surface proteins originally provided an ancestral eucaryotic cell with a protective coat that, unlike the rigid bacterial cell wall, allowed the cell freedom to change shape and move. But these sugar chains have since become modified to serve other purposes as well: the oligosaccharides attached to the cell-surface proteins called selectins, for example, function in cell-cell adhesion processes, as discussed in Chapter 10.

Summary

The Golgi apparatus receives newly synthesized proteins and lipids from the ER and distributes them to the plasma membrane, lysosomes, and secretory vesicles. It is a polarized structure containing one or more stacks of disc-shaped cisternae, which are organized as a series of at least three biochemically and functionally distinct compartments, termed cis, medial, and trans cisternae. Both the cis and trans cisternae are connected to sorting stations, called the cis Golgi network and the trans Golgi network, respectively. Correctly folded proteins are transferred indiscriminately from the lumen and membrane of the ER to the cis Golgi network, but the resident ER proteins are returned. Proteins destined for secretory vesicles, the plasma membrane, and lysosomes move through the Golgi stack in the cis -to- trans direction, passing from one cisterna to the next; they finally reach the trans Golgi network, from which each type of protein departs for its specific destination. Each of these many transport steps is mediated by transport vesicles, which bud off from one membrane and then fuse with another.

The Golgi apparatus, unlike the ER, contains many sugar nucleotides, which are used by a variety of glycosyl transferase enzymes to carry out glycosylation reactions on lipid and protein molecules as they pass through the Golgi apparatus. N- linked oligosaccharides, for example, which are added to proteins in the ER, are often initially trimmed by removal of mannoses, and then additional sugars - including N- acetylglucosamine, galactose, and sialic acid - are added. In addition, the Golgi is the site where O- linked glycosylation occurs and where glycosaminoglycan chains are added to core proteins to form proteoglycans. Sulfation of the sugars in proteoglycans and of selected tyrosines on proteins also occurs in a late Golgi compartment.

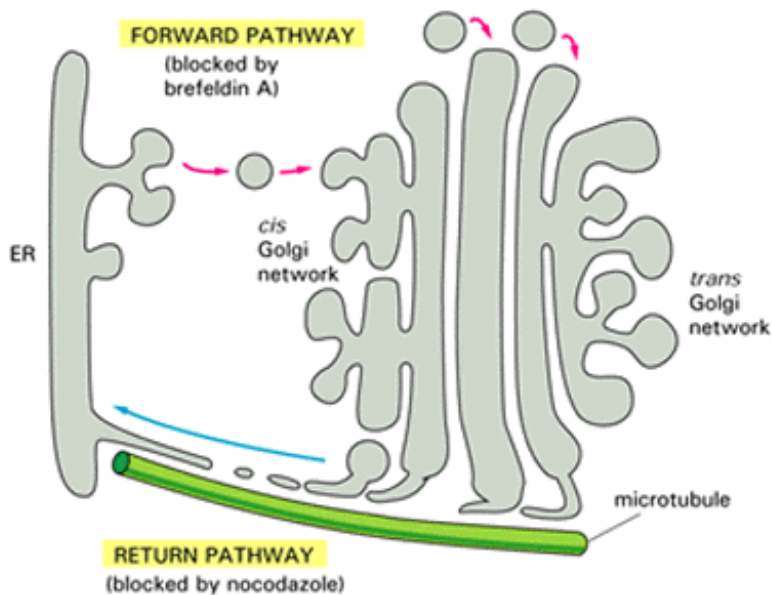
Figure 13-5. A goblet cell of the small intestine. This cell is specialized for secreting mucus, a mixture of glycoproteins and proteoglycans synthesized in the ER and Golgi apparatus. The Golgi apparatus in these cells is highly polarized, which facilitates the discharge of mucus by exocytosis at the apical surface. (After R.V. Krstic#180, Illustrated Encyclopedia of Human Histology. New York: Springer-Verlag, 1984.)
Figure 13-6. Electron micrograph of transitional elements and *cis* Golgi network. Transport vesicles bud from the transitional elements of the ER, which are nearly free of ribosomes and fuse with the *cis* Golgi network, thereby transferring newly made proteins and lipids from the ER to the Golgi apparatus. (Courtesy of Brij J. Gupta.)
Figure 13-7. The mechanism used to retain resident proteins in the ER. ER-resident proteins that escape to the *cis* Golgi network are returned to the ER by vesicular transport. A membrane receptor in the *cis* Golgi network captures the proteins and carries them in transport vesicles back to the ER. The ionic conditions in the ER dissociate the ER proteins from the receptor, and the receptor is then returned to the *cis* Golgi network for reuse. Receptors for the ER retention signal are also found in the *cis, medial,* and *trans* Golgi cisternae. Thus the retrieval of ER proteins begins in the *cis* Golgi network, but the return pathway operates from the later Golgi cisternae as well. The retention is aided by interactions between ER-resident proteins in the ER lumen. These interactions retard the exit of ER proteins relative to proteins that are destined for secretion (secretory proteins). Experiments in which the ER retention signal is removed from BiP show that BiP leaves the ER and is eventually secreted from cells but that its exit from the ER occurs much more slowly than that of *bona fide* secretory proteins, indicating that it is held there by weak interactions with other proteins.
Figure 13-8. Electron micrographs showing the effect of brefeldin A treatment on the Golgi apparatus. A histochemical stain shows the location of a Golgi enzyme (a mannosidase) before (A) and two hours after (B) brefeldin A treatment of cultured fibroblasts. Note that after the treatment the enzyme relocates from the *cis* and *medial*Golgi cisternae to the ER and to the nuclear envelope, which is continuous with the ER. (Courtesy of Jennifer Lippincott-Schwartz and Lydia Yuan.)


Figure 13-9. The postulated return pathway from the Golgi apparatus to the ER. Whereas the forward pathway requires transport vesicles and occurs independently of microtubules, the return pathway is thought to involve membrane tubes that are pulled from the Golgi apparatus to the ER along microtubules (which are disrupted by drugs such as nocodazole). As we discuss later, brefeldin A prevents the assembly of the coats that are required for budding of the transport vesicles, and this may block the forward vesicular transport steps while leaving the backward membrane-tube-dependent transport process intact.
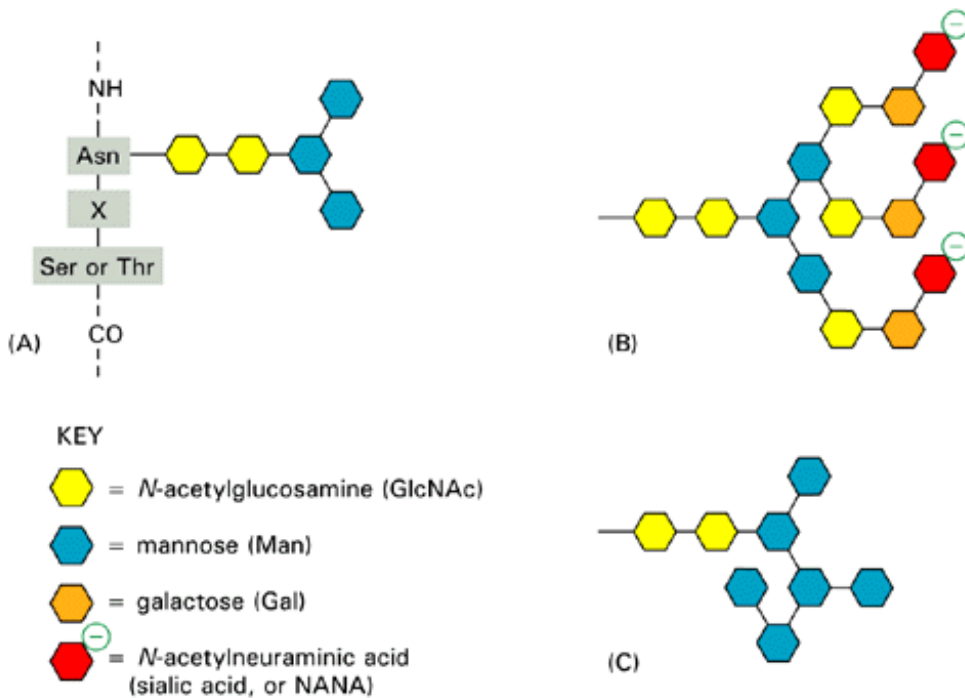

Figure 13-10. The two main classes of asparagine-linked (*N*-linked) oligosaccharides found in mature glycoproteins. A *complex oligosaccharide* is shown in (B) and a *high-mannose oligosaccharide* in (C). Each complex oligosaccharide consists of a *core region*(shown in color in A), derived from the original *N*-linked oligosaccharide added in the ER and typically containing two *N*-acetylglucosamines (GlcNAc) and three mannoses (Man), together with a *terminal region* that contains a variable number of trisaccharide units (*N*-acetylglucosamine-galactose-sialic acid) linked to the core mannoses. Frequently the terminal region is truncated and contains only GlcNAc and galactose (Gal) or just GlcNAc. In addition, a fucose residue may be added, usually to the core GlcNAc attached to the asparagine (Asn). Thus, although the steps of processing and subsequent sugar addition are rigidly ordered, complex oligosaccharides can be heterogeneous: while the complex oligosaccharide shown has three terminal branches, for example, two and four branches are also common, depending on the glycoprotein and the cell in which it is made. Hybrid oligosaccharides with one Man branch and one GlcNAc and Gal branch are also found. The indicated three amino acids constitute the sequence recognized by the oligosaccharyl transferase enzyme that adds the initial oligosaccharide to the protein. Ser = serine; Thr = threonine; X = any amino acid.
Figure 13-11. Oligosaccharide processing in the ER and the Golgi apparatus. The processing pathway is highly ordered so that each step shown is dependent on the previous one. Processing begins in the ER with the removal of the glucoses from the

oligosaccharide initially transferred to the protein. Then a mannosidase in the ER membrane removes a specific mannose. The remaining steps occur in the Golgi stack, where Golgi mannosidase I first removes three more mannoses and *N*-acetylglucosamine transferase I then adds an *N*-acetylglucosamine, which enables mannosidase II to remove two additional mannoses. This yields the final core of three mannoses that is present in a complex oligosaccharide. At this stage the bond between the two *N*-acetylglucosamines in the core becomes resistant to attack by a highly specific endoglycosidase (*Endo H*). Since all later structures in the pathway are also Endo H-resistant, treatment with this enzyme is widely used to distinguish complex from high-mannose oligosaccharides. Finally, as shown in Figure 13-10, additional *N*-acetylglucosamines, galactoses, and sialic acids are added. Some oligosaccharides will escape processing in the Golgi apparatus, whereas others will follow the pathway shown to varying extents: the extent of processing depends on the protein and on the location of the asparagine residue in the protein to which the oligosaccharide is attached.
Figure 13-12. The final steps in the synthesis of a complex oligosaccharide. The stepwise addition of sugars occurs in the cisternal compartments of the Golgi apparatus. Three types of glycosyl transferase enzymes act sequentially, using sugar substrates that have been activated by linkage to the indicated nucleotide. The membranes of the Golgi cisternae contain specific carrier proteins that allow each sugar nucleotide to enter in exchange for the nucleoside monophosphate that is released after the sugar is attached to the protein on the luminal face (not shown). The structures of the sugar nucleotides UDP- *N*-acetylglucosamine, UDP-galactose, and CMP- *N*-acetylneuraminic acid are shown at the top.

Panel 13-1: >Strategies used to study the molecular mechanisms involved in vesicular transport38

CELL-FREE SYSTEMS FOR STUDYING THE COMPONENTS AND MECHANISM OF VESICULAR TRANSPORT

Vesicular transport can be reconstituted in cell-free systems. This was first achieved for the Golgi stack. When Golgi stacks are isolated from cells and incubated with cytosol and with ATP as a source of energy, transport vesicles bud from their rims and appear to transport proteins between cisternae. By following the progressive processing of the oligosaccharides on a glycoprotein as it moves from one Golgi compartment to the next, it is possible to follow the process of vesicular transport.

To follow the transport, two distinct populations of Golgi stacks are incubated together. The "donor" population is isolated from mutant cells that lack the enzyme N-acetylglucosamine (GlcNAc) transferase I and that have been infected with a virus; because of the mutation, the major viral glycoprotein fails to be modified with GlcNAc in the Golgi apparatus of the mutant cells. The "acceptor" Golgi stacks are isolated from uninfected wild-type cells and thus contain a good copy of GlcNAc transferase I, but lack the viral glycoprotein. In the mixture of Golgi stacks the viral glycoprotein acquires GlcNAc, indicating that it must have been transported between the Golgi stacks—presumably by vesicles that bud from the *cis* compartment of the donor Golgi and fuse with the *medial* compartment of the acceptor Golgi. This transport-dependent glycosylation is monitored by measuring the transfer of ^{3}H-GlcNAc from UDP-^{3}H-GlcNAc to the viral glycoprotein. Transport occurs only when ATP and cytosol are added. By fractionating the cytosol, a number of specific cytosolic proteins have been identified that are required for the budding and fusion of transport vesicles.
Similar cell-free systems have been used to study transport from the *medial* to the *trans* Golgi network, from the *trans* Golgi network to the plasma membrane, from endosomes to lysosomes, and from the *trans* Golgi network to late endosomes.

GENETIC APPROACHES FOR STUDYING VESICULAR TRANSPORT

Genetic studies of mutant yeast cells defective for secretion at high temperature have identified more than 25 genes that are involved in the secretory pathway. Many of the mutant genes encode *temperature-sensitive* proteins. these function normally at 25°C, but when the mutant cells are shifted to 35°C, some of them fail to transport proteins from the ER to the Golgi apparatus, others from one Golgi cisternae to another, and still others from the Golgi apparatus to the vacuole (the yeast lysosome) or to the plasma membrane.

Once a protein required for secretion has been identified in this way, one can identify genes that encode proteins that interact with it by making use of a phenomenon called *multicopy suppression*. A temperature-sensitive mutant protein at high temperature often has too low an affinity for the proteins it normally interacts with to bind to them. If the interacting proteins are produced at much higher concentration than normal, however, sufficient binding occurs to cure the defect. For this reason yeast cells with a temperature-sensitive mutation in a gene involved in vesicular transport are often transfected with a yeast plasmid vector into which random yeast genomic DNA fragments have been cloned. Because this plasmid is maintained in cells at high copy number, those that carry intact genes will overproduce the normal gene product, allowing rare cells to survive at the high temperature. The relevant DNA fragments, which presumably encode proteins that interact with the original mutant protein, can then be isolated from the surviving cell clones.

The genetic and biochemical approaches complement each other, and many of the proteins involved in vesicular transport have been identified independently by biochemical studies of mammalian cell-free systems and by genetic studies in yeast.

SEMI-INTACT CELL SYSTEMS FOR STUDYING VESICULAR TRANSPORT

Vesicular transport can also be studied in cells whose plasma membrane has been permeabilized to allow small molecules and macromolecules to leave and enter the cell freely. Permeabilization is achieved by physical rupture or treatment with bacterial toxins that punch large holes in the plasma membrane. Such semi-intact cells are particularly useful for studying the transport from extended membrane systems that become extensively fragmented during conventional homogenization procedures, such as the ER and the *trans* Golgi network.

Semi-intact cells have been used to isolate transport vesicles that mediate transport from the *trans* Golgi network to the apical plasma membrane. Epithelial cells are infected with a virus that buds from the apical plasma membrane. The cells are grown at a reduced temperature (20°C) so that membrane traffic from the *trans* Golgi network to the cell surface is blocked, trapping the major viral protein in the *trans* Golgi network (A). When the cells are permeabilized (by laying a piece of nitrocellulose paper on top of them and then ripping it off again to rupture the plasma membrane), the cytosol leaks out of the cells, leaving the internal membrane systems behind (B). The temperature block is then released, and fresh cytosol and ATP are added, causing transport vesicles that contain the viral glycoprotein to bud off from the *trans* Golgi network and leave the semi-intact cells through the holes in the plasma membrane (C). The vesicles are collected and purified using an antibody that recognizes the cytosolic tail of the transmembrane viral glycoprotein, allowing the proteins that make up the transport vesicles to be identified (D).

Figure 13-14. The functional compartmentalization of the Golgi apparatus. The localization of each processing step shown was determined by a combination of techniques, including biochemical subfractionation of the Golgi apparatus membranes and electron microscopy after staining with antibodies specific to some of the processing enzymes. The locations of many other processing reactions have not been determined. Although only three distinguishable cisternal compartments have so far been demonstrated, each of these sometimes consists of a group of two or more cisternae in sequence, and it is possible that there are finer subdivisions still to be discovered. Alternatively, it may be that there are only three functionally distinct compartments and that the extra cisternae represent multiple copies of one of the three functional units. It is not clear, however, whether each processing enzyme is completely restricted to a particular cisterna or whether its distribution is graded across the stacksuch that early acting enzymes are present mostly in the *cis* Golgi cisternae while later acting enzymes are mostly in the *trans* Golgi cisternae.
Figure 13-15. The sugars on membrane glycoproteins and glycolipids are oriented away from the cytosol. The orientation of a transmembrane protein in the ER membrane is preserved when the protein is transported to other membranes. The *red ball* on the end of each glycoprotein molecule represents an *N*-linked oligosaccharide that is added to protein in the ER lumen. Note that these sugar residues are confined to the lumen of each of the internal organelles and become exposed to the extracellular space after a transport vesicle fuses with the plasma membrane. The same is true of the sugar residues on the glycolipids and *O*-linked oligosaccharides produced in the Golgi apparatus.
Figure 13-16. The three-dimensional structure of a small *N*-linked oligosaccharide. The structure was determined by x-ray crystallographic analysis of a glycoprotein. This oligosaccharide contains only 6 sugar residues, whereas there are 14 sugar residues in the *N*-linked oligosaccharide that is initially transferred to proteins in the ER (see Figure 12-48). Transport from the *Trans* Golgi Network to Lysosomes
Introduction

All of the proteins that pass through the Golgi apparatus, except those that are retained there as permanent residents, are sorted in the *trans* Golgi network according to their final destination. The mechanism of sorting is especially well understood for those proteins destined for the lumen of lysosomes, and in this section we consider this selective transport process. We begin with a brief account of lysosomal structure and function.

Lysosomes Are the Principal Sites of Intracellular Digestion 10

Lysosomes are membranous bags of hydrolytic enzymes used for the controlled intracellular digestion of macromolecules. They contain about 40 types of hydrolytic enzymes, including proteases, nucleases, glycosidases, lipases, phospholipases, phosphatases, and sulfatases. All are acid hydrolases. For optimal activity they require an acid environment, and the lysosome provides this by maintaining a pH of about 5 in its interior. In this way the contents of the cytosol are doubly protected against attack by the cell's own digestive system. The membrane of the lysosome normally keeps the digestive enzymes out of the cytosol, but even if they should leak out, they can do little damage at the cytosolic pH of about 7.2.

Like all other intracellular organelles, the lysosome not only contains a unique collection of enzymes, but also has a unique surrounding membrane. Transport proteins in this membrane allow the final products of the digestion of macromolecules, such as amino acids, sugars, and nucleotides, to be transported to the cytosol, from where they can be either excreted or reutilized by the cell. An H^+ pump in the lysosomal membrane utilizes the energy of ATP hydrolysis to pump H^+ into the lysosome, thereby maintaining the lumen at its acidic pH (Figure 13-17). Most of the lysosomal membrane proteins are unusually highly glycosylated, which is thought to help protect them from the lysosomal proteases in the lumen.

As we discuss later, endocytosed materials are initially delivered to organelles called *endosomes* before being delivered to lysosomes. Endosomes also have H^+ pumps that keep their lumen at a low pH, although not as low as that of lyso-somes (Figure 13-18). We shall see that these pH differences are often used to load and unload cargo molecules from their receptors during vesicular transport along the endocytic pathway.

Lysosomes Are Heterogeneous 11

Lysosomes were initially discovered by biochemical fractionations of cell extracts; only later were they seen clearly in the electron microscope. They are extraordinarily diverse in shape and size but can be identified as members of a single family of organelles by histochemistry, using the precipitate produced by the action of an acid hydrolase on its substrate to show which organelles contain the enzyme (Figure 13-19). By this criterion, lysosomes are found in all eucaryotic cells.

The heterogeneity of lysosomal morphology contrasts with the relatively uniform structures of most other cellular organelles.

The diversity reflects the wide variety of digestive functions mediated by acid hydrolases, including the breakdown of intra- and extracellular debris, the destruction of phagocytosed microorganisms, and the production of nutrients for the cell. For this reason lysosomes are sometimes viewed as a heterogeneous collection of distinct organelles whose common feature is a high content of hydrolytic enzymes. It is especially hard to apply a narrower definition than this in plant cells, as we see next.

Plant and Fungal Vacuoles Are Remarkably Versatile Lysosomes 12

Most plant and fungal cells (including yeasts) contain one or several very large, fluid-filled vesicles called vacuoles. They typically occupy more than 30% of the cell volume and as much as 90% in some cell types (Figure 13-20). Vacuoles are related to lysosomes of animal cells, containing a variety of hydrolytic enzymes, but their functions are remarkably diverse. The plant vacuole can act as a storage organelle for nutrients and for waste products, as a degradative compartment, as an economical way of increasing cell size (Figure 13-21), and as a controller of *turgor pressure* (the osmotic pressure that pushes outward on the cell wall and keeps the plant from wilting). Different vacuoles with distinct functions (for example, digestion and storage) are often present in the same cell.

The vacuole is important as a homeostatic device, enabling plant cells to withstand wide variations in their environment. When the pH in the environment drops, for example, the flux of H^+ into the cytosol is balanced, at least in part, by increased transport of H^+ into the vacuole so as to keep the pH in the cytosol constant. Similarly, many plant cells maintain an almost constant turgor pressure in the face of large changes in the tonicity of the fluid in their immediate environment. They do so by changing the osmotic pressure of the cytosol and vacuolein part by the controlled breakdown and resynthesis of polymers such as polyphosphate in the vacuole and in part by altering rates of transport of sugars, amino acids, and other metabolites across the plasma membrane and the vacuolar membrane. The turgor pressure controls these fluxes by regulating the activities of the distinct sets of transporters in each lipid bilayer.

Substances stored in plant vacuoles in different species range from rubber to opium to the flavoring of garlic. Often, the stored products have a metabolic function. Proteins, for example, can be preserved for years in the vacuoles of the storage cells of many seeds, such as those of peas and beans. When the seeds germinate, the proteins are hydrolyzed and the mobilized amino acids provide a food supply for the developing embryo. Anthocyanin pigments that are stored in vacuoles color the petals of many flowers to attract pollinating insects, while noxious molecules that are released from vacuoles when a plant is eaten or damaged provide a defense against predators.

Materials Are Delivered to Lysosomes by Multiple Pathways 13

Lysosomes in general are meeting places in which several streams of intracellular traffic converge. Digestive enzymes are delivered to them by a route that leads outward from the ER via the Golgi apparatus, while substances to be digested are fed in by at least three paths, according to their source.

Of the three paths to degradation in lysosomes, the best studied is that followed by macromolecules taken up from the external medium by endocytosis. In brief (for the details will be discussed later), the endocytosed molecules are initially delivered into small, irregularly shaped intracellular vesicles called *early endosomes*. From these, some of the ingested molecules are selectively retrieved and recycled to the plasma membrane, while others pass on into *late endosomes*. Here, by fusion of two streams of transport vesicles, the materials coming in for digestion first meet the lysosomal hydrolases coming out from the Golgi apparatus. The interior of the late endosomes is mildly acidic (pH~6), and it is thought to be the site where the hydrolytic digestion of the endocytosed molecules begins. Mature lysosomes form from the late endosomes, although it is not known precisely how this occurs. During the conversion process some distinct endosomal membrane proteins are lost, and there is a further decrease in internal pH.

A second pathway to degradation in lysosomes is used in all cell types for disposal of obsolete parts of the cell itself - a process called autophagy. In a liver cell, for example, an average mitochondrion has a lifetime of about 10 days, and electron microscopic images of normal cells reveal lysosomes containing (and presumably digesting) mitochondria as well as other organelles. The process seems to begin with the enclosure of an organelle by membranes derived from the ER, creating an *autophagosome,* which then fuses with a lysosome (or a late endosome). The process is highly regulated, and selected cell components can somehow be marked for destruction during cell remodeling: the smooth ER that proliferates in a liver cell in response to the drug phenobarbital (discussed in Chapter 12), for example, is selectively removed by autophagy when the drug is withdrawn.

As we discuss later, the third pathway that provides materials to lysosomes for degradation occurs mainly in cells specialized for the *phagocytosis* of large particles and microorganisms. Such professional phagocytes (macrophages and neutrophils in vertebrates) engulf objects to form a *phagosome,* which is then converted to a lysosome in the manner described for the autophagosome. The three pathways are summarized in Figure 13-22.

Some Cytosolic Proteins Are Directly Transported into Lysosomes for Degradation 14

There may be yet a fourth route for proteins to enter a lysosome for degradation: some proteins contain certain signals on their surface [called KFERQ sequences, KFERQ standing for lysine (K), phenylalanine (F), glutamate (E), arginine (R), and glutamine (Q)] that cause the proteins bearing them to be selectively delivered to lysosomes for degradation. It is possible that the KFERQ sequences attach these proteins to cytosolic organelles that are on the way to being autophago-cytosed, thereby dragging the proteins into the lysosome indirectly. Alternatively, there may be a specific transporter in the lysosomal membrane that recognizes these signals and transfers the proteins directly across the lysosomal membrane.

There are precedents for nonconventional mechanisms for moving proteins directly across membranes. A number of proteins that are secreted from cells, such as basic fibroblast growth factor or interleukin-1, for example, arrive at the cell surface without ever entering the classical secretory pathway through the ER and Golgi apparatus. In most cases it is not known which membrane the protein crosses or how its transmembrane transport is catalyzed. In the case of a small yeast peptide, the pheromone a-factor, the transport is known to be mediated directly across the plasma membrane by an ATP-driven peptide pump that belongs to the protein family of the ABC transporters (discussed in Chapter 11). Thus it is possible that similar pumps provide "private" transport systems, each specialized for the transfer of a small, specific subset of proteins across a particular membrane.

Lysosomal Enzymes Are Sorted from Other Proteins in the *Trans* Golgi Network by a Membrane-bound Receptor Protein That Recognizes Mannose 6-Phosphate 15

We now consider more closely the system that delivers the other half of the traffic into lysosomes - the specialized lysosomal hydrolases and membrane proteins. Both classes of proteins are synthesized in the rough ER and transported through the Golgi apparatus. Transport vesicles that deliver these proteins to late endosomes - which later form lysosomes - bud from the *trans* Golgi network, incorporating lysosomal proteins while excluding the many other proteins being packaged into different transport vesicles for delivery elsewhere.

How are lysosomal proteins recognized and selected with the required accuracy? For the lysosomal hydrolases the answer is known. They carry a unique marker in the form of mannose 6-phosphate (M6P) groups, which are added exclusively to the *N*-linked oligosaccharides of these soluble lysosomal enzymes, probably while they are in the lumen of the *cis* Golgi network. The M6P groups are recognized by M6P receptor proteins, which are transmembrane proteins present in the *trans* Golgi network. These receptor proteins bind the lysosomal hydrolases and help package them into specific transport vesicles that bud from the *trans* Golgi network and subsequently fuse with a late endosome, delivering their contents to the lumen of this organelle. As we discuss later, the M6P receptor proteins are selected for packaging into specific transport vesicles in the *trans* Golgi network by special coat proteins that assemble on the cytosolic surface of the membrane and help the vesicles bud from the membrane of the *trans* Golgi network.

The Mannose 6-Phosphate Receptor Shuttles Back and Forth Between Specific Membranes 16

The M6P receptor protein binds its specific oligosaccharide at pH 7 in the *trans* Golgi network and releases it at pH 6, which is the pH in the interior of late endosomes. Thus in the late endosomes the lysosomal hydrolases dissociate from the M6P receptor and can begin to digest the endocytosed material delivered from early endosomes. Having released their bound enzymes, the M6P receptors are retrieved into transport vesicles that bud from late endosomes and return to the membrane of the *trans* Golgi network for reuse (Figure 13-23). It is not clear whether transport back to the Golgi apparatus requires a specific signal peptide in the cytoplasmic tail of the M6P receptor or whether it will occur by default. This process of *membrane recycling* from late endosome back to the Golgi apparatus resembles the recycling that occurs between other subcompartments of the secretory and endocytic pathways that we discuss later.

The sorting of lysosomal hydrolases from other proteins is presently the best-understood example of the many sorting processes mediated by transport vesicles in a eucaryotic cell. Although an oligosaccharide marker is not likely to be used elsewhere, the

general strategy is probably typical of other vesicle-mediated sorting processes. Cargo molecules are recognized and picked up by membrane-bound *cargo receptors* during the budding of specific clathrin-coated vesicles. These loaded vesicles move off and fuse with a specific target membrane, the cargo molecules are released in the target compartment, and the empty receptors are recycled back to their original compartment.

Not all of the cargo that is tagged for delivery to lysosomes gets to its proper destination. It seems that some of the ly sosomal hydrolase molecules escape the normal packaging process in the *trans* Golgi network and instead are transported via the default pathway to the cell surface, where they are secreted into the extracellular fluid. Some M6P receptors, however, also take a detour to the plasma membrane, where they help undo the error in lysosomal hydrolase routing by recapturing the escaped enzymes and returning them by *receptor-mediated endocytosis* to lysosomes via early and late endosomes.

This *scavenger pathway* was originally discovered through studies of cells from humans who are genetically defective in a specific lysosomal hydrolase. An example is *Hurler's disease,* in which the enzyme required for breakdown of glycosaminoglycans is missing. In these mutant individuals the lysosomes accumulate massive quantities of the particular molecules that cannot be digested. For this reason these diseases are called *lysosomal storage diseases.* The same cellular abnormality is seen when cells from the mutant individuals are grown in culture. If the mutant cells are co-cultured with cells from a normal individual, however, the abnormality is no longer seen. The mutant cells are rescued because they can scavenge the lysosomal hydrolase that they lack from the culture medium, into which the normal cells have discharged it. We see below that studies of these diseases played a crucial part in the discovery of the lysosomal hydrolase-sorting mechanism.

A Signal Patch in the Polypeptide Chain Provides the Cue for Tagging a Lysosomal Enzyme with Mannose 6-Phosphate [17]

The sorting system that segregates lysosomal hydrolases and dispatches them to late endosomes works because M6P groups are added to only the appropriate glycoproteins in the Golgi apparatus. This requires specific recognition of the hydrolases by the Golgi enzyme responsible for adding M6P. Since all glycoproteins leave the ER with identical *N*-linked oligosaccharide chains, the signal for adding the M6P units to oligosaccharides must reside somewhere in the polypeptide chain of each hydrolase.

Two enzymes act sequentially to catalyze the addition of M6P groups to lysosomal hydrolases (Figure 13-24). The first is a phosphotransferase with a *recognition site* that specifically binds the hydrolase and a separate *catalytic site* for the phosphotransferase reaction; the signal recognized by the recognition site is a conformation-dependent *signal patch* in the hydrolase rather than a signal peptide (see Figure 12-8). Once the hydrolase is bound, the phosphotrans-ferase adds GlcNAc-phosphate to one or two of the mannose residues on each oligosaccharide chain (Figure 13-25). A second enzyme then cleaves off the GlcNAc residue, creating the mannose 6-phosphate marker (see Figure 13-24).

Since most lysosomal hydrolases have multiple oligosaccharides, they acquire many M6P residues, providing a strong and easily recognized signal for the M6P receptor. While a lysosomal hydrolase typically binds to the recognition site of the phosphotransferase with an affinity constant (K_a) of about 10^5 liters/mole, the multiply phosphorylated hydrolase binds to the M6P receptor with a K_a of about 10^9 liters/mole, a 10,000-fold increase in affinity.

Defects in the GlcNAc Phosphotransferase Cause a Lysosomal Storage Disease in Humans [18]

Lysosomal storage diseases are caused by genetic defects that affect one or more of the lysosomal hydrolases and result in accumulation of their undigested substrates in lysosomes, with severe pathological consequences. Most often, there is a mutation in a structural gene that codes for an individual lysosomal hydrolase; this is the case in Hurler's disease, mentioned above. The most dramatic form of lysosomal storage disease, however, is a very rare disorder called inclusion-cell disease (*I-cell disease*). In this disease almost all of the hydrolytic enzymes are missing from the lysosomes of fibroblasts, and their undigested substrates accumulate in lysosomes, which consequently form large "inclusions" in the patients' cells. I-cell disease is due to a single gene defect, and like most genetic enzyme deficiencies, it is recessive - that is, it is seen only in individuals in whom both copies of the gene are defective.

In these individuals all the hydrolases missing from lysosomes are found in the blood; because they fail to be sorted properly in the Golgi apparatus, the hydrolases are secreted rather than transported to lysosomes. The missorting has been traced to a defective or missing GlcNAc-phosphotransferase. Because lysosomal enzymes are not phosphorylated in the *cis* Golgi network, they are not segregated by M6P receptors into the appropriate transport vesicles in the *trans* Golgi network and instead are

carried to the cell surface and secreted by the default pathway. This was, in fact, the first evidence for such a default pathway; and it was through a biochemical comparison of normal lysosomal hydrolases with those from patients with I-cell disease that mannose 6-phosphate was discovered to be the lysosomal sorting signal and the whole lysosomal hydrolase-sorting pathway was elucidated.

In I-cell disease the lysosomes in some cell types, such as hepatocytes, contain a normal complement of lysosomal enzymes, implying that there is another pathway for directing hydrolases to lysosomes that is used by some cell types but not others. The nature of this M6P-independent pathway is unknown. Similarly, the lysosomal membrane proteins are sorted from the *trans* Golgi network to late endosomes by an M6P-independent pathway in all cells. It is unclear why cells should need more than one sorting pathway to construct a lysosome, although it is perhaps not surprising that different mechanisms should operate for soluble and membrane-bound proteins.

Summary

Lysosomes are specialized for intracellular digestion. They contain unique membrane proteins and a wide variety of hydrolytic enzymes that operate best at pH 5, the internal pH of lysosomes, which is maintained by an ATP-driven H^+ pump in the lysosomal membrane. Newly synthesized lysosomal proteins are transferred into the lumen of the ER, transported through the Golgi apparatus, and then carried from the trans Golgi network to late endosomes by means of transport vesicles.

The lysosomal hydrolases contain N- linked oligosaccharides that are covalently modified in a unique way in the cis Golgi network so that their mannose residues are phosphorylated. These mannose 6-phosphate (M6P) groups are recognized by an M6P receptor protein in the trans Golgi network that segregates the hydrolases and helps to package them into budding transport vesicles, which deliver their contents to late endosomes, and thereby to lysosomes. These transport vesicles act as shuttles that move the M6P receptor back and forth between the trans Golgi network and late endosomes. The low pH in the late endosome dissociates the lysosomal hydrolases from this receptor, making the transport of the hydrolases unidirectional.
Figure 13-17. Lysosomes. The acid hydrolases are hydrolytic enzymes that are active under acidic conditions. The lumen is maintained at an acidic pH by an H^+ ATPase in the membrane that pumps H^+ into the lysosome.
Figure 13-18. The low pH in lysosomes and endosomes. Proteins labeled with a pH-sensitive fluorescent probe (fluorescein) and then endocytosed by cells can be used to measure the pH in endosomes and lysosomes. The different colors reflect the pH that the fluorescent probe encounters in these organelles. The pH in lysosomes (*red*) is about 5, while the pH in various types of endosomes (*blue*and *green*) ranges from 5.5 to 6.5. This method was originally developed in the 1890s by Metchnikoff, who fed litmus particles to phagocytic cells and observed that the color of the particles changed from blue to red after ingestion. 200 nm
Figure 13-19. Histochemical visualization of lysosomes. Electron micro-graphs of two sections of a cell stained to reveal the location of acid phos-phatase, a marker enzyme for lysosomes. The larger membrane-bounded organelles, containing dense precipitates of lead phosphate, are lysosomes, whose diverse morphology reflects variations in the amount and nature of the material they are digesting. The precipitates are produced when tissue fixed with glutaraldehyde (to fix the enzyme in place) is incubated with a phosphatase substrate in the presence of lead ions. Two small vesicles thought to be carrying acid hydrolases

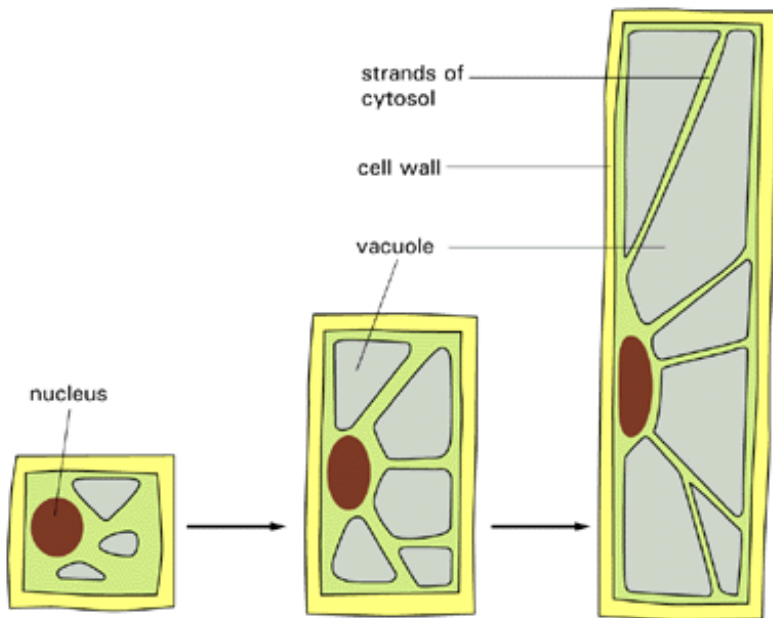
from the Golgi apparatus are indicated by *red arrows* in the top panel. (Courtesy of Daniel S. Friend.)
Figure 13-20. The plant cell vacuole. This electron micrograph of cells in a young tobacco leaf shows that the cytosol is confined by the enormous vacuole to a thin layer, containing chloroplasts, pressed against the cell wall. The membrane of the vacuole is called the tonoplast. (Courtesy of J. Burgess.)


Figure 13-21. The role of the vacuole in controlling the size of plant cells. A large increase in cell volume can be achieved without increasing the volume of the cytosol. Localized weakening of the cell wall orients a turgor-driven cell enlargement that accompanies the uptake of water into an expanding vacuole (see Figure 19-67). The cytosol is eventually confined to a thin peripheral layer that is connected to the nuclear region by strands of cytosol, which are stabilized by bundles of actin filaments (not shown).
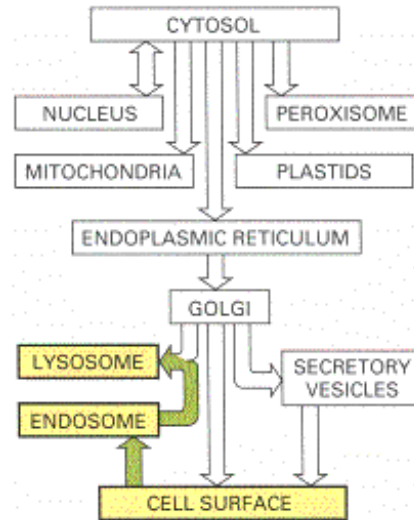
Figure 13-22. Three pathways to degradation in lysosomes. Each pathway leads to the intracellular digestion of materials derived from a different source. The compartments resulting from the three pathways can sometimes be distinguished morphologically - hence the terms "autophagolysosome," "phago-lysosome," and so on. Such lysosomes, however, may differ only because of the different materials they are digesting.
Figure 13-23. The transport of newly synthesized lysosomal hydrolases to lysosomes. The precursors of lysosomal hydrolases are covalently modified by the addition of mannose 6-phosphate groups (M6P) in the *cis* Golgi network. They then become segregated from all other types of proteins in the *trans* Golgi network because a specific class of transport vesicles (called clathrin-coated vesicles) budding from the *trans* Golgi network concentrates mannose 6-phosphate-specific receptors, which bind the modified lysosomal hydrolases. These vesicles subsequently fuse with late endosomes. At the low pH of the late endosome the hydrolases dissociate from the receptors, which are recycled to the Golgi apparatus for further rounds of transport. In late endosomes the phosphate is removed from the mannose on the hydrolases, further ensuring that the hydrolases do not return to the Golgi apparatus with the receptor.
Figure 13-24. Synthesis of the mannose 6-phosphate marker on a lysosomal hydrolase. The synthesis occurs in two steps. First, GlcNAc phosphotransferase transfers GlcNAc-P to the 6 position of several mannoses on the *N*-linked oligosaccharides of the lysosomal hydrolase. Second, a phospho-glycosidase cleaves off the GlcNAc, creating the mannose 6-phosphate marker. The first enzyme is specifically activated by a signal patch present on lysosomal hydrolases (see Figure 13-25), while the phospho-glycosidase is a nonspecific enzyme. This modification of selected mannose residues in the *cis* Golgi network protects these mannoses from removal by the mannosidases that will later be encountered in the *medial* Golgi compartment.
Figure 13-25. The recognition of a lysosomal hydrolase. The GlcNAc phosphotransferase enzyme that recognizes lysosomal hydrolases in the Golgi apparatus has separate catalytic and recognition sites. The catalytic site binds both high-mannose *N*-linked oligosaccharides and UDP-GlcNAc. The recognition site binds to a signal patch that is present only on the surface of lysosomal hydrolases.

Transport from the Plasma Membrane via Endosomes: Endocytosis [19]


Introduction

The routes that lead inward to lysosomes from the cell surface start with the process of endocytosis, by which cells take up macromolecules, particulate substances, and, in specialized cases, even other cells.

Material to be ingested is progressively enclosed by a small portion of the plasma membrane, which first invaginates and then pinches off to form an intracellular vesicle containing the ingested substance or particle. Two main types of endocytosis are distinguished on the basis of the size of the endocytic vesicles formed: *pinocytosis* ("cellular drinking"), which involves the ingestion of fluid and solutes via small vesicles ($\leq$ 150 nm in diameter), and *phagocytosis* ("cellular eating"), which involves the ingestion of large particles, such as microorganisms or cell debris, via large vesicles called *phagosomes,* generally > 250 nm in diameter. Although most eucaryotic cells are continually ingesting fluid and solutes by pinocytosis, large particles are ingested mainly by specialized phagocytic cells.

Specialized Phagocytic Cells Can Ingest Large Particles [20]

Phagocytosis is a special form of endocytosis in which large particles such as microorganisms and cell debris are ingested via large endocytic vesicles called *phagosomes.* In protozoa phagocytosis is a form of feeding: large particles taken up into phagosomes end up in lysosomes, and the products of the subsequent digestive processes pass into the cytosol to be utilized as food. Few cells in multicellular organisms are able to ingest large particles efficiently, however, and in the gut of animals, for example, large particles of food are broken down extracellularly before import into cells. Phagocytosis is important in most animals for purposes other than nutrition, and it is mainly carried out by specialized cells that are "professional" phagocytes. In mammals there are two classes of white blood cells that act as professional phagocytes - macrophages (which are widely distributed in tissues as well as in blood) and neutrophils. These two types of cells develop from a common precursor cell (discussed in Chapter 22), and they defend us against infection by ingesting invading microorganisms. Macrophages also play an important part in scavenging senescent and damaged cells and cellular debris. In quantitative terms the latter function is far more important: macrophages phagocytose more than 10 [11]senescent red blood cells in each of us every day, for example.

Whereas the endocytic vesicles involved in pinocytosis are small and uniform, phagosomes have diameters that are determined by the size of the ingested particle, and they can be almost as large as the phagocytic cell itself (Figure 13-26). The phagosomes fuse with lysosomes, and the ingested material is degraded; indigestible substances will remain in lysosomes, forming *residual bodies.* Some of the internalized plasma membrane components are retrieved from the phagosome by transport vesicles and returned to the plasma membrane.

In order to be phagocytosed, particles must first bind to the surface of the phagocyte. Not all particles that bind are ingested, however. Phagocytes have a variety of specialized surface receptors that are functionally linked to the phagocytic machinery of the cell. Unlike pinocytosis, which is a constitutive process that occurs continuously, phagocytosis is a triggered process that requires that activated receptors transmit signals to the cell interior to initiate the response. The best-characterized triggers are

antibodies, which protect us by binding to the surface of infectious microorganisms to form a coat in which the tail region of each antibody molecule (called the Fc region) is exposed on the exterior. This antibody coat is then recognized by specific *Fc receptors* on the surface of macrophages and neutrophils (see Figure 23-20). The binding of antibody-coated particles to these receptors induces the phagocytic cell to extend pseudopods that engulf the particle and fuse at their tips to form a phagosome (Figure 13-27).

Several other classes of receptors that promote phagocytosis have been characterized - those that recognize *complement* (a class of molecules that circulate in the blood and collaborate with antibodies in targeting undesirable cells for destruction, discussed in Chapter 23), for example, and those that directly recognize oligosaccharides on the surface of certain microorganisms. Which macrophage receptors recognize senescent or damaged cells is uncertain, although cell adhesion proteins of the integrin family are thought to be involved in some cases (discussed in Chapter 22).

Pinocytic Vesicles Form from Coated Pits in the Plasma Membrane 21

Virtually all eucaryotic cells continually ingest bits of their plasma membrane in the form of small pinocytic (endocytic) vesicles that are later returned to the cell surface. The rate at which plasma membrane is internalized in this process of pinocytosis varies from cell type to cell type, but it is usually surprisingly large. A macrophage, for example, ingests 25% of its own volume of fluid each hour. This means that it must ingest 3% of its plasma membrane each minute, or 100% in about half an hour. Fibroblasts endocytose at a somewhat lower rate, whereas some amoebae ingest their plasma membrane even more rapidly. Since a cell's surface area and volume remain unchanged during this process, it is clear that as much membrane as is being removed by endocytosis is being added to the cell surface by *exocytosis*the converse process, discussed later. In this sense endocytosis and exocytosis are linked processes that can be considered to constitute an endocytic-exocytic cycle.

The endocytic part of the cycle usually begins at specialized regions of the plasma membrane called clathrin-coated pits, which typically occupy about 2% of the total plasma membrane area. In electron micrographs of plasma membranes studied by the rapid-freeze, deep-etch technique, these pits appear as invaginations of the plasma membrane coated on their inner (cytosolic) surface with a densely packed material. These coats are made of the protein *clathrin,* which, with other proteins, forms a characteristic basket or cage, which we discuss later. The lifetime of clathrin-coated pits is short: within a minute or so of being formed, they invaginate into the cell and pinch off to form clathrin-coated vesicles (Figure 13-28). It has been estimated that about 2500 clathrin-coated vesicles leave the plasma membrane of a cultured fibroblast every minute. These coated vesicles are even more transient than the coated pits: within seconds of being formed, they shed their coat and are able to fuse with early endosomes. Since extracellular fluid is trapped in clathrin-coated pits as they invaginate to form coated vesicles, substances dissolved in the extracellular fluid are internalized - a process called fluid-phase endocytosis.

Clathrin-coated Pits Can Serve as a Concentrating Device for Internalizing Specific Extracellular Macromolecules 22

In most animal cells, clathrin-coated pits and vesicles provide an efficient pathway for taking up specific macromolecules from the extracellular fluid, a process called receptor-mediated endocytosis. The macromolecules bind to complementary cell-surface receptors (which are transmembrane proteins), accumulate in coated pits, and enter the cell as receptor-macromolecule complexes in clathrin-coated vesicles. The process is very similar to the packaging of lysosomal hydrolases in the Golgi apparatus. There too, as we have seen, the molecules to be transported bind to specific receptors in the membrane (the M6P receptors) and so become captured in membrane vesicles that detach from their original compartment and are released into the cytosol. Moreover, the budding of vesicles loaded with lysosomal enzymes from the Golgi apparatus also involves the formation of a clathrin coat (see Figure 13-23). As we discuss later, for both the plasma membrane and the Golgi membrane, the assembly of the coat on the cytosolic surface is thought to drive the membrane to invaginate there.

Receptor-mediated endocytosis provides a selective concentrating mechanism that increases the efficiency of internalization of particular ligands more than 1000-fold, so that even minor components of the extracellular fluid can be specifically taken up in large amounts without taking in a correspondingly large volume of extracellular fluid. A particularly well-understood and physiologically important example is the process whereby mammalian cells take up cholesterol.

Cells Import Cholesterol by Receptor-mediated Endocytosis 23

Many animal cells take up cholesterol through receptor-mediated endocytosis and in this way acquire most of the cholesterol they require to make new membrane. If the uptake is blocked, cholesterol accumulates in the blood and can contribute to the formation in blood vessel walls of atherosclerotic plaques - the deposits of lipid and fibrous tissue that cause strokes and heart

attacks by blocking blood flow. In fact, it was through a study of humans with a strong genetic predisposition for atherosclerosis that the mechanism of receptor-mediated endocytosis was first clearly revealed.

Most cholesterol is transported in the blood bound to protein in the form of particles known as low-density lipoproteins, or LDL (Figure 13-29). When a cell needs cholesterol for membrane synthesis, it makes transmembrane receptor proteins for LDL and inserts them into its plasma membrane. Once in the plasma membrane, the LDL receptors diffuse until they associate with clathrin-coated pits that are in the process of forming (Figure 13-30A). Since coated pits constantly pinch off to form coated vesicles, any LDL particles bound to LDL receptors in the coated pits are rapidly internalized in coated vesicles. After shedding their clathrin coats, these vesicles deliver their contents to early endosomes, which are located near the cell periphery. Once in the endosomal compartment, the LDL moves inward and is delivered via late endosomes to lysosomes, where the cholesteryl esters in the LDL particles are hydrolyzed to free cholesterol, which thereby becomes available to the cell for new membrane synthesis. If too much free cholesterol accumulates in a cell, it shuts off both the cell's own cholesterol synthesis and the synthesis of LDL receptor proteins, so that the cell ceases either to make or to take up cholesterol.

This regulated pathway for the uptake of cholesterol is disrupted in individuals who inherit defective genes encoding LDL receptor proteins and whose cells, consequently, are deficient in the capacity to take up LDL from the blood. The resulting high levels of blood cholesterol predispose these individuals to develop atherosclerosis prematurely, and most die at an early age of heart attacks resulting from coronary artery disease. In some cases the receptor is lacking altogether; in others the receptors are defective - either in the extracellular binding site for LDL or in the intracellular binding site that attaches the receptor to the coat of a clathrin-coated pit (see Figure 13-30B). In the latter case normal numbers of LDL-binding receptor proteins are present, but they fail to become localized in the clathrin-coated regions of the plasma membrane; although LDL binds to the surface of these mutant cells, it is not internalized, directly demonstrating the importance of clathrin-coated pits in the receptor-mediated endocytosis of cholesterol.

More than 25 different receptors are known to participate in receptor-mediated endocytosis of different types of molecules, and they all apparently utilize the same clathrin-coated-pit pathway. Many of these receptors, like the LDL receptor, enter coated pits irrespective of whether they have bound their specific ligands; others enter only with a specific ligand bound, suggesting that a ligand-induced conformational change is required for them to bind to the pits. Since most plasma membrane proteins fail to accumulate in clathrin-coated pits, the pits must function as molecular filters, collecting certain plasma membrane proteins (receptors) and excluding others. Electron microscopic studies of cultured cells exposed to different ligands (labeled to make them visible in the electron microscope) have demonstrated that many kinds of receptors cluster in the same coated pit. The plasma membrane of one clathrin-coated pit can probably accommodate about 1000 receptors of assorted varieties. Although all of the receptor-ligand complexes that utilize this endocytic pathway apparently are delivered to the same endosomal compartment, the subsequent fates of the endocytosed molecules vary, as we now discuss.

Endocytosed Materials Often End Up in Lysosomes [24]

The endosomal compartment can be made visible in the electron microscope by adding a readily detectable tracer molecule, such as the enzyme peroxidase, to the extracellular medium and leaving the cells for varying lengths of time to take it up by endocytosis. The distribution of the molecule after its uptake reveals the endosomal compartment as a complex set of heterogeneous membrane-bounded tubes and vesicles extending from the periphery of the cell to the perinuclear region, where it is often close to the Golgi apparatus, although they are clearly distinct. Two sets of endosomes can be readily distinguished in such labeling experiments: the tracer molecule appears in early endosomes, just beneath the plasma membrane, within a minute or so and in late endosomes, close to the Golgi apparatus and near the nucleus, after 5 to 15 minutes (Figure 13-31).

As mentioned earlier, the interior of the endosomal compartment is kept acidic (pH ~6) by ATP-driven H^+ pumps in the endosomal membrane that pump H^+ into the lumen from the cytosol; in general, late endosomes are more acidic than early endosomes. This acidic environment plays a crucial part in the function of these organelles. A similar or identical *vacuolar H^+ ATPase* is thought to acidify all endocytic and exocytic organelles, including phagosomes, lysosomes, selected compartments of the Golgi apparatus, and many transport and secretory vesicles.

We have already seen how endocytosed materials that reach the late endosomes become mixed with newly synthesized acid hydrolases and end up in lysosomes. Many molecules, however, are specifically diverted from this journey to destruction and are recycled instead from the early endosomes back to the plasma membrane via transport vesicles. Only those molecules that are not retrieved from endosomes are degraded.

Specific Proteins Are Removed from Early Endosomes and Returned to the Plasma Membrane <u>25</u>

The early endosomal compartment acts as the main sorting station in the endocytic pathway, just as the *trans* Golgi network serves this function in the biosynthetic-secretory pathway. In the acidic environment of the early endosome, many internalized receptor proteins change their conformation and release their ligand, just as the M6P receptors unload their cargo of acid hydrolases in the even more acidic late endosomes. Those endocytosed ligands that dissociate from their receptors in the early endosome are usually doomed to destruction in lysosomes, along with the other non-membrane-bound contents of the endosome. Some other endocytosed ligands, however, remain bound to, and thereby share the fate of, their receptors.

The fates of the receptor proteins - and of any ligands remaining bound to themvary according to the specific type of receptor. (1) Most receptors return to the same plasma membrane domain from which they came; (2) some receptors progress to lysosomes, where they are degraded; and (3) some receptors proceed to a different domain of the plasma membrane, thereby mediating a process called *transcytosis* (<u>Figure 13-32</u>).

The LDL receptor follows the first pathway. It dissociates from its ligand LDL in the endosome and is recycled to the plasma membrane for reuse, while the discharged LDL is carried to lysosomes (<u>Figure 13-33</u>). A similar but more complex recycling occurs following the endocytosis of transferrin, a protein that carries iron in the blood. Cell-surface transferrin receptors deliver transferrin with its bound iron to early endosomes by receptor-mediated endocytosis. The low pH in the endosome induces transferrin to release its bound iron, but the iron-free transferrin itself (called apotransferrin) remains bound to its receptor and is recycled back to the plasma membrane as a receptor-apotransferrin complex. When it has returned to the neutral pH of the extracellular fluid, the apotransferrin dissociates from the receptor and is thereby freed to pick up more iron and begin the cycle again. Thus the transferrin protein shuttles back and forth between the extracellular fluid and the endosomal compartment, avoiding lysosomes and delivering the iron that cells need to grow.

The second pathway that endocytosed receptors can follow from endosomes is taken by the receptor that binds *epidermal growth factor (EGF),* a small protein that stimulates epidermal and various other cells to divide. Unlike LDL receptors, these receptors accumulate in coated pits only after binding EGF. Moreover, most of them do not recycle but end up in lysosomes, where they are degraded along with the ingested EGF. EGF binding therefore leads to a decrease in the concentration of EGF receptors on the cell surface - a process called *receptor down-regulation.* As a result, the concentration of signaling ligand in the extracellular fluid regulates the number of its complementary receptor molecules on the target-cell surface (discussed in <u>Chapter 15</u>).

The Relationship Between Early and Late Endosomes Is Uncertain <u>26</u>

It is unclear how endocytosed molecules move from one endosomal compartment to another so as to end up in lysosomes. One view is that early endosomes slowly move inward to become late endosomes, which, as a result of fusion with hydrolase-bearing transport vesicles from the *trans* Golgi network, continuous membrane retrieval, and increasing acidification, are converted to lysosomes. Another view is that early and late endosomes are separate stationary compartments and that transport between them occurs via an intermediate transport compartment - either by a dynamic network of tubes or by the pinching off of pieces of the early endosome that are transported to the cell interior, where they eventually fuse with late endosomes (<u>Figure 13-34</u>). Early and late endosomes do, in fact, differ in their protein composition: in particular, they are associated with different rab proteins, which play an important part in directing vesicular transport, as we discuss later (see <u>Table 13-1</u>, pp. 644).

Macromolecules Can Be Transferred Across Epithelial Cell Sheets by Transcytosis <u>27</u>

Some receptors on the surface of polarized epithelial cells transfer specific macromolecules from one extracellular space to another by a process called transcytosis. These receptors follow the third pathway from endosomes (see <u>Figure 13-32</u>). A newborn rat, for example, obtains antibodies from its mother's milk (which help protect it against infection) by transporting them across the epithelium of its gut. The lumen of the gut is acidic, and at this low pH the antibodies in the milk bind to specific receptors on the apical (absorptive) surface of the gut epithelial cells and are internalized via clathrin-coated pits and vesicles and are delivered to early endosomes. The receptor-antibody complexes remain intact and are retrieved in transport vesicles that bud from the early endosome and subsequently fuse with the basolateral domain of the plasma membrane. On exposure to the neutral pH of the extracellular fluid that bathes the basolateral surface of the cells, the antibodies dissociate from their receptors and eventually enter the newborn's bloodstream. The secretion of these anti-bodies into the mother rat's milk also occurs by transcytosis, but in the reverse direction, from blood to milk. Other mammals, including humans, also transport antibodies into milk in this way, but the antibodies remain in the infant's gut and do not, as in the rat, enter the bloodstream.

The variety of pathways that different receptors follow from endosomes implies that, in addition to binding sites for their ligands and binding sites for coated pits, many receptors also possess sorting signals that guide them into the appropriate type of transport vesicle leaving the endosome and thereby to the appropriate target membrane in the cell.

Epithelial Cells Have Two Distinct Early Endosomal Compartments But a Common Late Endosomal Compartment 28

In polarized epithelial cells, endocytosis occurs from both the basolateral and the apical domains of the plasma membrane. Material endocytosed from either domain first enters an early endosomal compartment that is unique to that domain. This arrangement allows endocytosed receptors to be recycled back to their original membrane domain, unless they contain signals that mark them for transcytosis to the other domain. Molecules endocytosed from either domain that are not retrieved from the early endosomes are transported to a common late endosomal compartment near the cell center and are eventually degraded in lysosomes (Figure 13-35).

Summary

Cells ingest macromolecules by endocytosis, in which localized regions of the plasma membrane invaginate and pinch off to form endocytic vesicles; many of the endocytosed particles and molecules end up in lysosomes, where they are degraded. Endocytosis occurs both constitutively and as a triggered response to extracellular signals.

Endocytosis is so extensive in many cells that a large fraction of the plasma membrane is internalized every hour. The plasma membrane components (proteins and lipids) are continually returned to the cell surface in a large-scale endocytic-exocytic cycle that is largely mediated by clathrin-coated pits and vesicles. Many cell-surface receptors that bind specific extracellular macromolecules become localized in clathrin-coated pits and consequently are internalized in clathrin-coated vesicles - a process called receptor-mediated endocytosis. The coated endocytic vesicles rapidly shed their clathrin coats and fuse with early endosomes. Most ligands dissociate from their receptors in the acidic environment of the endosome and eventually end up in lysosomes, while most receptors are recycled via transport vesicles back to the cell surface for reuse. But receptor-ligand complexes can follow other pathways from the endosomal compartment. In some cases both the receptor and the ligand end up being degraded in lysosomes, causing "receptor down-regulation." In other cases both are transferred to a different plasma membrane domain, and the ligand is consequently released by exocytosis at a surface of the cell different from that where it originated - a process called transcytosis.

Figure 13-28. The formation of clathrin-coated vesicles from the plasma membrane. Electron micrographs illustrating the probable sequence of events in the formation of a clathrin-coated vesicle from a clathrin-coated pit. The clathrin-coated pits and vesicles are larger than those seen in normal-sized cells. They are involved in taking up lipoprotein particles into a very large hen oocyte to form yolk. The lipoprotein particles bound to their membrane-bound receptors can be seen as a dense, fuzzy layer on the extracellular surface of the plasma membrane. (Courtesy of M.M. Perry and A.B. Gilbert, *J. Cell Sci.* 39:257-272, 1979, by permission of the Company of Biologists.)
Figure 13-29. A low-density lipoprotein (LDL) particle. Each spherical particle has a mass of 3 x 10^6 daltons. It contains a core of about 1500 cholesterol molecules esterified to long-chain fatty acids that is surrounded by a lipid monolayer composed of about 800 phospholipid and 500 unesterified cholesterol molecules. A single molecule of a 500,000-dalton protein organizes the particle and mediates the specific binding of LDL to cell-surface receptor proteins.
Figure 13-30. Normal and mutant LDL receptors. (A) LDL receptor proteins binding to a coated pit in the plasma membrane of a normal cell. The human LDL receptor is a single-pass transmembrane glycoprotein composed of about 840 amino acid residues, only 50 of which are on the cytoplasmic side of the membrane. (B) A mutant cell in which the LDL receptor proteins are abnormal and lack the site in the cytoplasmic domain that enables them to bind to coated pits. Such cells bind LDL but cannot ingest it. In most human populations 1 in 500 individuals inherits one defective LDL receptor gene and, as a result, is likely to die prematurely from a heart attack caused by atherosclerosis.
Figure 13-31. The relationship of late endosomes to other membrane-bounded compartments. (A) Baby hamster kidney (BHK) cells in culture were incubated in a solution containing the enzyme peroxidase for 15 minutes, which was long enough for the peroxidase to be taken up by fluid-phase endocytosis and delivered to late endosomes but not long enough for it to be delivered to lysosomes. After the cells were fixed and exposed to a peroxidase substrate, the product of the enzymatic reaction was made electron dense by fixation with osmium tetroxide. (B) Serial reconstructions of late endosomes (*red*), ER (*yellow*), and Golgi apparatus (*blue*) prepared from electron micrographs, one of which is shown in (A). The reconstruction was drawn from 18 serial thin sections. The nucleus is indicated by N in (A) and is shown in *green* in (B). (A, from M. Marsh, G. Griffiths, G. Dean, I. Mellman, and A. Helenius, *Proc. Natl. Acad. Sci. USA* 83:2899-2903, 1986; B, courtesy of Mark Marsh.)
Figure 13-32. Possible fates for transmembrane receptor proteins that have been endocytosed. Three pathways from the

endosomal compartment in an epithelial cell are shown. Receptors that are not specifically retrieved from endosomes follow the pathway from the endosomal compartment to lysosomes, where they are degraded. Retrieved receptors are returned either to the same plasma membrane domain from which they came (*recycling*) or to a different domain of the plasma membrane (*transcytosis*). If the ligand that is endocytosed with its receptor stays bound to the receptor in the acidic environment of the endosome, it will follow the same pathway as the receptor; otherwise it will be delivered to lysosomes.
Figure 13-33. Receptor-mediated endocytosis of LDL. Note that the LDL dissociates from its receptors in the acidic environment of the endosome. After a number of steps (see <u>Figure 13-34</u>) the LDL ends up in lysosomes, where it is degraded to release free cholesterol. In contrast, the LDL receptor proteins are returned to the plasma membrane via transport vesicles that bud off from the tubular region of the endosome, as shown. For simplicity, only one LDL receptor is shown entering the cell and returning to the plasma membrane. Whether it is occupied or not, an LDL receptor typically makes one round trip into the cell and back to the plasma membrane every 10 minutes, making a total of several hundred trips in its 20-hour life-span.

Figure 13-34. The endocytic pathway from the plasma membrane to lysosomes. Transport from early to the late endosome is mediated by large *endosomal carrier vesicles,* which contain large amounts of invaginated membrane and are therefore called *multivesicular bodies.* It is uncertain whether they should be regarded as middle-aged endosomes moving toward the cell interior as they mature or as distinct transport compartments. The movement occurs along microtubules and can be experimentally blocked with microtubule-depolymerizing drugs. Eventually, the late endosome is thought to convert into a lysosome. Transport vesicles recycle material between the early endosome and the cell surface, while a different set of transport vesicles recycle material between the late endosome and the *trans* Golgi network.
Figure 13-35. Two distinct early endosomal compartments in an epithelial cell. The basolateral and the apical domain of the plasma membrane communicate with distinct early endosomal com-partments, although endocytosed molecules from both domains that do not contain signals for recycling or transcytosis meet in a common late endosomal compartment before being digested in lysosomes.

Transport from the *Trans* Golgi Network to the Cell Surface: Exocytosis [29]
Introduction

Having considered the cell's internal digestive system and the various types of incoming membrane traffic that converge on lysosomes, we now return to the Golgi apparatus and examine the secretory pathways that lead out to the cell exterior. Transport vesicles destined for the plasma membrane normally leave the *trans* Golgi network in a steady stream. The membrane proteins and the lipids in these vesicles provide new components for the cell's plasma membrane, while the soluble proteins inside the vesicles are secreted to the extracellular space. The fusion of the vesicles with the plasma membrane is called exocytosis. In this way, for example, cells produce and secrete most of the proteoglycans and glycoproteins of the *extracellular matrix,* which is discussed in Chapter 19.

All cells require this constitutive secretory pathway. Specialized secretory cells, however, have a second secretory pathway in which soluble proteins and other substances are initially stored in *secretory vesicles* for later release. This is the regulated secretory pathway, which is found mainly in cells that are specialized for secreting products such as hormones, neurotransmitters, or digestive enzymes rapidly on demand (Figure 13-36). In this section we consider the role of the Golgi apparatus in the two secretory pathways and compare the two mechanisms of secretion.

Many Proteins and Lipids Seem to Be Carried Automatically from the ER and Golgi Apparatus to the Cell Surface [30]

In a cell capable of regulated secretion, at least three classes of proteins must be separated before they leave the *trans* Golgi network - those destined for lysosomes (via late endosomes), those destined for secretory vesicles, and those destined for immediate delivery to the cell surface. We have already noted that proteins destined for lysosomes are tagged for packaging into specific departing vesicles (by M6P in the case of lysosomal hydrolases), and analogous signals are thought to direct proteins packaged into secretory vesicles. Most other proteins are transported directly to the cell surface by a nonselective default pathway (proteins that must be directed selectively to one cell-surface domain or another are exceptions) (Figure 13-37). Thus, in an unpolarized cell such as a white blood cell or a fibroblast, it seems that any protein in the lumen of the ER will automatically be carried through the Golgi apparatus to the cell surface by the constitutive secretory pathway unless it is either specifically retained as a resident of the ER or Golgi apparatus or selected for the pathways that lead to regulated secretion or to lysosomes. In polarized cells, where different products have to be delivered to different domains of the cell surface, we shall see that the options are slightly more complex.

Secretory Vesicles Bud from the *Trans* Golgi Network [31]

Cells that are specialized for secreting some of their products rapidly on demand concentrate and store these products in

secretory vesicles (frequently called *secretory granules* or *dense core vesicles* because they have dense cores when viewed in the electron microscope). Secretory vesicles form by clathrin-coated budding from the *trans* Golgi network, and they release their contents to the cell exterior by exocytosis in response to extracellular signals. The secreted product can be either a small molecule (such as histamine) or a protein (such as a hormone or digestive enzyme).

Proteins destined for secretory vesicles (often called *secretory proteins*) are packaged into appropriate vesicles in the *trans* Golgi network by a mechanism that is believed to involve the selective aggregation of the secretory proteins, which can be detected in the electron microscope as clumps of electron-dense material in the lumen of the *trans* Golgi network. The "sorting signal" that directs secretory proteins into such aggregates is not known, but it is thought to be a signal patch that is common to proteins of this class. When a gene encoding a secretory protein is transferred to a secretory cell that normally does not make the protein, the foreign protein is appropriately packaged into secretory vesicles.

It is unclear how the aggregates of secretory proteins are segregated into secretory vesicles. Secretory vesicles have unique proteins in their membrane, some of which might serve as receptors for aggregated material in the *trans* Golgi network. The aggregates are much too big, however, for each molecule of the secreted protein to be bound by its own cargo receptor, as proposed for transport of the lysosomal enzymes. The uptake of the aggregates into secretory vesicles may therefore more closely resemble the uptake of particles by phagocytosis at the cell surface, which can similarly be mediated by clathrin-coated membranes.

After the immature secretory vesicles bud from the *trans* Golgi network, their clathrin coat is removed and their contents become greatly condensed - as much as 200-fold relative to their concentration in the Golgi lumen (Figure 13-38). The condensation occurs suddenly, probably as the result of acidification of the vesicle lumen induced by ATP-driven H^+ pumps in the vesicle membrane. Because the mature vesicles are so densely filled, the secretory cell can disgorge large amounts of material promptly by exocytosis when triggered to do so (Figure 13-39).

Proteins Are Often Proteolytically Processed During the Formation of Secretory Vesicles [32]

Condensation is not the only process to which secretory proteins are subject as the secretory vesicles mature. Many polypeptide hormones and neuropeptides, as well as many secreted hydrolytic enzymes, are synthesized as inactive protein precursors from which the active molecules have to be liberated by proteolysis. These cleavages are thought to begin in the *trans* Golgi network, and they continue in the secretory vesicles and sometimes in the extracellular fluid after secretion has occurred. Many secreted polypeptides have, for example, an amino-terminal *pro-piece* that is cleaved off shortly before secretion to yield the mature protein. These proteins are thus synthesized as *pre-pro-proteins,* the *pre-piece* consisting of the ER signal peptide that is cleaved off earlier in the rough ER. In other cases peptide signaling molecules are made as *polyproteins* that contain multiple copies of the same amino acid sequence. In still more complex cases a variety of peptide signaling molecules are synthesized as parts of a single polyprotein that acts as a precursor for multiple end products, which are individually cleaved from the initial polypeptide chain; the same polyprotein may be processed in various ways to produce different peptides in different cell types (Figure 13-40).

Why is proteolytic processing so common in the secretory pathway? Some of the peptides produced in this way, such as the *enkephalins* (five amino acid neuropeptides with morphinelike activity), are undoubtedly too short in their mature forms to be co-translationally transported into the ER lumen or to include the necessary signals for packaging into secretory vesicles. For secreted hydrolytic enzymes, or any protein whose activity could be harmful inside the cell that makes it, delaying activation of the protein until it reaches a secretory vesicle or until after it has been secreted has the clear advantage of preventing it from acting prematurely inside the cell in which it is synthesized.

Secretory Vesicles Wait Near the Plasma Membrane Until Signaled to Release Their Contents [33]

Once loaded, a secretory vesicle has to get to the site of secretion, where it must wait until the cell receives the signal to secrete. In some cells the site of secretion is far removed from the Golgi apparatus. Nerve cells provide the most extreme example. Secretory proteins such as peptide neurotransmitters that are to be released from the end of the axon are made and packaged into vesicles in the cell body, where the ribosomes, ER, and Golgi apparatus are located. They must then travel out along the axon - a distance of anything up to a meter or more - to reach the axon terminal. As discussed in Chapter 16, the vesicles use motor proteins attached to their surface to propel themselves along axonal microtubules, whose uniform orientation guides this traffic down the axon in the proper direction. Microtubules may have a similar role in guiding secretory vesicles to the appropriate surface of polarized epithelial cells.

The last step along the regulated secretory pathway is the triggered release of the product by exocytosis. The signal to secrete is often a chemical messenger, such as a hormone, that binds to receptors on the cell surface. The resulting activation of the receptors generates intracellular signals, often including a transient increase in the concentration of free Ca^{2+} in the cytosol. In the case of a nerve axon the signal for exocytosis is usually an electrical excitation - an action potential - that has itself been triggered by a chemical transmitter binding to receptors elsewhere on the cell surface. The action potential causes an influx of Ca^{2+} into the axon terminal through voltage-gated Ca^{2+} channels. By an unknown mechanism, the sudden flush of Ca^{2+}, or some other intracellular signal in the secretory cell, triggers exocytosis, causing the secretory vesicles to fuse with the plasma membrane and release their contents to the extracellular space.

Regulated Exocytosis Is a Localized Response of the Plasma Membrane and Its Underlying Cytoplasm [34]

Histamine is a small molecule secreted by mast cells by the regulated pathway in response to specific ligands that bind to receptors on the mast-cell surface. It is responsible for many of the unpleasant symptoms, such as itching and sneezing, that accompany allergic reactions. When mast cells are incubated in fluid containing a soluble stimulant, exocytosis occurs all over the cell surface (Figure 13-41). Yet this is not a generalized response of the whole cell. This has been demonstrated by artificially attaching the stimulating ligand to a solid bead so that it can interact only with a localized region of the mast cell surface; now exocytosis is restricted to the region where the cell contacts the bead (Figure 13-42). Clearly, individual segments of the plasma membrane can function independently. As a result, the mast cell, unlike a nerve cell, does not respond as a whole when it is triggered; the activation of receptors, the resulting intracellular signals, and the subsequent exocytosis are all localized in the particular region of the cell that has been excited.

Secretory-Vesicle Membrane Components Are Recycled [35]

When a secretory vesicle fuses with the plasma membrane, its contents are discharged from the cell by exocytosis and its membrane becomes part of the plasma membrane. Although this should greatly increase the surface area of the plasma membrane, it does so only transiently because membrane components are removed from the surface by endocytosis almost as fast as they are added by exocytosis. This removal returns the proteins of the secretory vesicle membrane to the *trans* Golgi network (probably via endosomes), where they can be used again. Such recycling maintains a steady-state distribution of membrane components among the various cellular compartments. The amount of secretory vesicle membrane that is temporarily added to the plasma membrane can be enormous: in a pancreatic acinar cell discharging digestive enzymes, about 900 mm^2 of vesicle membrane is inserted into the apical plasma membrane (whose area is only 30 mm^2) when the cell is stimulated to secrete.

Synaptic Vesicles Form from Endosomes [36]

Nerve cells (and some endocrine cells) contain two types of secretory vesicles. As we have just discussed, these cells package proteins and peptides in dense-core secretory vesicles in the standard way for release by the regulated secretory pathway. In addition, however, they make use of another specialized class of tiny (~50-nm diameter) secretory vesicles that are generated in a different way. These synaptic vesicles store the small neurotransmitter molecules, such as acetylcholine, glutamate, and g-aminobutyric acid (GABA), that serve for rapid signaling from cell to cell at chemical synapses (and for local signaling in some endocrine tissues). The vesicles are triggered to release their contents within a fraction of a millisecond when an action potential arrives at a nerve terminal, and some neurons fire more than 1000 times per second, releasing synaptic vesicles each time. This demands very rapid replenishment of the vesicles that are believed to be generated not from the Golgi membrane but by local recycling from the plasma membrane in the following way. It is thought that the membrane components of the synaptic vesicles are initially delivered to the plasma membrane by the constitutive secretory pathway and then retrieved by endocytosis and delivered to endosomes, from which they are reassembled and bud off to form synaptic vesicles. The membrane components of the vesicles include carrier proteins specialized for the uptake of neurotransmitter from the cytosol, where it is synthesized. Once filled with neurotransmitter, the vesicles return to the plasma membrane, where they wait until the cell is stimulated. After they release their contents, their membrane components are retrieved in the same way and used again (Figure 13-43). The whole cycle, from endocytosis to exocytosis, can be observed by adding a tracer molecule, such as peroxidase, to the external medium and following its fate as it is first taken up into endosomes and then returned to the cell surface in synaptic vesicles.

Polarized Cells Direct Proteins from the *Trans* Golgi Network to the Appropriate Domain of the Plasma Membrane [37]

Most cells in tissues are *polarized* and have two (and sometimes more) distinct plasma membrane domains to which different types of secretory vesicles must be targeted. This raises the general problem of how the delivery of membrane from the Golgi apparatus is organized so as to maintain differences between one cell-surface domain and another. A typical epithelial cell, for example, has an *apical domain,* which faces the lumen and often has specialized features such as cilia or a brush border of microvilli, and a *basolateral domain,* which covers the rest of the cell. The two domains are demarcated by a ring of *tight junctions* (see Figure 23-35) . These specialized cell-cell junctions (discussed in Chapter 19) prevent proteins, and lipids in the outer leaflet of the lipid bilayer, from diffusing between the apical and basolateral regions, so that not only the protein but also the lipid composition of the two membrane domains is different. In particular, the apical membrane domain is greatly enriched in glycolipids, which are thought to help protect this exposed surface from damage by, for example, the digestive enzymes and the low pH encountered in sites such as the lumen of the gut. Plasma membrane proteins that are linked to the lipid bilayer by a glyco-sylphosphatidylinositol (GPI) anchor also are found exclusively in the apical plasma membrane. If a sequence providing for attachment of a GPI anchor is added (by genetic manipulation) to a protein that would normally be delivered to the basolateral surface, the protein is delivered to the apical surface instead. GPI-linked proteins seem to associate with glycolipids and may be targeted to the same region of the cell surface as a result of this association, but the nature of the targeting mechanism is not known.

In principle, differences between plasma membrane domains need not depend on targeted delivery of the appropriate membrane components. Instead, the membrane components, for example, could be delivered to all regions of the cell surface indiscriminately but then be selectively stabilized in some locations and selectively eliminated in others. This strategy of random delivery and selective retention or removal seems to be used in certain cases; there are many clear examples, however, where deliveries are specifically directed. Thus epithelial cells often secrete one set of products - such as digestive enzymes or mucus, in the case of cells in the lining of the gut - at their apical surface and another set of products - such as laminin and other basal lamina components - at their basolateral surface. Such cells must have ways of directing vesicles carrying different cargoes, wrapped in different types of membrane, to different plasma membrane domains. By examining polarized cells in culture, it has been found that proteins from the ER destined for different domains travel together until they reach the *trans* Golgi network. Here they are separated and dispatched in secretory or transport vesicles to the appropriate plasma membrane domain. In some cases both basolateral and apical proteins have distinct sorting signals that direct them to the appropriate domain - either directly or indirectly via endosomes (Figure 13-44); in other cases only proteins destined for one of the two membrane domains have a sorting signal, while the other domain is reached by a default pathway that requires no signal.

A nerve cell is an extreme example of a polarized cell: the plasma membrane of its axon terminals is specialized for signaling to other cells, and the plasma membrane of its cell body and dendrites is specialized to receive signals from other nerve cells. Both of these plasma membrane domains are not only functionally distinct but also have a distinct membrane protein composition. Studies of protein traffic in nerve cells in culture indicate that, so far as vesicular transport from the *trans* Golgi network to the cell surface is concerned, the plasma membrane of the nerve cell body and dendrites is equivalent to the basolateral membrane of a polarized epithelial cell, while the plasma membrane of the axon and nerve terminals is equivalent to the apical membrane of such a cell (Figure 13-45). Thus a protein that is targeted to a specific domain in the epithelial cell is usually found to be targeted to the corresponding domain in the nerve cell.

Summary

Proteins can be secreted from cells by exocytosis in either a constitutive or a regulated fashion. In the regulated pathways molecules are stored in secretory vesicles or synaptic vesicles, which do not fuse with the plasma membrane to release their contents until an extracellular signal is received. A selective condensation of the proteins directed to secretory vesicles accompanies their packaging into these vesicles in the trans Golgi network. Synaptic vesicles are confined to nerve cells and some endocrine cells; they form from endosomes and are responsible for the regulated secretion of small neurotransmitters. Whereas the regulated pathways operate only in specialized secretory cells, a constitutive secretory pathway operates in all cells, mediated by continual vesicular transport from the trans Golgi network to the plasma membrane.

Proteins made in the ER are automatically delivered to the trans Golgi network and then to the plasma membrane by the constitutive, or default, pathway unless they are diverted into other pathways or retained by specific sorting signals. In polarized cells, however, the transport pathways from the trans Golgi network to the plasma membrane must operate selectively to ensure that different sets of membrane proteins, secreted proteins, and lipids are delivered to the appropriate plasma membrane domains.
Figure 13-36. The regulated and constitutive secretory pathways. The two pathways diverge in the *trans* Golgi network. Many soluble proteins are continually secreted from the cell by the *constitutive secretory pathway* (also called the *default pathway*) , which operates in all cells. This pathway also supplies the plasma membrane with newly synthesized lipids and proteins. Specialized secretory cells also have a *regulated secretory pathway,* by which selected proteins in the *trans* Golgi network are diverted into secretory vesicles, where the proteins are concentrated and stored until an extracellular signal stimulates their secretion. The regulated secretion of small molecules, such as histamine, occurs by a similar pathway: these molecules are actively transported from the cytosol into preformed secretory vesicles. There they are often complexed to specific macro-molecules (proteoglycans in the case of histamine), so that they can be stored at high concentration without generating an excessively high osmotic pressure.
Figure 13-37. The best-understood pathways of protein sorting in the *trans* Golgi network. Proteins with the mannose 6-

phosphate marker are diverted to lysosomes (via late endosomes) in clathrin-coated transport vesicles (see Figure 13-23). Proteins with signals directing them to secretory vesicles are concentrated in large clathrin-coated vesicles that rapidly lose their coats to become secretory vesiclesa pathway that is present only in specialized secretory cells. In unpolarized cells proteins with no special features are thought to be delivered to the cell surface by default via the constitutive secretory pathway. In polarized cells, however, secreted and plasma membrane proteins are selectively directed to either the apical or the basolateral plasma membrane domain, so that at least one of these two pathways must be mediated by a specific signal, as we discuss later.
Figure 13-38. The formation of secretory vesicles. This electron micrograph shows secretory vesicles forming from the *trans* Golgi network in an insulin-secreting b cell of the pancreas. An antibody conjugated to gold spheres (*black dots*) has been used to locate clathrin molecules. The immature secretory vesicles (*black arrowheads*), which contain insulin precursor protein (proinsulin), are coated with clathrin. The clathrin coat is rapidly shed once the vesicle has formed and is not part of the mature secretory vesicle, which has a highly condensed core (*open arrowhead*). (Courtesy of Lelio Orci.)

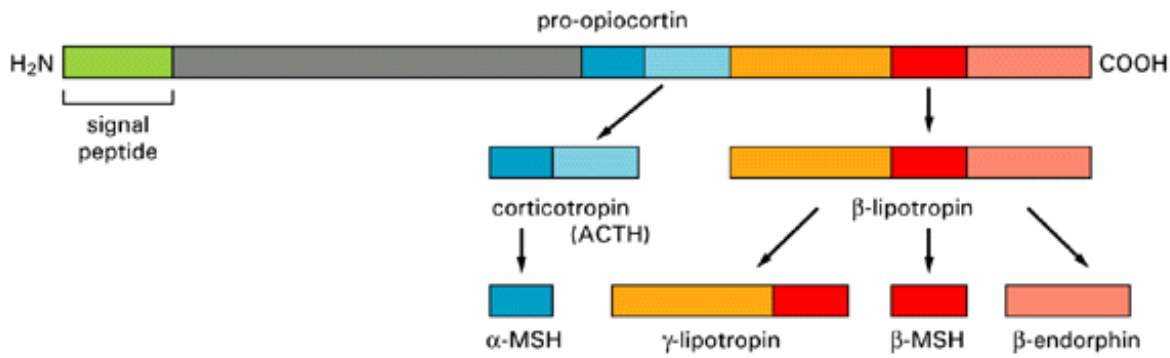
Figure 13-39. Exocytosis of secretory vesicles. The electron micrograph shows the release of insulin from a secretory vesicle of a pancreatic b cell. (Courtesy of Lelio Orci, from L. Orci, J-D. Vassali, and A. Perrelet, *Sci. Am.* 256:85-94, 1988.)


Figure 13-40. Alternative processing pathways of the prohormone pro-opiocortin. The initial cleavages are made by membrane-bound proteases that cut next to pairs of positively charged amino acid residues (Lys-Arg, Lys-Lys, Arg-Lys, or Arg-Arg pairs), and trimming reactions then produce the final secreted products. Different cell types contain different processing enzymes, so that the same prohormone precursor can be used to produce different peptide hormones. In the anterior lobe of the pituitary gland, for example, only corticotropin (ACTH) and b-lipotropin are produced from pro-opiocortin, whereas in the intermediate lobe of the pituitary, mainly a-MSH, g-lipotropin, b-MSH, and b-endorphin are produced.
Figure 13-41. Electron micrographs of exocytosis in rat mast cells. The cell in (A) has not been stimulated. The cell in (B) has been activated to secrete its stored histamine by a soluble extracellular ligand. Histamine-containing secretory vesicles are dark, while those that have released their histamine are light. The material remaining in the spent vesicles consists of a network of proteoglycans to which the stored histamine was bound. Once a secretory vesicle has fused with the plasma membrane, the secretory vesicle membrane often serves as a target to which other secretory vesicles fuse. Thus the cell in (B) contains several large cavities lined by the fused membranes of many spent secretory vesicles, which are now in continuity with the plasma membrane. This continuity is not always apparent in one plane of section through the cell. (From D. Lawson, C. Fewtrell, B. Gomperts, and M. Raff, *J. Exp. Med.* 142:391-402, 1975, by copyright permission of the Rockefeller University Press.)
Figure 13-42. Exocytosis as a localized response. Electron micrograph of a mast cell that has been activated to secrete histamine by a stimulant coupled to a large solid bead. Exocytosis has occurred only in the region of the cell that is in contact with the bead. (From D. Lawson, C. Fewtrell, and M. Raff, *J. Cell Biol.* 79:394-400, 1978, by copyright permission of the Rockefeller University Press.)

(A) DIRECT SORTING OF
MEMBRANE PROTEINS IN
THE *TRANS* GOLGI
NETWORK

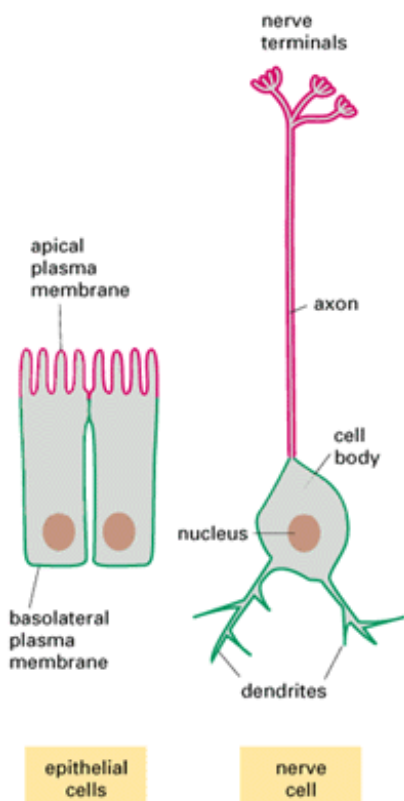
(B) INDIRECT SORTING VIA ENDOSOMES
Figure 13-44. Sorting of plasma membrane proteins in a polarized epithelial cell. Newly synthesized proteins can reach their proper plasma membrane domain by either a direct (A) or an indirect (B) pathway. In the indirect pathway a protein is retrieved from the inappropriate plasma membrane domain by endocytosis and then transported to the correct domain via early endosomesthat is, by transcytosis.


Figure 13-45. Comparison of two types of polarized cells. In terms of the mechanisms used to direct proteins to them, the plasma membrane of the nerve cell body and dendrites seems to be equivalent to the basolateral plasma membrane domain of a

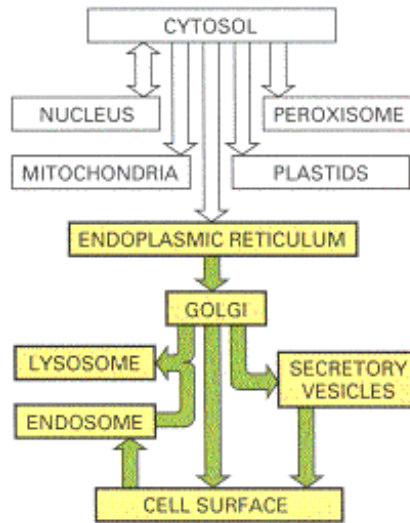
polarized epithelial cell, whereas the plasma membrane of the axon and nerve terminals seems to be equivalent to the apical membrane of an epithelial cell.

The Molecular Mechanisms of Vesicular Transport and the Maintenance of Compartmental Diversity <u>38</u>


Introduction

We come now to the most fundamental question in vesicular traffic. We have seen that the cell contains 10 or more chemically distinct membrane-bounded compartments and that vesicular transport mediates a continual exchange of components among them (see <u>Figure 13-3</u>). In the presence of this massive exchange, how does each compartment maintain its specialized character?

To answer this question, we must first consider what defines the character of a compartment. Above all, it seems to be the nature of the enclosing membrane: markers displayed on the cytosolic surface of the membrane guide the targeting of vesicles, ensuring that they fuse only with the correct compartment and so dictating the pattern of traffic between one compartment and another.

Given the presence of distinct membrane markers for each compartment, the problem is to explain how specific membrane components are kept at high concentration in one compartment and at low concentration in another. The answer depends, most fundamentally, on the mechanisms of transport vesicle formation and fusion, by which patches of membrane, enriched or depleted in specific components, are transferred from one compartment to another. In this section, therefore, we examine what is known about these processes at a molecular level.

We have already seen that the creation of a transport vesicle involves the assembly of a special coat on the cytosolic face of the budding membrane. Such coats serve as devices to suck membrane that is enriched in certain membrane proteins and depleted in others out of one compartment, so that specific proteins can be delivered to another compartment. We shall consider how coats form and what they are made of. We also discuss how transport proteins dock at the appropriate target membrane and how they then fuse with that membrane to deliver their contents to the target organelle. We shall see how a combination of genetics and biochemistry has uncovered a variety of GTP-binding proteins that help control vesicular transport. By coupling GTP hydrolysis to other catalytic events, they help give vesicular transport its directionality by linking vesicle budding and fusion to the expenditure of free energy, and they guarantee its fidelity by monitoring the accuracy with which a transport vesicle recognizes its specific target membrane. The basic genetic and biochemical strategies that have been used to study the molecular machinery involved in vesicular transport are outlined in <u>Panel 13-1</u>, pages 638-639.

Before discussing the details of the machinery, however, it is helpful to strip the fundamental problem down to its barest essentials, to see the basic general principles that must apply to any unidirectional vesicular transport process.

Maintenance of Differences Between Compartments Requires an Input of Free Energy <u>38</u>

Suppose there are two membrane-bounded compartments connected by transport vesicles that shuttle between them and that the

difference between the two compartments lies solely in the concentration of a single type of membrane-bound protein, P. If the system is left simply to drift toward equilibrium through the traffic of transport vesicles between the compartments, the concentrations of P will equalize and the difference between the compartments will disappear. The difference can be maintained by using free energy to transfer P molecules actively in one direction, against their concentration gradient. Protein P might be sequestered into the budding membrane of a forming transport vesicle in the low-concentration compartment, for example, but be kept out of the vesicles budding from the high-concentration compartment by a conformational change driven directly or indirectly by ATP or GTP hydrolysis on the membrane forming the bud (Figure 13-46). Although this example is much simpler than any known system used by cells, it serves to illustrate why there must be an input of free energy for transport vesicles to mediate selective directional transport between any two membrane-bounded compartments.

Selective directional vesicular transport is of central importance in the organization of the eucaryotic cell. We begin our discussion of the molecular mechanisms that underlie it by considering how transport vesicles are formed.

There Is More Than One Type of Coated Vesicle 39

Most transport vesicles form from specialized *coated regions* of membranes and so bud off as coated vesicles with a distinctive cage of proteins covering the surface facing the cytosol. Before the vesicle can fuse with a target membrane, this coat has to be discarded in order to let the two membranes interact directly.

There are two well-characterized types of coated vesicles - clathrin-coated and coatomer-coated (Figure 13-47). *Clathrin-coated vesicles,* as we saw earlier, mediate selective transport of transmembrane receptors, such as the M6P receptor from the *trans* Golgi network or the LDL receptor from the plasma membrane, together with any soluble molecules that these receptors may have bound and trapped in the vesicle lumen. *Coatomer-coated vesicles,* by contrast, mediate nonselective vesicular transport from the ER and Golgi cisternae.

There may be a third type of coated vesicle. The plasma membrane of most cells has morphologically and biochemically distinct invaginations called *caveolae* (Figure 13-48); although their function is uncertain, one possibility is that they bud off to form calveolin-coated vesicles. If so, it is unclear what they transport or what their destination is, and we shall not discuss them further.

Coated vesicles appear to mediate directional transfer of specific types of membrane. This transfer is usually balanced by a counterflow of membrane in the opposite direction, either in the form of vesicles of less well-characterized types or by means of elongated sacs or tubes of membrane that are dragged along microtubules (see Figure 13-9).

The Assembly of a Clathrin Coat Drives Bud Formation 40

The major protein component of clathrin-coated vesicles is clathrin itself, a protein complex that has been highly conserved in evolution. It consists of three large and three small polypeptide chains that together form a three-legged structure called a *triskelion.* Clathrin triskelions assemble into a basketlike convex framework of hexagons and pentagons to form coated pits on the cytoplasmic surface of membranes (Figure 13-49). Under appropriate conditions, isolated triskelions will spontaneously reassemble into typical polyhedral cages in a test tube, even in the absence of the membrane vesicles that these baskets normally enclose (Figure 13-50).

The formation of a clathrin-coated bud is believed to be driven by forces generated by the assembly of the coat proteins on the cytosolic surface of the membrane (Figure 13-51). It is not known what initiates the assembly process at a particular region of membrane or how the coated bud pinches off to form a coated vesicle. Once the vesicle pinches off, the coat is lost very rapidly. The mechanism of shedding is also uncertain, but a chaperone protein of the hsp70 family has been shown to act *in vitro* as an *uncoating ATPase* that uses the energy of ATP hydrolysis to remove the coat from clathrin-coated vesicles. Some additional control mechanism must operate in the cell, however, to prevent the clathrin coat from being removed from a coated bud before it has had time to form a vesicle, especially since the coated bud persists much longer than the coat on the vesicle. One possibility is that uncoating is controlled by Ca^{2+}, which can bind to clathrin light chains and destabilize clathrin coats. Ca^{2+} pumps in the plasma membrane pump Ca^{2+} out of the cell and thereby keep Ca^{2+} concentrations extremely low at the cytosolic face of the membrane, allowing coated pits to persist; but once coated vesicles form and migrate away from the membrane, they encounter a higher concentration of Ca^{2+}, which may be the trigger for uncoating.

While clathrin-coated pinocytic vesicles are usually small and uniform in size, clathrin is also involved in the formation of much larger vesicles, including secretory vesicles that contain large protein aggregates and phagosomes that contain large particles. In these cases clathrin forms patches rather than complete coats on the forming vesicles. The assembly of the clathrin patches is thought to help bend the membrane, but the large size of the cargo prevents the membrane from bending enough to allow the formation of a complete coat.

Adaptins Recognize Specific Transmembrane Proteins and Link Them to the Clathrin Cage 41

The assembly of the coat on clathrin-coated vesicles is thought to serve at least two functions: it provides the mechanical force to pull the membrane into a bud, and it helps to capture specific membrane receptors and their bound cargo molecules. A second major coat protein in these vesicles, a multisubunit complex called adaptin, plays a role in both of these functions. Adaptins are required both to bind the clathrin coat to the membrane and to trap various transmembrane receptor proteins, which in turn capture specific cargo molecules inside the vesicle. In this way a selected set of cargo molecules, bound to their specific *cargo receptors,* is incorporated into the lumen of each newly formed clathrin-coated transport vesicle (Figure 13-52).

Clathrin-coated vesicles are not all alike. We have seen, for example, that some, in transit from the Golgi apparatus to late endosomes, are rich in M6P receptors; others, in transit from the plasma membrane to early endosomes, are rich in receptors for extracellular materials such as LDL. Although the cage of clathrin itself seems to be the same in each case, the adaptins are different and mediate the capture of the different types of cargo receptors.

The adaptins recognize peptide signals in the cytoplasmic tail of cargo receptors. A characteristic stretch of four amino acid residues, which are thought to form a sharp turn in the polypeptide chain, forms an essential part of the *endocytosis signal* shared by those cell-surface receptors that function in receptor-mediated endocytosis from the plasma membrane (Figure 13-53). By contrast, a stretch of phosphorylated amino acids at the carboxyl terminus of M6P receptors is recognized by adaptins in the *trans* Golgi network.

Coatomer-coated Vesicles Mediate Nonselective Vesicular Transport 42

Coatomer-coated vesicles are thought to mediate the nonselective vesicular transport of the default pathway, which includes transport from the endoplasmic reticulum to the Golgi apparatus, from one Golgi cisterna to another, and from the *trans* Golgi network to the plasma membrane (Figure 13-54). None of these transport steps requires that the forming vesicle capture a specific cargo in its lumen.

The coat of these vesicles consists in part of a large protein complex called coatomer, comprising seven individual coat-protein subunits (called COPs). At least one of these shows sequence homology to adaptins of clathrin-coated vesicles, but there are important differences in the way that coatomer and clathrin coats behave. In contrast to clathrin coats, coatomer coats do not self-assemble but require ATP to drive their formation, and instead of disassembling as soon as the vesicle has pinched off from the donor membrane, the coatomer coat is retained until the vesicle docks with its target membrane.

Both the assembly and disassembly of the coatomer coat are thought to depend on a protein called ARF, which may also play a role in the assembly of clathrin coats. This is one of the many GTP-binding proteins that are key components in the control of vesicular transport. Before discussing the particulars of ARF, we pause to review some general properties of regulatory GTP-binding proteins.

Vesicular Transport Depends on Regulatory GTP-binding Proteins 43

As discussed in Chapter 5, cells contain large families of regulatory GTP-binding proteins. These proteins act as molecular switches that can flip between two conformational states - an active, charged state with GTP bound and an inactive, discharged state with GDP bound - and they function as regulators of many complex cellular processes. GTP-binding proteins operate in a cycle that typically depends on two auxiliary components: a *guanine-nucleotide-releasing protein (GNRP)* to catalyze exchange of GDP for GTP and a *GTPase-activating protein (GAP)* to trigger the hydrolysis of the bound GTP.

Many regulatory GTP-binding proteins have a covalently attached lipid group that helps them bind to membranes, and they are involved in a great variety of membrane-dependent transactions in the cell. Two structurally distinct classes are recognized: the *monomeric GTP-binding proteins* (also called *monomeric GTPases*), consisting of a single polypeptide chain, and the *trimeric*

GTP-binding proteins (also called *G proteins*), consisting of three different subunits. Although studies with inhibitors indicate that both classes have essential roles in vesicular transport, the roles of the monomeric GTPases are better understood, and so we shall focus our discussion on them.

ARF Seems to Signal the Assembly and Disassembly of the Coatomer Coat [44]

ARF is a monomeric GTPase with a fatty acid tail, and it is thought to play a crucial role in both the assembly and disassembly of coatomer coats. It is found in high concentration in the cytosol in its discharged, GDP-bound state. It seems that the donor membrane from which a coatomer-coated vesicle is to bud contains a specific guanine-nucleotide-releasing protein that causes ARF to release its GDP and bind GTP in its place (as GTP is present in much higher concentration in the cytosol than GDP). The binding of GTP is thought to cause the ARF to expose its fatty acid tail, which inserts into the lipid bilayer of the donor membrane. The tightly bound ARF now recruits coatomer subunits, which bind to it. The assembly of the coatomer coat, which consists of both the GTP-charged ARF and the coatomer proteins, pulls the membrane into a bud, which then pinches off as a coated vesicle (Figure 13-55).

When the coatomer-coated vesicle docks with its target membrane, a specific GTPase-activating protein in the target membrane triggers the ARF to hydrolyze its bound GTP to GDP. This is thought to lead to a conformational change in ARF so that its fatty acid chain pops out of the membrane, causing the vesicle's coat to disassemble and allowing membrane fusion to proceed, as discussed later. Thus ARF can be viewed as a protein that senses the circumstances and gives the appropriate signal, either for coat assembly and vesicle budding or for coat disassembly and vesicle docking, as the case may be. Most important, given a guanine-nucleotide-releasing protein in the donor membrane and a GTPase-activating protein in the target membrane, the direction of transport is defined: because of its cycle of GTP hydrolysis and GDP/GTP exchange, ARF facilitates transfer in one direction only.

Organelle Marker Proteins Called SNAREs Help Guide Vesicular Transport [45]

Transport vesicles, whether or not they are selective in the way they pick up cargo from the donor compartment, have to be highly selective as to the target membrane with which they fuse. This suggests that all types of transport vesicles in the cell should display surface markers that identify them according to their origin and cargo and that are recognized by complementary receptors in the proper target membrane. Although the mechanism of this recognition is not known for certain, an attractive hypothesis is that it involves proteins called SNAREs (for reasons that are discussed below), which exist as complementary sets - v-SNAREs on the vesicle membrane and t-SNAREs on the target membrane (Figure 13-56). SNAREs are best characterized in nerve cells, where they are thought to mediate the docking of synaptic vesicles at the nerve terminal plasma membrane in preparation for exocytosis: a v-SNARE is located on the synaptic vesicle and a complementary t-SNARE on the cytoplasmic face of the plasma membrane.

Rab Proteins Are Thought to Ensure the Specificity of Vesicle Docking [46]

Because there are many different membrane systems in the cell, the docking process must be highly selective. A vesicle is likely to inspect many potential target membranes before its v-SNARE finds a complementary t-SNARE. According to one view, this crucial recognition step is controlled by members of a family of monomeric GTPases called Rab proteins, which check that the fit between a v-SNARE and a t-SNARE is correct. In this view Rab proteins become attached to the surface of budding coated vesicles in the donor membrane. When a vesicle encounters the correct target membrane, the binding of v-SNARE to t-SNARE causes the vesicle to remain bound for long enough to allow the Rab protein to hydrolyze its bound GTP, which locks the vesicle onto the target membrane, readying it for subsequent fusion (Figure 13-57).

Eucaryotic cells contain many types of Rab proteins, each associated with a particular membrane-bounded organelle involved in the secretory or endocytic pathways. Each of these organelles has at least one Rab protein on its cytosolic surface (Table 13-1). The first Rab protein (called Sec4) was discovered in yeast by selecting for mutations (called *SEC* mutations) that interfere with secretion. It was subsequently shown to be a component of secretory vesicles and is required for their docking at the plasma membrane; mutations that disrupt it prevent secretory vesicles from discharging their contents to the exterior. The amino acid sequences of Rab proteins are most dissimilar near their carboxyl-terminal tails, and tail-swapping experiments using genetic engineering techniques indicate that it is the tail that determines the intracellular location of each family member, presumably by enabling it to bind to a complementary guanine-nucleotide-releasing factor on the surface of a particular organelle (see Figure 13-57). Before SNAREs became candidates for the organelle marker proteins that guide vesicular transport, Rab proteins were thought to play this role because of their remarkable organelle-specific distribution. It is now known, however, that at least some

Rab proteins are functionally interchangeable as long as they are experimentally engineered to become localized to the new organelle. Thus they cannot be the sole explanation for the selectivity of vesicular transport.

Vesicle Fusion Is Catalyzed by a "Membrane-Fusion Machine" [47]

Once a transport vesicle has recognized its target membrane and docked there, the vesicle has to unload its cargo by membrane fusion. Membrane fusion does not always follow immediately, however. As we have seen, in regulated exocytosis fusion does not occur until it is triggered by an extracellular signal.

Docking and fusion are two distinct and separable processes. It is possible, for example, to prevent fusion while permitting docking by keeping the cytosolic concentration of Ca^{2+} very low. This results in an accumulation of vesicles attached to but not fused with their target membrane. Docking requires only that the two membranes come close enough for proteins protruding from the lipid bilayers to interact and adhere. Fusion requires a much closer approach, bringing the lipid bilayers to within 1.5 nm of each other so that they can join. For this close approach water must be displaced from the hydrophilic surface of the membranea process that is energetically highly unfavorable. It seems likely that all membrane fusions in cells are catalyzed by specialized fusion proteins that provide a way to cross this energy barrier. The mechanism is still poorly understood. In the case of coatomer-coated transport vesicles at least, fusion with the target membrane requires ATP, GTP, acyl CoA, and several protein components. Two known essential protein components, called NSF and SNAPs (for reasons explained in the legend to Figure 13-58), cycle between the membranes to be fused and the cytosol. The SNAPs bind to both v-SNARE on the vesicle membrane and t-SNARE on the target membrane to initiate the assembly of the fusion apparatus, which catalyzes the fusion of the two lipid bilayers at the vesicle-target-membrane interface (Figure 13-58).

The Best-characterized Membrane-Fusion Protein Is Made by a Virus [48]

Membrane fusion is important in other processes besides vesicular transport, and in particular the simpler membrane fusions that are catalyzed by viral fusion proteins are understood in some detail. Viral fusion proteins play a crucial part in permitting the entry of enveloped viruses (which have a lipid-bilayer-based membrane coat) into the cells that they infect (discussed in Chapter 6). Viruses such as the influenza virus, for example, enter the cell by receptor-mediated endocytosis and are delivered to endosomes. The low pH in endosomes activates a fusion protein in the viral envelope that catalyzes the fusion of the viral and endosomal membranes, thereby allowing the viral nucleic acid to escape into the cytosol, where it can replicate (Figure 13-59).

The genes encoding several viral fusion proteins have been cloned and used to transfect eucaryotic cells in culture. These transfected cells express the viral proteins on their surface, and under appropriate conditions they fuse to form giant multinucleated cells. In the best-studied case, that of the influenza virus, the three-dimensional structure of the fusion protein has been determined by x-ray crystallography. It has been shown that low pH induces a large conformational change in the fusion protein, exposing a previously buried hydrophobic region on the surface of the protein that can interact with the lipid bilayer of a target membrane. A cluster of such hydrophobic regions on closely spaced fusion-protein molecules is thought to bring the two lipid bilayers into close apposition and to destabilize them so that the bilayers fuse (Figure 13-60).

Recently, a mammalian fusion protein has been identified that resembles viral fusion proteins, and it is thought to mediate the fusion of the plasma membranes of sperm and egg that occurs at fertilization (discussed in Chapter 20). As all of these examples emphasize, under normal circumstances membranes do not fuse easily. Membrane fusion requires special proteins and is subject to highly selective controls - a constraint that is crucial both for maintaining the identity of the cell itself and for maintaining the individuality of each of the intracellular compartments.

Summary

The differences between the membranous compartments of a cell are maintained by an input of free energy, driving directed, selective transport of particular membrane components from one compartment to another. Transport vesicles bud from specialized coated regions of the donor membrane. The assembly of the coat helps to drive the formation of the vesicle. There are two well-characterized types of coated vesicles: clathrin-coated vesicles mediate selective vesicular transport from the plasma membrane and the trans Golgi network, while coatomer-coated vesicles mediate non-selective vesicular transport from the ER and Golgi cisternae. Adaptins provide a molecular link between clathrin coats and specific membrane receptors and thereby mediate the selective uptake of cargo molecules into clathrin-coated vesicles. Coated vesicles have to lose their coat to fuse with their appropriate target membrane in the cell: clathrin coats are lost soon after the vesicle pinches off from the donor membrane, whereas coatomer coats are lost after the vesicle has docked on the target membrane.

Several classes of monomeric GTPases, including ARF and the Rab proteins, help regulate various steps in vesicular transport, including vesicle budding, docking, and fusion. ARF, Rab, and v-SNARE proteins are incorporated during budding into the transport vesicles and help ensure that the vesicles deliver their contents only to the appropriate membrane-bounded compartment: ARF is thought to mediate coatomer (and probably clathrin) coat assembly and coatomer coat disassembly, while Rab proteins are thought to help ensure the specificity of vesicle docking by locking the vesicle onto the target membrane only when complementary vesicle and target membrane snares interact. Membrane fusion is then catalyzed by a number of cytosolic proteins, including SNAPs and NSF, that assemble into a fusion complex at the docking site.
Figure 13-46. Chemical energy is used to give unidirectionality to vesicular transport. In this hypothetical example protein P is an ATP-driven H^+ pump that is present in low concentration in compartment A and in high concentration in compartment B. Because of the high concentration of P in compartment B, the lumen of this organelle will be at a much lower pH than that of compartment A. If P undergoes a pH-dependent conformational change that allows it to enter budding vesicles at the higher pH of compartment A but prevents it from doing so at the lower pH of compartment B, then a unidirectional flux of P will occur. As long as the pH difference between the two compartments is maintained through the continuous use of free energy in the form of ATP hydrolysis to drive the H^+ pump, the concentration gradient of P between the two compartments will be self-sustaining. As discussed in Chapter 12, most membranes are never created *de novo* but grow by expansion of existing membrane. Thus, although this simple model fails to address how the gradient of P between the two compartments was initially established, it does provide an example of how a cell could use energy to maintain the character of its compartments.

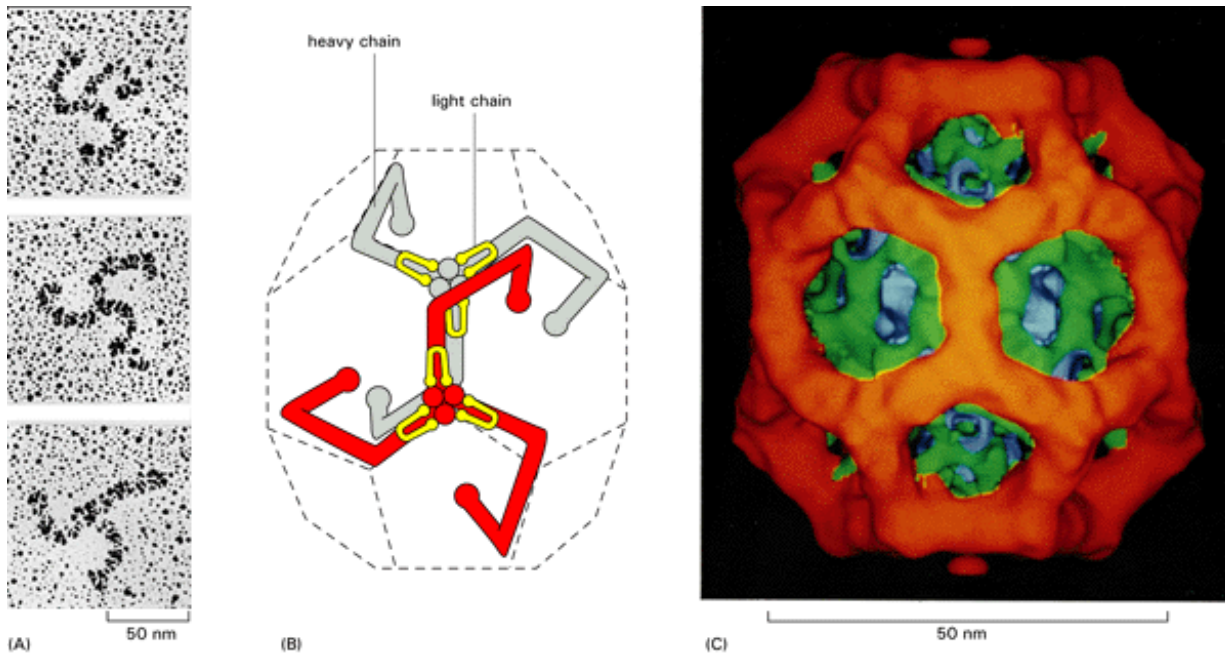
Figure 13-49. Clathrin-coated pits and vesicles. This rapid-freeze, deep-etch electron micrograph shows numerous clathrin-coated pits and vesicles on the inner surface of the plasma membrane of cultured fibroblasts. The cells were rapidly frozen in liquid helium, fractured, and deep-etched to expose the cytoplasmic surface of the plasma membrane. (From J. Heuser, *J. Cell Biol.* 84:560-583, 1980, by copyright permission of the Rockefeller University Press.)


Figure 13-50. The structure of a clathrin coat. (A) Electron micrographs of clathrin triskelions shadowed with platinum. Although this feature cannot be seen in these micrographs, each triskelion is composed of 3 clathrin heavy chains and 3 clathrin light chains. (B) A schematic drawing of the probable arrangement of triskelions on the cytosolic surface of a clathrin-coated vesicle. Two triskelions are shown, with the heavy chains of one in *red* and of the other in *gray;* the light chains are shown in *yellow.* The overlapping arrangement of the flexible triskelion arms provides both mechanical strength and flexibility. Note that the end of each leg of the triskelion turns inward, so that its amino-terminal domain forms an intermediate shell. (C) A three-dimensional reconstruction of a clathrin coat composed of 36 triskelions organized in a network of 12 pentagons and 6 hexagons. The outer, *red* polygonal shell represents the overlapping legs of the clathrin triskelions; the intermediate, *green* shell, the amino-terminal domains of the triskelions; and the inner, *blue* shell, the adaptor proteins that we discuss later. Although the coat shown is too small to enclose a membrane vesicle, the clathrin coats on vesicles are constructed in a similar way from 12 pentagons plus a larger number of hexagons. (A, from E. Ungewickell and D. Branton, *Nature* 289:420-422, 1981, © 1981 Macmillan Journals Ltd.; B, from I.S. Nathke et al., *Cell* 68:899-910, 1992. ©Cell Press, from G.P.A. Vigers, R.A. Crowther, and B.M.F. Pearse, *EMBO J.* 5:2079-2085, 1986.)
Figure 13-51. The assembly and disassembly of a clathrin coat. The assembly of the coat is thought to introduce curvature into the membrane, which leads in turn to the formation of uniformly sized coated buds. The pinching off of the bud to form a vesicle involves the more complex process of membrane fusion, which we discuss later. Although coats consist of multiple protein components, only clathrin is shown in this simplified schematic drawing. Whereas the coat of clathrin-coated vesicles is rapidly removed shortly after the vesicle forms, we shall see later that coatomer coats are removed after the vesicle docks on its

target membrane.
Figure 13-52. Selective transport mediated by clathrin-coated vesicles. The adaptins bind both clathrin triskelions and cargo receptors.
Figure 13-53. The peptide signal for endocytosis. The various cell-surface receptor proteins that are endocytosed in clathrin-coated vesicles are thought to share this signal, which is recognized by the adaptins that function in receptor-mediated endocytosis from the plasma membrane. The amino acids shown form an essential part of the signal.
Figure 13-54. Selected and nonselected vesicular transport in nonpolarized cells. Nonselected (constitutive) transport (*blue arrows*) is postulated to be mediated by coatomer-coated vesicles, while various forms of selected (signal-mediated) transport (*red arrows*) are postulated to be carried out by clathrin-coated vesicles. In polarized cells an additional signaled pathway from the *trans* Golgi network is required.
Figure 13-55. A current model of coatomer-coated vesicle formation. (A) Inactive, soluble ARF-GDP binds to a guanine-nucleotide-releasing protein in the donor membrane, causing the ARF to release its GDP and bind GTP. A GTP-triggered conformational change in ARF exposes its fatty acid chain, which inserts into the donor membrane. (B) Membrane-bound, active ARF-GTP recruits coatomer subunits to the membrane. This causes the membrane to form a bud. A sub-sequent membrane-fusion event pinches off and releases the coated vesicle. The drug brefeldin A blocks coatomer-coat assembly by inhibiting the exchange reaction of GDP to GTP. This blocks coatomer-coated vesicular traffic from the ER through the Golgi apparatus, causing the Golgi apparatus to empty into the ER, as explained on page 604.
Figure 13-56. The postulated role of SNAREs in guiding vesicular transport. Complementary sets of vesicle-SNAREs (v-SNAREs) and target-membrane SNAREs (t-SNAREs) determine the selectivity of transport-vesicle docking. v-SNAREs, which are co-packaged with the coat proteins during the budding of transport vesicles from the donor membrane, bind to complementary t-SNAREs in the target membrane.
Figure 13-57. Postulated role of Rab proteins in ensuring specificity in the docking of transport vesicles. The guanine-nucleotide-releasing protein in the donor membrane recognizes a specific Rab protein and induces it to exchange GDP for GTP. This exchange alters the conforma-tion of the Rab protein, exposing its covalently attached lipid group, which helps anchor the protein in the membrane. The Rab-GTP remains bound to the surface of the transport vesicle after it pinches off from the donor membrane. v-SNARE on the vesicle surface binds to t-SNARE in the target membrane, docking the vesicle. The Rab protein now hydrolyzes its bound GTP, locking the vesicle onto the target membrane and releasing Rab-GDP into the cytosol, from where it can be reused in a new round of transport. The vesicle then fuses with the target membrane. Note that the vesicle coats

have been omitted from the drawings for clarity.
Figure 13-58. A current model of protein-mediated vesicle fusion. A complex membrane-fusion machine catalyzes the fusion of a transport vesicle with its target membrane. Only two of the protein components of the fusion complex have been characterized: NSF (*N*-ethylmaleimide- *s*ensitive *f*usion protein) and SNAPs (*s*oluble *NSF a*ttachment *p*roteins). (NEM is a chemical that modifies free SH groups exposed on protein surfaces and thereby inactivates proteins whose exposed SH groups are required for activity.) SNAREs were first identified as SNAP receptors (hence their name): they bind to both v-SNAREs and t-SNAREs. The binding of the SNAPs allows NSF to bind. This complex, with the help of acyl CoA and as yet unidentified proteins, catalyzes the fusion of the two lipid bilayers. NSF is an ATPase that hydrolyzes ATP to release the complex once it has done its job (not shown).

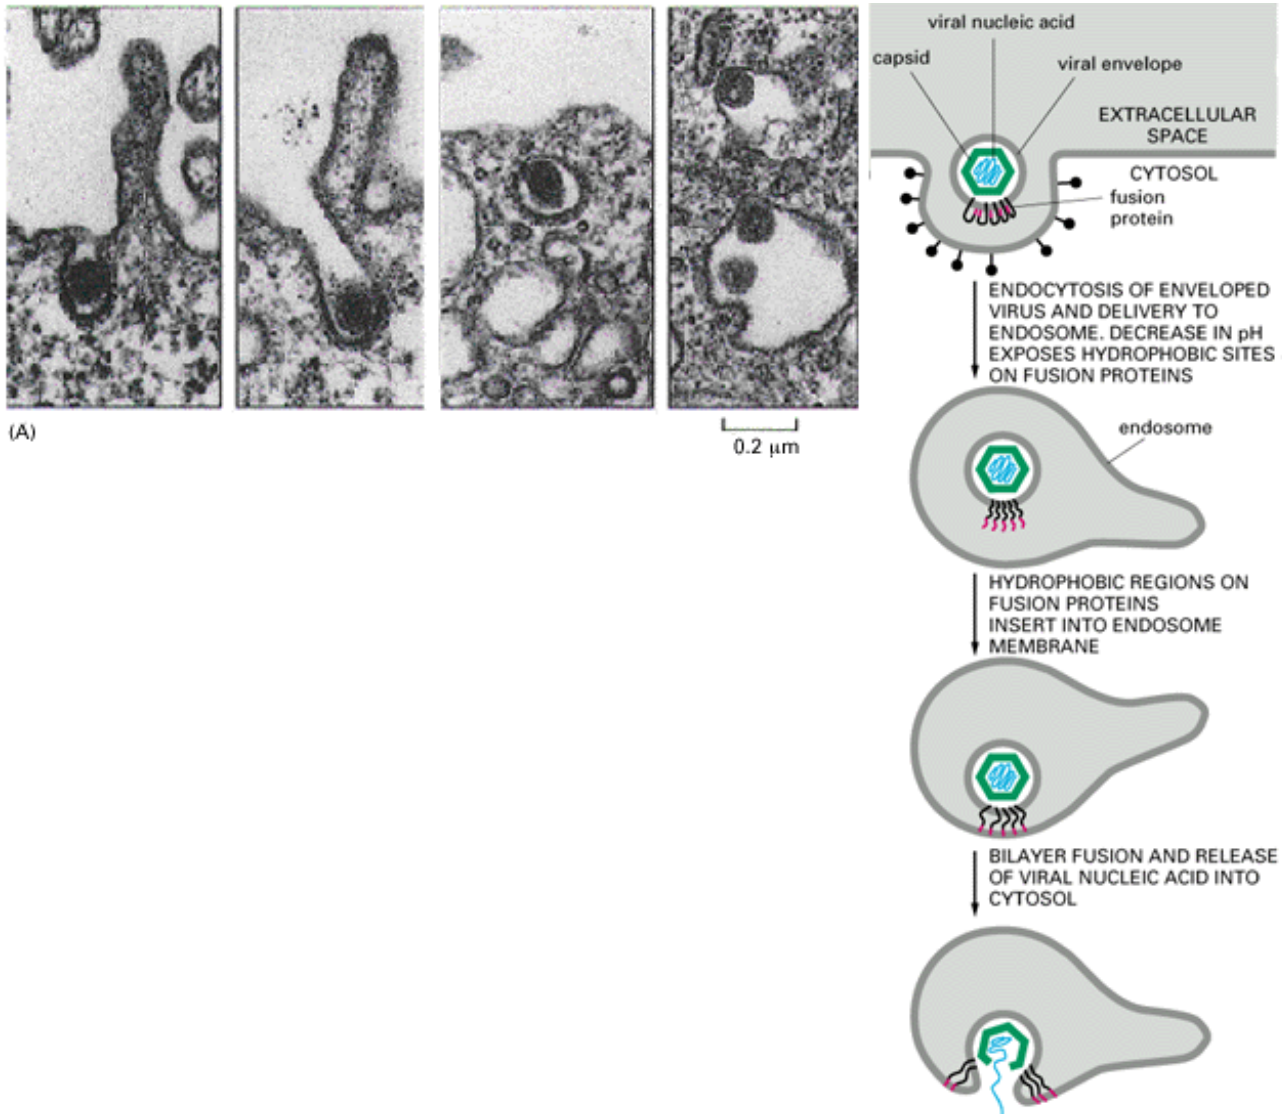
CYTOSOL


Figure 13-59. The entry of fowl plague virus into cells. (A) Electron micrographs showing how the virus is endocytosed in a clathrin-coated vesicle, is delivered to an endosome, and then escapes by fusing with the endosomal membrane. (B) Schematic drawing showing how fusion proteins on the surface of the virus mediate its escape from the endosome. (A, Courtesy of Karl Matlin and Hubert Reggio, from K.S. Matlin et al., *J. Cell Biol.* 91:601-613, 1981, by copyright permission of the Rockefeller University Press.)
Figure 13-60. A model for how a membrane-fusion protein catalyzes lipid bilayer fusion. A cell that expresses the influenza fusion protein on its surface rapidly fuses with neighboring cells after exposure to low pH. The fusion process proceeds through an intermediate (D and E) in which only the outer leaflets of the membranes are fused, while the inner two leaflets are still separate. Indeed, mutant forms of the fusion protein have been obtained that allow the reaction to proceed only to this intermediate state.

14. Energy Conversion: Mitochondria and Chloroplasts

Introduction

Mitochondria, which are present in virtually all eucaryotic cells, and plastids (most notably chloroplasts), which occur only in plants, are membrane-bounded organelles that convert energy to forms that can be used to drive cellular reactions. Consistent with their importance in metabolism, they generally occupy a major fraction of the total cell volume. In electron micrographs the most striking morphological feature of mitochondria and chloroplasts is the large amount of internal membrane they contain. As we shall see, this membrane has a crucial role in the function of these *energy-converting organelles* by providing a framework for electron-transport processes.

Although mitochondria convert energy derived from chemical fuels whereas chloroplasts convert energy derived from sunlight, the two types of organelles are organized similarly; moreover, both produce large amounts of ATP by the same mechanism. This striking conclusion emerged from painstaking studies carried out over the past 30 years.

The common pathway by which mitochondria, chloroplasts, and even bacteria harness energy for biological purposes operates by a process known as *chemiosmotic coupling.* The energy from the oxidation of foodstuffs or from sunlight is used to drive membrane-bound *proton pumps (H^+ pumps)* that transfer H^+ from one side of the membrane to the other. These pumps generate an *electrochemical proton gradient* across the membrane, which is used to drive various energy-requiring reactions when the protons flow back "downhill" through membrane-embedded protein machines (Figure 14-1). Foremost among these machines is the enzyme *ATP synthase*, which uses the energy of the H^+ flow to synthesize ATP from ADP and P_i. Other proteins couple the H^+ flow to the transport of specific metabolites into and out of the organelles. In bacteria the electrochemical proton gradient itself is as important a store of directly usable energy as is the ATP it generates: the gradient not only drives many transport processes, it also drives the rapid rotation of the bacterial flagellum, which allows the bacterium to swim.

How does the energy derived from food or light drive the H^+ pumps that are at the heart of the chemiosmotic mechanism? The answer lies in the reactions in which *electrons* are transferred from one compound to another. In the mitochondrion, for example, electrons released from a carbohydrate food molecule in the course of its degradation to CO_2 are transferred by a circuitous route to O_2, reducing the O_2 to form water. The free energy released as the electrons flow down this path from a high-energy state to a low-energy state is used to drive the H^+ pumps as part of an elaborate electron-transport process that takes place in the major mitochondrial membrane. The mechanism is analogous to an electric cell driving a current through a set of

electric motors. But in biological systems electrons are carried between one site and another not by conducting wires but by diffusible molecules that can pick up electrons at one location and deliver them to another. One of the most important of these *electron carriers* is NAD^+, which can take up two electrons (plus a H^+) to become NADH, which is a water-soluble small molecule that ferries electrons from the site where food molecules are degraded to the first of a series of electron carriers embedded in the mitochondrial membrane. These carriers diffuse in the plane of the membrane and ferry electrons from one H^+ pump to another. The third H^+ pump in the series catalyzes the final transfer of the electrons to O_2 (Figure 14-2A). The entire set of proteins and small molecules involved in this orderly sequence of electron transfers within the membrane is called an electron-transport chain.

Although the chloroplast can be described in similar terms, and several of its main components are very similar to those of the mitochondrion, the chloroplast membrane contains some crucial components not found in the mitochondrial membrane. Foremost among these are the *photosystems*, where light energy is captured and harnessed to drive the transfer of electrons, much as man-made photocells in solar panels absorb light energy and use it to drive an electric current. The electron-motive force generated by the chloroplast photosystems drives electron transfer in the direction opposite to that in mitochondria: electrons are taken *from* water to produce O_2, and they are donated (via NADPH) *to* CO_2 to synthesize carbohydrate. Thus the chloroplast generates O_2 and carbohydrate, while the mitochondrion consumes them (Figure 14-2B).

It is generally believed that the energy-converting organelles of eucaryotes evolved from procaryotes that were engulfed by primitive eucaryotic cells and developed a symbiotic relationship with them about 1.5×10^9 years ago. This would explain why mitochondria and chloroplasts contain their own DNA, which codes for some of their proteins. Since their initial uptake by a host cell, these organelles have lost much of their own genomes and have become heavily dependent on proteins that are encoded by genes in the nucleus, synthesized in the cytosol, and then imported into the organelle. Conversely, the host cells have become dependent on these organelles for much of the ATP they need to carry out biosyntheses, ion pumping, and movement - as well as requiring selected biosynthetic reactions that occur inside these organelles.
Figure 14-1. Chemiosmotic coupling. Energy from sunlight or the oxidation of foodstuffs is first used to create an *electrochemical proton gradient* across a membrane. This gradient serves as a versatile energy store and is used to drive a variety of reactions in mitochondria, chloroplasts, and bacteria.
Figure 14-2. The mitochondrion and chloroplast as electrical energy-conversion devices. Inputs are *light green,* products are *blue,* and the path of electron flow is indicated by *red arrows*. Note that the electron-motive force generated by the two chloroplast photosystems enables the chloroplast (B) to drive electron transfer from H_2O to carbohydrate, which is *opposite* to the direction of electron transfer in the mitochondrion (A).

The Mitochondrion 1

Introduction

Mitochondria occupy a substantial portion of the cytoplasmic volume of eucaryotic cells, and they have been essential for the evolution of complex animals. Without mitochondria present-day animal cells would be dependent on anaerobic glycolysis for all of their ATP. However, when glucose is converted to pyruvate by glycolysis, only a very small fraction of the total free energy potentially available from the glucose is released. In mitochondria the metabolism of sugars is completed: the pyruvate is imported into the mitochondrion and oxidized by molecular oxygen (O_2) to CO_2 and H_2O. The energy released is harnessed so efficiently that about 30 molecules of ATP are produced for each molecule of glucose oxidized. By contrast, only 2 molecules of ATP are produced by glycolysis alone.

Mitochondria are usually depicted as stiff, elongated cylinders with a diameter of 0.5 to 1 μm, resembling bacteria. Time-lapse microcinematography of living cells, however, shows that mitochondria are remarkably mobile and plastic organelles, constantly changing their shape (Figure 14-3) and even fusing with one another and then separating again. As they move about in the cytoplasm, they often appear to be associated with microtubules (Figure 14-4), which may determine the unique orientation and distribution of mitochondria in different types of cells. Thus the mitochondria in some cells form long moving filaments or chains, while in others they remain fixed in one position where they provide ATP directly to a site of unusually high ATP consumption - packed between adjacent myofibrils in a cardiac muscle cell, for example, or wrapped tightly around the flagellum in a sperm (Figure 14-5).

Although mitochondria are large enough to be seen in the light microscope and were first identified in the nineteenth century, real progress in understanding their function depended on procedures developed in 1948 for isolating intact mitochondria. For technical reasons many biochemical studies have been carried out with mitochondria purified from liver; each liver cell contains 1000 to 2000 mitochondria, which in total occupy roughly a fifth of the cell volume.

The Mitochondrion Contains an Outer Membrane and an Inner Membrane That Create Two Internal Compartments 2

Each mitochondrion is bounded by two highly specialized membranes that play a crucial part in its activities. Together they create two separate mitochondrial compartments: the internal matrix space and a much narrower intermembrane space. If purified mitochondria are gently disrupted and then fractionated into separate components (Figure 14-6), the biochemical composition of each of the two membranes and of the spaces enclosed by them can be determined. As described in Figure 14-7, each contains a unique collection of proteins.

The outer membrane contains many copies of a transport protein called *porin* (see Chapter 10) , which forms large aqueous channels through the lipid bilayer. This membrane thus resembles a sieve that is permeable to all molecules of 5000 daltons or less, including small proteins. Such molecules can enter the intermembrane space, but most of them cannot pass the impermeable inner membrane. Thus, while the intermembrane space is chemically equivalent to the cytosol with respect to the small molecules it contains, the matrix space contains a highly selected set of small molecules.

As we explain in detail later, the major working part of the mitochondrion is the matrix space and the inner membrane that surrounds it. The inner membrane is highly specialized. It contains a high proportion of the "double" phospholipid *cardiolipin,* which contains four fatty acids and may help make the membrane especially impermeable to ions. It also contains a variety of transport proteins that make it selectively permeable to those small molecules that are metabolized or required by the many mitochondrial enzymes concentrated in the matrix space. The matrix enzymes include those that metabolize pyruvate and fatty acids to produce acetyl CoA and those that oxidize acetyl CoA in the citric acid cycle. The principal end products of this oxidation are CO_2, which is released from the cell as waste, and NADH, which is the main source of electrons for transport along the respiratory chain - the name given to the electron-transport chain in mitochondria. The enzymes of the respiratory chain are embedded in the inner mitochondrial membrane, and they are essential to the process of *oxidative phosphorylation,* which generates most of the animal cell's ATP.

The inner membrane is usually highly convoluted, forming a series of infoldings, known as cristae, in the matrix space. These convolutions greatly increase the area of the inner membrane, so that in a liver cell, for example, it constitutes about a third of the total cell membrane. The number of cristae is three times greater in the mitochondrion of a cardiac muscle cell than in the mitochondrion of a liver cell, presumably because of the greater demand for ATP in heart cells. There are also substantial differences in the mitochondrial enzymes of different cell types. In this chapter we shall largely ignore the differences, however, and focus instead on the enzymes and properties that are common to all mitochondria.

Mitochondrial Oxidation Begins When Large Amounts of Acetyl CoA Are Produced in the Matrix Space from Fatty Acids and Pyruvate 3

Oxidative metabolism in mitochondria is fueled not only by the pyruvate produced from sugars by glycolysis in the cytosol but also by fatty acids. Pyruvate and fatty acids are selectively transported from the cytosol into the mitochondrial matrix, where they are broken down into the two-carbon acetyl group on acetyl coenzyme A (acetyl CoA) (Figure 14-8); the acetyl group is then fed into the citric acid cycle for further degradation, and the process ends with the passage of acetyl-derived high-energy electrons along the respiratory chain.

To ensure a continuous supply of fuel for oxidative metabolism, animal cells store fatty acids in the form of fats and glucose in the form of glycogen. Quantitatively, fat is a far more important storage form than glycogen, in part because its oxidation releases more than six times as much energy as the oxidation of an equal mass of glycogen in its hydrated form. An average adult human stores enough glycogen for only about a day of normal activities but enough fat to last for nearly a month. If our main fuel reservoir had to be carried as glycogen instead of fat, body weight would need to be increased by an average of about 60 pounds.

Most of our fat is stored in adipose tissue, from which it is released into the bloodstream for other cells to utilize as needed. The need arises after a period of not eating; even a normal overnight fast results in the mobilization of fat, so that in the morning most of the acetyl CoA entering the citric acid cycle is derived from fatty acids rather than from glucose. After a meal, however, most of the acetyl CoA entering the citric acid cycle comes from glucose derived from food, and any excess glucose is used to replenish depleted glycogen stores or to synthesize fats. (While animal cells readily convert sugars to fats, they cannot convert fatty acids to sugars.)

A fat molecule is composed of three molecules of fatty acid held in ester linkage to glycerol. Such triacylglycerols (*triglycerides*) have no charge and are virtually insoluble in water, coalescing into droplets in the cytosol (Figure 14-9). A single very large fat droplet accounts for most of the volume of *adipocytes* (fat cells), the large cells specialized for fat storage in adipose tissue. Much smaller fat droplets are common in cells that rely on the breakdown of fatty acids for their energy supply, such as cardiac muscle cells; these droplets are often closely associated with mitochondria (Figure 14-10). In all cells, enzymes in the outer and inner mitochondrial membranes mediate the movement of fatty acids derived from fat molecules into the mitochondrial matrix. In the matrix each fatty acid molecule (as *fatty acyl CoA*) is broken down completely by a cycle of reactions that trims two carbons at a time from its carboxyl end, generating one molecule of acetyl CoA in each turn of the cycle (Figure 14-11). The acetyl CoA produced is fed into the citric acid cycle to be oxidized further.

Glycogen is a large, branched polymer of glucose that is contained in granules in the cytoplasm ([Figure 14-12](#)); its synthesis and degradation are highly regulated according to need. When the need arises, cells break down glycogen to release glucose 1-phosphate, which is then subjected to *glycolysis*. The reactions of glycolysis convert the six-carbon glucose molecule (and related sugars) to two three-carbon pyruvate molecules, which still retain most of the energy that can be derived from the complete oxidation of sugars. This energy is harvested only after the pyruvate is transported from the cytosol into the mitochondrial matrix, where it encounters a giant multienzyme complex, the *pyruvate dehydrogenase complex*. This complex - containing multiple copies of three enzymes, five coenzymes, and two regulatory proteins - rapidly converts pyruvate to acetyl CoA, releasing CO_2 as a by-product ([Figure 14-13](#)). This acetyl CoA joins the acetyl CoA produced from fatty acids to fuel the citric acid cycle.

The Citric Acid Cycle Oxidizes the Acetyl Group on Acetyl CoA to Generate NADH and $FADH_2$ for the Respiratory Chain [4](#)

In the nineteenth century biologists noticed that in the absence of air (anaerobic conditions) cells produce lactic acid (or ethanol), while in its presence (aerobic conditions) they use O_2 to produce CO_2 and H_2O. Efforts to define the pathways of aerobic metabolism eventually focused on the oxidation of pyruvate and led in 1937 to the discovery of the citric acid cycle, also known as the *tricarboxylic acid cycle* or the *Krebs cycle*. The citric acid cycle accounts for about two-thirds of the total oxidation of carbon compounds in most cells, and its end products are CO_2 and high-energy electrons, which pass via NADH and $FADH_2$ to the respiratory chain. CO_2 is released as a waste product, while the high-energy electrons move along the respiratory chain, eventually combining with O_2 to produce H_2O.

The citric acid cycle begins when the acetyl CoA formed from fatty acids or pyruvate reacts with the four-carbon compound *oxaloacetate* to produce the six-carbon *citric acid* for which the cycle is named. Then, as a result of seven sequential enzyme-mediated reactions, two carbon atoms are removed as CO_2 and oxaloacetate is regenerated. Each such turn of the cycle produces two CO_2 molecules from two carbon atoms that entered in *previous* cycles ([Figure 14-14](#)). But the net result, insofar as the acetyl group on acetyl CoA is concerned, is

$$CH_3COOH \text{ (as acetyl CoA)} + 2H_2O + 3NAD^+ + \text{protein-bound FAD} \rightarrow$$
$$2CO_2 + 3H^+ + 3NADH + \text{protein-bound FADH}_2$$
This reaction also produces one molecule of ATP (via GTP) by the direct transfer of a phosphate from a sugar-phosphate intermediate to GDP; a very similar *substrate-level phosphorylation* reaction occurs in glycolysis, as explained in [Chapter 2](#).

The most important contribution of the citric acid cycle to metabolism is the extraction of high-energy electrons during the oxidation of the two acetyl carbon atoms to CO_2. These electrons, which are transiently held by NADH and $FADH_2$, are quickly passed to the respiratory chain in the mitochondrial inner membrane. $FADH_2$, which is part of the succinate dehydrogenase complex in the inner membrane, passes its electrons directly to the respiratory chain. The NADH, in contrast, forms a soluble pool of reducing equivalents in the mitochondrial matrix and passes on its electrons after a random collision with a membrane-bound dehydrogenase enzyme. We now consider how the energy stored in these electrons is used to synthesize ATP.

A Chemiosmotic Process Converts Oxidation Energy into ATP on the Inner Mitochondrial Membrane [5](#)

Although the citric acid cycle constitutes part of aerobic metabolism, none of the reactions leading to the production of NADH and $FADH_2$ makes direct use of molecular oxygen; only in the final catabolic reactions that take place on the mitochondrial inner membrane is oxygen directly consumed. Nearly all of the energy available from burning carbohydrates, fats, and other foodstuffs in the earlier stages of oxidation is initially saved in the form of high-energy electrons removed from substrates by NAD^+ and FAD. These electrons, carried by NADH and $FADH_2$, are then combined with molecular oxygen by means of the respiratory chain. Because the large amount of energy released is harnessed by the enzymes in the inner membrane to drive the conversion of ADP + P_i to ATP, the term oxidative phosphorylation is used to describe this last series of reactions ([Figure 14-15](#)).

As previously mentioned, the generation of ATP by oxidative phosphorylation via the respiratory chain depends on a

chemiosmotic process. When it was first proposed in 1961, this mechanism explained a long-standing puzzle in cell biology. Nonetheless, the idea was so novel that it was some years before enough supporting evidence accumulated to make it generally accepted. It was originally believed that the energy for ATP synthesis via the respiratory chain was supplied by the same process that operates during substrate-level phosphorylations: that is, the energy of oxidation was thought to generate a high-energy bond between a phosphate group and some intermediate compound, and the conversion of ADP to ATP was thought to be driven by the energy released when this bond was broken. Despite intensive efforts, however, the expected intermediates could not be detected.

A summary of our present view of mitochondrial energy metabolism is presented in Figure 14-16. According to the *chemiosmotic hypothesis,* the high-energy chemical intermediates are replaced by a link between chemical processes ("chemi") and transport processes ("osmotic"from the Greek *osmos,* push)hence chemiosmotic coupling (Table 14-1). As the high-energy electrons from the hydrogens on NADH and $FADH_2$ are transported down the respiratory chain in the mitochondrial inner membrane, the energy released as they pass from one carrier molecule to the next is used to pump protons (H^+) across the inner membrane from the mitochondrial matrix into the intermembrane space. This creates an *electrochemical proton gradient* across the mitochondrial inner membrane, and the backflow of H^+ down this gradient is in turn used to drive the membrane-bound enzyme *ATP synthase,* which catalyzes the conversion of ADP + P_i to ATP, completing the process of oxidative phosphorylation.

In the remainder of this section we briefly outline the type of reactions that make oxidative phosphorylation possible, saving the details of the respiratory chain for later.

Electrons Are Transferred from NADH to Oxygen Through Three Large Respiratory Enzyme Complexes [6]

Although the mechanism by which energy is harvested by the respiratory chain differs from that in other catabolic reactions, the principle is the same. The energetically favorable reaction $H_2 + 1/2\ O_2 \rightarrow H_2O$ is made to occur in many small steps, so that most of the energy released can be converted into a storage form instead of being lost to the environment as heat. As in the formation of ATP and NADH in glycolysis or the citric acid cycle, this involves employing an indirect pathway for the reaction. The respiratory chain is unique in that the hydrogen atoms are first separated into protons and electrons. The electrons pass through a series of electron carriers in the mitochondrial inner membrane. At several steps along the way, protons and electrons are transiently recombined. But only when the electrons reach the end of this electron-transport chain are the protons returned permanently, when they are used to neutralize the negative charges created by the final addition of the electrons to the oxygen molecule (Figure 14-17).

We shall outline the oxidation process starting from NADH, the major collector of reactive electrons derived from the oxidation of food molecules. Each hydrogen atom consists of one electron (e^-) and one proton (H^+). The mechanism by which electrons are acquired by NADH was discussed in Chapter 2 and is shown in greater detail in Figure 14-18. As this example makes clear, each molecule of NADH carries a *hydride ion* (a hydrogen atom plus an extra electron, which we can denote as $H:^-$, illustrating each of its two electrons as a dot), rather than a single hydrogen atom. Because protons are freely available in aqueous solutions, however, carrying the hydride ion on NADH is equivalent to carrying two hydrogen atoms, or a hydrogen molecule ($H:^- + H^+ \rightarrow H_2$).

The process of electron transport begins when the hydride ion is removed from NADH to regenerate NAD^+ and is converted into a proton and two electrons ($H:^- \rightarrow H^+ + 2\ e^-$). The two electrons are passed to the first of the more than 15 different electron carriers in the respiratory chain. The electrons start with very high energy and gradually lose it as they pass along the chain. For the most part, the electrons pass from one metal atom to another, each metal atom being tightly bound to a protein molecule, which alters the electron affinity of the metal atom. The various types of electron carriers in the respiratory chain will be discussed in detail later. Most important, the many proteins involved are grouped into three large *respiratory enzyme complexes,* each containing transmembrane proteins that hold the complex firmly in the mitochondrial inner membrane. Each complex in the chain has a greater affinity for electrons than its predecessor, and electrons pass sequentially from one complex to another until they are finally transferred to oxygen, which has the greatest affinity of all for electrons.

Energy Released by the Passage of Electrons Along the Respiratory Chain Is Stored as an Electrochemical Proton Gradient Across the Inner Membrane [7]

Oxidative phosphorylation is made possible by the close association of the electron carriers with protein molecules. The proteins guide the electrons along the respiratory chain so that the electrons move sequentially from one enzyme complex to another - with no short circuits. Most important, the transfer of electrons is coupled to oriented H^+ uptake and release and to allosteric changes in selected protein molecules. The net result is that the energetically favorable flow of electrons pumps H^+ across the inner membrane, from the matrix space to the intermembrane space. This movement of H^+ has two major consequences. (1) It generates a pH gradient across the inner mitochondrial membrane, with the pH higher in the matrix than in the cytosol, where the pH is generally close to 7. (Since small molecules equilibrate freely across the outer membrane of the mitochondrion, the pH in the intermembrane space is the same as in the cytosol.) (2) It generates a voltage gradient (membrane potential) across the inner mitochondrial membrane, with the inside negative and the outside positive (as a result of the net outflow of positive ions).

The pH gradient (DpH) drives H^+ back into the matrix and OH^- out of the matrix and thus reinforces the effect of the membrane potential (D V), which acts to attract any positive ion into the matrix and to push any negative ion out. Together, the DpH and the D V are said to constitute an electrochemical proton gradient (Figure 14-19).

The electrochemical proton gradient exerts a proton-motive force, which can be measured in units of millivolts (mV). Since each DpH of 1 pH unit has an effect equivalent to a membrane potential of about 60 mV, the total proton-motive force equals D V - 60(DpH). In a typical cell the proton-motive force across the inner membrane of a respiring mitochondrion is about 200 mV and is made up of a membrane potential of about 140 mV and a pH gradient of about -1 pH unit.

The Energy Stored in the Electrochemical Proton Gradient Is Used to Produce ATP and to Transport Metabolites and Inorganic Ions into the Matrix Space 8

The mitochondrial inner membrane contains an unusually high proportion of protein, being approximately 70% protein and 30% phospholipid by weight. Many of the proteins belong to the electron-transport chain, which establishes the electrochemical proton gradient across the membrane. Another major component is the enzyme *ATP synthase,* which catalyzes the synthesis of ATP. This is a large protein complex through which H^+ flows down its electrochemical gradient into the matrix. Like a turbine, ATP synthase converts one form of energy to another, synthesizing ATP from ADP and P_i in the mitochondrial matrix in a reaction that is coupled to the inward flow of H^+ (Figure 14-20).

ATP synthesis is not the only process that is driven by the electrochemical H^+ gradient. The enzymes in the mitochondrial matrix, where the citric acid cycle and other metabolic reactions take place, must be supplied with high concentrations of substrates, and ATP synthase must be supplied with ADP and phosphate. Thus many charged substrates must be transported across the inner membrane. This is achieved by various membrane carrier proteins, many of which actively transport specific molecules against their electrochemical gradients, a process that requires an input of energy. As discussed in Chapter 11, the energy often comes from *co-transporting* another molecule down its electrochemical gradient. The transport of ADP into the matrix space, for example, is mediated by an ADP-ATP antiport system: for each ADP molecule that moves in, an ATP molecule moves out in a process driven by the voltage gradient (the net outward movement of one negative charge is favorable). The transport of phosphate into the matrix space is mediated by a carrier protein that couples the inward movement of phosphate to the inward flow of H^+ down its electrochemical gradient so that the phosphate is dragged in. Pyruvate is transported into the matrix in the same way (Figure 14-21). The electrochemical H^+ gradient is also used to import Ca^{2+}, which is thought to be important in regulating the activity of selected mitochondrial enzymes; the import of Ca^{2+} into mitochondria may also be important for removing Ca^{2+} from the cytosol when cytosolic Ca^{2+} levels become dangerously high.

The more energy from the electrochemical proton gradient is used to transport molecules and ions into the mitochondrion, the less there is to drive the ATP synthase. If isolated mitochondria are incubated in a high concentration of Ca^{2+}, for example, they cease ATP production completely; all the energy in their electrochemical proton gradient is diverted to pumping Ca^{2+} into the matrix. Similarly, in certain specialized cells the electrochemical proton gradient is short-circuited so that the mitochondria produce heat instead of ATP, as we discuss later. In general, the use of the energy stored in the electrochemical proton gradient is regulated by cells so that it is directed toward those activities that are most needed at the time.

The Rapid Conversion of ADP to ATP in Mitochondria Maintains a High Ratio of ATP to ADP in Cells 8

Because of the antiporter in the inner membrane that pumps ADP into the matrix space in exchange for ATP (see Figure 14-21), ADP molecules produced by ATP hydrolysis in the cytosol rapidly enter mitochondria for recharging, while the ATP molecules

formed in the mitochondrial matrix by oxidative phosphorylation are rapidly pumped into the cytosol where they are needed. A typical ATP molecule in the human body shuttles into and out of a mitochondrion for recharging (as ADP) thousands of times a day, keeping the concentration of ATP in a cell about 10 times higher than that of ADP.

As discussed in <u>Chapter 2</u>, biosynthetic enzymes in cells guide their substrates along specific reaction paths, often driving energetically unfavorable reactions by coupling them to the energetically favorable hydrolysis of ATP (see <u>Figure 2-29</u>). The ATP pool is thereby used to drive cellular processes in much the same way that a battery can be used to drive electric engines: if the activity of the mitochondria is halted, ATP levels fall and the cell's battery runs down, so that, eventually, energetically unfavorable reactions can no longer be driven by ATP hydrolysis.

It might seem that this state would not be reached until the concentration of ATP is zero, but in fact it is reached much sooner than that, at a concentration of ATP that depends on the concentrations of ADP and P_i. To explain why, we must consider some elementary principles of thermodynamics.

The Difference Between D $G°$ and D G: A Large Negative Value of D G Is Required for ATP Hydrolysis to Be Useful to the Cell <u>9</u>

The second law of thermodynamics states that chemical reactions proceed spontaneously in the direction that corresponds to an increase in the disorder of the *universe*. In <u>Chapter 2</u> we noted that reactions that release energy to their surroundings as heat (such as the hydrolysis of ATP) tend to increase the disorder of the universe by increasing random molecular motions. For this reason reactions go in the direction that converts *free energy* (energy that is available to do work) into heat. Thus the reaction A $\rightleftharpoons$ B will go in the direction A $\rightarrow$ B when the associated free-energy change, D G, is negative, just as a tensed spring left to itself will relax and lose its stored energy to its surroundings as heat. For a chemical reaction, however, D G depends not only on the energy stored in each individual molecule but also on the concentrations of the molecules in the reaction mixture. This is because, for a reversible reaction A $\rightleftharpoons$ B, a large excess of B over A will tend to drive the reaction in the direction B $\rightarrow$ A; that is, there will be more molecules making the transition B $\rightarrow$ A than there are making the transition A $\rightarrow$ B. Just how much of a concentration difference is needed to compensate for a given amount of heat release is not obvious; it depends on *entropy* changes, which can be calculated as outlined in <u>Panel14-1</u>, pages 668-669.

The D G for a given reaction can be written as the sum of two parts: the first, called the standard free-energy change, D $G°$, depends on the intrinsic characters of the reacting molecules; the second depends on their concentrations. For the simple reaction A $\rightarrow$ B,

$$\Delta G = \Delta G° + RT \ln \frac{[B]}{[A]}$$

where [A] and [B] denote the concentrations of A and B, and ln is the natural logarithm. D $G°$ therefore equals the value of D G when the molar concentrations of A and B are equal (ln 1 = 0). Chemical equilibrium is reached when the concentration effect is just balanced by the effect of D $G°$, so that there is no net change of free energy to drive the reaction in either direction; then D $G = 0$, and so the concentrations of A and B are such that

$$-RT \ln \frac{[B]}{[A]} = \Delta G°$$

which means that there is chemical equilibrium when

$$\frac{[B]}{[A]} = e^{-\Delta G°/RT}$$

When ATP is hydrolyzed to ADP and P_i under the conditions that normally exist in a cell, the free-energy change is roughly -11

to -13 kcal/mole. This extremely favorable D *G* depends on having a high concentration of ATP in the cell compared to the concentration of ADP and P_i. When ATP, ADP, and P_i are all present at the same concentration of 1 mole/liter (so-called "standard conditions"), the D *G* for ATP hydrolysis is the *standard free-energy change*(D *G°*), which is only -7.3 kcal/mole. At much lower concentrations of ATP relative to ADP and P_i, D *G* will become zero. At this point the rate at which ADP and P_i will join to form ATP will be equal to the rate at which ATP hydrolyzes to form ADP and P_i. In other words, when D *G* = 0, the reaction is at *equilibrium* (Figure 14-22).

It is D *G,* not D *G°*, that indicates how far a reaction is from equilibrium and determines if it can be used to drive other reactions. Because the efficient conversion of ADP to ATP in mitochondria maintains such a high concentration of ATP relative to ADP and P_i, the ATP-hydrolysis reaction in cells is kept very far from equilibrium and D *G* is correspondingly very negative. Without this disequilibrium ATP hydrolysis could not be used to direct the reactions of the cell, and many biosynthetic reactions would run backward rather than forward.

Cellular Respiration Is Remarkably Efficient [10]

By means of oxidative phosphorylation, each pair of electrons in NADH is thought to provide energy for the formation of about 2.5 molecules of ATP. The pair of electrons in $FADH_2$, being at a lower energy, generates only about 1.5 ATP molecules. In all, about 10 molecules of ATP can be formed from each molecule of acetyl CoA that enters the citric acid cycle, which means that about 20 ATP molecules are produced from 1 molecule of glucose and 84 ATP molecules from 1 molecule of palmitate, a 16-carbon fatty acid. If one includes the energy-yielding reactions that occur before acetyl CoA is formed, the complete oxidation of 1 molecule of glucose gives a net yield of about 30 ATPs, while the complete oxidation of 1 molecule of palmitate gives a net yield of about 110 ATPs. These numbers are approximate maximal values. As previously discussed, the actual amount of ATP made in the mitochondrion depends on what fraction of the electrochemical gradient energy is used for purposes other than ATP synthesis.

When the free-energy changes for burning fats and carbohydrates directly into CO_2 and H_2O are compared to the total amount of energy generated and stored in the phosphate bonds of ATP during the corresponding biological oxidations, it is seen that the efficiency with which oxidation energy is converted into ATP bond energy is often greater than 40%. This is considerably better than the efficiency of most nonbiological energy-conversion devices. If cells worked with the efficiency of an electric motor or a gasoline engine (10-20%), an organism would have to eat voraciously in order to maintain itself. Moreover, since wasted energy is liberated as heat, large organisms would need more efficient mechanisms for giving up heat to the environment.

Students sometimes wonder why the chemical interconversions in cells follow such complex pathways. The oxidation of sugars to CO_2 plus H_2O could certainly be accomplished more directly, eliminating the citric acid cycle and many of the steps in the respiratory chain. Although this would have made respiration easier to learn, it would have been a disaster for the cell. Oxidation produces huge amounts of free energy, which can be utilized efficiently only in small bits. The complex oxidative pathways involve many intermediates, each differing only slightly from its predecessor. The energy released is thereby parceled out into small packets that can be efficiently converted to high-energy bonds in useful molecules such as ATP and NADH by means of coupled reactions (see Figure2-17).

Summary

The mitochondrion carries out most cellular oxidations and produces the bulk of the animal cell's ATP. The mitochondrial matrix space contains a large variety of enzymes, including those that convert pyruvate and fatty acids to acetyl CoA and those that oxidize this acetyl CoA to CO_2 through the citric acid cycle. Large amounts of NADH (and $FADH_2$) are produced by these oxidation reactions. The energy available from combining oxygen with the reactive electrons carried by NADH and $FADH_2$ is harnessed by an electron-transport chain in the mitochondrial inner membrane called the respiratory chain. The respiratory chain pumps H^+ out of the matrix to create a transmembrane electrochemical proton (H^+) gradient, which includes contributions from both a membrane potential and a pH difference. The transmembrane gradient in turn is used both to synthesize ATP and to drive the active transport of selected metabolites across the mitochondrial inner membrane. The combination of these reactions is responsible for an efficient ATP-ADP exchange between the mitochondrion and the cytosol that keeps the cell's ATP pool highly charged, so that ATP can be used to drive many of the cell's energy-requiring reactions.

Figure 14-6. Fractionation of purified mitochondria into separate components. These techniques have made it possible to study the different proteins in each mitochondrial compartment. The method shown, which allows the processing of large numbers of mitochondria at the same time, takes advantage of the fact that in media of low osmotic strength water flows into mitochondria and greatly expands the matrix space (*yellow*). While the cristae of the inner membrane allow it to unfold to accommodate the expansion, the outer membranewhich has no folds to begin withbreaks, releasing a structure composed of only the inner membrane and the matrix.

100 nm
Matrix. The matrix contains a highly concentrated mixture of hundreds of enzymes, including those required for the oxidation of pyruvate and fatty acids and for the citric acid cycle. The matrix also contains several identical copies of the mitochondrial DNA genome, special mitochondrial ribosomes, tRNAs, and various enzymes required for expression of the mitochondrial genes.

Inner membrane. The inner membrane is folded into numerous cristae, which greatly increases its total surface area. It contains proteins with three types of functions: (1) those that carry out the oxidation reactions of the respiratory chain, (2) an enzyme complex called *ATP synthase* that makes ATP in the

Inner membrane. The inner membrane is folded into numerous cristae, which greatly increases its total surface area. It contains proteins with three types of functions: (1) those that carry out the oxidation reactions of the respiratory chain, (2) an enzyme complex called *ATP synthase* that makes ATP in the matrix, and (3) specific transport proteins that regulate the passage of metabolites into and out of the matrix. Since an electrochemical gradient that drives the ATP synthase is established across this membrane by the respiratory chain, it is important that the membrane be impermeable to most small ions.

Outer membrane. Because it contains a large channel-forming protein (called porin), the outer membrane is permeable to all molecules of 5000 daltons or less. Other proteins in this membrane include enzymes involved in mitochondrial lipid synthesis and enzymes that convert lipid substrates into forms that are subsequently metabolized in the matrix.

Intermembrane space. This space contains several enzymes that use the ATP passing out of the matrix to phosphorylate other nucleotides.
Figure 14-7. The general organization of a mitochondrion. In the liver an estimated 67% of the total mitochondrial protein is located in the matrix, 21% is located in the inner membrane, 6% in the outer membrane, and 6% in the intermembrane space. As indicated below, each of these four regions contains a special set of proteins that mediate distinct functions. (Courtesy of Daniel S. Friend.)
Figure 14-8. Acetyl coenzyme A (acetyl CoA). This central intermediate is produced during the breakdown of foodstuffs in the mitochondrion. A space-filling model is shown above a common abbreviation (see also Figure2-20). The sulfur atom (S) forms a thioester linkage to acetate. Because this is a "high-energy" linkage, which releases a large amount of free energy when it is hydrolyzed, the acetate group can be readily transferred to other molecules, such as oxaloacetate (see Figure 14-14).

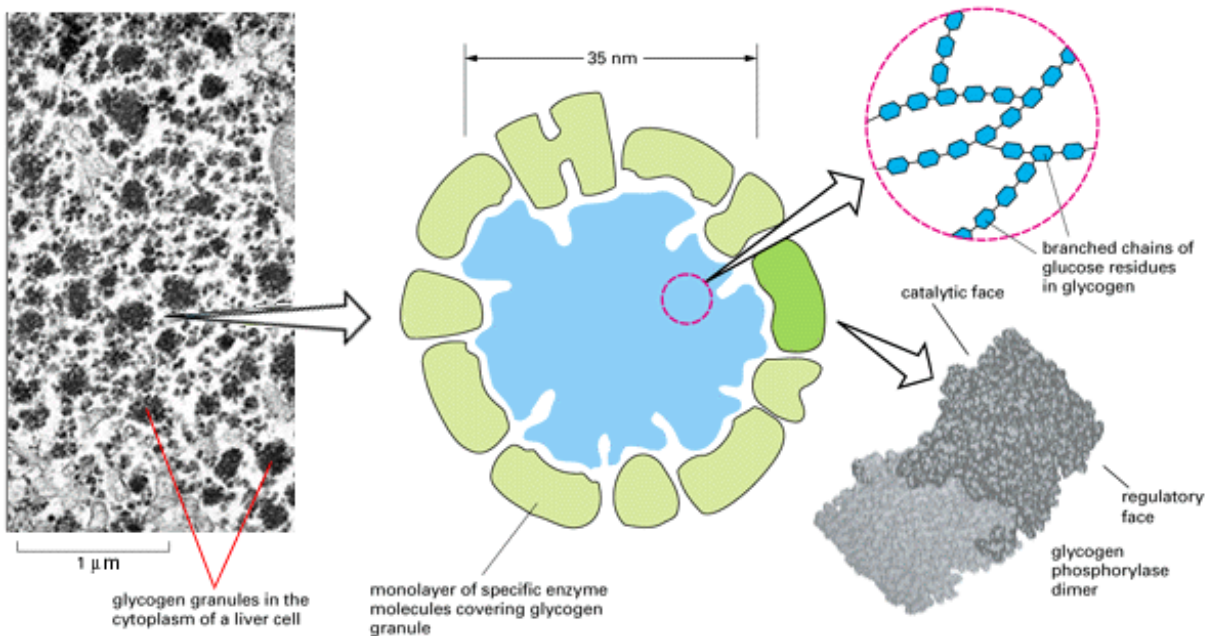
Figure 14-11. The fatty acid oxidation cycle. The cycle is catalyzed by a series of four enzymes in the mitochondrial matrix. Each turn of the cycle shortens the fatty acid chain by two carbons (shown in *red*), as indicated, and generates one molecule of acetyl CoA and one molecule each of NADH and FADH$_2$. The NADH is freely soluble in the matrix. The FADH$_2$, in contrast, remains tightly bound to the enzyme *fatty acyl-CoA dehydrogenase;*its two electrons will be rapidly transferred to the respiratory chain in the mitochondrial inner membrane, regenerating FAD.


Figure 14-12. Electron micrograph and schematic drawing of a glycogen granule. Glycogen is the major storage form of carbohydrate in vertebrate cells. It is a polymer of glucose, and each glycogen granule is a single, highly branched molecule. The synthesis and degradation of glycogen are catalyzed by enzymes bound to the granule surface, including the synthetic

enzyme *glycogen synthase* and the degradative enzyme *glycogen phosphorylase.* (Courtesy of Robert Fletterick and Daniel S. Friend.)
Figure 14-13. The reactions carried out by the pyruvate dehydrogenase complex. The complex converts pyruvate to acetyl CoA in the mitochondrial matrix; NADH is also produced in this reaction. A, B, and C are the three enzymes *pyruvate decarboxylase, lipoamide reductase-transacetylase,* and *dihydrolipoyl dehydrogenase,* whose activities are coupled as shown. The structure of the complex, which is larger than a ribosome, is shown in Figure2-41; the complex also contains a protein kinase and a protein phosphatase that regulate its activity, turning it off whenever ATP levels are high.
Figure 14-14. The citric acid cycle. The intermediates are shown as their free acids, although the carboxyl groups are actually ionized. Each of the indicated steps is catalyzed by a different enzyme located in the mitochondrial matrix. The two carbons from acetyl CoA that enter this turn of the cycle (shadowed in *red*) will be converted to CO_2 in subsequent turns of the cycle: it is the two carbons shadowed in *blue* that are converted to CO_2 in this cycle. Three molecules of NADH are formed. The GTP molecule produced can be converted to ATP by the exchange reaction GTP + ADP $\rightarrow$ GDP + ATP. The molecule of $FADH_2$ formed remains protein-bound as part of the *succinate dehydrogenase complex* in the mitochondrial inner membrane; this complex feeds the electrons acquired by $FADH_2$ directly to ubiquinone (see below).
Figure 14-15. The major net energy conversion catalyzed by the mitochondrion. In this process of *oxidative phosphorylation,* the mitochondrial inner membrane serves as a device that converts one form of chemical bond energy to another, changing a major part of the energy of NADH (and $FADH_2$) oxidation into phosphate-bond energy in ATP.
Figure 14-16. A summary of mitochondrial energy metabolism. Pyruvate and fatty acids enter the mitochondrion, are broken down to acetyl CoA, and are then metabolized by the citric acid cycle, which produces NADH (and $FADH_2$, which is not shown). In the process of oxidative phosphorylation, high-energy electrons from NADH (and $FADH_2$) are then passed to oxygen by means of the respiratory chain in the inner membrane, producing ATP by a chemiosmotic mechanism.NADH generated by glycolysis in the cytosol also passes electrons to the respiratory chain (not shown). Since NADH cannot pass across the mitochondrial inner membrane, the electron transfer from cytosolic NADH must be accomplished indirectly by means of one of several "shuttle" systems that transport another reduced compound into the mitochondrion; after being oxidized, this compound is returned to the cytosol, where it is reduced by NADH again.

Table 14-1. Chemiosmotic Coupling

The chemiosmotic hypothesis, as proposed in the early 1960s, consisted of four independent postulates. In terms of mitochondrial function they were as follows:

1. The mitochondrial respiratory chain in the inner membrane is proton translocating; it pumps H^+ out of the matrix space when electrons are transported along the chain.

2. The mitochondrial ATP synthase also translocates protons across the inner membrane. Being reversible, it can use the energy of ATP hydrolysis to pump H^+ across the membrane, but if a large enough electrochemical proton gradient is present, protons flow in the reverse direction through the complex and drive ATP synthesis.

3. The mitochondrial inner membrane is equipped with a set of carrier proteins that mediate the entry and exit of essential metabolites and selected inorganic ions.

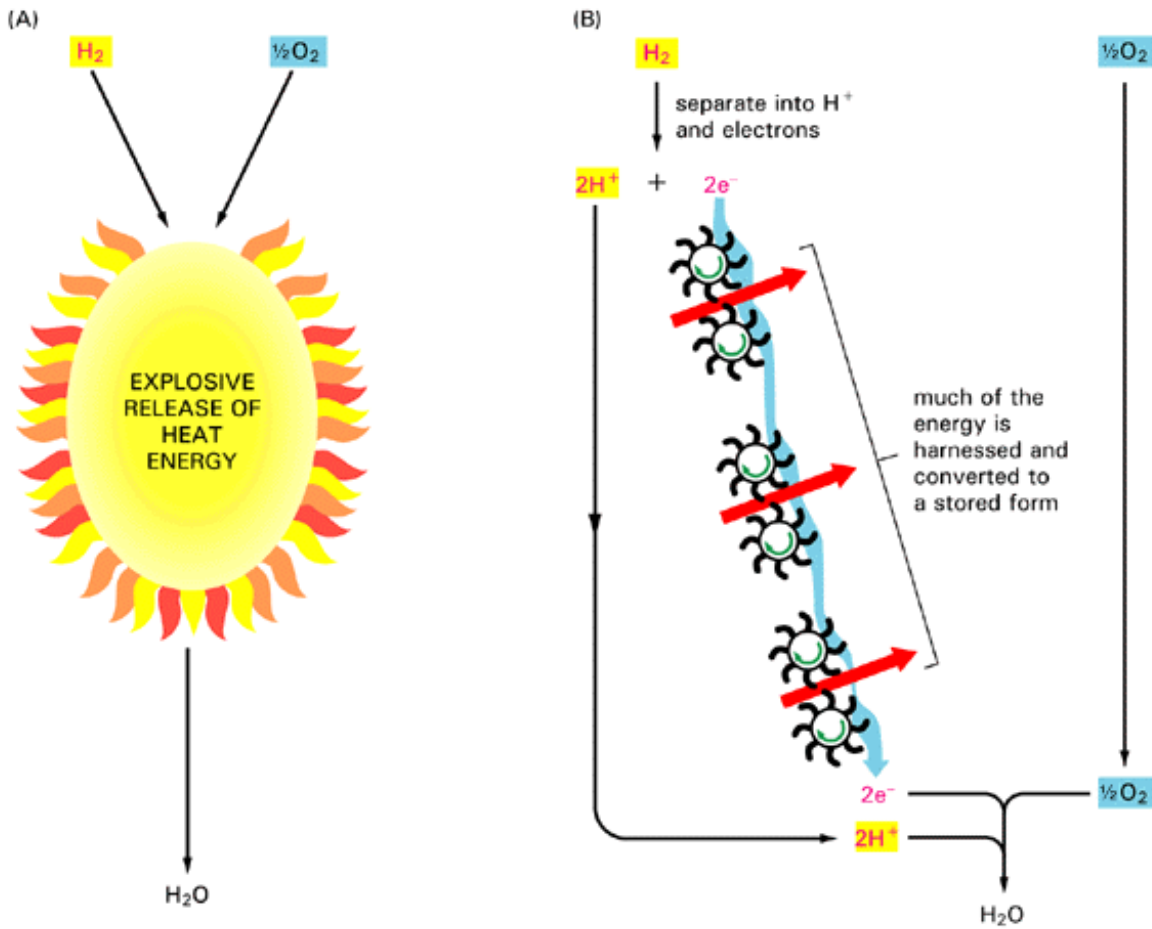
4. The mitochondrial inner membrane is otherwise impermeable to H^+, OH^-, and generally to anions and cations.


Figure 14-17. Comparison of biological oxidations with combustion. Highly schematic illustration showing how most of the energy that would be released as heat if hydrogen were burned (A) is instead harnessed and stored in a form useful to the cell by means of the electron-transport chain in the mitochondrial inner membrane (B). The rest of the oxidation energy is released as heat by the mitochondrion. In reality, the protons and electrons shown are removed from hydrogen atoms that are covalently linked to NADH or FADH$_2$ molecules (see Figure 14-18).

Figure 14-19. **The two components of the electrochemical proton gradient.** The total proton-motive force across the mitochondrial inner membrane consists of a large force due to the membrane potential (traditionally designated DY by experts, but designated D *V* in this text) and a smaller force due to the H$^+$ concentration gradient (DpH). Both forces act to drive H$^+$ into the matrix space.
Figure 14-20. The general mechanism of oxidative phosphorylation. As a high-energy electron is passed along the electron-transport chain, some of the energy released is used to drive three respiratory enzyme complexes that pump H+ out of the matrix space. The resulting electrochemical proton gradient across the inner membrane drives H+ back through the ATP synthase, a transmembrane protein complex that uses the energy of the H+ flow to synthesize ATP from ADP and P$_i$ in the matrix.
Figure 14-21. Some of the active transport processes driven by the electrochemical proton gradient across the mitochondrial inner membrane. The charge on each of the transported molecules is indicated for comparison with the membrane potential, which is negative inside, as shown. The outer membrane is freely permeable to all of these compounds. Membrane transport mechanisms are discussed in Chapter 11.

Panel 14-1: Free energy and biological reactions

THE IMPORTANCE OF FREE ENERGY FOR CELLS

Life is possible because of the complex network of interacting chemical reactions occurring in every cell. In viewing the metabolic pathways that comprise this network, one might suspect that the cell has had the ability to evolve an enzyme to carry out any reaction that it needs. But this is not so. Although enzymes are powerful catalysts, they can speed up only those reactions that are thermodynamically possible; other reactions proceed in cells only because they are *coupled* to very favorable reactions that drive them. The question of whether a reaction can occur spontaneously, or instead needs to be coupled to another reaction, is central to cell biology. The answer is obtained by reference to a quantity called the *free energy*: the total change in free energy during a set of reactions determines whether or not the entire reaction sequence can occur. In this panel we shall explain some of the fundamental ideas—derived from a special branch of chemistry and physics called *thermodynamics*—that are required for understanding what free energy is and why it is so important to cells.

ENERGY RELEASED BY CHANGES IN CHEMICAL BONDING IS CONVERTED INTO HEAT
UNIVERSE

An *enclosed system* is defined as a collection of molecules that does not exchange matter with the rest of the universe (for example, the "cell in a box" shown above). Any such system will contain molecules with a total energy E. This energy will be distributed in a variety of ways: some as the translational energy of the molecules, some as their vibrational and rotational energies, but most as the bonding energies between the individual atoms that make up the molecules. Suppose that a reaction occurs in the system. The first law of thermodynamics places a constraint on what types of reactions are possible: it states that "in any process, the total energy of the universe remains constant." For example, suppose that reaction A → B occurs somewhere in the box and releases a great deal of chemical bond energy. This energy will initially increase the intensity of molecular motions (translational, vibrational, and rotational) in the system, which is equivalent to raising its temperature. However, these increased motions will soon be transferred out of the system by a series of molecular collisions that heat up first the walls of the box and then the outside world (represented by the sea in our example). In the end, the system returns to its initial temperature, by which time all the chemical bond energy released in the box has been converted into heat energy and transferred out of the box to the surroundings. According to the first law, the change in the energy in the box (ΔE_{box}, which we shall denote as ΔE) must be equal and opposite to the amount of heat energy transferred, which we shall designate as h: that is, $\Delta E = -h$. Thus, the energy in the box (E) decreases when heat leaves the system.

E also can change during a reaction due to work being done on the outside world. For example, suppose that there is a small increase in the volume (ΔV) of the box during a reaction. Since the walls of the box must push against the constant pressure (P) in the surroundings in order to expand, this does work on the outside world and requires energy. The energy used is $P(\Delta V)$, which according to the first law must decrease the energy in the box (E) by the same amount. In most reactions chemical bond energy is converted into both work and heat. *Enthalpy* (H) is a composite function that includes both of these ($H = E + PV$). To be rigorous, it is the change in enthalpy (ΔH) in an enclosed system and not the change in energy that is equal to the heat transferred to the outside world during a reaction. Reactions in which H decreases release heat to the surroundings and are said to be "exothermic," while reactions in which H increases absorb heat from the surroundings and are said to be "endothermic." Thus, $-h = \Delta H$. However, the volume change is negligible in most biological reactions, so to a good approximation

$$-h = \Delta H \approx \Delta E$$

THE SECOND LAW OF THERMODYNAMICS

Consider a container in which 1000 coins are all lying heads up. If the container is shaken vigorously, subjecting the coins to the types of random motions that all molecules experience due to their frequent collisions with other molecules, one will end up with about half the coins oriented heads down. The reason for this reorientation is that there is only a single way in which the original orderly state of the coins can be reinstated (every coin must lie heads up), whereas there are many different ways (about 10^{298}) to achieve a disorderly state in which there is an equal mixture of heads and tails; in fact, there are more ways to achieve a 50-50 state than to achieve any other state. Each state has a probability of occurrence that is proportional to the number of ways it can be realized. The second law of thermodynamics states that "systems will change spontaneously from states of lower probability to states of higher probability." Since states of lower probability are more "ordered" than states of high probability, the second law can be restated: "the universe constantly changes so as to become more disordered."

THE ENTROPY, S

The second law (but not the first law) allows one to predict the *direction* of a particular reaction. But to make it useful for this purpose, one needs a convenient measure of the probability or, equivalently, the degree of disorder of a state. The entropy (S) is such a measure. It is a logarithmic function of the probability such that the *change in entropy* (ΔS) that occurs when the reaction A → B converts one mole of A into one mole of B is

$$\Delta S = R \ln p_B / p_A$$

where p_A and p_B are the probabilities of the two states A and B, R is the gas constant (2 cal deg^{-1} mole^{-1}), and ΔS is measured in entropy units (eu). In our initial example of 1000 coins, the relative probability of all heads (state A) versus half heads and half tails (state B) is equal to the ratio of the number of different ways that the two results can be obtained. One can calculate that $p_A = 1$ and $p_B = 1000!/(500! \times 500!) = 10^{298}$. Therefore, the entropy change for the reorientation of the coins when their container is vigorously shaken and an equal mixture of heads and tails is obtained is $R \ln (10^{298})$, or about 1370 eu per mole of such containers (6×10^{23} containers). We see that, because ΔS defined above is positive for the transition from state A to state B ($p_B / p_A > 1$), reactions with a large *increase* in S (that is, for which ΔS > 0) are favored and will occur spontaneously.

As discussed in Chapter 2, heat energy causes the random commotion of molecules. Because the transfer of heat from an enclosed system to its surroundings increases the number of different arrangements that the molecules in the outside world can have, it increases their entropy. It can be shown that the release of a fixed quantity of heat energy has a greater disordering effect at low temperature than at high temperature and that the value of ΔS for the surroundings, as defined above (ΔS$_{sea}$), is precisely equal to the amount of heat transferred to the surroundings from the system (h) divided by the absolute temperature (T):

$$\Delta S_{sea} = h/T$$

THE GIBBS FREE ENERGY, G

When dealing with an enclosed biological system, one would like to have a simple way of predicting whether a given reaction will or will not occur spontaneously in the system. We have seen that the crucial question is whether the entropy change for the universe is positive or negative when that reaction occurs. In our idealized system, the cell in a box, there are two separate components to the entropy change of the universe—the entropy change for the system enclosed in the box and the entropy change for the surrounding "sea"—and both must be added together before any prediction can be made. For example, it is possible for a reaction to absorb heat and thereby decrease the entropy of the sea (ΔS$_{sea}$ < 0) and at the same time to cause such a large degree of disordering inside the box (ΔS$_{box}$ > 0) that the total $\Delta S_{universe} = \Delta S_{sea} + \Delta S_{box}$ is greater than 0. In this case the reaction will occur spontaneously, even though the sea gives up heat to the box during the reaction. An example of such a reaction is the dissolving of sodium chloride in a beaker containing water (the "box"), which is a spontaneous process even though the temperature of the water drops as the salt goes into solution.

Chemists have found it useful to define a number of new "composite functions" that describe *combinations* of physical properties of a system. The properties that can be combined include the temperature (T), pressure (P), volume (V), energy (E), and entropy (S). The enthalpy (H) is one such composite function. But by far the most useful composite function for biologists is the *Gibbs free energy, G*. It serves as an accounting device that allows one to deduce the entropy change of the universe resulting from a chemical reaction in the box, while avoiding any separate consideration of the entropy change in the sea. The definition of G is

$$G = H - TS$$

where, for a box of volume V, H is the enthalpy described above ($E + PV$), T is the absolute temperature, and S is the entropy. Each of these quantities applies to the inside of the box only. The change in free energy of a reaction in the box (the G of the products minus the G of the starting materials) is denoted as ΔG and, as we shall now demonstrate, it is a direct measure of the amount of disorder that is created in the universe when the reaction occurs.

At constant temperature the change in free energy (ΔG) during a reaction equals $\Delta H - T\Delta S$. Remembering that $\Delta H = -h$, the heat absorbed from the sea, we have

$$-\Delta G = -\Delta H + T\Delta S$$
$$-\Delta G = h + T\Delta S, \text{ so } -\Delta G/T = h/T + \Delta S$$

But h/T is equal to the entropy change of the sea (ΔS$_{sea}$), and the ΔS in the above equation is ΔS$_{box}$. Therefore

$$-\Delta G/T = \Delta S_{sea} + \Delta S_{box} = \Delta S_{universe}$$

We conclude that **the free-energy change is a direct measure of the entropy change of the universe.** A reaction will proceed in the direction that causes the change in the free energy (ΔG) to be less than zero, because in this case there will be a positive entropy change in the universe when the reaction occurs.

For a complex set of coupled reactions involving many different molecules, the total free-energy change can be computed simply by adding up the free energies of all the different molecular species after the reaction and comparing this value to the sum of free energies before the reaction; for common substances the required free-energy values can be found from published tables. In this way one can predict the direction of a reaction and thereby readily check the feasibility of any proposed mechanism. Thus, for example, from the observed values for the magnitude of the electrochemical proton gradient across the inner mitochondrial membrane and the ΔG for ATP hydrolysis inside the mitochondrion, one can be certain that ATP synthase requires the passage of more than one proton for each molecule of ATP that it synthesizes.

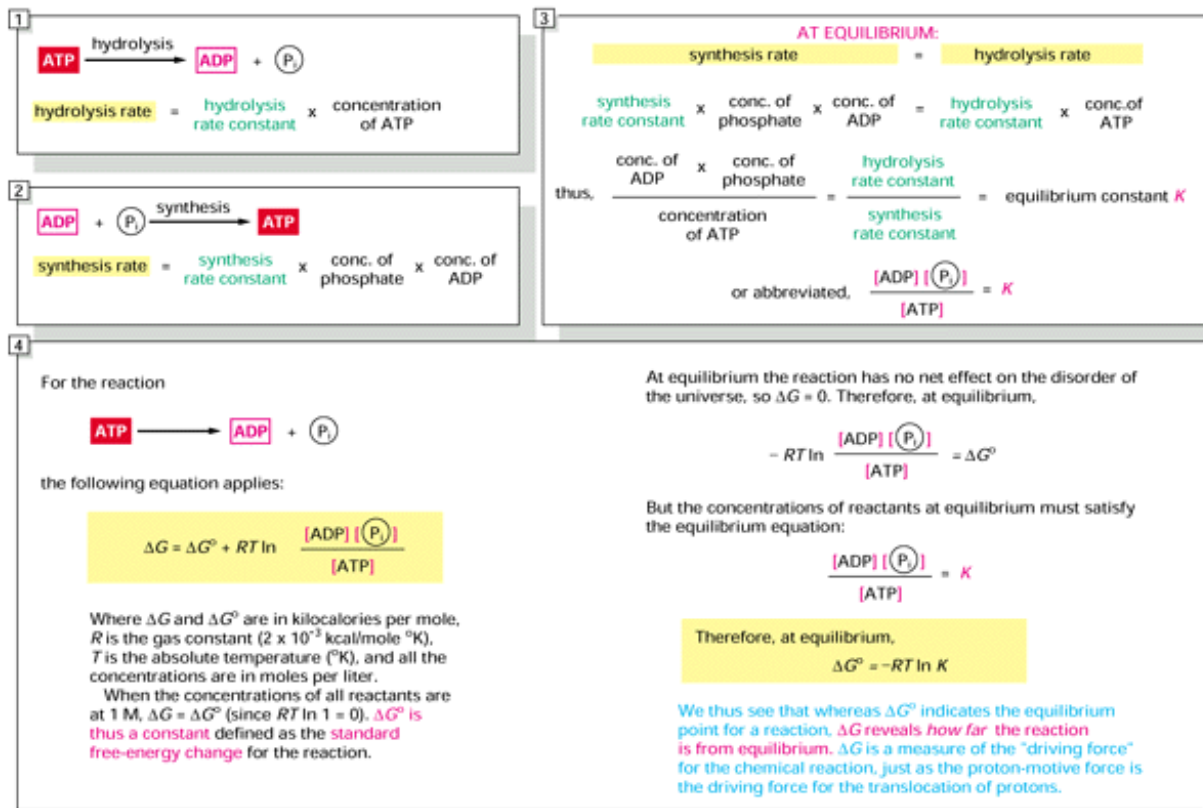
The value of ΔG for a reaction is a direct measure of how far the reaction is from equilibrium. The large negative value for ATP hydrolysis in a cell merely reflects the fact that cells keep the ATP hydrolysis reaction as much as 10 orders of magnitude away from equilibrium. If a reaction reaches equilibrium, ΔG = 0, the reaction then proceeds at precisely equal rates in the forward and backward direction. For ATP hydrolysis, equilibrium is reached when the vast majority of the ATP has been hydrolyzed, as occurs in a dead cell.


Figure 14-22. The basic relationship between free-energy changes and equilibrium, as illustrated by the ATP hydrolysis reaction. The rate constants in boxes (1) and (2) are determined from experiments in which product accumulation is measured as a function of time. The equilibrium constant shown here, *K,* is in units of moles per liter. (See Panel14-1, pp. 668-669, for a discussion of free energy and Figure 3-9 for a definition of the equilibrium constant.)

The Respiratory Chain and ATP Synthase 11

Introduction

Having considered in general terms how mitochondria function, let us now look in more detail at the respiratory chain - the electron-transport chain that is so crucial to all oxidative metabolism. Most of the elements of the chain are intrinsic components of the inner mitochondrial membrane, and they provide some of the clearest examples of the many complicated interactions that can occur among the individual proteins located in a biological membrane.

Functional Inside-out Particles Can Be Isolated from Mitochondria 12

The respiratory chain is relatively inaccessible to experimental manipulation in intact mitochondria. By disrupting mitochondria with ultrasound, however, it is possible to isolate functional *submitochondrial particles,* which consist of broken cristae that have resealed into small closed vesicles about 100 nm in diameter (Figure 14-23). When these submitochondrial particles are examined in an electron microscope, their outside surfaces are seen to be studded with tiny spheres attached to the membrane by stalks (Figure 14-24). In intact mitochondria these lollipoplike structures are located on the *inner* (matrix) side of the inner membrane. Thus the submitochondrial particles are inside-out vesicles of inner membrane, with what was previously their matrix-facing surface exposed to the surrounding medium. As a result, they can readily be provided with the membrane-impermeable metabolites that would normally be present in the matrix space. When NADH, ADP, and inorganic phosphate are added, such preparations transport electrons from NADH to O_2 and couple this oxidation to ATP synthesis, catalyzing the reaction $ADP + P_i \rightarrow ATP$. This cell-free system provides an assay that makes it possible to purify the many proteins responsible for oxidative phosphorylation in a functional form.

ATP Synthase Can Be Purified and Added Back to Membranes [13]

The first experiments to show that the various membrane proteins that catalyze oxidative phosphorylation can be separated without destroying their activity were performed in 1960. The tiny protein spheres studding the surface of submitochondrial particles were stripped from the particles, leaving the stem of the lollipop and the other inner membrane proteins still in the particle membrane. The stripped particles could still oxidize NADH in the presence of oxygen, but they could no longer synthesize ATP. On the other hand, the purified spheres on their own acted as ATPases, hydrolyzing ATP to ADP and P_i. When the purified spheres (referred to as $F_1ATPase$) were added back to stripped submitochondrial particles, however, the reconstituted particles once again made ATP from ADP and P_i.

Subsequent work showed that the $F_1ATPase$ is part of a larger transmembrane complex (~500,000 daltons) containing at least nine different polypeptide chains (Figure 14-25), which is now known as ATP synthase (also called $F_0F_1ATPase$). ATP synthase constitutes about 15% of the total inner membrane protein, and very similar enzyme complexes are present in both chloroplast and bacterial membranes. The transmembrane portion of the protein complex acts as a H^+ carrier, and the $F_1ATPase$ portion (the lollipop head) normally synthesizes ATP when protons pass through it down their electrochemical gradient. When separated from the H^+ carrier, however, the $F_1ATPase$ goes into reverse and catalyzes only ATP hydrolysis.

One of the most convincing demonstrations of the function of ATP synthase came from an experiment performed in 1974. By that time methods had been developed for transferring detergent-solubilized integral membrane proteins into lipid vesicles (liposomes) formed from purified phospholipids. It thus became possible to form a hybrid membrane that contained both a complete purified mitochondrial ATP synthase and bacteriorhodopsin (a bacterial light-driven H^+ pump, discussed in Chapter 10) but none of the proteins of the mitochondrial respiratory chain. When these vesicles were exposed to light, the H^+ pumped into the vesicle lumen by the bacteriorhodopsin flowed back out through the ATP synthase, causing ATP to be made in the medium outside (Figure 14-26). Be-cause a direct interaction between a bacterial H^+ pump and a mammalian ATP synthase seems highly unlikely, this experiment strongly suggests that in mitochondria the proton translocation driven by electron transport and the ATP synthesis are separate events.

ATP Synthase Can Function in Reverse to Hydrolyze ATP and Pump H^+ [13]

ATP synthase can either use the energy of ATP hydrolysis to pump H^+ across the inner mitochondrial membrane or it can harness the flow of H^+ down an electrochemical proton gradient to make ATP (Figure 14-27). It thus acts as a *reversible coupling device,* interconverting electrochemical-proton-gradient and chemical-bond energies. Its direction of action depends on the balance between the steepness of the electrochemical proton gradient and the local D G for ATP hydrolysis.

The enzyme complex is called ATP synthase because it is normally driven by the large electrochemical proton gradient maintained by the respiratory chain (see Figure 14-20) to make most of the cell's ATP. The exact number of protons needed to make each ATP molecule is not known with certainty. To facilitate the calculations to be described below, however, we shall assume that one molecule of ATP is made by the ATP synthase for every three protons driven through it.

Whether the ATP synthase works in its ATP-synthesizing or its ATP-hydrolyzing direction at any instant depends on the exact balance between the favorable free-energy change for moving the three protons across the membrane into the matrix space (D G $_{3H^+}$, which is less than zero) and the unfavorable free-energy change for ATP *synthesis* in the matrix (D G $_{ATP\ synthesis}$, which is greater than zero). As previously discussed, the value of D G $_{ATP\ synthesis}$ depends on the exact concentrations of the three reactants ATP, ADP, and P_i in the mitochondrial matrix space (see Figure 14-22). The value of D G $_{3H^+}$, on the other hand, is proportional to the value of the proton-motive force across the inner mitochondrial membrane. The following example will help to explain how the balance between these two free-energy changes affects the ATP synthase.

As explained in the legend to Figure 14-27, a single H^+ moving into the matrix down an electrochemical gradient of 200 mV liberates 4.6 kcal/mole of free energy, while the movement of three protons liberates three times this much free energy (D G $_{3H^+}$ = -13.8 kcal/mole). Thus, if the proton-motive force remains constant at 200 mV, the ATP synthase will synthesize ATP until a ratio of ATP to ADP and P_i is reached where D G $_{ATP\ synthesis}$ is just equal to +13.8 kcal/mole (here D G $_{ATP\ synthesis}$ + D G $_{3H^+}$ = 0). At this point there will be no further net ATP synthesis or hydrolysis by the ATP synthase.

Suppose that a large amount of ATP is suddenly hydrolyzed by energy-requiring reactions in the cytosol - causing the ATP: ADP ratio in the matrix to fall. Now the value of D $G_{\text{ATP synthesis}}$ will decrease (see Figure 14-22), and ATP synthase will begin to synthesize ATP again to restore the original ATP:ADP ratio. Alternatively, if the proton-motive force drops suddenly and is then maintained at a constant 160 mV, D G_{3H^+} will change to -11.0 kcal/mole. As a result, ATP synthase will start hydrolyzing some of the ATP in the matrix until a new balance of ATP to ADP and P_i is reached (where D $G_{\text{ATP synthesis}}$ = +11.0 kcal/mole) and so on.

In many bacteria ATP synthase is routinely reversed in a transition between aerobic and anaerobic metabolism, as we shall see later. The reversibility of the ATP synthase is a property shared by other membrane proteins that couple ion movement to ATP synthesis or hydrolysis. Both the Na^+-K^+ pump and the Ca^{2+} pump described in Chapter 11, for example, hydrolyze ATP and use the energy released to pump specific ions across a membrane. If either of these pumps is exposed to an abnormally steep gradient of the ions it transports, however, it will act in reverse - synthesizing ATP from ADP and P_i instead of hydrolyzing it. Thus, like ATP synthase, such pumps are able to convert the electrochemical energy stored in a transmembrane ion gradient directly into phosphate bond energy in ATP.

The Respiratory Chain Pumps H$^+$ Across the Inner Mitochondrial Membrane 14

The respiratory chain embedded in the inner mitochondrial membrane normally generates the electrochemical proton gradient that drives ATP synthesis. The ability of the respiratory chain to translocate H^+ outward from the matrix space can be demonstrated experimentally under special conditions. A suspension of isolated mitochondria, for example, can be provided with a suitable substrate for oxidation, and the H^+ flow through ATP synthase can be blocked. In the absence of air the injection of a small amount of oxygen into such a preparation causes a brief burst of respiration, which lasts for 1 to 2 seconds before all the oxygen is consumed. During this respiratory burst a sudden acidification of the medium resulting from the extrusion of H^+ from the matrix space can be measured with a sensitive pH electrode.

In a similar experiment carried out with a suspension of submitochondrial particles, the medium becomes more basic when oxygen is injected, since H^+ is pumped *into* each vesicle because of its inside-out orientation.

Spectroscopic Methods Have Been Used to Identify Many Electron Carriers in the Respiratory Chain 15

Many of the electron carriers in the respiratory chain absorb visible light and change color when they are oxidized or reduced. In general, each has an absorption spectrum and reactivity that is distinct enough to allow its behavior to be traced spectroscopically even in crude mixtures. It was therefore possible to purify these components long before their exact functions were known. Thus the *cytochromes* were discovered in 1925 as compounds that undergo rapid oxidation and reduction in living organisms as disparate as bacteria, yeasts, and insects. By observing cells and tissues with a spectroscope, three types of cytochromes were identified by their distinctive absorption spectra and designated cytochromes a, b, and c. This nomenclature has survived even though cells are now known to contain several cytochromes of each type and the classification into types is not functionally important.

The cytochromes constitute a family of colored proteins that are related by the presence of a bound *heme group* whose iron atom changes from the ferric (Fe III) to the ferrous (Fe II) state whenever it accepts an electron. The heme group consists of a *porphyrin* ring with a tightly bound iron atom held by four nitrogen atoms at the corners of a square (Figure 14-28). A related porphyrin ring is responsible for the red color of blood and the green color of leaves, being bound to iron in hemoglobin and to magnesium in chlorophyll. The best understood of the many proteins in the respiratory chain is *cytochrome c,* whose three-dimensional structure has been determined by x-ray crystallography (Figure 14-29).

Iron-sulfur proteins are a second major family of electron carriers. In these proteins either two or four iron atoms are bound to an equal number of sulfur atoms and to cysteine side chains, forming an iron-sulfur center on the protein (Figure 14-30). There are more iron-sulfur centers than cytochromes in the respiratory chain, but their spectroscopic detection requires electron spin resonance (ESR) spectroscopy, and they are less well characterized.

The simplest of the electron carriers is a small hydrophobic molecule dissolved in the lipid bilayer known as *ubiquinone,* or *coenzyme Q.* A quinone (Q) can pick up or donate either one or two electrons, and it temporarily picks up a proton from the medium along with each electron that it carries (Figure 14-31).

In addition to six different hemes linked to cytochromes, more than six iron-sulfur centers, and ubiquinone, there are also two copper atoms and a flavin serving as electron carriers tightly bound to respiratory-chain proteins in the pathway from NADH to oxygen. The pathway involves about 40 different proteins in all. The order of the individual electron carriers in the chain has been determined by sophisticated spectroscopic measurements (Figure 14-32), and many of the proteins were initially isolated and characterized as individual polypeptides. A major advance in understanding the respiratory chain, however, was the later realization that most of the proteins are organized into three large enzyme complexes.

The Respiratory Chain Contains Three Large Enzyme Complexes Embedded in the Inner Membrane [16]

Membrane proteins are difficult to purify as intact complexes because they are insoluble in most aqueous solutions, and some of the detergents required to solubilize them can destroy normal protein-protein interactions. In the early 1960s, however, it was found that relatively mild ionic detergents, such as deoxycholate, will solubilize selected components of the mitochondrial inner membrane in their native form. This permitted the identification and purification of the three major membrane-bound respiratory enzyme complexes in the pathway from NADH to oxygen (Figure 14-33). As we shall see, each of these complexes acts as an electron-transport-driven H^+ pump; they were initially characterized, however, in terms of the electron carriers that they interact with and contain.

1. The NADH dehydrogenase complex is the largest of the respiratory enzyme complexes, with a mass of about 800,000 daltons and more than 22 polypeptide chains. It accepts electrons from NADH and passes them through a flavin and at least five iron-sulfur centers to ubiquinone, which transfers its electrons to a second respiratory enzyme complex, the *b-c_1 complex.*

2. The cytochrome b-c_1 complex contains at least 8 different polypeptide chains and is thought to function as a dimer of about 500,000 daltons. Each monomer contains three hemes bound to cytochromes and an iron-sulfur protein. The complex accepts electrons from ubiquinone and passes them on to cytochrome c, which carries its electron to the *cytochrome oxidase complex.*

The cytochrome oxidase complex (cytochrome aa_3) is the best characterized of the three complexes. It is isolated as a dimer of about 300,000 daltons; each monomer contains at least 9 different polypeptide chains, including two cytochromes and two copper atoms. The complex accepts electrons from cytochrome c and passes them to oxygen.

The cytochromes, iron-sulfur centers, and copper atoms can carry only one electron at a time. Yet each NADH donates two electrons, and each O_2 molecule must receive four electrons to produce water. There are several electron-collecting and electron-dispersing points along the electron-transport chain where these changes in electron number are accommodated.

An Iron-Copper Center in Cytochrome Oxidase Catalyzes Efficient O_2 Reduction [17]

Because oxygen has a high affinity for electrons, it releases a large amount of free energy when it is reduced to form water. Thus the evolution of cellular respiration, in which O_2 is converted to water, enabled organisms to harness much more energy than can be derived from anaerobic metabolism. This is presumably why all higher organisms respire. For biological systems to use O_2 in this way, however, requires a very sophisticated chemistry. We can tolerate O_2 in the air we breathe because it has trouble picking up its first electron, which allows its initial reaction in cells to be controlled closely by enzymatic catalysis. But once a molecule of O_2 has picked up one electron to form a superoxide radical (O_2^-), it becomes dangerously reactive and will rapidly take up an additional three electrons wherever it can find them. The cell can use O_2 for respiration only because cytochrome oxidase holds onto oxygen at a special bimetallic center (Figure 14-34B), where it remains clamped between a heme-linked iron atom and a copper atom until it has picked up a total of four electrons; only then can the two oxygen atoms of the oxygen molecule be safely released as two molecules of water (Figure 14-34C).

Although cytochrome oxidase contains many protein subunits, most of these appear to have a subsidiary role, helping to regulate either the activity or the assembly of the three subunits that form the core of the enzyme. One of the core subunits contains the bimetallic center where oxygen is bound, and it is responsible for pumping the four protons that are transferred across the inner mitochondrial membrane for each O_2 molecule that is reduced to water (see Figure 14-34).

The cytochrome oxidase reaction is estimated to account for 90% of the total oxygen uptake in most cells. Cyanide and azide are toxic to cells because they bind tightly to this complex and thereby block all electron transport.

Electron Transfers Are Mediated by Random Collisions Between Diffusing Donors and Acceptors in the Mitochondrial Inner Membrane [18]

The two components that carry electrons between the three major enzyme complexes of the respiratory chain - ubiquinone and cytochrome c - diffuse rapidly in the plane of the inner mitochondrial membrane. The expected rate of random collisions between these mobile carriers and the enzyme complexes can account for the observed rates of electron transfer (each complex donates and receives an electron about once every 5 to 20 milliseconds). Thus there is no need to postulate a structurally ordered chain of electron-transfer proteins in the lipid bilayer; indeed, the three enzyme complexes appear to exist as independent entities in the plane of the inner membrane, and the ordered transfer of electrons is due entirely to the specificity of the functional interactions among the components of the chain.

This view is supported by the observation that the various components of the respiratory chain are present in different amounts. For each molecule of NADH dehydrogenase complex in heart mitochondria, for example, it is estimated that there are 3 molecules of b-c_1 complex, 7 molecules of cytochrome oxidase complex, 9 molecules of cytochrome c, and 50 molecules of ubiquinone; very different ratios are found in the mitochondria of some other cells. These components form a chain in the sense that each interacts specifically only with the carrier adjacent to it in the sequence shown in Figure 14-33, and there is a net flow of electrons from NADH dehydrogenase to cytochrome oxidase because each of the enzyme complexes in the sequence has a higher affinity for electrons than its predecessor. The affinity of a molecule for electrons is its *redox potential.* The changes in redox potential from one electron carrier to the next are exploited to pump proteins out of the mitochondrial matrix, as we now discuss.

A Large Drop in Redox Potential Across Each of the Three Respiratory Enzyme Complexes Provides the Energy for H+ Pumping [19]

Pairs of compounds such as H_2O and $1/2\ O_2$, or NADH and NAD+, are called conjugate redox pairs, since one compound is converted to the other by adding one or more electrons plus one or more protons - the protons being readily available in any aqueous solution. Thus, for example,

$$\tfrac{1}{2}O_2 + 2e^- + 2H^+ \rightarrow H_2O$$
Many readers will know that a 50-50 (equimolar) mixture of the members of a *conjugate acid-base pair* acts as a *buffer,* maintaining a defined "H+ pressure," or pH, which is a measure of the dissociation constant of the acid. In exactly the same way a 50-50 mixture of the members of a conjugate redox pair maintains a defined "electron pressure," or redox (reduction-oxidation) potential, *E*, that is a measure of the electron carrier's affinity for electrons.

By placing electrodes in contact with solutions that contain the appropriate conjugate redox pairs, one can measure the redox potential of each of the various electron carriers that participate in biological oxidation-reduction reactions. For biological systems each redox potential is determined at pH 7.0, where $[H^+] = 10^{-7}$M. Those pairs of compounds that have the most negative redox potentials have the weakest affinity for electrons and therefore contain carriers with the strongest tendency to donate electrons, whereas pairs that have the most positive redox potentials have the strongest affinity for electrons and contain carriers with the strongest tendency to accept electrons. Thus a 50-50 mixture of NADH and NAD+ has a redox potential of -320 mV, indicating that NADH has a strong tendency to donate electrons; a 50-50 mixture of H_2O and $1/2\ O_2$ has a redox potential of +820 mV, indicating that O_2 has a strong tendency to accept electrons.

Redox potentials can be readily determined for all the electron carriers in the respiratory chain that can be distinguished by their spectra, and they can be shown to increase as one passes along the chain of electron carriers. As most cytochromes have higher redox potentials than iron-sulfur centers, they generally serve as electron carriers near the O_2 end of the respiratory chain, whereas the iron-sulfur proteins serve as carriers near the NADH end.

An outline of the redox potentials measured along the respiratory chain is shown in Figure 14-35. The potentials drop in three large steps, one across each major enzyme complex. The change in redox potential between any two electron carriers is directly proportional to the free energy released by an electron transfer between them (see Figure 14-35). Each complex acts as an energy-conversion device, harnessing this free-energy change to pump H+ across the inner membrane, thereby creating an

electrochemical proton gradient as electrons pass through. This conversion can be demonstrated by incorporating each purified complex separately into liposomes: when an appropriate electron donor and acceptor is added so that electrons can pass through the complex, H^+ is translocated across the liposome membrane.

The Mechanism of H^+ Pumping Is Best Understood in Bacteriorhodopsin [20]

Because some respiratory enzyme complexes pump one H^+ per electron across the inner mitochondrial membrane whereas others pump two, the molecular mechanism by which electron transport is coupled to H^+ pumping is presumably different for the three different enzyme complexes. The details of the actual mechanisms are not known. In the case of the bc_1 complex, the quinones clearly play a part. As mentioned previously, a quinone picks up a H^+ from the aqueous medium along with each electron it carries and liberates it when it releases the electron (see Figure 14-31). Since ubiquinone is freely mobile in the lipid bilayer, it could accept electrons near the inside surface of the membrane and donate them to the bc_1 complex near the outside surface, thereby transferring one H^+ across the bilayer for every electron transported. Two protons are pumped per electron in the bc_1 complex, however, and there is evidence for a so-called *Q-cycle,* in which ubiquinone is recycled through the complex in an ordered way that makes this two-for-one transfer possible.

Allosteric changes in protein conformations driven by electron transport can also pump H^+, just as H^+ is pumped when ATP is hydrolyzed by the ATP synthase running in reverse. For both the NADH dehydrogenase complex and the cytochrome oxidase complex, it seems likely that electron transport drives orderly allosteric changes in protein conformation that cause a portion of the protein to pump H^+ across the inner mitochondrial membrane. This type of proton pumping is best understood for bacteriorhodopsin, a light-driven H^+ pump found in the plasma membrane of certain highly specialized bacteria (see Figure 10-32). A general mechanism for H^+ pumping based on structural and functional studies of this protein is presented in Figure 14-36.

H^+ Ionophores Dissipate the H^+ Gradient and Thereby Uncouple Electron Transport from ATP Synthesis [21]

Since the 1940s several substances, such as 2,4-dinitrophenol, have been known to act as *uncoupling agents,* uncoupling electron transport from ATP synthesis. The addition of these low-molecular-weight organic compounds to cells stops ATP synthesis by mitochondria without blocking their uptake of oxygen. In the presence of an uncoupling agent electron transport and H^+ pumping continue at a rapid rate, but no H^+ gradient is generated. The explanation for this effect is both simple and elegant: uncoupling agents are lipid-soluble weak acids that act as H^+ carriers (H^+ ionophores) and provide a pathway in addition to the ATP synthase for the flow of H^+ across the inner mitochondrial membrane. As a result of this "short-circuiting," the proton-motive force is dissipated completely, and ATP can no longer be made.

Respiratory Control Normally Restrains Electron Flow Through the Chain [22]

When an uncoupler such as dinitrophenol is added to cells, mitochondria increase their oxygen uptake substantially because of an increased rate of electron transport. This increase reflects the existence of respiratory control. The control is thought to act via a direct inhibitory influence of the electrochemical proton gradient on the rate of electron transport. When the gradient is collapsed by an uncoupler, electron transport is free to run unchecked at the maximal rate. As the gradient increases, electron transport becomes more difficult and the process slows. Moreover, if an artificially large electrochemical proton gradient is experimentally created across the inner membrane, normal electron transport stops completely and a *reverse electron flow* can be detected in some sections of the respiratory chain. This observation suggests that respiratory control reflects a simple balance between the free-energy change for electron-transport-linked proton pumping and the free-energy change for electron transport - that is, the magnitude of the electrochemical proton gradient affects both the rate and the direction of electron transport, just as it affects the directionality of the ATP synthase (see Figure 14-27).

Respiratory control is just one part of an elaborate interlocking system of feedback controls that coordinates the rates of glycolysis, fatty acid breakdown, the citric acid cycle, and electron transport. The rates of all of these processes are adjusted to the ATP:ADP ratio, increasing whenever increased utilization of ATP causes the ratio to fall. The ATP synthase in the inner mitochondrial membrane, for example, works faster as the concentrations of its substrates ADP and P_i increase. As it speeds up, the enzyme lets more H^+ flow into the matrix and thereby dissipates the electrochemical proton gradient more rapidly. The falling gradient, in turn, enhances the rate of electron transport.

Similar controls, including feedback inhibition of several key enzymes by ATP (see Figure 14-13, for example), act to adjust the

rates of NADH production to the rate of NADH utilization by the respiratory chain and so on. As a result of these many control mechanisms, the body oxidizes fats and sugars 5 to 10 times more rapidly during a period of strenuous exercise than during a period of rest.

Natural Uncouplers Convert the Mitochondria in Brown Fat into Heat-generating Machines [23]

In some specialized fat cells mitochondrial respiration is normally uncoupled from ATP synthesis. In these cells, known as brown fat cells, most of the energy of oxidation is dissipated as heat rather than being converted into ATP. The inner membranes of the large mitochondria in these cells contain a special transport protein that allows protons to move down their electrochemical gradient without activating ATP synthase. As a result, the cells oxidize their fat stores at a rapid rate and produce more heat than ATP. Tissues containing brown fat thereby serve as "heating pads" that revive hibernating animals and protect sensitive areas of newborn human babies from the cold.

All Bacteria Use Chemiosmotic Mechanisms to Harness Energy [24]

Bacteria use enormously diverse energy sources. Some, like animal cells, are aerobic and synthesize ATP from sugars that they oxidize to CO_2 and H_2O by glycolysis and the citric acid cycle through a respiratory chain in their plasma membrane similar to that in the mitochondrial inner membrane. Others are strict anaerobes, deriving their energy either from glycolysis alone (by fermentation) or, in addition, from an electron-transport chain that employs a molecule other than oxygen as the final electron acceptor. The alternative electron acceptor can be a nitrogen compound (nitrate or nitrite), a sulfur compound (sulfate or sulfite), or a carbon compound (fumarate or carbonate), for example. The electrons are transferred to these acceptors by a series of electron carriers in the plasma membrane that are comparable to those in mitochondrial respiratory chains.

Despite this diversity, the plasma membrane of the vast majority of bacteria contains an ATP synthase that is very similar to that in mitochondria (and chloroplasts). In aerobic bacteria the electron-transport chain pumps H^+ out of the cell and thereby establishes a proton-motive force that drives the ATP synthase to make ATP. In anaerobic bacteria that lack an electron-transport chain, the ATP synthase works in reverse, using the ATP produced by glycolysis to pump H^+ and establish a proton-motive force across the bacterial plasma membrane.

Thus most bacteria, including the strict anaerobes, maintain a proton-motive force across their plasma membrane. It can be harnessed to drive a flagellar motor that enables the bacterium to swim and is used to pump Na^+ out of the bacterium via a Na^+-H^+ antiporter that takes the place of the Na^+-K^+ ATPase of eucaryotic cells. It is also used for the active transport of nutrients, such as most amino acids and many sugars, into bacteria: each nutrient is dragged into the cell along with one or more H^+ through a specific symporter (Figure 14-37). In animal cells, by contrast, most inward transport across the plasma membrane is driven by the Na^+ gradient established by the Na^+-K^+ ATPase.

Some unusual bacteria have adapted to live in a very alkaline environment and yet must maintain their cytoplasm at a physiological pH. For these cells any attempt to generate an electrochemical H^+ gradient would be opposed by a large H^+ concentration gradient in the wrong direction (H^+ higher inside than outside). Presumably for this reason, at least some of these bacteria substitute Na^+ for H^+ in all of their chemiosmotic mechanisms. The respiratory chain pumps Na^+ out of the cell, the transport systems and flagellar motor are driven by an inward flux of Na^+, and a Na^+-driven ATP synthase synthesizes ATP. The existence of such bacteria demonstrates that the principle of chemiosmosis is more fundamental than the proton-motive force on which it is normally based.

Summary

The respiratory chain in the inner mitochondrial membrane contains three major enzyme complexes through which electrons pass on their way from NADH to O_2. Each of these can be purified, inserted into synthetic lipid vesicles, and then shown to pump H^+ when electrons are transported through it. In the native membrane the mobile electron carriers ubiquinone and cytochrome c complete the electron-transport chain by shuttling between the enzyme complexes. The path of electron flow is NADH $\rightarrow$ NADH dehydrogenase complex $\rightarrow$ ubiquinone $\rightarrow$ b-c_1 complex $\rightarrow$ cytochrome c $\rightarrow$ cytochrome oxidase complex $\rightarrow$ molecular oxygen (O_2).

The respiratory enzyme complexes couple the energetically favorable transport of electrons to the pumping of H^+ out of the

matrix. The resulting electrochemical proton gradient is harnessed to make ATP by another transmembrane protein complex, ATP synthase, through which H^+ flows back into the matrix. The ATP synthase is a reversible coupling device that normally converts a backflow of H^+ into ATP phosphate-bond energy by catalyzing the reaction $ADP + P_i \rightarrow ATP$, but it can also work in the opposite direction and hydrolyze ATP to pump H^+ if the electrochemical proton gradient is reduced. Its universal presence in mitochondria, chloroplasts, and bacteria testifies to the central importance of chemiosmotic mechanisms in cells.

Figure 14-25. ATP synthase. As indicated, the F_1ATPase portion is formed from multiple subunits (*Greek letters*), as is the transmembrane H^+ carrier.
Figure 14-26. An experiment demonstrating that the ATP synthase is driven by proton flow. By combining a light-driven bacterial proton pump (bacteriorhodopsin), an ATP synthase purified from ox heart mitochondria, and phospholipids, vesicles were produced that synthesized ATP in response to light.
Figure 14-27. ATP synthase is a reversible coupling device that interconverts the energies of the electrochemical proton gradient and chemical bonds. The ATP synthase can either synthesize ATP by harnessing the proton-motive force (*top*) or pump protons against their electrochemical gradient by hydrolyzing ATP (*bottom*). As explained in the text, the direction of operation at any given instant depends on the net free-energy change for the coupled processes of H$^+$translocation across the membrane and the synthesis of ATP from ADP and P$_i$. We have previously shown how the free-energy change (D G) for ATP hydrolysis depends on the concentrations of the three reactants ATP, ADP, and P$_i$ (Figure 14-22); the D $G$for ATP synthesis is the negative of this value. The D G for proton translocation across the membrane is proportional to the proton-motive force. The conversion factor between them is the faraday. Thus, D G_{H+} = -0.023 (proton-motive force), where D G_{H+} is in kilocalories per mole (kcal/mole) and the proton-motive force is in millivolts (mV). For an electrochemical H$^+$ gradient of 200 mV, D G_{H+} = -4.6 kcal/mole.
Figure 14-28. The structure of the heme group attached covalently to cytochrome c. The porphyrin ring is shown in *blue*. There are five different cytochromes in the respiratory chain. Because the hemes in different cytochromes have slightly different structures and are held by their respective proteins in different ways, each of the cytochromes has a different affinity for an electron.
Figure 14-29. The three-dimensional structure of cytochrome c, an electron carrier in the electron-transport chain. This

small protein contains just over 100 amino acids and is held loosely on the membrane by ionic interactions (see Figure 14-33). The iron atom (*orange*) on the bound heme (*blue*) can carry a single electron (see also Figure3-59).

Figure 14-31. Quinones. Each of these electron carriers in the respiratory chain picks up one H+ from the aqueous environment for every electron it accepts, and it can carry either one or two electrons as part of a hydrogen atom (*yellow*). When it donates its electrons to the next carrier in the chain, these protons are released. In mitochondria the quinone is ubiquinone (coenzyme Q), shown here; the long hydrophobic tail, which confines ubiquinone to the membrane, consists of 6 to 10 five-carbon isoprene units, depending on the organism. The corresponding electron carrier in plants is plastoquinone, which is almost identical. For

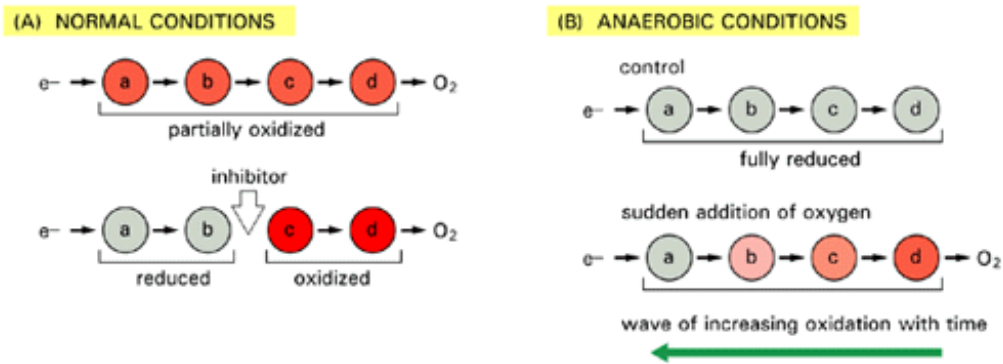
simplicity, both ubiquinone and plastoquinone will normally be referred to as *quinone* and abbreviated as Q.


Figure 14-32. The general methods used to determine the path of electrons along an electron-transport chain. The extent of oxidation of electron carriers a, b, c, and d is continuously monitored by following their distinct spectra, which differ in their oxidized and reduced states. In this schematic an increased degree of oxidation is indicated by a *darker red*. (A) Under normal conditions, where oxygen is abundant, all carriers are in a partially oxidized state. Addition of a specific inhibitor causes the downstream carriers to become more oxidized (*red*) and the upstream carriers to become more reduced. (B) In the absence of oxygen all carriers are in their fully reduced state (*gray*). The sudden addition of oxygen converts each carrier to its partially oxidized form with a delay that is greatest for the most upstream carriers.
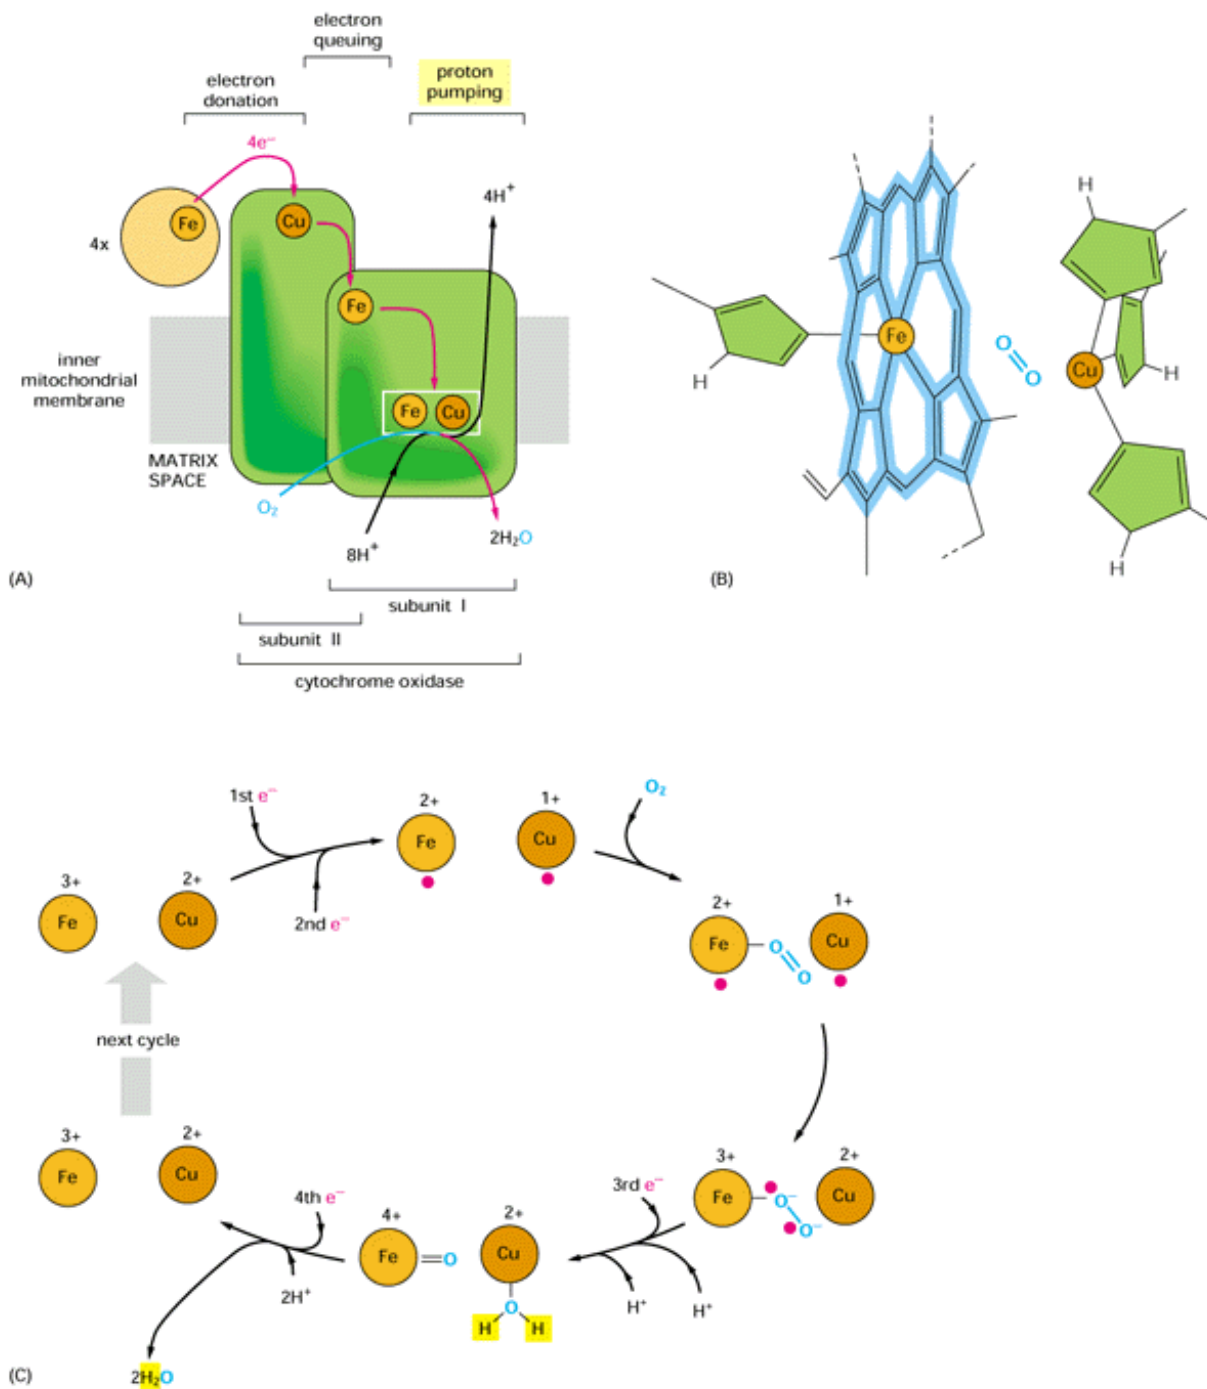
Figure 14-33. The path of electrons through the three respiratory enzyme complexes. The size and shape of each complex is shown, as determined from images of two-dimensional crystals (crystalline sheets) viewed in the electron microscope at various tilt angles. During the transfer of two electrons from NADH to oxygen (*red lines*) ubiquinone and cytochrome c serve as carriers between the complexes.


Figure 14-34. The reaction of O₂ with electrons in cytochrome oxidase. (A) The arrangement of electron carriers in cytochrome oxidase. Subunit I, which has 12 membrane-spanning alpha helices, contains two heme-linked iron atoms; one of these serves as an electron queuing point that feeds electrons into the bimetallic center (*boxed*), which is formed by the other iron and a closely opposed copper atom. Note that four protons are pumped out of the matrix for each O_2 molecule that reacts and that this requires a total of four electrons. (B) An enlarged view of the bimetallic iron-copper center with O_2 bound. (C) An outline of the pathway used for oxygen reduction at the bimetallic center, giving some idea of the complexity of the reactions involved. Electrons are shown as *red dots* until they become incorporated into hydrogen atoms (*yellow*). (Based on G.T. Babcock and M. Wikström, *Nature* 356:301-309, 1992. © 1992 Macmillan Magazines Ltd.)
Figure 14-35. The redox potential (denoted E'_0 or E_h) increases as electrons flow down the respiratory chain to oxygen.
The standard free-energy change, D $G°$(in kilocalories per mole), for the transfer of the two electrons donated by an NADH molecule can be obtained from the right-hand ordinate (D $G°$ = - $n(0.023)$ D E'_0, where n is the number of electrons transferred across a redox potential change of D E'_0 mV). Electrons flow through an enzyme complex by passing in sequence to the four or more electron carriers in each complex. As indicated, part of the favorable free-energy change is harnessed by each enzyme complex to pump H^+ across the mitochondrial inner membrane. Although the number of H^+pumped per electron (n) is uncertain, it is estimated that the NADH dehydrogenase and b-c_1 complexes each pump two H^+ per electron, whereas the cytochrome oxidase complex pumps one.The two electrons transported from $FADH_2$, generated by fatty acid oxidation (see Figure 14-11) and by the citric acid cycle (see Figure 14-14), are passed directly to ubiquinone, and they therefore cause less H^+ pumping than the two electrons transported from NADH (not shown).
Figure 14-36. H⁺ pumping. This general model for energy-driven H⁺ pumping is based on the mechanism that is thought to be utilized by bacteriorhodopsin. The transmembrane protein shown is driven through a cycle of three conformations, denoted here as A, B, and C. In conformation C the protein has a low affinity for H⁺, causing it to release an H⁺ on the outside of the lipid bilayer; in conformation A the protein has a high affinity for H⁺, causing it to pick up an H⁺ on the inside of the lipid bilayer. As indicated, the transition from conformation B to conformation C is energetically unfavorable but is driven by being coupled to an energetically favorable reaction occurring elsewhere on the protein (*blue arrow*). The other conformational changes lead to states of lower energy and proceed spontaneously. The cycle A →B →C →A therefore goes only one way, causing H⁺ to be pumped from the inside to the outside. For bacteriorhodopsin the energy for the transition B →C is provided by light, whereas in the mitochondria this energy is provided by electron transport.
Figure 14-37. H⁺-driven transport in bacteria. A proton-motive force generated across the plasma membrane pumps nutrients into the cell and expels sodium. In (A) the electrochemical proton gradient is generated in an aerobic bacterium by a respiratory chain and is then used by ATP synthase to make ATP and to transport some nutrients into the cell. In (B) the same bacterium growing under anaerobic conditions can derive its ATP from glycolysis. Part of this ATP is hydrolyzed by ATP synthase to establish the transmembrane proton-motive force that drives transport processes.

Introduction

All animals and most microorganisms rely on the continual uptake of large amounts of organic compounds from their environment. These compounds provide both the carbon skeletons for biosynthesis and the metabolic energy that drives all cellular processes. It is believed that the first organisms on primitive earth had access to an abundance of organic compounds produced by geochemical processes (see Chapter 1) but that most of these original compounds were used up billions of years ago. Since that time virtually all of the organic materials required by living cells have been produced by *photosynthetic organisms,* including many types of photosynthetic bacteria. The most advanced photosynthetic bacteria are the cyanobacteria, which have minimal nutrient requirements. They use electrons from water and the energy of sunlight to convert atmospheric CO_2 into organic compounds. In the course of splitting water [in the reaction $nH_2O + nCO_2 \xrightarrow{\text{light}} (CH_2O)_n + nO_2$], they liberate into the atmosphere the oxygen required for oxidative phosphorylation. As we shall see, it is thought that the evolution of cyanobacteria from more primitive photosynthetic bacteria first made possible the development of aerobic life forms.

In plants, which developed later, photosynthesis occurs in a specialized intracellular organelle - the chloroplast. Chloroplasts carry out photosynthesis during the daylight hours. The products of photosynthesis are used directly by the photosynthetic cells for biosynthesis and are also converted to a low-molecular-weight sugar (usually sucrose) that is exported to meet the metabolic needs of the many nonphotosynthetic cells of the plant. Alternatively, the products can be stored as an osmotically inert polysaccharide (usually starch) that is kept available as a source of sugar for future use.

Biochemical evidence suggests that chloroplasts are descendants of oxygen-producing photosynthetic bacteria that were endocytosed and lived in symbiosis with primitive eucaryotic cells. Mitochondria are also generally believed to be descended from endocytosed bacteria. The many differences between chloroplasts and mitochondria are thought to reflect their different bacterial ancestors as well as their subsequent evolutionary divergence. Nevertheless, the fundamental mechanisms involved in light-driven ATP synthesis in chloroplasts and in respiration-driven ATP synthesis in mitochondria are very similar.

The Chloroplast Is One Member of a Family of Organelles That Is Unique to Plants - the Plastids 26

Chloroplasts are the most prominent member of the plastid family of organelles. Plastids are present in all living plant cells, each cell type having its own characteristic complement. All plastids share certain features. Most notably, all plastids in a particular plant species contain multiple copies of the same relatively small genome (see Table 14-3, p. 706) and are enclosed by an envelope composed of two concentric membranes.

All plastids develop from *proplastids,* which are relatively small organelles present in the immature cells of plant meristems (Figure 14-38A). Proplastids develop according to the requirements of each differentiated cell, and which type is present is determined in large part by the nuclear genome. If a leaf is grown in darkness, its proplastids enlarge and develop into *etioplasts,* which have a semicrystalline array of internal membranes that contain a yellow chlorophyll precursor instead of chlorophyll. When exposed to light, the etioplasts rapidly develop into chloroplasts by converting this precursor to chlorophyll and by synthesizing new membrane, pigments, photosynthetic enzymes, and components of the electron-transport chain.

Leucoplasts are plastids that occur in many epidermal and internal tissues that do not become green and photosynthetic. They are little more than enlarged proplastids. A common form of leucoplast is the *amyloplast* (Figure 14-38B), which accumulates starch in storage tissues. In some plants, such as potatoes, the amyloplasts can grow to be as large as an average animal cell.

It is important to realize that plastids are not just sites for photosynthesis and the deposition of storage materials. Plants have exploited their plastids in the cellular compartmentalization of intermediary metabolism. Plastids produce more than the energy and reducing power (as ATP and NADPH) that is used for the plant's biosynthetic reactions. Purine and pyrimidine, most amino acid, and all of the fatty acid synthesis of plants takes place in the plastids, whereas in animal cells these compounds are produced in the cytosol.

Chloroplasts Resemble Mitochondria But Have an Extra Compartment 27

Chloroplasts carry out their energy interconversions by chemiosmotic mechanisms in much the same way that mitochondria do,

and they are organized on the same principles (Figures 14-39 and 14-40). They have a highly permeable outer membrane, a much less permeable inner membrane, in which special carrier proteins are embedded, and a narrow intermembrane space. The inner membrane surrounds a large space called the stroma, which is analogous to the mitochondrial matrix and contains various enzymes, ribosomes, RNA, and DNA.

There is, however, an important difference between the organization of mitochondria and that of chloroplasts. The inner membrane of the chloroplast is not folded into cristae and does not contain an electron-transport chain. Instead, the electron-transport chain as well as the photosynthetic light-absorbing system and an ATP synthase are all contained in a third distinct membrane that forms a set of flattened disclike sacs, the thylakoids (see Figure 14-39). The lumen of each thylakoid is thought to be connected with the lumen of other thylakoids, thereby defining a third internal compartment called the *thylakoid space,* which is separated from the stroma by the *thylakoid membrane.*

The structural similarities and differences between mitochondria and chloroplasts are illustrated in Figure 14-41. Superficially, the chloroplast resembles a greatly enlarged mitochondrion in which the cristae have been converted into a series of interconnected submitochondrial particles in the matrix space. The knobbed end of the chloroplast ATP synthase, where ATP is made, protrudes from the thylakoid membrane into the stroma, just as it protrudes into the matrix from the membrane of each mitochondrial crista.

Two Unique Reactions in Chloroplasts: The Light-driven Production of ATP and NADPH and the Conversion of CO_2 to Carbohydrate 25

The many reactions that occur during photosynthesis can be grouped into two broad categories. (1) In the photosynthetic electron-transfer reactions (also called the "light reactions") energy derived from sunlight energizes an electron in *chlorophyll,* enabling the electron to move along an electron-transport chain in the thylakoid membrane in much the same way that an electron moves along the respiratory chain in mitochondria. The chlorophyll obtains its electrons from water, with the liberation of O_2. During the electron-transport process H^+ is pumped across the thylakoid membrane, and the resulting proton-motive force drives the synthesis of ATP in the stroma. As the final step in this series of reactions, high-energy electrons are loaded (together with H^+) onto $NADP^+$, converting it to NADPH. All of these reactions are confined to the chloroplast. (2) In the carbon-fixation reactions (also called the "dark reactions") the ATP and NADPH produced by the photosynthetic electron-transfer reactions serve as the source of energy and reducing power, respectively, to drive the conversion of CO_2 to carbohydrate. The carbon-fixation reactions, which begin in the chloroplast stroma and continue in the cytosol, produce sucrose in the leaves of the plant; from there it is exported to other tissues as a source of both organic molecules and energy for growth.

Thus the formation of oxygen (which requires light energy directly) and the conversion of carbon dioxide to carbohydrate (which requires light energy only indirectly) are separate processes (Figure 14-42). We shall see, however, that elaborate feedback mechanisms interconnect the two in order to balance biosynthesis. Changes in the cell's ATP and NADPH requirements, for example, regulate the production of these two molecules in the thylakoid membrane, and several of the chloroplast enzymes required for carbon fixation are inactivated in the dark and reactivated by light-stimulated electron-transport processes.

Carbon Fixation Is Catalyzed by Ribulose Bisphosphate Carboxylase 28

We have seen earlier in this chapter how cells produce ATP by using the large amount of free energy released when carbohydrates are oxidized to CO_2 and H_2O. Clearly, therefore, the reverse reaction, in which CO_2 and H_2O combine to make carbohydrate, must be a very unfavorable one and must be coupled to other, very favorable reactions to drive it.

The central reaction of carbon fixation, in which an atom of inorganic carbon is converted to organic carbon, is illustrated in Figure 14-43: CO_2 from the atmosphere combines with the five-carbon compound ribulose 1,5-bisphosphate plus water to give two molecules of the three-carbon compound 3-phosphoglycerate. This "carbon-fixing" reaction, which was discovered in 1948, is catalyzed in the chloroplast stroma by a large enzyme called *ribulose bisphosphate carboxylase* (~500,000 daltons). Since each copy of the complex works sluggishly (processing only about 3 molecules of substrate per second compared to 1000 molecules per second for a typical enzyme), many copies are needed. Ribulose bisphosphate carboxylase often constitutes more than 50% of the total chloroplast protein and is thought to be the most abundant protein on earth.

Three Molecules of ATP and Two Molecules of NADPH Are Consumed for Each CO_2 Molecule That Is Fixed in the Carbon-Fixation Cycle [29]

The actual reaction in which CO_2 is fixed is energetically favorable because of the reactivity of the energy-rich compound *ribulose 1,5-bisphosphate,* to which each molecule of CO_2 is added (see Figure 14-43). But to produce a supply of ribulose 1,5-bisphosphate requires a series of reactions that use up large amounts of NADPH and ATP. The elaborate pathway by which this compound is regenerated was worked out in one of the most successful early applications of radioisotopes. As outlined in Figure 14-44, 3 molecules of CO_2 are fixed by ribulose bisphosphate carboxylase to produce 6 molecules of 3-phosphoglycerate (containing 6 x 3 = 18 carbon atoms in all: 3 from the CO_2 and 15 from ribulose 1,5-bisphosphate). The 18 carbon atoms then undergo a cycle of reactions that regenerates the 3 molecules of ribulose 1,5-bisphosphate used in the initial carbon-fixation step (containing 3 x 5 = 15 carbon atoms). This leaves 1 molecule of *glyceraldehyde 3-phosphate* (3 carbon atoms) as the net gain. In this carbon-fixation cycle (or Calvin-Benson cycle), 3 molecules of ATP and 2 molecules of NADPH are consumed for each CO_2 molecule converted into carbohydrate. The net equation is

$3CO_2 + 9ATP + 6NADPH + \text{water} \longrightarrow \text{glyceraldehyde 3-phosphate} + 8P_i + 9ADP + 6NADP^+$

Thus both *phosphate-bond energy* (as ATP) and *reducing power* (as NADPH) are required for the formation of organic molecules from CO_2 and H_2O. We return to this important point later.

The glyceraldehyde 3-phosphate produced in chloroplasts by the carbon-fixation cycle is a three-carbon sugar that serves as a central intermediate in glycolysis. Much of it is exported to the cytosol, where it can be converted into fructose 6-phosphate and glucose 1-phosphate by reversal of several reactions in glycolysis (see Figure 2-21). Glucose 1-phosphate is then converted to the sugar nucleotide UDP-glucose, and this combines with fructose 6-phosphate to form sucrose phosphate, the immediate precursor of the disaccharide sucrose. Sucrose is the major form in which sugar is transported between plant cells: just as glucose is transported in the blood of animals, sucrose is exported from the leaves via vascular bundles, providing the carbohydrate required by the rest of the plant.

Most of the glyceraldehyde 3-phosphate that remains in the chloroplast is converted to *starch* in the stroma. Like glycogen in animal cells, starch is a large polymer of glucose that serves as a carbohydrate reserve. The production of starch is regulated so that it is produced and stored as large grains in the chloroplast stroma (see Figure 14-38B) during periods of excess photosynthetic capacity. This occurs through reactions in the stroma that are the reverse of those in glycolysis: they convert glyceraldehyde 3-phosphate to glucose 1-phosphate, which is then used to produce the sugar nucleotide ADP-glucose, the immediate precursor of starch. At night the starch is broken down to help support the metabolic needs of the plant.

Carbon Fixation in Some Plants Is Compartmentalized to Facilitate Growth at Low CO_2 Concentrations [30]

Although ribulose bisphosphate carboxylase preferentially adds CO_2 to ribulose 1,5-bisphosphate, it can use O_2 in addition to CO_2, and if the concentration of CO_2 is low, it will add O_2 instead. This is the first step in a pathway called *photorespiration,* whose ultimate effect is to use up O_2 and liberate CO_2 without the production of useful energy stores. In many plants about one-third of the CO_2 fixed is lost again as CO_2 because of photorespiration.

Photorespiration can be a serious liability for plants in hot, dry conditions, where they close their stomata (the gas exchange pores in their leaves) to avoid excessive water loss. This causes the CO_2 levels in the leaf to fall precipitously and thereby favors photorespiration. A special adaptation, however, occurs in the leaves of many plants, such as corn and sugar cane, that live in hot, dry environments. In these plants the carbon-fixation cycle shown in Figure 14-44 occurs only in the chloroplasts of specialized *bundle-sheath cells,* which contain all of the plant's ribulose bisphosphate carboxylase. These cells are protected from the air and are surrounded by a specialized layer of *mesophyll cells* that "pump" CO_2 into the bundle-sheath cells, supplying the ribulose bisphosphate carboxylase with a high concentration of CO_2, which greatly reduces photorespiration.

The CO_2 pump is produced by a reaction cycle that begins in the cytosol of the mesophyll cells with a CO_2-fixation step catalyzed by an enzyme that binds carbon dioxide (as bicarbonate) and combines it with an activated three-carbon molecule to produce a four-carbon molecule. The four-carbon molecule diffuses into the bundle-sheath cells, where it is broken down to

release the CO_2 and generate a molecule with three carbons. The pumping cycle is completed when this three-carbon molecule is returned to the mesophyll cells and converted to its original activated form. Because the CO_2 is initially captured by converting it into a compound containing four carbons, the CO_2-pumping plants are called *C_4 plants*. All other plants are called *C_3 plants* ([Figure 14-45](#)) because they capture CO_2 directly into the three-carbon compound 3-phosphoglycerate.

As for any vectorial transport process, pumping CO_2 into the bundle-sheath cells in C_4 plants costs energy. In hot, dry environments, however, this cost may be much less than the energy lost by photorespiration in C_3 plants, and so C_4 plants have a potential advantage. Moreover, because C_4 plants can carry out photosynthesis at a lower concentration of CO_2 inside the leaf, they need to open their stomata less and therefore can fix about twice as much net carbon as C_3 plants per unit of water lost.

Photosynthesis Depends on the Photochemistry of Chlorophyll Molecules <u>31</u>

Having discussed the carbon-fixation reactions, we now return to the question of how the photosynthetic electron-transfer reactions in the chloroplast generate the ATP and the NADPH needed to drive the production of carbohydrates from CO_2 and H_2O (see [Figure 14-42](#)). The required energy is derived from sunlight absorbed by chlorophyll molecules ([Figure 14-46](#)). The process of energy conversion begins when a chlorophyll molecule is excited by a quantum of light (a photon) and an electron is moved from one molecular orbital to another of higher energy. Such an excited molecule is unstable and will tend to return to its original, unexcited state in one of three ways: (1) by converting the extra energy into heat (molecular motions) or to some combination of heat and light of a longer wavelength (fluorescence), which is what happens when light energy is absorbed by an isolated chlorophyll molecule in solution; (2) by transferring the energy - but not the electron - directly to a neighboring chlorophyll molecule by a process called *resonance energy transfer;* or (3) by transferring the high-energy electron to another nearby molecule (an *electron acceptor*) and then returning to its original state by taking up a low-energy electron from some other molecule (an *electron donor,* [Figure 14-47](#)). The last two mechanisms are exploited in the process of photosynthesis.

A Photosystem Contains a Reaction Center Plus an Antenna Complex <u>32</u>

Multiprotein complexes called photosystems catalyze the conversion of the light energy captured in excited chlorophyll molecules to useful forms. A photosystem consists of two closely linked components: a *photochemical reaction center* consisting of a complex of proteins and chlorophyll molecules that enable light energy to be converted into chemical energy and an *antenna complex* consisting of pigment molecules that capture light energy and feed it to the reaction center.

The antenna complex is important for capturing light. In chloroplasts it consists of a cluster of several hundred chlorophyll molecules linked together by proteins that hold them tightly on the thylakoid membrane. Depending on the plant, varying amounts of accessory pigments called *carotenoids,* which can help collect light of other wavelengths, are also located in each complex. When a chlorophyll molecule in the antenna complex is excited, the energy is rapidly transferred from one molecule to another by resonance energy transfer until it reaches a special pair of chlorophyll molecules in the photochemical reaction center. Each antenna complex thereby acts as a "funnel," collecting light energy and directing it to a specific site where it can be used effectively ([Figure 14-48](#)).

The photochemical reaction center is a transmembrane protein-pigment complex that lies at the heart of photosynthesis. It is thought to have evolved more than 3 billion years ago in primitive photosynthetic bacteria. The special pair of chlorophyll molecules in the reaction center acts as an irreversible trap for excitation quanta because its excited electron is immediately passed to a chain of electron acceptors that are precisely positioned as neighbors in the same protein complex ([Figure 14-49](#)). By moving the high-energy electron rapidly away from the chlorophylls, the reaction center transfers it to an environment where it is much more stable. The electron is thereby suitably positioned for subsequent photochemical reactions, which require more time to complete.

In a Reaction Center, Light Energy Captured by Chlorophyll Creates a Strong Electron Donor from a Weak One <u>33</u>

The electron transfers involved in the photochemical reactions just outlined have been analyzed extensively by rapid spectroscopic methods, especially in the photosystem of purple bacteria, which is simpler than the evolutionarily related photosystem in chloroplasts. The bacterial reaction center is a large protein-pigment complex that can be solubilized with detergent and purified in active form. In 1985 its complete three-dimensional structure was determined by x-ray crystallography (see [Figure 10-33](#)and [Figure 14-49](#)). This structure, combined with kinetic data, provides the best picture we have of the initial

electron-transfer reactions that underlie photosynthesis.

The sequence of transfers that take place in the reaction center of purple bacteria is shown in Figure 14-50. As outlined previously (Figure 14-48), in a reaction center, light causes a net electron transfer from a weak electron donor to a molecule that is a strong electron donor in its reduced form. In this way the excitation energy that would otherwise be released as fluorescence or heat or both is used instead to raise the energy of an electron and thereby create a strong electron donor where none had been before. In this bacterium the weak electron donor is a cytochrome (*orange box*), and the strong electron donor is a quinone (*yellow box*). In the chloroplasts of higher plants, as we discuss later, water, rather than cytochrome, serves as the initial electron donor, which is why oxygen is released by photosynthesis in plants.

In Plants and Cyanobacteria Noncyclic Photophosphorylation Produces Both NADPH and ATP [31], [34]

Photosynthesis in plants and cyanobacteria produces both ATP and NADPH directly by a two-step process called noncyclic photophosphorylation. Because two photosystems are used in series to energize an electron, the electron can be transferred all the way from water to NADPH. As the high-energy electrons pass through the coupled photosystems to generate NADPH, some of their energy is siphoned off for ATP synthesis.

In the first of the two photosystems - called *photosystem II* for historical reasons - the oxygens of two water molecules bind to a cluster of manganese atoms in a poorly understood water-splitting enzyme that enables electrons to be removed one at a time to fill the holes created by light in chlorophyll molecules in the reaction center. As soon as four electrons have been removed from the two water molecules (requiring four quanta of light), O_2 is released; photosystem II thus catalyzes the reaction $2H_2O + 4$ photons $\rightarrow 4H^+ + 4\ e^- + O_2$.

The core of the reaction center in photosystem II is homologous to the bacterial reaction center just described, and it likewise produces strong electron donors in the form of reduced quinone molecules in the membrane. The quinones pass their electrons to a H^+ pump called the b_6-*f complex,* which closely resembles the b-c$_1$ complex in the respiratory chain of mitochondria and a related complex in bacteria. As in mitochondria, the complex pumps H^+ into the thylakoid space across the thylakoid membrane (or out of the cytosol across the plasma membrane in cyanobacteria), and the resulting electrochemical gradient drives the synthesis of ATP by an ATP synthase (Figures14-51 and 14-52). The final electron acceptor in this electron-transport chain is the second photosystem (*photosystem I*), which accepts an electron into the hole created by light in the chlorophyll molecule in its reaction center. Each electron that enters photosystem I is boosted to a very high energy level that allows it to be passed to the iron-sulfur center in ferredoxin and then to $NADP^+$ to generate NADPH; this last step also involves the uptake of a $H^+$from the medium (Figure 14-52).

The scheme for photosynthesis shown in Figure 14-52 is known as the *Z scheme*. By means of its two electron-energizing steps, one catalyzed by each photosystem, an electron is passed from water, which normally holds on to its electrons very tightly (redox potential = +820 mV), to NADPH, which normally holds on to its electrons more loosely (redox potential = -320 mV). There is not enough energy in a single quantum of visible light to energize an electron all the way from the bottom of photosystem II to the top of photosystem I, which is probably the energy change required to pass an electron efficiently from water to $NADP^+$. The use of two separate photosystems in series also means that there is enough energy left over to enable the electron-transport chain that links the two photosystems to pump H^+ across the thylakoid membrane (or the plasma membrane of cyanobacteria), which allows ATP synthase to harness some of the light-derived energy for ATP production.

Chloroplasts Can Make ATP by Cyclic Photophosphorylation Without Making NADPH [31], [35]

In the noncyclic photophosphorylation scheme just discussed, high-energy electrons leaving photosystem II are harnessed to generate ATP and are passed on to photosystem I to drive the production of NADPH. This produces slightly more than one molecule of ATP for every pair of electrons that passes from H_2O to $NADP^+$ to generate a molecule of NADPH. But one and a half molecules of ATP per NADPH are needed for carbon fixation (see Figure 14-44). To produce extra ATP, the chloroplasts in some species of plants can switch photosystem I into a cyclic mode so that it produces ATP instead of NADPH. In this process, called *cyclic photophosphorylation,*the high-energy electrons from photosystem I are transferred back to the b_6-f complex rather than being passed on to $NADP^+$, and the electron is then recycled to photosystem I at a low energy. The only net result, besides the conversion of some light energy to heat, is that H^+ is pumped across the thylakoid membrane by the b_6-f complex to increase the electrochemical proton gradient that drives the ATP synthase.

In summary, cyclic photophosphorylation involves only photosystem I, and it produces ATP without the formation of either NADPH or O_2. Thus the relative activities of cyclic and noncyclic electron flows can determine how much light energy is converted into reducing power (NADPH) and how much into high-energy phosphate bonds (ATP).

The Electrochemical Proton Gradient Is Similar in Mitochondria and Chloroplasts [36]

The presence of the thylakoid space separates a chloroplast into three rather than the two internal compartments of a mitochondrion. The net effect of H^+ translocation in the two organelles, however, is similar. As illustrated in Figure 14-53, in chloroplasts H^+ is pumped out of the stroma (pH 8) into the thylakoid space (pH about 5), creating a gradient of 3 to 3.5 pH units. This represents a proton-motive force of about 200 mV across the thylakoid membrane (nearly all of which is contributed by the pH gradient rather than by a membrane potential), which drives ATP synthesis by the ATP synthase embedded in this membrane.

Like the stroma, the mitochondrial matrix has a pH of about 8, but this is created by pumping H^+ out of the mitochondrion into the cytosol (pH about 7) rather than into an interior space in the organelle. Thus the pH gradient is relatively small, and most of the proton-motive force across the mitochondrial inner membrane, which is about the same as that across the chloroplast thylakoid membrane, is caused by the resulting membrane potential. For both mitochondria and chloroplasts, however, the catalytic site of the ATP synthase is at a pH of about 8 and is located in a large organelle compartment (matrix or stroma) packed full of soluble enzymes. Consequently, it is here that all of the organelle's ATP is made (Figure 14-53).

Although there are many similarities between mitochondria and chloroplasts, the structure of chloroplasts makes their electron- and proton-transport processes easier to study: by breaking both the inner and outer membranes of a chloroplast, isolated thylakoid discs can be obtained intact. These thylakoids resemble submitochondrial particles in that they have a membrane whose electron-transport chain has its utilization sites for $NADP^+$, ADP, and phosphate all freely accessible to the outside. But isolated thylakoids retain their undisturbed native structure and are much more active than isolated submitochondrial particles. For this reason several of the experiments that first demonstrated the central role of chemiosmotic mechanisms were carried out with chloroplasts rather than with mitochondria.

Like the Mitochondrial Inner Membrane, the Chloroplast Inner Membrane Contains Carrier Proteins That Facilitate Metabolite Exchange with the Cytosol [37]

If chloroplasts are isolated in a way that leaves their inner membrane intact, this membrane can be shown to have a selective permeability, reflecting the presence of specific carrier proteins. Most notably, much of the glyceraldehyde 3-phosphate produced by CO_2 fixation in the chloroplast stroma is transported out of the chloroplast by an efficient antiport system that exchanges three-carbon sugar-phosphates for inorganic phosphate.

Glyceraldehyde 3-phosphate normally provides the cytosol with an abundant source of carbohydrate, which is used by the cell as the starting point for many other biosyntheses - including the production of sucrose for export. But this is not all it provides. Once the glyceraldehyde 3-phosphate reaches the cytosol, it is readily converted (by part of the glycolytic pathway) to 3-phosphoglycerate, generating one molecule of ATP and one of NADH. (A very similar two-step reaction working in reverse forms glyceraldehyde 3-phosphate in the carbon-fixation cycle - see Figure 14-44.) As a result, the export of glyceraldehyde 3-phosphate from the chloroplast provides not only the main source of fixed carbon to the rest of the cell, but also the reducing power and ATP needed for metabolism outside the chloroplast.

Chloroplasts Carry Out Other Biosyntheses

The chloroplast carries out many biosyntheses in addition to photosynthesis. All of the cell's fatty acids and a number of amino acids, for example, are made by enzymes in the chloroplast stroma. Similarly, the reducing power of light-activated electrons drives the reduction of nitrite (NO_2^-) to ammonia (NH_3) in the chloroplast; this ammonia provides the plant with nitrogen for the synthesis of amino acids and nucleotides. The metabolic importance of the chloroplast for plants and algae therefore extends far beyond its role in photosynthesis.

Summary

Chloroplasts and photosynthetic bacteria obtain high-energy electrons by means of photosystems that capture the electrons excited when sunlight is absorbed by chlorophyll molecules. Photosystems are composed of an antenna complex attached to a photochemical reaction center, which is a precisely ordered complex of proteins and pigments in which the photochemistry of photosynthesis occurs. By far the best-understood photochemical reaction center is that of the purple photosynthetic bacteria, for which the complete three-dimensional structure is known. Whereas these bacteria contain only a single photosystem, there are two photosystems in chloroplasts and cyanobacteria. The two photosystems are normally linked in series and transfer electrons from water to $NADP^+$ to form NADPH, with the concomitant production of a transmembrane electrochemical proton gradient; molecular oxygen (O_2) is generated as a by-product.

Compared to mitochondria, chloroplasts have an additional internal membrane (the thylakoid membrane) and internal space (the thylakoid space). All electron-transport processes occur in the thylakoid membrane: to make ATP, H^+ is pumped into the thylakoid space and a backflow of H^+ through an ATP synthase then produces the ATP in the chloroplast stroma. This ATP is used in conjunction with the NADPH made by photosynthesis to drive a large number of biosynthetic reactions in the chloroplast stroma, including the all-important carbon-fixation cycle, which creates carbohydrate from CO_2. Along with other chloroplast products, this carbohydrate is exported to the cell cytosol, where - as glyceraldehyde 3-phosphate - it provides organic carbon, ATP, and reducing power to the rest of the cell.

Table 14-3. Relative Amounts of Organelle DNA in Some Cells and Tissues

Organism	Tissue or Cell Type	DNA Molecules per Organelle	Organelles per Cell	Organelle DNA as Percent of Total Cellular DNA
Mitochondrial DNA				
Rat	liver	5-10	1000	1
Yeast*	vegetative	2-50	1-50	15
Frog	egg	5-10	10^7	99
Chloroplast DNA				
Chlamydomonas	vegetative	80	1	7
Maize	leaves	20-40	20-40	15

*. The large variation in the number and size of mitochondria per cell in yeast is due to mitochondrial fusion and fragmentation.

(B) Three *amyloplasts* (a form of leucoplast), or starch-storing plastids, in a root tip cell of soybean. (From B. Gunning and M. Steer, Ultrastructure and the Biology of Plant Cells. London: Arnold, 1975.)
Figure 14-39. The chloroplast. This photosynthetic organelle contains three distinct membranes (the outer membrane, the inner membrane, and the thylakoid membrane) that define three separate internal compartments (the intermembrane space, the stroma, and the thylakoid space). The thylakoid membrane contains all of the energy-generating systems of the chloroplast. In electron micrographs this membrane appears to be broken up into separate units that enclose individual flattened vesicles (see Figure 14-40), but these are probably joined into a single, highly folded membrane in each chloroplast. As indicated, the individual thylakoids are interconnected, and they tend to stack to form aggregates called grana.

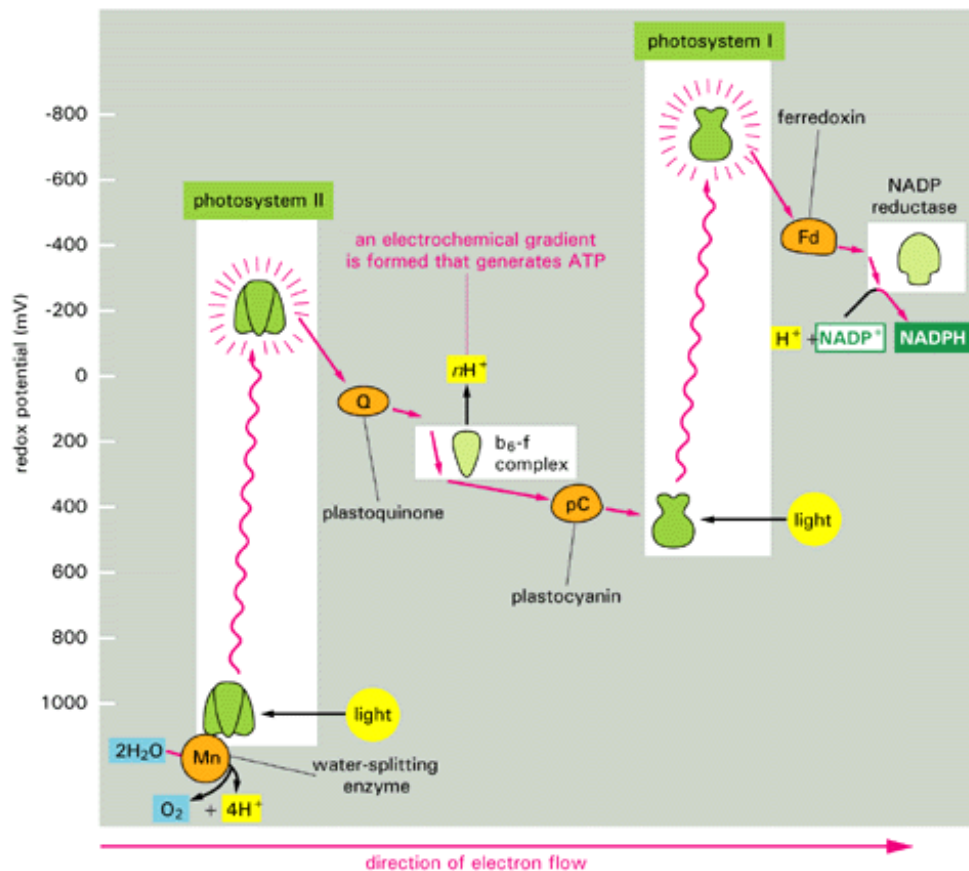
Figure 14-47. Three ways for an excited chlorophyll molecule to return to its original, unexcited state. The light energy absorbed by an isolated chlorophyll molecule is completely released as light and heat by process 1. In photosynthesis, by contrast, chlorophylls undergo process 2 in the antenna complex and process 3 in the reaction center, as described in the text.
Figure 14-48. The reaction center and antenna in a photosystem. Molecules A (electron donor) and B (electron acceptor) differ according to the photosystem.
Figure 14-49. The arrangement of the electron carriers in a bacterial photochemical reaction center as determined by x-ray crystallography. The pigment molecules shown are held in the interior of a transmembrane protein and are surrounded by the lipid bilayer, as indicated. An electron in the special pair is excited by resonance from an antenna complex chlorophyll (process 2 in Figure 14-47), and the excited electron is then transferred stepwise from the special pair to the quinone (see Figure 14-50).
Figure 14-50. The electron transfers that occur in the photochemical reaction center of a purple bacterium. A similar set of reactions is believed to occur in the evolutionarily related photosystem II in plants. At the top right is a schematic diagram showing the molecules that carry electrons, which are those in Figure 14-49, plus an exchangeable quinone (Q_B) and a freely mobile quinone (Q) dissolved in the lipid bilayer. Electron carriers 1 through 5 are each bound in a specific position on a 596-amino-acid trans-membrane protein formed from two separate subunits (see Figure 10-33). Following excitation by a photon of light, a high-energy electron passes from pigment molecule to pigment molecule, very rapidly creating a charge separation as shown in the sequence in steps A through D above, where the pigment molecule carrying high-energy electrons is colored *green*. Step E occurs more slowly. Once released into the bilayer, the quinone with two electrons loses its charge by picking up two protons (see Figure 14-31).
Figure 14-51. Electron flow during photosynthesis in the thylakoid membrane. The mobile electron carriers in the chain are plastoquinone (which closely resembles the ubiquinone of mitochondria), plastocyanin (a small copper-containing protein), and ferredoxin (a small protein containing an iron-sulfur center). The b_6-f complex closely resembles the b-c$_1$ complex of mitochondria and the b-c complex of bacteria (see Figure 14-61): all three complexes accept electrons from quinones and pump H$^+$ across the membrane. Note that the H$^+$ released by water oxidation and the H$^+$ taken up during NADPH formation also contribute to the generation of the electrochemical H$^+$ gradient, which drives ATP synthesis by an ATP synthase present in this same membrane (not shown).


Figure 14-52. Changes in redox potential during photosynthesis. The redox potential for each molecule is indicated by its position along the vertical axis. Photosystem II closely resembles the reaction center in purple bacteria. Photosystem I is different: it passes electrons from its excited chlorophyll through a series of tightly bound iron-sulfur centers. The net electron flow through the two photosystems in series is from water to NADP+, and it produces NADPH as well as ATP, which is synthesized by an ATP synthase (not shown) that harnesses the electrochemical proton gradient produced by the three sites of H+ activity that are highlighted in Figure 14-51. This *Z scheme* for ATP production is called *noncyclic photophosphorylation* to distinguish it from a cyclic scheme that utilizes only photosystem I (see the text).
Figure 14-53. Comparison of the flow of H$^+$ and the orientation of ATP synthase in mitochondria and chloroplasts. Those compartments with a similar pH have been colored similarly. The proton-motive force across the thylakoid membrane consists almost entirely of the pH gradient; a high permeability of this membrane to Mg^{2+} and Cl$^-$ ions allows the flow of these ions to dissipate most of the membrane potential. Mitochondria presumably need a large membrane potential because they could not tolerate having their matrix at pH 10, as would be required to generate their proton-motive force without one.

The Evolution of Electron-Transport Chains [38]

Introduction

Much of the structure, function, and evolution of cells and organisms can be related to their need for energy. We have seen that the fundamental mechanisms for harnessing energy from such disparate sources as light and the oxidation of glucose are the same. Apparently, an effective method for synthesizing ATP arose early in evolution and has since been conserved with only small variations. How did the crucial individual components - ATP synthase, redox-driven H$^+$ pumps, and photosystems - first arise? Hypotheses about events occurring on an evolutionary time scale are difficult to test. But clues abound, both in the many different primitive electron-transport chains that survive in some present-day bacteria and in geological evidence concerning the environment of the earth billions of years ago.

The Earliest Cells Probably Produced ATP by Fermentation [39]

As explained in Chapter 1, the first living cells are thought to have arisen more than 3.5×10^9 years ago, when the earth was not more than about 10^9 years old. Because the environment lacked oxygen but was rich in geochemically produced organic molecules, the earliest metabolic pathways for producing ATP presumably resembled present-day forms of fermentation.

In the process of fermentation, ATP is made by a phosphorylation event that harnesses the energy released when a hydrogen-rich organic molecule, such as glucose, is partly oxidized (see Figure 2-14). Without O_2 to serve as the final electron acceptor, the electrons lost from the oxidized organic molecules must be transferred (via NADH or NADPH) to a different organic molecule (or to a different part of the same molecule), which thereby becomes more reduced. At the end of the fermentation process one (or more) of the organic molecules produced is excreted into the medium as a metabolic waste product; others, such as pyruvate, are retained by the cell for biosynthesis.

The excreted end products are different in different organisms, but they tend to be organic acids (carbon compounds that carry a COOH group). Among the most important of such products in bacterial cells are lactic acid (which also accumulates in anaerobic mammalian glycolysis) and formic, acetic, propionic, butyric, and succinic acids. Two fermentation pathways of present-day bacteria are illustrated in Figure 14-54.

The Evolution of Energy-conserving Electron-transport Chains Enabled Anaerobic Bacteria to Use Non-fermentable Organic Compounds as a Source of Energy 40

The early fermentation processes would have provided not only the ATP but also the reducing power (as NADH or NADPH) required for essential biosyntheses, and many of the major metabolic pathways probably evolved while fermentation was the only mode of energy production. With time, however, the metabolic activities of these procaryotic organisms must have changed the local environment, forcing organisms to evolve new biochemical pathways. The accumulation of waste products of fermentation, for example, might have resulted in the following series of changes:

Stage 1. The continuous excretion of organic acids lowered the pH of the environment, favoring the evolution of proteins that function as transmembrane H^+ pumps that could pump H^+ out of the cell to protect it from the dangerous effects of intracellular acidification. One of these pumps may have used the energy available from ATP hydrolysis and could have been the ancestor of the present-day ATP synthase.

Stage 2. At the same time that nonfermentable organic acids were accumulating in the environment and favoring the evolution of an ATP-consuming H^+ pump, the supply of geochemically generated fermentable nutrients, which provided the energy for the pumps and for all other cellular processes, was dwindling. This favored bacteria that could excrete H^+ without hydrolyzing ATP, allowing the ATP to be conserved for other cellular activities. Selective pressures of this kind might have led to the first membrane-bound proteins that could use electron transport between molecules of different redox potential as the energy source for transporting H^+ across the plasma membrane. Some of these proteins would have found their electron donors and electron acceptors among the nonfermentable organic acids that had accumulated. Many such electron-transport proteins can be found in present-day bacteria: some bacteria that grow on formic acid, for example, pump H^+ by using the small amount of redox energy derived from the transfer of electrons from formic acid to fumarate (Figure 14-55). Others have similar electron-transport components devoted solely to the oxidation and reduction of inorganic substrates (see Figure 14-57, for example).

Stage 3. Eventually some bacteria developed H^+-pumping electron-transport systems that were efficient enough to harness more redox energy than they needed just to maintain their internal pH. Now, bacteria that carried both types of H^+ pumps were at an advantage. In these cells a large electrochemical proton gradient generated by excessive H^+ pumping allowed protons to leak back into the cell through the ATP-driven H^+ pumps, thereby running them in reverse, so that they functioned as ATP synthases to make ATP. Because such bacteria required much less of the increasingly scarce supply of fermentable nutrients, they proliferated at the expense of their neighbors.

These three hypothetical stages in the evolution of oxidative phosphorylation mechanisms are summarized in Figure 14-56.

By Providing an Inexhaustible Source of Reducing Power, Photosynthetic Bacteria Overcame a Major Obstacle in the Evolution of Cells 41

The evolutionary steps just outlined would have solved the problem of main-taining both a neutral intracellular pH and an

abundant store of energy, but they would not have solved another problem that was equally serious. The depletion of organic nutrients from the environment meant that organisms had to find some alternative source of carbon to make the sugars that served as the precursors for so many other cellular molecules. Although the CO_2 in the atmosphere provided an abundant potential carbon source, to convert it into an organic molecule such as a carbohydrate requires that the fixed CO_2 be reduced by a strong electron donor, such as NADH or NADPH, which can provide the high-energy electrons needed to generate each (CH_2O) unit from CO_2 (see Figure 14-44). Early in cellular evolution, strong reducing agents (electron donors) would have been plentiful as products of fermentation. But as the supply of fermentable nutrients dwindled and a membrane-bound ATP synthase began to produce most of the ATP, the plentiful supply of NADH and other reducing agents would have disappeared. It thus became imperative for cells to evolve a new way of generating strong reducing agents.

Presumably, the main reducing agents still available were the organic acids produced by the anaerobic metabolism of carbohydrates, inorganic molecules such as hydrogen sulfide (H_2S) generated geochemically, and water. But the reducing power of all of these molecules is far too weak to be useful for CO_2 fixation. An early supply of strong electron donors could have been generated by using the electrochemical proton gradient across the plasma membrane to drive a *reverse electron flow*. This would have required the evolution of membrane-bound enzyme complexes resembling a NADH dehydrogenase, and mechanisms of this kind survive in the anaerobic metabolism of some present-day bacteria (Figure 14-57). The major evolutionary breakthrough in energy metabolism, however, was almost certainly the development of photochemical reaction centers that could use the energy of sunlight to produce molecules such as NADH. It is thought that this occurred early in the process of cellular evolution - probably more than 3×10^9 years ago, in the ancestors of the green sulfur bacteria. Present-day green sulfur bacteria use light energy to transfer hydrogen atoms (as an electron plus a proton) from H_2S to NADPH, thereby creating the strong reducing power required for carbon fixation (Figure 14-58). Because the electrons removed from H_2S are at a much more negative redox potential than those of H_2O (-230 mV compared to +820 mV for H_2O), one quantum of light absorbed by the single photosystem in these bacteria is sufficient to achieve a high enough redox potential to generate NADPH via a relatively simple photosynthetic electron-transport chain.

The More Complex Photosynthetic Electron-Transport Chains of Cyanobacteria Produced Atmospheric Oxygen and Permitted New Life Forms 42

The next step, which is thought to have occurred with the development of the cyanobacteria at least 3×10^9 years ago, was the evolution of organisms capable of using water as the electron source for CO_2 reduction. This entailed the evolution of a water-splitting enzyme and also required the addition of a second photo-system, acting in series with the first, to bridge the enormous gap in redox potential between H_2O and NADPH. Present-day structural homologies between photosystems suggest that this change involved the cooperation of a photosystem derived from green bacteria (photosystem I) with a photosystem derived from purple bacteria (photosystem II). The biological consequences of this evolutionary step were far-reaching. For the first time there were organisms that made only very minimal chemical demands on their environment and therefore could spread and evolve in ways denied the earlier photosynthetic bacteria, which needed H_2S or organic acids as a source of electrons. Consequently, large amounts of biologically synthesized, reduced organic materials accumulated. Moreover, oxygen entered the atmosphere for the first time.

Oxygen is highly toxic because the oxidation reactions it brings about can randomly alter biological molecules. Many present-day anaerobic bacteria, for example, are rapidly killed when exposed to air. Thus organisms on the primitive earth would have had to evolve protective measures against the rising O_2 levels in the environment. Late evolutionary arrivals, such as ourselves, have numerous detoxifying mechanisms that protect our cells from the ill effects of oxygen.

The increase in atmospheric O_2 was very slow at first and would have allowed a gradual evolution of protective devices. The early seas contained large amounts of ferrous iron (Fe[II]), and nearly all the O_2 produced by early photosynthetic bacteria was utilized in converting Fe(II) to Fe(III). This conversion caused the precipitation of huge amounts of ferric oxides, and the extensive banded iron formations beginning about 2.7×10^9 years ago help to date the rise of the cyanobacteria. By about 2×10^9 years ago the supply of ferrous iron was exhausted and the deposition of further iron precipitates ceased. The geological evidence suggests that O_2 levels in the atmosphere then began to rise, reaching current levels between 0.5 and 1.5×10^9 years ago (Figure 14-59).

The availability of O_2 made possible the development of bacteria that relied on aerobic metabolism to make their ATP. As

explained previously, these organisms could harness the large amount of energy released by breaking down carbohydrates and other reduced organic molecules all the way to CO_2 and H_2O. Components of preexisting electron-transport complexes were modified to produce a cytochrome oxidase, so that the electrons obtained from organic or in-organic substrates could be transported to O_2 as the terminal electron acceptor. Many present-day purple photosynthetic bacteria can switch between photosynthesis and respiration, depending on the availability of light and O_2, by surprisingly minor reorganizations of their electron-transport chains.

As organic materials accumulated on earth as a result of photosynthesis, some photosynthetic bacteria (including the precursors of *E. coli*) lost their ability to survive on light energy alone and came to rely entirely on respiration. It is believed that mitochondria first arose some 1.5×10^9 years ago, when a primitive eucaryotic cell endocytosed such a respiration-dependent bacterium. Plants are believed to have evolved when a descendant of this early aerobic eucaryotic cell endocytosed a photosynthetic bacterium that became the precursor of chloroplasts; present-day chloroplasts are so different in different types of algae, however, that chloroplasts probably evolved separately in these different lineages. Figure 14-60 outlines some of the suspected evolutionary pathways just discussed.

Evolution is always conservative, taking parts of the old and building upon them to create something new. Thus parts of the electron-transport chains that were derived to service anaerobic bacteria 3 to 4 billion years ago probably survive, in altered form, in the mitochondria and chloroplasts of today's higher eucaryotes. As one example, there is a striking homology in structure and function between the enzyme complexes that pump H^+ in the central segment of the mitochondrial respiratory chain (the b-c_1 complex) and the corresponding segments of the electron-transport chains of both bacteria and chloroplasts (Figure 14-61).

Summary

Early cells are believed to have been bacteriumlike organisms living in an environment rich in highly reduced organic molecules that had been formed by geochemical processes over the course of hundreds of millions of years. They probably derived most of their ATP by converting these reduced organic molecules to a variety of organic acids, which were then released as waste products. By acidifying the environment, these fermentations may have led to the evolution of the first membrane-bound H^+ pumps, which could maintain a neutral pH in the cell interior. The properties of present-day bacteria suggest that an electron-transport-driven H^+ pump and an ATP-driven H^+ pump first arose in this anaerobic environment. Reversal of the ATP-driven pump would have allowed it to function as an ATP synthase. As more effective electron-transport chains developed, the energy released by redox reactions between inorganic molecules and accumulated nonfermentable compounds produced a large electrochemical proton gradient, which could be harnessed by the ATP-driven pump for ATP production.

Because preformed organic molecules were replenished only very slowly by geochemical processes, the proliferation of bacteria that used them as the source of both carbon and reducing power could not go on forever. The depletion of fermentable organic nutrients presumably led to the evolution of bacteria that could use CO_2 to make carbohydrates. By combining parts of the electron-transport chains that had developed earlier, light energy was harvested by a single photosystem in photosynthetic bacteria to generate the NADPH required for carbon fixation. The subsequent appearance of the more complex photosynthetic electron-transport chains of the cyanobacteria allowed H_2O to be used as the electron donor for NADPH formation, rather than the much less abundant electron donors required by other photosynthetic bacteria. Life could then proliferate over large areas of the earth, so that reduced organic molecules accumulated again. About 2 billion years ago, the O_2 released by photosynthesis in cyanobacteria began to accumulate in the atmosphere. Once both organic molecules and O_2 were abundant, electron-transport chains became adapted for the transport of electrons from NADH to O_2, and efficient aerobic metabolism developed in many bacteria. Exactly the same aerobic mechanisms operate in the mitochondria of eucaryotes, and there is considerable evidence that both mitochondria and chloroplasts evolved from aerobic bacteria that were endocytosed by primitive eucaryotic cells.
Figure 14-54. Two types of fermentation processes. The end products are highlighted by *green boxes.* In both cases two molecules of NAD$^+$ are used for each molecule of glucose that undergoes glycolysis, and these are regenerated by the transfer of hydride ions from NADH. In (A) the hydride ions are transferred to pyruvate to produce two molecules of lactic acid, which is excreted. In (B) the two hydride ions are successively transferred from two NADH molecules to compounds derived from pyruvate that produce succinic acid; for each molecule of succinic acid excreted, a molecule of pyruvate (*red*) is saved for biosyntheses inside the cell. In both (A) and (B) an organic acid must be excreted to re-form NAD$^+$ and thereby enable glycolysis to continue in the absence of oxygen.
Figure 14-55. The oxidation of formic acid in some present-day bacteria. In such anaerobic bacteria, including *E. coli*, the oxidation is mediated by an energy-conserving electron-transport chain in the plasma membrane. As indicated, the starting materials are formic acid and fumarate, and the products are succinate and CO_2. Note that H$^+$ is consumed inside the cell and generated outside the cell, which is equivalent to pumping H$^+$ to the cell exterior. Thus this membrane-bound electron-transport

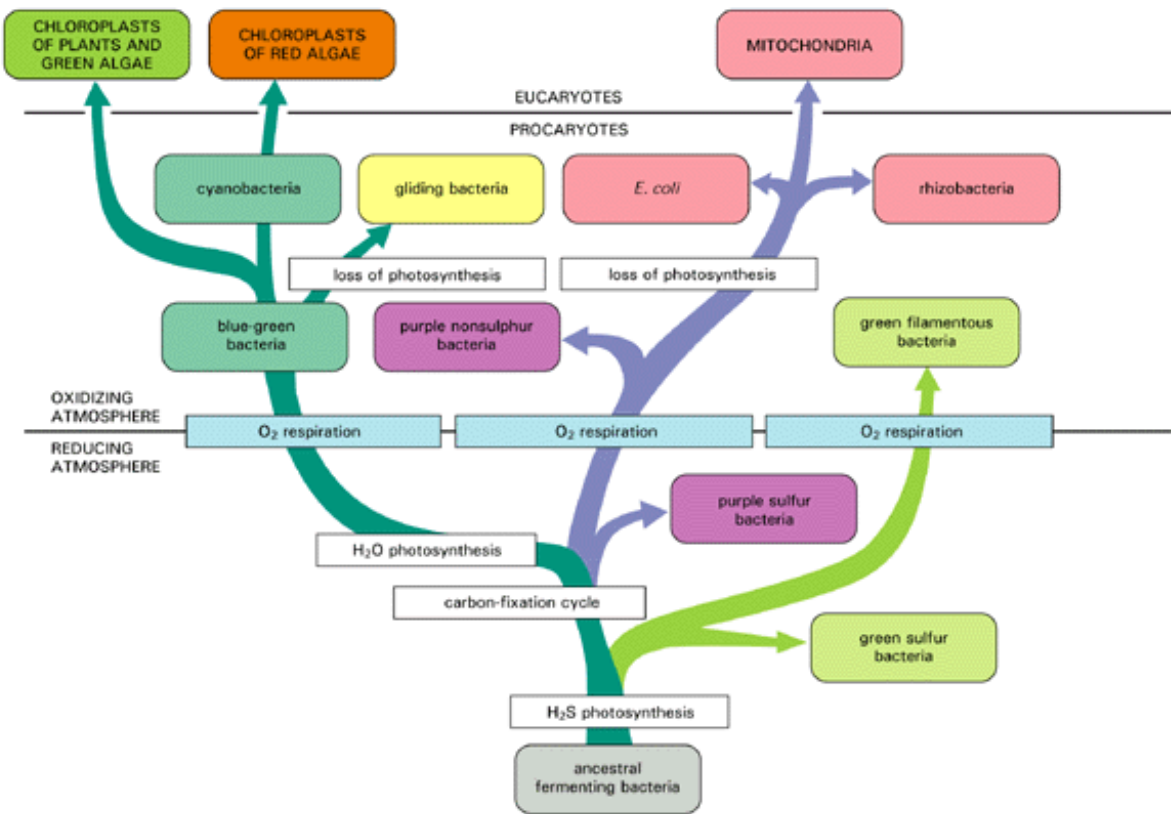
system can generate an electrochemical proton gradient across the plasma membrane. The redox potential of the formic-acid-CO_2 pair is -420 mV, while that of the fumarate-succinate pair is +30 mV.
Figure 14-57. Some of the electron-transport pathways in present-day bacteria. These pathways generate all the cell's ATP and reducing power from the oxidation of inorganic molecules, such as iron, ammonia, nitrite, and sulfur compounds. As indicated, some species can grow anaerobically by substituting nitrate for oxygen as the terminal electron acceptor. Most use the carbon-fixation cycle and synthesize their organic molecules entirely from carbon dioxide. The forward electron flows cause H^+ to be pumped out of the cell, and the resulting H^+gradient drives the production of ATP by an ATP synthase (not shown). The NADPH required for carbon fixation is produced by a reverse electron flow that is also driven by the H^+gradient, as indicated.
Figure 14-58. The general flow of electrons in a relatively primitive form of photosynthesis observed in present-day green sulfur bacteria. The photosystem in green bacteria resembles photosystem I in plants and cyanobacteria in using a series of iron-sulfur centers as primary electron acceptors that eventually donate their high-energy electrons to ferredoxin (Fd).
Figure 14-59. The relationship between changes in atmospheric O$_2$ levels and some of the major stages that are believed to have occurred during the evolution of living organisms on earth. As indicated, geological evidence suggests that there was more than a billion-year delay between the rise of cyanobacteria (thought to be the first organisms to release O$_2$) and the time that high O$_2$ levels began to accumulate in the atmosphere. This delay was probably due largely to the rich supply of dissolved ferrous iron in the oceans, which reacted with the released O$_2$ to form enormous iron oxide deposits.


Figure 14-60. A phylogenetic tree of the probable evolution of mitochondria and chloroplasts and their bacterial ancestors. Oxygen respiration is thought to have begun developing about 2×10^9 years ago. As indicated, it seems to have evolved independently in the green, purple, and blue-green (cyanobacterial) lines of photosynthetic bacteria. It is thought that an aerobic purple bacterium that had lost its ability to photosynthesize gave rise to the mitochondrion, while several different blue-green bacteria gave rise to chloroplasts. Nucleotide sequence analyses suggest that mitochondria arose from bacteria that resembled the rhizobacteria, agrobacteria, and rickettsias - three closely related species known to form intimate associations with present-day eucaryotic cells.
Figure 14-61. A comparison of three electron-transport chains discussed in this chapter. Bacteria, chloroplasts, and mitochondria all contain a membrane-bound enzyme complex that closely resembles the cytochrome b-c$_1$ complex of mitochondria. These complexes all accept electrons from a quinone carrier (designated as Q) and pump H$^+$ across their respective membranes. Moreover, in reconstituted *in vitro* systems the different complexes can substitute for one another, and the amino acid sequences of their protein components reveal that they are evolutionarily related.

The Genomes of Mitochondria and Chloroplasts

Introduction

Cells must generate new cytoplasmic organelles if they are to grow and divide. They must also replenish organelles that are degraded as part of the continual process of organelle turnover in nonproliferating cells. Organelle biosynthesis requires the ordered synthesis of the requisite proteins and lipids and the delivery of each component to the correct organelle subcompartment. In Chapter 12we discussed how selected proteins and lipids are imported into mitochondria and chloroplasts from elsewhere in the cell. Here we describe the contributions that these energy-converting organelles make to their own biogenesis.

The Biosynthesis of Mitochondria and Chloroplasts Involves the Contribution of Two Separate Genetic Systems 43

While most of the proteins in mitochondria and chloroplasts are encoded by nuclear DNA and imported into the organelle from the cytosol after they are synthesized on cytosolic ribosomes, some are encoded by organelle DNA and synthesized on ribosomes within the organelle. The protein traffic between the cytosol and these organelles seems to be unidirectional, as no protein is known to be exported from mitochondria or chloroplasts to the cytosol.

The contributions from the two genetic systems to the construction of mitochondria and chloroplasts are closely coordinated in the cell. Isolated organelles in a test tube continue to make organelle DNA, RNA, and proteins for brief periods, however, thereby providing one means of determining which proteins are encoded in organelle DNA and which in nuclear DNA. Another approach uses specific inhibitors on intact cells. The drug *cycloheximide,* for example, inhibits cytosolic protein synthesis but does not inhibit organelle protein synthesis. Conversely, various antibiotics (such as chloramphenicol, tetracycline, and erythromycin) inhibit protein synthesis in mitochondria and chloroplasts but have little effect on cytosolic protein synthesis (Figure 14-62). These inhibitors are widely used in studies of the functions of these organelles.

Organelle Growth and Division Maintain the Number of Mitochondria and Chloroplasts in a Cell 44

Mitochondria and chloroplasts are never made *de novo*. They always arise by the growth and division of existing mitochondria and chloroplasts. Observations of living cells indicate that mitochondria not only divide but also fuse with one another. On average, however, each organelle must double in mass and then divide in half once in each cell generation. Electron microscopic studies suggest that organelle division begins by an inward furrowing of the inner membrane, as occurs in cell division in many bacteria (Figures14-63 and 14-64), implying that it is a controlled process rather than a chance pinching in two.

In most cells individual energy-converting organelles divide throughout interphase, out of phase with one another and with the division of the cell. Similarly, the replication of organelle DNA is not limited to the S phase, when nuclear DNA replicates, but occurs throughout the cell cycle. Individual organelle DNA molecules seem to be selected at random for replication, so that in a given cell cycle some may replicate more than once and others not at all. Nonetheless, under constant conditions the process is regulated to ensure that the total number of organelle DNA molecules doubles in every cell cycle, so that each cell type maintains a constant amount of organelle DNA.

The number of organelles per cell can be regulated according to need; a large increase in mitochondria (as much as five- to tenfold), for example, is observed if a resting skeletal muscle is repeatedly stimulated to contract for a prolonged period. Moreover, in special circumstances, organelle division is precisely controlled by the cell: thus, in some algae that contain only one or a few chloroplasts, the organelle divides just prior to cytokinesis in a plane that is identical to the future plane of cell division.

The Genomes of Chloroplasts and Mitochondria Are Usually Circular DNA Molecules 45

Organelle DNA molecules are relatively small and simple, and, except for the mitochondrial genomes of some algae and protozoans, they are circular. The chloroplast genome (which is identical to the genomes of the other plastids in a plant) has a similar size in all organisms examined, but the mitochondrial genome is very much larger in plants than in animals (Table 14-2).

Many organelle DNA molecules are about the same size as typical viral DNAs. In mammals, for example, the mitochondrial genome is a DNA circle of about 16,500 base pairs (less than 10^{-5} times the size of the nuclear genome). It is nearly the same size in animals as diverse as *Drosophila* and sea urchins (Figure 14-65). Plants, however, contain a circular mitochondrial genome that is 10 to 150 times larger, depending on the plant. The largest of these are about half the size of typical bacterial genomes, which are also circular DNA molecules.

All mitochondria and chloroplasts contain multiple copies of the organelle DNA molecule (Table 14-3). The molecules are usually distributed in several clusters in the matrix of the mitochondrion and in the stroma of the chloroplast, where they are thought to be attached to the inner membrane. Although it is not known how the DNA is packaged, the genome structure is likely to resemble that in bacteria rather than eucaryotic chromatin. As in bacteria, for example, there are no histones.

In mammalian cells mitochondrial DNA makes up less than 1% of the total cellular DNA. In other cells, however, such as the leaves of higher plants or the very large egg cells of amphibia, a much larger fraction of the cellular DNA may be present in the energy-converting organelles (see Table 14-3), and a larger fraction of RNA and protein synthesis takes place there.

Mitochondria and Chloroplasts Contain Complete Genetic Systems 46

Despite the small number of proteins encoded in their genomes, mitochondria and plastids carry out their own DNA replication, DNA transcription, and protein synthesis. These processes take place in the matrix in mitochondria and in the stroma in

chloroplasts. Although the proteins that mediate these genetic processes are unique to the organelle, most of them are encoded in the nuclear genome. This is all the more surprising because the protein-synthesis machinery of the organelles resembles that of bacteria rather than that of eucaryotes. The resemblance is particularly close in the case of chloroplasts:

1. Chloroplast ribosomes are very similar to *E. coli* ribosomes, both in their sensitivity to various antibiotics (such as chloramphenicol, streptomycin, erythromycin, and tetracycline) and in their structure. Not only are the nucleotide sequences of the ribosomal RNAs of chloroplasts and *E. coli* strikingly similar, but chloroplast ribosomes are able to use bacterial tRNAs in protein synthesis. In all these respects, chloroplast ribosomes differ from those found in the cytosol of the same plant cell.

2. Protein synthesis in chloroplasts starts with *N*-formylmethionine, as in bacteria, and not with methionine, as in the cytosol of eucaryotic cells.

3. Unlike nuclear DNA, chloroplast DNA can be transcribed by the RNA polymerase enzyme from *E. coli* to produce chloroplast mRNAs, and these mRNAs are efficiently translated by an *E. coli* protein-synthesizing system.

Although mitochondrial genetic systems are much less similar to those of present-day bacteria than are the genetic systems of chloroplasts, their ribosomes are also sensitive to antibacterial antibiotics, and protein synthesis in mitochondria also starts with *N*-formylmethionine.

The Chloroplast Genome of Higher Plants Contains About 120 Genes [47]

The best-studied chloroplast genomes are those of green algae and higher plants, whose chloroplasts are very similar circular DNA molecules. The complete nucleotide sequences have been determined for the chloroplasts of tobacco and liver-wort. The results indicate that these two distantly related higher plants contain nearly identical chloroplast genes. In addition to four ribosomal RNAs, these genomes encode about 20 chloroplast ribosomal proteins, selected subunits of the chloroplast RNA polymerase, several proteins that are part of photosystems I and II, subunits of the ATP synthase, portions of enzyme complexes in the electron-transport chain, one of the two subunits of ribulose bisphosphate carbox-ylase, and 30 tRNAs (Figure 14-66). In addition, the DNA sequences present seem to encode at least 40 proteins whose functions are unknown. Paradoxically, all of the known proteins encoded in the chloroplast are part of larger protein complexes that also contain one or more subunits encoded in the nucleus. Possible reasons will be discussed later.

The similarities between the genomes of chloroplasts and bacteria are striking. The basic regulatory sequences, such as transcription promoters and terminators, are virtually identical in the two cases. Protein sequences encoded in chloroplasts are clearly recognizable as bacterial, and several clusters of genes with related functions (for example, those encoding ribosomal proteins) are organized in the same way in the genomes of chloroplasts, *E. coli,* and cyanobacteria.

Detailed comparisons of large numbers of homologous nucleotide sequences should help to clarify the exact evolutionary pathway from bacteria to chloroplasts, but several conclusions can already be drawn. (1) Chloroplasts in higher plants arose from photosynthetic bacteria. (2) The chloroplast genome has been stably maintained for at least several hundred million years, the estimated time of divergence of liverwort and tobacco. (3) Many of the genes of the original bacterium are now present in the nuclear genome, where they have been transferred and stably maintained. In higher plants, for example, two-thirds of the 60 or so chloroplast ribosomal proteins are encoded in the cell nucleus, although the genes have a clear bacterial ancestry and the chloroplast ribosomes retain their original bacterial properties.

Mitochondrial Genomes Have Several Surprising Features [48]

The chloroplast genome was not the first organelle genome to be sequenced completely. The relatively small size of the human mitochondrial genome made it a particularly attractive target for molecular geneticists equipped with newly devised DNA-sequencing techniques, and in 1981 the complete sequence of its 16,569 nucleotides was published. By comparing this sequence with known mitochondrial tRNA sequences and with the partial amino acid sequences available for proteins encoded by the mitochondrial DNA, it has been possible to locate all of the human mitochondrial genes on the circular DNA molecule (Figure 14-67).

Compared to nuclear, chloroplast, and bacterial genomes, the human mitochondrial genome has several surprising features. (1) Unlike other genomes, nearly every nucleotide appears to be part of a coding sequence, either for a protein or for one of the rRNAs or tRNAs. Since these coding sequences run directly into each other, there is very little room left for regulatory DNA

sequences. (2) Whereas 30 or more tRNAs specify amino acids in the cytosol and in chloroplasts, only 22 tRNAs are required for mitochondrial protein synthesis. The normal codon-anticodon pairing rules are relaxed in mitochondria, so that many tRNA molecules recognize any one of the four nucleotides in the third (wobble) position. Such "2 out of 3" pairing allows one tRNA to pair with any one of four codons and permits protein synthesis with fewer tRNA molecules. (3) Perhaps most surprising, comparison of mitochondrial gene sequences and the amino acid sequences of the corresponding proteins indicates that the genetic code is different, so that 4 of the 64 codons have different "meanings" from those of the same codons in other genomes (Table 14-4).

Codon	"Universal" Code	Mitochondrial Codes			
		Mammals	Drosophila	Yeasts	Plants
UGA	STOP	Trp	Trp	Trp	STOP
AUA	Ile	Met	Met	Met	Ile
CUA	Leu	Leu	Leu	Thr	Leu
AGA ⎫ AGG ⎭	Arg	STOP	Ser	Arg	Arg

*Italics and color shading indicate that the code differs from the "universal" code.

The observation that the genetic code is nearly the same in all organisms provides strong evidence that all cells have evolved from a common ancestor. How, then, does one explain the few differences in the genetic code in mitochondria? A hint comes from the recent finding that the mitochondrial genetic code is different in different organisms. Thus UGA, which is a stop codon elsewhere, is read as tryptophan in mitochondria of mammals, fungi, and protozoans but as *stop* in plant mitochondria. Similarly, the codon AGG normally codes for arginine, but it codes for *stop* in the mitochondria of mammals and for serine in *Drosophila* (see Table 14-4). Such variation suggests that a random drift can occur in the genetic code in mitochondria. Presumably, the unusually small number of proteins encoded by the mitochondrial genome makes an occasional change in the meaning of a rare codon tolerable, whereas such a change in a large genome would alter the function of many proteins and thereby destroy the cell.

Animal Mitochondria Contain the Simplest Genetic Systems Known 49

Comparisons of DNA sequences in different organisms reveal that the rate of nucleotide substitution during evolution has been 10 times greater in mitochondrial genomes than in nuclear genomes, which presumably is due to a reduced fidelity of mitochondrial DNA replication, DNA repair, or both. Because only about 16,500 DNA nucleotides need to be replicated and expressed as RNAs and proteins in animal cell mitochondria, the error rate *per nucleotide* copied by DNA replication, maintained by DNA repair, transcribed by RNA polymerase, or translated into protein by mitochondrial ribosomes can be relatively high without damaging one of the relatively few gene products. This could explain why the mechanisms that carry out these processes are relatively simple compared to those used for the same purpose elsewhere in cells. The presence of only 22 tRNAs and the unusually small size of the rRNAs (less than two-thirds the size of the *E. coli* rRNAs), for example, would be expected to reduce the fidelity of protein synthesis in mitochondria, although this has not yet been tested adequately.

The relatively high rate of evolution of mitochondrial genes makes mitochondrial DNA sequence comparisons especially useful for estimating the dates of relatively recent evolutionary events, such as the steps in primate development.

Why Are Plant Mitochondrial Genomes So Large? 50

Mitochondrial genomes are much larger in plant than in animal cells, and they vary remarkably in their DNA content, ranging from about 150,000 to about 2.5×10^6 nucleotide pairs. Yet these genomes seem to encode only a few more proteins than do animal mitochondrial genomes. The paradox is compounded by the observation that in one family of plants, the cucurbits, mitochondrial genomes vary in size by as much as sevenfold. The green alga *Chlamydomonas* has a linear mitochondrial genome of only 16,000 nucleotide pairs, the same size as in animals.

Although very little sequence information is available for higher plant mitochondrial DNA molecules, almost all of the 70,000

nucleotide pairs in the large mitochondrial genome of the yeast *Saccharomyces cerevisiae* have been sequenced, and only about one-third of them code for protein. This finding raises the possibility that much of the extra DNA in yeast mitochondria, and possibly in plant mitochondria as well, is "junk DNA" of little consequence to the organism.

Some Organelle Genes Contain Introns 51

The processing of precursor RNAs plays an important role in the two mitochondrial systems studied in most detail - human and yeast. In human cells both strands of the mitochondrial DNA are transcribed at the same rate from a single promoter region on each strand, producing two different giant RNA molecules, each containing a full-length copy of one DNA strand. Transcription is, therefore, completely symmetric. The transcripts made on one strand - called the *heavy strand (H strand)* because of its density in CsCl - are extensively processed by nuclease cleavage to yield the two rRNAs, most of the tRNAs, and about 10 poly-A-containing RNAs. In contrast, the *light strand (L strand)* transcript is processed to produce only eight tRNAs and one small poly-A-containing RNA; the remaining 90% of this transcript apparently contains no useful information (being complementary to coding sequences synthesized on the other strand) and is degraded. The poly-A-containing RNAs are the mitochondrial mRNAs: although they lack a cap structure at their 5' end, they carry a poly-A tail at their 3' end that is added posttranscriptionally by a mitochondrial poly-A polymerase.

Unlike human mitochondrial genes, some plant and fungal (including yeast) mitochondrial genes contain *introns,* which must be removed by RNA splicing. Introns have also been found in about 20 plant chloroplast genes. Many of the introns in organelle genes consist of related nucleotide sequences that are capable of splicing themselves out of the RNA transcripts by RNA-mediated catalysis (see p. 109), although these self-splicing reactions are generally aided by proteins. The presence of introns in organelle genes is surprising, as introns are not common in the genes of the bacteria whose ancestors are thought to have given rise to mitochondria and plant chloroplasts.

In yeasts the same mitochondrial gene may have an intron in one strain but not in another. Such "optional introns" seem to be able to move in and out of genomes like transposable elements. On the other hand, introns in other yeast mitochondrial genes have been found in a corresponding position in the mitochondria of *Aspergillus* and *Neurospora,* implying that they were inherited from a common ancestor of these three fungi. It seems likely that the intron sequences themselves are of ancient origin and that, while they have been lost from many bacteria, they have been preferentially retained in those organelle genomes where RNA splicing is regulated to help control gene expression.

Mitochondrial Genes Can Be Distinguished from Nuclear Genes by Their Non-Mendelian (Cytoplasmic) Inheritance 52

Most experiments on the mechanisms of mitochondrial biogenesis have been performed with *Saccharomyces cerevisiae* (baker's yeast). There are several reasons for this. First, when grown on glucose, this yeast has an ability to live by glycolysis alone and can therefore survive without functional mitochondria, which are required for oxidative phosphorylation. This makes it possible to grow cells with mutations in mitochondrial or nuclear DNA that drastically interfere with mitochondrial biogenesis; such mutations are lethal in many other eucaryotes. Second, yeasts are simple unicellular eucaryotes that are easy to grow and characterize biochemically. Finally, these yeast cells normally reproduce asexually by budding (asymmetrical mitosis), but they can also reproduce sexually. During sexual reproduction two haploid cells mate and fuse to form a diploid zygote, which can either grow mitotically or divide by meiosis to produce new haploid cells. The ability to control the alternation between asexual and sexual reproduction in the laboratory greatly facilitates genetic analyses. Because mutations in mitochondrial genes are not inherited according to the Mendelian rules that govern the inheritance of nuclear genes, genetic studies reveal which of the genes involved in mitochondrial function are located in the nucleus and which in the mitochondria.

An example of non-Mendelian (cytoplasmic) inheritance of mitochondrial genes in a haploid yeast cell is illustrated in <u>Figure 14-68</u>. In this example we follow the inheritance of a mutant gene that makes mitochondrial protein synthesis resistant to chloramphenicol. When a chloramphenicol-resistant haploid cell mates with a chloramphenicol-sensitive wild-type haploid cell, the resulting diploid zygote will contain a mixture of mutant and wild-type mitochondria. But when the zygote undergoes mitosis to produce a diploid daughter, the mutant and wild-type mitochondria will be distributed at random between the mother and the daughter cell, so that each daughter is likely to inherit more mutant or more wild-type mitochondria. With successive mitotic divisions, either the mutant or the wild-type mitochondria will gradually be diluted out of some daughters by the same random process, leaving mitochondria of only one type. Thereafter, all of the progeny from that daughter will have mitochondria that are genetically identical. Thus this random process, called *mitotic segregation,* will eventually produce diploid yeast cells with only a single type of mitochondrial DNA. When such diploid cells undergo meiosis to form four haploid daughter cells, each of the four daughters receives the same mitochondrial genes. This type of inheritance is called *non-*

Mendelian, or *cytoplasmic,* to contrast it with the Mendelian inheritance of nuclear genes (see Figure 14-68). When it occurs, it demonstrates that the gene in question is located outside the nuclear chromosomes and therefore probably in the yeast mitochondria.

Organelle Genes Are Maternally Inherited in Many Organisms 53

The consequences of cytoplasmic inheritance are more profound for some organisms, including ourselves, than they are for yeasts. In yeasts, when two haploid cells mate, they are equal in size and contribute equal amounts of mitochondrial DNA to the zygote (see Figure 14-68). Mitochondrial inheritance in yeasts is therefore *biparental:* both parents contribute equally to the mitochondrial gene pool of the progeny (although, as we have just seen, after several generations of vegetative growth the *individual* progeny often contain mitochondria from only one parent). In higher animals, by contrast, the egg cell always contributes much more cytoplasm to the zygote than does the sperm. One would expect mitochondrial inheritance in higher animals, therefore, to be nearly *uniparental* (or more precisely, *maternal*). Such *maternal inheritance* has been demonstrated in laboratory animals. When animals carrying type A mitochondrial DNA are crossed with animals carrying type B, the progeny contain only the maternal type of mitochondrial DNA. Similarly, by following the distribution of variant mitochondrial DNA sequences in large families, human mitochondrial DNA has been shown to be maternally inherited.

In about two-thirds of higher plants the chloroplasts from the male parent (contained in pollen grains) do not enter the zygote, so that chloroplast as well as mitochondrial DNA is maternally inherited. In other plants the pollen chloroplasts enter the zygote, making chloroplast inheritance biparental. In such plants defective chloroplasts are a cause of *variegation:* a mixture of normal and defective chloroplasts in a zygote may sort out by mitotic segregation during plant growth and development, thereby producing alternating green and white patches in leaves. The green patches contain normal chloroplasts, while the white patches contain defective chloroplasts.

Petite Mutants in Yeasts Demonstrate the Overwhelming Importance of the Cell Nucleus for Mitochondrial Biogenesis 54

Genetic studies of yeasts have played a crucial part in the analysis of mitochondrial biogenesis. A striking example is provided by studies of yeast mutants that contain large deletions in their mitochondrial DNA, so that all mitochondrial protein synthesis is abolished. Not surprisingly, these mutants cannot make respiring mitochondria. Some of these mutants lack mitochondrial DNA altogether. Because they form unusually small colonies when grown in media with low glucose, all mutants with such defective mitochondria are called *cytoplasmic petite mutants.*

Although petite mutants cannot synthesize proteins in their mitochondria and therefore cannot make mitochondria that produce ATP, they nevertheless contain mitochondria. These mitochondria have a normal outer membrane and an inner membrane with poorly developed cristae (Figure 14-69), and they contain virtually all of the mitochondrial proteins that are specified by nuclear genes and imported from the cytosol - including DNA and RNA polymerases, all of the citric acid cycle enzymes, and most inner membrane proteins - demonstrating the overwhelming importance of the nucleus in mitochondrial biogenesis. The petite mutants also show that an organelle that divides by fission can replicate indefinitely in the cytoplasm of proliferating eucaryotic cells even in the complete absence of its own genome. Many biologists believe that peroxisomes normally replicate in this way (see Figure 12-29).

For chloroplasts the nearest equivalent to yeast mitochondrial petite mutants are mutants of unicellular algae such as *Euglena.* Cells in which no chloroplast protein synthesis occurs still contain chloroplasts and are perfectly viable if oxidizable substrates are provided. If the development of mature chloroplasts is blocked in higher plants, however, either by raising the plants in the dark or because chloroplast DNA is defective or absent, the plants die as soon as their food stores run out.

Mitochondria and Chloroplasts Contain Tissue-specific Proteins 55

Mitochondria can have specialized functions in particular types of cells. The *urea cycle,* for example, is the central metabolic pathway in mammals for disposing of cellular breakdown products that contain nitrogen. These products are excreted in the urine as urea. Nuclear-encoded enzymes in the mitochondrial matrix carry out several steps in the cycle. Urea synthesis occurs in only a few tissues, such as the liver, and the required enzymes are synthesized and imported into mitochondria only in these tissues. In addition, the respiratory enzyme complexes in the mitochondrial inner membrane of mammals contain several tissue-specific, nuclear-encoded subunits that are thought to act as regulators of electron transport. Thus some humans with a genetic muscle disease have a defective subunit of cytochrome oxidase; since the subunit is specific to skeletal muscle cells, their other

cells, including their heart muscle cells, function normally, allowing the individuals to survive. As would be expected, tissue-specific differences are also found among the nuclear-encoded proteins in chloroplasts.

Mitochondria Import Most of Their Lipids; Chloroplasts Make Most of Theirs [56]

The biosynthesis of new mitochondria and chloroplasts requires lipids in addition to nucleic acids and proteins. Chloroplasts tend to make the lipids they require. In spinach leaves, for example, all cellular fatty acid synthesis takes place in the chloroplast, although desaturation of the fatty acids occurs elsewhere. The major glycolipids of the chloroplast are also synthesized locally.

Mitochondria, on the other hand, import most of their lipids. In animal cells the phospholipids phosphatidylcholine and phosphatidylserine are synthesized in the endoplasmic reticulum and then transferred to the outer membrane of mitochondria. In addition to decarboxylating imported phosphatidylserine to phosphatidylethanolamine, the main reaction of lipid biosynthesis catalyzed by the mitochondria themselves is the conversion of imported lipids to cardiolipin (bisphosphatidylglycerol). Cardiolipin is a "double" phospholipid that contains four fatty-acid tails; it is found mainly in the mitochondrial inner membrane, where it constitutes about 20% of the total lipid.

We have discussed the important question of how specific cytosolic proteins are imported into mitochondria and chloroplasts in detail in Chapter 12.

Both Mitochondria and Chloroplasts Probably Evolved from Endosymbiotic Bacteria [57]

As discussed in Chapter 1, the procaryotic character of the organelle genetic systems, especially striking in chloroplasts, suggests that mitochondria and chloroplasts evolved from bacteria that were endocytosed more than a billion years ago. According to this endosymbiont hypothesis, eucaryotic cells started out as anaerobic organisms without mitochondria or chloroplasts and then established a stable endosymbiotic relation with a bacterium, whose oxidative phosphorylation system they subverted for their own use (Figure 14-70). The endocytic event that led to the development of mitochondria is presumed to have occurred when oxygen entered the atmosphere in substantial amounts, about 1.5×10^9 years ago, before animals and plants separated (see Figure 14-59). Plant and algal chloroplasts seem to have been derived later from an endocytic event involving an oxygen-evolving photosynthetic bacterium. In order to explain the different pigments and properties of the chloroplasts found in present-day higher plants and algae, it is usually assumed that at least three separate events of this kind occurred.

Since most of the genes encoding present-day mitochondrial and chloroplast proteins are in the cell nucleus, it seems that an extensive transfer of genes from organelle to nuclear DNA has occurred during eucaryote evolution. This would explain why some of the nuclear genes encoding mitochondrial proteins resemble bacterial genes: the amino acid sequence of the chicken mitochondrial enzyme *superoxide dismutase,* for example, resembles the corresponding bacterial enzyme much more than it resembles the superoxide dismutase found in the cytosol of the same eucaryotic cells. Further evidence that such DNA transfers have occurred during evolution comes from the discovery of some noncoding DNA sequences in nuclear DNA that seem to be of recent mitochondrial origin; they have apparently integrated into the nuclear genome as "junk DNA."

What type of bacterium gave rise to the mitochondrion? Protein and nucleotide sequence analyses have provided evidence for the evolutionary tree shown previously in Figure 14-60. It appears that mitochondria are descendants of a particular type of purple photosynthetic bacterium that had previously lost its ability to carry out photosynthesis and was left with only a respiratory chain. It is not clear that all mitochondria have originated from a single endosymbiotic event, however. While the mitochondria from protozoans have distinctly procaryotic features, for example, some of them are sufficiently different from plant and animal mitochondria to suggest a separate origin.

Why Do Mitochondria and Chloroplasts Have Their Own Genetic Systems? [58]

Why do mitochondria and chloroplasts require their own separate genetic systems when other organelles that share the same cytoplasm, such as peroxisomes and lysosomes, do not? The question is not trivial because maintaining a separate genetic system is costly: more than 90 proteins - including many ribosomal proteins, aminoacyl-tRNA synthases, DNA and RNA polymerases, and RNA-processing and -modifying enzymes - must be encoded by nuclear genes specifically for this purpose (Figure 14-71). The amino acid sequences of most of these proteins in mitochondria and chloroplasts differ from those of their counterparts in the nucleus and cytosol, and there is reason to think that these organelles have relatively few proteins in common

with the rest of the cell. This means that the nucleus must provide at least 90 genes just to maintain each organelle genetic system. The reason for such a costly arrangement is not clear, and the hope that the nucleotide sequences of mitochondrial and chloroplast genomes would provide the answer has proved unfounded. We cannot think of compelling reasons why the proteins made in mitochondria and chloroplasts should be made there rather than in the cytosol.

At one time it was suggested that some proteins have to be made in the organelle because they are too hydrophobic to get to their site in the membrane from the cytosol. More recent studies, however, make this explanation implausible. In many cases even highly hydrophobic subunits are synthesized in the cytosol. Moreover, although the individual protein subunits in the various mitochondrial enzyme complexes are highly conserved in evolution, their site of synthesis is not. The diversity in the location of the genes coding for the subunits of functionally equivalent proteins in different organisms is difficult to explain by any hypothesis that postulates a specific evolutionary advantage of present-day mitochondrial or chloroplast genetic systems.

Perhaps the organelle genetic systems are an evolutionary dead end. In terms of the endosymbiont hypothesis, this would mean that the process whereby the endosymbionts transferred most of their genes to the nucleus stopped before it was complete. Further transfers may have been ruled out, in the case of mitochondria, by recent alterations in the mitochondrial genetic code that made the remaining mitochondrial genes nonfunctional if they were transferred to the nucleus.

Summary

Mitochondria and chloroplasts grow and divide in two in a coordinated process that requires the contribution of two separate genetic systems - that of the organelle and that of the cell nucleus. Most of the proteins in these organelles are encoded by nuclear DNA, synthesized in the cytosol, and then imported individually into the organelle. Some organelle proteins and RNAs are encoded by the organelle DNA and are synthesized in the organelle itself. The human mitochondrial genome contains about 16,500 nucleotides and encodes 2 ribosomal RNAs, 22 transfer RNAs, and 13 different polypeptide chains. Chloroplast genomes are about 10 times larger and contain about 120 genes. But partially functional organelles will form in normal numbers even in mutants that lack a functional organelle genome, demonstrating the overwhelming importance of the nucleus for the biogenesis of both organelles.

The ribosomes of chloroplasts closely resemble bacterial ribosomes, while mitochondrial ribosomes show both similarities and differences that make their origin more difficult to trace. Protein similarities, however, suggest that both organelles originated when a primitive eucaryotic cell entered into a stable endosymbiotic relationship with a bacterium: a purple bacterium is thought to have given rise to the mitochondrion, and (later) a relative of a cyanobacterium is thought to have given rise to the plant chloroplast. Although many of the genes of these ancient bacteria still function to make organelle proteins, most of them have become integrated into the nuclear genome, where they encode bacterial-like enzymes that are synthesized on cytosolic ribosomes and then imported into the organelle.

Table 14-2. The Size of Organelle Genomes*

Type of DNA	Size (thousands of nucleotide pairs)
Chloroplast DNA	
Higher plants	120-200
Chlamydomonas(green alga)	180
Mitochondrial DNA	
Animals (including flatworms, insects, and mammals)	16-19
Higher plants	150-2500
Fungi	
Schizosaccharomyces pombe(fission yeast)	17
Aspergillus nidulans	32
Neurospora crassa	60
Saccharomyces cerevisiae(budding yeast)	78
Chlamydomonas(green alga)	16 (linear molecule)
Protozoa	
Trypanosoma brucei	22
Paramecium	40 (linear molecule)

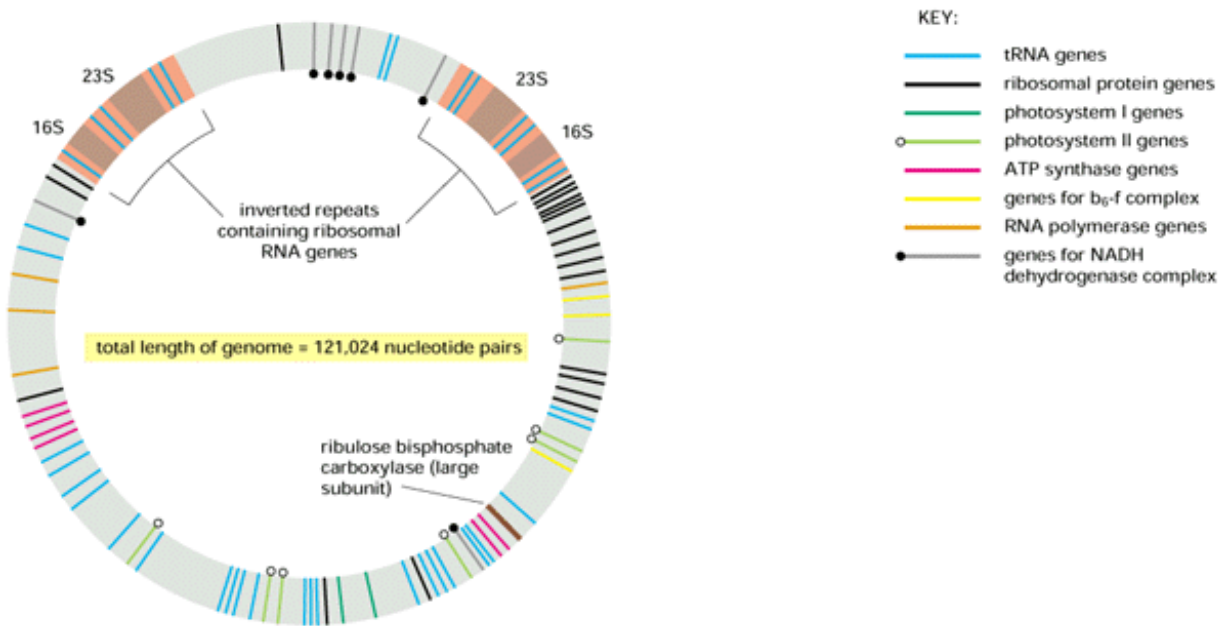
*. These genomes are circular DNA molecules unless indicated otherwise.
Figure 14-65. Electron micrograph of an animal mitochondrial DNA molecule caught during the process of DNA replication. The circular DNA genome has replicated only between the two points marked by arrows (*yellow strands*). (Courtesy of David Clayton.)


Figure 14-66. The organization of the liverwort chloroplast genome. The complete nucleotide sequence of this genome has been determined. The organization of the chloroplast genome is very similar in all higher plants, although the size varies from species to species depending on how much of the DNA surrounding the genes encoding the chloroplast's 16S and 23S ribosomal RNAs is present in two copies.
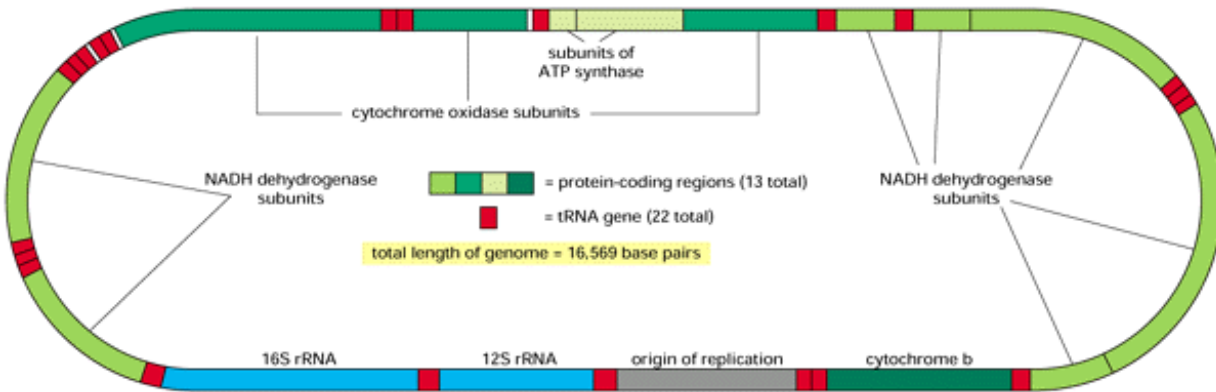

Figure 14-67. The organization of the human mitochondrial genome. The genome contains 2 rRNA genes, 22 tRNA genes, and 13 protein-coding sequences. The DNAs of several other animal mitochondrial genomes have also been completely sequenced and have the same genes and gene organization.

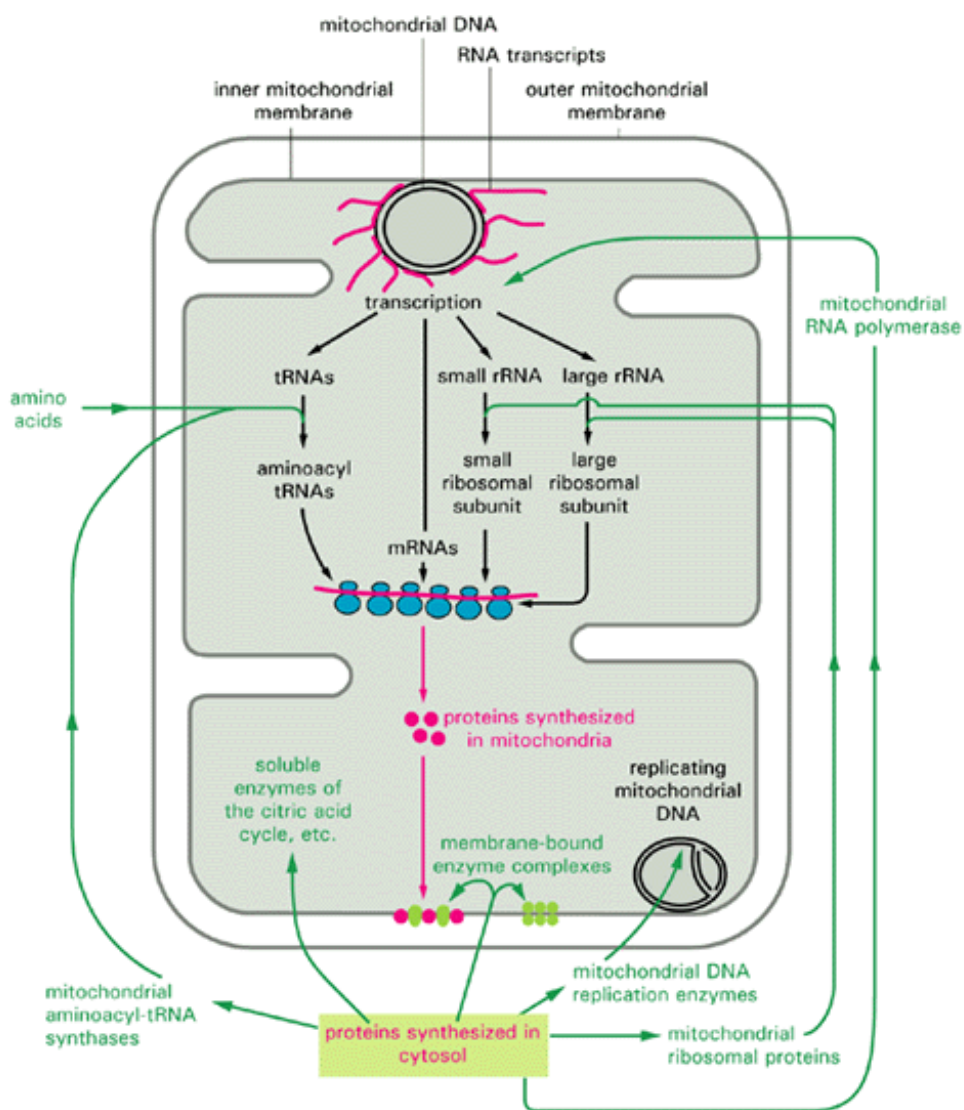
Table 14-4. Some Differences Between the "Universal" Code and Mitochondrial Genetic Codes*
Figure 14-68. The difference in the pattern of inheritance between mitochondrial and nuclear genes of yeast. For each nuclear gene two of the four cells that result from meiosis inherit the gene from one of the original haploid parent cells and the remaining two cells inherit the gene from the other (*Mendelian inheritance*). In contrast, because of the gradual mitotic segregation of mitochondria during vegetative growth (see text), it is possible for all four of the cells that result from meiosis to inherit their mitochondrial genes from only one of the two original haploid cells (*non-Mendelian,* or *cytoplasmic, inheritance*). In this example the mitochondrial gene is one that (in its mutant form) makes protein synthesis in the mitochondrion resistant to chloramphenicol, a protein synthesis inhibitor that acts specifically on energy-converting organelles and bacteria. Yeast cells that contain the mutant gene can be detected by their ability to grow in the presence of chloramphenicol on a substrate, such as glycerol, that cannot be used for glycolysis. With glycolysis blocked, ATP must be provided by functional mitochondria, and therefore only cells that carry chloramphenicol-resistant mitochondria will grow.
Figure 14-69. Electron micrographs of yeast cells showing the structure of normal mitochondria (A) and mitochondria in a petite mutant (B). In petite mutants all of the mitochondrion-encoded gene products are missing, and so the organelle is constructed entirely from nucleus-encoded proteins. (Courtesy of Barbara Stevens.)
Figure 14-70. A suggested evolutionary pathway for the origin of mitochondria. *Microsporidia* and *Giardia* are two present-day anaerobic single-celled eucaryotes (protozoa) without mitochondria. Because they have an rRNA sequence that suggests a great deal of evolutionary distance from all other known eucaryotes, it has been postulated that their ancestors were also anaerobic and resembled the eucaryote that first engulfed the precursors of mitochondria.


Figure 14-71. The origins of mitochondrial RNAs and proteins. The proteins imported from the cytosol play a major part in creating the genetic system of the mitochondrion in addition to contributing most of the organelle protein. The mitochondrion itself contributes only mRNAs, rRNAs, and tRNAs to its genetic system. Not indicated in this diagram are the additional nucleus-encoded proteins that regulate the expression of individual mitochondrial genes at posttranscriptional levels.

15. Cell Signaling

Introduction

The fossil record suggests that sophisticated unicellular organisms resembling present-day bacteria were present on earth 3.5 billion years ago but that it apparently required more than another 2.5 billion years for the first multicellular organisms to appear (see Figure 1-17). Why was multicellularity so slow to evolve? Although the answer cannot be known, it seems likely to be related to the need in a multicellular organism for elaborate signaling mechanisms that enable its cells to communicate with one another so as to coordinate their behavior for the benefit of the organism as a whole. Intercellular signals, interpreted by complex machinery in the responding cell, allow each cell to determine its position and specialized role in the body and ensure, for example, that each cell divides only when its neighbors dictate that it should do so. The importance of such "social controls" on cell division becomes apparent when the controls fail, resulting in cancer, which usually kills the multicellular organism.

As more and more powerful techniques become available to study cells and the mechanisms they use to communicate with one another, the intricacy of the signaling processes used by higher eucaryotes is slowly coming into focus. An animal cell contains an elaborate system of proteins that enables the cell to respond to signals from other cells. The system includes cell-surface and intracellular receptor proteins, protein kinases, protein phosphatases, GTP-binding proteins, and the many intracellular proteins with which these signaling proteins interact. In this chapter we first discuss the general principles of intercellular signaling. In the subsequent two sections we consider in turn the two main families of cell-surface receptor proteins and how they generate intracellular signals. We then examine how cells continuously adapt in order to respond sensitively to small changes in the concentration of an extracellular signaling molecule. Finally, we consider an analogy with computer-based neural networks,

which provides insights into how complex intracellular signaling networks operate.

General Principles of Cell Signaling [1]

Introduction

Mechanisms enabling one cell to influence the behavior of another almost certainly existed in the world of unicellular organisms long before multicellular organisms appeared on earth. Evidence comes from studies of some present-day unicellular eucaryotes such as yeasts. Although these cells normally lead independent lives, they can communicate and influence one another's proliferation in preparation for sexual mating. In the budding yeast *Saccharomyces cerevisiae,* for example, when a haploid individual is ready to mate, it secretes a peptide *mating factor* that signals cells of opposite mating types to stop proliferating and prepare to conjugate; the subsequent fusion of two haploid cells of the opposite mating type produces a diploid cell, which can then undergo meiosis and sporulate to generate haploid cells with new assortments of genes.

Studies of yeast mutants that are unable to mate have identified many proteins that are required in the signaling process. These proteins form a signaling network that includes cell-surface receptors, GTP-binding proteins, and protein kinases, each of which has close relatives among the proteins involved in signaling in animal cells. Through gene duplication and divergence, however, the signaling systems in animals have become much more elaborate than those in yeasts.

Extracellular Signaling Molecules Are Recognized by Specific Receptors on or in Target Cells [2]

Whereas yeast cells communicate with one another for mating by secreting several kinds of small peptides, cells in higher animals communicate by means of hundreds of kinds of signaling molecules, including proteins, small peptides, amino acids, nucleotides, steroids, retinoids, fatty acid derivatives, and even dissolved gases such as nitric oxide and carbon monoxide. Most of these signaling molecules are secreted from the *signaling cell* by exocytosis (discussed in Chapter 13). Others are released by diffusion through the plasma membrane, while some remain tightly bound to the cell surface and influence only cells that contact the signaling cell (Figure 15-1).

Regardless of the nature of the signal, the *target cell* responds by means of a specific protein called a receptor. It specifically binds the signaling molecule and then initiates a response in the target cell. Many of the extracellular signaling molecules act at very low concentrations (typically $\leq 10^{-8}$ M), and the receptors that recognize them usually bind them with high affinity (affinity constant $K_a \geq 10^8$ liters/mole; see Figure3-9). In most cases the receptors are transmembrane proteins on the target-cell surface; when they bind an extracellular signaling molecule (a *ligand*), they become activated so as to generate a cascade of intracellular signals that alter the behavior of the cell. In some cases, however, the receptors are inside the target cell and the signaling ligand has to enter the cell to activate them: these signaling molecules therefore must be sufficiently small and hydrophobic to diffuse across the plasma membrane (Figure 15-2).

In this chapter we concentrate mainly on the communication between animal cells that is mediated by secreted chemical signals. This emphasis reflects the state of current knowledge: secreted molecules are very much easier to study than those that are membrane-bound, and we know much more about how they work. Contact-dependent signaling via membrane-bound molecules, although harder to study and less well understood, nonetheless, is crucially important, especially during development and in immune responses; its molecular basis can be very similar to that for signaling at a distance, as we see later.

Secreted Molecules Mediate Three Forms of Signaling: Paracrine, Synaptic, and Endocrine [2]

Signaling molecules that a cell secretes may be carried far afield to act on distant targets, or they may act as local mediators, affecting only cells in the immediate environment of the signaling cell. This latter process is called paracrine signaling (Figure 15-3A). For paracrine signals to be delivered only to their proper targets, the secreted signaling molecules must not be allowed to diffuse too far; for this reason they are often rapidly taken up by neighboring target cells, destroyed by extracellular enzymes, or immobilized by the extracellular matrix.

For a large, complex multicellular organism, short-range signaling is not sufficient on its own to coordinate the behavior of the organism's cells. Sets of specialized cells have evolved with a specific role in signaling between widely separate parts of the

body. The most sophisticated of these are nerve cells, or neurons, which typically extend long processes (axons) that contact target cells far away. When activated by signals from the environment or from other nerve cells, a neuron sends electrical impulses (action potentials) along its axon; when an impulse reaches the nerve terminals at the end of the axon, it stimulates the terminals to secrete a chemical signal called a neurotransmitter. The nerve terminals contact their target cell at specialized cell junctions called *chemical synapses*, which are designed to ensure that the neurotransmitter is delivered to the postsynaptic target cell rapidly and specifically (Figure 15-3B). This synaptic signaling process is discussed in detail in Chapter 11 and will not be considered further here.

The other specialized signaling cells that control the behavior of the organism as a whole are endocrine cells. They secrete their signaling molecules, called hormones, into the bloodstream (of an animal) or the sap (of a plant), which carries the signal to target cells distributed widely throughout the body (Figure 15-3C). The distinctive ways that endocrine cells and nerve cells coordinate cell behavior in animals are contrasted in Figure 15-4.

Because endocrine signaling relies on diffusion and blood flow, it is relatively slow. Nerve cells, by contrast, can achieve much greater speed and precision. They can transmit information over long distances by electrical impulses that travel at rates of up to 100 meters per second; once released from a nerve terminal, a neurotransmitter has to diffuse less than 100 nm to the target cell, a process that takes less than a millisecond. Another difference between endocrine and synaptic signaling is that whereas hormones are greatly diluted in the bloodstream and interstitial fluid and therefore must be able to act at very low concentrations (typically $< 10^{-8}$M), neurotransmitters are diluted much less and can achieve high local concentrations. The concentration of acetylcholine in the synaptic cleft of an active neuromuscular junction, for example, is about 5×10^{-4} M. Correspondingly, neurotransmitter receptors have a relatively low affinity for their ligand, which means that the neurotransmitter can dissociate rapidly from the receptor to terminate a response. (Neurotransmitters are quickly removed from the synaptic cleft either by specific hydrolytic enzymes or by specific membrane transport proteins that pump the neurotransmitter back into either the nerve terminal or neighboring glial cells.)

Autocrine Signaling Can Coordinate Decisions by Groups of Identical Cells 3

All of the forms of signaling discussed so far allow one cell type to influence another. By the same mechanisms, however, cells can send signals to other cells of the same type, and it follows from this that they can also send signals to themselves. In such autocrine signaling a cell secretes signaling molecules that can bind back to its own receptors. During development, for example, once a cell has been directed into a particular path of differentiation, it may begin to secrete autocrine signals that reinforce this developmental decision.

Because autocrine signaling is most effective when carried out simultaneously by neighboring cells of the same type, it may be used to encourage groups of identical cells to make the same developmental decisions (Figure 15-5). Thus autocrine signaling is thought to be one possible mechanism underlying the "community effect" observed in early development, where a group of identical cells can respond to a differentiation-inducing signal but a single isolated cell of the same type cannot.

Autocrine signaling is not confined to development, however. Eicosanoids are signaling molecules that often act in an autocrine mode in mature mammals. These fatty-acid derivatives are made by cells in all mammalian tissues. They are continuously synthesized in the plasma membrane and released to the cell exterior, where they are rapidly degraded by enzymes in extracellular fluid. Made from precursors (mainly *arachidonic acid*) that are cleaved from membrane phospholipids by phospholipases (Figure 15-6), they have a wide variety of biological activities, influencing the contraction of smooth muscle and the aggregation of platelets, for example, and participating in pain and inflammatory responses. When cells are activated by tissue damage or by some types of chemical signals, the rate of eicosanoid synthesis is increased; the resulting increase in the local level of eicosanoid influences both the cells that make it and their immediate neighbors.

Gap Junctions Allow Signaling Information to Be Shared by Neighboring Cells 4

Another way to coordinate the activities of neighboring cells is through gap junctions. These are specialized cell-cell junctions that can form between closely apposed plasma membranes, directly connecting the cytoplasms of the joined cells via narrow water-filled channels (see Figure 19-15). The channels allow the exchange of small intracellular signaling molecules (*intracellular mediators*), such as Ca^{2+} and cyclic AMP, but not of macromolecules, such as proteins or nucleic acids. Thus cells connected by gap junctions can communicate with each other directly without having to deal with the barrier presented by the intervening plasma membranes (Figure 15-7).

As discussed in Chapter 19, the pattern of gap-junction connections in a tissue can be revealed either electrically, with intracellular electrodes, or visually, after the microinjection of water-soluble dyes. Studies of this kind indicate that the cells in a developing embryo make and break gap-junction connections in specific and interesting patterns, suggesting that these junctions play an important part in the signaling processes that occur between these cells. One suspects that, like autocrine signaling described above, gap-junction communication helps adjacent cells of a similar type to coordinate their behavior. It is not known, however, which particular small molecules are important as carriers of signals through gap junctions; nor has the precise function of gap-junction communication in animal development been defined.

Each Cell Is Programmed to Respond to Specific Combinations of Signaling Molecules 5

Any given cell in a multicellular organism is exposed to many - perhaps hundreds - of different signals from its environment. These signals can be soluble, or bound to the extracellular matrix, or bound to the surface of a neighboring cell, and they can act in many millions of possible combinations. The cell must respond to this babel selectively, according to its own specific character, acquired through progressive cell specialization in the course of development. Thus a cell may be programmed to respond to one set of signals by differentiating, to another set by proliferating, and to yet another by carrying out some specialized function.

Most cells in higher animals, moreover, are programmed to depend on a specific set of signals simply for survival: when deprived of the appropriate signals (in a culture dish, for example), a cell will activate a suicide program and kill itself - a process called *programmed cell death,* which is discussed further in Chapter 21 (Figure 15-8). Different types of cells require different sets of survival signals and so are restricted to different environments in the body.

Because signaling molecules generally act in combinations, an animal can control the behavior of its cells in highly specific ways using a limited diversity of such molecules: hundreds of such signals can be used in millions of combinations.

Different Cells Can Respond Differently to the Same Chemical Signal 6

The specific way a cell reacts to its environment varies, first, according to the set of receptor proteins that the cell possesses through which it is tuned to detect a particular subset of the available signals and, second, according to the intracellular machinery by which the cell integrates and interprets the information that it receives. Thus a single signaling molecule often has different effects on different target cells. The neurotransmitter acetylcholine, for example, stimulates the contraction of skeletal muscle cells but decreases the rate and force of contraction in heart muscle cells. This is because the acetylcholine receptor proteins on skeletal muscle cells are different from those on heart muscle cells. But receptor differences are not always the explanation for the different effects. In many cases the same signaling molecule binds to identical receptor proteins and yet produces very different responses in different types of target cells, reflecting differences in the internal machinery to which the receptors are coupled (Figure 15-9).

The Concentration of a Molecule Can Be Adjusted Quickly Only If the Lifetime of the Molecule Is Short 6

It is natural to think of signaling systems in terms of the changes produced when a signal is delivered. But it is just as important to consider what happens when a signal is withdrawn. During development transient signals often produce lasting effects: they can trigger a change that persists indefinitely, through cell memory mechanisms such as those discussed in Chapters 9 and 21. But in most cases, especially in adult tissues, when a signal ceases, the response fades. The signal acts on a system of molecules that is undergoing continual turnover, and when the signal is shut off, the replacement of the old molecules by new ones wipes out the traces of its action. It follows that the speed of reaction to shutting off the signal depends on the rate of turnover of the molecules that the signal affects. It may not be as obvious that this turnover rate also determines the promptness of the response when the signal is turned on.

Consider, for example, two intracellular molecules X and Y, both of which are normally maintained at a concentration of 1000 molecules per cell. Molecule X has a slow turnover rate: it is synthesized and degraded at a rate of 10 molecules per second, so that each molecule has an average lifetime in the cell of 100 seconds. Molecule Y turns over 10 times as quickly: it is synthesized and degraded at a rate of 100 molecules per second, with each molecule having an average lifetime of 10 seconds. If a signal acting on the cell boosts the rates of synthesis of both X and Y tenfold without any change in the molecular lifetimes, at the end of 1 second the concentration of Y will have increased by nearly 900 molecules per cell (10 x 100 - 100) while the concentration of X will have increased by only 90 molecules per cell. In fact, after its synthesis rate has been either increased or

decreased abruptly, the time required for a molecule to shift halfway from its old to its new equilibrium concentration is equal to its normal half-life - that is, it is equal to the time that would be required for its concentration to fall by half if all synthesis were stopped (Figure 15-10).

The same principles apply to proteins as well as to small molecules and to molecules in the extracellular space as well as to those in cells. Many intracellular proteins that are rapidly degraded have short half-lives, some surviving less than 10 minutes; in most cases these are proteins with key regulatory roles, whose concentrations are rapidly regulated in the cell by changes in their rates of synthesis. Likewise, any covalent modifications of proteins that occur as part of a rapid signaling process - most commonly the addition of a phosphate group to an amino acid side chain - must be continuously removed at a rapid rate to make such signaling possible. We discuss some of these molecular events in detail later, for the case of signaling pathways that operate via cell-surface receptors. But the principles apply generally, as the next example illustrates.

Nitric Oxide Gas Signals by Binding Directly to an Enzyme Inside the Target Cell [7]

Although most extracellular signals are mediated by hydrophilic molecules that bind to receptors on the surface of the target cell, some signaling molecules are hydrophobic enough and/or small enough to pass readily across the target-cell plasma membrane; once inside, they directly regulate the activity of specific intracellular proteins. A remarkable example is the gas nitric oxide (NO), which only recently has been recognized to act as a signaling molecule in vertebrates. When acetylcholine is released by autonomic nerves in the walls of a blood vessel, for example, it causes smooth muscle cells in the vessel wall to relax. The acetylcholine acts indirectly by inducing the endothelial cells to make and release NO, which then signals the smooth muscle cells to relax. This effect of NO on blood vessels provides an explanation for the mechanism of action of nitroglycerine, which has been used for almost 100 years to treat patients with angina (pain due to inadequate blood flow to heart muscle). The nitroglycerine is converted to NO, which relaxes blood vessels, thereby reducing the workload on the heart and, as a consequence, the oxygen requirement of the heart muscle. NO is also produced as a local mediator by activated macrophages and neutrophils to help them kill invading microorganisms. In addition, it is used by many types of nerve cells to signal neighboring cells: NO released by autonomic nerves in the penis, for example, causes the local blood vessel dilation that is responsible for penile erection.

NO is made by the enzyme *NO synthase* by the deamination of the amino acid arginine. Because it diffuses readily across membranes, the NO diffuses out of the cell where it is produced and passes directly into neighboring cells. It acts only locally because it has a short half-life - about 5-10 seconds - in the extracellular space before it is converted to nitrates and nitrites by oxygen and water. In many target cells, such as endothelial cells, NO reacts with iron in the active site of the enzyme *guanylyl cyclase,* stimulating it to produce the intracellular mediator *cyclic GMP,* which we discuss later. The effects of NO can be rapid, occurring within seconds, because the rate of turnover of cyclic GMP is high: rapid production from GTP by guanylyl cyclase is balanced by rapid degradation to GMP by a phosphodiesterase. There is recent evidence that *carbon monoxide (CO)* is also used as an intercellular signal and can act in the same way as NO, by stimulating guanylyl cyclase.

Gases such as NO and CO are not the only signaling molecules that can pass directly across the target-cell plasma membrane. A group of small, hydrophobic, nongaseous hormones and local mediators also enter target cells in this way, but instead of binding to enzymes, they bind to intracellular receptor proteins that directly regulate gene transcription.

Steroid Hormones, Thyroid Hormones, Retinoids, and Vitamin D Bind to Intracellular Receptors That Are Ligand-activated Gene Regulatory Proteins [8]

Steroid hormones, thyroid hormones, retinoids, and *vitamin D* are small hydrophobic molecules that differ greatly from one another in both chemical structure (Figure 15-11) and function. Nonetheless, they all act by a similar mechanism. They diffuse directly across the plasma membrane of target cells and bind to intracellular receptor proteins. Ligand binding activates the receptors, which then directly regulate the transcription of specific genes. These receptors are structurally related and constitute the intracellular receptor superfamily (or *steroid-hormone receptor superfamily*) (Figure 15-12).

Steroid hormones, including cortisol, the steroid sex hormones, vitamin D (in vertebrates), and the moulting hormone ecdysone (in insects), are all made from cholesterol. *Cortisol* is produced in the cortex of the adrenal gland and influences the metabolism of many cell types. The steroid sex hormones are made in the testis and ovary and are responsible for the secondary sex characteristics that distinguish males from females. Vitamin D is synthesized in the skin in response to sunlight; after it is converted to an active form in the liver or kidneys, it functions to regulate Ca^{2+} metabolism, promoting Ca^{2+} uptake in the gut and reducing its excretion in the kidney. The thyroid hormones, which are made from the amino acid tyrosine, act to increase

metabolism in a wide variety of cell types, while the retinoids, such as retinoic acid, which are made from vitamin A, play important roles as local mediators in vertebrate development. Although all of these signaling molecules are relatively insoluble in water, they are made soluble for transport in the bloodstream and other extracellular fluids by binding to specific carrier proteins, from which they dissociate before entering a target cell (see Figure 15-2).

Besides the fundamental difference in the way they signal their target cells, most water-insoluble signaling molecules differ from water-soluble ones in the length of time that they persist in the bloodstream or tissue fluids. Most water-soluble hormones are removed and/or broken down within minutes of entering the blood, and local mediators and neurotransmitters are removed from the extracellular space even faster - within seconds or milliseconds. Steroid hormones, by contrast, persist in the blood for hours and thyroid hormones for days. Consequently, water-soluble signaling molecules usually mediate responses of short duration, whereas the water-insoluble ones tend to mediate longer-lasting responses.

The intracellular receptors for the steroid and thyroid hormones, retinoids, and vitamin D all bind to specific DNA sequences adjacent to the genes that the ligand regulates. Some, such as cortisol receptors, are located primarily in the cytosol and bind to DNA only following ligand binding (see Figure 15-12); others, such as retinoid receptors, are located primarily in the nucleus and bind to DNA even in the absence of ligand. In either case, ligand binding alters the conformation of the receptor protein, which then activates (or occasionally suppresses) gene transcription. In many cases the response takes place in two steps: the direct induction of the transcription of a small number of specific genes within about 30 minutes is known as the *primary response;*the products of these genes in turn activate other genes and produce a delayed, *secondary response*. Thus a simple hormonal trigger can cause a very complex change in the pattern of gene expression (Figure 15-13).

The responses to steroid and thyroid hormones, vitamin D, and retinoids, like responses to extracellular signals in general, are determined as much by the nature of the target cell as by the nature of the signaling molecule. Even when different types of cells have the identical intracellular receptor, the set of genes that the receptor regulates is different. This is because more than one type of gene regulatory protein generally must bind to a eucaryotic gene in order to activate its transcription. An intracellular receptor can activate a gene, therefore, only if the right combination of other gene regulatory proteins is also present, and some of these are cell-type specific. Thus thyroid hormone, vitamin D, and each steroid hormone and retinoid induces a characteristic set of responses in an animal because (1) only certain types of cells have receptors for it and (2) each of these cell types contains a different combination of other cell-type-specific gene regulatory proteins that collaborate with the activated receptor to influence the transcription of specific sets of genes. The molecular details of how intracellular receptors and other gene regulatory proteins control specific gene transcription are discussed in Chapter 9.

There Are Three Known Classes of Cell-Surface Receptor Proteins: Ion-Channel-linked, G-Protein-linked, and Enzyme-linked 9

Recombinant DNA techniques have revolutionized the study of the receptors and intracellular proteins involved in cell signaling. Because these proteins often constitute less than 0.01% of the total mass of protein in the cell, it has been extremely difficult to purify them. Cloning the DNA sequences that encode the proteins has greatly accelerated the process of characterization, and most of the signaling proteins discussed in this chapter have been characterized in this way. A major contribution of these DNA-cloning and -sequencing studies has been to reveal that the bewildering diversity of known receptor proteins can be reduced to a much smaller number of large families. The intracellular receptors that we have just discussed constitute one such family. We now consider the family groups that can be identified within the other, larger, class of signal receptors - those located on the cell surface.

All water-soluble signaling molecules (including neurotransmitters, protein hormones, and protein growth factors), as well as some lipid-soluble ones, bind to specific receptor proteins on the surface of the target cells they influence. These cell-surface receptor proteins act as signal transducers: they bind the signaling ligand with high affinity and convert this extracellular event into one or more intracellular signals that alter the behavior of the target cell.

Most cell-surface receptor proteins belong to one of three classes, defined by the transduction mechanism used. Ion-channel-linked receptors, also known as *transmitter-gated ion channels,* are involved in rapid synaptic signaling between electrically excitable cells. This type of signaling is mediated by a small number of neurotransmitters that transiently open or close the ion channel formed by the protein to which they bind, briefly changing the ion permeability of the plasma membrane and thereby the excitability of the postsynaptic cell (Figure 15-14A). The ion-channel-linked receptors belong to a family of homologous, multipass transmembrane proteins. They are discussed in Chapter 11and will not be considered further here.

G-protein-linked receptors act indirectly to regulate the activity of a separate plasma-membrane-bound target protein, which can be an enzyme or an ion channel. The interaction between the receptor and the target protein is mediated by a third protein, called a *trimeric GTP-binding regulatory protein (G protein)* (Figure 15-14B). The activation of the target protein either alters the concentration of one or more intracellular mediators (if the target protein is an enzyme) or alters the ion permeability of the plasma membrane (if the target protein is an ion channel). The intracellular mediators act in turn to alter the behavior of yet other proteins in the cell. All of the G-protein-linked receptors belong to a large superfamily of homologous, seven-pass transmembrane proteins.

Enzyme-linked receptors, when activated, either function directly as enzymes or are associated with enzymes (Figure 15-14C). Most are single-pass transmembrane proteins, with their ligand-binding site outside the cell and their catalytic site inside. Compared with the other two classes, enzyme-linked receptors are heterogeneous, although the great majority are protein kinases, or are associated with protein kinases, that phosphorylate specific sets of proteins in the target cell.

Activated Cell-Surface Receptors Trigger Phosphate-Group Additions to a Network of Intracellular Proteins 9, 10

Much of the remainder of this chapter is concerned with how G-protein-linked receptors and enzyme-linked receptors operate. Signals received at the surface of a cell by both of these classes of receptors are often relayed to the nucleus, where they alter the expression of specific genes and thereby alter the behavior of the cell. Elaborate sets of intracellular signaling proteins form the relay systems. The majority of these proteins are of one of two kinds: proteins that become phosphorylated by protein kinases, and proteins that are induced to bind GTP when the signal arrives. In both cases the proteins gain one or more phosphates in their activated state and lose the phosphates when the signal decays (Figure 15-15). These proteins in turn generally cause the phosphorylation of downstream proteins as part of a *phosphorylation cascade.*

The phosphorylation cascades are mediated by two main types of protein kinases: *serine/threonine kinases,* which phosphorylate proteins on serines and (less often) threonines, and *tyrosine kinases,* which phosphorylate proteins on tyrosines. An occasional kinase can do both. It is estimated that about 1% of our genes encode protein kinases and that a single mammalian cell may contain more than 100 distinct kinds of these enzymes, most of which are serine/threonine kinases. Although fewer than 0.1% of the phosphorylated proteins in cells contain phosphotyrosine, we shall see that this small minority plays a crucial part in signaling by most enzyme-linked receptors.

As discussed previously, complex cell behaviors, such as survival or proliferation, are generally stimulated by specific combinations of signals rather than by a single signal acting alone (see Figure 15-8). The cell has to integrate the information coming from separate signals so as to make a proper responseto live or die, or to proliferate or stay quiescent. The integration seems to depend on interactions between the various protein phosphorylation cascades that are activated by different extracellular signals. In particular, some of the signaling proteins in the cascades function as integrating devices, equivalent to micro-processors in a computer: in response to multiple signal inputs, they produce an output that is calibrated to cause the desired biological effect. Two examples of how such integrating proteins could operate are illustrated in Figure 15-16.

The complexity of such signal-response systems, with multiple interacting relay chains of signaling proteins, is daunting. But recombinant DNA technology, combined with classical genetic analyses in *Drosophila,* the nematode *C. elegans,* and yeasts, as well as more conventional biochemical and pharmacological methods, is rapidly uncovering the intricate details of these mechanisms by which activated receptor proteins change the behavior of the cell.

Summary

Each cell in a multicellular animal is programmed during development to respond to a specific set of signals that act in various combinations to regulate the behavior of the cell and to determine whether the cell lives or dies and whether it proliferates or stays quiescent. Most of these signals mediate paracrine signaling, in which local mediators are rapidly taken up, destroyed, or immobilized, so that they act only on neighboring cells. In addition, centralized control is exerted both by endocrine signaling, in which hormones secreted by endocrine cells are carried in the blood to target cells throughout the body, and by synaptic signaling, in which neurotransmitters secreted by nerve cells act locally on the postsynaptic cells that their axons contact.

Cell signaling requires both extracellular signaling molecules and a complementary set of receptor proteins in each cell that enable it to bind and respond to them in a programmed and characteristic way. Some small hydrophobic signaling molecules, including the steroid and thyroid hormones and the retinoids, diffuse across the plasma membrane of the target cell and activate intracellular receptor proteins, which directly regulate the transcription of specific genes. Some dissolved gases, such as nitric

oxide and carbon monoxide, act as local mediators by diffusing across the plasma membrane of the target cell and activating an intracellular enzyme - usually guanylyl cyclase, which produces cyclic GMP in the target cell. But most extracellular signaling molecules are hydrophilic and are able to activate receptor proteins only on the surface of the target cell; these receptors act as signal transducers, converting the extracellular binding event into intracellular signals that alter the behavior of the target cell. There are three main families of cell-surface receptors, each of which transduces extracellular signals in a different way. Ion-channel-linked receptors are transmitter-gated ion channels that open or close briefly in response to the binding of a neurotransmitter. G-protein-linked receptors indirectly activate or inactivate plasma-membrane-bound enzymes or ion channels via trimeric GTP-binding proteins (G proteins). Enzyme-linked receptors either act directly as enzymes or are associated with enzymes; the enzymes are usually protein kinases that phosphorylate specific proteins in the target cell. Through cascades of highly regulated protein phosphorylations, elaborate sets of interacting proteins relay most signals from the cell surface to the nucleus, thereby altering the cell's pattern of gene expression and, as a consequence, its behavior. Cross-talk between different signaling cascades enables a cell to integrate information from the multiple signals that it receives.

Figure 15-2. Extracellular signaling molecules bind to either cell-surface receptors or intracellular receptors. Most signaling molecules are hydrophilic and are therefore unable to cross the plasma membrane directly; instead, they bind to cell-surface receptors, which in turn generate one or more signals inside the target cell. Some small signaling molecules, by contrast, diffuse across the plasma membrane and bind to receptors inside the target celleither in the cytosol or in the nucleus (as shown). Many of these small signaling molecules are hydrophobic and nearly insoluble in aqueous solutions; they are therefore transported in the bloodstream and other extracellular fluids bound to carrier proteins, from which they dissociate before entering the target cell.

Figure 15-4. The contrast between endocrine and synaptic signaling. Endocrine cells and nerve cells work together to coordinate the diverse activities of the billions of cells in a higher animal. Endocrine cells secrete many different hormones into the blood to signal specific target cells. The target cells have receptors for binding specific hormones and thereby "pull" the appropriate hormones from the extracellular fluid. In synaptic signaling, by contrast, the specificity arises from the contacts between nerve processes and the specific target cells they signal: usually only a target cell that is in synaptic contact with a nerve cell is exposed to the neurotransmitter released from the nerve terminal (although some neurotransmitters act in a paracrine mode as local mediators that influence multiple target cells in the area). Whereas different endocrine cells must use different hormones in order to communicate specifically with their target cells, many nerve cells can use the same

neurotransmitter and still communicate in a specific manner.

Figure 15-6. The synthesis of an eicosanoid. Eicosanoids are continuously synthesized in membranes from 20-carbon fatty acid chains that contain at least three double bonds, as shown for the synthesis of prostaglandin PGE_2 in (A). The subscript refers to the two carbon-carbon double bonds outside the ring of PGE_2. There are four major classes of eicosanoids - *prostaglandins, prostacyclins, thromboxanes,* and *leukotrienes* - and they are all made mainly from arachidonic acid. The synthesis of all but the leukotrienes involves the enzyme *cyclooxygenase;* the synthesis of leukotrienes involves the enzyme *lipoxygenase* (B). These synthetic pathways are targets for a large number of therapeutic drugs, since eicosanoids play an important part in pain, fever, and inflammation. Corticosteroid hormones such as cortisone, for example, which inhibit the activity of the phospholipase in the first step of the eicosanoid synthesis pathway shown, are widely used clinically to treat noninfectious inflammatory diseases, such as some forms of arthritis. Nonsteroid anti-inflammatory drugs such as aspirin and ibuprofen, by contrast, block the first oxidation step, which is catalyzed by cyclooxygenase. Certain prostaglandins that are produced in large amounts in the uterus at the time of childbirth to stimulate the contraction of the uterine smooth muscle cells are widely used as pharmacological agents to induce abortion.
Figure 15-7. Signaling via gap junctions. Cells connected by gap junctions share small molecules, including small intracellular signaling molecules, and therefore can respond to extracellular signals in a coordinated way.
Figure 15-8. Combinatorial signaling. Each cell type displays a set of receptors that enables it to respond to a corresponding set of signaling molecules produced by other cells. These signaling molecules work in combinations to regulate the behavior of the cell. As shown here, many cells require multiple signals (*green arrows*) to survive and additional signals (*red arrows*) to proliferate; if deprived of all signals, these cells undergo programmed cell death.

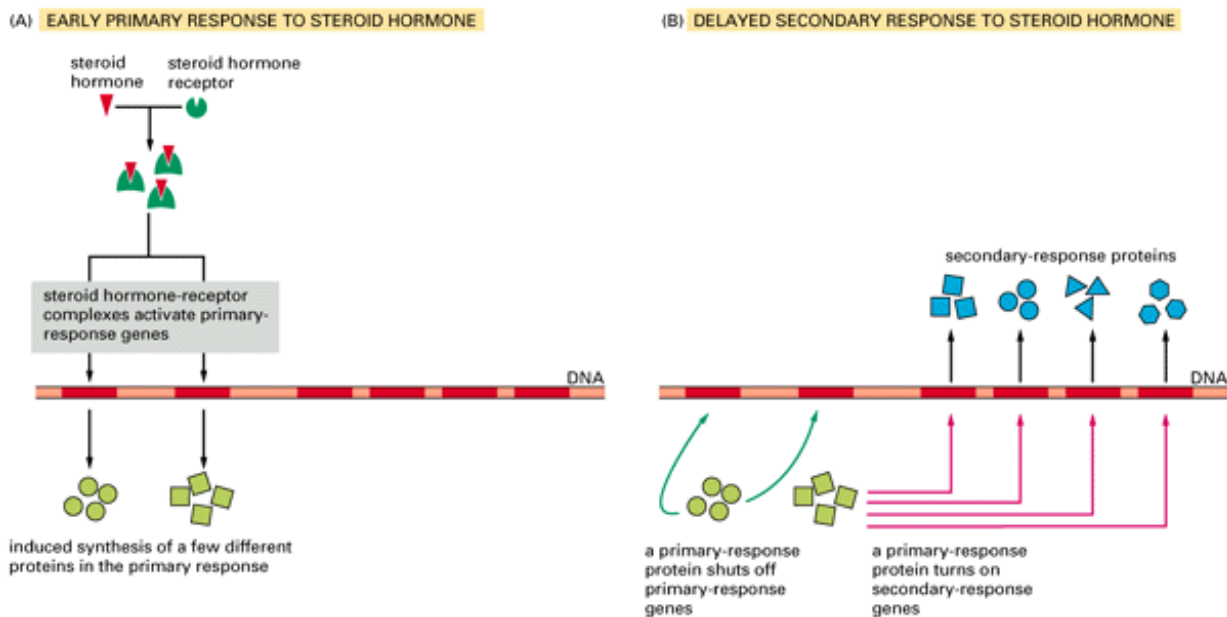
Figure 15-12. The intracellular receptor superfamily. (A) A model of an intracellular receptor protein. In its inactive state the receptor is bound to an inhibitory protein complex that contains a heat-shock protein called Hsp90 (discussed in Chapter 5). The binding of ligand to the receptor causes the inhibitory complex to dissociate, thereby activating the receptor by exposing its DNA-binding site. The model shown is based on the receptor for cortisol, but all of the receptors in this superfamily have a related structure, as shown in (B), where the short DNA-binding domain in each receptor is shown in *green*. Domain-swap experiments suggest that many of the hormone-binding, transcription-activating, and DNA-binding domains in these receptors can function as interchangeable modules. It is thought that all of the intracellular receptor proteins bind to DNA as either homodimers or heterodimers.


Figure 15-13. Early primary response (A) and delayed secondary response (B) that result from the activation of an intracellular receptor protein. The response to a steroid hormone is illustrated, but the same principles apply for all ligands that activate this family of receptor proteins. Some of the primary-response proteins turn on secondary-response genes, whereas others turn off the primary-response genes. The actual number of primary- and secondary-response genes is greater than shown.

As expected, drugs that inhibit protein synthesis suppress the transcription of secondary-response genes but not primary-response genes.

(A) SIGNALING BY PHOSPORYLATION

(B) SIGNALING BY GTP-BINDING PROTEIN
Figure 15-15. Two major intracellular signaling mechanisms share common features. In both cases a signaling protein is

activated by the addition of a phosphate group and inactivated by the removal of the phosphate. In (A) the phosphate is added covalently to the signaling protein by a protein kinase; in (B) a signaling protein is induced to exchange its bound GDP for GTP. To emphasize the similarity in the two mechanisms, ATP is shown as APP(P), ADP as APP, GTP as GPP(P), and GDP as GPP.
Figure 15-16. Signal integration. In (A) signals A and B activate different cascades of protein phosphorylations, each of which leads to the phosphorylation of protein Y but at different sites on the protein. Protein Y is activated only when both of these sites are phosphorylated, and therefore it is active only when signals A and B are simultaneously present. In (B) signals A and B lead to the phosphorylation of two proteins, a and b, which then bind to each other to create the active protein ab. In both of the examples illustrated the proteins themselves are phospho-rylated: an equivalent form of control can also occur, however, by the exchange of GTP for GDP on a GTP-binding protein (see Figure 15-15).

➡ ➡

Signaling via G-Protein-linked Cell-Surface Receptors 11

Introduction

G-protein-linked receptors are the largest family of cell-surface receptors. More than 100 members have already been defined in mammals. Many of these have been identified by *homology cloning*, in which low stringency hybridization with existing cDNA probes is used to detect related DNA sequences (see Figure7-17). Other family members have been found by *expression cloning*, using their ligand-binding or cell-activation properties to identify them. In one form of this approach, a library of cDNA molecules prepared from cells or tissues that express the receptor are copied into RNA molecules, which are then injected into *Xenopus* oocytes. The oocytes translate the RNA molecules into proteins. These proteins are inserted into the plasma membrane, where their ligand-binding or cell-activation properties allow them to be detected.

G-protein-linked receptors mediate the cellular responses to an enormous diversity of signaling molecules, including hormones, neurotransmitters, and local mediators, which are as varied in structure as they are in function: the list includes proteins and small peptides, as well as amino acid and fatty acid derivatives. The same ligand can activate many different family members. At least 9 distinct G-protein-linked receptors are activated by adrenaline, for example, another 5 or more by acetylcholine, and at least 15 by serotonin.

Despite the chemical and functional diversity of the signaling molecules that bind to them, all of the G-protein-linked receptors whose amino acid sequences are known from DNA sequencing studies have a similar structure and are almost certainly evolutionarily related. They consist of a single polypeptide chain that threads back and forth across the lipid bilayer seven times (Figure 15-17). As we discuss later, this superfamily of seven-pass transmembrane receptor proteins includes *rhodopsin,* the light-activated protein in the vertebrate eye, as well as olfactory receptors in the vertebrate nose. Other family members are found in unicellular organisms: the receptors in yeasts that recognize the yeast mating factors are an example. This ancient

structural motif is also shared by bacteriorhodopsin, a bacterial light-activated H$^+$ pump discussed in Chapter 10, although, unlike the other family members, bacteriorhodopsin is not a receptor and does not act via a G protein. Taken together, these findings suggest that the G-protein-linked receptors that mediate cell-cell signaling in multicellular organisms may have evolved from sensory receptors possessed by their unicellular ancestors. The members of this receptor family have conserved not only their amino acid sequence but also their functional relationship to G proteins by means of which they broadcast into the interior of the cell the message that an extracellular ligand is present. It is the intracellular sequence of events beginning with the activation of G proteins that mainly concern us in this section.

Trimeric G Proteins Relay the Intracellular Signal from G-Protein-linked Receptors 11, 12

The trimeric GTP-binding proteins (G proteins) that functionally couple these receptors to their target enzymes or ion channels in the plasma membrane are structurally distinct from the single-chain GTP-binding proteins (called *monomeric GTP-binding proteins* or *monomeric GTPases*) that help relay intracellular signals and regulate vesicular traffic and many other processes in eucaryotic cells. The monomeric GTPases are discussed later in this chapter as well as in other chapters. Both classes of GTP-binding proteins, however, are GTPases and function as molecular switches that can flip between two states: active, when GTP is bound, and inactive, when GDP is bound. "Active" in this context usually means that the molecule acts as a signal to trigger other events in the cell. When an extracellular ligand binds to a G-protein-linked receptor, the receptor changes its conformation and switches on the trimeric G proteins that associate with it by causing them to eject their GDP and replace it with GTP. The switch is turned off when the G protein hydrolyzes its own bound GTP, converting it back to GDP. But before that occurs, the active protein has an opportunity to diffuse away from the receptor and deliver its message for a prolonged period to its downstream target.

Most G-protein-linked receptors activate a chain of events that alters the concentration of one or more small intracellular signaling molecules. These small molecules, often referred to as intracellular mediators (also called *intracellular messengers* or *second messengers*), in turn pass the signal on by altering the behavior of selected cellular proteins. Two of the most widely used intracellular mediators are *cyclic AMP (cAMP)* and Ca^{2+} : changes in their concentrations are stimulated by distinct pathways in most animal cells, and most G-protein-linked receptors regulate one or the other of them, as outlined in Figure 15-18.

Some Receptors Increase Intracellular Cyclic AMP by Activating Adenylyl Cyclase via a Stimulatory G Protein (G$_s$) 13

Cyclic AMP (Figure 15-19) was first identified as an intracellular mediator of hormone action in 1959 and has since been found to act as an intracellular signaling molecule in all procaryotic and animal cells that have been studied. For cyclic AMP to function as an intracellular mediator, its intracellular concentration (normally $\leq 10^{-7}$ M) must be able to change up or down in response to extracellular signals: upon hormonal stimulation, cyclic AMP levels can change fivefold in seconds. As explained earlier (see Figure 15-10), such responsiveness requires that rapid synthesis of the molecule be balanced by rapid breakdown or removal. Cyclic AMP is synthesized from ATP by a plasma-membrane-bound enzyme adenylyl cyclase, and it is rapidly and continuously destroyed by one or more cyclic AMP phosphodiesterases, which hydrolyze cyclic AMP to adenosine 5'-monophosphate (5'-AMP) (Figure 15-20).

Many extracellular signaling molecules work by controlling cyclic AMP levels, and they do so by altering the activity of adenylyl cyclase (Figure 15-21) rather than the activity of phosphodiesterase. Just as the same steroid hormone produces different effects in different target cells, so different target cells respond very differently to external signals that change intracellular cyclic AMP levels (Table 15-1). All ligands that activate adenylyl cyclase in a given type of target cell, however, usually produce the same effect: at least four hormones activate adenylyl cyclase in fat cells, for example, and all of them stimulate the breakdown of triglyceride (the storage form of fat) to fatty acids (see Table 15-1). The different receptors for these hormones activate a common pool of adenylyl cyclase molecules, to which they are coupled by a trimeric G protein. Because this G protein is involved in enzyme *activation,* it is called stimulatory G protein (G$_s$). Individuals who are genetically deficient in G$_s$ show decreased responses to certain hormones and, consequently, have metabolic abnormalities, abnormal bone development, and are mentally retarded.

The best-studied examples of receptors coupled to the activation of adenylyl cyclase are the β-adrenergic receptors, which mediate some of the actions of *adrenaline* and *noradrenaline* (Figure 15-22, and see Table 15-1). An adrenaline-activated adenylyl cyclase system can be reconstituted in synthetic phospholipid vesicles using purified β-adrenergic receptors, G$_s$, and adenylyl cyclase molecules, indicating that no other proteins are required for the activation process. But precisely how does G$_s$

mediate the coupling? The answer depends on the trimeric structure of the G protein, as we now discuss.

Trimeric G Proteins Are Thought to Disassemble When Activated <u>11</u>, <u>12</u>, <u>14</u>

A trimeric G protein is composed of three different polypeptide chains, called α, β, and γ. The G_s α *chain*($α_s$) binds and hydrolyzes GTP and activates adenylyl cyclase. The G_s β *chain* and γ *chain* form a tight complex (βγ), which anchors G_s to the cytoplasmic face of the plasma membrane, at least partly by a lipid chain (a prenyl group) that is covalently attached to the γ subunit. In its inactive form G_s exists as a trimer with GDP bound to $α_s$. When stimulated by binding to a ligand-activated receptor, $α_s$ exchanges its GDP for GTP. This is thought to cause $α_s$ to dissociate from βγ, allowing $α_s$ to bind instead to an adenylyl cyclase molecule, which it activates to produce cyclic AMP.

If cells are to be able to respond rapidly to changes in the concentration of an extracellular signaling molecule, the activation of adenylyl cyclase must be reversed quickly once the signaling ligand dissociates from its receptor. This ability to respond rapidly to change is assured because the lifetime of the active form of $α_s$ is short: the GTPase activity of $α_s$ is stimulated when $α_s$ binds to adenylyl cyclase, so that the bound GTP is hydrolyzed to GDP, rendering both $α_s$ and the adenylyl cyclase inactive. The $α_s$ then reassociates with βγ to re-form an inactive G_s molecule (<u>Figure 15-23</u>).

The importance of the GTPase activity of $α_s$ in shutting off the response can be readily demonstrated in a test tube. If cells are broken open and exposed to an analogue of GTP (GTPγS) in which the terminal phosphate cannot be hydrolyzed, cyclic AMP production after hormone treatment is greatly prolonged. A similar phenomenon is seen in patients suffering from *cholera,* where the bacterial toxin responsible for the symptoms of the disease inhibits the self-inactivating mechanism of $α_s$. Cholera toxin is an enzyme that catalyzes the transfer of ADP ribose from intracellular NAD^+ to $α_s$. The ADP ribosylation alters the $α_s$ so that it can no longer hydrolyze its bound GTP. An adenylyl cyclase molecule activated by such an altered $α_s$ subunit thus remains in the active state indefinitely. The resulting prolonged elevation in cyclic AMP levels within intestinal epithelial cells causes a large efflux of Na^+ and water into the gut, which is responsible for the severe diarrhea that is characteristic of cholera.

Some Receptors Decrease Cyclic AMP by Inhibiting Adenylyl Cyclase via an Inhibitory Trimeric G Protein (G_i) <u>11</u>, <u>12</u>, <u>15</u>

The same signaling molecule can either increase or decrease the intracellular concentration of cyclic AMP depending on the type of receptor to which it binds. When adrenaline binds to β-*adrenergic receptors,* for example, it activates adenylyl cyclase, whereas when it binds to $α_2$-*adrenergic receptors,* it inhibits the enzyme. The difference reflects the type of G proteins that couple these receptors to the cyclase. While the β-adrenergic receptors are functionally coupled to adenylyl cyclase by G_s, the $α_2$-adrenergic receptors are coupled to this enzyme by an inhibitory G protein (G_i). G_i can contain the same β-γ complex as G_s, but it has a different α subunit ($α_i$). When activated, $α_2$-adrenergic receptors bind to G_i, causing $α_i$ to bind GTP and dissociate from the βγ complex. Both the released $α_i$ and βγ are thought to contribute to the inhibition of adenylyl cyclase. $α_i$ inhibits the cyclase, probably indirectly, whereas βγ may inhibit cyclic AMP synthesis in two ways - directly, by binding to the cyclase itself, and indirectly, by binding to any free $α_s$ subunits in the same cell, thereby preventing them from activating cyclase molecules. We see later that G_i also acts to open K^+ channels in the plasma membrane, and it seems likely that this function is more important than the inhibition of adenylyl cyclase.

Whereas cholera toxin catalyzes the ADP ribosylation of $α_s$ and thereby inactivates the GTPase activity of $α_s$, pertussis toxin, made by the bacterium that causes pertussis (whooping cough), catalyzes the ADP ribosylation of $α_i$. The ADP ribosylation of $α_i$ prevents the G_i complex from interacting with receptors, and so the complex remains bound to GDP and is unable to inhibit adenylyl cyclase or open K^+ channels.

The trimeric G proteins are remarkably versatile intracellular signaling molecules. In the examples considered so far, either the α subunit or both the α and the β-γ subunits are the active components. But in other cases receptors are coupled to their target proteins only by the released β-γ complex. Moreover, β-γ complexes can also act as conditional regulators of effector proteins: they can enhance the activation of some forms of adenylyl cyclase, for example, but only if the cyclase has already been

activated by α_s.

Cyclic-AMP-dependent Protein Kinase (A-Kinase) Mediates the Effects of Cyclic AMP <u>16</u>

Cyclic AMP exerts its effects in animal cells mainly by activating the enzyme cyclic-AMP-dependent protein kinase (A-kinase), which catalyzes the transfer of the terminal phosphate group from ATP to specific serines or threonines of selected proteins. The amino acids phosphorylated by A-kinase are marked by the presence of two or more basic amino acids on their amino-terminal side. Covalent phosphorylation of the appropriate amino acids in turn regulates the activity of the target protein.

A-kinase is found in all animal cells and is thought to account for all of the effects of cyclic AMP in most of these cells. (The only other known function of cyclic AMP in animals is to regulate a special class of ion channels in smell-responsive olfactory neurons, as we discuss later.) The substrates for A-kinase differ in different cell types, explaining why the effects of cyclic AMP vary depending on the target cell.

In the inactive state A-kinase consists of a complex of two catalytic subunits and two regulatory subunits that bind cyclic AMP. The binding of cyclic AMP alters the conformation of the regulatory subunits, causing them to dissociate from the complex. The released catalytic subunits are thereby activated to phosphorylate specific substrate protein molecules (<u>Figure 15-24</u>).

Cyclic-AMP-mediated protein phosphorylation was first demonstrated in studies of glycogen metabolism in skeletal muscle cells. Glycogen is the major storage form of glucose, and both its synthesis and degradation in skeletal muscle cells are regulated by adrenaline. When an animal is frightened or otherwise stressed, for example, the adrenal gland secretes adrenaline into the blood, "alerting" various tissues in the body. Among other effects, the circulating adrenaline induces muscle cells to break down glycogen to glucose 1-phosphate and at the same time to stop synthesizing glycogen. The glucose is then oxidized by glycolysis to provide ATP for sustained muscle contraction. In this way adrenaline prepares the muscle cells for anticipated strenuous activity. Adrenaline acts by binding to β-adrenergic receptors on the muscle cell surface, thereby causing an increase in the level of cyclic AMP in the cytosol. The cyclic AMP activates A-kinase, which phosphorylates two other enzymes. The first, *phosphorylase kinase,* which was the first protein kinase to be discovered (in 1956), phos-phorylates in turn the enzyme *glycogen phosphorylase,* thereby activating the phosphorylase to release glucose residues from the glycogen molecule (<u>Figure 15-25</u>). The second enzyme phosphorylated by activated A-kinase is *glycogen synthase,* which performs the final step in glycogen synthesis from glucose. This phosphorylation inhibits the enzyme's activity, thereby shutting off glycogen synthesis. By means of this cascade of interactions, an increase in cyclic AMP levels both stimulates glycogen breakdown and inhibits glycogen synthesis, thus maximizing the amount of glucose available to the cell.

In some animal cells an increase in cyclic AMP activates the transcription of specific genes. In cells that secrete the peptide hormone *somatostatin,* for example, cyclic AMP turns on the gene that encodes this hormone. The regulatory region of the somatostatin gene contains a short DNA sequence, called the *cyclic AMP response element (CRE),* that is also found in the regulatory region of other genes that are activated by cyclic AMP. This sequence is recognized by a specific gene regulatory protein called CRE-binding (CREB) protein. When CREB is phosphorylated by A-kinase on a single serine residue, it is activated to turn on the transcription of these genes; the phosphorylation stimulates the transcriptional activity of CREB without affecting its DNA-binding properties. If this serine residue is mutated, CREB is inactivated and no longer stimulates gene transcription in response to a rise in cyclic AMP levels.

Serine/Threonine Protein Phosphatases Rapidly Reverse the Effects of A-Kinase <u>17</u>

Since it is usually important that the effects of cyclic AMP are transient, cells must be able to dephosphorylate the proteins that have been phosphorylated by A-kinase. In general, the dephosphorylation of phosphorylated serines and threonines is catalyzed by four groups of serine/threonine phosphoprotein phosphatases - protein phosphatases I, IIA, IIB, and IIC. Except for protein phosphatase-IIC (which is a minor phosphatase, unrelated to the others), all of these phosphatases are composed of a homologous catalytic subunit complexed with one or more regulatory subunits. *Protein phosphatase-I* plays an important role in the response to cyclic AMP, as we discuss below. *Protein phosphatase-IIA* has a broad specificity and seems to be the main phosphatase responsible for reversing many of the phosphorylations catalyzed by serine/threonine kinases; it plays an important part in regulating the cell cycle. *Protein phosphatase-IIB,* also called *calcineurin,* is activated by Ca^{2+} and is especially abundant in the brain.

The activity of any protein regulated by phosphorylation depends on the balance at any instant between the activities of the

kinases that phosphorylate it and the phosphatases that are constantly dephosphorylating it. Protein phosphatase-I is responsible for dephosphorylating many of the proteins phosphorylated by A-kinase. It inactivates CREB, for example, by removing its activating phosphate, thereby turning off the transcriptional response caused by a rise in cyclic AMP. In skeletal muscle cells it dephosphorylates each of the three key enzymes in the glycogen pathway that, as mentioned earlier, are phosphorylated in response to adrenaline by A-kinase and switch the cells from synthesizing glycogen to degrading it. Protein phosphatase-I tends to counteract these phosphorylations, but its activity is suppressed in adrenaline-stimulated muscle cells by yet another target of A-kinase, which is a specific *phosphatase inhibitor protein*. When this inhibitor protein is phosphorylated by A-kinase, it binds to protein phosphatase-I and inactivates it (Figure 15-26). By simultaneously activating phosphorylase kinase and inhibiting the opposing action of protein phosphatase-I, the A-kinase causes a much larger change in glycogen metabolism than could be obtained by its action on any one of these enzymes alone.

Having discussed how trimeric G proteins couple receptors to adenylyl cyclase to alter the levels of cyclic AMP in cells, we now consider how G proteins couple receptors to another crucial enzyme - *phospholipase C*. The activation of this enzyme leads to an increase in the concentration of Ca^{2+} in the cytosol, and Ca^{2+} is even more widely used as an intracellular mediator than cyclic AMP.

To Use Ca^{2+} as an Intracellular Signal, Cells Must Keep Resting Cytosolic Ca^{2+} Levels Low [18]

The concentration of free Ca^{2+} in the cytosol of any cell is extremely low ($\leq 10^{-7}$ M), whereas its concentration in the extracellular fluid (~10^{-3} M) and in the endoplasmic reticulum (ER) is high. Thus there is a large gradient tending to drive Ca^{2+} into the cytosol across both the plasma membrane and the ER membrane. When a signal transiently opens Ca^{2+} channels in either of these membranes, Ca^{2+} rushes into the cytosol, dramatically increasing the local Ca^{2+} concentration and triggering Ca^{2+}-responsive proteins in the cell.

For this signaling mechanism to work, the resting concentration of Ca^{2+} in the cytosol must be kept low, and this is achieved in several ways. All eucaryotic cells have a Ca^{2+}-ATPase in their plasma membrane that uses the energy of ATP hydrolysis to pump Ca^{2+} out of the cytosol. Cells such as muscle and nerve cells, which make extensive use of Ca^{2+} signaling, have an additional Ca^{2+} pump in their plasma membrane that couples the efflux of Ca^{2+} to the influx of Na^+. This Na^+-Ca^{2+} exchanger has a relatively low affinity for Ca^{2+} and therefore begins to operate efficiently only when cytosolic Ca^{2+} levels rise to about 10 times their normal level, as occurs after repeated muscle or nerve cell stimulation. A Ca^{2+} pump in the ER membrane also plays an important part in keeping the cytosolic Ca^{2+} concentration low: this Ca^{2+}-ATPase enables the ER to take up large amounts of Ca^{2+} from the cytosol against a steep concentration gradient, even when Ca^{2+} levels in the cytosol are low.

Normally, the concentration of free Ca^{2+} in the cytosol varies from about 10^{-7} M, when the cell is at rest, to about 5×10^{-6} M, when the cell is activated by an extracellular signal. But when a cell is damaged and cannot pump Ca^{2+} out of the cytosol efficiently, the Ca^{2+} concentration can rise beyond that to dangerously high levels ($> 10^{-5}$ M). In these circumstances a low-affinity, high-capacity Ca^{2+} pump in the inner mitochondrial membrane comes into action and uses the electrochemical gradient generated across this membrane during the electron-transfer steps of oxidative phosphorylation to take up Ca^{2+} from the cytosol. These mechanisms are summarized in Figure 15-27.

Ca^{2+} Functions as a Ubiquitous Intracellular Messenger [19]

The first direct evidence that Ca^{2+} functions as an intracellular mediator came from an experiment done in 1947 showing that the intracellular injection of a small amount of Ca^{2+} causes a skeletal muscle cell to contract. In recent years it has become clear that Ca^{2+} also acts as an intracellular messenger in a wide variety of other cellular responses, including secretion and cell proliferation. Two pathways of Ca^{2+} signaling have been well defined, one used mainly by electrically active (excitable) cells and the other used by almost all eucaryotic cells. The first of these pathways has been particularly well studied in nerve cells, in which depolarization of the plasma membrane causes an influx of Ca^{2+} into the nerve terminal, initiating the secretion of neurotransmitter; the Ca^{2+} enters through voltage-gated Ca^{2+} channels that open when the plasma membrane of the nerve terminal is depolarized by an invading action potential (see Figure 11-34). In the second, ubiquitous pathway the binding of extracellular signaling molecules to cell-surface receptors causes the release of Ca^{2+} from the ER. The events at the cell surface are coupled to the opening of Ca^{2+} channels in the ER through yet another intracellular messenger molecule, *inositol trisphosphate* (Figure 15-28) *,* as we discuss next.

Some G-Protein-linked Receptors Activate the Inositol Phospholipid Signaling Pathway by Activating Phospholipase C-β [20]

A role for inositol phospholipids (*phosphoinositides*) in signal transduction was first suggested in 1953, when it was found that some extracellular signaling molecules stimulate the incorporation of radioactive phosphate into phosphatidylinositol (PI), a minor phospholipid in cell membranes. It was later shown that this incorporation results from the breakdown and subsequent resynthesis of inositol phospholipids. The inositol phospholipids found to be most important in signal transduction were two phosphorylated derivatives of PI, *PI phosphate (PIP)* and *PI bisphosphate (PIP$_2$),* which are thought to be located mainly in the inner half of the plasma membrane lipid bilayer (Figure 15-29). Although PIP$_2$ is less plentiful in animal cell membranes than PI, it is the hydrolysis of PIP$_2$ that matters most.

The chain of events leading to PIP$_2$ breakdown begins with the binding of a signaling molecule to a G-protein-linked receptor in the plasma membrane. More than 25 different cell-surface receptors have been shown to utilize this transduction pathway; several examples of responses mediated in this way are given in Table 15-2. Although the details of the activation process are not as well understood as they are in the cyclic AMP pathway, the same type of multistep mechanism is thought to operate in the plasma membrane. An activated receptor stimulates a trimeric G protein called G$_q$, which in turn activates a *phospho-inositide-specific phospholipase C* called phospholipase C- β. In less than a second, this enzyme cleaves PIP$_2$ to generate two products: *inositol trisphosphate* and *diacylglycerol* (Figure 15-30). At this step the signaling pathway splits into two branches. Since both molecules play crucial parts in signaling the cell, we consider them in turn.

Inositol Trisphosphate (IP$_3$) Couples Receptor Activation to Ca^{2+} Release from the ER [21]

The inositol trisphosphate (IP$_3$) produced by PIP$_2$ hydrolysis is a small water-soluble molecule that leaves the plasma membrane and diffuses rapidly through the cytosol. There it releases Ca^{2+} from the ER by binding to *IP$_3$-gated Ca^{2+}-release channels* in the ER membrane. The channels are structurally similar to the Ca^{2+}-release channels (*ryanodine receptors*) in the sarcoplasmic reticulum of muscle cells, which release the Ca^{2+} that triggers muscle contraction (see Figure 16-92). Both types of channels are regulated by positive feedback, in which the released Ca^{2+} can bind back to the channels to increase the Ca^{2+} release, which tends to make the release occur in a sudden, all-or-none fashion. In many cells, including muscle cells, both types of Ca^{2+}-release channels are present.

Two mechanisms operate to terminate the initial Ca^{2+} response: (1) IP$_3$ is rapidly dephosphorylated (and thereby inactivated) by specific phosphatases, and (2) Ca^{2+} that enters the cytosol is rapidly pumped out, mainly out of the cell.

Not all of the IP$_3$ is dephosphorylated, however: some is instead phosphorylated to form inositol 1,3,4,5-tetrakisphosphate (IP$_4$), which may mediate slower and more prolonged responses in the cell or promote the refilling of the intracellular Ca^{2+} stores from the extracellular fluid, or both. The enzyme that catalyzes the production of IP$_4$ is activated by the increase in cytosolic Ca^{2+} induced by IP$_3$, providing a form of negative feedback regulation on IP$_3$ levels.

Ca^{2+} Oscillations Often Prolong the Initial IP$_3$-induced Ca^{2+} Response [22]

When Ca^{2+}-sensitive fluorescent indicators, such as aequorin or fura-2 (discussed in Chapter 4), are used to monitor cytosolic Ca^{2+} in individual cells in which the inositol phospholipid signaling pathway has been activated, the initial Ca^{2+} signal is often seen to propagate as a wave through the cytosol from a localized region of the cell. Moreover, the initial transient increase in Ca^{2+} is often followed by a series of Ca^{2+} "spikes," each lasting seconds or minutes; these Ca^{2+} oscillations can persist for as long as receptors are activated on the cell surface (Figure 15-31).

The mechanisms responsible for the propagation of Ca^{2+} waves and for generating the oscillations are uncertain, although a number of models have been proposed. In most models both the propagation and oscillations depend on positive feedback, whereby Ca^{2+} activates its own release, thereby producing an all-or-none Ca^{2+} spike. The models differ mainly in whether Ca^{2+} acts directly on the Ca^{2+}-release channels in the ER to stimulate its own release or whether it acts indirectly, by increasing the activity of phospholipase C, thereby generating surges of IP$_3$, which in turn induce surges of Ca^{2+} release.

The biological significance of the Ca^{2+} oscillations is also uncertain. Their frequency often depends on the concentration of the extracellular signaling ligand (see Figure 15-31) and might, in principle, be translated into a frequency-dependent cellular response. In hormone-secreting pituitary cells, for example, stimulation by an extracellular signaling molecule induces repeated Ca^{2+} spikes, each of which is associated with a burst of hormone secretion. It has been suggested that this arrangement might maximize secretory output while avoiding the toxic effects of a sustained rise in cytosolic Ca^{2+}.

Diacylglycerol Activates Protein Kinase C (C-Kinase) [23]

At the same time that the IP_3 produced by hydrolysis of PIP_2 is increasing the concentration of Ca^{2+} in the cytosol, the other cleavage product of PIP_2 - diacylglycerol - is exerting different effects. Diacylglycerol has two potential signaling roles. First, it can be further cleaved to release arachidonic acid, which either can act as a messenger in its own right or be used in the synthesis of eicosanoids (see Figure 15-6). Second, and more important, it activates a crucial serine/threonine protein kinase that phosphorylates selected proteins in the target cell.

The enzyme activated by diacylglycerol is called protein kinase C (C-kinase, or PKC) because it is Ca^{2+}-dependent. The initial rise in cytosolic Ca^{2+} induced by IP_3 is thought to alter the C-kinase so that it translocates from the cytosol to the cytoplasmic face of the plasma membrane. There it is activated by the combination of Ca^{2+}, diacylglycerol, and the negatively charged membrane phospholipid phosphatidylserine. Of the eight or more distinct isoforms of C-kinase in mammals, at least four are activated by diacylglycerol.

Because the diacylglycerol produced initially by the cleavage of PIP_2 is rapidly metabolized, it cannot sustain the activity of C-kinase, as would be required for long-term responses such as cell proliferation or differentiation. Prolonged activation of C-kinase depends on a second wave of diacylglycerol production, catalyzed by phospholipases that cleave the major membrane phospholipid phosphatidylcholine. It is uncertain how these later-acting phospholipases become activated.

When activated, C-kinase phosphorylates specific serine or threonine residues on target proteins that vary depending on the cell type. The highest concentrations of C-kinase are found in the brain, where (among other things) it phosphorylates ion channels in nerve cells, thereby changing their properties and altering the excitability of the nerve cell plasma membrane.

In many cells the activation of C-kinase increases the transcription of specific genes. At least two pathways are known. In one, C-kinase activates a protein kinase cascade that leads to the phosphorylation and activation of a DNA-bound gene regulatory protein; in another, C-kinase activation leads to the phosphorylation of an inhibitor protein, thereby releasing a cytoplasmic gene regulatory protein so that it can migrate into the nucleus and stimulate the transcription of specific genes (Figure 15-32).

The two branches of the inositol phospholipid signaling pathway are summarized in Figure 15-33. As indicated in the figure, each branch of the pathway can be mimicked by the addition of specific pharmacological agents to intact cells. The effects of IP_3 can be mimicked by using a *Ca^{2+} ionophore,* such as A23187 or ionomycin, which allows Ca^{2+} to move into the cytosol from the extracellular fluid (discussed in Chapter 11). The effects of diacylglycerol can be mimicked by *phorbol esters,* plant products that bind to C-kinase and activate it directly. Using these reagents, it has been shown that the two branches of the pathway often collaborate in producing a full cellular response. A number of cell types, for example, can be stimulated to proliferate in culture when treated with both a Ca^{2+} ionophore and a C-kinase activator but not when they are treated with either reagent alone.

Calmodulin Is a Ubiquitous Intracellular Ca^{2+} Receptor [24]

Since the free Ca^{2+} concentration in the cytosol is usually $\leq 10^{-7}$ M and generally does not rise above 6×10^{-6} M even when the cell is activated by an influx of Ca^{2+}, any structure in the cell that is to serve as a direct target for Ca^{2+}-dependent regulation must have an affinity constant (K_a) for Ca^{2+} of around 10^6 liters/mole. Moreover, since the concentration of free Mg^{2+} in the cytosol is relatively constant at about 10^{-3} M, these Ca^{2+}-binding sites must have a selectivity for Ca^{2+} over Mg^{2+} of at least 1000-fold. Several specific Ca^{2+}-binding proteins fulfill these criteria.

The first such protein to be discovered was *troponin C* in skeletal muscle cells; its role in muscle contraction is discussed in

Chapter 16. A closely related Ca^{2+}-binding protein, known as calmodulin, is found in all eucaryotic cells that have been examined. A typical animal cell contains more than 10^7 molecules of calmodulin, which can constitute as much as 1% of the total protein mass of the cell. Calmodulin functions as a multipurpose intracellular Ca^{2+} receptor, mediating many Ca^{2+}-regulated processes. It is a highly conserved, single polypeptide chain of about 150 amino acids, with four high-affinity Ca^{2+}-binding sites (Figure 15-34A), and it undergoes a conformational change when it binds Ca^{2+}.

The allosteric activation of calmodulin by Ca^{2+} is analogous to the allosteric activation of A-kinase by cyclic AMP, except that Ca^{2+}/calmodulin has no enzyme activity itself but acts by binding to other proteins. In some cases calmodulin serves as a permanent regulatory subunit of an enzyme complex, but in most cases the binding of Ca^{2+} enables calmodulin to bind to various target proteins in the cell and thereby alter their activity. When Ca^{2+}/calmodulin binds to its target protein, it can undergo a further and more dramatic change in conformation (Figure 15-34B).

Among the targets regulated by Ca^{2+}/calmodulin are various enzymes and membrane transport proteins. In many cells, for example, Ca^{2+}/calmodulin binds to and activates the plasma membrane Ca^{2+}-ATPase that pumps Ca^{2+} out of the cell. Thus, if the concentration of Ca^{2+} in the cytosol rises, the pump is activated, which helps return the cytosolic Ca^{2+}level to normal. Most effects of Ca^{2+}/calmodulin, however, are more indirect and are mediated by *Ca^{2+}/calmodulin-dependent protein kinases.*

Ca^{2+}/Calmodulin-dependent Protein Kinases (CaM-Kinases) Mediate Most of the Actions of Ca^{2+} in Animal Cells 25

Most of the effects of Ca^{2+} in cells are mediated by protein phosphorylations catalyzed by a family of Ca^{2+}/calmodulin-dependent protein kinases (CaM-kinases). These kinases phosphorylate serines or threonines in proteins, and, as in the case of cyclic AMP, the response of a target cell to an increase in free Ca^{2+} concentration in the cytosol depends on which CaM-kinase-regulated target proteins are present in the cell. The first CaM-kinases to be discovered - *myosin light-chain kinase,* which activates smooth muscle contraction, and *phosphorylase kinase,* which activates glycogen breakdown - have narrow substrate specificities. More recently, however, a number of CaM-kinases have been identified that have much broader specificities, and these seem to be responsible for mediating many of the actions of Ca^{2+} in animal cells.

The best-studied example of such a *multifunctional CaM-kinase* is CaM-kinase II, which is found in all animal cells but is especially enriched in the nervous system. It constitutes up to 2% of the total protein mass in some regions of the brain, where it is highly concentrated in synapses. When neurons that use *catecholamines* (dopamine, noradrenaline, or adrenaline) as their neurotransmitter are activated, for example, the influx of Ca^{2+} through voltage-gated Ca^{2+} channels in the plasma membrane stimulates the cells to secrete their neurotransmitter. The Ca^{2+}influx also activates CaM-kinase II to phosphorylate, and thereby activate, *tyrosine hydroxylase,* which is the rate-limiting enzyme in catecholamine synthesis. In this way, both the secretion and resynthesis of the neurotransmitter are stimulated when the cell is activated.

CaM-kinase II has a remarkable property: it can function as a molecular memory device, switching to an active state when exposed to Ca^{2+}/calmodulin and then remaining active even after the Ca^{2+} is withdrawn. This is because the kinase phosphorylates itself (a process called *autophosphorylation*) as well as other cell proteins when it is activated by Ca^{2+}/calmodulin. In its autophosphorylated state the enzyme remains active in the absence of Ca^{2+}, thereby prolonging the duration of the kinase activity beyond the duration of the initial activating Ca^{2+} signal; the activity is maintained until phosphatases overwhelm the autophosphorylating activity of the enzyme and shut it off (Figure 15-35).

Because of these properties, CaM-kinase II activation can serve as a memory trace of a prior Ca^{2+} pulse, and it seems to play an important part in some types of memory and learning in the vertebrate nervous system. Mutant mice that are missing the brain-specific subunit illustrated in Figure 15-35 have specific defects in their ability to remember the location of an object - that is, in spatial learning.

The Cyclic AMP and Ca^{2+} Pathways Interact 26

The cyclic AMP and Ca^{2+} intracellular signaling pathways interact at several levels in the hierarchy of control. First, cytosolic Ca^{2+} and cyclic AMP levels can influence each other. For example, some forms of the enzymes that break down and make cyclic AMPcyclic AMP phosphodiesterase and adenylyl cyclase, respectively - are regulated by Ca^{2+}-calmodulin complexes. Conversely, A-kinase can phosphorylate some Ca^{2+} channels and pumps and alter their activity; A-kinase phosphorylates the

IP_3 receptor in the ER, for example, which can either inhibit or promote IP_3-induced Ca^{2+} release, depending on the cell type. Second, the enzymes directly regulated by Ca^{2+} and cyclic AMP can influence each other. Some CaM-kinases are phosphorylated by A-kinase, for example. Third, these enzymes can have interacting effects on shared downstream target molecules. Thus A-kinase and CaM-kinases frequently phosphorylate different sites on the same proteins, which are thereby regulated by both cyclic AMP and Ca^{2+}; the CREB gene regulatory protein, which we discussed earlier (see p. 741), is one example.

As an example of how Ca^{2+} and cyclic AMP pathways can interact, consider the *phosphorylase kinase* of skeletal muscle, whose role in glycogen degradation we have already discussed. This kinase phosphorylates glycogen phosphorylase, causing it to break down glycogen (see Figure 15-25). The kinase is a multisubunit enzyme, but only one of its four subunits actually catalyzes the phosphorylation reaction: the other three subunits are regulatory and enable the enzyme complex to be activated both by cyclic AMP and by Ca^{2+}. The four subunits are designated α, β, γ, and delta. The γ subunit carries the catalytic activity; the delta subunit is calmodulin and is largely responsible for the Ca^{2+} dependence of the enzyme; the α and β subunits are targets for cyclic AMP-mediated regulation, both being phosphorylated by the A-kinase (Figure 15-36).

The same Ca^{2+} signal that initiates muscle contraction also ensures that there is adequate glucose to power the contraction. The large influx of Ca^{2+} into the cytosol discussed in Chapter 16 alters the conformation of the calmodulin subunit of phosphorylase kinase, increasing kinase activity and thereby increasing the rate of the glycogen breakdown catalyzed by glycogen phosphorylase several hundredfold within seconds. In addition, the Ca^{2+} influx activates CaM-kinases that phosphorylate and inhibit glycogen synthase, thereby shutting off glycogen synthesis. By contrast, the adrenaline-induced A-kinase phosphorylations previously discussed adjust muscle cell metabolism in anticipation of an increased energy demand, allowing the enzyme to be activated when fewer calcium ions are bound to calmodulin, thereby making it more sensitive to Ca^{2+}.

Some Trimeric G Proteins Directly Regulate Ion Channels 27

Trimeric G proteins do not act exclusively by regulating the activity of enzymes and altering the concentration of cyclic nucleotides or Ca^{2+} in the cytosol. In some cases they directly activate or inactivate ion channels in the plasma membrane of the target cell, thereby altering the ion permeability, and hence the excitability, of the membrane. Acetylcholine released by the vagus nerve, for example, reduces both the rate and strength of heart muscle cell contraction. The effect is mediated by a special class of acetylcholine receptors that activate the inhibitory G protein, G_i, discussed previously. (These receptors, which can be activated by the fungal alkaloid muscarine, are called *muscarinic acetylcholine receptors* to distinguish them from the very different *nicotinic acetylcholine receptors,* which are ion-channel-linked receptors on skeletal muscle cells and nerve cells that can be activated by nicotine.) Once activated, the α subunit of G_i not only inhibits adenylyl cyclase (as described previously), it also directly opens K^+ channels in the muscle cell plasma membrane. The opening of these K^+ channels makes it harder to depolarize the cell, which contributes to the inhibitory effect of acetylcholine on the heart.

Other trimeric G proteins regulate the activity of ion channels less directly, either by regulating channel phosphorylation (by A-kinase, C-kinase, or CaM-kinase, for example) or by causing the production or destruction of cyclic nucleotides that directly activate or inactivate ion channels. Such *cyclic-nucleotide-gated ion channels* play a crucial role in both smell (olfaction) and vision.

Smell and Vision Depend on G-Protein-linked Receptors and Cyclic-Nucleotide-gated Ion Channels 28

Humans can distinguish more than 10,000 different smells (*odorants*), which are detected by specialized olfactory receptor neurons in the lining of the nose. These cells recognize odorants by means of specific G-protein-linked olfactory receptors, which are displayed on the surface of the modified cilia that extend from each cell (Figure 15-37). Many of these receptors act through cyclic AMP: when stimulated by odorant binding, they activate an olfactory-specific trimeric G protein (G_{olf}), which in turn activates adenylyl cyclase; the resulting increase in cyclic AMP opens *cyclic-AMP-gated cation channels,* which allows an influx of Na^+ that depolarizes the cell and initiates a nerve impulse that travels along the axon to the brain. Other olfactory receptors act via the inositol phospholipid pathway and IP_3-gated Ca^{2+} channels in the plasma membrane, but less is known about this transduction mechanism.

It is thought that there are hundreds of different olfactory receptors, each encoded by a different gene and each recognizing different odorants but all belonging to the G-protein-linked receptor superfamily. Although it is known that each olfactory cell

responds to a specific set of odorants, it is not yet clear if each cell contains only one type of receptor that recognizes a set of odorants or whether each cell contains a set of receptors, each specific for a single odorant. G-protein-linked receptors also seem to mediate some forms of taste, but less is known about them.

Cyclic-nucleotide-gated ion channels are also involved in signal transduction in vertebrate vision, but here the crucial cyclic nucleotide is cyclic GMP (Figure 15-38) rather than cyclic AMP. Like cyclic AMP, the concentration of cyclic GMP in cells is controlled by rapid synthesis (by *guanylyl cyclase*) and rapid degradation (by *cyclic GMP phosphodiesterase*).

In visual transduction, receptor activation is caused by light, and it leads to a fall rather than a rise in the level of the cyclic nucleotide. The pathway has been especially well studied in rod photoreceptors (rods) in the vertebrate retina. Rods are responsible for monochromatic vision in dim light, whereas *cone photoreceptors (cones)* are responsible for color vision in bright light. A rod photoreceptor is a highly specialized cell with an outer and an inner segment, a cell body, and a synaptic region where the rod passes a chemical signal to a retinal nerve cell, which relays the signal along the visual pathway (Figure 15-39). The phototransduction apparatus is in the outer segment, which contains a stack of *discs,* each formed by a closed sac of membrane in which photosensitive rhodopsin molecules are embedded. The plasma membrane surrounding the outer segment contains cyclic-GMP-gated Na^+ channels. These Na^+ channels are kept open in the dark by cyclic GMP molecules bound to the channels. Paradoxically, light causes a hyperpolarization (which inhibits synaptic signaling) rather than a depolarization of the plasma membrane (which could stimulate synaptic signaling), because the activation by light of rhodopsin molecules in the disc membrane leads to the *closure* of the Na^+ channels in the surrounding plasma membrane (Figure 15-40).

Rhodopsin, as we noted earlier, is a seven-pass transmembrane molecule homologous to other members of the G-protein-linked receptor family, and, like its cousins, it acts through a trimeric G protein. The activating extracellular signal, however, is not a molecule but a photon of light. Each rhodopsin molecule contains a covalently attached chromophore, 11- *cis* retinal, which isomerizes almost instantaneously to all- *trans* retinal when it absorbs a single photon. The isomerization alters the shape of the retinal, forcing a slower conformational change in the protein (opsin). The activated protein then binds to the trimeric G-protein *transducin* (G_t), causing the α subunit (α_t) to dissociate and activate cyclic GMP phosphodiesterase, which hydrolyzes cyclic GMP, so that cyclic GMP levels in the cytosol drop. As a consequence, cyclic GMP dissociates from the plasma membrane Na^+ channels, allowing them to close. In this way the signal passes from the disc membrane to the plasma membrane, and a light signal is converted into an electrical one.

The Na^+ channels are also permeable to Ca^{2+}, so that when they close, the normal influx of Ca^{2+} is inhibited, causing the Ca^{2+} concentration in the cytosol to fall; the fall in Ca^{2+} stimulates guanylyl cyclase to replenish the cyclic GMP, rapidly returning the cell toward the state it was in before the light was switched on. The activation of guanylyl cyclase by the fall in Ca^{2+} is mediated by a Ca^{2+}-sensitive protein called *recoverin,* which, in contrast to calmodulin, is inactive when Ca^{2+} is bound to it and active when it is Ca^{2+}-free; it stimulates the cyclase when Ca^{2+} levels are low following a light response. This Ca^{2+}-dependent mechanism is of crucial importance in two ways. First, it allows the photoreceptor to revert quickly to its resting, dark state in the aftermath of a flash of light, making it possible to perceive the shortness of the flash. Second, it helps to enable the photoreceptor to *adapt,* stepping down the response when it is exposed to light continuously. Adaptation, as we explain later, means that the receptor cell can function as a sensitive detector of *changes* in stimulus intensity over an enormously wide range of baseline levels of stimulation.

The various trimeric G proteins that we have discussed in this chapter are summarized in Table 15-3.

Extracellular Signals Are Greatly Amplified by the Use of Intracellular Mediators and Enzymatic Cascades 29

Despite the differences in molecular details, all of the signaling systems that are triggered by G-protein-linked receptors share certain features and are governed by similar general principles. Most of them depend on complex cascades, or relay chains, of intracellular mediators. By contrast with the more direct signaling pathways used by intracellular receptors discussed earlier and by ion-channel-linked receptors discussed in Chapter 11, catalytic cascades of intracellular mediators provide numerous opportunities for amplifying the responses to extracellular signals. In the visual transduction cascade just described, for example, a single activated rhodopsin molecule catalyzes the activation of hundreds of molecules of transducin at a rate of about 1000 transducin molecules per second. Each activated transducin molecule activates a molecule of cyclic GMP phosphodiesterase, each of which hydrolyzes about 4000 molecules of cyclic GMP per second. This catalytic cascade lasts for about 1 second and results in the hydrolysis of more than 10^5 cyclic GMP molecules for a single quantum of light absorbed, which transiently closes hundreds of Na^{2+} channels in the plasma membrane (Figure 15-41).

Similarly, when an extracellular signaling molecule binds to a receptor that indirectly activates adenylyl cyclase via G_s, each receptor protein may activate many molecules of G_s protein, each of which can activate a cyclase molecule. As each G_s molecule activated persists in its active form for seconds before it hydrolyzes its bound GTP to shut itself off, it can keep its bound cyclase molecule active for seconds, so that the cyclase can catalyze the conversion of a large number of ATP molecules to cyclic AMP molecules (Figure 15-42). The same type of amplification operates in the inositol-phospholipid pathway. As a result, a nanomolar (10^{-9} M) concentration of an extracellular signal often induces micromolar (10^{-6} M) concentrations of an intracellular second messenger such as cyclic AMP or Ca^{2+}. Since these messengers themselves function as allosteric effectors to activate specific enzymes or ion channels, a single extracellular signaling molecule can cause many thousands of molecules to be altered within the target cell. Moreover, each protein in the relay chain of signals can be a separate target for regulation, as, for example, in the glycogen breakdown cascade in skeletal muscle cells.

Any such amplifying cascade of stimulatory signals requires that there should be counterbalancing mechanisms at every step of the cascade to restore the system to its resting state when stimulation ceases. Cells therefore have efficient mechanisms for rapidly degrading (and resynthesizing) cyclic nucleotides and for buffering and removing cytosolic Ca^{2+}, as well as for inactivating the responding enzymes and transport proteins once they have been activated. This is not only essential for turning a response off, it is also important for defining the resting state from which a response takes off. As we saw earlier (see p. 727), in general the response to stimulation can be rapid only if the inactivating mechanisms also are rapid.

Cells Can Respond Suddenly to a Gradually Increasing Concentration of an Extracellular Signal [30]

Some cellular responses to signaling ligands are smoothly graded in simple proportion to the concentration of the ligand. The primary responses to steroid hormones (see Figure 15-13) often follow this pattern, presumably because each intracellular hormone receptor protein binds a single molecule of hormone and each specific DNA recognition sequence in a steroid-hormone-responsive gene acts independently. As the concentration of hormone increases, the concentration of hormone-receptor complexes increases proportionally, as does the number of complexes bound to specific recognition sequences in the responsive genes; the cellular response is therefore a gradual and linear one.

Other responses to signaling ligands, however, begin more abruptly as the concentration of ligand increases. Some may even occur in a nearly all-or-none manner, being undetectable below a threshold concentration of ligand and then reaching a maximum as soon as this concentration is exceeded. What might be the molecular basis for such steep or even switchlike responses to graded signals?

One mechanism for steepening the response is to require that more than one intracellular effector molecule or complex bind to some target macromolecule in order to induce a response. In some steroid-hormone-induced responses, for example, it appears that more than one hormone-receptor complex must bind simultaneously to specific regulatory sequences in the DNA in order to activate a particular gene. As a result, as the hormone concentration rises, gene activation begins more abruptly than it would if only one bound complex were sufficient for activation (Figure 15-43). A similar mechanism operates in the activation of A-kinase and calmodulin, as discussed earlier. Two or more Ca^{2+} ions, for example, must bind before calmodulin adopts its activating conformation; as a result, a fiftyfold increase in activation occurs when the free intracellular Ca^{2+} concentration increases only tenfold. Such responses become sharper as the number of cooperating molecules increases, and if the number is large enough, responses approaching the all-or-none type can be achieved (Figures 15-44 and 15-45).

Responses are also sharpened when a ligand activates one enzyme and at the same time inhibits another that catalyzes the opposite reaction. We have already discussed one example of this common type of regulation in the stimulation of glycogen breakdown in skeletal muscle cells, where a rise in the intracellular cyclic AMP level both activates phosphorylase kinase and inhibits the opposing action of phosphoprotein phosphatase.

The above mechanisms can produce responses that are very steep but, nevertheless, always smoothly graded according to the concentration of the signaling ligand. Another mechanism, however, can produce true all-or-none responses, such that raising the signal above a critical threshold level trips a sudden switch in the responding system. All-or-none threshold responses of this type generally depend on *positive feedback*. Thus, by positive feedback nerve and muscle cells generate all-or-none *action potentials* in response to neurotransmitters (discussed in Chapter 11). The activation of acetylcholine receptors at a neuromuscular junction, for example, opens cation channels in the muscle cell plasma membrane. The result is a net influx of Na$^+$ that locally depolarizes the membrane. This causes voltage-gated Na$^+$ channels to open in the same membrane region,

producing a further influx of Na^+, which further depolarizes the membrane and thereby opens more Na^+ channels. If the initial depolarization exceeds a certain threshold, this positive feedback has an explosive "runaway" effect, producing an action potential that propagates to involve the entire muscle membrane. As discussed earlier, a similar phenomenon occurs when Ca^{2+} is released from the ER or sarcoplasmic reticulum by Ca^{2+}-release channels: the released Ca^{2+} can bind back to the channels, increasing Ca^{2+} release, thereby producing an all-or-none Ca^{2+} spike.

The Effect of Some Signals Can Be Remembered by the Cell 31

An accelerating positive feedback mechanism can operate through signaling proteins that are enzymes rather than ion channels. Suppose, for example, that a particular signaling ligand activates an enzyme located downstream in the signal relay pathway and that two or more molecules of the product of the enzymatic reaction bind back to the same enzyme to activate it further (Figure 15-46). The consequence will be a very low rate of synthesis of the enzyme product in the absence of the ligand, increasing slowly with the concentration of ligand until, at some threshold level of ligand, enough of the product is being synthesized to activate the enzyme in a self-accelerating, runaway fashion; the concentration of the enzyme product then suddenly increases to a much higher level. In this way the cell can translate a gradual change in the concentration of a signaling ligand into a switchlike change in the level of a particular enzyme product, creating an all-or-none response by the cell.

This type of mechanism has an important property that makes it unsuitable for some purposes and uniquely valuable for others. If such a system has been switched on by raising the concentration of signaling ligand above threshold, it will generally remain switched on even when the signal disappears: instead of faithfully reflecting the current level of signal, the response system displays a memory. We have already discussed one example - CaM-kinase II, which is activated by Ca^{2+}/calmodulin to phosphorylate itself and other proteins. The autophosphorylation keeps the kinase active long after Ca^{2+} levels return to normal and Ca^{2+}/calmodulin has dissociated from the enzyme (see Figure 15-35). A self-activating memory mechanism can also operate further downstream in a signaling pathway, at the level of gene transcription. The signals that trigger muscle cell determination, for example, turn on a series of muscle-specific gene regulatory proteins that stimulate the transcription of their own genes as well as genes producing many other muscle cell proteins (see p. 445).

Summary

G-protein-linked receptors indirectly activate or inactivate plasma-membrane-bound enzymes or ion channels via trimeric GTP-binding regulatory proteins (G proteins) that shut themselves off by hydrolyzing their bound GTP. Some G-protein-linked receptors activate or inactivate adenylyl cyclase, thereby altering the intracellular concentration of the intracellular mediator cyclic AMP. Others activate a phosphoinositide-specific phospholipase C (phospholipase C-b), which hydrolyzes phosphatidylinositol bisphosphate (PIP_2) to generate two intracellular mediators - inositol trisphosphate (IP_3), which releases Ca^{2+} from the ER and thereby increases the concentration of Ca^{2+} in the cytosol, and diacylglycerol, which remains in the plasma membrane and activates C-kinase. A rise in cyclic AMP or Ca^{2+} levels affects cells by stimulating A-kinase and CaM-kinases, respectively. C-kinase, A-kinase, and CaM-kinases phosphorylate specific target proteins on serine or threonine residues and thereby alter the activity of the proteins. Each type of cell has characteristic sets of target proteins that are regulated in these ways, enabling the cell to make its own distinctive response to these intracellular mediators. Through the intracellular signaling cascades activated by G-protein-linked receptors, the responses to extracellular signals can be greatly amplified.

The various responses mediated by these receptors are rapidly turned off when the extracellular signaling ligand is removed. This is because the G proteins self-inactivate by hydrolyzing their bound GTP, IP_3 is rapidly dephosphorylated by a phosphatase (or phosphorylated by a kinase), diacylglycerol is rapidly broken down, cyclic nucleotides are hydrolyzed by phosphodiesterases, Ca^{2+} is rapidly pumped out of the cytosol, and proteins are dephosphorylated by protein phosphatases. The continuous rapid turnover of these intracellular mediators makes possible rapid increases in their concentrations when cells respond to extracellular signals. In addition, cells make use of both cooperativity and positive feedback to sharpen their responses.
Figure 15-17. A schematic drawing of a G-protein-linked receptor. Receptors that bind protein ligands have a large extracellular ligand-binding domain formed by the part of the polypeptide chain shown in *light green*. Receptors for small ligands such as adrenaline have small extracellular domains, and the ligand-binding site is usually deep within the plane of the membrane, formed by amino acids from several of the transmembrane segments. The parts of the intracellular domains that are mainly responsible for binding to trimeric G proteins are shown in *orange,* while those that become phosphorylated during receptor desensitization (discussed later) are shown in *red*.
Figure 15-18. Two major pathways by which G-protein-linked cell-surface receptors generate small intracellular mediators. In both cases the binding of an extracellular ligand alters the conformation of the cytoplasmic domain of the receptor, causing it to bind to a G protein that activates (or inactivates) a plasma membrane enzyme. In the cyclic AMP (cAMP)

pathway the enzyme directly produces cyclic AMP. In the Ca^{2+} pathway the enzyme produces a soluble mediator (inositol trisphosphate, discussed later) that releases Ca^{2+} from the endoplasmic reticulum. Like other small intracellular mediators, both cyclic AMP and Ca^{2+} relay the signal by acting as allosteric effectors: they bind to specific proteins in the cell, altering their conformation and thereby their activity.
Figure 15-19. Cyclic AMP. It is shown as a formula, a ball-and-stick model, and as a space-filling model. (C, H, N, O, and P indicate carbon, hydrogen, nitrogen, oxygen, and phosphorus atoms, respectively.)
Figure 15-20. The synthesis and degradation of cyclic AMP (cAMP). A pyrophosphatase makes the synthesis of cyclic AMP an irreversible reaction by hydrolyzing the released pyrophosphate Ⓟ-Ⓟ (not shown).

Table 15-1. Some Hormone-induced Cellular Responses Mediated by Cyclic AMP

Target Tissue	Hormone	Major Response
Thyroid gland	thyroid-stimulating hormone (TSH)	thyroid hormone synthesis and secretion
Adrenal cortex	adrenocorticotropic hormone (ACTH)	cortisol secretion
Ovary	luteinizing hormone (LH)	progesterone secretion
Muscle	adrenaline	glycogen breakdown
Bone	parathormone	bone resorption
Heart	adrenaline	increase in heart rate and force of contraction
Liver	glucagon	glycogen breakdown
Kidney	vasopressin	water resorption
Fat	adrenaline, ACTH, glucagon, TSH	triglyceride breakdown
Figure 15-21. Adenylyl cyclase. In vertebrates the enzyme usually contains about 1100 amino acid residues and is thought to have two clusters of six transmembrane segments separating two similar cytoplasmic catalytic domains. There are at least six types of this form of adenylyl cyclase in mammals (types I-VI). All of them are stimulated by G_s, but type I, which is found mainly in the brain, is also stimulated by complexes of Ca^{2+} bound to the Ca^{2+}-binding protein calmodulin (discussed later).
Figure 15-22. Adrenaline. This hormone (also called epinephrine) is made from tyrosine and is secreted by the adrenal gland when a mammal is stressed.

P$_i$

hydrolysis of the GTP by the α subunit returns the subunit to its original conformation, causing it to dissociate from the adenylyl cyclase (which becomes inactive) and to reassociate with βγ complex to re-form G$_s$

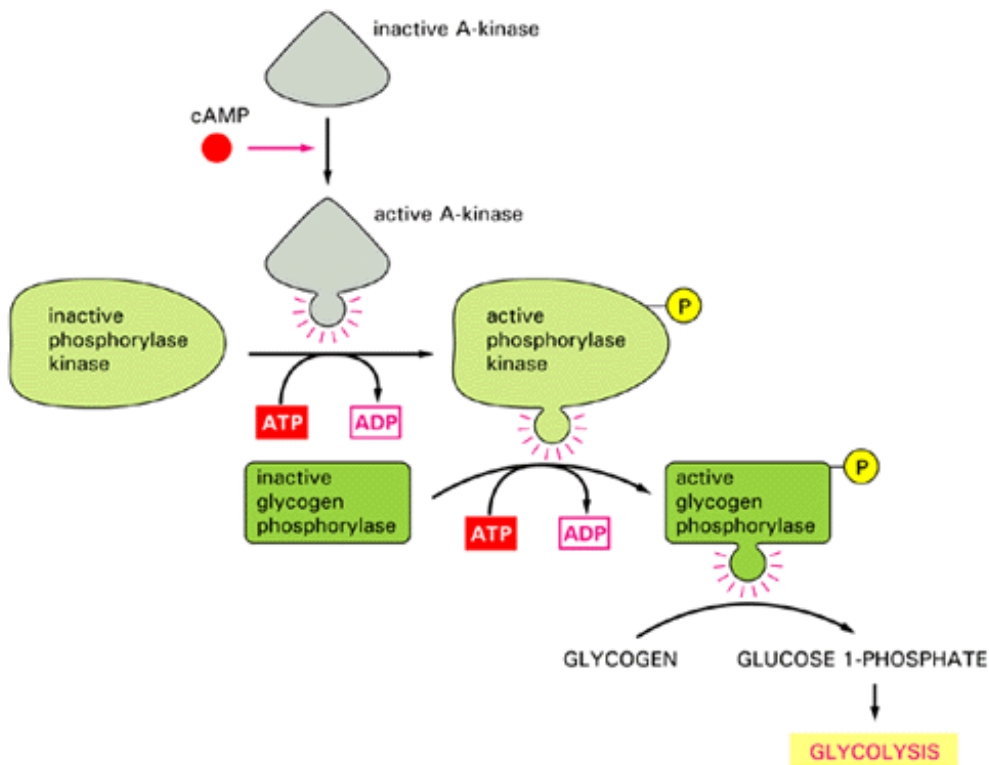
Figure 15-23. A current model of how G$_s$ couples receptor activation to adenylyl cyclase activation. As long as the extracellular signaling ligand remains bound, the receptor protein can continue to activate molecules of G$_s$ protein, thereby amplifying the response. More important, an a$_s$ can remain active and continue to stimulate a cyclase molecule for many seconds after the signaling ligand dissociates from the receptor, providing even greater amplification.
Figure 15-24. The activation of cyclic-AMP-dependent protein kinase (A-kinase). The binding of cyclic AMP to the regulatory subunits induces a conformational change, causing these subunits to dissociate from the complex, thereby activating the catalytic subunits. Each regulatory subunit has two cyclic-AMP-binding sites, and the release of the catalytic subunits requires the binding of more than two cyclic AMP molecules to the tetramer. This greatly sharpens the response of the kinase to changes in cyclic AMP concentration, as we discuss later. There are at least two types of A-kinase in most mammalian cells: type I is mainly in the cytosol, whereas type II is bound via its regulatory subunit to the plasma membrane, nuclear membrane, and microtubules. In both cases, however, once the catalytic subunits are freed and active, they can migrate into the nucleus (where they can phosphorylate gene regulatory proteins), while the regulatory subunits remain in the cytoplasm. The three-dimensional structure of the protein kinase domain of the A-kinase catalytic subunit is shown in Figure 5-12.


Figure 15-25. The stimulation of glycogen breakdown by cyclic AMP in skeletal muscle cells. The binding of cyclic AMP to A-kinase activates this enzyme to phosphorylate and thereby activate phosphorylase kinase, which in turn phosphorylates and activates glycogen phosphorylase, the enzyme that breaks down glycogen. The A-kinase also directly and indirectly increases the phosphorylation of glycogen synthase, which inhibits the enzyme, thereby shutting off glycogen synthesis (not shown).
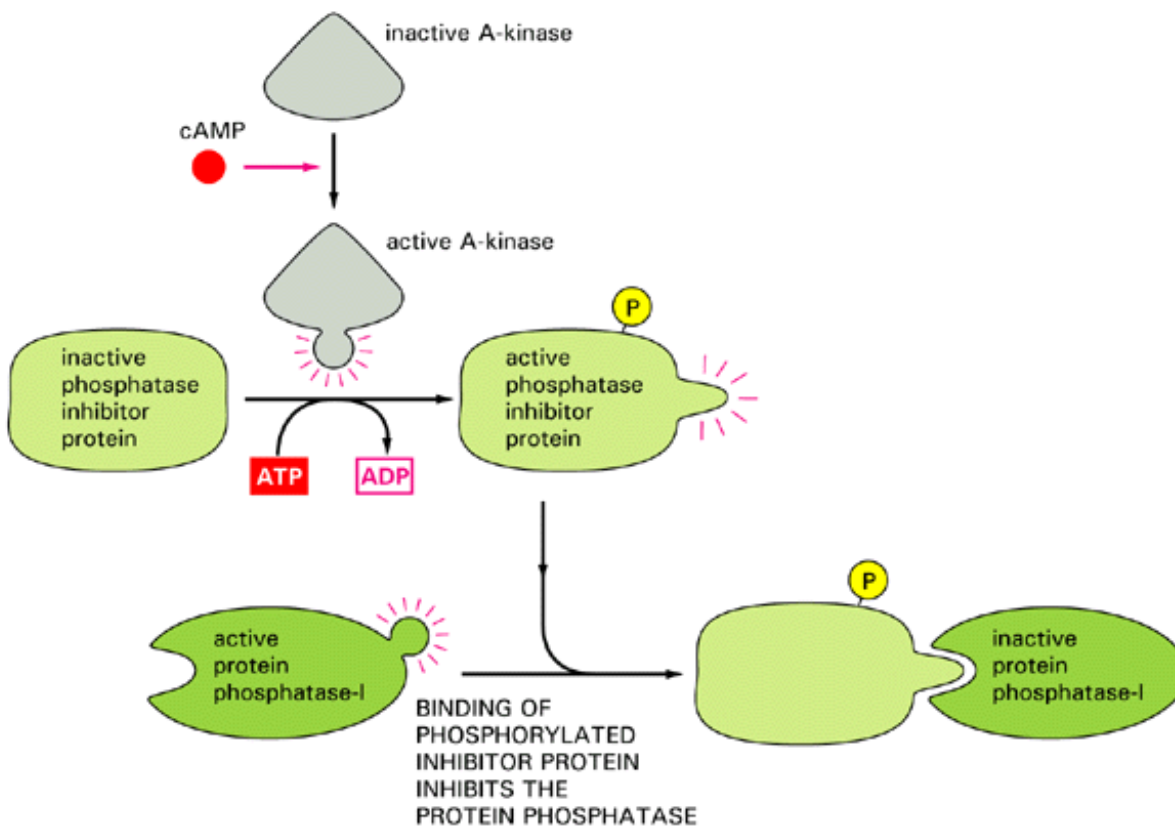

Figure 15-26. The role of protein phosphatase-I in the regulation of glycogen metabolism by cyclic AMP. Cyclic AMP

inhibits protein phosphatase-I, which would otherwise oppose the phosphorylation reactions stimulated by cyclic AMP. It does so by activating A-kinase to phosphorylate a phosphatase inhibitor protein, which then binds to and inhibits protein phosphatase-I.
Figure 15-27. Controls on cytosolic Ca^{2+}. The schematic drawing shows the main ways in which cells maintain a very low concentration of free Ca^{2+} in the cytosol in the face of high concentrations of Ca^{2+} in the extracellular fluid. Ca^{2+} is actively pumped out of the cytosol to the cell exterior (A) and into the ER (B). In addition, various molecules in the cell bind free Ca^{2+} tightly. Mitochondria can also pump Ca^{2+} out of the cytosol, but they do so efficiently only when Ca^{2+} levels are extremely high - usually as a result of cell damage.
Figure 15-28. Two common pathways by which Ca^{2+} can enter the cytosol in response to extracellular signals. In (A) Ca^2 $^+$ enters a nerve terminal from the extracellular fluid through voltage-gated Ca^{2+} channels when the nerve terminal membrane is depolarized by an action potential. In (B) the binding of an extracellular signaling molecule to a cell-surface receptor generates inositol trisphosphate, which stimulates the release of Ca^{2+} from the ER.
Figure 15-29. Inositol phospholipids (phosphoinositides). The polyphosphoinositides (PIP and PIP$_2$) are produced by the phosphorylation of phosphatidylinositol (PI). Although all three inositol phospholipids may be broken down in the signaling response, it is the breakdown of PIP$_2$ that is most critical, even though it is the least abundant, constituting less than 10% of the total inositol lipids and less than 1% of the total phospholipids.

Table 15-2. Some Cellular Responses Mediated by G-Protein-linked Receptors Coupled to the Inositol-Phospholipid Signaling Pathway

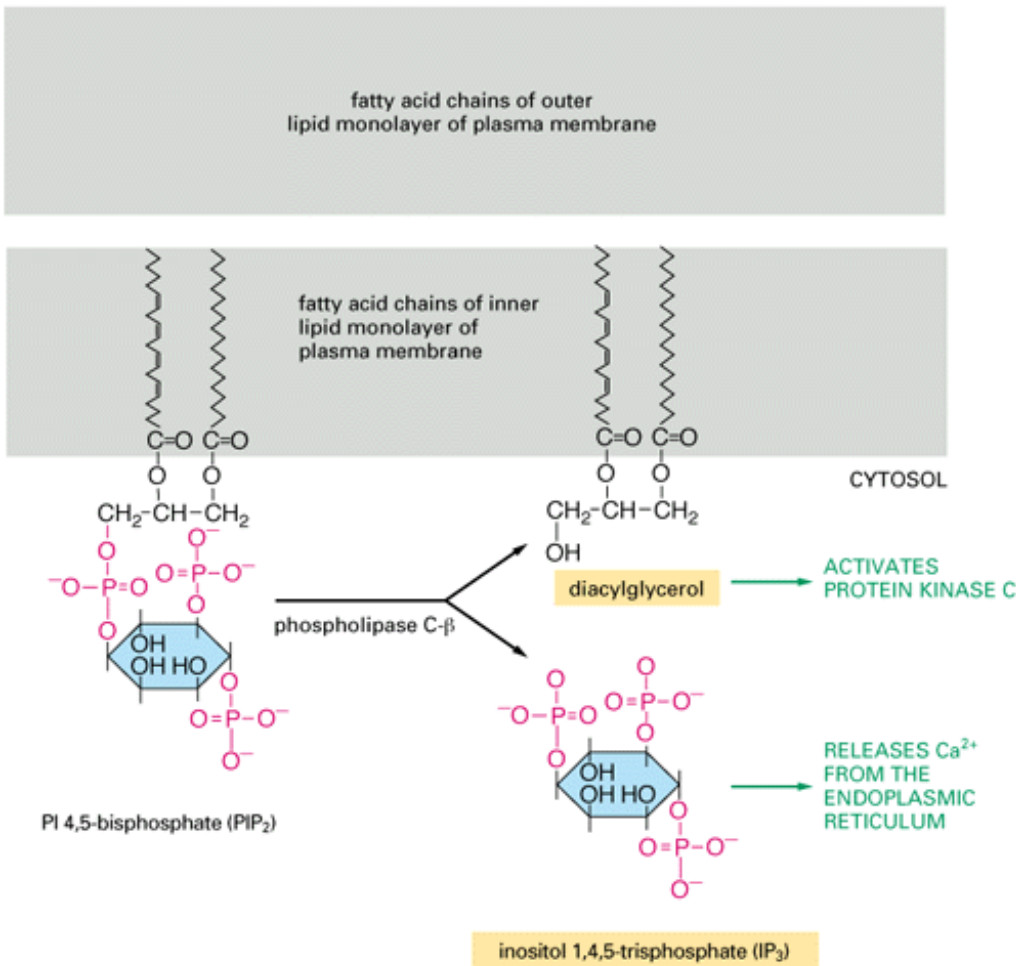
Target Tissue	Signaling Molecule	Major Response
Liver	vasopressin	glycogen breakdown
Pancreas	acetylcholine	amylase secretion
Smooth muscle	acetylcholine	contraction
Mast cells	antigen	histamine secretion
Blood platelets	thrombin	aggregation


Figure 15-30. The hydrolysis of PIP$_2$. Two intracellular mediators are produced when PIP$_2$ is hydrolyzed: *inositol trisphosphate (IP$_3$),* which diffuses through the cytosol and releases Ca^{2+} from the ER, and *diacylglycerol,* which remains in the membrane and helps activate the enzyme protein kinase C (see below). There are at least three classes of phospholipase C - b, g, and delta - and it is the b class that is activated by G-protein-linked receptors. We shall see later that the g class is activated by a second class of receptors, called *receptor tyrosine kinases,*that activate the inositol-phospholipid signaling pathway without an intermediary G protein.
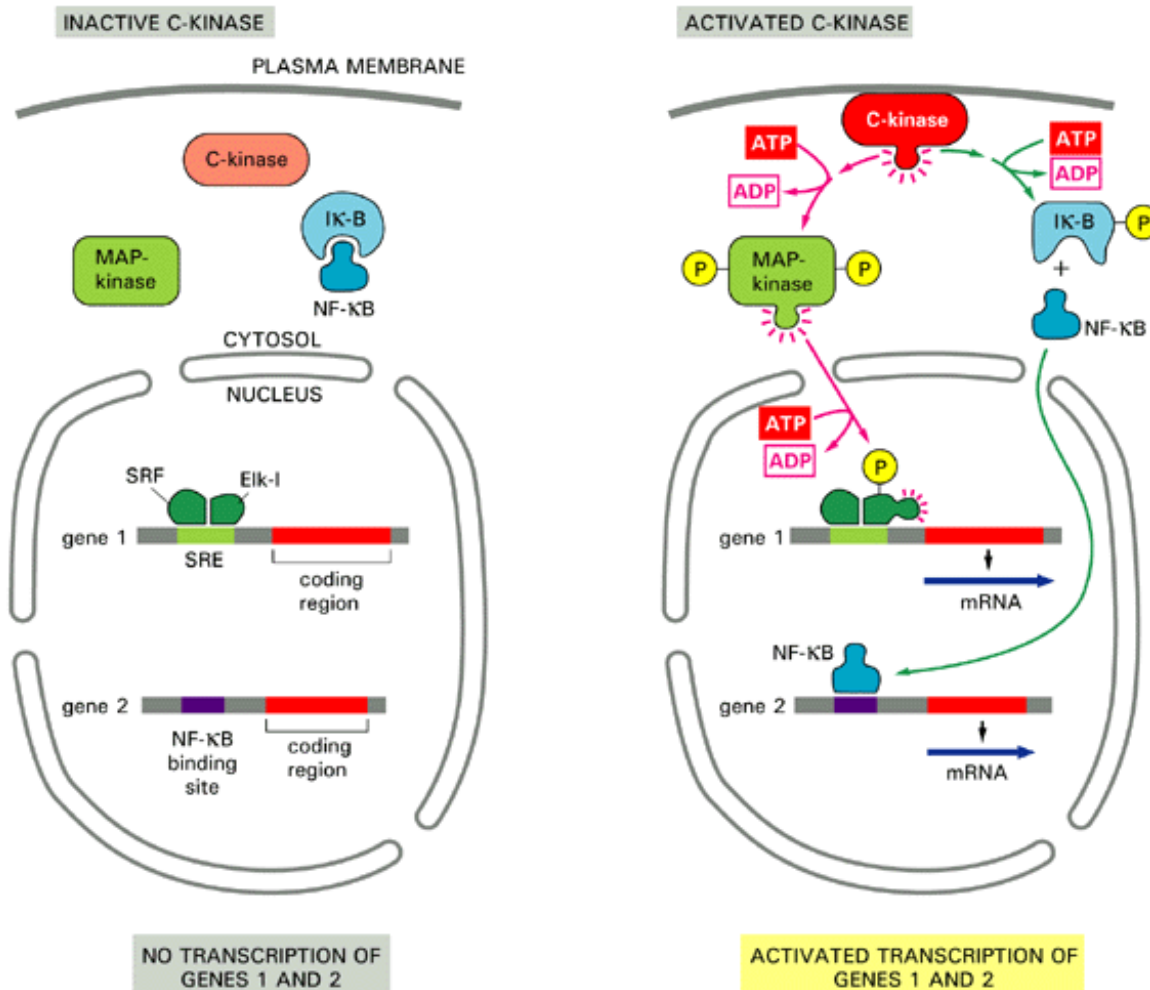
Figure 15-31. Vasopressin-induced Ca^{2+} oscillations in a liver cell. The cell was loaded with the Ca^{2+}-sensitive protein aequorin and then exposed to increasing concentrations of vasopressin. Note that the frequency of the Ca^{2+} spikes increases with increasing concentration of vasopressin but that the amplitude of the spikes is not affected. (Adapted from N.M. Woods, K.S.R. Cuthbertson, and P.H. Cobbold, *Nature* 319:600-602, 1986. © 1986 Macmillan Magazines Ltd.)


Figure 15-32. Two intracellular pathways by which activated C-kinase can activate the transcription of specific genes. In one (*red arrows*) C-kinase activates a phosphorylation cascade that leads to the phosphorylation of a pivotal protein kinase called *MAP-kinase* (discussed later), which in turn phosphorylates and activates the gene regulatory protein Elk-1. Elk-1 is bound to a short DNA sequence (called *serum response element, SRE*) in association with another DNA-binding protein (called *serum response factor, SRF*) . In the other pathway (*green arrows*) C-kinase activation leads to the phosphorylation of Ik-B, which releases the gene regulatory protein NF-kB so that it can migrate into the nucleus and activate the transcription of specific genes.
Figure 15-33. The two branches of the inositol phospholipid pathway. The activated receptor binds to a specific trimeric G protein (G_q), causing the a subunit to dissociate and activate phospholipase C-b, which cleaves PIP_2 to generate IP_3 and diacylglycerol. The diacylglycerol (together with bound Ca^{2+} and phosphatidylserine - not shown) activates C-kinase. Both phospholipase C-b and C-kinase are water-soluble enzymes that translocate from the cytosol to the inner face of the plasma membrane in the process of being activated. The effects of IP_3 can be mimicked experimentally in intact cells by treatment with Ca^{2+} ionophores, while the effects of diacylglycerol can be mimicked by treatment with phorbol esters, which bind to C-kinase and activate it.
Figure 15-34. The structure of Ca^{2+}/calmodulin based on x-ray diffraction and NMR studies. (A) The molecule has a "dumbbell" shape, with two globular ends connected by a long, exposed a helix. Each end has two Ca^{2+}-binding domains, each

with a loop of 12 amino acid residues in which aspartic acid and glutamic acid side chains form ionic bonds with Ca^{2+}. The two Ca^{2+}-binding sites in the carboxyl-terminal part of the molecule have a tenfold higher affinity for Ca^{2+} than those in the amino-terminal part. In solution the molecule is flexible, displaying a range of forms, from extended (as shown) to more compact. (B) The structural changes in Ca^{2+}/calmodulin that occurs when it binds to a target protein (in this example a peptide that consists of the Ca^{2+}/calmodulin-binding domain of a Ca^{2+}/calmodulin-dependent protein kinase [myosin light-chain kinase, discussed below]). Note that the Ca^{2+}/calmodulin has "jack-knifed" to surround the peptide. (A, based on x-ray crystallographic data from Y.S. Babu et al., *Nature* 315:37-40, 1985. © 1985 Macmillan Magazines Ltd.; B, based on x-ray crystallographic data from W. E. Meador, A.R. Means, and F.A. Quiocho, *Science* 257:1251-1255, 1992, and on NMR data from M. Ikura et al., *Science* 256:632-638, 1992. © 1992 the AAAS.)
Figure 15-35. The activation of CaM-kinase II. The enzyme is a protein complex of about 12 subunits. The subunits are of four homologous kinds (a, b, g, and delta), which are expressed in different proportions in different cell types. Only the a subunit, which is expressed only in the brain, is shown (in *gray*). In the absence of Ca^{2+}/calmodulin the enzyme is inactive as the result of an interaction between the inhibitory domain and the catalytic domain. The binding of Ca^{2+}/calmodulin alters the conformation of the protein, allowing the catalytic domain to phosphorylate the inhibitory domain of neighboring subunits in the complex, as well as other proteins in the cell (not shown). The autophosphorylation of the enzyme complex (by mutual phosphorylation of its subunits) prolongs the activity of the enzyme in two ways: (1) it traps the bound Ca^{2+}/calmodulin so that it does not dissociate from the enzyme complex until cytosolic Ca^{2+} levels return to basal values for at least 10 seconds (not shown); (2) it converts the enzyme to a Ca^{2+}-independent form so that the kinase remains active even after the Ca^{2+}/calmodulin dissociates from it. Activity continues until the autophosphorylation process is overwhelmed by a protein phosphatase.

Figure 15-42. Amplification in a ligand-induced catalytic cascade. The first amplification step requires that the signaling ligand remain bound to the receptor long enough for the complex to activate many G_S molecules; in many cases the ligand will dissociate too quickly for this amplification to occur.
Figure 15-43. Response of chick oviduct cells to the steroid sex hormone estradiol. When activated, estradiol receptors turn on the transcription of several genes. Dose-response curves for two of these genes, one coding for the egg protein *conalbumin* and the other coding for the egg protein *ovalbumin,* are shown. The linear response curve for conalbumin indicates that each activated receptor molecule that binds to the conalbumin gene increases the activity of the gene by the same amount. In contrast, the lag followed by the steep increase in the response curve for ovalbumin suggests that more than one activated receptor (in this case two receptors) must bind simultaneously to the ovalbumin gene in order to initiate its transcription. (Adapted from E.R. Mulvihill and R.D. Palmiter, *J. Biol. Chem.* 252:2060-2068, 1977.)
Figure 15-44. Activation curves as a function of signal-molecule concentration. The curves show how the sharpness of the response increases as the number of effector molecules that must bind simultaneously to activate a target macromolecule increases. The curves shown are those expected if the activation requires the simultaneous binding of 1, 2, 8, or 16 effector molecules, respectively.

Figure 15-45. One type of signaling mechanism expected to show a steep thresholdlike response. Here the simultaneous binding of eight molecules of a signaling ligand to a set of eight subunits is required to form an active protein complex: the ability of the subunits to assemble into the active complex depends on an allosteric conformational change that the subunits undergo when they bind their ligand. The binding of the ligand in the formation of such a complex is generally a cooperative process, causing a steep response as the ligand concentration is changed, as explained in Chapter 5. At low ligand concentrations the number of active complexes will increase roughly in proportion to the eighth power of the ligand concentration.
Figure 15-46. An accelerating positive feedback mechanism. The initial binding of the signaling ligand activates the enzyme to generate a product that binds back to the enzyme, further increasing the enzyme's activity.

Signaling via Enzyme-linked Cell-Surface Receptors

Introduction

Like G-protein-linked receptors, enzyme-linked receptors are transmembrane proteins with their ligand-binding domain on the outer surface of the plasma membrane. Instead of having a cytosolic domain that associates with a trimeric G protein, however, their cytosolic domains either have an intrinsic enzyme activity or associate directly with an enzyme. Whereas a G-protein-linked receptor protein has seven transmembrane segments, each subunit of a catalytic receptor usually has only one.

There are five known classes of enzyme-linked receptors: (1) *receptor guanylyl cyclases,* which catalyze the production of cyclic GMP in the cytosol; (2) *receptor tyrosine kinases,* which phosphorylate specific tyrosine residues on a small set of intracellular signaling proteins; (3) *tyrosine-kinase-associated receptors,* which associate with proteins that have tyrosine kinase activity; (4) *receptor tyrosine phosphatases,* which remove phosphate groups from tyrosine residues of specific intracellular signaling proteins; and (5) *receptor serine/threonine kinases,* which phosphorylate specific serine or threonine residues on some intracellular proteins.

We begin our discussion with the receptor guanylyl cyclases.

Receptor Guanylyl Cyclases Generate Cyclic GMP Directly [31]

Atrial natriuretic peptides (ANPs) are a family of closely related peptide hormones secreted by muscle cells in the atrium of the heart when blood pressure rises. ANPs stimulate the kidney to excrete Na^+ and water and induce the smooth muscle cells in the walls of blood vessels to relax. Both of these effects tend to lower blood pressure. The ANP receptor that mediates these responses is present on kidney cells and the smooth muscle cells of blood vessels; it is a single-pass transmembrane protein that has an extracellular binding site for ANPs and an intracellular guanylyl cyclase catalytic domain. The binding of ANPs activates the cyclase to produce cyclic GMP, which in turn binds to and activates a *cyclic GMP-dependent protein kinase (G-kinase),* which phosphorylates specific proteins on serine or threonine residues. Thus receptor guanylyl cyclases use cyclic GMP as an intracellular mediator in the same way that some G-protein-linked receptors use cyclic AMP, except that the linkage between ligand binding and cyclase activity is direct rather than via a trimeric G protein.

While relatively few known receptors belong to the guanylyl cyclase family, many known receptors belong to the *tyrosine kinase* family, which we consider next.

The Receptors for Most Growth Factors Are Transmembrane Tyrosine-specific Protein Kinases [32]

The first receptor protein recognized to be a tyrosine-specific protein kinase (in 1982) was the receptor for *epidermal growth factor (EGF).* EGF is a small protein (53 amino acids) that stimulates the proliferation of epidermal cells and a variety of other cell types. Its receptor is a single-pass transmembrane protein of about 1200 amino acids, with a large glycosylated extracellular portion that binds EGF. An intracellular tyrosine kinase domain is activated when EGF binds to the receptor. Once activated, the receptors transfer a phosphate group from ATP to selected tyrosine side chains, both on the receptor proteins themselves and on specific cellular proteins. Many other receptors for growth and differentiation factors are also receptor tyrosine kinases. These include the receptors for *platelet-derived growth factor (PDGF), fibroblast growth factors (FGFs), hepatocyte growth factor (HGF), insulin, insulinlike growth factor-1 (IGF-1), nerve growth factor (NGF), vascular endothelial growth factor (VEGF),* and *macrophage colony stimulating factor (M-CSF),* all of which are proteins. As shown in Figure 15-47, the family of receptor tyrosine kinases can be divided into a number of structural subfamilies; in each case the receptors phosphorylate themselves to initiate the intracellular signaling cascade.

How does the binding of a specific protein to the extracellular portion of a receptor tyrosine kinase activate the catalytic domain on the other side of the plasma membrane? It is difficult to imagine how a conformational change could propagate across the lipid bilayer through a single transmembrane α helix. The puzzle was solved when it was demonstrated that ligand binding causes the EGF receptor to assemble into dimers, which enables the two cytoplasmic domains to cross-phosphorylate each other on multiple tyrosine residues. This cross-phosphorylation is referred to as *autophosphorylation* because it occurs within the receptor dimer. In the case of PDGF receptors the ligand is a dimer that cross-links two receptors together (Figure 15-48). EGF, by contrast, is a monomer that is thought to induce a conformational change in the extracellular domain of its receptors to induce receptor dimerization. It is thought that receptor dimerization is a general mechanism for activating enzyme-linked receptors with a single transmembrane domain.

Receptor dimerization can be exploited experimentally to inactivate specific receptors in order to determine their importance for a particular cell response. The strategy involves transfecting cells with DNA that encodes a mutant form of a receptor tyrosine kinase that dimerizes normally but has an inactive kinase domain. When coexpressed at a high level with normal receptors, the mutant receptor acts in a *dominant-negative* way (see Figure7-44), disabling the normal receptors by forming an inactive dimer with them.

The signaling pathways triggered by EGF, PDGF, and FGF receptors have been analyzed in the greatest detail. In each case the autophosphorylated tyrosines serve as high-affinity binding sites for a number of intracellular signaling proteins in the target cell. Each of these proteins binds to a different phosphorylated site on the activated receptor, recognizing surrounding features of the polypeptide chain in addition to the phosphotyrosine. Once bound, many of these proteins become phosphorylated themselves on tyrosines and are thereby activated. In this way tyrosine autophosphorylation is thought to serve as a switch to trigger the transient assembly of an intracellular signaling complex, which serves to relay the signal into the cell interior. Different receptor tyrosine kinases bind different combinations of these signaling proteins and therefore activate different responses.

The receptor for insulin and IGF-1 acts in a slightly different way. First, because the receptors are tetramers to start with (see Figure 15-47), ligand binding is thought to induce an allosteric interaction of the two receptor halves rather than receptor dimerization. Second, insulin binding causes the receptor to phosphorylate its catalytic domains, which activates them to

phosphorylate a separate protein (called *insulin receptor substrate-1,* or *IRS-1*) on multiple tyrosines. The phosphotyrosines on IRS-1 then serve as high-affinity binding sites for the docking and activation of intracellular signaling proteins, many of which also bind directly to other activated receptor tyrosine kinases.

Phosphorylated Tyrosine Residues Are Recognized by Proteins with SH2 Domains [33]

A whole menagerie of intracellular signaling proteins have been found to bind to the phosphotyrosines on activated receptor tyrosine kinases. Some of these proteins - a *GTPase-activating protein (GAP), phospholipase C-γ (PLC-γ),* and the *Src-like nonreceptor protein tyrosine kinases* - have functions that are more or less understood, as we see in the following pages. Phospholipase C-γ, for example, functions in the same way as phospholipase C-β to activate the inositol phospholipid signaling pathway, discussed earlier in connection with signaling via G proteins. Other proteins that bind to activated receptor tyrosine kinases are more of a mystery. The enzyme *phosphatidylinositol 3'-kinase (PI3-kinase),* for example, is thought to be important in regulating cell proliferation; its immediate action is to phosphorylate the inositol ring of phosphotidylinositol at the 3 position (see Figure 15-29), but the functions of the special phosphoinositides produced in this way are unknown.

Although the intracellular signaling proteins that bind to phosphotyrosine residues on activated receptor tyrosine kinases (and to IRS-1) have varied structures and functions, they usually share two highly conserved noncatalytic domains, called *SH2* and *SH3* for *Src homology regions 2*and *3* because they were first found in the Src protein (famous for its role in cancer research, as discussed in Chapter 24). The SH2 domains recognize phosphorylated tyrosines and enable proteins that contain them to bind to the activated receptor tyrosine kinases as well as to other intracellular signaling proteins that have been transiently phosphorylated on tyrosines (Figure 15-49). The function of the SH3 domain is less clear, but it is thought to bind to other proteins in the cell.

A protein-binding function for the SH3 domain is suggested by studies of a class of small "adaptor" proteins that consist only of SH2 and SH3 domains. These *small SH adaptor proteins* have no intrinsic catalytic function and serve to couple tyrosine-phosphorylated proteins such as activated receptor tyrosine kinases to other proteins that do not have their own SH2 or SH3 domains. One such SH adaptor protein, called *Sem-5,* was discovered through genetic studies in the nematode worm *C. elegans,* as discussed in Chapter 21. Mutations in the *sem-5* gene block the signaling pathways from several receptor tyrosine kinases and have profound effects on the development of the worm. The signaling pathways are blocked equally effectively by mutations that disrupt the single SH2 domain or either of the two SH3 domains in the molecule, which suggests that both SH3 domains are required to bind a downstream signaling component (see Figure 15-53). In fact, homologues of the Sem-5 protein seem to be present in most animal cells, and there is both genetic an d biochemical evidence that they couple activated receptor tyrosine kinases to the important downstream signaling protein Ras, to which we now turn.

The Ras Proteins Provide a Crucial Link in the Intracellular Signaling Cascades Activated by Receptor Tyrosine Kinases [34]

The *Ras proteins* belong to the large Ras superfamily of monomeric GTPases, which also contains two other subfamilies: (1) the *Rho* and *Rac* proteins, involved in relaying signals from cell-surface receptors to the actin cytoskeleton (discussed in Chapter 16), and (2) the *Rab family,* involved in regulating the traffic of intracellular transport vesicles (discussed in Chapter 13). Like almost all of these monomeric GTPases, the Ras proteins contain a covalently attached prenyl group that helps anchor the protein to a membrane, in this case to the cytoplasmic face of the plasma membrane where the protein functions.

The Ras proteins help relay signals from receptor tyrosine kinases to the nucleus to stimulate cell proliferation or differentiation. If Ras function is inhibited by the microinjection of either neutralizing anti-Ras antibodies or dominant-negative mutant forms of Ras, the cell proliferation or differentiation responses normally induced by activated receptor tyrosine kinases do not occur; conversely, if a hyperactive mutant Ras protein is introduced into a cell, the effect on proliferation or differentiation is usually the same as that induced by the binding of ligand to the cell-surface receptors. In fact, Ras proteins were first discovered as the hyperactive products of mutant *ras* genes, which promote cancer by disrupting the normal controls on cell proliferation and differentiation; about 30% of human cancers have such mutations in a *ras* gene.

Like the other monomeric GTPases and the trimeric G proteins, Ras proteins function as switches, cycling between two distinct conformational states - active when GTP is bound (see Figure 15-18) and inactive when GDP is bound. Ras hydrolyzes GTP at least 100 times more slowly than the α subunit of the stimulatory trimeric G protein G_s discussed earlier, and because GTP is present in the cytosol at 10 times higher concentration than GDP, this means that in the absence of other influences, once GTP is

bound, Ras would remain constantly active. In the cell, however, two classes of signaling proteins regulate Ras activity by influencing the transition between the active and inactive states. GTPase-activating proteins (GAPs) increase the rate of hydrolysis of bound GTP by Ras, thereby inactivating it. These negative regulators are counteracted by guanine nucleotide releasing proteins (GNRPs), which promote the exchange of bound nucleotide by stimulating the loss of GDP and the subsequent uptake of GTP from the cytosol; they therefore tend to activate Ras (Figure 15-50). In principle, therefore, receptor tyrosine kinases could activate Ras either by activating a GNRP or by inhibiting a GAP. Activated receptor tyrosine kinases bind GAPs directly, as we noted earlier, and bind GNRPs only indirectly, as we discuss below. Nonetheless, it is the indirect coupling to GNRPs that is usually responsible for driving Ras into its active, GTP-bound state.

Ras proteins and the proteins that regulate Ras activity have been highly conserved in evolution, and genetic analyses in *Drosophila* and *C. elegans* provided the first clues as to how receptor tyrosine kinases activate Ras. Genetic studies of photoreceptor cell development in the *Drosophila* eye have been particularly informative.

An SH Adaptor Protein Couples Receptor Tyrosine Kinases to Ras: Evidence from the Developing *Drosophila* Eye 35

The *Drosophila* compound eye consists of about 800 identical units called *ommatidia,*each composed of 8 photoreceptor cells (R1-R8) and 12 accessory cells (Figure 15-51). The eye develops from a simple epithelial sheet, and the cells that make up each ommatidium are recruited from the sheet in a fixed sequence by a series of cell-cell interactions. Beginning with the development of R8, each differentiating cell induces its uncommitted immediate neighbor to adopt a specific fate and assemble into the developing ommatidium (Figure 15-52).

The development of the R7 photoreceptor, which is required for the detection of ultraviolet light, has been studied most intensively, beginning in 1976 with the description of a mutant fly called *sevenless (sev),* in which the only observed defect is that R7 fails to develop. Such mutants are easy to select on the basis of their blindness to ultraviolet light. The *sev* gene was eventually isolated and shown to encode a receptor tyrosine kinase that is expressed on R7 precursor cells. Further genetic analysis of mutants in which R7 development is blocked but the Sev protein itself is not affected led to the identification of the gene *bride-of-sevenless (boss),* which encodes the ligand for the Sev receptor protein. Boss is a seven-pass transmembrane protein that is expressed exclusively on the surface of the adjacent R8 cell, and when it binds to and activates Sev, it induces the R7 precursor cell to differentiate into an R7 photoreceptor. The Sev protein is also expressed on several other precursor cells in the developing ommatidium. But none of these cells contact R8; therefore, the Sev protein is not activated, and the cells do not differentiate into R7 photoreceptors. Although one suspects that multicellular organisms make widespread use of cell-surface-bound signaling ligands like Boss, such molecules have been hard to identify and characterize by standard biochemical techniques. The identification of Boss illustrates the power of the genetic approach.

The components of the intracellular signaling pathway activated by Sev in the R7 precursor cell proved more difficult to identify than the receptor or its ligand because they are used by cells in a variety of developing organs besides the eye and mutations that inactivate them are lethal. Some of these mutations, however, are lethal only when both copies of the gene are affected and so can be maintained in heterozygous animals, carrying one normal and one mutant copy of the gene. By isolating such mutants, as well as by using other genetic strategies, several genes encoding some of the intracellular signaling proteins were identified. One encodes a Ras protein. Whereas flies in which both copies of the *ras* gene are inactivated by mutation die, flies with only one inactivated copy survive but lack R7. Conversely, if one of the *ras* genes is rendered overactive by mutation, R7 develops even in mutants in which both *sev* and *boss* are inactive. Thus activation of Ras seems to be necessary and sufficient to induce R7 differentiation. A second gene, *son-of-sevenless (sos),* encodes a guanine nucleotide releasing protein (GNRP), which is required for the Sev receptor tyrosine kinase to activate Ras. A third gene encodes a Sem-5-like protein called *Drk* (*d* ownstream of *r* eceptor *k* inases), which couples the Sev receptor to the Sos protein; the SH2 domain of Drk binds to activated Sev, while the two SH3 domains are thought to bind to Sos. A fourth gene encodes a GTPase-activating protein (GAP). If this gene is inactivated, R7 develops even if *sev* has been inactivated, presumably because Ras is hyperactive in the absence of inhibition by GAP (Figure 15-53). In this signaling system, therefore, and in most others that have been studied, the activation of Ras by receptor tyrosine kinases depends on the activation of a GNRP rather than on the inactivation of a GAP.

Once activated, Ras relays the signal downstream by activating a serine/threonine phosphorylation cascade that is highly conserved in eucaryotic cells from yeasts to humans. A crucial component in this cascade is a novel type of protein kinase called *MAP-kinase,* which we consider next.

Ras Activates a Serine/Threonine Phosphorylation Cascade That Activates MAP-Kinase 36

The tyrosine phosphorylations and the activation of Ras, which are stimulated by receptor tyrosine kinases at the cytoplasmic surface of the plasma membrane, are very short-lived: the phosphorylations are quickly reversed by tyrosine-specific protein phosphatases (discussed later), and activated Ras inactivates itself by hydrolyzing its bound GTP to GDP. To stimulate cells to proliferate or differentiate, these short-lived signaling events need to be converted into longer-lasting ones that can sustain the signal and relay it downstream to the nucleus. The relay systems involve multiple, interacting cascades of serine/threonine phosphorylations, which are much longer-lived than tyrosine phosphorylations. Many serine/threonine kinases are involved in these cascades, but one family, which contains at least five members, seems to play an especially important role - the mitogen-activated protein (MAP) kinases (also called *extracellular-signal-regulated kinases [ERKs]*). These kinases are turned on by a wide range of extracellular proliferation- and differentiation-inducing signals, some of which activate receptor tyrosine kinases, while others activate G-protein-linked receptors.

An unusual feature of the MAP-kinases is that their full activation requires phosphorylation of both a threonine and a tyrosine, which are separated in the protein by a single amino acid. The protein kinase that catalyzes both of these phosphorylations is called *MAP-kinase-kinase.* The requirement for both tyrosine and threonine phosphorylation ensures that MAP-kinases are kept inactive unless specifically activated by MAP-kinase-kinase, whose only known substrates are MAP-kinases. MAP-kinase-kinase is itself activated by serine/threonine phosphorylation catalyzed by a MAP-kinase-kinase-kinase, which is thought to be activated by the binding of activated Ras (Figure 15-54).

Once a MAP-kinase is activated, it relays signals downstream by phosphorylating various proteins in the cell, including other protein kinases and gene regulatory proteins. Often, transcription of a set of *immediate early genes* is activated within minutes of a cell's being stimulated by a growth factor. One protein complex that plays an important part in this transcriptional activation is the complex discussed earlier that is formed by the serum response factor (SRF) and Elk-1. The complex is constitutively bound to a specific DNA sequence (the serum response element) found in the regulatory region of a gene called *fos* and some other immediate early genes. When activated, MAP-kinases migrate from the cytosol into the nucleus and phosphorylate Elk-1, thereby activating it to turn on the transcription of the *fos* gene (see Figure 15-32). In addition, MAP-kinases may phosphorylate the Jun protein, which combines with the newly made Fos protein to form an active gene regulatory protein called AP-1. The AP-1 protein then turns on additional genes, although its exact role in stimulating cell proliferation remains to be defined.

C-kinase also can phosphorylate Jun, and, as illustrated in Figure 15-54, it can activate MAP-kinase-kinase-kinase, so that both Jun and MAP-kinase-kinase-kinase are examples of integration points where several signaling pathways converge.

Tyrosine-Kinase-associated Receptors Depend on Nonreceptor Tyrosine Kinases for Their Activity 37

Many of the cell-surface receptor proteins that have been isolated and characterized do not fall into any of the main families of receptors that we have described so far: they are neither ion-channel-linked nor G-protein-linked, and they lack an obvious catalytic domain. This large and heterogeneous assortment includes receptors for most of the local mediators (called *cytokines*) that regulate proliferation and differentiation in the hemopoietic system as well as receptors for some hormones (growth hormone and prolactin, for example) and the antigen-specific receptors on T and B lymphocytes. Many receptors in this category work through associated tyrosine kinases, which phosphorylate various target proteins when the receptor binds its ligand. The kinases involved with these tyrosine-kinase-associated receptors are mostly members of the well-characterized *Src family* of nonreceptor protein tyrosine kinases mentioned earlier, or of the recently described *Janus family* of nonreceptor protein tyrosine kinases. It is thought that these receptors function in much the same way as receptor tyrosine kinases except that their kinase domain is encoded by a separate gene and is noncovalently associated with the receptor polypeptide chain. As with receptor tyrosine kinases, their activation is thought often to involve ligand-induced receptor dimerization (Figure 15-55).

There are at least eight members of the Src family of nonreceptor protein tyrosine kinases in mammals: *Src, Yes, Fgr, Fyn, Lck, Lyn, Hck,* and *Blk.* They contain SH2 and SH3 domains and are all located on the cytoplasmic side of the plasma membrane, held there partly by their interaction with transmembrane receptor proteins and partly by covalently attached lipid chains. Different family members are associated with different receptors and phosphorylate overlapping but distinct sets of target proteins. Lyn, Fyn, and Lck, for example, are each associated with different sets of receptors in lymphocytes. In each case the Src-family tyrosine kinase is activated when an extracellular ligand binds to the appropriate receptor protein.

The same Src-family kinase can associate both with receptors that do not have intrinsic tyrosine kinase activity and with receptors that do. In various non-lymphocyte cells, for example, Fyn binds via its SH2 domain to activated PDGF receptors, which phosphorylate the Fyn protein on tyrosine residues and thereby activate its kinase activity. It is not surprising, therefore, that receptor tyrosine kinases and Src-family-tyrosine-kinase-associated receptors activate some of the same signaling pathways.

Much less is known about the Janus family of nonreceptor protein tyrosine kinases, which includes JAK1, JAK2, and Tyk2. They are involved in signaling from a number of tyrosine-kinase-associated receptors, including those for growth hormone, prolactin, and various cytokines that act on hemopoietic cells (discussed in Chapter 22).

For many tyrosine-kinase-associated receptors, ligand binding causes the assembly of two or more different transmembrane receptor subunits. A well-studied example is the receptor for *interleukin-2 (IL-2),* a local mediator secreted by T lymphocytes that stimulates lymphocyte proliferation (discussed in Chapter 23). The IL-2 receptor is composed of three polypeptide chains (α, β, and γ), which are thought to assemble after ligand binding to form a functional receptor complex, as illustrated in Figure 15-56.

Some Receptors Are Protein Tyrosine Phosphatases 38

As mentioned previously, the tyrosine residues that are phosphorylated by protein tyrosine kinases are very rapidly dephosphorylated by protein tyrosine phosphatases. These enzymes are structurally unrelated to the serine/threonine protein phosphatases discussed earlier, and they remove phosphate groups only from selected phosphotyrosines on particular types of proteins. These phosphatases are found in both soluble and membrane-bound forms and come in many more varieties than do serine/threonine phosphatases. Their high specific activity ensures that tyrosine phosphorylations are very short-lived and that the level of tyrosine phosphorylation in resting cells is very low. Protein tyrosine phosphatases do not simply continuously reverse the effects of protein tyrosine kinases, however; they can be regulated to play specific roles in cell signaling, as well as in controlling the cell cycle (discussed in Chapter 17).

An important example of a regulated protein tyrosine phosphatase is the *CD45 protein,* which is found on the surface of white blood cells and plays an essential part in the activation of both T and B lymphocytes by foreign antigens. CD45 is a single-pass transmembrane glycoprotein with its tyrosine phosphatase domain exposed on the cytoplasmic side of the plasma membrane. When cross-linked by extracellular antibodies (its normal ligand is unknown), its catalytic domain is activated to remove phosphate groups from tyrosine residues on specific target proteins in the cell. One such target protein is thought to be the Lck tyrosine kinase mentioned earlier. When dephosphorylated by CD45, Lck is apparently activated to phosphorylate other proteins in the cell.

Cancer-promoting Oncogenes Have Helped Identify Many Components in the Receptor Tyrosine Kinase Signaling Pathways 39

Cells in higher animals normally divide only when they are stimulated by growth factors, which are produced by other cells and usually act by binding to receptor tyrosine kinases. Cancer cells proliferate excessively mainly because, as a result of accumulated mutations, they are able to divide without stimulation from other cells and therefore are no longer subject to the normal "social" controls on cell proliferation (discussed in Chapter 17). Not surprisingly, many of these mutations affect genes that code for proteins involved in the signaling pathways utilized by receptor tyrosine kinases. Indeed, a number of the genes that encode the signaling proteins discussed in this section, including Ras, Src (and the other members of the Src family), Raf, Fos, and Jun, were first identified as mutant forms in cancer cells or in cancer-promoting tumor viruses. As discussed in Chapter 24, the mutant genes were called *oncogenes* before their origin from normal genes was understood; the normal genes are therefore sometimes referred to as *proto-oncogenes.*

In principle, one might expect that any mutation that results in the production of an abnormally active protein anywhere along the signaling pathways that lead from growth factor to the nucleus could promote cancer by encouraging the cell to proliferate in the absence of the appropriate extracellular signals. The evidence to date supports such a view. The *sis* oncogene, for example, encodes a functionally active form of PDGF that is expressed inappropriately; cells that carry the *sis* oncogene and also express PDGF receptors continuously stimulate themselves to proliferate. The *erbB* oncogene encodes a truncated form of the EGF receptor that has an intracellular tyrosine kinase domain that is continuously active; cells expressing this oncogene behave as though they are constantly being signaled to proliferate by a growth factor. Cells behave in a similar way if they are infected with a tumor virus carrying the *v-src* oncogene, which encodes a constitutively active form of the Src tyrosine kinase, or if they express a *ras* oncogene, which encodes an abnormal form of a Ras protein that cannot shut itself off because it has lost the ability to hydrolyze GTP. Similarly, cells proliferate abnormally if they express an oncogene that encodes a constitutively active form of a growth-factor-activated gene regulatory protein, such as Jun or Fos. Studies of such oncogenes have not only illuminated the molecular mechanisms underlying cancer, they have also uncovered many previously unknown proteins in the signaling pathways activated by growth factors.

Some hormones that stimulate their target cells to proliferate bind to G-protein-linked receptors rather than to receptor tyrosine kinases. *Growth-hormone-releasing factor (GHF),* for example, stimulates growth-hormone-secreting cells in the pituitary gland to proliferate; the GHF binds to GHF receptors that activate adenylyl cyclase via the stimulatory G protein G_s. The resulting rise in cyclic AMP stimulates the pituitary cells to divide. As might be expected, mutations in the α_s gene that inactivate the GTPase activity of the α subunit of G_s (and thereby render the protein constitutively active) produce an oncogene that is frequently found in human pituitary tumors.

Proteins in the TGF-β Superfamily Activate Receptors That Are Serine/Threonine Protein Kinases [40]

Transforming growth factor-βs (TGF-βs) constitute a family of local mediators that regulate the proliferation and functions of most vertebrate cell types. The five members of the family (TGF-β1 to β5) are proteins with similar structures and functions. Their effects on cells are varied. Depending on the cell type, they can suppress proliferation, stimulate the synthesis of extracellular matrix, stimulate bone formation, and attract cells by chemotaxis. The TGF-βs are synthesized as large precursors and are secreted as inactive complexes that are later activated by proteolytic processing.

A number of other extracellular signaling proteins are structurally related to the TGF-βs. These include the *activins,* which play an important part in mesoderm induction in vertebrate development (discussed in Chapter 21), and the *bone morphogenetic proteins,* which stimulate bone formation. Together these proteins constitute the *TGF-β superfamily.*

Recently, the cDNAs encoding several receptors for members of this superfamily have been cloned and sequenced. The receptors were found to be single-pass transmembrane proteins with a serine/threonine kinase domain on the cytosolic side of the plasma membrane. These are the first receptor serine/threonine kinases to be identified, and little is known about the signaling pathways that they activate.

Some of the tyrosine-specific and serine/threonine-specific protein kinases that we have discussed in this chapter are reviewed in Figure 15-57.

The Notch Transmembrane Receptor Mediates Lateral Inhibition by an Unknown Mechanism [41]

The class of enzyme-linked cell-surface receptors is large and varied. It includes, in addition to those we have already considered, the *integrins,* which bind to components of the extracellular matrix. As discussed in Chapter 19, these transmembrane proteins not only attach cells to the matrix through focal contacts but also generate intracellular signals at such attachment sites, presumably by triggering the assembly of an intracellular signaling complex (see Figure 17-42).

The signaling mechanisms used by some receptor proteins are still so poorly understood that it is uncertain how to classify the receptors. An important example is the *Drosophila* protein Notch. As explained in Chapter 21, this single-pass transmembrane protein plays a crucial part in the cell-cell interactions that control the fine-grained pattern of cell diversification during fly development. Typically, a cell that lacks Notch is unresponsive to *lateral inhibition* - the inhibitory signals from its immediate neighbors that would normally cause it to differentiate in a way different from them. In a normal fly embryo, for example, a nerve cell precursor inhibits its neighbors from also becoming nerve cells, and they instead become epidermal cells; in Notch mutants the inhibition fails, and all of these cells become nerve cells.

Like the Sev protein discussed earlier, Notch is activated by binding to proteins displayed on the surface of adjacent cells rather than by soluble signaling molecules. Although the sequence of Notch is known and several of the proteins downstream from it have been identified by genetic analysis, it is still unclear how Notch relays its signal into the interior of the cell. Notch-like proteins also play an important role in vertebrate development, but here too the signaling mechanisms involved remain a mystery.

Summary

There are five known classes of enzyme-linked receptors: (1) transmembrane guanylyl cyclases, which generate cyclic GMP directly; (2) receptor tyrosine phosphatases, which remove phosphate from phosphotyrosine side chains of specific proteins; (3) transmembrane receptor serine/threonine kinases, which add a phosphate group to serine and threonine side chains on target

proteins; (4) receptor tyrosine kinases; and (5) tyrosine-kinase-associated receptors. The last two types of receptors are by far the most numerous, and they are thought to work in a similar way: ligand binding usually induces the receptors to dimerize, which activates the kinase activity of either the receptor or its associated nonreceptor tyrosine kinase. When activated, receptor tyrosine kinases usually cross-phosphorylate themselves on multiple tyrosine residues, which then serve as docking sites for a small set of intracellular signaling proteins, which bind via their SH2 domains to specific phosphotyrosine residues. In this way a multiprotein signaling complex is activated from which the signal spreads to the cell interior.

The Ras proteins serve as crucial links in the intracellular relay system. They are monomeric GTPases that behave as molecular switches; they are activated by guanine nucleotide releasing proteins and inactivated by GAPs. When Ras proteins are activated, they initiate a cascade of serine/threonine phosphorylations that converge on MAP-kinases, which help relay the signal to the nucleus. Many of the genes that encode the proteins in the intracellular signaling cascades that are activated by receptor tyrosine kinases were first identified as oncogenes in cancer cells or tumor viruses, since their inappropriate activation causes a cell to proliferate excessively.
Figure 15-47. Six subfamilies of receptor tyrosine kinases. Only one or two members of each subfamily are indicated. Note that the tyrosine kinase domain is interrupted by a "kinase insert region" in some of the subfamilies. The functional significance of the cysteine-rich and immunoglobulinlike domains is unknown.
Figure 15-48. Platelet-derived growth factor (PDGF). (A) The dimeric structure of the protein, with the receptor-binding regions shaded in *yellow*. The dimer is held together by three disulfide bonds (not shown). (B) Because PDGF is a dimer with two receptor-binding sites, it can cross-link adjacent receptors to initiate the intracellular signaling process. Nerve growth factor (NGF) as well as the other proteins of the *neurotrophin* family (discussed in Chapter 21) also function as dimers that cross-link their receptor tyrosine kinases.
Figure 15-49. Binding of SH2-containing intracellular signaling proteins to an activated PDGF receptor. (A) Schematic drawing of a PDGF receptor, showing five tyrosine autophosphorylation sites, three in the kinase insert region and two on the carboxyl-terminal tail, to which the three signaling proteins shown on the left bind as indicated. (There are two additional tyrosine autophosphorylation sites on the receptor that are not shown, located between the membrane-spanning domain and the start of the kinase domain, which serve as a binding site for Src-like nonreceptor tyrosine kinases.) The numbers on the right indicate the position of the tyrosines in the polypeptide chain. These binding sites have been identified by using recombinant DNA technology to mutate specific tyrosines in the receptor: mutation of tyrosines 1009 and 1021, for example, prevents the binding and activation of PLC-g, so that receptor activation no longer stimulates the inositol phospholipid signaling pathway. The locations of the SH2 (*red*) and SH3 (*blue*) domains in the three signaling proteins are indicated. (B) The three-dimensional structure of an SH2 domain as determined by x-ray crystallography. The binding pocket for phosphotyrosine is shown in *yellow* on the right, while a pocket for binding a specific amino acid side chain (isoleucine in this case) is shown in *yellow* on the left. (C) The SH2 domain is a compact module, which can be inserted almost anywhere in a protein without disturbing the protein's folding or function. Because each domain has distinct sites for recognizing phosphotyrosine and for recognizing a particular amino acid side chain, different SH2 domains recognize phosphotyrosine in the context of different flanking amino acid sequences. (B, based on data from G. Waksman et al., *Cell* 72:1-20, 1993. © Cell Press.)
Figure 15-53. Early cell-signaling events in R7 development. The activation of the Sev receptor tyrosine kinase on the surface of the R7 precursor cell by the Boss protein on the surface of R8 is coupled to the activation of the guanine nucleotide releasing protein Sos by the small SH adaptor protein Drk. Drk recognizes a specific autophosphorylated tyrosine on the Sev protein by means of an SH2 domain and interacts with Sos by means of two SH3 domains. Sos stimulates the inactive Ras protein to give up its bound GDP and take up GTP, which activates Ras to relay the signal downstream. (Although not shown here, Ras is bound to the cytosolic face of the plasma membrane.) It is thought that activated Sev also represses GAP, which otherwise would counteract the function of Sos by stimulating Ras to hydrolyze its bound GTP and become inactive. The coupling of receptor tyrosine kinases to Ras seems to occur by the same mechanism in mammalian cells.
Figure 15-50. The regulation of Ras activity. GTPase-activating proteins (GAPs) inactivate Ras by stimulating it to hydrolyze its bound GTP. Guanine nucleotide releasing proteins (GNRPs) activate Ras by stimulating it to give up its GDP; as the concentration of GTP in the cytosol is 10 times greater than the concentration of GDP, Ras will tend to bind GTP once GDP is ejected. Two Ras-regulating GAPs (*Ras GAPs*) have been characterized in mammalian cells so far - *p120^{GAP}* and *neurofibromin* (so called because it is encoded by the gene that is mutated in the common human genetic disease

neurofibromatosis, which is associated with tumors of nerves). Although both Ras GAPs are expressed ubiquitously, one or the other seems to predominate (depending on the cell type) in maintaining most of the Ras protein (~95%) in an inactive GDP-bound state.
Figure 15-51. Scanning electron micrograph of a compound eye of *Drosophila*. The eye is composed of about 800 identical units (ommatidia), each having a separate lens that focuses light onto eight photoreceptor cells at its base. (Courtesy of Ernst Hafen.)
Figure 15-52. The assembly of photoreceptor cells in a developing *Drosophila* ommatidium. Schematic drawing of the sequential recruitment of photoreceptors, beginning with R8 and ending with R7, which is the last photoreceptor cell to develop.
Figure 15-54. The serine/threonine phosphorylation cascade activated by Ras and C-kinase. In the pathway activated by receptor tyrosine kinases via Ras, the MAP-kinase-kinase-kinase is often a serine/threonine kinase called *Raf,* which is thought to be activated by the binding of activated Ras. In the pathway activated by G-protein-linked receptors via C-kinase, the MAP-kinase-kinase-kinase can either be Raf or a different serine/threonine kinase. A similar serine/threonine phosphorylation cascade involving structurally and functionally related proteins operates in yeasts and in all animals that have been studied, where it integrates and amplifies signals from different extracellular stimuli. Receptor tyrosine kinases may also activate a more direct signaling pathway to the nucleus by directly phosphorylating, and thereby activating, gene regulatory proteins that contain SH2 domains.
Figure 15-55. The three-dimensional structure of human growth hormone bound to its receptor. The hormone (*red*) has cross-linked two identical receptors (one shown in *green* and the other in *blue*) to form a receptor homodimer. (It was entirely unexpected that a monomeric ligand such as growth hormone would cross-link its receptors, as it requires that the two identical receptors recognize different parts of the hormone.) Ligand-induced dimerization is thought to bring together the cytoplasmic domains of the two single-pass, transmembrane receptor proteins. This in turn activates a nonreceptor tyrosine kinase (not shown). The structures shown were determined by x-ray crystallographic studies of complexes formed between the hormone

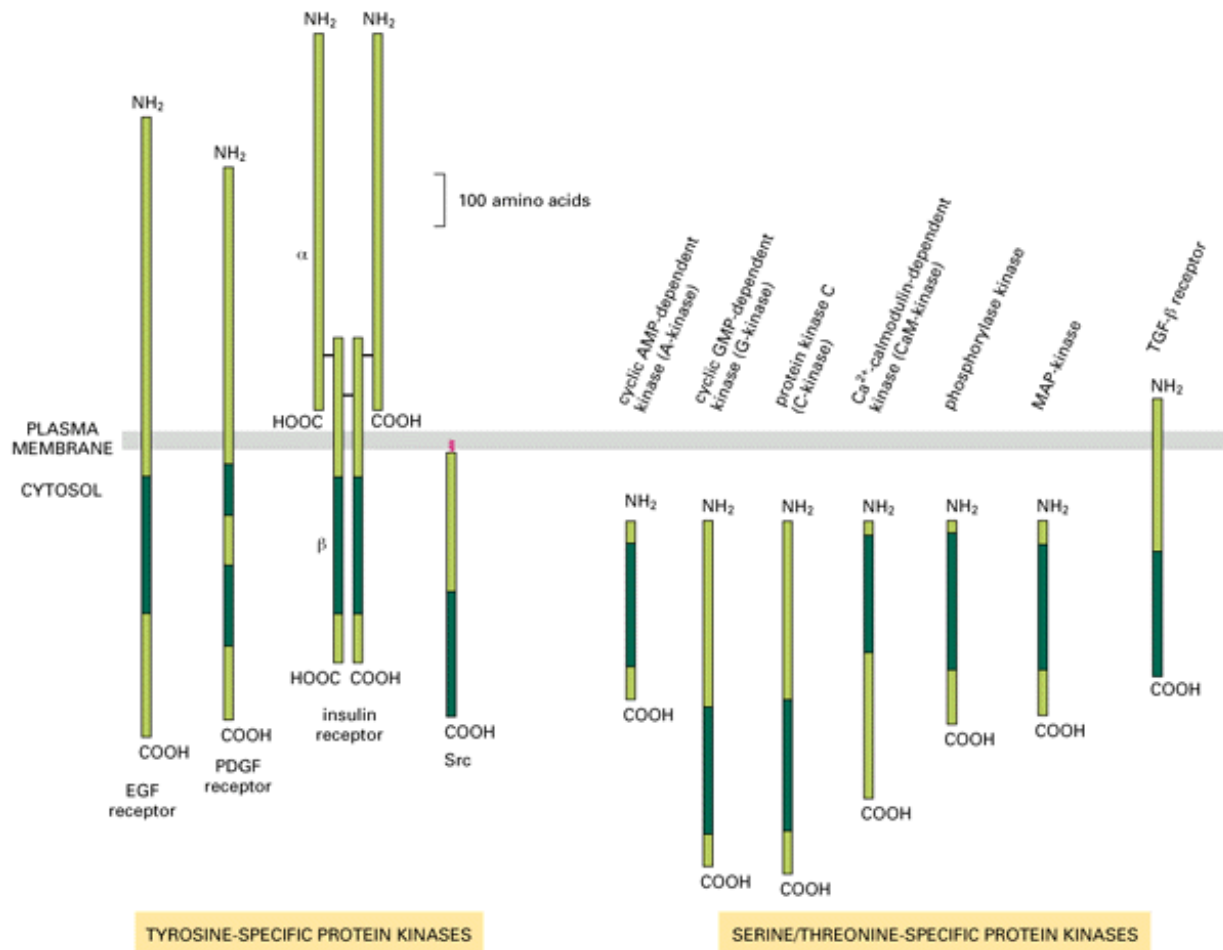
and the extracellular receptor domain produced by recombinant DNA technology. (From A.M. deVos, M. Ultech, and A.A. Kossiakoff, *Science* 255:306-312, 1992. © 1992 the AAAS.)
Figure 15-56. The ligand-induced assembly of an IL-2 receptor. The low-affinity binding of IL-2 to the a chain is thought to trigger the assembly of the heterotrimeric high-affinity receptor, which then binds and activates the Lck tyrosine kinase through an interaction with the cytoplasmic tail of the b subunit.


Figure 15-57. Some of the protein kinases discussed in this chapter. The size and location of their catalytic domains (*dark green*) are shown. In each case the catalytic domain is about 250 amino acid residues long. These domains are all similar in amino acid sequence, suggesting that they have all evolved from a common primordial kinase. Note that all of the tyrosine kinases shown are bound to the plasma membrane, whereas most of the serine/threonine kinases are in the cytosol.

Target-Cell Adaptation

Introduction

In responding to almost any type of stimulus, cells and organisms typically can detect the same percent change in a signal over a very wide range of stimulus intensities. At the cellular level this requires that target cells undergo a process of adaptation or desensitization, whereby, when they are exposed to a stimulus for a prolonged period, their response to it decreases. In this way a cell reversibly adjusts its sensitivity to the stimulus. In the case of chemical signaling, adaptation enables cells to respond to *changes* in the concentration of a signaling ligand (rather than to the absolute concentration of the ligand) over a very wide range of absolute concentrations. The general principle is simple: adaptation is achieved through a negative feedback that operates with a delay. The negative feedback means that a strong response modifies the machinery for making that response and so turns itself off; but thanks to the delay, a sudden change in the stimulus is able to make itself felt strongly for a short period before the negative feedback has time to act.

Adaptation to chemical signals can occur in various ways. In some cases it results from a gradual decrease in the number of specific cell-surface receptor proteins, which generally takes hours. In other cases it results from a rapid inactivation of such receptors, which can occur in minutes. In still other cases it is due to change in the proteins involved in transducing the signal following receptor activation, which usually occurs with an intermediate time course.

Slow Adaptation Depends on Receptor Down-Regulation 42

After a protein hormone or growth factor binds to its receptor on the surface of a target cell, it is usually ingested by receptor-mediated endocytosis and delivered to endosomes (discussed in Chapter 13). Most receptors discharge their ligand in the acidic environment of endosomes and recycle back to the plasma membrane for reuse, while the ligand is delivered to lysosomes and is degraded. This process, therefore, represents a major pathway for the breakdown of many signaling proteins. Although many receptor molecules are retrieved from the endosome and recycled, a proportion of them fail to release their ligand and end up in lysosomes, where they are degraded along with the ligand. Thus, with continuous exposure to high concentrations of ligand, the number of cell-surface receptors gradually decreases, with a concomitant decrease in the sensitivity of the target cell to the ligand. By this type of mechanism, known as receptor down-regulation, a cell can slowly (over hours) adjust its sensitivity to the concentration of a stimulating ligand.

Rapid Adaptation Often Involves Receptor Phosphorylation 43

Target-cell adaptation frequently involves a rapid ligand-induced phosphorylation of receptors, in addition to the slower down-regulation of the number of receptor molecules on the target cell. The best-understood example is the β_2-adrenergic receptor, which activates adenylyl cyclase via the stimulatory G protein G_s. When cells are exposed to a high concentration of adrenaline, they can desensitize within minutes by two pathways that depend on β_2-adrenergic receptor phosphorylation. In one, the rise in cyclic AMP caused by adrenaline binding activates A-kinase, which phosphorylates the β_2 receptor on a serine residue, thereby interfering with the receptor's ability to activate G_s. In the other, the activated β_2 receptor becomes a substrate for another, more specific protein kinase (called β-*adrenergic kinase*) that phosphorylates the carboxyl-terminal cytoplasmic tail of the activated receptor on multiple serine and threonine residues; this phosphorylated tail binds an inhibitory protein called β *arrestin,* which blocks the receptor's ability to activate G_s (Figure 15-58). In vertebrate photoreceptor cells, rhodopsin, which, as we have seen, is structurally related to β-adrenergic receptors, is inactivated by a closely similar arrestin-based mechanism after it has been activated by the switching on of light. These cells have exceptionally rapid and sophisticated powers of adaptation, involving several mechanisms in addition to that based on arrestin; one of these was discussed earlier, on page 754.

The A-kinase-dependent mechanism that desensitizes the β_2-adrenergic receptor operates whenever cyclic AMP levels rise in the cell. Hence, the activation of any type of receptor in the target cell that activates adenylyl cyclase can desensitize the β_2 receptor - an example of *heterologous desensitization,* where one ligand desensitizes target cells to another. The β-arrestin-dependent mechanism, by contrast, operates only when the β_2 receptor itself is activated by ligand binding - an example of *homologous desensitization,* where a ligand desensitizes target cells only to itself.

Some Forms of Adaptation Are Due to Downstream Changes [44]

Although most known mechanisms of adaptation involve changes in receptor proteins, adaptation can, in principle, result from a change in any of the components in the signaling pathway. There are several cases in which target-cell adaptation has been shown to involve a change in a trimeric G protein. This occurs, for example, in the response of yeast cells to mating pheromones.

Changes downstream from G proteins can also contribute to target-cell adaptation, as in the photoreceptor (see p. 754). In morphine addicts, for example, opiate-sensitive neurons in the brain become desensitized to morphine so that the addicts require much higher doses than normal individuals to relieve pain or to feel euphoric (Figure 15-59). The adapted cells, however, usually have normal levels of functional cell-surface morphine (opiate) receptors. The mechanism of adaptation has been studied both in rats and in morphine-sensitive neural cell lines in culture. Morphine receptors activate the inhibitory G protein G_i, which inhibits adenylyl cyclase and thereby causes a decrease in intracellular cyclic AMP levels. This in turn decreases the activity of A-kinase and thereby the phosphorylation of several types of ion channels, which decreases the electrical firing of the neurons. Cells maintained for a long time in the presence of a high concentration of morphine adapt by a compensatory increase in their expression of the A-kinase and adenylyl cyclase genes, with the net effect that both adenylyl cyclase activity and intracellular cyclic AMP levels return to normal even though morphine is still bound to cell-surface receptors. Because the adapted cells have increased levels of adenylyl cyclase and A-kinase, however, when morphine is withdrawn, there is a marked increase in adenylyl cyclase and A-kinase activity, which causes cyclic AMP concentrations to rise to abnormally high levels. This increases the firing of the neurons and gives rise to the extremely unpleasant withdrawal symptoms (anxiety, sweating, tremors, hallucinations, etc.) experienced by morphine addicts who go "cold turkey."

Adaptation Plays a Crucial Role in Bacterial Chemotaxis [45]

Many of the mechanisms involved in chemical signaling between cells in multi-cellular animals have evolved from mechanisms used by unicellular organisms to respond to chemical changes in their environment. In fact, some of the same intracellular mediators, such as cyclic nucleotides, are used by both types of organisms. Among the best-studied reactions of unicellular organisms to extracellular signals are chemotactic responses, in which cell movement is oriented toward or away from a source of some chemical in the environment. We conclude this section with an account of bacterial chemotaxis, which, largely through the power of genetic analysis, provides a particularly clear and elegant illustration of the crucial role of adaptation in the response to chemical signals. The chemotaxis of eucaryotic cells is discussed in Chapter 16.

Motile bacteria will swim toward higher concentrations of nutrients (*attractants*), such as sugars, amino acids, and small peptides, and away from higher concentrations of various noxious chemicals (*repellents*) (Figure 15-60). This relatively simple but highly adaptive chemotactic behavior has been most studied in *E. coli* and *Salmonella typhimurium.* We concentrate here chiefly on chemotaxis toward attractants; chemotaxis away from repellents depends on essentially the same mechanisms operating in reverse.

Bacteria swim by means of flagella that are completely different from the flagella of eucaryotic cells. The bacterial flagellum consists of a helical tube formed from a single type of protein subunit, called *flagellin.* Each flagellum is attached by a short flexible hook at its base to a small protein disc embedded in the bacterial membrane. Incredible though it may seem, this disc is part of a tiny "motor" that uses the energy stored in the transmembrane H^+ gradient to rotate rapidly and turn the helical flagellum (Figure 15-61).

Because the flagella on the bacterial surface have an intrinsic "handedness," different directions of rotation have different effects on movement. Counterclockwise rotation allows all the flagella to draw together into a coherent bundle so that the bacterium swims uniformly in one direction. Clockwise rotation causes them to fly apart, so that the bacterium tumbles chaotically without moving forward (Figure 15-62). In the absence of any environmental stimulus, the direction of rotation of the disc reverses every few seconds, producing a characteristic pattern of movement in which smooth swimming in a straight line is interrupted by abrupt, random changes in direction caused by tumbling (Figure 15-63A).

The normal swimming behavior of bacteria is modified by chemotactic attractants or repellents, which bind to specific receptor proteins and affect the frequency of tumbling by increasing or decreasing the time that elapses between successive changes in direction of flagellar rotation. When bacteria are swimming in a favorable direction (toward a higher concentration of an attractant or away from a higher concentration of a repellent), they tumble less frequently than when they are swimming in an unfavorable direction (or when no gradient is present). Since the periods of smooth swimming are longer when a bacterium is traveling in a favorable direction, it will gradually progress in that direction - toward an attractant (Figure 15-63B) or away

from a repellent.

In its natural environment a bacterium detects a spatial gradient of attractants or repellents in the medium by swimming at a constant velocity and comparing the concentration of chemicals over *time.* (It does not monitor changes in concentration by using a *spatial* separation of receptors over its length; this would be extremely difficult given the very small size of a bacterium.) Changes over time can be produced artificially in the laboratory by the sudden addition or removal of a chemical to the culture medium. When an attractant is added in this way, tumbling is suppressed within a few tenths of a second, as expected. But after some time, even in the continuing presence of the attractant, tumbling frequency returns to normal. The bacteria remain in this adapted state as long as there is no increase or decrease in the concentration of the attractant; addition of more attractant will briefly suppress tumbling, whereas removal of the attractant will briefly enhance tumbling until the bacteria again adapt to the new level. Adaptation is a crucial part of the chemotactic response in that it enables bacteria to respond to *changes* in concentration rather than to steady-state levels of an attractant and to respond to these changes over an astonishingly wide range of attractant concentrations (from less than 10^{-10} M to over 10^{-3} M for some attractants).

Bacterial Chemotaxis Is Mediated by a Family of Four Homologous Transmembrane Receptors and a Phosphorylation Relay System [46]

The unraveling of the molecular mechanisms responsible for bacterial chemotaxis has depended largely on the isolation and analysis of mutants with defective chemotactic behavior. In this way it has been shown that chemotaxis to a number of chemicals depends on a small family of closely related transmembrane receptor proteins that are responsible for transmitting chemotactic signals across the plasma membrane. These chemotaxis receptors are methylated during adaptation (see below) and so are also called *methyl-accepting chemotaxis proteins (MCPs).* As we shall see, receptor activity is stimulated by an increase in repellent concentration and decreased by an increase in attractant concentration: a single receptor is affected by both sorts of molecules, with opposite consequences.

There are four types of plasma membrane chemotaxis receptors, each concerned with the response to a small group of chemicals. Type 1 and 2 receptors mediate responses to serine and aspartate, respectively, by directly binding these amino acids and transducing the binding event into an intracellular signal. A model of the structure of one of these receptors is shown in Figure 15-64. Type 3 and 4 receptors mediate responses to sugars and dipeptides, respectively, in a slightly less direct fashion (Figure 15-65).

Genetic studies indicate that four cytoplasmic proteins - *CheA, CheW, CheY,* and *CheZ* - are involved in the intracellular signaling pathway that couples the chemotactic receptors to the flagellar motor. CheY acts at the effector end of the pathway to control the direction of flagellar rotation. When activated, it binds to the motor, causing it to rotate clockwise and thereby inducing tumbling; mutants that lack this protein swim constantly without tumbling. CheA is a histidine protein kinase. When bound to both an activated chemotactic receptor and CheW, it phosphorylates itself on a histidine residue and almost immediately transfers the phosphate to an aspartic acid residue on CheY. The phosphorylation of CheY activates the protein so that it binds to the flagellar motor and causes clockwise rotation and tumbling. CheZ rapidly inactivates phosphorylated CheY by stimulating its dephosphorylation (Figure 15-66).

The binding of a repellent to a chemotactic receptor increases the activity of the receptor, which in turn increases the activity of CheA and thereby the phosphorylation of CheY, which causes tumbling. These phosphorylations occur rapidly: the time required for the tumbling response after adding a repellent is about 200 milliseconds. The binding of an attractant has the opposite effect. It decreases the activity of the receptor, which decreases the activity of CheA, so that CheY remains dephosphorylated, the motor continues to rotate counterclockwise, and the bacterium swims smoothly.

The function of CheY in bacterial chemotaxis is analogous to the function of Ras proteins in animal cell signaling. Like Ras, CheY functions as an on/off switch: it is on when phosphorylated and off when dephosphorylated, just as Ras is on with GTP bound and off with GDP bound. CheY is activated by CheA and inactivated by CheZ, just as Ras is activated by GNRPs and inactivated by GAPs (see Figure 15-50). Indeed, the three-dimensional structures of CheY and Ras are similar.

Receptor Methylation Is Responsible for Adaptation in Bacterial Chemotaxis [46]

Adaptation in bacterial chemotaxis results from the covalent methylation of the chemotaxis receptor proteins. When methylation is blocked by mutation, adaptation is markedly inhibited, and exposure of the mutant bacteria to an attractant results in the

suppression of tumbling for days instead of for a minute or so. Binding of a chemoattractant to a chemotaxis receptor, therefore, has two separable consequences. (1) It rapidly decreases the activity of the receptor, thereby decreasing the activity of CheA and CheY and causing the flagellar motor to continue to rotate counterclockwise; this results in a suppression of tumbling. (2) It causes adaptation because, while the attractant is bound, the receptor is methylated by an enzyme in the cytoplasm, which increases the activity of the receptor over a period of a few minutes (Figure 15-67).

Receptor methylation is catalyzed by an enzyme (*methyl transferase*) that acts on the receptor protein. As many as eight methyl groups can be transferred to a single receptor, the extent of methylation increasing at higher concentrations of attractant (where each receptor spends a larger proportion of its time with ligand bound). When the attractant is removed, the receptor is demethylated by a demethylating enzyme (methylesterase). Although the level of methylation changes during a chemotactic response, it remains constant once a bacterium is adapted because a balance is reached between the rates of methylation and demethylation. The methylesterase that removes methyl groups from the chemotactic receptors is also regulated by CheA-mediated phosphorylation, and this provides another form of negative feedback regulation that makes a further contribution to adaptation.

A variety of other regulatory interactions and feedback loops are probably still to be discovered in bacterial chemotaxis. Nonetheless, all of the genes and proteins involved in this highly adaptive behavior may now have been identified, and in most cases the protein sequences are known and the proteins are available in large quantities. It therefore seems likely that bacterial chemotaxis will be the first cell-signaling system to be understood completely in molecular terms. But even when all the molecules and their interactions have been defined, it may be difficult to comprehend how the signaling system operates as an integrated network, as we discuss next.

Summary

By adapting to high concentrations of a signaling ligand in a time-dependent, reversible manner, cells can adjust their sensitivity to the level of a stimulus and thereby respond to changes in a ligand's concentration over an enormously large range rather than to the absolute concentration of the ligand. Adaptation occurs in various ways: (1) ligand binding can induce the internalization of receptors, some of which are then degraded in lysosomes - a process called receptor down-regulation; (2) activated receptors can be reversibly inactivated by being phosphorylated or methylated; (3) G proteins can be reversibly inactivated; and (4) proteins downstream of G proteins in the signaling pathway can be up-regulated or down-regulated. At a molecular level the best-understood example of adaptation occurs in bacterial chemotaxis, in which the reversible methylation of key signal-transducing proteins in the plasma membrane helps the cell to swim toward an optimal environment.
Figure 15-58. Two mechanisms for the rapid desensitization of the b_2 -adrenergic receptor. Both depend on receptor phosphorylation. Both the phosphorylation in (A) and the binding of arrestin in (B) inhibit the ability of the activated receptor to interact with G_s and therefore decrease the response to adrenaline.
morphine

Figure 15-59. The structure of morphine. Why do some of our cells have receptors for a drug that comes from poppy seeds? Pharmacologists long suspected that morphine may mimic some endogenous signaling molecule that regulates pain perception and mood. In 1975 two pentapeptides with morphinelike activity, called enkephalins, were isolated from pig brain, and soon thereafter larger polypeptides with similar activity, called endorphins, were isolated from the pituitary gland and other tissues. All of these so-called *endogenous opiates* contain a common sequence of four amino acids and bind to the same cell-surface receptors as morphine (and related narcotics). Unlike morphine, however, they are rapidly degraded after release and so do not accumulate in quantities large enough to induce the tolerance seen in morphine addicts.

(A) (B)
Figure 15-60. Bacterial chemotaxis. The photographs show *Salmonella typhimurium* bacteria being attracted to a small glass capillary tube containing the amino acid serine (A) and repelled from a capillary tube containing phenol (B). The pictures were taken 5 minutes after the capillary tubes had been introduced into the culture dishes containing the bacteria. This capillary tube assay is a simple method of demonstrating bacterial chemotaxis. (From B.A. Rubik and D.E. Koshland, *Proc. Natl. Acad. Sci. USA* 75:2820-2824, 1978.)
Figure 15-61. Schematic drawing of the bacterial flagellar motor. The flagellum is linked to a flexible hook. The hook is attached to a series of protein rings (shown in *red*), which are embedded in the outer and inner (plasma) membranes and rotate with the flagellum at about 150 revolutions per second. The rotation is thought to be driven by a flow of protons through an outer ring of proteins (the *stator*), which also contains the proteins responsible for switching the direction of rotation. (Based on data from T. Kubori et al., *J. Mol. Biol.* 226:433-446, 1992, and N.R. Francis et al., *Proc. Natl. Acad. Sci. USA* 89:6304-6308, 1992.)
Figure 15-62. Positions of the flagella on *E. coli* during swimming.. When the flagella rotate counterclockwise (A), they are drawn together into a single bundle, which acts as a propeller to produce smooth swimming. When the flagella rotate clockwise (B), they fly apart and produce tumbling.

(A)

(B)
Figure 15-63. The tracks of a swimming bacterium. In the absence of a chemotactic signal (A), periods of smooth swimming (runs) are interrupted by brief tumbles that randomly change the direction of swimming. Thus runs and tumbles occur in alternating sequence, each run constituting a step in a three-dimensional random walk. In the presence of a chemotactic attractant (B), tumbling is partially suppressed whenever the bacterium happens to be swimming toward a higher concentration of the attractant, so that it gradually moves in the direction of the attractant - a biased random walk.

Figure 15-64. A model of the homodimeric structure of the aspartate chemotaxis receptor protein. The three-dimensional structure of the extracellular domain has been obtained by x-ray diffraction. The intracellular coiled-coil domains are predicted from amino acid sequence analysis. They contain the methylation sites (shown as *black dots*), of which there are four on each of the two polypeptide chains (the sites on one of the chains are out of view). The binding of the ligand in the periplasmic space is thought to induce a conformational change in the receptor that is propagated through the membrane by a scissorlike movement of the whole molecule. (Based on M.V. Milburn et al., *Science* 254:1342-1347, 1991. ©1991 the AAAs; and J.B. Stock et al., *J. Biol. Chem.* 267:19753-19756, 1992, ASBMB publisher.)
Figure 15-65. The different types of chemotaxis receptors. Chemical attractants bind to type 1 or type 2 receptors in the plasma membrane or to binding proteins in the periplasmic space (between the inner and outer bacterial membranes) that then bind to type 3 or type 4 receptors. The binding of an attractant decreases the activity of the chemotaxis receptor, shutting off the intracellular signaling cascade and causing the flagellar motor to continue to rotate counterclockwise, thereby suppressing tumbling and causing continuous smooth swimming. The attractants diffuse into the periplasmic space from outside the cell through large channels in the outer membrane (not shown).
Figure 15-66. The phosphorylation relay system that enables the chemotaxis receptors to control the flagellar motor. The binding of a repellent increases the activity of the receptor, which binds CheW and CheA, thereby stimulating CheA to phosphorylate itself. CheA quickly transfers its covalently bound, high-energy phosphate directly to CheY to generate CheY-phosphate, which binds to the flagellar motor and causes it to rotate clockwise, resulting in tumbling. The binding of an attractant has the opposite effect. It decreases the activity of the receptor and therefore decreases the phosphorylation of CheA and CheY, which results in counterclockwise flagellar rotation and smooth swimming. CheZ accelerates the dephosphorylation of CheY-phosphate, thereby inactivating it. Each of the phosphorylated intermediates decays in about 10 seconds, enabling the bacterium to respond very quickly to changes in its environment (see Figure 15-10).
Figure 15-67. The sequential activation and adaptation (via methylation) of a chemotaxis receptor. Note that the activity of the receptor, and there-fore the tumbling frequency of the bacterium, is the same in the resting and adapted states. The receptor is shown with two methylation sites for simplicity; in fact, there are eight on each receptor. As the concentration of attractant increases, the fraction of time that the receptor is occupied by the attractant increases. A higher level of attractant will thereby initially cause a greater change in the conformation of the receptor than a low level, pushing the receptor more toward its fully inactivated state. An increase in methylation ensues, however, so that within minutes the conformational strain on the receptor is exactly reversed, and the activity of the receptor increases to its previous level. The receptor has now adapted.

The Logic of Intracellular Signaling: Lessons from Computer-based "Neural Networks"

Introduction

Each cell in a complex multicellular animal is bombarded with chemical signals that are made by other cells - signals that regulate its metabolism, signals that alter or maintain its differentiated state, signals that determine whether it should divide, and signals that dictate whether it will live or die. In general, these signals bind to cell-surface receptors that activate several intracellular signaling pathways, so that the intracellular signals generated from different receptors will interact with one another in complex ways.

How does a cell integrate all of this information so as to behave in a way that is optimal for the animal as a whole? The task of

understanding how a cell manages this feat seems overwhelming. Even in the relatively simple case of bacterial chemotaxis, where there are relatively few components, all of which are probably known, the complexities of the interactions are still too great to be easily visualized and completely understood at present. We still cannot reliably predict, for example, the behavior of a mutant bacterium in which the level of a membrane receptor or a cytoplasmic signaling protein has been altered, especially if the chemotactic stimulus includes more than one attractant or repellent or if the stimulus changes rapidly with time. How then can we hope to understand the much more complex networks of intracellular signaling pathways in animal cells, where hundreds of components, many still undiscovered, are involved?

As more quantitative data become available it is likely that computer-based simulations will play an increasingly important role in our attempts to understand how these signaling pathways operate. By modeling the pathways on a computer, one can display and manipulate the network of interacting components in ways that are not possible in cells.

Computer-based analysis is useful in another way - one that does not depend on detailed quantitative knowledge of the reactions involved. The intracellular signaling pathways, seen as a whole, form a highly interconnected network in which signals are processed along multiple parallel routes that interact with one another. One can therefore learn about the behavior of signaling networks by comparing them to other highly interconnected networks. Computer-based networks, often called neural networks, were originally developed to understand how nerve cells relay and process information in the brain, but they have properties that are also relevant to intracellular signaling.

Computer-based Neural Networks Can Be Trained [47]

One of the simplest types of computer-based neural networks is composed of three layers of interconnected *units* - an *input layer,* a *hidden layer,* and an *output layer.* Each of the many units in the network acts as a model nerve cell (neuron), with its individual output controlled by multiple inputs. The connections between units are analogous to synapses and have modifiable *connection weights* that control the strength with which one unit influences another. The activity of the network as a whole depends on the values of these connection weights as well as on the mathematical rules by which each unit sums its inputs to generate an output. A pattern of inputs received by the input units is transformed according to these weights and rules into a different pattern of activity in the output units via connections through the hidden units (Figure 19-68).

The most remarkable and useful feature of computer-based neural networks is that they can be *trained* to recognize specific patterns of inputs and respond to each pattern with a specific pattern of output activity. The training is achieved by presenting the network with training examples in the form of a series of inputs together with the desired pattern of outputs. The input, for example, might be a series of letters presented in any orientation on a screen and the desired output simply the correct identification of each letter. Or the input could be the amino acid sequences of a number of polypeptide chains and the output the types of secondary structures that the polypeptide chains form. Whatever the task, as each training example is presented, the output of the network is compared to the desired output and an "error" score is assigned based on how closely the actual and desired outputs match. After processing all examples in the training set, an overall performance measure is calculated that characterizes how well the network performed on the entire training set.

The goal of training is to change the weights in the network so that its performance will improve on subsequent presentations of the training set. A number of training algorithms have been devised for making these weight changes. One of the conceptually simplest methods, and perhaps the most relevant to cell signaling (as discussed below), is one in which the weights are changed randomly and those changes that result in an improved performance are preferentially maintained. Whatever algorithm is used, the training process is repeated over and over until the actual output of the network is close to the desired one. The final weights in the network are not predetermined by the training algorithm but instead emerge autonomously as a result of repeated presentation of the training examples. Once the network has "learned" the desired task, it can often recognize and give the correct output for novel input patterns that were not part of the original training set. The Logic of Intracellular Signaling: Lessons from Computer-based "Neural Networks"

Cell Signaling Networks Can Be Viewed as Neural Networks Trained by Evolution [48]

Although neural networks were originally used to model systems of interconnected neurons, there is no reason why the units in such a network have to represent neurons. They could be enzymes or other types of intracellular signaling molecules, for example. Consider the protein kinases involved in cell signaling. These enzymes receive inputs (in the form of phosphorylations or simple protein binding) from components of a number of intracellular signaling pathways, and these inputs collectively regulate the catalytic activity of the kinase. Each kinase in turn has an output (the phosphorylation of other proteins) that

regulates the activity of specific target proteins, which can be either downstream components in the same signaling pathway or components of a parallel signaling pathway. In terms of a network, the kinases in this example function just as neurons do: they integrate various inputs and respond with an appropriate output.

In principle, at least, a highly interconnected network of intracellular signaling reactions could be trained to recognize certain input patterns of signals and to respond with specific output patterns in a way similar to that just described for a computer-based neural network. In this scheme the training would occur during evolution, by mutation and natural selection, with random mutations in the genes that encode signaling proteins serving the same function as random changes in connection weights made on a computer. A mutation that changed the activity of a signaling protein kinase, for example, might increase the weight of one or more connections in the network, while a change in the binding specificity of an SH adaptor protein could add new connections. Mutations that improved the performance of a signaling network, by enabling it, for example, to recognize a new combination of growth factors or to discriminate between two extracellular signals that were previously indistinguishable to a cell, could give the organism a selective advantage and hence be retained for further improvement. In this way an increasingly complex network of signaling reactions would evolve.

Signaling Networks Enable Cells to Respond to Complex Patterns of Extracellular Signals [47], [49]

When trained neural networks are analyzed to see how they recognize complex patterns of inputs, it is found that individual units in the hidden layer (see Figure 15-68) have become strongly connected to meaningful sets of units in the input layer, so that the hidden units come to represent signification features of the input pattern applied to the network. In a network trained to recognize letters presented in any orientation on a screen, for example, specific hidden units might come to recognize curved lines or pairs of lines at right angles, while in a network trained to pronounce written words, specific hidden units might come to represent vowel sounds or consonants.

In a similar way specific intracellular signaling molecules in a cell might come to recognize a particular combination of extracellular signals and help to translate this combination of signals into a particular cellular response. Consider the hypothetical network shown in Figure 15-69, which almost certainly is far simpler than any signaling network found in a cell. It consists of six types of cell-surface receptors that are functionally coupled to three cytosolic protein kinases. Receptors I, II, and III each recognize distinct components of the extracellular matrix, while receptors A, B, and C each recognize distinct growth factors. Kinase 3 lies downstream of kinases 1 and 2 and serves as the output of the network, perhaps stimulating the cell to proliferate by phosphorylating a set of gene regulatory proteins. Because of the different strengths of the connections in the network, some of which are excitatory and some of which are inhibitory, each of the three kinases will be optimally stimulated by different combinations of extracellular signals. Kinase 1 is most active when the cell encounters matrix components I and II in the absence of III, while kinase 2 is most active when the cell encounters growth factors A, B, and C in the absence of the matrix component III. For kinase 3 the requirements for optimal activity are more complex, as it senses the extracellular environment only through kinases 1 and 2. It will be maximally active and stimulate the cell to proliferate when kinases 1 and 2 are simultaneously active - that is, when the cell encounters growth factors A, B, and C and matrix molecules I and II in the absence of III, which is a surprisingly complex pattern considering the simplicity of the network. According to this view, kinase 3 has "learned" through evolution to associate this particular combination of extracellular stimuli with the need of the cell to proliferate. In the same way some of the important signaling molecules in a real cell will have come to recognize and respond to relevant combinations of features in the cell's environment.

Signaling Networks Are Robust

An important consequence of the highly interconnected architecture of a neural network is that once it has been trained to perform a task, its performance is not easily destroyed by modifying or removing individual units of the network. If a specific unit responds optimally when it receives inputs from six other units, it will also respond, although less well, to a subset of five of these inputs. If random changes in the strengths of connections are introduced into a neural network that has been trained to recognize letters, for example, the ability to do this task is not abolished but only somewhat degraded.

In a similar way a cellular response that depends on highly interconnected intracellular signaling pathways will not be easily disrupted by removing or changing a single signaling element in one of these pathways. We should not be too surprised, therefore, to find that a eucaryotic cell can function nearly normally when a protein kinase is inactivated by mutation, even though that protein kinase has been highly conserved during evolution. This stability of signaling networks is probably important to perfectly normal cells, as cells do not contain precisely determined numbers of intracellular proteins; moreover, the concentrations of important metabolites can fluctuate with the metabolic state of the cell. The extensive cross-talk between

signaling pathways in animal cells may have evolved, in part, to allow the pathways to function normally in the face of such fluctuations.

The neural-network-like properties of highly interconnected systems of proteins can help us to understand other aspects of cell biology besides cell signaling. The same considerations apply to the complex networks of interacting proteins that form the cell's cytoskeleton, for example, which is the subject of the next chapter.

Summary

Computer modeling can help to illuminate the complex behaviors of the interacting signaling cascades that are found in cells. In particular, computer-based neural networks have a number of properties that are likely to be shared by intracellular signaling networks. Just as neural networks can be trained to respond appropriately to specific patterns of inputs, so these signaling networks, by a Darwinian process of random change and selection, may have evolved the capacity to respond appropriately to complex combinations of extracellular signals. The highly interactive architecture of neural networks is mimicked by the networks of intracellular signaling proteins. Both networks can in principle function as pattern-recognition devices, which respond optimally to selected combinations of input stimuli. Networks of this kind are also relatively resistant to noise fluctuations or to damage, and eliminating one component does not totally disable the network.
Figure 15-68. A simple neural network. The activity of each neural unit (shown as a circle) is determined by the unit's inputs. The output of each unit is usually a nonlinear function of the unit's inputs. Each connection between units has a particular strength, or "weight," which is indicated by differences in thickness of the connecting arrows.
Figure 15-69. A simple hypothetical signaling network. The network consists of six receptors and three cytosolic protein kinases. Each receptor activates (*green arrows*) or inhibits (*black lines*) kinase 1 or 2 or both by an unspecified mechanism. Because signals converge onto kinase 3 (the output kinase), this network will be maximally active only when specific combinations of extracellular stimuli are present. Although this network is far simpler than any likely to be found in a living cell, it could form part of a more complex signaling pathway.

16. The Cytoskeleton

➡ ➡

Introduction

The ability of eucaryotic cells to adopt a variety of shapes and to carry out coordinated and directed movements depends on a complex network of protein filaments that extends throughout the cytoplasm (Figure16-1). This network is called the cytoskeleton, although, unlike a skeleton made of bone, it is a highly dynamic structure that reorganizes continuously as the cell changes shape, divides, and responds to its environment. In fact, the cytoskeleton might equally well be called the "cytomusculature" because it is directly responsible for such movements as the crawling of cells on a substratum, muscle contraction, and the many changes in shape of a developing vertebrate embryo; it also provides the machinery for intracellular movements, such as the transport of organelles from one place to another in the cytoplasm and the segregation of chromosomes at mitosis. The cytoskeleton is apparently absent from bacteria, and it may have been a crucial factor in the evolution of eucaryotic cells.

The diverse activities of the cytoskeleton depend on three types of protein filaments *actin filaments, microtubules,* and *intermediate filaments.* Each type of filament is formed from a different protein subunit: actin for actin filaments, tubulin for microtubules, and a family of related fibrous proteins, such as vimentin or lamin, for intermediate filaments. Actin and tubulin have been especially highly conserved throughout the evolution of eucaryotes; their protein filaments bind a large variety of accessory proteins, which enable the same filament to participate in distinct functions in different regions of a cell. Some of these accessory proteins link filaments to one another or to other cell components, such as the plasma membrane. Others control where and when actin filaments and microtubules are assembled in the cell by regulating the rate and extent of their polymerization. Yet others are motor proteins, which hydrolyze ATP to produce force and directed movement along the filament.

We begin this chapter by introducing the three main types of cytoskeletal filaments and by illustrating some of the general principles by which they function. After this overview we consider each type of filament in turn: first, inter-mediate filaments, whose ropelike structure seems to have the relatively simple function of providing cells with mechanical strength; second, microtubules, which are thought to be the primary organizers of the cytoskeleton; finally, actin filaments, which are essential for many movements of the cell, especially those of its surface.

The Nature of the Cytoskeleton

Introduction

A eucaryotic cell contains a billion or so protein molecules, which constitute about 60% of its dry mass. There are thought to be about 10,000 different types of protein in an individual vertebrate cell, and most of them are highly organized spatially. This organization is present at multiple levels. In all cells proteins are arranged into functional complexes, most consisting of perhaps 5 to 10 proteins but others as large or larger than ribosomes. A further level of organization involves the confinement of functionally related proteins within the same membrane or aqueous compartment of a membrane-bounded organelle, such as the nucleus, mitochondria, or Golgi apparatus. An even higher level of organization is created and maintained by the cytoskeleton. It enables the living cell, like a city, to have many specialized services concentrated in different areas but extensively interconnected by paths of communication. In this section we review some of the basic strategies that enable the cytoskeleton to control the spatial location of protein complexes and organelles, as well as to provide communication paths between them.

The Cytoplasm of a Eucaryotic Cell Is Spatially Organized by Actin Filaments, Microtubules, and Intermediate Filaments [1]

How can a eucaryotic cell, with a diameter of 10 mm or more, be spatially organized by cytoskeletal protein molecules that are typically 2000 times smaller in linear dimensions? The answer lies in *polymerization.*For each of the three major types of cytoskeletal protein, thousands of identical protein molecules assemble into linear filaments that can be long enough, if necessary, to stretch from one side of the cell to the other. Such filaments connect protein complexes and organelles in different regions of the cell and serve as tracks for transport between them. In addition, they provide mechanical support, which is especially important for animal cells, since they do not have rigid external walls. The cytoskeleton forms an internal framework for the large volume of cytoplasm, supporting it like a framework of girders supporting a building.

It is easy to see how filaments arose in evolution: any protein with an appropriately oriented pair of complementary self-binding sites on its surface can form a long helical filament (see p. 124). Each of the three principal types of protein filaments that make up the cytoskeleton is a helical polymer that has a different arrangement in the cell and a distinct function (Figure16-2). By themselves, however, the three types of filaments could provide neither shape nor strength to the cell. Their functions depend on a large retine of accessory proteins that link the filaments to one another and to other cell components. Accessory proteins are also essential for the controlled assembly of the protein filaments in particular locations, and they provide the motors that either move organelles along the filaments or move the filaments themselves.

Dynamic Microtubules Emanate from the Centrosome 2

Microtubules are polar structures: one end (the *plus end*) is capable of rapid growth, while the other end (the *minus end*) tends to lose subunits if not stabilized. In most cells, the minus ends of microtubules are stabilized by embedding them in a structure called the centrosome, and the rapidly growing ends are then free to add tubulin molecules (Figure 16-3). The centrosome generally lies next to the nucleus, near the center of the cell.

At any one time, several hundred microtubules are growing outward from a centrosome, with some extending for many microns, so that their plus end is at the edge of the cell. Each of these microtubules is a highly dynamic structure that can shorten as well as lengthen: after growing outward for many minutes by adding subunits, its plus end may undergo a sudden transition that causes it to lose subunits, so that the microtubule shrinks rapidly inward and may disappear. The microtubule network that emanates starlike from the centrosome is constantly sending out new microtubules to replace the old ones that have depolymerized (Figure 16-4).

The Microtubule Network Can Find the Center of the Cell 3

What determines how the cytoplasmic array of microtubules is normally positioned in a cell? Important clues have been provided by experiments on cultured pigment cells isolated from fish scales: large flat cells containing many pigment granules. The granules, which can be dark brown, yellow, red, or iridescent, depending on the species of fish, are attached to microtubules and can either aggregate in the center of the cell or disperse throughout the cytoplasm. The movement of the pigment granules occurs along the microtubules and can be controlled by the fish to change its skin color. In a cultured pigment cell, the movement can be conveniently controlled by applying hormones or other reagents that change the concentration of cyclic AMP in the cytosol: raising cyclic AMP causes the granules to disperse, whereas lowering it causes the granules to aggregate. The pigment granules therefore provide a useful marker for the arrangement of microtubules in the cell (Figure 16-5).

If one part of a fish pigment cell is cut off with a needle, the cell fragment can survive for long periods even though it lacks a nucleus. The same operation, performed when the pigment granules are dispersed, causes some granules to be trapped in the cell fragment. If the pigment granules in the fragment are induced to aggregate by hormonal treatment immediately after the surgery, they move toward the site of the cut. But if they are induced to aggregate 4 hours after the surgery, they do not move to the cut site but instead move to the exact center of the cell fragment. Further investigation shows that this change results from a major rearrangement of the microtubules within the fragment, so that their minus ends are now at the center of the fragment, just as they were at the center of the intact cell. In effect, the isolated cell fragment has become a minicell with respect to its microtubule organization, the microtubules having reorganized around a new microtubule organizing center (Figure 16-6).

This simple experiment suggests that the cytoplasmic array of microtubules emanating from the centrosome can act as a surveying device that is able to find the center of the cell. This is a useful starting point if the array is to be able to organize the cell interior. But it is only a starting point; as we see later in this introductory section, a cell can position the array by specifically moving its centrosome to a location displaced from the cell center.

Motor Proteins Use the Microtubule Network as a Scaffold to Position Membrane-bounded Organelles 4

As we have just seen in the case of fish pigment cells, cytoskeletal filaments serve not only as structural supports but also as lines of transport. If a living vertebrate cell is observed in a light microscope, its cytoplasm is seen to be in continual motion. Over the course of minutes, mitochondria and smaller membrane-bounded organelles change their positions by periodic *saltatory movements,* which are much more sustained and directional than the continual small Brownian movements caused by random thermal motions. These and other intracellular movements in eucaryotic cells are generated by motor proteins, which bind to either an actin filament or a microtubule and use the energy derived from repeated cycles of ATP hydrolysis to move steadily along it (see p. 208). Dozens of different motor proteins have now been identified. They differ in the type of filament they bind to, the direction in which they move along the filament, and the "cargo" they carry.

The first motor protein to be discovered was *myosin,* a protein that moves along actin filaments and is especially abundant in skeletal muscle, where it forms a major part of the contractile apparatus. Other types of myosins were subsequently found in nonmuscle cells. All myosins have similar motor domains (the part of the protein that generates movement), but they differ markedly in the domains that are responsible for attaching the myosin molecule to other components of the cell.

The motor proteins that move along microtubules are distinct from the myosins and belong to one of two families: the *kinesins,*

which generally move toward the plus end of a microtubule (away from the centrosome), and the *dyneins,* which move toward the minus end (toward the centrosome). As with the myosins, each type of microtubule-dependent motor protein carries a distinct cargo with it as it moves (Figure 16-7).

Microtubule-dependent motor proteins play an important part in positioning membrane-bounded organelles within a eucaryotic cell. The membrane tubules of the endoplasmic reticulum (ER), for example, align with microtubules and extend almost to the edge of the cell, whereas the Golgi apparatus is located near the centrosome. When cells are treated with a drug that depolymerizes microtubules, both of these organelles change their location: the ER collapses to the center of the cell, while the Golgi apparatus fragments into small vesicles that disperse throughout the cytoplasm. When the drug is removed, the organelles return to their original positions, dragged by motor proteins moving along the re-formed microtubules. Thus the normal position of each of these organelles is thought to be determined by a receptor protein on the cytosolic surface of its membrane that binds a specific microtubule-dependent motor - a kinesin for the ER and a dynein for the Golgi apparatus (Figure16-8).

The Actin Cortex Can Generate and Maintain Cell Polarity 5

In general, microtubules in the cytoplasm function as individuals, whereas actin filaments work in networks or bundles. Actin filaments lying just beneath the plasma membrane, for example, are cross-linked into a network by various actin-binding proteins to form the cell cortex. As we discuss later, the network is highly dynamic and functions with various myosins to control cell-surface movements. The location and orientation of the cortical actin filaments are controlled by nucleation sites in the plasma membrane, and different regions of the membrane direct the formation of distinct actin-filament-based structures.

Localized extracellular signals that impinge on a portion of the cell surface can induce a local restructuring of the actin cortex beneath the corresponding part of the plasma membrane. In a reciprocal way the organization of the actin cortex can have a major influence on the behavior of the overlying plasma membrane. Mechanisms based on cortical actin filaments, for example, can push the plasma membrane outward to form long, thin *microspikes* or sheetlike *lamellipodia,* or they can pull the plasma membrane inward to divide the cell in two (Figure 16-9).

In extreme cases the actin cortex can integrate movements of an animal cell over its entire surface and maintain cell polarity independently of the microtubule array. This is illustrated by experiments on a nonpigmented type of cell isolated from fish scales. These epidermal cells, known as *keratocytes,* migrate unusually rapidly in culture, traveling at speeds of 30 μm/minute or more. Immunostaining with antibodies indicates that intermediate filaments and microtubules are present only in the trailing region around the cell nucleus, whereas the flattened leading edge of the cells is rich in actin filaments (Figure16-10). Furthermore, cells that are treated with a drug that depolymerizes microtubules migrate just as rapidly as untreated cells, whereas the migration is immediately halted by agents that interfere with actin filaments. Evidently, actin filaments (acting with other proteins) are able to move a keratocyte over a surface and also maintain this cell's distinctive shape and polarity; the details of the mechanism involved, however, are unclear.

Actin Filaments and Microtubules Usually Act Together to Polarize the Cell 6

In a living cell the three major types of cytoskeletal filaments are connected to one another and their functions are coordinated. The distribution of intermediate filaments in an epithelial cell in culture, for example, is radically altered if the microtubules are depolymerized by drug treatment: the intermediate filaments, which are normally arrayed throughout the cytoplasm, pull back to a region close to the nucleus. There are also many situations in which microtubules and actin filaments act in a coordinated way to polarize the whole cell. We discuss just one example: the killing of specific target cells by cytotoxic T lymphocytes.

Cytotoxic T cells kill other cells that carry foreign antigens on their surface. This is an important part of a vertebrate's immune response to infection, as discussed in Chapter 23. When receptors on the surface of the T cell recognize antigen on the surface of a target cell, the receptors signal to the underlying cortex of the T cell, altering the cytoskeleton in several ways. First, proteins associated with actin filaments in the T cell reorganize under the zone of contact between the two cells. The centrosome then reorients, moving with its microtubules to the zone of T-cell-target contact (Figure 16-11A). The microtubules, in turn, position the Golgi apparatus right under the contact zone, focusing the killing machinery - which is associated with secretion from the Golgi - on the target cell.

In this example, as in many others, a cell becomes polarized in the following general way. First, the plasma membrane senses some difference on one side of the cell that generates a transmembrane signal. The actin cortex is then reorganized in a local

area beneath the affected membrane, which in turn moves the centrosome to that part of the cell, presumably by pulling on its microtubules. The centrosome in turn positions the internal membrane systems in a polarized way. The net result is a cell with a strong directional focus (Figure 16-11B).

The Functions of the Cytoskeleton Are Difficult to Study

Although the main subunits of the three classes of cytoskeletal polymers, as well as many of the hundreds of accessory proteins that associate with them, have been isolated and their amino acid sequences determined, it has been frustratingly difficult to establish how these proteins function in the cell. Besides the complexity that stems from the large number of proteins involved, two general features make the cytoskeleton especially difficult to understand. First, the function of the cytoskeleton depends on complex assemblies of proteins, which bind in cooperative groups to the cytoskeletal filaments. It is relatively straightforward to examine the effect on a filament of a single accessory protein but very much more difficult to analyze the effects of a mixture of many different proteins. This problem is not unique to the cytoskeleton, but it is especially acute here. Secondly, the functions of the cytoskeleton are much more difficult to analyze than the functions of many other large protein complexes. The processes of RNA and DNA synthesis, for example, which involve the formation of new polymers held together by covalent bonds, can be readily analyzed *in vitro,* in part because the products of the *in vitro* reactions can easily be measured and compared with the corresponding products made in a cell. The cytoskeleton, in contrast, exerts forces and generates movements without any major chemical change. This makes it especially difficult to assay the function of a cytoskeletal system that has been reconstituted *in vitro* from purified components.

Summary

The cytoplasm of eucaryotic cells is spatially organized by a network of protein filaments known as the cytoskeleton. This network contains three principal types of filaments: microtubules, actin filaments, and intermediate filaments. Microtubules are stiff structures that usually have one end anchored in the centrosome and the other free in the cytoplasm. In many cells microtubules are highly dynamic structures that alternately grow and shrink by the addition and loss of tubulin subunits. Motor proteins move in one direction or the other along microtubules, carrying specific membrane-bounded organelles to desired locations in the cell. Actin filaments are also dynamic structures, but they normally exist in bundles or networks rather than as single filaments. A layer called the cortex is formed just beneath the plasma membrane from actin filaments and a variety of actin-binding proteins. This actin-rich layer controls the shape and surface movements of most animal cells. Intermediate filaments are relatively tough, ropelike structures that provide mechanical stability to cells and tissues. The three types of filaments are connected to one another, and their functions are coordinated.

ACTIN FILAMENTS
25 nm
25 mm

Actin filaments (also known as *microfilaments*) are two-stranded helical polymers of the protein actin. They appear as flexible structures, with a diameter of 5-9 nm, that are organized into a variety of linear bundles, two-dimensional networks, and three-dimensional gels. Although actin filaments are dispersed throughout the cell, they are most highly concentrated in the *cortex*, just beneath the plasma membrane.

MICROTUBULES
25 nm

25 mm

Microtubules are long, hollow cylinders made of the protein tubulin. With an outer diameter of 25 nm, they are much more rigid than actin filaments. Microtubules are long and straight and typically have one end attached to a single microtubule-organizing center (MTOC) called a *centrosome*, as shown here.

INTERMEDIATE FILAMENTS
25 nm

25 mm

Intermediate filaments are ropelike fibers with a diameter of around 10 nm; they are made of intermediate filament proteins, which constitute a large and heterogeneous family. One type of intermediate filament forms a meshwork called the nuclear lamina just beneath the inner nuclear membrane. Other types extend across the cytoplasm, giving cells mechanical strength and carrying the mechanical stresses in an epithelial tissue by spanning the cytoplasm from one cell-cell junction to another.

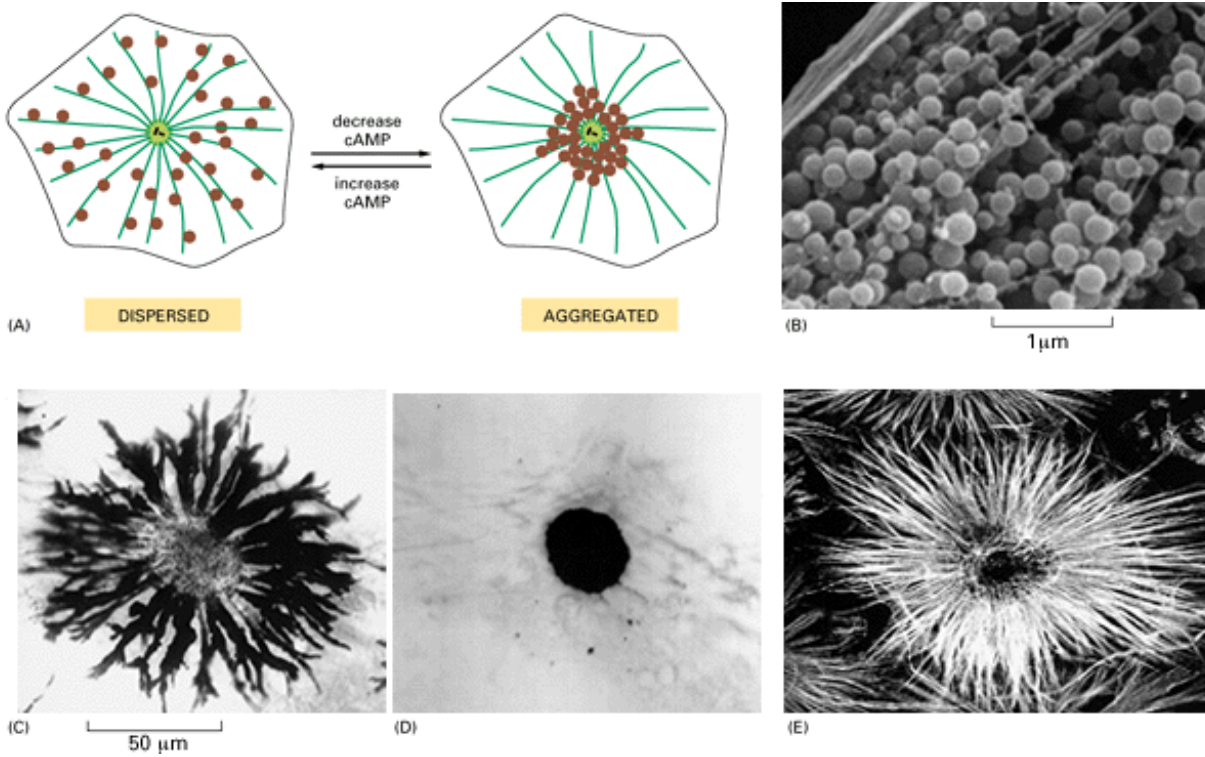
Figure 16-2. The three types of protein filaments that form the cytoskeleton. Each type of filament is shown in an electron micrograph and as a schematic diagram showing how it is built from subunits. The distribution of each filament in one type of epithelial cell is also shown schematically. The colors used here for each type of filament are used in this way throughout the chapter. (Micrographs of actin filaments, microtubules, and intermediate filaments courtesy of Roger Craig, Richard Wade, and Roy Quinlan, respectively.)
Figure 16-3. A centrosome with attached microtubules. As indicated, the slow-growing minus end of each microtubule is embedded in the *centrosome* matrix (*light green*) that surrounds a pair of structures called *centrioles.* By nucleating the growth of new microtubules, this matrix helps to determine the number of microtubules in a cell.
Figure 16-4. Growth and shrinkage in a microtubule array. The array of microtubules anchored in a centrosome is continually changing, as new microtubules grow (*red arrows*) and old microtubules shrink (*blue arrows*).


Figure 16-5. Fish pigment cells. These giant cells, which are responsible for changes in skin coloration in several species of fish, contain large pigment granules (*brown*), which can change their location in the cell in response to a neuronal or hormonal stimulus. (A) Schematic view of a pigment cell, showing the dispersal and aggregation of pigment granules, which occur along microtubules. (B) Scanning electron micrograph of a pigment cell following a brief exposure to detergent. The plasma membrane and soluble contents of the cytoplasm have been removed, exposing the array of microtubules and associated pigment granules. (C and D) Bright-field images of the same cell in a scale of an African cichlid fish, showing its pigment granules either dispersed throughout the cytoplasm or aggregated in the center of the cell. (E) An immunofluorescence picture of another cell from the same fish stained with antibodies to tubulin, showing large bundles of parallel microtubules extending from the centrosome to the periphery of the cell. (B, from M.A. McNiven and K.R. Porter, *J. Cell Biol.* 103:1547-1555, 1986, by copyright permission of the Rockefeller University Press; C, D, and E, courtesy of Leah Haimo.)

Intermediate Filaments 7

Introduction

Intermediate filaments are tough and durable protein fibers found in the cytoplasm of most, but not all, animal cells. They are called "intermediate" because in electron micrographs their apparent diameter (8-10 nm) is between that of the thin actin filaments and the thick myosin filaments of muscle cells, where they were first described (they are also intermediate in diameter between actin filaments and microtubules). In most animal cells an extensive network of intermediate filaments surrounds the nucleus and extends out to the cell periphery, where they interact with the plasma membrane (Figure16-12). In addition, a tightly woven basketwork of intermediate filaments - the *nuclear lamina* - underlies the nuclear envelope.

Intermediate filaments are particularly prominent in the cytoplasm of cells that are subject to mechanical stress. They are present in large numbers, for example, in epithelia, where they are linked from cell to cell at specialized junctions, along the length of nerve cell axons, and in all kinds of muscle cells. When cells are treated with concentrated salt solutions and nonionic detergents, the intermediate filaments remain behind while most of the rest of the cytoskeleton is lost. In fact, the term "cytoskeleton" was originally coined to describe this unusually stable and insoluble fiber system.

Intermediate Filaments Are Polymers of Fibrous Proteins 8

Unlike actin and tubulin, which are globular proteins, the many types of intermediate filament protein monomers are all highly elongated fibrous molecules that have an amino-terminal *head,* a carboxyl-terminal *tail,* and a central *rod domain*(Figure16-13). The central rod domain consists of an extended α-helical region containing long tandem repeats of a distinctive amino acid sequence motif called the *heptad repeat.*As discussed in Chapter 3, this seven amino acid motif promotes the formation of coiled-coil dimers between two parallel α helices (see Figure 3-48). Long stretches of heptad repeats are also found in many other elongated cytoskeletal proteins with coiled-coil dimeric structures, including tropomyosin and the tail of myosin, which we discuss later.

In the next stage of assembly, two of the coiled-coil dimers associate in an antiparallel manner to form a tetrameric subunit (Figure16-14). Soluble tetramers are found in small amounts in cells, suggesting that they are the fundamental subunit from which intermediate filaments assemble. The antiparallel arrangement of dimers implies that the tetramer, and hence the intermediate filament that it forms, is a nonpolarized structure - that is, it is the same at both ends and symmetrical along its length. This distinguishes intermediate filaments from microtubules and actin filaments, which are polarized and whose functions depend on this polarity. The final stages of intermediate filament assembly are less well characterized, but it seems

that tetramers add to an elongating intermediate filament in a simple binding reaction in which they align along the axis of the filament and pack together in a helical pattern (see Figure16-14).

The central rod domain, which is structurally similar in all intermediate filament proteins, mediates the lateral interactions that form the assembled filament. The globular head and tail domains, by contrast, can vary greatly in both size and amino acid sequence without affecting the basic axial structure of the filament; they often project from the surface of the filament and mediate its interactions with other components. This structural design means that intermediate filaments can be made from proteins of a surprisingly wide range of sizes (from about 40,000 to about 200,000 daltons).

In most cells, almost all intermediate filament protein molecules are in the fully polymerized state, with very little free tetramer. Nonetheless, a cell can regulate the assembly of its intermediate filaments and determine their number, length, and position. One mechanism of control involves the phosphorylation of specific serine residues in the amino-terminal head domain of intermediate filament proteins. In the most dramatic example, phosphorylation of the protein subunits that form the nuclear lamina causes them to disassemble completely at mitosis; when mitosis finishes, the specific serines are dephosphorylated and the nuclear lamina re-forms (see Figure12-18). Cytoplasmic intermediate filaments can also undergo a radical reorganization during mitosis, as well as in response to some extracellular signals. Although these changes are usually accompanied by an increase in subunit phosphorylation, other factors may also help mediate them.

Epithelial Cells Contain a Highly Diverse Family of Keratin Filaments [9]

The cytoplasmic intermediate filaments in vertebrate cells can be grouped into three classes: (1) *keratin filaments,* (2) *vimentin and vimentin-related filaments,* and (3) *neurofilaments,* each formed by polymerization of their corresponding subunit proteins (Table 16-1). By far the most diverse family of these subunits is the keratins (also called *cytokeratins*), which form keratin filaments, primarily in epithelial cells. There are over 20 distinct keratins in human epithelia. At least 8 more keratins, called *hard keratins,* are specific to hair and nails. (The keratins of epithelial cells, hair, and nails are sometimes referred to as α-*keratins* to distinguish them from the evolutionarily distinct β-keratins found in bird feathers, which have an entirely different structure and are not discussed in this chapter.)

Based on their amino acid sequence, the keratins can be subdivided into two types: the *type I (acidic) keratins* and the *type II (neutral/basic) keratins.* In reassembly experiments it is found that heterodimers of type I and type II keratins can form intermediate filaments but homodimers cannot, which explains why keratin filaments are always heteropolymers formed from equal numbers of type I and type II keratin polypeptides.

A single epithelial cell can make a variety of keratins, all of which copolymerize into a single keratin filament system. The simplest epithelia, such as those found in early embryos and in some adult tissues such as the liver, contain only a single type I and a single type II keratin. Epithelia in other locations, such as the tongue, bladder, and sweat glands, contain six or more keratins - the particular blend depending on the cell's location in the organ. The diversity is most pronounced in skin, where distinct sets of keratins are expressed by the cells in the different layers of the epidermis (see Figure22-19). There are also keratins characteristic of actively proliferating epithelial cells. This heterogeneity of keratins is clinically useful: in the diagnosis of epithelial cancers (*carcinomas*), the particular set of keratins expressed can be used to determine the epithelial tissue in which the tumor originated and thus help to decide the type of treatment that is likely to be most effective.

Many Nonepithelial Cells Contain Their Own Distinctive Cytoplasmic Intermediate Filaments [10]

Unlike keratins, *vimentin* and the *vimentin-related proteins* can form intermediate filaments that are polymers of a single protein species. *Vimentin* itself is the most widely distributed of the cytoplasmic intermediate filament proteins, being present in many cells of mesodermal origin, including fibroblasts, endothelial cells, and white blood cells; in addition, many cells express it transiently during development. *Desmin* is found mainly in muscle cells: it is distributed throughout the cytoplasm of smooth muscle cells, and it links together adjacent myofibrils (ordered bundles of filamentous actin and myosin, discussed later) in skeletal and heart muscle cells. *Glial fibrillary acidic protein* forms *glial filaments* in astrocytes in the central nervous system and in some Schwann cells in peripheral nerves (Figure 16-15). All of these proteins co-polymerize readily with one another, and co-polymers of vimentin and a vimentin-related protein are found in a number of adult cell types. By contrast, none of these proteins co-polymerize with keratins: when keratins and vimentin-related proteins are expressed in the same cell, they form separate filament systems.

Nerve cells contain a variety of unique intermediate filaments, which are expressed in different regions of the nervous system or

at specific stages of development. By far the most abundant are the *neurofilaments,* which extend along the length of an axon and form its primary cytoskeletal component, especially in mature nerve cells. In mammals, three *neurofilament proteins* have long been recognized: termed *NF-L, NF-M,* and *NF-H,* for low, middle, and high molecular weight, respectively, all three are usually found in each neurofilament. NF-M and NF-H have especially long carboxyl-terminal tails, which are thought to project from the neurofilament axis and contribute to the regular side-to-side spacing of neuro-filaments in an axon (Figure16-16).

If a cell in culture is stained with an antibody to a cytoplasmic intermediate filament protein, a delicate network of threadlike filaments is usually seen surrounding the nucleus and extending through the cytoplasm to the plasma membrane (see Figure 16-12). In epithelial cells, keratin filaments are attached to specialized cell junctions - both to *desmosomes,* which bond neighboring cells together, and to *hemidesmosomes,* which anchor cells to the underlying basal lamina (discussed in Chapter 19). Because the keratin filaments in each cell are connected via desmosomes to those of its neighbors, they form a continuous network throughout the entire epithelium (Figure16-17). Similarly, desmin filaments are often anchored to specialized cell junctions in muscle cells.

The Nuclear Lamina Is Constructed from a Special Class of Intermediate Filament Proteins - the Lamins <u>11</u>

The nuclear lamina is a meshwork of intermediate filaments that lines the inside surface of the inner nuclear membrane in eucaryotic cells (Figure16-18). It is typically 10-20 nm thick and is interrupted in the region of nuclear pores to provide a passageway for macromolecules entering and leaving the nucleus. In mammalian cells the nuclear lamina is composed of lamins, which are homologous to other intermediate filament proteins but differ from them in at least four ways: (1) Their central rod domain is somewhat longer (see Figure16-13). (2) They contain a nuclear transport signal that directs them from the cytosol, where they are made, into the nucleus. (3) They assemble into a two-dimensional, sheetlike lattice, which is thought to require their association with other proteins. (4) The meshwork they form is unusually dynamic and rapidly disassembles at the start of mitosis and reassembles at the end of mitosis; as already mentioned, the disassembly and reassembly are mediated by the phosphorylation and dephosphorylation of several serine residues on the lamins.

Unlike microtubules and actin filaments, which are a defining characteristic of eucaryotic cells, cytoplasmic intermediate filaments have been described only in multicellular animals, and even in these organisms they are not required in every cell type. The specialized glial cells that make myelin in the vertebrate central nervous system, for example, do not contain intermediate filaments. Moreover, intermediate filaments can be disrupted in muscle cells, fibroblasts, and epithelial cells in culture without detectable effects on cell behavior.

It seems likely that the first type of intermediate filament protein to appear in evolution was a nuclear lamin and that the various kinds of cytoplasmic intermediate filaments are later adaptations of this primitive form. The intermediate filament proteins in invertebrates, for example, more closely resemble lamins than vertebrate cytoplasmic intermediate filament proteins.

Intermediate Filaments Provide Mechanical Stability to Animal Cells <u>12</u>

There is increasing evidence that a major function of cytoplasmic intermediate filaments is to resist mechanical stress. In the human genetic disease *epidermolysis bullosa simplex,* mutations in keratin genes that are normally expressed in the basal cell layer of the epidermis disrupt the keratin filament network in these cells, making them very sensitive to mechanical injury: a gentle squeeze can cause the mutant basal cells to rupture, and the skin in affected individuals is blistered. A similar condition can be produced in transgenic mice that express mutant keratins of this type (Figure16-19). In both humans and mice the epidermis can be so weakened that individuals carrying the mutation can die from mechanical trauma. Cytoplasmic intermediate filaments are thought to strengthen nonepithelial cells in a similar way.

The structure of intermediate filaments is ideally suited for such a mechanical function. Because the fibrous subunits associate side by side in overlapping arrays, the filaments can withstand very much larger stretching forces than microtubules or actin filaments (Figure 16-20). In the skin, keratin filaments in the outermost layers of the epidermis become covalently cross-linked to one another and to associated proteins, and as the cells die, the cross-linked keratins persist as a major part of the protective outer layer of the animal. Specialized epithelial cells at particular locations in the skin provide regional variation by generating surface appendages rich in keratin, such as hairs and nails.

But if intermediate filaments function simply to provide tensile strength to cells and tissues, why are there so many different types? And what is the function of the head and tail domains of the proteins, which show such large variations in sequence?

Detailed answers to these questions cannot be given at present, but it is clear that the way that intermediate filaments are linked to other cellular components varies greatly among cell types. The desmin filaments that tie the edges of the myofibrils together in skeletal muscle cells are likely to have binding sites for specific myofibril-associated proteins. Neurofilaments in axons are linked side by side by their carboxyl-terminal tail domains to provide a continuous rope of filaments that can be a meter or more in length. Some keratins are specialized to form the tough, protective outer layer of the skin, while others specifically strengthen epithelia undergoing shape changes during morphogenesis. These different functional requirements must be accommodated by the variable regions of the different intermediate filament proteins, which project from the surface of the intermediate filaments and determine their ability to associate with one another and with other components in the cell. In a sense, therefore, the variable regions of intermediate filament proteins serve functions similar to those of the accessory proteins of actin filaments and microtubules. The difference is that the variable regions are an integral part of the intermediate filament subunit, rather than being a separate protein.

Summary

Intermediate filaments are strong, ropelike polymers of fibrous polypeptides that resist stretch and play a structural or tension-bearing role in the cell. A variety of tissue-specific forms are known that differ in the type of polypeptide they contain: these include the keratin filaments of epithelial cells, the neurofilaments of nerve cells, the glial filaments of astrocytes and Schwann cells, the desmin filaments of muscle cells, and the vimentin filaments of fibroblasts and many other cell types. Nuclear lamins, which form the fibrous lamina that underlies the nuclear envelope, are a separate family of intermediate filament proteins.

The monomers of the different types of intermediate filaments differ in amino acid sequence and have very different molecular weights. But they all contain a homologous central rod domain that forms an extended coiled-coil structure when the protein dimerizes. Two coiled-coil dimers associate with each other to form a symmetrical tetramer, which in turn assembles in large overlapping arrays to form the nonpolarized intermediate filament. The rod domains of the subunits form the structural core of the intermediate filament, whereas the domains at either end can project outward. One function of the variable terminal domains may be to allow each type of filament to associate with specific other components in the cell, so as to position the filaments appropriately for a particular cell type.

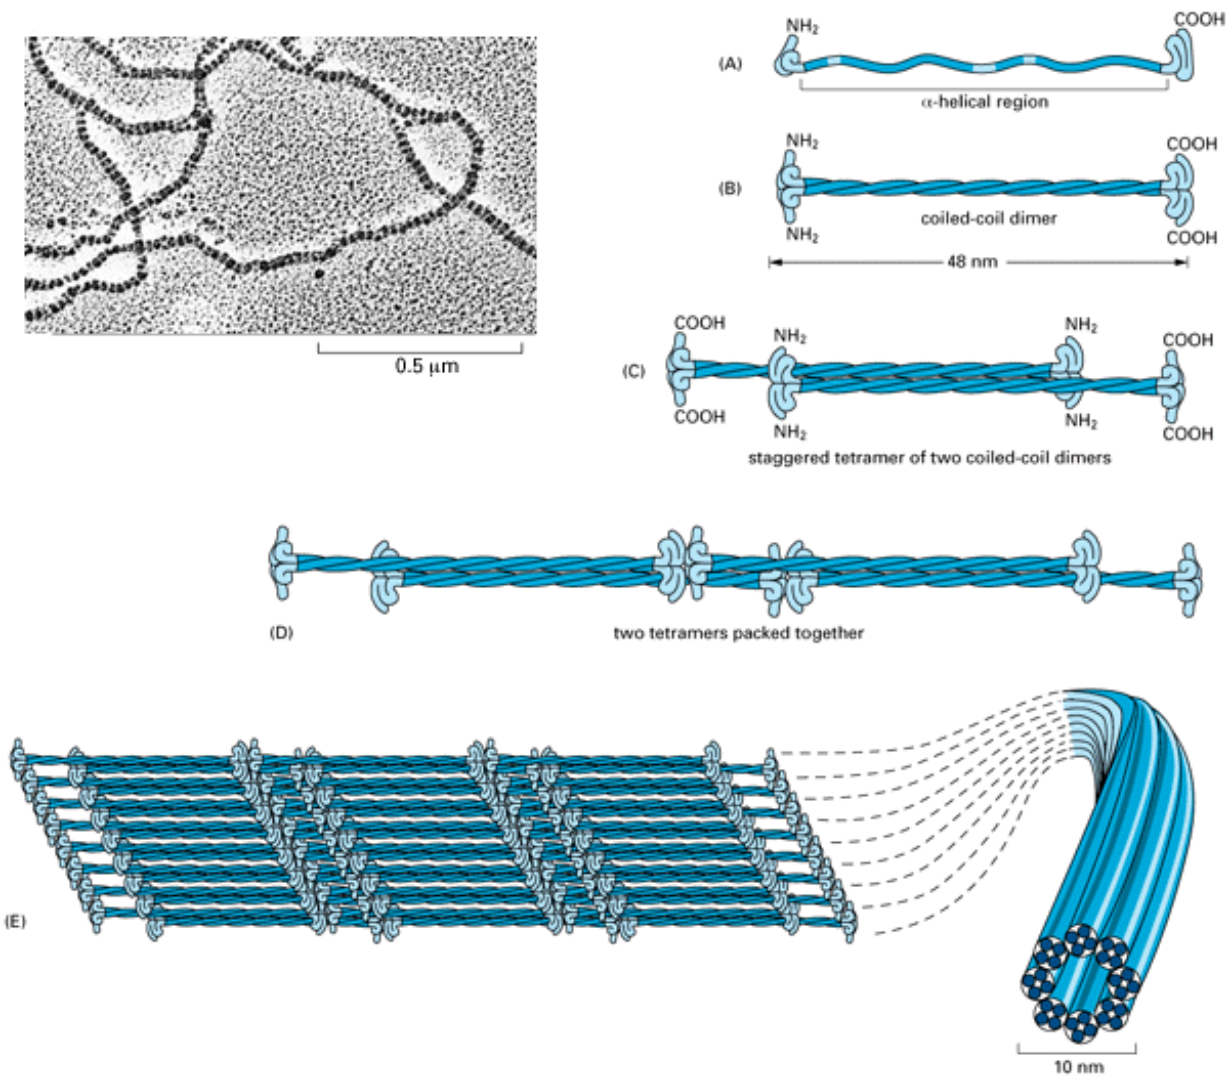
Figure 16-13. The domain organization of intermediate filament protein monomers. Most intermediate filament proteins share a similar rod domain that is usually about 310 amino acids long and forms an extended a helix. The amino-terminal and carboxyl-terminal domains are non-a-helical and vary greatly in size and sequence in different intermediate filaments.


Figure 16-14. A current model of intermediate filament construction. The monomer shown in (A) pairs with an identical monomer to form a dimer (B) in which the conserved central rod domains are aligned in parallel and wound together into a coiled-coil. Two dimers then line up side by side to form an antiparallel tetramer of four polypeptide chains (C). Within each tetramer the dimers are staggered with respect to one another, thereby allowing it to associate with another tetramer, as shown in (D). In the final 10-nm ropelike intermediate filament, tetramers are packed together in a helical array (E). An electron micrograph of the final filament is shown upper left. Quinlan.)

Table 16-1. Major Types of Intermediate Filament Proteins in Vertebrate Cells

Type of IF	Component Polypeptides (mass in daltons)	Cellular Location
Nuclear lamins	lamins A, B, and C (65,000–75,000)	nuclear lamina of eucaryotic cells
Vimentinlike proteins	vimentin (54,000)	many cells of mesenchymal origin, often expressed transiently during development
	desmin (53,000)	muscle
	glial fibrillary acidic protein (50,000)	glial cells (astrocytes and Schwann cells)
	peripherin (66,000)	neurons
Keratins	type I (acidic) (40,000–70,000) type II (neutral/basic) (40,000–70,000)	epithelial cells and their derivatives (e.g., hair and nails)
Neuronal intermediate filaments	neurofilament proteins NF-L, NF-M, and NF-H (60,000–130,000)	neurons

The lamina is associated with both the chromatin and the inner nuclear membrane. (B) Electron micrograph of a portion of the nuclear lamina in a frog oocyte prepared by freeze-drying and metal shadowing. The lamina is formed from a square lattice of intermediate filaments composed of nuclear lamins (not always as highly organized as that shown here). (C) Electron micrograph of metal-shadowed isolated lamin dimers (marked L). They have an overall form similar to muscle myosin (marked M), with a rodlike tail and two globular heads, but they are much smaller molecules. The globular heads are formed from the two large carboxyl-terminal domains. (B and C, courtesy of Ueli Aebi.)
Figure 16-19. Blistering of the skin caused by a mutant keratin gene. A mutant gene encoding a truncated keratin protein (lacking both the amino- and carboxyl-terminal domains) was expressed in a transgenic mouse. The defective protein assembles with the normal keratins and thereby disrupts the keratin filament network in the basal cells. Light micrographs of normal (A) and mutant (B) skin show that the blistering results from the rupturing of cells in the basal layer of the mutant epidermis. The sketch in (C) of three cells observed by electron microscopy in the basal layer of the mutant epidermis shows that the cells rupture between the nucleus and the hemidesmosomes, which connect the keratin filaments to the underlying basal lamina. Figure 16-20. Mechanical properties of actin, tubulin, and vimentin polymers. Networks composed of either microtubules or actin filaments or vimentin filaments, all at equal concentration, were exposed to a shear force in a viscometer and the resulting degree of stretch measured. The results show that microtubule networks are easily deformed but that they rupture (indicated by *red starburst*) and begin to flow without limit when stretched beyond 50% of their original length. Actin filament networks are much more rigid, but they also rupture easily. Vimentin networks, by contrast, are easily deformed, but unlike microtubule networks, they withstand large stresses and strains without rupture. Vimentin filaments are therefore well suited to maintain cell integrity. (Adapted from P. Jamney et al. *, J. Cell Biol.* 113:155-160, 1991.)

Microtubules 13

Introduction

Microtubules, as we have seen, are long, stiff polymers that extend throughout the cytoplasm and govern the location of membrane-bounded organelles and other cell components. In this section we discuss the assembly of these remarkable structures from tubulin molecules and explain how their polymerization and depolymerization are controlled by the nucleotide GTP. We then examine some ways in which selected microtubules are stabilized in the cell by their association with specific accessory proteins. Finally, we discuss the importance of microtubule-dependent motors that transport membrane vesicles and various protein complexes along microtubules.

Microtubules Are Hollow Tubes Formed from Tubulin 14

Microtubules are formed from molecules of tubulin, each of which is a heterodimer consisting of two closely related and tightly linked globular polypeptides called α-*tubulin* and β-*tubulin.* Although tubulin is present in virtually all eucaryotic cells, the most abundant source for biochemical studies is the vertebrate brain. Extraction procedures yield 10 to 20% of the total soluble protein in brain as tubulin, reflecting the unusually high density of microtubules in the elongated processes of nerve cells.

Tubulin molecules themselves are diverse. In mammals there are at least six forms of α-tubulin and a similar number of forms of β-tubulin, each encoded by a different gene. The different forms of tubulin are very similar, and they will generally co-polymerize into mixed microtubules in the test tube, although they can have distinct locations in the cell and perform subtly different functions. The microtubules in six specialized touch-sensitive neurons in the nematode *Caenorhabditis elegans,* for example, contain a specific form of β-tubulin, and mutations in the gene for this protein result in the specific loss of touch-sensitivity with no apparent defect in other cell functions.

A microtubule can be regarded as a cylindrical structure in which the tubulin heterodimers are packed around a central core, which appears empty in electron micrographs. More accurately, perhaps, one can view the structure as being built from 13 linear protofilaments, each composed of alternating α- and β-tubulin subunits and bundled in parallel to form a cylinder (Figure 16-21). Since the 13 protofilaments are aligned in parallel with the same polarity, the microtubule itself is a polar structure, and it is possible to distinguish a *plus* (fast-growing) and a *minus* (slow-growing) end.

Microtubules Are Highly Labile Structures That Are Sensitive to Specific Antimitotic Drugs 15

Many of the microtubule arrays in cells are labile and depend on this lability for their function. One of the most striking examples is the mitotic spindle, which forms after the cytoplasmic microtubules disassemble at the onset of mitosis. The mitotic spindle is the target of a variety of specific *antimitotic drugs* that act by interfering with the exchange of tubulin subunits between the microtubules and the free tubulin pool. One of these is *colchicine*(Figure 16-22), an alkaloid extracted from the meadow saffron that has been used medicinally in the treatment of gout since ancient Egyptian times. Each molecule of colchicine binds tightly to one tubulin molecule and prevents its polymerization, but it cannot bind to tubulin once the tubulin has polymerized into a microtubule. The exposure of a dividing cell to colchicine, or to the closely related drug *colcemid,* causes the rapid disappearance of the mitotic spindle, indicating that a chemical equilibrium is maintained through continual exchange of subunits between the spindle microtubules and the pool of free tubulin. Because the temporary disruption of spindle microtubules preferentially kills many abnormally dividing cells, antimitotic drugs, such as vinblastine and vincristine (whose effects are similar to those of colcemid), are widely used in the treatment of cancer.

The drug *taxol* (Figure16-22), extracted from the bark of yew trees, has the opposite effect. It binds tightly to microtubules and stabilizes them, and when added to cells, it causes much of the free tubulin to assemble into microtubules. The stabilization of microtubules by taxol arrests dividing cells in mitosis, indicating that microtubules must be able not only to polymerize but also to depolymerize during mitosis. Taxol is also widely used as an anticancer drug.

Elongation of a Microtubule Is Rapid, Whereas the Nucleation of a New Microtubule Is Slow 16

Microtubule polymerization and depolymerization are complex and interesting processes with important biological roles. Most of what we know about the dynamic behavior of microtubules has come from studying the polymerization of purified tubulin molecules *in vitro.* Pure tubulin will polymerize into microtubules at 37°C in a test tube as long as Mg^{2+} and GTP are present. If the polymerization is followed either by light-scattering measurements or by microscopy, it shows an initial lag phase, after which microtubules form rapidly until a plateau level of polymerization is reached. The lag phase occurs because it is much easier to add subunits to an existing microtubule, a process called *elongation,* than to start a new microtubule *de novo,* a process called *nucleation*.

During the rapid polymerization phase, the high concentration of free tubulin causes microtubules to polymerize faster than they depolymerize (see below). When the plateau of polymerization is reached, however, not all of the tubulin will have polymerized because subunits are dissociating (depolymerizing) from the ends of microtubules as well as adding to them. The rate of polymerization drops with time because this rate is proportional to the concentration of free tubulin; the final concentration of free tubulin at the plateau, where the polymerization and depolymerization rates are exactly balanced, is called the *critical concentration* (Figure 16-23).

We saw at the beginning of the chapter that the microtubules in a cell usually grow from a specific nucleating site (in most cases, the centrosome); because of a kinetic barrier to nucleation in solution, tubulin polymerization occurs only at this site. As in the test tube, not all the tubulin in the cell becomes polymerized. A typical fibroblast cell contains approximately 20 micromolar tubulin (2mg/ml), of which 50% is in microtubules and 50% is free.

The Two Ends of a Microtubule Are Different and Grow at Different Rates 17

The structural polarity of a microtubule, which reflects the regular orientation of its tubulin subunits, makes the two ends of the polymer different in ways that have a profound effect on its rate of growth. If purified tubulin molecules are allowed to polymerize for a short time at the ends of fragments of stable microtubules and the mixture is then examined in the electron microscope, one end can be seen to elongate at three times the rate of the other (Figure16-24). The fast-growing end is thereby defined as the plus end and the other as the minus end.

It is possible to detect the polarity of microtubules in cross-section by adding free tubulin molecules to existing microtubules: under special conditions the tubulin monomers, instead of adding to the ends of the microtubules, add to the sides, forming curved protofilament sheets. In cross-section the sheets resemble hooks and, depending on the orientation of the microtubule, will appear to point either clockwise or counterclockwise (Figure16-25). In this way it has been shown that the plus ends of the microtubules in a cell extend away from microtubule-nucleating sites such as the centrosome, the poles of a mitotic spindle, or the basal body of a cilium (Figure 16-26).

Centrosomes Are the Primary Site of Nucleation of Microtubules in Animal Cells 18

The microtubules in the cytoplasm of an interphase cell in culture can be visualized by staining the cell with fluorescent anti-tubulin antibodies after the cells have been fixed. The microtubules are seen in greatest density around the nucleus and radiate out into the cell periphery in fine lacelike threads (Figure16-27). The origin of the microtubules is seen most clearly if they are first depolymerized with colcemid and then allowed to repolymerize after the drug is washed out. The new microtubules grow out from the centrosome to form a small starlike structure called an aster and then elongate toward the cell periphery until the original microtubule distribution is reestablished (Figure16-28). If the microtubules in cultured cells are decorated with tubulin hooks to determine their polarity, they are all seen to have their plus ends facing away from the *centrosome,* indicating that this organizing center has the capacity to nucleate microtubule polymerization with a specific polarity.

The centrosome is the major microtubule-organizing center in almost all animal cells. In interphase it is typically located to one side of the nucleus, close to the outer surface of the nuclear envelope. Embedded in the centrosome is a pair of cylindrical structures arranged at right angles to each other in an L-shaped configuration. These are *centrioles,* and we discuss their structure later. The centrosome duplicates and splits into two equal parts during interphase, each half containing a duplicated centriole pair. These two daughter centrosomes move to opposite sides of the nucleus when mitosis begins, and they form the two poles of the mitotic spindle (see Figure 18-5).

Surrounding each centriole pair, in both interphase and metaphase, is a region of the cytoplasm that stains darkly when viewed by electron microscopy and appears in the best micrographs to be made of a network of small fibers (Figure 16-29A). This is the pericentriolar material, or centrosome matrix, and it is the part of the centrosome that nucleates microtubule polymerization. The protein composition of the centrosome matrix is only partly known, as is the mechanism by which it nucleates microtubules. However, it contains a number of centrosome-specific proteins, including a special minor form of tubulin, called γ-*tubulin* (Figure 16-29B), which may interact with the normal α/β tubulin dimer to help nucleate microtubules.

Not all microtubule-organizing centers contain centrioles. In mitotic cells of higher plants, for example, the microtubules terminate in poorly defined regions of electron density that are completely devoid of centrioles. Similarly, centrioles are not present in the meiotic spindle of mouse oocytes, although they appear later in the developing embryo. In fungi and diatoms the microtubule-organizing center is a plaque called the *spindle pole body,* which is embedded in the nuclear envelope. Despite these morphological differences (Figure16-30), all of the organizing centers contain a matrix that nucleates microtubule polymerization, and they usually contain gamma-tubulin and other centrosome-specific proteins. Thus the molecular mechanism of microtubule nucleation is likely to be highly conserved.

Microtubules Depolymerize and Repolymerize Continually in Animal Cells [19]

In a cell such as a cultured fibroblast the entire microtubule array is turning over rapidly. The half-life of an individual microtubule is about 10 minutes, while the average lifetime of a tubulin molecule, between its synthesis and proteolytic degradation, is more than 20 hours. Thus each tubulin molecule will participate in the formation and dismantling of many microtubules in its lifetime, a process that can be investigated by direct observation of living cells. One way is to inject tubulin that has been covalently linked to a fluorescent dye and then follow the behavior of microtubules that incorporate the tagged tubulin using fluorescence microscopy. Alternatively, in certain very flat cells one can visualize microtubules directly, without labeling them, using video-enhanced differential-interference-contrast microscopy (see Figure4-12). When microtubules in a cell are watched over time by either method, a remarkable phenomenon is observed. Individual microtubules grow toward the cell periphery at a constant rate for some period and then suddenly shrink rapidly back toward the centrosome. They may shrink partially and then recommence growing, or they may disappear completely, to be replaced by a different microtubule (Figure16-31). These fluctuations in length occur over many micrometers and involve the polymerization and then depolymerization of tens of thousands of tubulin subunits. Transitions between prolonged periods of polymerization and depolymerization are also seen when pure microtubules are studied in a test tube (Figure16-32). This behavior, called *dynamic instability,* plays a major role in positioning microtubules in the cell, as we discuss below.

GTP Hydrolysis Can Explain the Dynamic Instability of Individual Microtubules [20]

The dynamic instability of microtubules requires an input of energy to shift the chemical balance between polymerization and depolymerization - energy that comes from the hydrolysis of GTP. GTP binds to the β-tubulin subunit of the heterodimeric tubulin molecule, and when a tubulin molecule adds to the end of a microtubule, this GTP molecule is hydrolyzed to GDP. (The α-tubulin subunit also carries GTP, but this cannot be exchanged for free GTP and is not hydrolyzed, so we can consider it a

fixed part of the tubulin protein structure.)

The role of GTP hydrolysis in microtubule polymerization has been examined using analogues of GTP that cannot be hydrolyzed. Tubulin molecules containing such nonhydrolyzable GTP analogues form microtubules normally, indicating that, while the binding of this nucleotide is required for microtubule polymerization, its hydrolysis is not. These microtubules, however, are abnormally stable and do not depolymerize like normal microtubules when the tubulin concentration in the surrounding fluid is lowered or when they are treated with colchicine. Thus the normal role of GTP hydrolysis is apparently to allow microtubules to depolymerize by weakening the bonds between tubulin subunits in the microtubule.

Dynamic instability is thought to be a consequence of the delayed hydrolysis of GTP after tubulin assembly. When a microtubule grows rapidly, tubulin molecules add to a polymer end faster than the GTP they carry can be hydrolyzed. This results in the presence of a *GTP cap* on the end of the microtubule, and because tubulin molecules carrying GTP bind to one another with higher affinity than tubulin molecules carrying GDP, the GTP cap will encourage a growing microtubule to continue growing. Conversely, once a microtubule has lost its GTP cap - for example, if the instantaneous rate of polymerization slows down - it will start to shrink and then tend to go on shrinking.

A model for the structural changes that accompany dynamic instability is shown schematically in Figure 16-33. Some general principles that apply to the polymerization of both actin filaments and microtubules are discussed in Panel 16-1, pages 824-825.

Cells can modify the dynamic instability of their microtubules for specific purposes. In each M phase of the cell cycle, for example, the rapidity with which microtubules form and break down is greatly increased, so that the chromosomes can readily capture growing microtubules and a mitotic spindle can rapidly assemble (discussed in Chapter 18). Conversely, when a cell differentiates and takes on a defined morphology, the dynamic instability of its microtubules is often suppressed by proteins that bind to the microtubules and stabilize them against depolymerization. The ability to stabilize microtubules in a particular configuration provides an important mechanism by which a cell can organize its cytoplasm.

The Dynamic Instability of Microtubules Provides an Organizing Principle for Cell Morphogenesis 21

Cytoplasmic microtubules in animal cells tend to radiate out in all directions from the centrosome, where their minus ends are anchored. Most animal cells are polarized, however, and the assembly and disassembly of tubulin molecules are spatially controlled so that microtubules extending toward specific regions of the cell predominate. It is not known for certain how this is achieved, but it seems likely that the mechanisms depend on the dynamic instability of microtubules.

We have seen that individual microtubules *in vitro* tend to exist in one of two states - steady growth or rapid, "catastrophic" disassembly - and that microtubules in a cell can also exist in these two states. The inherent instability of microtubules helps to explain how they can become organized in specific directions in a cell - toward the leading edge of a crawling cell, for example. The array of microtubules radiating from the centrosome is continually changing as new microtubules grow and replace others that have depolymerized. A microtubule that grows from a centrosome can be stabilized if its plus end is somehow stabilized, or *capped,* so as to prevent its depolymerization. If capped by a structure in a particular region of the cell, it will establish a relatively stable link between that structure and the centrosome. Microtubules originating in the centrosome can thus be selectively stabilized by events elsewhere in the cell. Cell polarity is thought to be determined in this way by unknown structures or factors localized in particular regions of the cell cortex that "capture" the plus ends of microtubules (Figure 16-34).

In many cells the initial stabilization of microtubules at their plus ends is consolidated to produce a more permanent polarization of the cell, as we now discuss.

Microtubules Undergo a Slow "Maturation" Revealed by Posttranslational Modifications of Their Tubulin 22

Tubulin subunits can be covalently modified after they polymerize. Two such modifications are especially interesting in that they provide a form of molecular clock, which can be used to tell how long it has been since a given microtubule polymerized. These modifications are the acetylation of α-tubulin on a particular lysine and the removal of the tyrosine residue from the carboxyl terminus of α-tubulin. *Acetylation* and *detyrosination* are both relatively slow enzymatic reactions that occur only on microtubules and not on free tubulin molecules; moreover, they are rapidly reversed as soon as a tubulin molecule depolymerizes. Thus the longer the time that has elapsed since a particular microtubule polymerized, the higher will be the fraction of its subunits that are acetylated and detyrosinated. Complete modification takes several hours, so that in fibroblasts,

where microtubules turn over rapidly, relatively few of them are modified. In nerve axons, by contrast, the majority of microtubules are stable and most are modified.

Acetylation and detyrosination can be detected by specific antibodies, and they provide a useful indication of the stability of microtubules in cells in which it is difficult to study microtubule dynamics directly. The role of these modifications is unknown, but it is thought that they provide sites for the binding of specific microtubule-associated proteins that further stabilize mature microtubules.

Microtubule-associated Proteins (MAPs) Bind to Microtubules and Modify Their Properties 23

Whereas the posttranslational modification of tubulin marks certain microtubules as "mature" and may promote their stability, the most far-reaching and versatile modifications of microtubules are those conferred by the binding of other proteins. These microtubule-associated proteins, or MAPs, serve both to stabilize microtubules against disassembly and to mediate their interaction with other cell components. As one might expect from the diverse functions of microtubules, there are many kinds of MAPs; some are widely distributed in most cells, whereas others are found only in specific cell types.

Two major classes of MAPs can be isolated from brain in association with microtubules: *HMW proteins* (high-molecular-weight proteins), which have molecular weights of 200,000 to 300,000 or more and include *MAP-1* and *MAP-2;* and *tau proteins*, which have molecular weights of 55,000 to 62,000. Proteins in both classes have two domains, only one of which binds to microtubules; the other is thought to help link the microtubule to other cell components (Figure 16-35). Because the microtubule-binding domain binds to several unpolymerized tubulin molecules simultaneously, these MAPs speed up the nucleation step of tubulin polymerization *in vitro*. More important, they inhibit the dissociation of tubulin from the microtubule ends and thus stabilize the microtubules once they have formed. Staining with antibodies to MAP-2 and tau shows that both proteins bind along the entire length of cytoplasmic microtubules.

Many other MAPs have been isolated. Some act as structural components and provide permanent links to other cell components, including other parts of the cytoskeleton. Others are microtubule motors, which use the energy of ATP hydrolysis to move along microtubules, as we discuss below.

MAPs Help Create Functionally Differentiated Cytoplasm 24

Many cell types specifically stabilize microtubules in specialized regions of cytoplasm. An especially well-studied example is provided by nerve cells, which extend two kinds of processes *axons* and *dendrites*. Axons, which are uniform in diameter and can be many centimeters long, are responsible for propagating electrical signals away from the cell body, whereas dendrites, which taper away from the cell body and rarely exceed 500 μm in length, are responsible for receiving electrical information from other neurons and relaying it to the cell body. Most nerve cells form several dendrites but only a single axon (see Figure 11-20).

Axons and dendrites are both packed with microtubules, although with different arrangements. In axons microtubules are very long and are all oriented with their plus ends away from the cell body. In dendrites the microtubules are shorter and their polarity is mixed: some have their plus ends pointing away from the cell body, while others have their plus ends pointing toward the cell body. When the distribution of MAPs in cultured neurons is studied with specific antibodies, certain forms of the tau protein are found to be present only in axons; MAP-2, on the other hand, is present in both dendrites and the cell body but completely excluded from axons (Figure 16-36). Axons and dendrites are different in many other ways as well: mRNAs, ribosomes, and some kinds of ion channels, for example, are present in dendrites and the cell body but are excluded from axons, while certain cell-adhesion molecules and the Na^+ channels involved in the generation of action potentials are selectively localized to axons. Thus both the cytoplasm and the plasma membrane of a nerve cell are divided into axonal and dendritic *compartments*. These compartments within a single cell differ from membrane-bounded compartments such as the endoplasmic reticulum or mitochondria, since they are not separated from each other by a membrane; instead, the difference seems to be one of structural organization and the types of proteins present.

The generation of axons and dendrites during the differentiation of nerve cells is discussed in Chapter 21. Although it is unclear how the cytoplasm and plasma membrane of a nerve cell become compartmentalized, MAPs may be essential for this process. When the production of tau protein is inhibited in cultured neurons by treatment with specific antisense oligonucleotides, the formation of axons is suppressed, whereas the formation of dendrites is unaffected. Conversely, when nonneuronal cells are genetically manipulated so that they express tau protein (which is normally expressed only in nerve cells), they form long

axonlike processes, which contain bundles of microtubules arranged with their plus ends pointing away from the cell body, just as in nerve cells.

Because different components of the cell move along microtubules in different directions, one can postulate that an initial difference in microtubule polarity is created by a different distribution of MAPs, which will in turn lead to further differences between dendrites and axons. Secretory vesicles, for example, move toward the plus end of microtubules and therefore will be carried down the axon to the nerve terminals where they function; conversely, if ribosomes and mRNAs move toward the minus end of microtubules, they could be excluded from axons.

Kinesin and Dynein Direct Organelle Movement Along Microtubules 25

Important advances in cell biology have often followed the introduction of a new experimental technique, and it was the improved ability to see small faint objects by video-enhanced light microscopy that led to the discovery of the microtubule motors responsible for organelle transport. Once it became possible to visualize single microtubules in an unfixed specimen, investigators could follow the movement of organelles and other particles along these microtubules *in vitro.* Alternatively, they could observe and measure the gliding movement of individual microtubules over glass surfaces coated with cell extracts.

Such *in vitro* motility assays were used to identify and isolate two classes of microtubule-dependent motor proteins - the *kinesins* and the *cytoplasmic dyneins.* Cytoplasmic dyneins are involved in organelle transport and mitosis and are closely related to *ciliary dynein,* the motor protein in cilia and flagella (discussed later). Kinesins are more diverse than the dyneins, and different family members are involved in organelle transport, in mitosis, in meiosis, and in the transport of synaptic vesicles along axons. Both the cytoplasmic dyneins and the kinesins are composed of two heavy chains plus several light chains. Each heavy chain contains a conserved, globular, ATP-binding head and a tail composed of a string of rodlike domains. The two head domains are ATPase motors that bind to microtubules, while the tails generally bind to specific cell components and thereby specify the type of cargo that the protein transports (Figure16-37).

The Rate and Direction of Movement Along a Microtubule Are Specified by the Head Domain of Motor Proteins 26

Most known motor proteins move in only one direction along microtubules - either toward the plus end or toward the minus end. This directionality can be analyzed *in vitro* by allowing polystyrene beads coated with the motor protein to move along microtubules that have been polymerized on centrosomes. Because the microtubules in such arrays have their plus ends outermost, the direction of movement can be readily determined with a light microscope. Whereas polystyrene beads coated with crude extracts of cytoplasm move in both directions, beads coated with kinesin isolated from axons move only outward toward the plus end of the microtubules. Beads coated with cytoplasmic dyneins, by contrast, move toward the minus ends of the microtubules, which are embedded in the centrosome.

Studies of intact nerve axons have confirmed the results obtained in *in vitro* experiments: organelle movement away from the cell body is driven mainly by kinesin, whereas organelle movement back from the nerve terminal toward the cell body is driven by cytoplasmic dynein (Figure16-38). Since all proteins are made in the nerve cell body, cytoplasmic dynein must be carried first in a nonfunctional state to the nerve terminal before it can begin to work to transport organelles back to the cell body.

Surprisingly, not all kinesins move organelles toward the plus end of microtubules. A *Drosophila* kinesin called *Ncd,* for example, which is required for normal meiosis, differs from axonal kinesin in both the direction and the rate at which it moves along microtubules: whereas axonal kinesin walks toward the plus end at approximately 2 μm/second, the Ncd protein walks toward the *minus* end at about 0.1 μm/second.

The mechanism by which these motor proteins convert the energy of ATP hydrolysis into vectorial movement is not known. Finding out how two closely related head domains can move in opposite directions along a microtubule will require detailed structural studies and is likely to illuminate the energy transduction process itself.

Summary

Microtubules are stiff polymers of tubulin molecules. They assemble by addition of GTP-containing tubulin molecules to the free end of the microtubule, with one end (the plus end) growing faster than the other. Hydrolysis of the bound GTP takes place after assembly and weakens the bonds that hold the microtubule together. Slowly growing microtubules are especially unstable

and liable to catastrophic disassembly, but they can be stabilized in cells by association with other structures that cap their two ends. Microtubule-organizing centers such as centrosomes protect the minus ends of microtubules and continually nucleate the formation of new microtubules, which grow out in random directions. Any microtubule that happens to encounter a structure that stabilizes its free plus end will be selectively retained, while other microtubules will depolymerize. It is thought that this selective process largely determines the position of the microtubule arrays in a cell.

The tubulin subunits in microtubules that have been selectively stabilized are modified by acetylation and detyrosination. These alterations are thought to label the microtubule as "mature" and provide sites for the binding of specific microtubule-associated proteins (MAPs), which further stabilize the microtubule against disassembly. Microtubule motor proteins constitute an important class of MAPs that use the energy of ATP hydrolysis to move unidirectionally along a microtubule, carrying specific cargo. In general, dyneins move cargo toward the minus ends of microtubules, while most kinesins move cargo toward the plus ends. Such motor proteins are largely responsible for the spatial organization and directed movements of organelles in the cytoplasm.

colchicine

taxol

Figure 16-22. Chemical structures of colchicine and taxol. A third drug, colcemid, is a close relative of colchicine in which the group shown in *yellow* is replaced by -CH$_3$. Its binding to tubulin, unlike that of colchicine, is readily reversible.
Figure 16-23. Polymerization of pure tubulin. A mixture of tubulin, buffer, and GTP is warmed to 37°C at time zero. The amount of microtubule polymer, measured by light-scattering, follows a sigmoidal curve. During the lag phase individual tubulin molecules associate to form metastable aggregates, some of which go on to nucleate microtubules. The lag phase reflects a kinetic barrier to this nucleation process. During the rapid elongation phase, subunits add to the free ends of existing micro-tubules. During the plateau phase, polymerization and depolymerization are balanced because the amount of free tubulin has dropped to the point where a *critical concentration* has been reached. For simplicity, subunits are shown coming on and off the microtubule at only one end.
Figure 16-24. Electron micrograph showing preferential polymerization of tubulin onto the plus ends of microtubules. A stable bundle of microtubules obtained from the core of a cilium (discussed later) was incubated with tubulin subunits under polymerizing conditions. Microtubules grow fastest from the plus end of the microtubule bundle (the end above the bundle in this figure). (Courtesy of Gary Borisy.)

Figure 16-25. Microtubule polarity as revealed by the hook-decoration method. All the microtubules in this electron micrograph (seen in cross-section) have the same orientation. The hooks formed by the added tubulin curve clockwise, which indicates that the microtubules are being viewed as though looking along each filament from its plus end toward its minus end. Microtubule polarity can also be determined by decoration with dynein molecules (not shown). (Courtesy of Ursula Euteneuer.)

Figure 16-31. Microtubule dynamics in a living cell. A fibroblast was injected with tubulin that had been covalently linked to rhodamine, so that approximately 1 tubulin subunit in 10 in the cell was labeled with a fluorescent dye. The fluorescence at an edge of the cell was then observed using an extremely sensitive electronic imaging device. Below are tracings of the micrographs that show selected microtubules more clearly. Note, for example, that microtubule #1 first grows and then shrinks rapidly, whereas microtubule #4 grows continuously. (From P.J. Sammak and G.G. Borisy, *Nature* 332:724-736, 1988. © 1988 Macmillan Journals Ltd.)
Figure 16-32. The dynamic instability of microtubule growth. Fluctuations in length of a single microtubule in a solution of pure tubulin as seen by video-enhanced dark-field microscopy. Images of the same microtubule were recorded at intervals of 1 to 2 minutes and displayed in sequential order on a monitor screen. The two ends go through cycles of elongation and shortening independently, with the plus end showing the greatest fluctuations. (From T. Horio and H. Hotani, *Nature* 321:605-607, 1986. © 1986 Macmillan Journals Ltd.)

Panel 16-1: The polymerization of actin and tubulin

ON RATES AND OFF RATES

A linear polymer of protein molecules, such as an actin filament or a microtubule, assembles (polymerizes) and disassembles (depolymerizes) by the addition and removal of subunits at the ends of the polymer. The rate of addition of monomers is given by the rate constant k_{on}, which has units of $M^{-1}\ sec^{-1}$. The rate of loss is given by k_{off} (units of sec^{-1}).

subunit   polymer (with n subunits)

k_{on} | k_{off}

polymer (with n +1 subunits)
NUCLEATION

A helical polymer is stabilized by multiple contacts between adjacent subunits. In the case of actin, two actin molecules bind relatively weakly to each other, but addition of a third actin monomer to form a trimer makes the entire group more stable.

monomer   dimer   trimer
Further addition can take place onto this trimer, which therefore acts as a nucleation site for polymerization. For tubulin the nucleation site is larger and has a more complicated structure (possibly a ring of 13 or more molecules)—but the principle is the same.

The assembly of a nucleation site is relatively slow, and this explains the lag phase seen during polymerization. The lag phase can be reduced or abolished entirely if premade nucleation sites, such as fragments of already polymerized microtubules or actin filaments, are added to serve this role.

THE CRITICAL CONCENTRATION

The number of monomers that add to the polymer (actin filament or microtubule) per second will be proportional to the concentration of the free subunit ($k_{on}C$), but the subunits will leave the polymer end at a constant rate (k_{off}) that does not depend on C. As the polymer grows, subunits are used up and C is observed to drop until it reaches a constant value, called the critical concentration (C_c). At this concentration the rate of subunit addition equals the rate of subunit loss.

At this equilibrium phase,

$$k_{on}C = k_{off}$$

so that

$$C_c = \frac{k_{off}}{k_{on}} = \frac{1}{K}$$

(where K is the equilibrium constant for subunit addition, see Figure 3–9).

TIME COURSE OF POLYMERIZATION

The assembly of a protein into a long helical polymer such as a cytoskeletal filament or a bacterial flagellum typically shows the following time course:
The lag phase is due to a kinetic barrier to nucleation.

The growth phase occurs as monomers add to the exposed ends of the growing polymer.

The equilibrium phase is reached when the growth of the polymer due to monomer addition is precisely balanced by the shrinkage of the polymer due to monomer loss.

PLUS AND MINUS ENDS

The two ends of an actin filament or microtubule polymerize at different rates. The fast-growing end is called the plus end, whereas the slow-growing end is called the minus end. The difference in the rates of growth at the two ends is made possible by changes in the conformation of each subunit as it enters the polymer.

free subunit → subunit in polymer

This conformational change affects the rates at which subunits add to the two ends.

Even though k_{on} and k_{off} will have different values for the plus and minus ends of the polymer, their ratio k_{off}/k_{on}—and hence C_c—must be the same at both ends. This is because exactly the same subunit interactions are broken when a subunit is lost at either end, and the final state of the subunit after dissociation is
identical. Therefore the ΔG for subunit loss, which determines the equilibrium constant for its association with the end (see Table 3–3, p. 97), is identical at both ends: if the plus end grows four times faster than the minus end, it must also shrink four times faster. Thus, for C > C_c both ends grow; for C < C_c both ends shrink.

TREADMILLING

One consequence of the nucleotide hydrolysis that accompanies polymer formation is to change the critical concentration at the two ends of the polymer. Since k^D_{off} and k^T_{on} refer to different reactions, their ratio k^D_{off}/k^T_{on} need not be the same at both ends of the polymer, so that:

$$C_c \text{ (minus end)} > C_c \text{ (plus end)}$$

Thus, if both ends of a polymer are exposed, polymerization will proceed until the concentration of free monomer reaches a value that is above C_c for the plus end but below C_c for the minus end. At this steady state, subunits will undergo a net assembly at the plus end and a net disassembly at the minus end at an identical rate. The polymer will maintain a constant length, even though there is a net flux of subunits through the polymer, known as treadmilling.
NUCLEOTIDE HYDROLYSIS

Each actin molecule carries a tightly bound ATP molecule that is hydrolyzed to a tightly bound ADP molecule soon after its assembly into polymer. Similarly, each tubulin molecule carries a tightly bound GTP that is converted to a GDP molecule soon after the molecule assembles into the polymer.

(T = ATP or GTP)
(D = ADP or GDP)

free monomer   subunit in polymer
Hydrolysis of the bound nucleotide reduces the binding affinity of the subunit for neighboring subunits and makes it more likely to dissociate from each end of the filament (see Figure 16–33 for a possible mechanism). It is usually the T form that adds to the filament and the D form that leaves.

Considering events at the plus end only:
As before, the polymer will grow until $C = C_c$. For illustrative purposes, we can ignore k^D_{on} and k^T_{off} since they are usually very small, so that polymer growth ceases when

$$k^T_{on} C = k^D_{off} \quad \text{or} \quad C_c = \frac{k^D_{off}}{k^T_{on}}$$

This is a steady state and not a true equilibrium, because the ATP or GTP that is hydrolyzed must be replenished by a nucleotide exchange reaction of the free subunit $\left(\boxed{D} \rightarrow \boxed{T} \right)$.

DYNAMIC INSTABILITY and TREADMILLING are two behaviors observed in cytoskeletal polymers. Both are associated with nucleoside triphosphate hydrolysis. Dynamic instability is believed to predominate in microtubules, whereas treadmilling may predominate in actin filaments.

ATP CAPS / GTP CAPS

The rate of addition of subunits to a growing actin filament or microtubule can be faster than the rate at which their bound nucleotide is hydrolyzed. Under such conditions subunits at the end form a "cap" of subunits containing the nucleoside triphosphate—an ATP cap on an actin filament or a GTP cap on a microtubule.

ATP/GTP cap
DYNAMIC INSTABILITY

Microtubules depolymerize about 100 times faster from an end containing GDP tubulin than from one containing GTP tubulin. A GTP cap favors growth, but if it is lost, then depolymerization ensues.

GTP cap

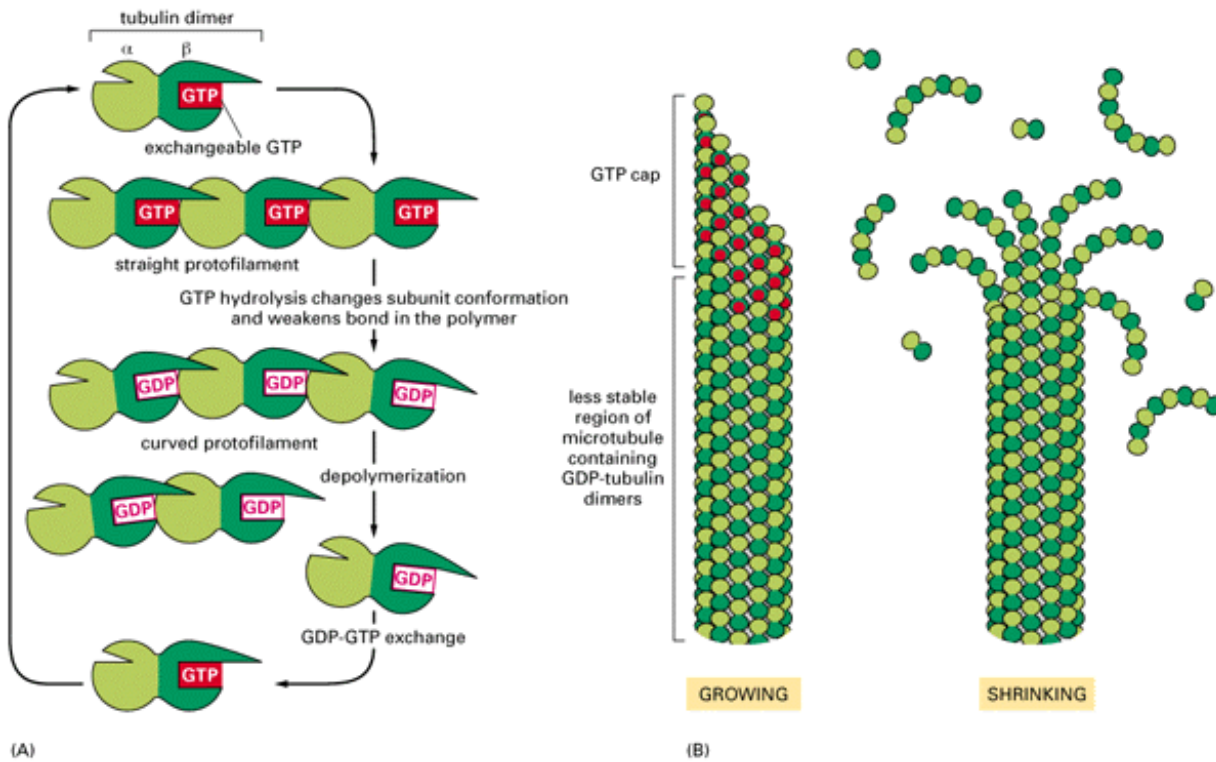
GROWING   SHRINKING
Individual microtubules can therefore alternate between periods of slow growth and rapid disassembly, a phenomenon called dynamic instability.


Figure 16-33. GTP hydrolysis after polymerization destabilizes microtubules. Analysis of the growth and shrinkage of microtubules *in vitro* suggests the following model for dynamic instability. (A) Addition of tubulin heterodimers carrying GTP to the end of a protofilament causes it to grow in a linear conformation that can readily pack into the cylindrical wall of the microtubule, thereby becoming stabilized. Hydrolysis of GTP after assembly changes the conformation of the subunits and tends to force the protofilament into a curved shape that is less able to pack into the microtubule wall. (B) In an intact microtubule, protofilaments made from GDP-containing subunits are forced into a linear conformation by the many lateral bonds within the microtubule wall, especially in the stable cap of GTP-containing subunits. Loss of the GTP cap, however, allows the GDP-containing protofilaments to relax to their more curved conformation. This leads to progressive disruption of the microtubule and the eventual disassembly of protofilaments into free tubulin dimers.
Figure 16-34. The selective stabilization of microtubules can polarize a cell. A newly formed microtubule will persist only if both of its ends are protected from depolymerizing. In cells the minus ends of microtubules are generally protected by the organizing centers from which these filaments grow. The plus ends are initially free but can be stabilized by other proteins. Here, for example, a nonpolarized cell is depicted in (A) with new micro-tubules growing and shrinking from a centrosome in all directions randomly. The array of microtubules then encounters hypothetical structures in a specific region of the cell cortex that can cap (stabilize) the free plus end of the microtubules (B). The selective stabilization of those microtubules that happen by chance to encounter these structures will lead to a rapid redistribution of the arrays and convert the cell to a polarized form (C and D).

Cilia and Centrioles 27

Introduction

Ciliary beating is an extensively studied form of cellular movement. Cilia are tiny hairlike appendages about 0.25 μm in diameter with a bundle of microtubules at their core; they extend from the surface of many kinds of cells and are found in most animal species, many protozoa, and some lower plants. The primary function of cilia is to move fluid over the surface of the cell or to propel single cells through a fluid. Protozoa, for example, use cilia both to collect food particles and for locomotion. On the epithelial cells lining the human respiratory tract, huge numbers of cilia (10^9/cm^2 or more) sweep layers of mucus, together with trapped particles of dust and dead cells, up toward the mouth, where they are swallowed and eliminated. Cilia also help to sweep eggs along the oviduct, and a related structure, the flagellum, propels sperm.

Cilia Move by the Bending of an Axoneme - a Complex Bundle of Microtubules 27

Fields of cilia bend in coordinated unidirectional waves (Figure 16-39). Each cilium moves with a whiplike motion: a forward active stroke, in which the cilium is fully extended and beating against the surrounding liquid, is followed by a recovery phase, in which the cilium returns to its original position with an unrolling movement that minimizes viscous drag (Figure16-40A). The cycles of adjacent cilia are almost but not quite in synchrony, creating the wavelike patterns that can be seen in fields of beating cilia under the microscope.

The simple flagella of sperm and of many protozoa are much like cilia in their internal structure, but they are usually very much longer. Instead of making whiplike movements, they propagate quasi-sinusoidal waves (Figure16-40B). Nevertheless, the molecular basis for their movement is the same as that in cilia. It should be noted that the flagella of bacteria (described in Chapter 15) are completely different from the cilia and flagella of eucaryotic cells.

The movement of a cilium or a flagellum is produced by the bending of its core, which is called the axoneme. The axoneme is composed entirely of microtubules and their associated proteins. The microtubules are modified and arranged in a pattern whose curious and distinctive appearance was one of the most striking revelations of early electron microscopy: nine special doublet microtubules are arranged in a ring around a pair of single microtubules (Figure 16-41). This "9 + 2" array is characteristic of almost all forms of cilia and eucaryotic flagella - from those of protozoa to those found in humans. The microtubules extend continuously for the length of the axoneme, which is usually about 10 µ long but may be as long as 200 µ in some cells.

While each member of the pair of single microtubules (the *central pair*) is a complete microtubule, each of the outer doublets is composed of one complete and one partial microtubule fused together so that they share a common tubule wall. In transverse sections each complete microtubule appears to be formed from a ring of 13 subunits, while the incomplete tubule of the outer doublet is formed from only 11.

Dynein Drives the Movements of Cilia and Flagella 28

The microtubules of an axoneme are associated with numerous proteins, which project at regular positions along the length of the microtubules. Some serve as cross-links that hold the bundle of microtubules together. Others generate the force that drives the bending motion, while still others form a mechanically activated relay system that controls the motion to produce the desired waveform. The most important of these accessory proteins is ciliary dynein, whose heads interact with adjacent microtubules to generate a sliding force between the microtubules. Because of the multiple links that hold adjacent microtubule doublets together, what would be a sliding movement between free microtubules (Figure 16-42) is converted to a bending motion in the cilium (Figure 16-43).

Like cytoplasmic dynein, ciliary dynein has a motor domain, which hydrolyzes ATP to move along a microtubule toward its minus end, and a tail region that carries a cargo, which in this case is an adjacent microtubule. Ciliary dynein is considerably larger than cytoplasmic dynein, both in the size of its heavy chains and in the number and complexity of its polypeptide chains. In flagella of the unicellular green algae *Chlamydomonas,* for example, the dynein is composed of either 2 or 3 heavy chains (there are multiple forms of dynein in the flagellum) and 10 or more smaller polypeptides (Figure16-44). Note that the tail of ciliary dynein binds only to the A tubule and not to the B tubule, which has a slightly different structure. The resulting asymmetry in the arrangement of the dynein molecules is required to prevent a fruitless tug-of-war between neighboring microtubules, which presumably explains why each of the nine outer microtubules is an A-B doublet.

Flagella and Cilia Grow from Basal Bodies That Are Closely Related to Centrioles 29

If the two flagella of the green alga *Chlamydomonas* are sheared from the cell, they rapidly re-form by elongating from structures called *basal bodies.* The basal bodies have the same structure as the centrioles that are found embedded in the center of animal centrosomes. Indeed, in some organisms, basal bodies and centrioles seem to be functionally interconvertible: during each mitosis in *Chlamydomonas,* for example, the flagella are resorbed and the basal bodies move into the cell interior and become embedded in the spindle poles.

Centrioles and basal bodies are cylindrical structures about 0.2 µ wide and 0.4 µ long. Nine groups of three microtubules, fused into triplets, form the wall of the centriole, each triplet being tilted inward like the blades of a turbine (Figure 16-45). Adjacent triplets are linked at intervals along their length, while faint protein spokes can often be seen in electron micrographs to radiate out to each triplet from a central core, forming a pattern like a cartwheel (see Figure 16-45A).

During the formation or regeneration of a cilium, each doublet microtubule of the axoneme grows from two of the microtubules in the triplet microtubules of the basal body so that the ninefold symmetry of the basal body microtubules is preserved in the ciliary axoneme. Autoradiographic evidence suggests that the addition of tubulin and other proteins of the axoneme takes place at the distal tip of the structure, at the plus end of the microtubules. How the central pair of single microtubules forms in the axoneme is not known; there is no central pair in basal bodies or centrioles.

It is not known how the length of flagella and cilia is determined. The length is constant for a given species of cell, and it is not limited by the availability of components or the kinetics of elongation. If one of the two flagella is removed in *Chlamydomonas,* for example, the remaining flagellum begins to shrink while the lost flagellum simultaneously regenerates. Once the shrinking flagellum and the regrowing flagellum reach the same length, they then both grow out together to reach their final characteristic length. This experiment suggests that flagellar length is constantly monitored in some way (Figure16-46).

Centrioles Usually Arise by the Duplication of Preexisting Centrioles 30

The otherwise continuous increase in cell mass throughout the animal cell cycle is punctuated by two discrete duplication events: the replication of DNA and the doubling of the centrosome, which usually has a centriole pair at its center. The two centrioles of the pair are positioned at right angles to each other (Figure16-47). In cultured fibroblasts centriole doubling begins at around the time that DNA synthesis begins: first the two members of a pair separate, and then a daughter centriole is formed perpendicular to each original centriole (see Figure 18-4). An immature centriole contains a ninefold symmetric array of *single* microtubules; each microtubule then presumably acts as a template for the assembly of the triplet microtubule of mature centrioles.

The two centrioles of a pair are not identical: the daughter centriole not only has a distinct orientation but differs also in detailed morphology and function. In many vertebrate cells, for example, one of the two centrioles is distinguished by its ability to nucleate a so-called *primary cilium* - an isolated nonmotile cilium that has no known function.

Parent/daughter differences also exist in basal bodies and can lead to asymmetries in the cytoskeleton. In ciliated protozoa, basal body replication is coordinated with cell division and the stereospecificity of the duplication process is thought to be important for maintaining the orientation of cilia on the cell surface. This was clearly demonstrated in a classic experiment performed in the 1960s on *Paramecium,* a large protozoan whose surface is covered with rows of motile cilia. Normally, all of the rows are aligned with the same polarity through the coordinated replication of basal bodies, which consistently produce daughter basal bodies with the same orientation relative to the cell surface. The array of cilia growing from these basal bodies enables the cell to swim with great efficiency. By grafting experiments, however, it is possible to disturb this pattern and produce some inverted rows of cilia that beat in the direction opposite to that of their neighbors (Figure 16-48). Once established, such altered patterns are passed on from parent to daughter *Paramecium* for more than 100 generations. This form of heredity has nothing to do with DNA: the modified cells inherit a particular pattern of ciliary rows through the stereospecific replication of their basal bodies.

Summary

The axoneme of a cilium and a eucaryotic flagellum contains a cylindrical bundle of nine outer doublet microtubules. Dynein side arms extend between adjacent microtubule doublets and hydrolyze ATP to generate a sliding force between the doublets. Accessory proteins bundle the ring of microtubule doublets together and convert the sliding force into the bending movement that underlies ciliary beating. The complex structure of the ciliary axoneme forms by the self-assembly of its component proteins and is nucleated by a centriole (basal body), which serves as a template for the distinct 9 + 2 pattern of microtubules that forms the core axoneme. The centriole duplicates in a highly controlled process in which a daughter centriole is nucleated from the side of a mother centriole and grows at right angles to it. Oriented replication of basal bodies underlies the heritable pattern of beating cilia on the surface of ciliated protozoa.

Figure 16-40. The contrasting motions of beating cilia and flagella. (A) The beat of a cilium such as that on an epithelial cell from the human respiratory tract resembles the breast stroke in swimming. A fast *power stroke*(stages 1 and 2), in which fluid is driven over the surface of the cell, is followed by a slow *recovery stroke*(stages 3, 4, and 5). Each cycle typically requires 0.1 to

0.2 second and generates a force perpendicular to the axis of the axoneme. For comparison, the wavelike movements of the flagellum of a sperm cell from a tunicate are shown in (B). The cell was photographed on moving film with stroboscopic illumination at 400 flashes per second. Note that waves of constant amplitude move continuously from the base to the tip of a flagellum. The cell is thereby pushed forward, a distinctly different effect from that caused by a cilium. (B, courtesy of C.J. Brokaw.)

The various projections from the microtubules link them together and occur at regular intervals along the length of the axoneme. (A, courtesy of Lewis Tilney.)

Figure 16-42. Microtubule sliding in an axoneme. Electron micrograph of an isolated axoneme (from a cilium of *Tetrahymena*) that has been briefly exposed to the proteolytic enzyme trypsin to loosen the protein ties that normally hold it together. Following treatment with ATP, the individual microtubule doublets slide against each other, as shown schematically in Figure 16-43A. Because there are nine microtubule doublets in the axoneme, the original structure can increase as much as

ninefold in length. (From F.D. Warner and D.R. Mitchell, *J. Cell Biol.* 89:35-44, 1981, by copyright permission of the Rockefeller University Press.)
Figure 16-43. **The bending of an axoneme.** (A) The sliding of outer microtubule doublets against each other causes the axoneme to elongate if the proteins that link the doublets together are removed by proteolysis. (B) If the doublets are tied to each other at one end, the axoneme bends.
Figure 16-44. **Ciliary dynein.** Ciliary dynein is a large protein assembly (nearly 2 million daltons) composed of 9 to 12 polypeptide chains, the largest of which is the heavy chain of 512,000 daltons. (A) The heavy chains are believed to form the major portion of the globular head and stem domains, and many of the smaller chains are clustered around the base of the stem. The base of the molecule binds tightly to an A microtubule in an ATP-independent manner, while the large globular heads have an ATP-dependent-binding site for a B microtubule (see Figure 16-41). When the heads hydrolyze their bound ATP, they move toward the minus end of this second microtubule, thereby producing a sliding force between the adjacent microtubule doublets in a cilium or flagellum (see Figure 16-43). The three-headed form of ciliary dynein, formed from three heavy chains, is illustrated here. (B) Schematic diagram of the rows of cilia on the surface of a normal *Paramecium* and on a *Paramecium* in which rows of cilia have been inverted so that they beat in the opposite direction. Such altered patterns are propagated indefinitely as the *Paramecium* divides, even though the information in the DNA is unchanged. (A, courtesy of Sidney Tamm.)

Actin Filaments [31]

Introduction

All eucaryotic species contain actin. This cytoskeletal protein is the most abundant protein in many eucaryotic cells, often constituting 5% or more of the total cell protein. Vertebrate skeletal muscle cells are the usual source of actin for experiments done *in vitro,* as about 20% of their mass is actin. If dry powdered muscle is treated with a very dilute salt solution, the *actin filaments* dissociate into their actin subunits. Each actin molecule is a single polypeptide 375 amino acids long that has a molecule of ATP tightly associated with it.

Actin filaments can form both stable and labile structures in cells. Stable actin filaments form the core of microvilli and are a

crucial component of the contractile apparatus of muscle cells. Many cell movements, however, depend on labile structures constructed from actin filaments. In this section we focus on the question of how the cell controls the assembly of dynamic actin filaments from pools of soluble actin subunits in the cytosol.

Actin Filaments Are Thin and Flexible 32

Actin filaments appear in electron micrographs as threads about 8 nm wide. They consist of a tight helix of uniformly oriented actin molecules (also known as globular actin, or *G actin*) (Figure16-49). Like a microtubule, an actin filament is a polar structure, with two structurally different ends - a relatively inert and slow-growing *minus end* and a faster-growing *plus end.* Because of the oriented "arrowhead" appearance of the complex formed between actin filaments and the motor protein myosin, which we describe later, the minus end is also referred to as the "pointed end" and the plus end as the "barbed end." The three-dimensional structure of the actin molecule has been solved by x-ray diffraction analysis, and this information has been used to deduce the structure of an actin filament at the level of individual amino acids (Figure16-50).

Some lower eucaryotes, such as yeasts, have only one actin gene, encoding a single protein. All higher eucaryotes, however, have several isoforms encoded by a family of actin genes. At least six types of actin are present in mammalian tissues; these fall into three classes, depending on their isoelectric point. Alpha actins are found in various types of muscle, whereas β and γ actins are the principal constituents of nonmuscle cells. Although there are subtle differences in the properties of different forms of actin, the amino acid sequences have been highly conserved in evolution, and all assemble into filaments that are essentially identical in most tests performed *in vitro.*

The total length of all of the actin filaments in a cell is at least 30 times greater than the total length of the microtubules, reflecting a fundamental difference in the way these two cytoskeletal polymers are organized and function in cells. Actin filaments are thinner and more flexible, and usually much shorter, than microtubules. We shall see that actin filaments rarely occur in isolation in the cell but rather in cross-linked aggregates and bundles, which are much stronger than the individual filaments.

Actin and Tubulin Polymerize by Similar Mechanisms 33

Polymerization of pure actin *in vitro* requires ATP as well as both monovalent and divalent cations, which are usually K^+ and Mg^{2+}. The reaction is often studied either by observing the change in the light emission from a fluorescent probe that has been covalently attached to the actin or by monitoring the large increase in viscosity caused by the polymerization. When K^+ and Mg^{2+} are added to monomeric actin in the presence of ATP, there is initially a lag phase, as new filaments are nucleated, and then a rapid polymerization phase, as the short filaments elongate. The lag in polymerization with pure actin is due to the same kinetic barrier to nucleation that we discussed for tubulin polymerization (see Figure 16-23). For actin the rate of nucleation is proportional to the cube of the actin concentration, suggesting that the nucleating structure for the spontaneous polymerization of pure actin is a trimer of actin molecules. By contrast, the rate at which each filament elongates is proportional, as for microtubules, to the concentration of the free subunit, indicating that the filament elongates by the addition of one actin molecule at a time.

The polymerization rate is different at the two ends of the actin filament, and this difference is greater than for microtubules: the plus (or barbed) end of actin filaments polymerizes at up to 10 times the rate of the minus (or pointed) end. The *critical concentration* for actin polymerization - that is, the free actin monomer concentration at which the proportion of actin in polymer stops increasing - is around 0.2 micromolar (about 8 μg/ml). This concentration is very much lower than the concentration of unpolymerized actin in a cell, and the cell has evolved special mechanisms to prevent most of its monomeric actin from assembling into filaments, as we discuss later.

Shortly after polymerization, the terminal phosphate of the ATP bound to the actin molecule is hydrolyzed, leaving the resulting ADP trapped in the polymer. The hydrolysis of ATP during actin polymerization is analogous to the GTP hydrolysis that accompanies microtubule assembly, but in the case of actin we can understand the conformational changes involved because the three-dimensional structure of actin is known. The actin molecule is clam-shaped and binds ATP in the crevice between its two halves; like a clam shell, it can open and close. When actin polymerizes, the shell is clamped shut by interactions between amino acids on both lips of the shell and the back side of the next subunit in the polymer. It is thought that ATP hydrolysis is triggered by the closing of the clam shell as each actin molecule is incorporated into the filament, leaving ADP trapped inside (Figure 16-51).

ATP Hydrolysis Is Required for the Dynamic Behavior of Actin Filaments 34

The role of ATP hydrolysis in actin polymerization is similar to the role of GTP hydrolysis in tubulin polymerization, as explained in Panel16-1 (pp. 824-825). In neither case is hydrolysis required to form the filament; instead, it serves to weaken the bonds in the polymer and thereby promote depolymerization. There are, however, important differences in the behavior of the bound nucleotide in the subunits of these two polymers. An especially interesting difference is that ATP-ADP exchange (the replacement of bound ADP by ATP) is relatively slow for free actin (half-time of minutes), while GTP-GDP exchange is very rapid for free tubulin (half-time of seconds); thus, when actin molecules are released by disassembly of a filament, there is a relatively long delay before they can be re-used in filament assembly. In principle, this property of actin allows the cell to maintain a high cytosolic concentration of unpolymerized actin molecules in the form of ADP actin; furthermore, the ADP-actin monomer in a cell can be stabilized by binding to another protein, and this could provide a way to regulate actin polymerization.

The effect of ATP hydrolysis on actin is subtle, and there are still many questions about its precise consequences for the cell. Actin filaments, unlike microtubules, do not seem to show drastic dynamic instability *in vitro.* Instead, they can engage in an interesting dynamic behavior called *treadmilling,* which occurs when actin molecules are added continually to the plus end of the filament and are lost continually from the minus end, with no net change in filament length (see Panel 16-1, pp. 824-825). Treadmilling, like dynamic instability, is a nonequilibrium behavior that requires an input of energy, which is provided by the ATP hydrolysis that accompanies polymerization. This phenomenon is thought to contribute to the rapid exchange of the subunits of actin filaments that takes place in cells.

It is remarkable that actin and tubulin have both evolved nucleoside tri-phosphate hydrolysis for the same basic reason - to enable them, having polymerized, to depolymerize readily. Actin and tubulin are completely unrelated in amino acid sequence: actin is distantly related in structure to the glycolytic enzyme hexokinase, whereas tubulin is distantly related to a large family of GTPases that includes the heterotrimeric G proteins and monomeric GTPases such as Ras. (Both types of structures are discussed in detail in Chapter 5.) The convergent evolution of the capacity for nucleotide hydrolysis in actin and tubulin demonstrates just how important it is to microtubule and actin filament function: the dynamic assembly and disassembly of these cytoskeletal polymers that hydrolysis makes possible lies at the heart of cytoplasmic organization.

The Functions of Actin Filaments Are Inhibited by Both Polymer-stabilizing and Polymer-destabilizing Drugs 35

Drugs that stabilize or destabilize actin filaments provide important tools to investigate their dynamic behavior in cells. The *cytochalasins* are fungal products that prevent actin from polymerizing by binding to the plus end of actin filaments. The *phalloidins* are toxins isolated from the *Amanita* mushroom that bind tightly all along the side of actin filaments and stabilize them against depolymerization. (One remedy for *Amanita* mushroom poisoning is to eat a large quantity of raw meat: the high concentration of actin filaments in the muscle tissue binds the phalloidin and thereby reduces its toxicity.) Both of these drugs cause dramatic changes in the actin cytoskeleton. We saw earlier for microtubules that both polymer-destabilizing drugs such as colchicine and polymer-stabilizing drugs such as taxol are toxic to cells, and the same is true for drugs affecting the stability of actin filaments, indicating that the function of actin filaments also depends on a dynamic equilibrium between the filaments and actin monomer.

Cytochalasin has found its greatest use in studying cell locomotion. In particular, the leading edge of a moving cell contains actin filaments that are continually polymerizing and are therefore very sensitive to cytochalasin. In most moving cells cytochalasin causes the leading edge rapidly to retract. If the plasma membrane of the leading edge is very firmly attached to the substratum, however, cytochalasin causes the actin filaments to retract but leaves the membrane behind, stuck to the substratum (Figure16-52).

Phalloidin is widely used, as a fluorescent derivative, to stain actin filaments in fixed cells, and it also has a profound effect on living cells. When it is microinjected into a living fibroblast, for example, it drives all of the actin monomer into filaments at random positions in the cytoplasm, causing a drastic blebbing and contraction that often destroys the cell.

The Actin Molecule Binds to Small Proteins That Help to Control Its Polymerization 36

In a fibroblast cell approximately 50% of the actin is in filaments and 50% is in monomer. The monomer concentration is typically 50-200 micromolar (2-8 mg/ml) in a variety of cell types; this is surprisingly high, given the low critical concentration of pure actin (less than 1 micromolar), and it reflects the presence of special proteins that bind to the actin molecule and inhibit

its addition to the ends of actin filaments. The most abundant of these actin-monomer-binding proteins in many cells is thymosin, an unusually small protein with a molecular weight of about 5000. In the cells in which it has been most carefully studied (blood platelets and neutrophils), it is present in concentrations that are sufficient to sequester all of the monomeric actin. It is not clear how this protein inhibits actin polymerization: it could sterically block polymerization by covering a site where one monomer binds to another, or it could trap ADP on actin by inhibiting ADP-ATP exchange, thereby making the actin molecule unlikely to polymerize (Figure 16-53).

Another actin-monomer-binding protein is profilin, which is present in all cells and is thought to play a part in controlling actin polymerization in response to extracellular stimuli. Profilin, which in many cells is largely associated with the plasma membrane, accelerates the exchange of ATP for ADP when bound to actin monomers and is thought to play a part in promoting the regulated polymerization of actin during cell movement, although this is still controversial. A mutant yeast cell that is deficient in profilin has a deficit of actin filaments, which supports a role for this molecule in stimulating the polymerization of actin.

In addition to thymosin and profilin, cells contain other abundant proteins that are able to bind actin monomers, and some of these, such as *actin-depolymerizing factor (ADF),* inhibit the assembly of actin into filaments. Evidently cells have a variety of mechanisms, the details of which are not yet understood, by which they hold stocks of actin monomer in reserve in order to assemble actin filaments only when and where they are needed.

Many Cells Extend Dynamic Actin-containing Microspikes and Lamellipodia from Their Leading Edge 37

Dynamic surface extensions containing actin filaments are a common feature of animal cells, especially when the cells are moving or changing shape. The large, free-living cells of *Amoeba proteus,*for example, produce *pseudopodia* - stubby distensions of the actin cortex - with which they walk over surfaces. Many cells in vertebrate tissues are also capable of independent migration over surfaces, especially when put into tissue culture. The leading edge of a crawling fibroblast regularly extends a thin, sheetlike process known as a lamellipodium, which contains a dense meshwork of actin filaments. Many cells also extend thin, stiff protrusions called *microspikes,* which are about 0.1 μ wide and 5 to 10 μ long and contain a loose bundle of about 20 actin filaments oriented with their plus ends pointing outward (see Figure 16-9). The growing tip (growth cone) of a developing nerve cell axon extends even longer microspikes, called *filopodia,* which can be up to 50 μ long.

A lamellipodium can be viewed as a two-dimensional version of a micro-spike; indeed, short microspikes often project from the edges of a lamellipodium. When carefully fixed and stained for examination in an electron microscope, the actin filaments in the lamellipodium of a moving cell appear to be more organized than they are in other regions of the cell cortex. Many of the filaments project outward in an orderly array, with their plus ends inserted into the leading edge of the plasma membrane (Figure16-54). The lamellipodium behaves as a structural unit; if it fails to adhere to the substratum, it is usually swept rapidly backward over the top of the cell as a "ruffle" (Figure16-55).

Both lamellipodia and microspikes are motile structures that can form and retract with great speed. As we discuss next, it is thought that microspikes and lamellipodia are generated by local actin polymerization at the plasma membrane and that such actin polymerization can rapidly push out the plasma membrane without tearing it.

The Leading Edge of Motile Cells Nucleates Actin Polymerization 38

When the behavior of actin filaments at the leading edge is studied by labeling a small patch of actin and following its movement, it is seen that actin is continually moving back toward the cell body at a speed of about 1 μm/minute, suggesting that actin is continuously polymerizing near the tip of the leading edge and continuously depolymerizing at more internal sites (Figure16-56). This highly dynamic behavior of actin filaments at the leading edge is thought to be crucial for such processes as directed cell locomotion and chemotaxis. It gives the impression that the leading edge is propelling itself forward by pushing actin filaments backward.

The leading edge of a cell seems to organize actin filaments much as a centrosome organizes microtubules but with one crucial difference: it not only nucleates the growth of new filaments, but also seems to be the site at which monomers are added subsequently to enable the filaments to elongate. This role can be demonstrated by gently lysing a fibroblast and then adding rhodamine-tagged actin monomers, which are seen to polymerize preferentially at the tip of the leading edge (Figure 16-57). Moreover, if the actin filaments in a cell are decorated to reveal their polarity, the fast-growing plus end of each actin filament is found to be attached to the membrane at the leading edge.

There are many unanswered questions about the mechanism by which the leading edge nucleates actin filament polymerization. Does the leading edge hold on to the plus end of a filament that it nucleates, for example, or does it nucleate a new filament and then quickly release it? Because of the continuous backward movement of actin (see Figure 16-56), any model that postulates that the leading edge holds onto actin filament ends would require that the filaments in the lamellipodium undergo continuous treadmilling by insertion of actin monomers at the site where the filaments are held by the membrane. In an alternative model, individual actin filaments are released and move away from the membrane (presumably as a cross-linked meshwork) soon after they form (Figure16-58).

The rapid assembly of actin filaments at the leading edge of a moving cell requires that actin monomers be released from the actin-monomer-binding proteins that normally restrain their polymerization into filaments. We discuss below how signals in the cell's environment may regulate the release of actin monomers for polymerization at the tip of the leading edge.

Some Pathogenic Bacteria Use Actin to Move Within and Between Cells 39

Listeria monocytogenes, a bacterium that causes a severe form of food poisoning, has provided unexpected insights into the mechanism by which the local polymerization of actin is controlled in cells. This pathogenic bacterium enters cells by being phagocytosed; it then escapes into the host cell cytosol by secreting enzymes that break down the membrane of the phagosome. Once in the cytosol, the bacteria not only grow and divide, but they also spread to adjoining cells by mobilizing the actin-based motility system of the host cell. By nucleating actin filaments at one region of its surface, an individual bacterium moves through the cytosol at rates of 10 μm/minute or more, laying down a tail of actin filaments behind it. When it collides with the plasma membrane of the host cell, it keeps moving outward, inducing the formation of a long, thin microspike with a bacterium at its tip. This projection is often engulfed by a neighboring cell, allowing the bacterium to enter its cytoplasm without exposure to the extracellular environment, thereby avoiding recognition by antibodies produced by the host (Figure 16-59).

This form of movement suggests that the bacterium may be using actin to propel itself forward in the same way that the plasma membrane of a eucaryotic cell uses actin to propel itself forward during the formation of a normal microspike or lamellipodium.

If the actin filaments in the tail behind a *Listeria* bacterium migrating in the cytosol are marked with a fluorescent tag and observed by fluorescence microscopy, they are found to be stationary. The filaments form at the rear of the bacterium and are left behind like a rocket trail as the bacterium advances, depolymerizing again within a minute or so as they encounter depolymerizing factors in the cytosol. Assembly is induced by a specific protein on the surface of the bacterium that acts indirectly by sequestering host-cell proteins, including profilin. Since bacterium-induced movement can be reproduced in a concentrated cell-free extract, details of the mechanism should emerge from biochemical studies. These details should help us to understand how actin nucleation and polymerization occur in the microspikes and lamellipodia of a normal, uninfected cell and how these processes power the forward movement of the cell.

Polymerization of Actin in the Cell Cortex Is Controlled by Cell-Surface Receptors 40

The production of movement is of little use unless it is properly directed according to the environment. As discussed earlier, the dynamic cortical meshwork of actin filaments rearranges rapidly in response to signals from outside the cell that impinge on the plasma membrane. The actin cytoskeleton can therefore be considered to be an integral part of the cell's signal-transduction systems, discussed in Chapter 15: when certain growth factors are added to the medium bathing quiescent cells in culture, for example, they immediately cause actin-containing lamellipodia to form and move over the cell surface.

The response of the actin cortex to external signals conveying spatial information can be highly localized. We considered one example earlier when we discussed the polarization of a cytotoxic T cell that is induced by contact with the target cell it subsequently kills (see Figure16-11). A signal-induced polarization of the actin cortex also occurs in animal cells that are capable of *chemotaxis,* which is defined as movement in a direction controlled by a gradient of a diffusible chemical sensed by the cell. One well-studied example is the chemotactic movement of certain white blood cells (*neutrophils*) toward a source of bacterial infection. Neutrophils have receptor proteins on their surface that enable them to detect the very low concentrations of the N-formylated peptides derived from bacterial proteins (only procaryotes begin protein synthesis with N-formyl methionine). The neutrophils can be guided to their targets by a difference of only 1% in the concentration of these diffusible peptides on one side of the cell versus the other.

Another example of chemotaxis is provided by the cellular slime mold *Dictyostelium discoideum.* These eucaryotes live on the forest floor as independent motile cells called *amoebae,* which feed on bacteria and yeast and, under optimal conditions, divide every few hours. When their food supply is exhausted, the amoebae stop dividing and gather together to form tiny (1-2 mm), multicellular, wormlike structures, which crawl about as glistening slugs and leave trails of slime behind them (Figure 16-60). As the slug migrates, the cells begin to differentiate, initiating a process that ends with the production of a tiny plantlike structure consisting of a stalk and a *fruiting body* some 30 hours after the beginning of aggregation (Figure 16-61). The fruiting body contains large numbers of spores, which can survive for long periods of time even in extremely hostile environments. Only when conditions are favorable do the spores germinate to produce the free-living amoebae that start the cycle again.

The *Dictyostelium* amoebae aggregate by chemotaxis, migrating toward a source of cyclic AMP, which is secreted by the starved amoebae. Like neutrophils, the amoebae reorient their leading edge in order to migrate up a shallow chemoattractant gradient. And when they are exposed to a local source of cyclic AMP leaking from a micropipette, they extend actin-containing processes directly toward the pipette (Figure 16-62). This experiment shows that eucaryotic chemotaxis involves detecting a spatial gradient of attractant concentration directly, in contrast to bacterial chemotaxis, which uses a time-dependent variation in concentration to detect gradients, as discussed in Chapter 15.

The cytoskeletal reaction of *Dictyostelium* amoebae to cyclic AMP can be examined by making lysates of these cells very shortly after bulk stimulation with cyclic AMP in solution. As shown in Figure16-63, a dramatic burst of actin polymerization occurs 5-10 seconds after adding cyclic AMP, which corresponds to the time required for flattening of the cells on the substratum. Between 20 and 40 seconds after the pulse of cyclic AMP, actin depolymerizes and the cells round up. Then there is a more prolonged burst of actin polymerization as actin-binding proteins are recruited into the cytoskeleton from soluble pools; during this latter period the cells that respond to cyclic AMP begin to extend lamellipodia and other actin-rich processes.

Heterotrimeric G Proteins and Small GTPases Relay Signals from the Cell Surface to the Actin Cortex 41

How does cyclic AMP binding to its receptor in *Dictyostelium* amoebae trigger massive actin polymerization? The receptor is known to activate a heterotrimeric G protein. The cytoplasm contains a reservoir of actin monomers, which, as we saw earlier, are stabilized by actin-monomer-binding proteins. Stimulation of actin polymerization requires that these actin molecules be made available in a form that can polymerize and also that nucleation sites for actin filaments be provided to overcome the kinetic barrier to nucleation. The actin-monomer-binding protein profilin binds tightly to the inositol phospholipids in the plasma membrane that generate intracellular signals in response to extracellular ligands (see Figure 15-30). According to one hypothesis, activation of this signaling pathway (which occurs via a heterotrimeric G protein) could release profilin from the plasma membrane into the cytosol. Profilin can catalyze ATP-ADP exchange on actin *in vitro,* and so when it is released from the plasma membrane, it may rapidly convert inactive ADP actin to active ATP actin to induce the local formation of actin filaments.

G proteins have also been implicated in the signaling processes that activate the actin cortex during the chemotactic response of neutrophils and the activation of blood platelets. There is evidence that two Ras-related small GTPases known as Rho and Rac act downstream; these proteins have been shown to have distinct effects on the actin cytoskeleton in fibroblasts. Microinjection of Rac protein into cultured cells causes a dramatic increase in the formation of lamellipodia within 5 minutes. Moreover, a dominant-negative mutant form of Rac inhibits the formation of lamellipodia normally induced by various growth factors, indicating that this response to growth factors depends on Rac. Microinjection of Rho protein leads to the appearance of large bundles of actin filaments known as *stress fibers* and to the enhancement of *focal contacts,* where the cell is attached to the substratum externally and stress fibers are anchored internally (as we discuss later). Rho is also thought to be needed to assemble the contractile ring during cell division. Thus Rac and Rho not only control the polymerization of actin into filaments but also govern the organization of these filaments into specific types of structures.

Mechanisms of Cell Polarization Can Be Analyzed in Yeast Cells 42

Further clues to how cells may orient the activities of their cytoskeleton have come from the behavior of yeast cells. The ease of genetic analysis in yeasts has made them an important source of fundamental information about biological mechanisms that are common to all eucaryotic cells. In particular, studies on the interactions between yeast cells during mating have begun to identify mechanisms by which eucaryotic cells become structurally polarized. In the budding yeast *Saccharomyces cerevisiae,* cells of two mating types, a and α, secrete hormones, known as a-factor and α-factor, respectively. These hormones act by binding to cell-surface receptors that belong to the large G-protein-linked receptors discussed in Chapter 15. One consequence of the binding of α-factor to its receptors on an a-cell is to cause the cell to become polarized so that it adopts a shape known as

a "shmoo" (Figure16-64). If an α-factor gradient is present, the shmoo tip is directed toward the highest concentration of this signaling molecule.

During this polarization response the yeast cell undergoes cytoskeletal reorganizations that parallel those of an animal cell that is becoming polarized. Actin filaments congregate at the pointed shmoo tip, where they are thought to direct the local secretion of cell-wall components - possibly by directing the transport vesicles carrying these components to the shmoo tip. At the same time, the microtubule organizing center (in this case the *spindle pole body,* see Figure 17-24) moves to the side of the nucleus that is closest to the shmoo tip, and microtubules extend from it toward the tip. By screening for mutant cells that fail to form a shmoo during mating, many of the genes involved in yeast-cell polarization are being identified. It is likely that some of the proteins that these genes encode will also be involved in polarizing an animal cell.

Summary

Actin is a highly conserved cytoskeletal protein that is present at high concentrations in nearly all eucaryotic cells. Purified actin exists as a monomer in low ionic strength solutions and spontaneously assembles into actin filaments on addition of salt provided ATP is present. As with tubulin, the polymerization of actin is a dynamic process that is regulated by the hydrolysis of a tightly bound nucleotide (ATP in this case). In cells, approximately half of the actin is kept in a monomeric form through its binding to small proteins such as thymosin. In the cortex of animal cells, actin molecules continually polymerize and depolymerize to generate cell-surface protrusions such as lamellipodia and microspikes. Polymerization can be regulated by extracellular signals binding to cell-surface receptors that act through heterotrimeric G proteins and the small GTPases Rac and Rho.

Figure 16-51. The trapping of ADP in an actin filament. An actin molecule has a structure that is related to that of the ubiquitous enzyme hexokinase (see Figure 5-2), with two domains that are hinged around an ATP-binding site. The bound ATP is hydrolyzed to ADP immediately after the molecule becomes incorporated into an actin filament. In order for the ADP to be replaced by ATP, the hinge would have to open. But in the actin filament the two domains in each actin molecule are held together by interactions with neighboring subunits, thereby keeping the hinge closed and trapping the ADP in the actin filament until the filament depolymerizes.

Actin-binding Proteins [43]

Introduction

Actin is involved in a remarkably wide range of structures, from stiff and relatively permanent extensions of the cell surface to the dynamic three-dimensional networks at the leading edge of a migrating cell. Very different structures based on actin coexist in every living cell. In every case the fundamental structure of the actin filament is the same. It is the length of these filaments, their stability, and the number and geometry of their attachments (both to one another and to other components of the cell) that varies in different cytoskeletal assemblies. These properties in turn depend on a large retinue of actin-binding proteins, which bind to actin filaments and modulate their properties and functions.

In this section we describe some of the most important actin-binding proteins and the structures they form. Many of these are found at the perimeter of the cell in the actin-rich layer just beneath the plasma membrane called the *cell cortex*. This layer gives

an animal cell mechanical strength and enables it to perform a variety of surface movements, such as phagocytosis, cytokinesis (cell division), and cell locomotion.

A Simple Membrane-attached Cytoskeleton Provides Mechanical Support to the Plasma Membrane of Erythrocytes 44

As noted in Chapter 10, the proteins spectrin and ankyrin were first discovered as prominent components of the membrane-associated cytoskeleton of mammalian red blood cells (erythrocytes). These unusual cells have lost their nucleus and internal membranes, and so the plasma membrane is the only membrane. It is supported by a two-dimensional network of spectrin tetramers that are connected at their ends by very short actin filaments. The spectrin is linked to the cytoplasmic tail of an abundant transmembrane carrier protein (band 3) by means of ankyrin bridges (see Figure 10-26). Close relatives of spectrin (also called *fodrin*) and of ankyrin are found in the cortex of many vertebrate cells. Thus the detailed arrangement of proteins in the erythrocyte cortex provides a simplified model for the actin-based cytoskeletal network that supports the plasma membrane in all other animal cells.

The actin filaments in the erythrocyte cortex are very short, acting only as cross-linking elements between spectrin tetramers. Those in a more typical cell cortex, by contrast, are much longer and thus project into the cytoplasm, where they form the basis of a three-dimensional actin filament network. It is uncertain whether ankyrinlike molecules anchor these more typical cortical arrays to the plasma membrane, although in some epithelial cells the transmembrane Na^+/K^+ ATPase (discussed in Chapter 11) is thought to link the plasma membrane to the cortical actin filament network through such molecules.

The cortical actin filament network generally determines the shape and mechanical properties of the plasma membrane. Many types of membrane attachments are needed for actin filaments to perform their various functions in the cortex; coupling to transmembrane proteins through ankyrin is only one. More dynamic attachments also exist, but the proteins that mediate them are just beginning to be characterized.

Cross-linking Proteins with Different Properties Organize Particular Actin Assemblies 43

The cortical actin filaments in animal cells are organized into three general types of arrays (Figure 16-65). In *parallel bundles,* as found in microspikes and filopodia, the filaments are oriented with the same polarity and are often closely spaced (10-20 nm apart). In *contractile bundles,* as found in stress fibers and in the contractile ring that divides cells in two during mitosis, filaments are arranged with opposite polarities; they are more loosely spaced (30-60 nm apart) and contain the motor protein myosin-II (discussed later). In the *gel-like networks* of the cell cortex the filaments are arranged in a relatively loose, open array with many orthogonal interconnections. How are these different arrangements of the same actin filament generated and maintained within a single cell? While we do not know the complete answer, *actin filament cross-linking proteins* are clearly of central importance.

Actin filament cross-linking proteins can be divided into two classes - *bundling proteins* and *gel-forming proteins* - according to their effect on pure actin filaments *in vitro.* Bundling proteins cross-link actin filaments into a parallel array and are important for forming both the tight parallel arrays and the looser contractile bundles of actin filaments described above. Gel-forming proteins, by contrast, cross-link actin filaments at crosswise intersections, creating loose gels.

Fimbrin and α-*actinin* are widely distributed bundling proteins. Fimbrin is enriched in the parallel filament bundles at the leading edge of cells, particularly in microspikes and filopodia, and it is thought to be responsible for the tight association of actin filaments in these arrays. The second actin-bundling protein, α-actinin, is concentrated in stress fibers, where it is thought to be partly responsible for the relatively loose cross-linking of actin filaments in these contractile bundles; it also helps to form the anchorage for the ends of stress fibers where they terminate on the plasma membrane at *focal contacts.* As explained later, myosin is the motor protein in stress fibers and other contractile arrays that is responsible for their contractility. It seems likely that the very close packing of actin filaments caused by fimbrin excludes myosin, whereas the looser packing caused by α-actinin allows myosin molecules to enter; likewise, the very different spacing causes each of the two bundling proteins to exclude the other (Figure 16-66).

Filamin is a widely distributed gel-forming protein. Although it is not present in stress fibers or the leading edge, it is enriched elsewhere in the cortex. Filamin is a homodimer that promotes the formation of a loose and highly viscous network by clamping together two actin filaments that cross each other (Figure16-67). It is an abundant protein in many animal cells, reflecting the prevalence of the loose-network type of actin organization.

Actin-binding Proteins with Different Properties Are Built Up from Similar Modules [45]

Fimbrin, α-actinin, filamin, and spectrin each contain two actin-filament-binding domains, which is not surprising given that each needs to cross-link two filaments. Unexpectedly, however, in all of these proteins the actin-binding domains have a similar structure. The length and flexibility of the spacer sequences that separate the two actin-binding sites differ in the four proteins, and these differences determine the different properties of the four cross-linkers. Evidently, these proteins have diverged from a common ancestral actin-binding protein by adding different spacer sequences (Figure 16-68).

Gelsolin Fragments Actin Filaments in Response to Ca^{2+} Activation [46]

Extracts prepared from many types of animal cells form a gel in the presence of ATP when they are warmed to 37°C. Although this *gelation* depends on both actin filaments and a cross-linking protein such as filamin, the gels exhibit more complex behavior than simple mixtures of actin filaments and filamin. If the Ca^{2+} concentration is raised above $10^{-7}M$, for example, the semisolid actin gel begins to liquefy - a process known as *solation* - and regions of the solating gel show vigorous local streaming when examined under a microscope. Clearly, there must be components besides actin and filamin in the extracts to account for this behavior. These components are likely to be involved in the *cytoplasmic streaming* observed in some large cells, where vigorous flowing movements are required to maintain an even distribution of metabolites and other cytoplasmic components. These movements seem to be associated with sudden local changes in the cytoplasm from a solid gel-like consistency to a more fluid state.

A number of proteins have been isolated from cell extracts that, when added to a gel formed from purified actin filaments and filamin, cause it to change to a more fluid state in the presence of Ca^{2+}. The best characterized of these is gelsolin, which, when activated by the binding of Ca^{2+}, severs an actin filament and forms a cap on the newly exposed plus end of the filament, thus breaking up the cross-linked network of actin filaments. Similar proteins are found in the cortex of many types of vertebrate cells; these *severing proteins* are activated by concentrations of Ca^{2+} (about 10^{-6} M) that occur only transiently in the cytosol.

One of the postulated functions of severing proteins is to help loosen or liquefy the cell cortex locally to allow membrane fusion events. When a phagocytic white blood cell engulfs a microorganism, for example, the resulting phagosome is initially coated on its cytoplasmic side with a thick network of actin filaments originating from the cortex. In order for this phagosome to fuse with lysosomes, these actin filaments must be depolymerized to allow intimate contact between the phagosome and lysosome membranes. This removal of actin can be prevented by artificially reducing the Ca^{2+} ion concentration, and it is thought that removal may depend on a local rise in Ca^{2+} through the action of gelsolin (or a similar protein). Gelsolin is also thought to be required for a cell to crawl along a substratum, although its exact role in this process is not clear.

While a mixture of purified actin filaments, filamin, and gelsolin is capable of undergoing Ca^{2+}-dependent gel-to-sol transitions, it will not contract or show the streaming movements displayed by the cruder actin-rich gels obtained from cells. These activities require another type of actin-binding protein - the motor protein myosin. If myosin is selectively removed from the crude actin-rich gels, contractions and streaming no longer occur, suggesting that an interaction between actin and myosin generates the force for cytoplasmic streaming.

Multiple Types of Myosin Are Found in Eucaryotic Cells [47]

Time-lapse cinematography reveals the cortex of cells to be continually moving. In the previous section we emphasized the importance of actin filament polymerization and depolymerization in these movements, but, as with microtubules, motor proteins are also important. All of the actin filament motor proteins identified to date belong to the *myosin* family. Myosins were originally isolated on the basis of their ability to hydrolyze ATP to ADP and P_i when stimulated by binding to actin filaments, and this remains a useful biochemical criterion for their identification. It is also possible to observe the motor activity of myosins directly by adsorbing them onto a glass coverslip: when fluorescent actin filaments are added together with ATP, the filaments can be observed with a fluorescence microscope to glide over the myosin-coated glass surface. Novel myosins have also been identified by DNA sequencing even before being characterized biochemically or functionally.

Myosin, along with actin, was first discovered in skeletal muscle, and much of what we know about the interaction of these two proteins was learned there. Muscle myosin belongs to the myosin-II subfamily of myosins, all of which have two heads and a long, rodlike tail: each head has both ATPase and motor activity. A myosin-II protein is composed of two identical heavy

chains, each of which is complexed to a pair of light chains. The amino-terminal portion of the heavy chain forms the motor-domain head, while the carboxyl-terminal half of the heavy chain forms an extended α helix. Two heavy chains associate by twisting their α-helical tail domains together into a coiled-coil to form a stable dimer that has two heads and a single rodlike tail (Figure16-69).

A major role of the rodlike tail of myosin-II is to allow the molecules to polymerize into bipolar filaments. This polymerization is crucial for the function of myosin-II, which is to move groups of oppositely oriented actin filaments past each other, as seen most clearly in muscle contraction. Myosin-II is relatively abundant in the cell cortex; in fibroblasts, for example, there is roughly one myosin-II molecule per 100 actin molecules. Myosin-II filaments in the contractile ring are responsible for driving membrane furrowing during cell division, as discussed in Chapter 18, and they are thought to generate tension in stress fibers as well as much of the cortical tension that keeps the cell surface taut. Their role in muscle contraction is described at the end of the chapter.

In addition to myosin-II, which is generally the most abundant myosin in the cell, nonmuscle cells contain various smaller myosins, the best characterized of which is called myosin-I (Figure 16-70). Myosin-I is thought to be more like the original, more primitive myosin from which myosin-II evolved. A single cell can contain multiple smaller myosins, each encoded by a different gene and performing a distinct function; the cellular slime mold *Dictyostelium,* for example, has at least nine. The common feature of all myosins is a conserved motor domain (motor head); the other domains vary from myosin to myosin and determine the specific role of the molecule in the cell. Thus myosin tails may have a membrane-binding site and/or a site that binds to a second actin filament independently of the head domain. Depending on its tail, a myosin molecule can move a vesicle along an actin filament, attach an actin filament to the plasma membrane, or cause two actin filaments to align closely and then slide past each other (Figure 16-71).

All known myosins hydrolyze ATP to move along actin filaments from the minus end toward the plus end. Given the importance of oppositely directed motor proteins that move along microtubules (see Figure16-37), it would not be surprising to discover an additional class of motor proteins that move toward the minus end of an actin filament.

There Are Transient Musclelike Assemblies in Nonmuscle Cells 48

In higher eucaryotic cells, organized contractile bundles of actin filaments and myosin-II filaments often form transiently to perform a specific function and then disassemble. Most notably, cell division in animal cells is made possible by a beltlike bundle of actin filaments and myosin-II filaments known as the contractile ring. This ring appears beneath the plasma membrane during the M phase of the cell-division cycle; forces generated by it pull inward on the plasma membrane and thereby constrict the middle of the cell, leading to the eventual separation of the two daughter cells by a process known as cytokinesis (Figure16-72). The contractile ring must be assembled from actin, myosin, and other proteins at the start of cell division, a process that can be monitored by staining dividing cells with fluorescent anti-myosin antibodies. In sea urchin eggs that are about to divide, for example, myosin-II molecules are at first distributed evenly beneath the plasma membrane and then move to the equatorial region as the contractile ring forms. Once cell division is complete, the myosin-II molecules disperse. It is not known how this process is controlled, but it seems likely that Ca^{2+} is involved, as Ca^{2+}-dependent phosphorylation of myosin-II both increases its interaction with actin and promotes its assembly into short bipolar filaments (Figure 16-73).

Stress fibers, which are prominent components of the cytoskeleton of fibroblast cells in culture (see Figure 16-72), are a second example of a temporary contractile bundle of actin filaments and myosin-II. Although smaller and less highly organized, they resemble the tiny *myofibrils* in muscle (discussed later) in their structure and function. At one end they insert into the plasma membrane at special sites called *focal contacts,* where the external face of the cell is closely attached to the extracellular matrix (Figure16-74); at the other end they insert into a second focal contact or into a meshwork of intermediate filaments that surrounds the cell nucleus. Stress fibers form in response to tension generated across a cell and are disassembled at mitosis when the cell rounds up and loses its attachments to the substratum. They also disappear rapidly if tension is released by suddenly detaching one end of the stress fiber from the focal contact by means of a laser beam. Stress fibers within fibroblasts in tissues are thought to allow the cells to exert tension on the matrix of collagen surrounding them - an essential process in both wound healing and morphogenesis (see Figure19-48). In epithelia, actin filament bundles spanning the cytoplasm from one cell-cell junction to another can appear and disappear in a similar way; such filament bundles, linked end to end via the cell-cell junctions, can form cables that transmit and generate tension along lines of particular stress in the multicellular sheet.

Not all contractile assemblies of actin filaments and myosin in nonmuscle cells are transitory. Those associated with the intercellular anchoring junctions called *adhesion belts,* for example, are often more lasting. Adhesion belts (discussed in Chapter

are found near the apical surface of epithelial cells (see Figure 16-72). Among other functions, they are thought to play an important part in the folding of epithelial cell sheets during embryogenesis.

The mechanism of contraction of all of these cytoskeletal bundles is based on the ATP-driven sliding of interdigitated actin and myosin filaments, and it is thought to require a particular type of ordered assembly, which will be explained later when we discuss muscle.

Focal Contacts Allow Actin Filaments to Pull Against the Substratum 49

To pull on the extracellular matrix or on another cell, a stress fiber must be strongly anchored in the plasma membrane at the appropriate site. Attachments between actin filaments inside the cell and extracellular matrix on the outside of the cell are mediated by transmembrane linker glycoproteins in the plasma membrane. Those formed by cultured fibroblasts with the extracellular matrix are the best characterized. When fibroblasts grow on a culture dish, most of their cell surface is separated from the substratum by a gap of more than 50 nm; but at focal contacts (*adhesion plaques*), this gap is reduced to 10 to 15 nm. Here the plasma membrane is attached to components of the extracellular matrix that have become adsorbed to the culture dish. Staining with anti-actin antibodies clearly shows these regions to be the sites where the ends of stress fibers attach to the plasma membrane (see Figure 16-74).

The main transmembrane linker proteins of focal contacts are members of the *integrin* family, whose external domain binds to an extracellular matrix component while the cytoplasmic domain is linked to actin filaments in stress fibers. The linkage is indirect and is mediated by multiple *attachment proteins* (Figure 16-75). The cytoplasmic domain of the integrin binds to the protein *talin,* which in turn binds to *vinculin,* a protein found also in other actin-containing cell junctions, such as *adherens junctions* (discussed in Chapter 19). Vinculin associates with α-actinin and is thereby linked to an actin filament. Although the exact topology of protein interactions in the focal contact has not been established, a possible arrangement is shown in Figure 16-75B.

Besides their role as anchors for the cell, focal contacts can also relay signals from the extracellular matrix to the cytoskeleton. Several protein kinases, including the tyrosine kinase encoded by the *src* gene, are localized to focal contacts, and there are indications that their activity changes with the type of substratum on which the cell rests. These kinases can phosphorylate various target proteins, including components of the cytoskeleton, and hence regulate the survival, growth, morphology, movement, and differentiation of cells in response to the extracellular matrix in their environment.

Microvilli Illustrate How Bundles of Cross-linked Actin Filaments Can Stabilize Local Extensions of the Plasma Membrane 50

Microvilli are fingerlike extensions found on the surface of many animal cells. They are especially abundant on those epithelial cells that require a very large surface area to function efficiently. A single absorptive epithelial cell in the human small intestine, for example, has several thousand microvilli on its apical surface. Each is about 0.08 μm wide and 1 μm long, making the cell's absorptive surface area 20 times greater than it would be without them. The plasma membrane that covers these microvilli is highly specialized, bearing a thick extracellular coat of polysaccharide and digestive enzymes. The cytoskeleton of the microvillus has been studied in detail - a task that is made easier by its highly ordered structure, compared with the less specialized regions of cell cortex.

At the core of each intestinal microvillus is a rigid bundle of 20 to 30 parallel actin filaments that extend from the tip of the microvillus down into the cell cortex. The actin filaments in the bundle are all oriented with their plus ends pointing away from the cell body and are held together at regular intervals by actin-bundling proteins. Although fimbrin, the bundling protein in microspikes and filopodia, helps to bundle actin filaments into microvilli, the most important bundling protein is villin, which is found only in microvilli (Figure 16-76). Villin, like fimbrin, cross-links actin filaments into tight parallel bundles, but it has a different actin-binding sequence. When villin is introduced into cultured fibroblasts, which do not normally contain villin and have only a few small microvilli, the existing microvilli become greatly elongated and stabilized, and new ones may also be induced, suggesting that villin is mainly responsible for the formation of the long microvilli in epithelial cells.

At the base of the microvillus the actin filament bundle is anchored into a specialized region of cortex at the apical end of the intestinal epithelial cell. This cortex, known as the *terminal web,* contains a dense network of spectrin molecules overlying a layer of intermediate filaments (Figure16-77). The spectrin is thought to provide rigidity and stability to the cortex in this region, and the anchoring of the actin filaments to the terminal web is thought to stiffen the microvilli, keeping their actin

bundles projecting outward at a right angle to the apical cell surface.

The actin filament bundle is attached to the overlying plasma membrane of the microvillus by lateral bridges that can be seen in electron micrographs. The bridges are composed of a form of myosin-I that has several molecules of calmodulin (discussed in Chapter 15) bound to its tail region. The myosin is oriented with this tail region embedded in the membrane and its active ATP-binding head contacting the actin filaments. It is a mystery why a motor protein is used to link actin filaments to the membrane in microvilli. If the myosin-I in microvilli is motile, it should move toward the plus end of the actin filaments at the microvillus tip. This has lead to speculation that the myosin-I helps to pull the membrane up over the microvillus core, forming vesicles at its tip that are then released into the lumen of the intestine, where the digestive enzymes they carry continue their action.

The Behavior of the Cell Cortex Depends on a Balance of Cooperative and Competitive Interactions Among a Large Set of Actin-binding Proteins

The preceding examples show that the same actin filament can interact with different sets of actin-binding proteins at different locations in the cortex and that the actin-binding proteins can be segregated to different parts of the cell. What prevents the various sets of actin-binding proteins from mixing in the cytoplasm? It seems likely that both cooperative and competitive interactions among these proteins are important. One class of actin-binding proteins not yet discussed, for example, binds along the length of the actin filaments. The most widespread members of this class are the tropomyosins, which are rigid rod-shaped proteins named for similarities in their x-ray diffraction pattern to myosin-II. Like the tail of myosin-II, tropomyosin is a dimer of two identical α-helical chains that wind around each other in a coiled-coil. By binding along the length of an actin filament, the tropomyosin stabilizes and stiffens the filament. It also inhibits the binding of filamin to actin filaments, which probably explains why tropomyosin and filamin tend to be differentially distributed in cells. By contrast, tropomyosin binding to an actin filament increases the binding of myosin-II to the filament - an example of a *cooperative* interaction (Figure16-78).

We can now begin to see how stress fibers and cortical networks of actin filaments can coexist in a common cytoplasm. At one site in a cell - perhaps nucleated at a forming focal adhesion under the influence of activated Rho protein - tropomyosin, myosin-II, and α-actinin associate with actin filaments and exclude filamin; the contractile activity of myosin-II then promotes further organizational changes to produce a stress fiber. At another site in the cell tropomyosin-deficient actin filaments bind filamin, producing a loose network that provides few sites where α-actinin can bind to two filaments at once, so that it is excluded; bending of the filaments in the loose meshwork may also discourage tropomyosin-binding, since this molecule prefers a straight filament. While this picture is partly speculative, it illustrates the basic pathway by which a combination of cooperative and competitive interactions can give rise to spatially differentiated actin filament arrays in a common cytoplasm. It is not known how the postulated local differences that initiate the formation of these assemblages are established; nor is it known how many distinct types of actin filament arrays can coexist in the same cell - there are certainly more than the two we have just mentioned.

Some of the actin-binding proteins discussed in this section are summarized in Figure 16-79.

The Migration of Animal Cells Can Be Divided into Three Distinct Actin-dependent Subprocesses [51]

The crawling movements of animal cells are among the most difficult to explain at the molecular level. Different parts of the cell change at the same time, and there is not a single, easily identifiable locomotory organelle (analogous to a flagellum, for example). Although actin forms the basis of animal cell migration, it undergoes many different transformations as the cell moves forward, assembling into lamellipodia and microspikes, associating with focal contacts, forming stress fibers, and so on. A complete account would have to give a molecular explanation for these transformations, explain how they are coordinated in time and space, and also account for important biophysical parameters such as the development of tension in the cortex and the formation of strong adhesions between the cell and its substratum.

In broad terms, three distinct processes can be identified in the crawling movements of animal cells: *protrusion,* in which lamellipodia and microspikes (or filopodia) are extended from the front of the cell; *attachment,* where the actin cytoskeleton makes a connection with the substratum; and *traction,* where the body of the cell moves forward.

Protrusion is a function of the leading edge of the cell. Actin-rich lamellipodia and microspikes (or filopodia) extend forward over the substratum, a process that is accompanied by actin polymerization, as described previously. It seems likely that the protrusion is driven by actin polymerization at the leading edge (see Figure 16-58), although this is still debated. Myosin-I motors attached to the plasma membrane could also drive the cell forward by actively walking along actin filaments. Yet

another possibility, which has been suggested to apply in particular to the locomotion of giant amoebae, is that protrusions are squeezed out of the front of the cell by hydrostatic pressure generated by the contraction of the cortex elsewhere in the cell.

The attachment of cortical actin filaments to the substratum was discussed earlier when we described focal contacts, although these are specialized attachment structures present in fibroblasts in culture and associated with the ends of stress fibers. Rapidly motile cells - such as *Dictyostelium* amoebae and white blood cells - make more diffuse contacts with the substratum. It is thought, however, that similar principles apply to these contacts: transmembrane receptors for extracellular matrix proteins link the plasma membrane to the substratum, and actin filaments in the cytoplasm interact with the cytoplasmic domains of these receptors through actin-binding proteins. The details of these important interactions are uncertain, but it is clear that the cell contacts with the substratum must be continually made and broken as the cell moves forward.

Traction is perhaps the most mysterious part of cell locomotion. In many cases it is thought that the force for cell locomotion is generated near the front of the cell and that the nucleus and bulk cytoplasm are dragged forward passively. The force generation can be viewed in different ways. The leading part of the cell might actively contract like a muscle fiber and thus pull on the back of the cell. In another view polymerization of actin filaments at the front of the cell extends the actin cortex forward, and the rear of the cell is then carried forward by the contractile force of the resulting cortical tension (Figure16-80).

The Mechanism of Cell Locomotion Can Be Dissected Genetically 52

One of the most powerful ways to analyze the mechanism of a complex cellular process is to examine the effect of mutations that result in the deletion, overexpression, or modification of specific proteins. In the case of eucaryotic cell locomotion, the amoeboid cells of the slime mold *Dictyostelium* are particularly suitable for genetic analysis. These cells have a shape and a manner of moving that closely resemble those of the cells of higher organisms. But because they are haploid, they are readily manipulated by reverse genetic methods. Thus it has been possible to delete a number of actin-binding proteins from these cells and examine the consequences for cell locomotion.

The role of myosin-II, for example, has been tested genetically by two methods. In one, a defective form of the myosin-II gene is substituted for the existing gene by homologous recombination (see Figure7-47), leading to a mutant strain with no myosin-II. The second strategy is to use anti-sense RNA (see Figure7-43) to inactivate myosin-II mRNA, which has essentially the same effect. In a normal crawling *Dictyostelium* myosin-II is concentrated near the rear of the cell and myosin-I is concentrated in the leading edge (Figure16-81). In the mutants the myosin-I is unchanged but myosin-II is gone.

Remarkably, *Dictyostelium*cells without myosin-II can still move over the substratum and respond chemotactically to a source of cyclic AMP, although both processes are somewhat impaired. Thus myosin-II is not absolutely essential for cell locomotion. Although protrusive activity at the leading edge of such mutant cells is quite normal, movement of the cell body forward is somewhat impaired, suggesting that myosin-II plays a role in generating traction. Nevertheless, myosin-I and/or actin polymerization must be able to drive the cell forward at a reasonable rate without the help of myosin-II.

Not surprisingly, the mutant cells are unable to form a contractile ring following mitosis and therefore develop into multinucleated giant cells. These cells eventually divide by using cell locomotion to tear themselves in two. It is interesting to speculate that such locomotion-dependent cytokinesis may represent a primitive cell division mechanism and that myosin-II might have evolved from myosin-I through natural selection for a more efficient cytokinetic apparatus.

Summary

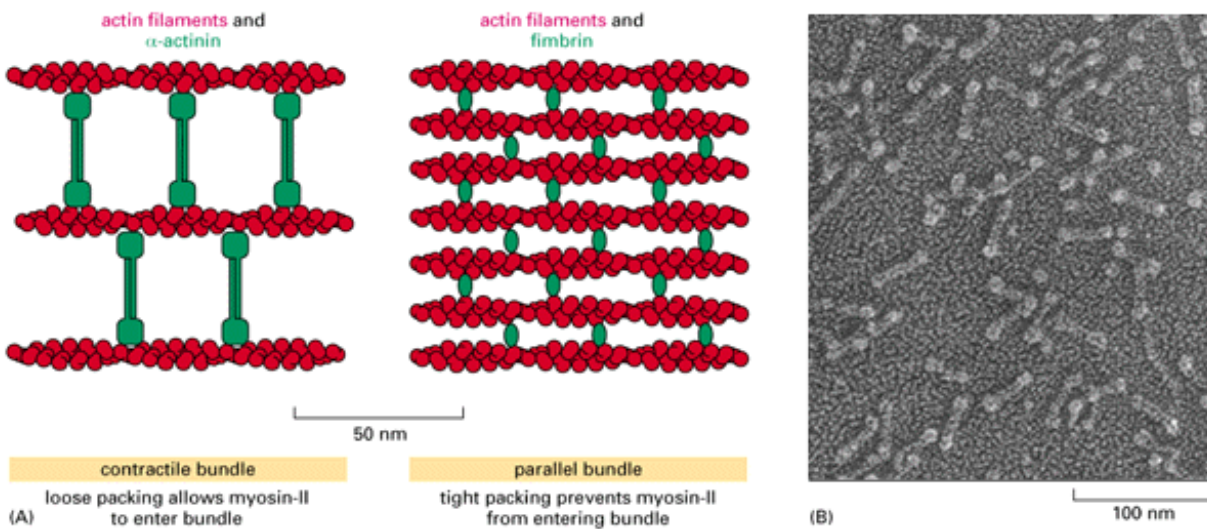
The varied forms and functions of actin in eucaryotic cells depend on a versatile repertoire of actin-binding proteins that cross-link actin filaments into loose gels, bind them into stiff bundles, attach them to the plasma membrane, or forcibly move them relative to one another. Tropomyosin, for example, binds along the length of actin filaments, making them more rigid and altering their affinity for other proteins. Filamin cross-links actin filaments into a loose gel. Fimbrin and a-actinin form bundles of parallel actin filaments. Gelsolin mediates Ca^{2+}-dependent fragmentation of actin filaments, thereby causing a rapid solation of actin gels. Various forms of myosin use the energy of ATP hydrolysis to move along actin filaments, either carrying membrane-bounded organelles from one location in the cell to another or moving adjacent actin filaments against each other. Sets of actin-binding proteins are thought to act cooperatively in generating the movements of the cell surface, including cytokinesis, phagocytosis, and cell locomotion. These movements are difficult to analyze because of the many components involved, but genetic approaches, in which genes encoding specific actin-binding proteins are mutated, can show the function of individual proteins in each process.
Figure 16-65. Three types of cortical arrays of actin filaments. A crawling cell is shown with three areas enlarged to show the arrangement of actin filaments drawn to scale. Arrowheads point toward the plus end of the filaments.


Figure 16-66. The formation of two types of actin filament bundles. (A) a-actinin, which is a homodimer, cross-links actin filaments into loose bundles, which allow the motor protein myosin-II (not shown) to participate in the assembly. Fimbrin cross-links actin filaments into tight bundles, which exclude this motor protein. Fimbrin and a-actinin tend to exclude each other because of the very different spacing of the actin filament bundles that they form. (B) Electron micrograph of purified a-actinin molecules. 50 nm
Figure 16-67. Filamin cross-links actin filaments into a three-dimensional network with the physical properties of a gel. Each filamin homo-dimer is about 160 nm long when fully extended and forms a flexible, high-angle link between two adjacent actin filaments. Filamin can constitute 1% of the cell protein, or about one molecule per 50 actin monomers.

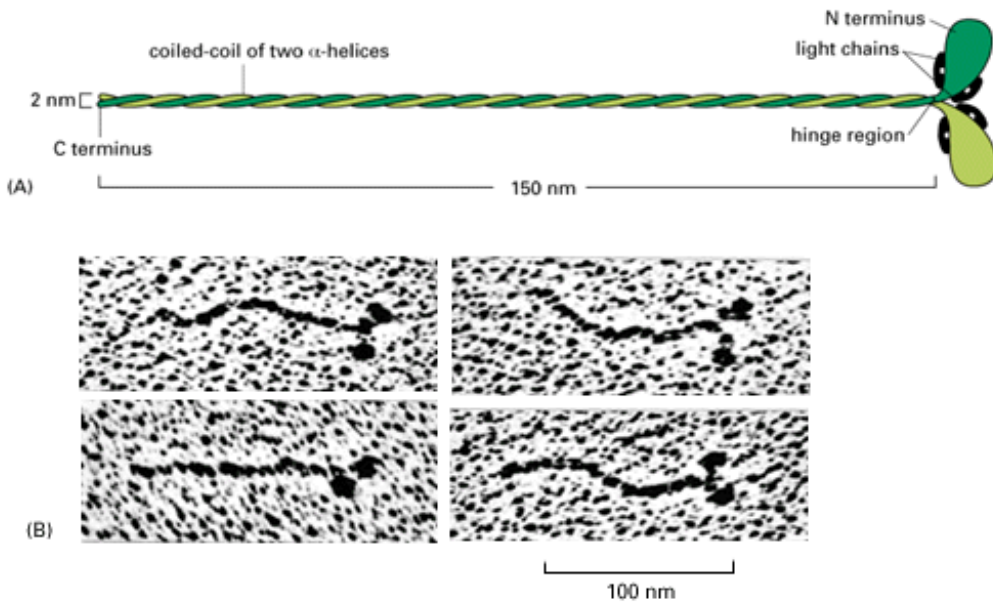
50 nm
Figure 16-68. The modular structures of four actin-binding proteins. Each of the proteins shown has two actin-binding sites (*red*) that are related in sequence. Fimbrin has two directly adjacent actin-binding sites, so that it holds its two actin filaments very close together (14 nm apart), aligned with the same polarity (see Figure 16-66). The two actin-binding sites in a-actinin are more widely separated and are linked by a somewhat flexible spacer 30 nm long, so that it forms actin filament bundles with a greater separation between the filaments (40 nm apart) than does fimbrin. Filamin has two actin-binding sites that are very widely spaced, with a V-shaped linkage between them, so that it cross-links actin filaments into a network with the filaments oriented almost at right angles to one another (see Figure 16-67). Spectrin is a tetramer of two a and two b subunits, and the tetramer has two actin-binding sites spaced about 200 nm apart. The spacer regions of these various proteins are built in a modular fashion from repeating units that include a-helical motifs (*light green*), b-sheet motifs (*dark green*), and Ca^{2+}-binding domains (*blue ovals*).


Figure 16-69. Myosin-II. (A) A myosin-II molecule is composed of two heavy chains (each about 2000 amino acids long) and four light chains. The light chains are of two types (one containing about 190 and the other about 170 amino acids), and one molecule of each type is present on each myosin head (see Figure 5-23). Dimerization occurs by the two a helices wrapping around each other to form an a-helical coiled-coil, driven by the associa-tion of regularly spaced hydrophobic amino acids (see Figure3-48). The coiled-coil arrangement makes an extended rod in solution, and this part of the molecule is termed the rod domain, or the tail. This type of structural motif is found in many other cytoskeletal proteins, enabling them to form an extended structure. (B) The two globular heads and the tail can be clearly seen in electron micrographs of myosin molecules shadowed with platinum. (B, courtesy of David Shotton.)
Figure 16-70. Two myosin family members. On the left, myosin-I and myosin-II are drawn to scale and aligned with respect to their conserved ATP-binding and actin-binding sites. The relative shapes of the folded proteins are shown on the right.
Figure 16-71. Possible roles of myosin-I and myosin-II in a typical eucaryotic cell. The short tail of a myosin-I molecule contains sites that bind either to other actin filaments or to membranes. This allows the head domain to move one actin filament relative to another (1), a vesicle relative to an actin filament (2), or an actin filament and membrane relative to each other (4). In addition, small antiparallel assemblies of myosin-II molecules can slide actin filaments over each other, thus mediating local contractions in an actin filament bundle (3). In all four cases the head group "walks" toward the plus end of the actin filament it contacts.
Figure 16-72. Musclelike contractile assemblies in nonmuscle cells. Each assembly contains myosin-II filaments in addition to actin filaments.
Figure 16-73. The controlled assembly of myosin-II into filaments. (A) The controlled phosphorylation of one of the two light chains has at least two effects *in vitro:* it causes a change in the conformation of the myosin head, exposing its actin-binding site, and it releases the myosin tail from a "sticky patch" on the myosin head, thereby allowing the myosin molecules to assemble into short bipolar filaments. The enzyme responsible for this phosphorylation (myosin light-chain kinase) is described later in connection with smooth muscle (see Figure 16-98). (B) Negatively stained short filaments of myosin-II that have been induced to assemble by the phosphorylation of their light chains. (B, courtesy of John Kendrick-Jones.)
Figure 16-74. The relation between focal contacts and stress fibers in cultured fibroblasts. Focal contacts are best seen in living cells by reflection-interference microscopy (A). In this technique, light is reflected from the lower surface of a cell attached to a glass slide, and the focal contacts appear as dark patches. (B) Immunofluorescence staining of the same cell (after fixation) with antibodies to actin shows that most of the cell's actin filament bundles (or stress fibers) terminate at or close to a focal contact. (Courtesy of Grenham Ireland.)
Figure 16-75. A model for how integrins in the plasma membrane connect intracellular actin filaments to the extracellular matrix at a focal contact. The formation of a focal contact occurs when the binding of matrix glycoproteins (such as fibronectin) on the outside of the cell causes the integrin molecules to cluster at the contact site, as illustrated schematically in (A). A possible arrangement of some of the intracellular attachment proteins that mediate the linkage between an integrin and actin filaments is shown in (B).
Figure 16-76. A microvillus. A bundle of parallel actin filaments held together by the actin-bundling proteins villin and fimbrin forms the core of a microvillus. Lateral arms (composed of myosin-I and the Ca^{2+}-binding protein calmodulin) connect the sides of the actin filament bundle to the overlying plasma membrane. The plus ends of the actin filaments are all at the tip of the microvillus, where they are embedded in an amorphous, densely staining substance of unknown composition.
Figure 16-77. Freeze-etch electron micrograph of an intestinal epithelial cell, showing the terminal web beneath the apical plasma membrane. Bundles of actin filaments forming the core of microvilli extend into the terminal web, where they are linked together by a complex set of cytoskeletal proteins that includes spectrin and myosin-II. Beneath the terminal web is a layer of intermediate filaments. (From N. Hirokawa and J.E. Heuser, *J. Cell Biol.* 91:399-409, 1981, by copyright permission of the Rockefeller University Press.)
Figure 16-78. Some examples of competitive and cooperative interactions between actin-binding proteins. The arrowhead at the end of each actin filament indicates the minus end. Tropomyosin and filamin both bind strongly to actin filaments, but their binding is competitive. Because tropomyosin binds cooperatively to actin filaments, either tropomyosin or filamin will predominate over large regions of the actin filament network. Other actin-binding proteins, such as a-actinin or myosin-II, will be excluded from specific sites by a competitive interaction; thus, for example, a-actinin binds all along pure actin filaments *in vitro,* but it binds relatively weakly to actin filaments in cells, where it is largely confined to sites near the plus ends because of competition with other proteins. Alternatively, binding can be enhanced through cooperative interaction; thus tropomyosin appears to enhance the binding of myosin-II to actin filaments. Multiple interactions of these types between the many different types of actin-binding proteins are thought to be responsible for the complex variety of actin networks found in all eucaryotic cells (see Figure16-79 for key to symbols).

Figure 16-79. Some of the major classes of actin-binding proteins found in most vertebrate cells. Actin is shown in *red,* while the actin-binding proteins are shown in *green.* The molecular mass of each protein is given in kilodaltons (kD).
Figure 16-80. One model of how forces generated in the actin-rich cortex might move a cell forward. The actin-dependent extension and firm attachment of a lamellipodium at the leading edge stretches the actin cortex. The cortical tension then draws the body of the cell forward to relax some of the tension. New focal contracts are made and old ones are disassembled as the cell crawls forward. The same cycle can be repeated over and over again, moving the cell forward in a stepwise fashion. The newly polymerized cortical actin is shown in *red.*
Figure 16-81. The locations of myosin-I and myosin-II in a normal crawling *Dictyostelium* amoeba. The two forms of myosin were stained with specific antibodies, each coupled to a different fluorescent dye, and examined in a fluorescence microscope. Myosin-II (*orange*) shows the highest accumulation in the posterior cortex, whereas myosin-I (*green*) is mainly restricted to the leading edge of lamellipodia at the front of the cell. Some myosin is also seen in phagocytic vesicles in the

cytoplasm. (Courtesy of Yoshio Fukui.)

Muscle 53

Introduction

Many of the proteins that associate with actin filaments in eucaryotic cells were first discovered in muscle. Muscle contraction is the most familiar and the best understood of all the kinds of movement of which animals are capable. In vertebrates, for example, running, walking, swimming, and flying all depend on the ability of *skeletal muscle* to contract rapidly on its scaffolding of bone, while involuntary movements such as heart pumping and gut peristalsis depend on the contraction of *cardiac* and *smooth muscle,* respectively.

Although muscle is the best-understood example of actin-based motility, it was a relatively late development in evolution, and it is highly specialized compared with more typical animal cells. In particular, the actin- and myosin-based contractile units of muscle cells, the *myofibrils,* are not labile like the actin- and myosin-based structures of nonmuscle cells.

Myofibrils Are Composed of Repeating Assemblies of Thick and Thin Filaments 54

The long thin *muscle fibers* of skeletal muscle are huge single cells formed during development by the fusion of many separate cells (discussed in Chapter 22). The nuclei of the contributing cells are retained in this large cell and lie just beneath the plasma membrane. But the bulk of the cytoplasm (about two-thirds of its dry mass) is made up of myofibrils, which are the contractile elements of the muscle cell. They are cylindrical structures 1 to 2 μm in diameter and are often as long as the muscle cell itself (Figure16-82).

Each myofibril consists of a chain of tiny contractile units, or sarcomeres, each about 2.2 μm long, which give the vertebrate myofibril its striated appearance. At high magnification a series of broad light and dark bands can be seen in each sarcomere; a dense line in the center of each light band separates one sarcomere from the next and is known as the Z line, or *Z disc* (Figure 16-83).

Each sarcomere comprises a miniature, precisely arranged assembly of parallel and partly overlapping filaments. *Thin filaments* composed of actin with associated proteins are attached to the Z discs at either end of the sarcomere. They extend in toward the middle of the sarcomere, where they overlap with *thick filaments,* which are polymers of specific muscle isoforms of myosin-II (Figure 16-83C). When this region of overlap is examined in cross-section by electron microscopy, the myosin filaments are seen to be arranged in a regular hexagonal lattice, with the actin filaments placed regularly between them (Figure16-84).

Contraction Occurs as the Myosin and Actin Filaments Slide Past Each Other

Sarcomere shortening is caused by the myosin filaments sliding past the actin filaments with no change in the length of either type of filament (Figure16-85). This *sliding filament model,* first proposed in 1954, was crucial to understanding the contractile mechanism.

The ultrastructural basis for the force-generating interaction is visible at very high magnification in electron micrographs. The myosin filaments are seen to possess numerous tiny side arms, or *cross-bridges,* that extend about 13 nm to make contact with adjacent actin filaments (Figure 16-86). These cross-bridges are myosin-II heads, and when a muscle contracts, the myosin and actin filaments are pulled past each other by the cross-bridges acting cyclically, like banks of tiny oars.

As stated previously, the globular head, or motor domain, of the myosin-II molecule both binds to actin filaments and hydrolyzes ATP. Isolated myosin-II heads, which can be prepared by papain digestion, retain both the ATPase activity and the actin-filament-binding properties of the intact myosin-II molecule and therefore can be used to analyze the interaction between actin and myosin.

Each actin molecule in an actin filament is capable of binding one myosin-II head to form a complex that reveals the structural polarity of the actin filament. With negative staining, such complexes can be seen in the electron microscope to have a regular and distinctive form: each myosin head forms a lateral projection, and the superimposed image of many such projections gives the appearance of arrowheads along the actin filament. The *pointed end* created by these myosin arrows corresponds to the slow-

growing minus end of the actin filament described earlier (see p. 821). The other, *barbed end* corresponds to the fast-growing plus end (Figure16-87).

As shown in Figure16-88, myosin heads face in opposite directions on either side of the bare central region of a myosin-II filament. Since the heads must interact with actin filaments in the region of overlap, the actin filaments on either side of the sarcomere should be of opposite polarity. This has been demonstrated by using myosin-II heads to decorate the actin filaments attached to isolated Z discs. All of the myosin arrowheads are found to point away from the Z disc. Therefore, the plus end of each actin filament is embedded in the Z disc, while the minus end points toward the myosin filaments (Figure16-89).

A Myosin Head "Walks" Toward the Plus End of an Actin Filament 55

Muscle contraction is driven by the interaction between myosin-II heads and adjacent actin filaments, during which the myosin head hydrolyzes ATP. The ATP hydrolysis and subsequent dissociation of the tightly bound products (ADP and P_i) produce an ordered series of allosteric changes in the conformation of myosin. As a result, part of the energy released is coupled to the production of movement. A major advance in understanding these concerted changes in protein structure, and hence in understanding how ATP hydrolysis is coupled to directed movement of the myosin molecule, came with the determination of the three-dimensional structure of the myosin head by x-ray diffraction analysis (Figure16-90). In conjunction with a wealth of other data, this structure suggests that unidi-rectional movement is generated by the sequence of events illustrated in Figure 16-91.

Because each turn of the cycle illustrated in Figure 16-91 results in the hydrolysis and release of one ATP molecule, the series of conformational changes just described is driven by a large favorable change in free energy, making it unidirectional. Each individual myosin head, therefore, "walks" in a single direction along an adjacent actin filament, always moving toward the filament's plus end (see Figure 16-89). As it undergoes its cyclical change in conformation, the myosin head pulls against the actin filament, causing this filament to slide against the myosin filament. Once an individual myosin head has detached from the actin filament, it is carried along by the action of other myosin heads in the same myosin filament, so that a snapshot of an entire myosin filament in a contracting muscle would show some of the myosin heads attached to actin filaments and others unattached. (A certain amount of springlike elasticity in the myosin molecule is essential to allow this to happen.) Each myosin filament has about 300 myosin heads (294 in frog muscle), and each head cycles about 5 times per second in the course of a rapid contraction - sliding the myosin and actin filaments past one another at rates of up to 15 μm/second.

Muscle Contraction Is Initiated by a Sudden Rise in Cytosolic Ca^{2+} 56

The force-generating molecular interaction just described takes place only when a signal passes to the skeletal muscle from its motor nerve. The signal from the nerve triggers an action potential in the muscle cell plasma membrane, and this electrical excitation spreads rapidly into a series of membranous folds, the *transverse tubules,* or *T tubules,* that extend inward from the plasma membrane around each myofibril. The signal is then relayed across a small gap to the sarcoplasmic reticulum, an adjacent sheath of anastomosing flattened vesicles that surrounds each myofibril like a net stocking (Figure16-92A).

In the junctional region, large *Ca^{2+} release channels* extend like pillars from the sarcoplasmic reticulum membrane to make contact with the T-tubule membrane on the other side (Figure 16-92C). When voltage-sensitive proteins in the T-tubule membrane are activated by the incoming action potential, they trigger some of the Ca^{2+} release channels to open, probably by direct mechanical coupling. Ca^{2+} ions then escape from the sarcoplasmic reticulum (where they are stored in high concentration) into the cleft of the junction, causing more of the Ca^{2+} release channels to open, thereby amplifying the response. Ca^{2+} ions flooding into the cytosol then initiate the contraction of each myofibril.

Because the signal from the muscle-cell plasma membrane is passed within milliseconds (via the T tubules and sarcoplasmic reticulum) to every sarcomere in the cell, all of the myofibrils in the cell contract at the same time. The increase in Ca^{2+} concentration in the cytosol is transient because the Ca^{2+} is rapidly pumped back into the sarcoplasmic reticulum by an abundant Ca^{2+}-ATPase in its membrane (discussed in Chapter 11). Typically, the cytosolic Ca^{2+} concentration is restored to resting levels within 30 milliseconds, causing the myofibrils to relax.

Troponin and Tropomyosin Mediate the Ca^{2+} Regulation of Skeletal Muscle Contraction 57

The Ca^{2+} dependence of vertebrate skeletal muscle contraction, and hence its dependence on motor commands transmitted via nerves, is due entirely to a set of specialized accessory proteins closely associated with actin filaments. If myosin is mixed with pure actin filaments in a test tube, the ATPase activity of myosin is stimulated whether or not Ca^{2+} is present; in a normal myofibril, on the other hand, where the actin filaments are associated with accessory proteins, the stimulation of myosin ATPase activity depends on Ca^{2+}.

One of these accessory proteins is a muscle form of *tropomyosin,* the rod-shaped molecule introduced earlier that binds in the groove of the actin helix (see Figure 16-78). The other major accessory protein involved in Ca^{2+} regulation in vertebrate skeletal muscle is *troponin,* a complex of three polypeptides - troponins T, I, and C (named for their *T*ropomyosin-binding, *I*nhibitory, and *C*alcium-binding activities). The troponin complex has an elongated shape, with subunits C and I forming a globular head region and T forming a long tail. The tail of *troponin T* binds to tropomyosin and is thought to be responsible for positioning the complex on the thin filament (Figure16-93A). *Troponin I* binds to actin, and when it is added to troponin T and tropomyosin, the complex inhibits the interaction of actin and myosin, even in the presence of Ca^{2+}.

The further addition of *troponin C* completes the troponin complex and makes its effects sensitive to Ca^{2+}. Troponin C binds up to four molecules of Ca^{2+}, and with Ca^{2+} bound, it relieves the inhibition of myosin binding to actin produced by the other two troponin components. Troponin C is closely related to calmodulin, which mediates Ca^{2+}-signaled responses in all cells, including the activation of smooth muscle myosin. Troponin C may therefore be regarded as a specialized form of calmodulin that has evolved permanent binding sites for troponin I and troponin T, thereby ensuring that the myofibril responds extremely rapidly to an increase in Ca^{2+} concentration.

There is only one molecule of the troponin complex for every seven actin monomers in an actin filament (see Figure16-93A). Structural studies suggest that in a resting muscle the binding of troponin I to actin moves the tropomyosin molecules to a position on the actin filaments that in an actively contracting muscle is occupied by the myosin heads and thus inhibits the interaction of actin and myosin. When the level of Ca^{2+} is raised, troponin C causes the troponin I to release its hold on actin, thereby allowing the tropomyosin molecules to shift their position slightly so that the myosin heads can bind to the actin filament (Figure 16-93B).

Other Accessory Proteins Maintain the Architecture of the Myofibril and Provide It with Elasticity 58

The remarkable speed and power of muscle contraction depend on the filaments of actin and myosin in each myofibril being held at the optimal distance from one another and in correct alignment. More than a dozen structural proteins contribute to the precise architecture of the myofibril: the order in which they assemble, and the controls over this process, are important topics of contemporary research.

Actin filaments are anchored by their plus ends to the Z disc, where they are held in a square lattice arrangement by other proteins. One of the most important structural proteins in this region is α-actinin, the actin cross-linking protein discussed earlier that is abundant in most animal cells and is concentrated in the Z-disc region of the myofibril (Figure 16-94). Myosin filaments are also held in a regular lattice - in this case a hexagonal one - through associated proteins that bind midway along the bipolar thick filaments.

Skeletal muscle cells contain two extraordinarily large proteins, called *titin* and *nebulin,* which form a network of fibers associated with the actin and myosin filaments. Titin, which has a molecular weight of 3×10^6, is the largest polypeptide yet described. Stringlike titin molecules extend from the thick filaments to the Z disc; they are thought to act like springs to keep the myosin thick filaments centered in the sarcomere (Figure 16-95). By contrast, nebulin, which is also large, is closely associated with the actin thin filaments and consists almost entirely of a repeating, 35-amino-acid actin-binding motif. The number of these motifs, and hence the total length of the nebulin molecule, is that needed to extend from one end of the actin filament to the other. Nebulin therefore could act as a "molecular ruler" to regulate the assembly of actin and the length of the actin filaments during muscle development (see Figure 3-52).

The myofibrils are bound to one another side by side by a system of desmin intermediate filaments, and the entire array is then anchored to the plasma membrane of the muscle cell by various proteins, including a flexible, elongated actin-binding protein called *dystrophin.* This protein, which is either absent or defective in patients with muscular dystrophy, has a close structural resemblance to spectrin, and it may link specific muscle membrane proteins to actin filaments in the myofibril.

The Same Contractile Machinery, in Modified Form, Is Found in Heart Muscle and Smooth Muscle <u>59</u>

Thus far we have described only one of the three major types of muscle present in vertebrates - skeletal muscle. The others are *heart (cardiac) muscle,* which contracts about 3 billion times in the course of an average human life-span, and *smooth muscle,* which produces the slower and longer-lasting contractions characteristic of organs such as the intestines. All three types of muscle cells, together with another class of contractile cells known as *myoepithelial cells* (see <u>Figure22-36E</u>), contract by an actin and myosin-II sliding filament mechanism.

Like skeletal muscle, heart muscle is striated, reflecting a very similar organization of actin filaments and myosin filaments. It is also triggered to contract by a similar mechanism: an action potential triggers the sarcoplasmic reticulum to release Ca^{2+}, which activates contraction by means of a troponin-tropomyosin complex. Heart muscle cells, however, are not syncytial but are cells with a single nucleus. They are joined end to end by special structures called *inter-calated discs* (<u>Figure 16-96</u>). The intercalated discs serve at least three functions. (1) They attach one cell to the next by means of desmosomes (discussed in <u>Chapter 19</u>). (2) They connect the actin filaments of the myofibrils of adjacent cells (performing a function analogous to that of the Z discs inside the cells). (3) They contain gap junctions, which allow an action potential to spread rapidly from one cell to the next, synchronizing the contractions of the heart muscle cells.

The most "primitive" muscle, in the sense of being most like nonmuscle cells, has no striations and is therefore called smooth muscle. It forms the contractile portion of the stomach, intestine, and uterus, the walls of arteries, and many other structures in which slow and sustained contractions are needed. It is composed of sheets of highly elongated spindle-shaped cells, each with a single nucleus. The cells contain both myosin-II and actin filaments, but these are not arranged in the strictly ordered pattern found in skeletal and cardiac muscle and do not form distinct myofibrils. Instead, the filaments form a more loosely arranged contractile apparatus, which is roughly aligned with the long axis of the cell - but is attached obliquely to the plasma membrane at disclike junctions connecting adjacent cells together.

Although the contractile apparatus in smooth muscle does not contract as rapidly as the myofibrils in a striated muscle cell, it has the advantage of permitting a much greater degree of shortening and therefore can produce large movements even though it lacks the leverage provided by attachments to bones. The organization of the actin filaments and myosin that makes this possible is poorly understood; one model is presented in <u>Figure16-97</u>.

The Activation of Myosin in Many Cells Depends on Myosin Light-Chain Phosphorylation <u>60</u>

The highly specialized contractile mechanisms that we have described in muscle cells evolved from the simpler force-generating mechanisms found in all eucaryotic cells. Not surprisingly, the myosin-II in nonmuscle cells most closely resembles the myosin-II in smooth muscle cells, the least specialized type of muscle. Contraction in smooth muscle cells is triggered by a rise in cytosolic Ca^{2+}, but unlike the mechanism in skeletal and heart muscle, contraction is initiated mainly by phosphorylation of one of the two myosin-II light chains, which in turn controls the interaction of myosin with actin. A similar mechanism regulates nonmuscle myosin-II activity.

The two light chains on each head of the myosin-II molecule (see <u>Figure5-23</u>) are different, and one of them is phosphorylated during nonmuscle and smooth muscle contraction. When this light chain is phosphorylated, the myosin head can interact with an actin filament and thereby cause contraction; when it is dephosphorylated, the myosin head tends to dissociate from actin and becomes inactive. In both smooth muscle and nonmuscle cells the phosphorylation is catalyzed by the enzyme *myosin light-chain kinase,* whose action requires the binding of a Ca^{2+}/calmodulin complex. As a result, contraction is controlled by the level of cytosolic Ca^{2+}, as in cardiac and skeletal muscle (<u>Figure16-98</u>).

Light-chain phosphorylation can also influence the state of aggregation of myosin-II molecules in the cell, as already mentioned in connection with motility in nonmuscle cells (see <u>Figure 16-73</u>). The phosphorylation of myosin-II occurs relatively slowly, so that even though it has assembled into a contractile bundle with actin, maximum contraction often requires nearly a second (compared with the few milliseconds required for a striated muscle cell). But rapid activation of contraction is not important in smooth muscle or nonmuscle cells: myosin-IIs in such cells hydrolyze ATP about 10 times more slowly than skeletal muscle myosin, producing a slow cross-bridge cycle and a slow contraction.

Summary

Muscle contraction is produced by the sliding of actin filaments against myosin filaments. The head regions of myosin molecules, which project from myosin filaments, engage in an ATP-driven cycle in which they attach to adjacent actin filaments, undergo a conformational change that pulls the myosin filament against the actin filament, and then detach. This cycle is facilitated by special accessory proteins in muscle that hold the actin and myosin filaments in parallel overlapping arrays with the correct orientation and spacing for sliding to occur. Two other accessory proteins - troponin and tropomyosin - allow the contraction of skeletal and cardiac muscle to be regulated by Ca^{2+}.

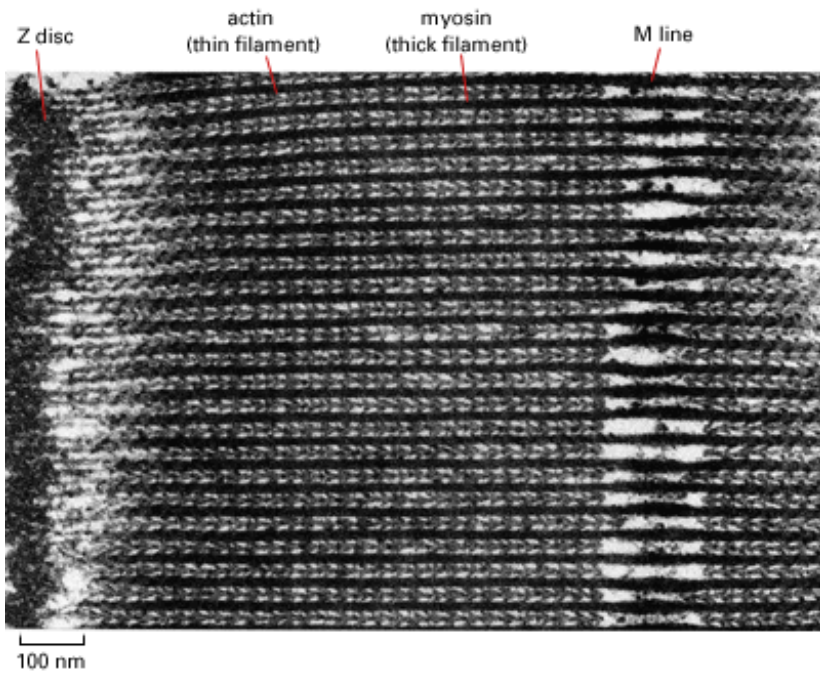
In smooth muscle cells, and in most nonmuscle cells, actin and myosin produce contraction in fundamentally the same way as in skeletal and cardiac muscle. The contractile units are smaller, however, and less highly ordered in such cells; both their activity and their state of assembly are controlled by Ca^{2+}-regulated phosphorylation of a myosin light chain.
Figure 16-82. Skeletal muscle cells (also called muscle fibers). (A) In an adult human these huge multinucleated cells are typically 50 μm in diameter, and they can be several centimeters long. (B) Fluorescence micrograph of rat muscle showing the peripherally located nuclei (*blue*). (B, courtesy of Nancy L. Kedersha.)
Figure 16-83. Skeletal muscle myofibrils. (A) Low-magnification electron micrograph of a longitudinal section through a skeletal muscle cell of a rabbit, showing the regular pattern of cross-striations. The cell contains many myofibrils aligned in parallel (see Figure16-82). (B) Detail of the skeletal muscle cell shown in (A), showing portions of two adjacent myofibrils and the definition of a sarcomere. (C) Schematic diagram of a single sarcomere, showing the origin of the dark and light bands seen in the electron micrographs. Z discs, at either end of the sarcomere, are attachment sites for thin filaments (actin filaments); the M line, or midline, is the location of specific proteins that link adjacent thick filaments (myosin-II filaments) to each other. The *broad green bands,* which mark the location of the thick filaments, are sometimes referred to as *A bands* because they appear anisotropic in polarized light (that is, their refractive index changes with the plane of polarization). The *light red bands,*which contain only thin filaments and therefore have a lower density of protein, are relatively isotropic in polarized light and are sometimes called *I bands*. (A and B, courtesy of Roger Craig.)
Figure 16-84. Electron micrographs of an insect flight muscle viewed in cross-section. The myosin and actin filaments are packed together with almost crystalline regularity. Unlike their vertebrate counterparts, these myosin filaments have a hollow center, as seen in the enlargement on the right. A longitudinal section of this muscle is shown in Figure16-86. The geometry of the hexagonal lattice is slightly different in vertebrate muscle. (From J. Auber, *J. de Microsc.* 8:197-232, 1969.)
Figure 16-85. The sliding filament model of muscle contraction. The actin and myosin filaments slide past one another without shortening.


Figure 16-86. Electron micrograph of a longitudinal section of an insect flight muscle. This very thin section shows clearly the alternating myosin and actin filaments and the cross-bridges that link the two. Note that insect flight muscle has an unusually high degree of overlap between the myosin and actin filaments. (Courtesy of Mary C. Reedy.)
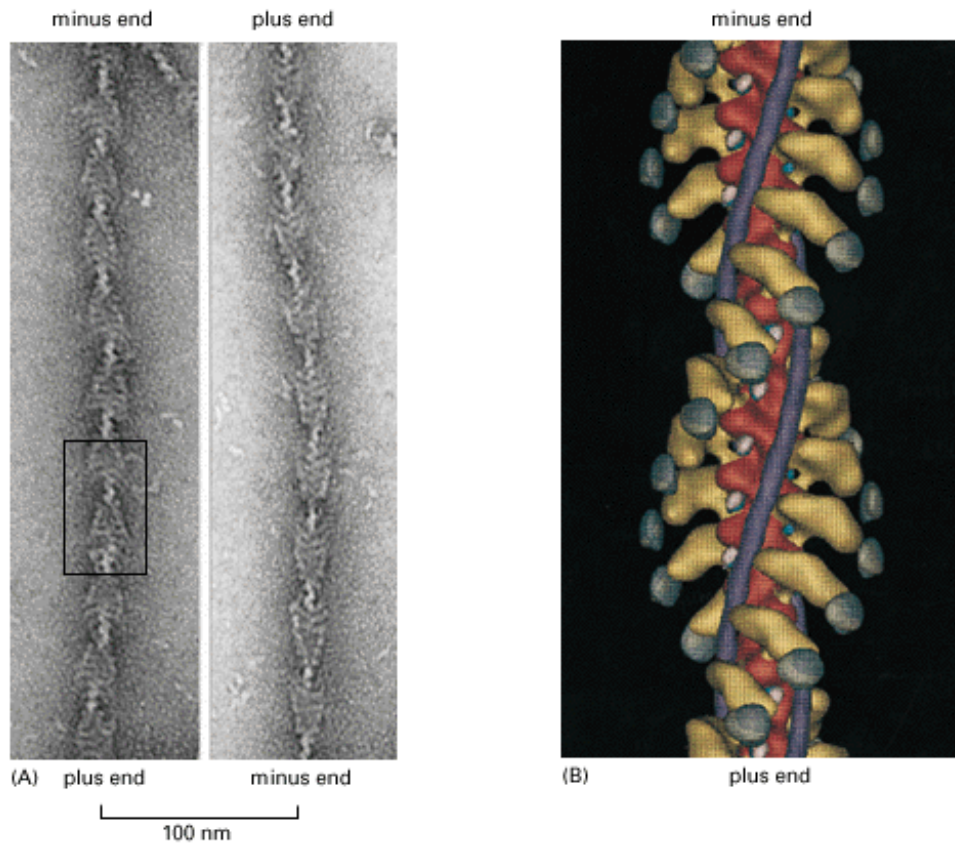

Figure 16-87. Actin filaments decorated with isolated myosin-II heads. (A) In the electron microscope the helical arrangement of the bound myosin heads, which are tilted in one direction, gives the appearance of arrowheads and indicates the polarity of the actin filament. The pointed end corresponds to the *minus end,* the barbed end to the *plus end.* (B) A three-dimensional reconstruction from electron micrographs of a similar decorated actin filament. The region shown corresponds to the boxed area in (A). The actin filament is shown in *red,* the myosin heads are *yellow,* the myosin light chains are *gray,* and the

position of tropomyosin is shown in *purple*. (A, courtesy of Roger Craig; B, courtesy of Ron Milligan.)

Figure 16-88. The myosin-II thick filament. (A) Electron micrograph of a myosin-II thick filament isolated from frog muscle. Note the central bare zone. (B) Schematic diagram, not drawn to scale. The myosin-II molecules aggregate together by means of their tail regions, with their heads projecting to the outside. The bare zone in the center of the filament consists entirely of myosin-II tails. (C) A small section of a myosin-II filament as reconstructed from electron micrographs. An individual myosin molecule is highlighted in *green*. (A, courtesy of Murray Stewart; C, based on R.A. Crowther, R. Padron, and R. Craig, *J. Mol. Biol.*184:429-439, 1985.)
The myosin and actin filaments of a sarcomere overlap with the same relative polarity on either side of the midline.
Figure 16-90. Space-filling model of the head of muscle myosin. The model is oriented so that the actin-binding surface is located at the lower right-hand corner. Three domains of the myosin heavy chain are colored *green, red,* and *blue,* respectively, whereas the two light chains are shown in *yellow* and *purple*. (From I. Rayment et al., *Science,* 261:50-58, 1993. © 1993 the AAAS.)
ATTACHED—At the start of the cycle shown in this figure, a myosin head lacking a bound nucleotide is locked tightly onto an actin filament in a *rigor* configuration (so named because it is responsible for *rigor mortis*, the rigidity of death). In an actively contracting muscle this state is very short-lived, being rapidly terminated by the binding of a molecule of ATP.

RELEASED—A molecule of ATP binds to the large cleft on the "back" of the head (that is, on the side farthest from the actin filament) and immediately causes a slight change in the conformation of the domains that make up the actin-binding site (see Figure 16–90). This reduces the affinity of the head for actin and allows it to move along the filament. (The space drawn here between the head and actin emphasizes this change, although in reality the head probably remains very close to the actin.)

COCKED—The cleft closes like a clam shell around the ATP molecule, triggering a large shape change that causes the head to be displaced along the filament by a distance of about 5 nm. Hydrolysis of ATP occurs, but the ADP and P$_i$ produced remain tightly bound to the protein.

FORCE-GENERATING—The weak binding of the myosin head to a new site on the actin filament causes release of the inorganic phosphate produced by ATP hydrolysis, concomitantly with the tight binding of the head to actin. This release triggers the power stroke—the force-generating change in shape during which the head regains its original conformation. In the course of the power stroke, the head loses its bound ADP, thereby returning to the start of a new cycle.

ATTACHED—At the end of the cycle, the myosin head is again locked tightly to the actin filament in a rigor configuration. Note that the head has moved to a new position on the actin filament.

Figure 16-91. The cycle of changes by which a myosin molecule walks along an actin filament. (Based on I. Rayment et al., *Science* 261:50-58, 1993. © 1993 the AAAS.)
Figure 16-92. T tubules and the sarcoplasmic reticulum. (A) Drawing of the two systems of membranes that relay the signal to contract from the muscle cell plasma membrane to all of the myofibrils in the cell. (B) Electron micrograph showing two T tubules. Note the position of the large Ca^{2+} release channels in the sarcoplasmic reticulum membrane; they look like square-shaped "feet" that connect to the adjacent T-tubule membrane. (C) Schematic diagram showing how a Ca^{2+} release channel in the sarcoplasmic reticulum membrane is thought to be opened by a voltage-sensitive transmembrane protein in the adjacent T-tubule membrane. (B, courtesy of Clara Franzini-Armstrong.)
Figure 16-93. The control of skeletal muscle contraction by troponin. (A) A muscle thin filament showing the positions of tropomyosin and troponin along the actin filament. Each tropomyosin molecule has seven evenly spaced regions of homologous sequence, each of which is thought to bind to an actin monomer as shown. (B) A thin filament shown end-on, illustrating how Ca^{2+} binding to troponin is thought to relieve the tropomyosin blockage of the interaction of the myosin head with actin. (A, adapted from G.N. Phillips, J.P. Fillers, and C. Cohen, *J. Mol. Biol.* 192:111-131, 1986.)
Figure 16-94. Location of a-actinin in muscle. This confocal immuno-fluorescence image shows a group of myofibrils from a cultured heart muscle cell. Actin is stained *red* with rhodamine-labeled phalloidin, and a-actinin is stained *green* with a fluorescein-labeled antibody, but because actin and a-actinin are co-localized in the Z disc, this region actually appears *yellow*. (From M.H. Lu et al., *J. Cell Biol.* 117:1017-1022, 1992, by copyright permission of the Rockefeller University Press.)
Figure 16-95. Location of titin and nebulin in a skeletal muscle sarcomere. Each giant titin molecule extends from the Z disc to the M line - a distance of over 1 μm. Part of each titin molecule is closely associated with myosin molecules in the thick filament; the rest of the molecule is elastic and changes length as the muscle contracts and relaxes. Each nebulin molecule extends from the Z disc along the length of one thin actin filament and could thereby determine thin filament length.
Figure 16-96. The structure of heart muscle. Schematic diagram of heart muscle showing two cells joined end to end by specialized junctions known as intercalated discs. Actin filaments from sarcomeres in adjacent cells insert into the dense material associated with the plasma membrane in the region of each intercalated disc as though they were Z discs. Thus the

myofibrils continue across the muscle, ignoring cell boundaries.
Figure 16-97. A model for the contractile apparatus in a smooth muscle cell. In this hypothetical view, bundles of contractile filaments containing actin and myosin (*red*) are anchored at one end to sites in the plasma membrane and at the other end, through cytoplasmic "dense bodies," to noncontractile bundles of intermediate filaments (*blue*). The contractile actin-myosin bundles are oriented obliquely to the long axis of the cell (which is generally much more elongated than shown), and their contraction greatly shortens the cell. Only a few of the many bundles are shown.
Figure 16-98. The regulation of smooth muscle contraction by Ca^{2+}. The contraction is activated in the presence of Ca^{2+} by *myosin light-chain kinase,* which catalyzes the phosphorylation of a particular site on one of the two types of myosin light chains. Nonmuscle myosin molecules are regulated by the same mechanism (see Figure16-73).

17. The Cell-Division Cycle

➜ ➜

Introduction

Cells reproduce by duplicating their contents and then dividing in two. This cell-division cycle is the fundamental means by which all living things are propagated. In unicellular species, such as bacteria and yeasts, each cell division produces an additional organism. In multicellular species many rounds of cell division are required to make a new individual, and cell division is needed in the adult body, too, to replace cells that are lost by wear and tear or by programmed cell death. Thus an adult human must manufacture many millions of new cells each second simply to maintain the status quo, and if all cell division is halted - for example, by a large dose of ionizing radiation - the individual will die within a few days.

The details of the cell cycle may vary, but certain requirements are universal. First and foremost, to produce a pair of genetically identical daughter cells, the DNA must be faithfully replicated, and the replicated chromosomes must be segregated into two separate cells (Figure17-1). The cell cycle comprises, at a minimum, the set of processes that a cell must perform to accomplish

these tasks. The vast majority of cells also double their mass and duplicate all their cytoplasmic organelles in each cell cycle. Thus a complex set of cytoplasmic and nuclear processes have to be coordinated with one another during the cell cycle. The central problem is to explain how this coordination is achieved.

Our understanding of the cell cycle has undergone a revolution in recent years. In the past the cell cycle was monitored by observing the events of chromosome segregation with a light microscope and by following DNA replication by measuring the incorporation of radioactive precursors into DNA. The focus of attention, therefore, was on the chromosomes, and there seemed to be large differences between the cell cycles of different organisms and different types of cells. Recent experiments have provided a new and simpler perspective, revealing a cell-cycle control system that coordinates the cycle as a whole. The proteins of this control system first appeared over a billion years ago and have been so well conserved in evolution that many of them function perfectly when transferred from a human cell to a yeast cell. We can therefore study the control system in a variety of eucaryotic organisms and use the findings from all of them to assemble a unified picture of how cells grow and divide.

This chapter is concerned with how the processes of the cell cycle are controlled and coordinated with one another. Other chapters discuss in detail some of the individual processes themselves: Chapters 6 and 8 deal with the machinery of DNA replication, and Chapter 18 describes the cytoskeletal apparatus that segregates the chromosomes and divides the cell in two. Here, after briefly outlining the events of the cell cycle, we discuss experiments performed on early animal embryos and yeasts that have provided the main insights into the basic control system. We then consider how extracellular signals act on the control system to regulate cell division in a multicellular organism.
The cell-division cycle.
➔ ➔

The General Strategy of the Cell Cycle

Introduction

The duration of the cell cycle varies greatly from one cell type to another. Fly embryos have the shortest known cell cycles, each lasting as little as 8 minutes, while the cell cycle of a mammalian liver cell can last longer than a year. We begin our discussion, however, with a more typical example and describe the sequence of events in a fairly rapidly dividing mammalian cell, with a cycle time of about 24 hours.

The cell cycle is traditionally divided into several distinct phases, of which the most dramatic is mitosis, the process of nuclear division, leading up to the moment of cell division itself. As discussed in detail in Chapter 18, in mitosis the nuclear envelope breaks down, the contents of the nucleus condense into visible chromosomes, and the cell's microtubules reorganize to form the *mitotic spindle* that will eventually separate the chromosomes. As mitosis proceeds, the cell seems to pause briefly in a state called *metaphase,* in which the chromosomes, already duplicated, are aligned on the mitotic spindle, poised for segregation. The separation of the duplicated chromosomes marks the beginning of *anaphase,* during which the chromosomes move to the poles of the spindle, where they decondense and re-form intact nuclei. The cell is then pinched in two by a process called cytokinesis, which is traditionally viewed as the end of the mitotic phase, or M phase, of the cell cycle (Figure 17-2).

In most cells the whole of M phase takes only about an hour, which is only a small fraction of the total cycle time. The much longer period that elapses between one M phase and the next is known as interphase. Under the microscope this appears, deceptively, as an uneventful interlude in which the cell simply grows in size. But other techniques reveal that interphase is actually a busy time for the proliferating cell, during which elaborate preparations for cell division are occurring in a closely ordered sequence. In particular, it is during interphase that the DNA in the nucleus is replicated.

Replication of the Nuclear DNA Occurs During a Specific Part of Interphase - the S Phase [1]

Replication of the nuclear DNA usually occupies only a portion of interphase, called the S phase of the cell cycle (S = synthesis). The interval between the completion of mitosis and the beginning of DNA synthesis is called the G_1 phase (G = gap), and the interval between the end of DNA synthesis and the beginning of mitosis is called the G_2 phase. G_1 and G_2 provide additional time for growth: if interphase lasted only long enough for DNA replication, the cell would not have time to double its mass before it divided. During G_1 the cell monitors its environment and its own size and, when the time is ripe, takes a decisive step that commits it to DNA replication and completion of a division cycle. The G_2 phase provides a safety gap, allowing the cell to ensure that DNA replication is complete before it plunges into mitosis. G_1, S, G_2, and M are the traditional subdivisions of the standard cell cycle (Figure17-3). We shall see that most, but not all, cell cycles conform to this standard scheme.

Because cells require time to grow before they divide, the standard cell cycle is generally quite long - 12 hours or more for fast growing tissues in a mammal, for example. Although the lengths of all phases of the cycle are variable to some extent, by far the greatest variation, in most of the commonly studied types of cells, occurs in the duration of G_1. Cells in G_1, if they have not yet committed themselves to DNA replication, can pause in their progress around the cycle and enter a specialized resting state, often called G_0 (G zero), where they can remain for days, weeks, or even years before resuming proliferation.

The shortest eucaryotic division cycles of all - shorter even than those of many bacteria - are the *early embryonic cell cycles* that occur in certain animal embryos immediately after fertilization, serving to subdivide a giant egg cell into many smaller cells as quickly as possible. In these cycles no growth occurs, the $G_1$and G_2 phases are drastically curtailed, and the time from one division to the next is between 8 and 60 minutes, spent half in S phase, half in M (Figure17-4). We shall have more to say about these early embryonic cycles later.

How can one tell where a cell is in the cycle? Cells in S phase can be recognized by supplying them with labeled molecules of thymidine - a compound that cells use exclusively for the synthesis of DNA. The label can be radioactive, usually in the form of ^{3}H-thymidine, or chemical, usually in the form of bromo-deoxyuridine (BrdU), an artificial thymidine analog. Cell nuclei that have incorporated the labeled compound are recognized by autoradiography (Figure17-5) or by staining with anti-BrdU antibody, respectively. Typically, in a population of growing cells that are all proliferating rapidly but asynchronously, about 30% will be in S phase at any instant and so will become labeled by a brief pulse of the DNA precursor. From the fraction of cells that are labeled (the *labeling index*), one can estimate the duration of S phase as a fraction of the whole cycle. Similarly, from the fraction of cells seen in mitosis (the *mitotic index*), one can estimate the duration of M phase as a fraction of the whole cycle. In addition, by giving a pulse of ^{3}H-thymidine or BrdU and allowing the cells to continue around the cycle for measured lengths of time, one can find out how long it takes an S-phase cell to progress through G_2into M phase, through M phase into G_1, and finally through G_1 back to S phase.

Alternatively, one can assess where a cell is in the cycle by measuring the DNA content, which doubles during S phase. This approach is greatly facilitated by the use of a *fluorescence-activated cell sorter*(Figure 17-6), which allows large numbers of cells to be analyzed automatically. One can go on to discover the lengths of the G_1, S, and G_2 + M phases by following a population of cells that are selected to be all in one particular phase and using DNA measurements to monitor the subsequent progress of these cells through the cycle.

Discrete Cell-Cycle Events Occur Against a Background of Continuous Growth [2]

In conditions that favor growth, the total protein content of a typical cell increases more or less continuously throughout the cycle. Likewise, RNA synthesis continues at a steady rate, except during M phase, when the chromosomes are apparently too condensed to allow transcription. When the pattern of synthesis of individual proteins is analyzed, the vast majority are seen to be synthesized throughout the cycle. For most of the constituents of the cell, therefore, growth is a steady, continuous process,

interrupted only briefly at M phase, when the nucleus and then the cell divide into two.

DNA synthesis and the visible events of mitosis are, however, not the only discrete processes occurring against this background of continuous growth. The centrosome, for example, has to be duplicated in preparation for mitosis, so as to form the two poles of the mitotic spindle (see Figure17-2). And production of a few key proteins - although only a very few - is switched on at a high rate at a specific stage of the cycle. Histones, for example, which are required for the formation of new chromatin, are made at a high rate only in S phase, and the same is true for some of the enzymes that manufacture deoxyribonucleotides and replicate DNA.

The turning on and off of genes and the starting and stopping of processes such as DNA synthesis and mitosis are the overt consequences of a much less easily observed series of sudden transitions in the state of the cell-cycle control system, whose broad principles we discuss next.

A Central Control System Triggers the Essential Processes of the Cell Cycle 3

From the point of view of its control, the cell cycle operates like an automatic clothes washing machine. The function of the washing machine is to take in water and detergent, wash the clothes, rinse them, and spin them dry. These essential processes of the washing cycle are analogous to the essential processes of DNA replication, mitosis, and so on in the cell cycle (Figure17-7). In both cases a central controller triggers each process in turn in a specific sequence. Although the controller could in principle operate as a simple clock that allots a fixed time for each process, usually, in both the washing machine and the cell cycle, it is itself regulated at certain critical points of the cycle by feedback from the processes that are being performed. In the washtub, sensors monitor the water level, for example, and send signals back to the controller to prevent the next process from beginning before the previous one has finished. Without such feedback a delay or interruption in any of the processes can cause a disaster.

This distinction between the control system and the machinery performing the essential processes of the cell cycle was not generally recognized until recently. Instead, it was thought that each of the major essential processes might somehow directly trigger the next process, as in a chain of falling dominoes (Figure 17-8). The turning point in our understanding came with the identification of key components of the central cell-cycle control system and the recognition that these were distinct from the molecules that perform the essential processes of DNA replication, chromosome segregation, and so forth.

The cell-cycle control system is a cyclically operating biochemical device constructed from a set of interacting proteins that induce and coordinate the essential *downstream processes* that duplicate and divide the cell's contents ("downstream" in this context meaning simply that they occupy a subordinate position in the hierarchy of cell-cycle control). In the standard cell cycle the control system is regulated by brakes that can stop the cycle at specific *checkpoints*. Here, feedback signals conveying information about the downstream processes can delay progress of the control system itself, so as to prevent it from triggering the next downstream process before the previous one has finished.

The brakes are important also in another way: they allow the cell-cycle control system to be regulated by signals from the environment. These environmental controls generally act on the control system at one or other of two major checkpoints in its cycle - one in G_1, just before entry into S phase; the other in G_2, at the entry to mitosis. In higher eucaryotic cells signals that arrest the cycle usually act at the G_1 control point. This checkpoint is called *Start* in yeast, and in mammalian cells we shall call it simply the G_1 checkpoint (Figure 17-9). When circumstances forbid cell division, it is at this point in the cycle that many cells halt. In a continuously cycling cell the G_1 checkpoint is the point where the cell-cycle control system triggers a process that will initiate S phase, and the G_2 checkpoint is where it triggers a process that will initiate M phase.

The Cell-Cycle Control System Is a Protein-Kinase-based Machine 3

For historical reasons most of what we know about the mechanism of the cell-cycle control system has been learned from studies on the G_2 checkpoint at the entry to mitosis. In our initial description of this control system, consequently, we focus on the mechanisms that drive the cell past the G_2 checkpoint into M phase. It is thought likely that a similar mechanism operates at the G_1 checkpoint, although the precise components are different.

The cell-cycle control system is based on two key families of proteins. The first is the family of cyclin-dependent protein kinases (Cdk for short), which induce downstream processes by phosphorylating selected proteins on serines and threonines.

The second is a family of specialized activating proteins, called *cyclins,* that bind to Cdk molecules and control their ability to phosphorylate appropriate target proteins (Figure 17-10). The cyclic assembly, activation, and disassembly of cyclin-Cdk complexes are the pivotal events driving the cell cycle. Cyclins are so called because they undergo a cycle of synthesis and degradation in each division cycle of the cell. There are two main classes of cyclins: mitotic cyclins, which bind to Cdk molecules during G_2 and are required for entry into mitosis, and G_1 cyclins, which bind to Cdk molecules during G_1 and are required for entry into S phase (Figure17-11). In yeast cells, which have played an essential part in research on the cell cycle, the same member of the Cdk family provides the kinase activity at both checkpoints; in mammalian cells there are at least two different Cdk proteins, one for each checkpoint.

In outline, the events that drive the cell into mitosis are as follows: Mitotic cyclin accumulates gradually during G_2 and binds to Cdk to form a complex known as *M-phase-promoting factor (MPF)*. This complex is at first inactive, but through the action of other enzymes that phosphorylate and dephosphorylate it, it is converted to an active form. The ultimate activation of MPF is almost explosive. This is believed to be due to a positive feedback mechanism whereby active MPF increases the activity of the enzymes that activate MPF: thus the concentration of active MPF builds up at an accelerating pace until a critical flashpoint is reached, whereupon a flood of active MPF triggers the downstream events that propel the cell into mitosis. MPF is inactivated equally suddenly by the degradation of mitotic cyclin at the metaphase-anaphase boundary, enabling the cell to exit from mitosis.

Each step of Cdk activation or inactivation marks a *cell-cycle transition* and presumably has an effect on the cell-cycle control system itself, initiating reactions that will eventually lead it to trigger the next downstream process. The mechanism operating at the G_1 checkpoint is much less well understood than that at the G_2 checkpoint, but the principles are believed to be similar: just as the assembly of MPF ultimately triggers the events of mitosis, so the assembly of a related complex comprising a Cdk protein and G_1 cyclin is thought to drive the cell past the G_1 checkpoint, triggering the events that lead to DNA replication. The downstream events induced by the activation of Cdk at the G_1 and G_2 checkpoints are completely different, even though in yeast the same Cdk protein serves for both. The particular proteins that are phosphorylated by activated Cdk protein are therefore thought to depend on the cyclin component of the complex. We now turn to the evidence on which this view of the cell cycle is based.

Summary

In each division cycle a cell must replicate its DNA. Most cells also grow and duplicate all of their contents. During M phase the replicated chromosomes are segregated into separate nuclei (by mitosis) and the cell splits into two (by cytokinesis). The other, much longer part of the cycle is known as interphase. This period of continuous cell growth includes S phase, when DNA replication occurs, and two gaps, the G_1 and G_2 phases, between S phase and M phase. The sequence of cell-cycle events is governed by a cell-cycle control system, which cyclically triggers the essential processes of cell reproduction, such as DNA replication and chromosome segregation. At the heart of this system is a set of protein complexes formed from two basic types of components: protein kinase subunits (called Cdk proteins) and activating proteins called cyclins. At least two such protein complexes regulate the normal cell cycle - one at a late G_1 checkpoint, just before S phase, and the other late in G_2, just before M Phase. These protein complexes exert control through their kinase activities, which are abruptly switched on or off at particular points in the cycle.
Figure 17-2. The events of cell division as seen under a microscope. The easily visible processes of nuclear division (mitosis) and cell fission (cytokinesis), which are together called the M phase, typically occupy only a small fraction of the cell cycle. The other, much longer part of the cycle is known as *interphase*. During M phase an abrupt change in the biochemical state of the cell occurs at the transition from metaphase to anaphase; a cell can pause in metaphase before this transition point, but once the point is passed, the cell will carry on smoothly to the end of mitosis and through cytokinesis into interphase.
Figure 17-3. The four successive phases of a standard eucaryotic cell cycle. During interphase the cell grows continuously; during M phase it divides. DNA replication is confined to the part of interphase known as S phase. G_1 phase is the gap between M phase and S phase; G_2 is the gap between S phase and M phase.
Figure 17-4. The standard cell cycle compared with the early embryonic cell cycle. In the early embryonic cycle no growth occurs, so that each of the two daughter cells of each division is half the size of the parent cell. The cycle time is extraordinarily short, and S phases and M phases alternate without any intervening G_1 or G_2 phases.
Figure 17-5. Labeling of S-phase cells by autoradiography. The tissue has been exposed for a short period to ^{3}H-thymidine. Silver grains (*black dots*) in the photographic emulsion over a nucleus indicate that the cell incorporated ^{3}H-thymidine into its DNA, and thus was in S phase, sometime during the labeling period. In this specimen, showing sensory epithelium from the inner ear, the presence of an S-phase cell is evidence of cell proliferation occurring in response to damage. (Courtesy of Mark Warchol and Jeffrey Corwin.)
Figure 17-6. Analysis of DNA content with a fluorescence-activated cell sorter. The graph shows typical results obtained for a growing cell population when the DNA content of its individual cells is determined. The fluorescence-activated cell sorter (see Figure4-31) is used here simply to make measurements on the individual cells, rather than to sort them. The cells are stained with a dye that becomes fluorescent when it binds to DNA, so that the amount of fluorescence is directly proportional to the amount of DNA in each cell. The cells fall into three categories: those that have an unreplicated complement of DNA (one arbitrary unit) and are therefore in G_1 phase, those that have a fully replicated complement of DNA (two arbitrary units) and are

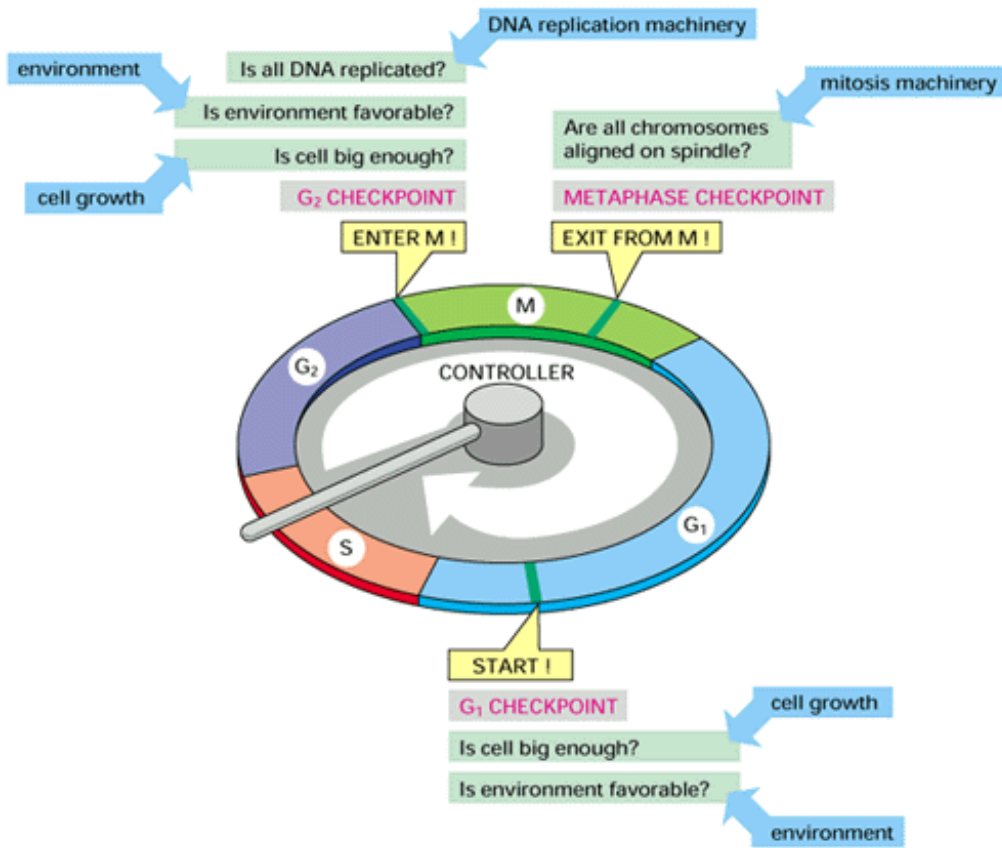
in G_2 or M phase, and those that have an intermediate amount of DNA and are in S phase. The distribution of cells in the case illustrated indicates that there are greater numbers of cells in G_1 than in $G_2 + M$, implying that G_1 is longer than $G_2 + M$ in this population.
Figure 17-7. The control of the cell cycle. The essential processes, such as DNA replication and mitosis and cytokinesis, are triggered by a central cell-cycle control system. By analogy with a washing machine, the control system is drawn as an indicator that rotates clockwise, triggering essential processes when it reaches specific points on the outer dial.
Figure 17-8. Two alternative conceptions of cell-cycle control. The *green slabs* represent essential processes of the cell cycle, such as DNA replication, chromosome condensation, spindle formation, and so on. In (A) the performance of one process is the trigger for the next, as in a chain of falling dominoes. In (B) the processes are not directly coupled in this way but are caused to occur in succession by a control device that operates independently of them. The mechanism shown in (B) corresponds more closely to the real cell cycle, where a cyclic control device, which we shall call the *cell-cycle control system,* triggers the *downstream processes* of the cycle.


Figure 17-9. Checkpoints and inputs of regulatory information to the cell-cycle control system. Feedback from downstream processes and signals from the environment can prevent the control system from passing through certain specific checkpoints. The most prominent checkpoints are where the control system activates the triggers shown in *yellow* boxes.
Figure 17-10. Two key components of the cell-cycle control system. A complex of cyclin with Cdk acts as a protein kinase to trigger downstream processes. Without cyclin, Cdk is inactive.
Figure 17-11. The core of the cell-cycle control system. Cdk is thought to associate successively with different cyclins to trigger the different downstream processes of the cycle. Cdk activity is terminated by cyclin degradation.

The Early Embryonic Cell Cycle and the Role of MPF [4]

Introduction

In a standard cycle the cell has to undergo a period of growth in order to duplicate all of its DNA, as well as all of the components of its cytoplasm, before it can divide. This takes time - a variable amount of time if the environment is variable. Thus the standard cell cycle is prolonged, and control mechanisms are required to guarantee that all the necessary preparations are completed in the correct sequence before division occurs.

The early embryos of many animal species undergo cell-division cycles that are not standard: they occur without growth and at extraordinary speed and lack most of the usual checks and controls. These early embryonic cell cycles reveal the workings of the cell-cycle control system stripped down and simplified to the bare minimum needed to achieve the most fundamental requirement - the duplication of the genome and its segregation into two daughter cells. Although these cell cycles are exceptional, they illuminate the mechanisms of the division cycle in all eucaryotic cells. In this section we see how studies of the early embryonic cycles of the frog *Xenopus* led to the identification of MPF as a central component of the cell-cycle control system; we discuss how the simplified control system performs its repeated cycles of activation and inactivation of MPF; and we see how each such cycle of the control system drives precisely one round of chromosome replication and segregation.

Growth of the *Xenopus* Oocyte Is Balanced by Cleavage of the Egg [5]

The egg of *Xenopus,* like that of many other species, is a giant spherical cell (Figure 17-12), just over a millimeter in diameter. It thus has more than 100,000 times more cytoplasm than an average cell in the body but only a single nucleus. The cytoplasm is filled with a stockpile of the materials that will be required for the construction of the tadpole. These materials have accumulated during a long period of growth of the immature egg, known as the *oocyte,* while it is in the ovary of the mother. In this way the early embryo is relieved of the need to find nourishment and can develop quickly into a free-living organism that can fend for itself (Figure 17-13).

In preparation for its later sexual fusion with a sperm, the growing oocyte has also embarked on the process of *meiosis,* by which it eventually reduces its chromosome number to half the normal value. The reduction is achieved through a single round

of DNA replication followed by two specialized cell divisions in which no further DNA replication occurs (as discussed in Chapter 20). Oocyte growth is spread over a long period, during which progress through meiosis is arrested at a stage traditionally called meiotic prophase but better described as the G_2 phase of the first meiotic division cycle: this point of arrest, just before entry into M phase, corresponds to the G_2 checkpoint in a standard cell cycle.

To produce a mature egg, hormones act on the oocyte, releasing the G_2 arrest and causing the oocyte to progress through meiosis until it comes to a halt at an unusual second point of arrest, in M phase of its second meiotic division (Figure 17-14). In this state the egg travels down the oviduct and gets fertilized as it is laid.

Fertilization triggers an astonishingly rapid sequence of cell divisions in which the single giant cell *cleaves,* without growing, to generate an embryo consisting of thousands of smaller cells (see Figure17-13). In this process almost the only macromolecules synthesized are DNA - required to produce the thousands of nuclei - and a small amount of protein. After a first division that takes about 90 minutes, the next 11 cleavage divisions occur, more or less synchronously, at 30-minute intervals, producing about $4096(2^{12})$ cells within about 7 hours. Each cycle consists of a 15-minute M phase and a 15-minute interphase that is largely occupied by DNA synthesis. There are no detectable G_1 or G_2 phases.

A Cytoplasmic Regulator, MPF, Controls Entry into Mitosis [6], [7]

Two crucial experiments established the existence of a cytoplasmic control mechanism that operates in all dividing cells to initiate mitosis. The first was based on a *Xenopus* oocyte assay technique that has been crucially important in identifying the components of the cell-cycle control system.

The *Xenopus* oocyte, as we have seen, is arrested in meiotic G_2, whereas the egg is arrested in meiotic M phase. The *Xenopus* oocyte and egg therefore provide abundant sources of cytoplasm from these defined stages ofthe cell cycle. Moreover, because they are so big, it is easy to inject substances into their cytoplasm. When M-phase cytoplasm from a mature unfertilized egg is injected into a G_2-phase oocyte, the recipient oocyte is driven into M phase and completes its maturation (Figure 17-15). The activity identified in the egg cytoplasm in this way was initially called maturation-promoting factor because it induces the maturation of an immature oocyte into a mature egg.

The other crucial experiment was performed with mammalian cells in culture. Mammalian cells are generally not large enough for cytoplasmic injections to be easy, but a logically equivalent test can be performed by fusing a mitotic cell with an interphase cell, so that the nucleus of the interphase cell is exposed to any active components that may be present in the cytoplasm of the mitotic cell. In such experiments the interphase cell is driven directly into mitosis, whether it has replicated its DNA or not (Figure17-16).

It was subsequently shown that the activity that drives the oocyte to maturation and the interphase cell into mitosis is the same: maturation-promoting factor is identical to M-phase-promoting factor - two names for one substance, MPF.

Oscillations in MPF Activity Control the Cell-Division Cycle [8]

Xenopus eggs and oocytes provide a good source of material for both purifying MPF and assaying its activity. Once purified, MPF was found to be a protein kinase that phosphorylates proteins on serine and threonine residues and to consist of two essential subunits - a cyclin-dependent kinase (Cdk) called Cdc2 and a mitotic cyclin (Figure17-17). Even before it was purified and biochemically characterized, however, it was possible to demonstrate the crucial role of MPF in the cell cycle.

Experiments using the oocyte assay to test samples of cytoplasm from early embryonic cell cycles as well as from maturing oocytes and eggs showed that MPF activity is high in every mitosis and low in every interphase, peaking every 30 minutes in a cleaving egg. Moreover, MPF activity was found to be a universal feature of the eucaryotic cell cycle: in every species, from yeasts to mammals, cells that are in mitosis contain MPF activity that can be detected by the oocyte injection assay.

It was quickly established that the surge of MPF activity that occurs every 30 minutes in the cleaving *Xenopus* embryo is generated by a cytoplasmic oscillator that operates even in the absence of a nucleus. By constricting an activated egg before it has completed its first division, one can split it into two separate parts - one containing a nucleus, the other not. As expected, the nucleated part continues with the normal program of rapid cleavages. Remarkably, the nonnucleated part also goes through a

series of oscillations, seen as repeated cycles of contraction and stiffening of the cortical cytoplasm. These recurrent spasms occur in almost perfect synchrony with the cleavage divisions of the nucleated half-egg (Figure 17-18). A starfish egg whose nucleus has been removed goes even further: provided it retains a centrosome, it will cleave repeatedly to form smaller and smaller cells, all without nuclei.

If samples of cytoplasm are taken at intervals from the nonnucleated *Xenopus*cell and assayed by injection into oocytes, it can be shown that the visible oscillations reflect oscillations of MPF activity. In these giant egg cells the oscillations that drive the division cycles evidently run independently of any signals from the relatively tiny amount of nuclear DNA that is normally present. We shall see later that this is not the case in standard cell cycles, where strict control mechanisms operate to ensure that chromosome replication and cell division are correctly coupled.

Cyclin Accumulation and Destruction Control the Activation and Inactivation of MPF 9

Although division cycles in the cleaving embryo can occur in the absence of DNA, they cannot occur in the absence of protein synthesis: blocking protein synthesis in early interphase prevents both the activation of MPF and the next mitosis. The explanation for this observation became clear with the identification of cyclin.

The synthesis of proteins in fertilized sea urchin eggs (whose cell cycle is similar to that of *Xenopus* embryos) was examined by fertilizing a batch of eggs in sea water containing a radioactive amino acid (^{35}S-methionine), removing samples periodically, and running them on a gel. Once they had been separated on the gel, the freshly made proteins could be visualized by virtue of their radioactivity. These experiments revealed that whereas most proteins accumulate continuously after fertilization, one class of proteins shows a periodic pattern: they accumulate steadily during each interphase until the metaphase-anaphase transition, and then are suddenly destroyed (Figure17-19). This pattern of events earned the proteins the name cyclin and led to the hypothesis that one or more cyclins had to build up to a threshold concentration to activate MPF and that destruction of cyclin was coupled to inactivation of MPF and exit from mitosis.

The development of cell-free extracts that would undergo the cell cycle *in vitro* was crucial in elucidating the role of cyclin. These extracts are prepared by centrifuging frog eggs so as to break them open and collect their cytoplasm. Sperm nuclei added to such a cytoplasmic extract can swell, replicate their DNA, and pass through mitosis, just as they would in a fertilized egg: they thus serve as indicators of the cell-cycle phase of the extract (Figure17-20). If all of the mRNA in the extract is then destroyed, the cell cycle arrests in interphase, just as it does when protein synthesis is inhibited in the embryo. Remarkably, the addition of purified cyclin mRNA alone restores the ability of the extract to activate MPF and induce mitosis, indicating that it is only the lack of cyclin synthesis in the mRNA-depleted extract that arrests the cycle. The simplest hypothesis would be that the activation of MPF is normally triggered as soon as the cyclin concentration reaches a threshold value. In reality, as already discussed, the timing of MPF activation is not governed exclusively by cyclin but depends as well on the regulation of the Cdk subunit of MPF by other proteins. These other controls are hard to investigate in the *Xenopus* embryo, but they can be deciphered by the powerful tools of yeast genetics, as we discuss later.

Degradation of Cyclin Triggers Exit from Mitosis 10

The destruction of cyclin is as important for exit from mitosis as its synthesis is for entry. Normally, cyclin is suddenly destroyed by proteolysis at the metaphase-anaphase transition. This process requires a signal sequence in the cyclin polypeptide chain that targets it for degradation (by providing a site for attachment of ubiquitin - see p. 218), and it is dependent on the activation of MPF. The role of cyclin degradation has been tested by constructing a truncated form of cyclin that is still able to stimulate the activation of MPF but cannot be degraded because it lacks the appropriate signal sequence. When mRNA for the indestructible cyclin is added to the frog cell-cycle extract, the extract enters mitosis but cannot escape from it. Thus the activation of MPF that induces mitosis requires cyclin synthesis, and the inactivation of MPF that leads to the next interphase requires cyclin degradation.

Cyclin is an essential component of MPF and is found in all eucaryotic cells. As mentioned earlier, there are many varieties of cyclin, produced by a family of related genes. The main mitotic cyclin is known as *cyclin B*. Standard cell cycles depend also on several other cyclins: the G_1 *cyclins,* in particular, appear to play a key role in the activation of the protein kinase that drives cells out of G_1 and commits them to embark on DNA replication. For this too the chief evidence comes from genetic studies in yeasts and is discussed later.

MPF Can Act Autocatalytically to Stimulate Its Own Activation 6

Xenopus oocyte experiments have suggested an explanation for one further feature of MPF - its sudden, all-or-none activation at the onset of mitosis. When a small amount of active MPF is injected into an arrested oocyte, the oocyte is triggered to generate additional active MPF, implying that production of active MPF is an autocatalytic process. The operation of the cell-cycle control system in the early embryo thus can be outlined as follows: The gradual accumulation of cyclin acts like a slow-burning fuse, which eventually ignites an autocatalytic explosion of MPF activity that triggers the early events of mitosis and initiates the destruction of cyclin. The destruction of cyclin terminates the MPF activity, and a new round of cyclin accumulation begins.

Active MPF Induces the Downstream Events of Mitosis 11

MPF has to bring about many radical changes in the cell to drive it into mitosis. The chromosomes must condense, the nuclear envelope must break down, and the cytoskeleton must be reorganized to form a mitotic spindle. MPF induces all of these essential events through its protein kinase activity. It brings about some changes directly by phosphorylating key architectural components of the cell. Other events may be induced indirectly - for example, by phosphorylations that activate other protein kinases that act in a cascade to alter the state of the cell.

The breakdown of the nucleus requires the disassembly of the nuclear lamina - the underlying shell of polymerized lamin filaments (discussed in Chapter 12). MPF catalyzes this process directly, forcing the lamin molecules to disassemble by phosphorylating them on key serine residues (see Figure12-18). In cells containing genetically engineered mutant lamins that lack these MPF phosphorylation sites, the nuclear lamina fails to break down at mitosis, although the membranous nuclear envelope breaks up into vesicles and the other events of mitosis take place almost normally.

Another of the molecules that MPF can phosphorylate directly is histone H1, which plays a part in the packaging of DNA into nucleosomes. It is possible, but not proven, that its phosphorylation may help to induce chromosome condensation.

MPF changes the behavior of microtubules in mitosis by phosphorylating microtubule-associated proteins. In interphase the centrosome nucleates long microtubules that extend throughout the cytoplasm. At mitosis this cytoplasmic array of microtubules disassembles and the centrosomes nucleate a larger number of shorter, less stable microtubules, which interact with one another to form the mitotic spindle (discussed in Chapter 18). This transformation reflects a chemical change in the centrosome, the microtubules, or both, and it can be reproduced *in vitro* by adding MPF to a cell-free system containing centrosomes and tubulin and other components of interphase cytoplasm. Both of the components of MPF - mitotic cyclin and the Cdc2 kinase - can be found bound strongly to centrosomes in the living cell: the mitotic cyclin is thought to recognize components of the centrosome and recruit the Cdc2 kinase to the site.

Although the pathways are not known in detail, it is clear that MPF directly or indirectly induces the phosphorylations of many proteins. To escape from mitosis, cells have to reverse these phosphorylations, and it has been shown in flies and fission yeasts that mutations that inactivate protein phosphatase I - one of the major general-purpose phosphatases in the cell - will prevent or greatly delay the downstream events that normally follow the inactivation of MPF, such as reconstruction of the nuclear envelope.

The Cell-Cycle Control System Allows Time for One Round of DNA Replication in Each Interphase 12

We have now seen in outline how components of the cell-cycle control system are periodically activated and inactivated to drive the cell into and out of mitosis and how the activated components trigger the downstream processes. The downstream processes themselves take time, however. How does the control system ensure that it allows enough time for each of these processes to go to completion before it triggers the next?

Of the processes that must be given adequate time for completion, one of the most critical is DNA replication. If the control system activates the M-phase trigger before DNA replication is complete, the cell enters a suicidal mitosis with its chromosomes only partially replicated. We shall see later that in standard cell cycles a feedback signal from incompletely replicated DNA protects the cell from this type of disaster by arresting the progress of the control system.

For the first few embryonic cycles of the developing frog, however, no such feedback operates. Here, the time required for each downstream process is predictable and invariant, thanks to the stockpiles of nutrients in the egg and the protected environment

of the embryo; consequently, it is sufficient for the control system to go through its cycle at a suitable rate, with appropriate preset delays between the activation of one trigger and the next. The DNA polymerase and other components required for DNA replication are permanently at the ready and can complete a round of DNA replication faster than the control system can complete its cycle. In fact, the control system in the early embryo is oblivious to the progress of DNA replication, so that if replication is artificially halted by an inhibitor of DNA synthesis, the cell is driven on regardless into a disastrous mitosis. During the early cleavages of the embryo, it seems that the quantity of DNA is simply too tiny in relation to the quantity of cytoplasm for DNA-dependent signals to make themselves felt by the cytoplasmic control system. Over the first 12 division cycles, as the egg is subdivided and new nuclei are formed, the ratio of nuclear DNA to cytoplasm increases by a factor of more than 4000, and toward the end of this period the feedback controls of the standard cell cycle begin to operate.

A Re-replication Block Ensures That No Segment of DNA Is Replicated More Than Once in a Cell Cycle [7]

Another type of control is required to solve a complementary problem: while it is essential in each cell cycle that all of the cell's DNA should be replicated, it is equally important that none of the cell's DNA should be replicated more than once. The cell solves this problem not by feedback regulation of the cell-cycle control system but by a self-limiting device that is built into the process of DNA replication itself: as discussed in Chapter 8, each segment of chromatin, as soon as it has been replicated, becomes altered in some way so as to prevent it from being replicated again during the current cycle.

Although the nature of this re-replication block is still unknown, there is clear evidence for its existence, and it appears to be fundamental to the operation of the cell cycle in all eucaryotes. A neat demonstration is provided by experiments on mammalian cells undergoing standard division cycles in culture. As we saw earlier in Figure 17-16, two cells that are in different phases of the cycle can be fused with each other. When a cell in G_1, with its DNA still unreplicated, is fused with a cell in S phase, the G_1 nucleus in the hybrid cytoplasm is induced to begin DNA synthesis immediately. The S-phase cell evidently contains inducers of DNA synthesis in its cytoplasm, and the G_1 nucleus is susceptible to them. In contrast, when a G_2 cell, which has just finished DNA synthesis, is fused with an S-phase cell, the G_2 nucleus does not resume DNA synthesis, even though DNA synthesis continues in the S-phase nucleus in the shared cytoplasm. It seems that the machinery for DNA replication is present in the hybrid cell, but the G_2 nucleus is refractory to its action (Figure17-21). Passage from G_1 via S into G_2 has created a block to further DNA replication.

Passage Through Mitosis Removes the Re-replication Block [13]

The block to re-replication has to be removed at some stage between the end of G_2 and the beginning of the next S phase to allow the next cycle of DNA replication to begin. It is not known precisely when or how the block is lifted, but in the early embryonic cell cycle, at least, this change appears to depend on the breakdown of the nuclear envelope at mitosis. The experiments that show this also illustrate how the cell-cycle control system drives the chromosomes through cycles of replication and segregation in strict alternation.

As discussed previously, the early embryonic cell-cycle control system can operate in cell-free frog-egg extracts, where it can be arrested in interphase by blocking protein synthesis or be driven into M phase by adding MPF. Sperm nuclei added to an interphase-arrested extract undergo exactly one round of DNA replication and then halt. This is not because there has been any change in the extract (which can still support replication of fresh nuclei added later) but because of a re-replication block imposed on the sperm nuclei. If MPF is added to the extract, the nuclei break down, and when they re-form (following inactivation of MPF), they undergo a single additional round of replication and halt again. Thus each burst of MPF activity gives the nuclei a license to undergo one round of replication. Although the nature of this license is not known, there is evidence to suggest that it depends on a factor from the cytoplasm that has to get into the nucleus to act and is able to do so only when the nuclear envelope breaks down at mitosis.

Thus the control of DNA replication in the early embryo can be summarized as follows. The trigger for mitosis is activated at fixed time intervals, and at each mitosis the DNA receives a license for replication. The DNA replication machinery has time to complete one round of replication before the next mitosis begins, and it is prevented from going beyond one round by the re-replication block. This is enough to ensure that S phases precisely replicate the chromosomes and alternate regularly with M phases, which segregate the chromosomes into separate cells.

In standard cell-division cycles the control system is more complex, but the re-replication block plays a similar role in guaranteeing that the DNA is replicated only once in each cycle. Like most "rules" in the cell cycle, however, the block to re-

replication has some exceptions. In flies, for example, many of the larval cells go through multiple rounds of chromosome replication without intervening mitosis or cell division, thereby forming giant polytene chromosomes in which hundreds or thousands of copies of the genome are bundled together in parallel (see Figure 8-19). In this special case the re-replication block is somehow removed without disruption of the nuclear envelope.

To take our account of the cell-cycle control system further, and to see how cells coordinate the more complex events of the standard cell cycle, we must now turn from the early frog embryo to yeasts, where the problem can be approached genetically.

Summary

The early embryos of many animal species undergo exceptionally rapid cell cycles, through which the large egg cell becomes subdivided into many smaller cells without growing. These early embryonic cell cycles, in which S and M phases alternate in quick succession without intervening G_1 or G_2 phases, demonstrate the workings of the cell-cycle control system in its simplest form. The key component of the control system is a protein kinase, MPF, whose activation, by an explosive autocatalytic process, drives the cell into mitosis; inactivation of MPF then allows the cell to exit from mitosis and replicate its DNA. MPF is cyclically activated and inactivated in the early embryonic cycles independently of the nucleus. It consists of two major subunits - a cyclin-dependent kinase called Cdc2, and cyclin. Cdc2 must associate with cyclin to become active as MPF. Destruction of the cyclin inactivates MPF at the point of exit from mitosis, and accumulation of freshly synthesized cyclin allows reactivation of MPF in the next cycle. In these early embryos the time taken to reactivate MPF after exit from mitosis is just long enough to allow one round of DNA replication. A re-replication block is imposed on each segment of DNA as it is replicated, and the re-replication block is removed only on passage through mitosis. In this way the cell-cycle control system drives alternating rounds of DNA replication and chromosome segregation.

0.5 mm

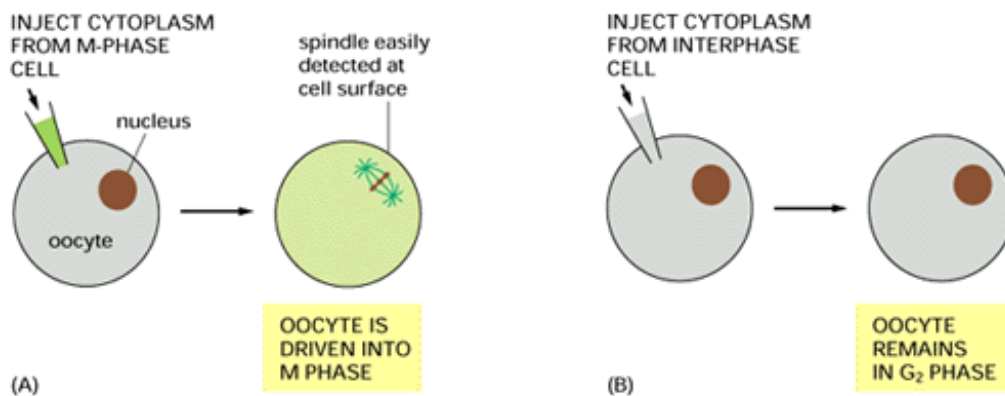
Figure 17-12. A mature *Xenopus* egg, ready for fertilization. The pale spot near the top shows the site of the nucleus, which has displaced the brown pigment in the surface layer of the egg cytoplasm and whose envelope has broken down during the process of egg maturation. (Courtesy of Tony Mills.)
Figure 17-13. Oocyte growth and egg cleavage in *Xenopus*. The oocyte grows for many months in the ovary of the mother frog, without dividing, and finally matures into an egg. Upon fertilization, the egg cleaves very rapidly - initially at a rate of one division cycle every 30 minutes - forming a multicellular tadpole within a day or two. The cells get progressively smaller with each division as no growth can occur until the tadpole begins feeding. The drawings in the top row are all on the same scale (but the frog below is not).
Figure 17-14. *Xenopus* egg maturation and activation. Hormones acting on the fully grown oocyte drive it from its state of G_2 arrest into M phase of meiosis: it completes the first meiotic division and becomes arrested in metaphase of the second meiotic division. In this state, now called a *mature egg,* it is laid. The two meiotic divisions follow one another in quick succession, without an intervening S phase; the chromosomes remain condensed throughout. Fertilization releases the metaphase arrest, so that the egg completes its second meiotic division and enters interphase of the first embryonic cell cycle. Each of the two meiotic divisions generates one large cell - the future egg - and one tiny cell, called a polar body, which eventually degenerates.


Figure 17-15. Assaying for MPF by injection into a *Xenopus* oocyte. MPF can be detected because it drives the oocyte into M phase. The large nucleus (or "germinal vesicle") of the oocyte breaks down as the mitotic spindle forms.
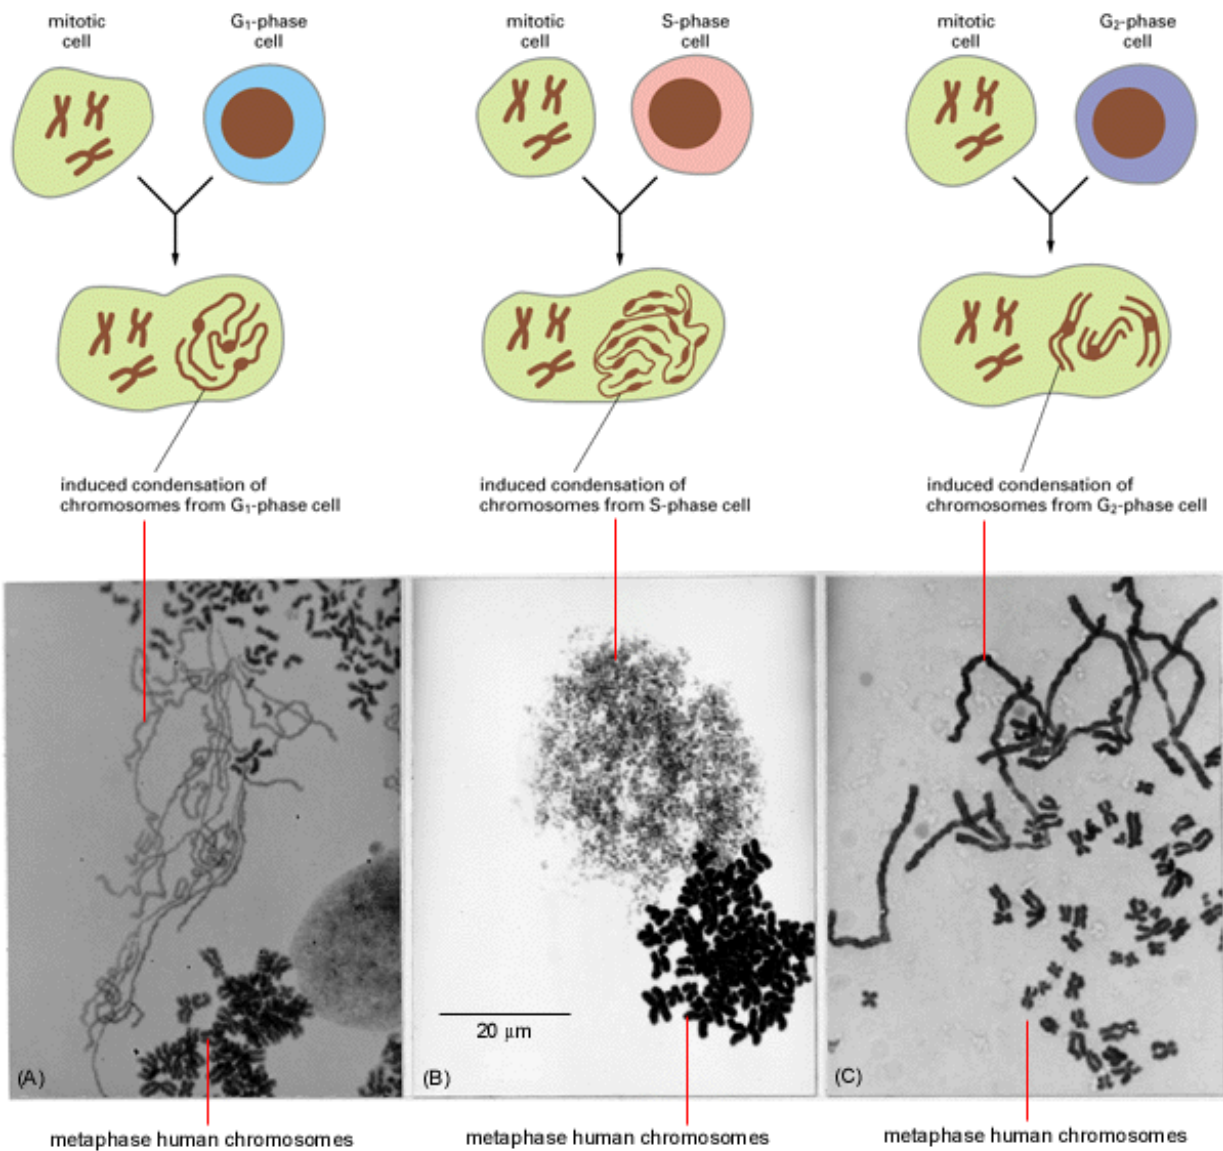

Figure 17-16. Results of fusing a mitotic mammalian cell with an interphase mammalian cell. The cells are induced to fuse by adding an appropriate agent to the culture medium (see p. 160). The interphase nucleus is driven directly into a mitotic state, with chromosomes condensed regardless of their state of replication. The photographs show fusions of mitotic human cells with interphase marsupial (PtK) cells. In (A) the PtK cell was in G_1 phase; consequently, its prematurely condensed chromosomes are still single chromatids. In (B) the PtK cell was in S phase, and its chromatin adopts a "pulverized" appearance. In (C) the PtK cell was in G_2 phase, and now the chromatids, although very long compared to the normal (human) metaphase chromosomes, are double. (From K. Sperling and P. Rao, *Humangenetik* 23:235-258, 1974.)
Figure 17-17. The two key subunits of MPF. The Cdk subunit is named Cdc2 after the gene in fission yeast that encodes it.

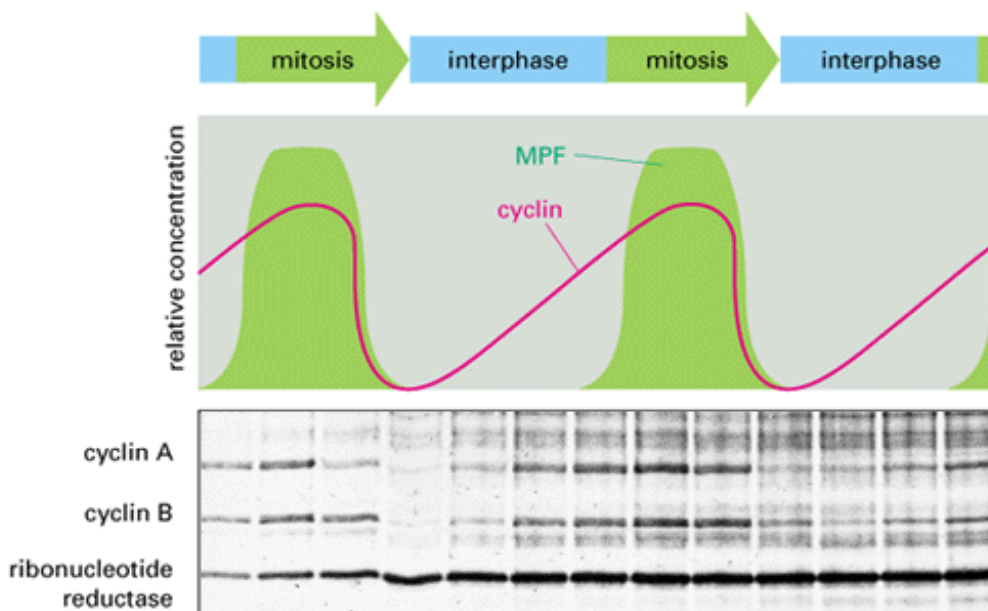
time postfertilization ⟶
Figure 17-18. A *Xenopus* egg split into two parts - one nucleated, the other not. A loop of fine human hair is tightened around the egg so as to cut it in two. The half containing the nucleus goes on to divide; the other half, lacking a nucleus, does not divide. Time-lapse cinematography shows, however, that the nonnucleated half periodically changes its height through changes in the stiffness of the of the cell cortex, oscillating in close synchrony with the divisions of the nucleated half. (From K. Hara, P. Tydeman, and M. Kirschner, *Proc. Natl. Acad. Sci. USA* 77:462-466, 1980.)


Figure 17-19. Rise and fall in levels of MPF and cyclin during the early embryonic cell cycle. The cyclin measurements

have been made chiefly in the eggs of marine invertebrates, where cyclin accounts for 5% of the protein synthesized during a brief pulse with radioactive amino acids. The gels below the graph show the amounts of labeled cyclin of two varieties, A and B, at different stages of the cycle of a clam egg. The bottom line in the gel shows the synthesis of a house-keeping enzyme that serves as a standard of comparison. (Adapted from T. Hunt, F.C. Luca, and J.V. Ruderman, *J. Cell Biol.* 116:707-724, 1992.)
Figure 17-20. Cycling in a cell-free system. A large batch of activated frog eggs are broken open by gentle centrifugation, which also separates their cytoplasm from other components. The undiluted cytoplasm is collected, and sperm nuclei are added to it, together with ATP. The sperm nuclei decondense and then go through repeated cycles of mitosis and DNA replication, indicating that the cell-cycle control system is operating in this cell-free cytoplasmic extract.
Figure 17-21. The re-replication block: evidence from cell-fusion experiments with cultured mammalian cells. The results show that S-phase cytoplasm contains factors that drive a G_1 nucleus directly into DNA synthesis (A); but a G_2 nucleus, having already replicated its DNA, is refractory to their action (B). Note that fusion of a G_2 cell with a G_1 cell does not drive the G_1 nucleus into DNA synthesis (C); therefore, the cytoplasmic factors for DNA replication that were present in the S-phase cell disappear when the cell moves from S phase into G_2.

Yeasts and the Molecular Genetics of Cell-Cycle Control [14]

Introduction

Yeasts are unicellular fungi - a large, heterogeneous group of eucaryotic organisms. They are ideal for genetic studies of eucaryotic cell biology because they reproduce almost as rapidly as bacteria and have a genome size less than 1/100th that of a mammal. Yeasts and frogs have complementary strengths and weaknesses for studies on the cell cycle. Yeasts are very well suited for identifying, cloning, and characterizing the genes involved in controlling the cycle; but the yeast cells are too tiny for microinjection studies, and their cell cycles are more complex and cannot yet be reproduced in a cell-free system *in vitro.* Yet these two very different organisms use fundamentally similar cell-cycle machinery, and in combination they have allowed the cell-cycle control system to be dissected into its component parts.

The two yeast species that we shall discuss are the budding yeast *Saccharomyces cerevisiae,* used by brewers and bakers, and the fission yeast *Schizosaccharomyces pombe,* whose second name comes from the African beer it is used to produce. Although the evolutionary lineages leading to budding and fission yeasts diverged many hundreds of millions of years ago, the two organisms have similar life cycles. Both yeasts can proliferate in either a diploid or a haploid state: the diploid cells, as an alternative to dividing in the ordinary way, can go through meiosis to form haploid cells (see Chapter 20); the haploid cells, as an alternative to dividing, can mate (*conjugate*) with one another to form diploid cells (Figure 17-22). The haploid phase makes it easy to isolate and study mutations that inactivate a gene without the complication of having a second gene copy in the cell. In both species of yeasts, food and sex play important parts in controlling the cell-division cycle, so that these organisms can be used to investigate the general question of how the division cycle is regulated by environmental factors and by cell-cell interactions.

Cell Growth Requires a Prolonged Interphase with Cell-Cycle Checkpoints [3], [15]

The yeast cell cycle is more complex than that of the early frog embryo because a yeast, like the vast majority of cells, has to grow before it divides. Since it takes a cell longer to double its total mass than it does to replicate its DNA and segregate its chromosomes, the cell cycle of growing cells includes - G_1 and G_2 interludes - G_1 between the end of M phase and the onset of DNA synthesis, and G_2 between the end of DNA synthesis and the onset of M phase. G_1 and G_2 allow for controls that couple the length of the cell cycle to the cell's growth rate.

To maintain a constant average cell size, the length of the cell cycle must exactly match the time it takes a cell to double in size. If the cycle time is shorter than the time required to double in size, the cells will get smaller in each generation; conversely, if the cycle time is longer than the size-doubling time, the cells will get bigger in each generation. Because a cell's growth rate is at the mercy of the environment, varying according to the supply of nutrients and other factors, the length of the cell cycle has to be correspondingly adjustable (Figure17-23). To achieve this coordination, the cell-cycle control system has specific *size checkpoints* where the control system halts and waits until the cell has reached a critical size. These checkpoints occur both in G_1, allowing the system to halt before it triggers a new round of DNA replication, and in G_2, allowing the system to halt before it triggers mitosis.

Although both of these checkpoints operate in all cells, the G_1 checkpoint is more prominent in some cells and the G_2 checkpoint is more prominent in others, depending on where the stricter size criteria, or the majority of environmental controls, are applied. Thus in budding yeast the G_1 checkpoint, called Start, is the most important size checkpoint, and a cell that is large enough to pass this checkpoint will generally pass the G_2 checkpoint; the G_1 checkpoint is also the one at which most environmental controls act in the yeasts and in mammalian cells. In fission yeast, by contrast, the G_2, or *mitotic entry,* checkpoint is the more stringent size checkpoint.

Fission and Budding Yeasts Change Their Shape as They Progress Around the Cell Cycle [14]

Although yeasts serve as useful models for study of the standard cell cycle, their cycles differ from those of animal and plant cells in some respects. Like all fungi they keep their nuclear envelope intact throughout mitosis: a mitotic spindle forms *inside* the nucleus, and after chromosome segregation has been completed, the nucleus pinches in half.

Certain details of the cell cycle, moreover, are different in the two types of yeast. Fission yeasts are rod-shaped cells that grow by elongation at their ends. After mitosis the cell divides in two by laying down a septum at the center of the rod. Budding yeasts, by contrast, divide by forming a bud. The bud is initiated during G_1, grows steadily, and finally separates from its mother after mitosis (Figure 17-24). The presence of the bud is a signal that the cell has passed Start and embarked on a division cycle, and the size of the bud provides an indication of how far beyond that point the cell has progressed around the cycle.

Cell-Division-Cycle Mutations Halt the Cycle at Specific Points; *wee* Mutations Let the Cycle Skip Past a Size Checkpoint 16

The foundations of our present understanding of the cell cycle in yeasts come from a systematic search for mutations in genes encoding components of the cell-cycle machinery.

To identify genes that directly control the cell cycle, the search was focused on two mutant phenotypes. In the first all of the cells in the mutant population arrest at the same specific point in the cell cycle. The affected genes in these mutants are called cell-division-cycle, or *cdc,* genes; each *cdc* mutant is typically deficient in a gene product required to get the cell past the specific point in the cycle at which the mutant cells arrest. The second type of mutation is called *wee,* from the Scottish word for small, because the mutant cells divide at a smaller size than normal. *Wee* mutants are expected to be deficient in a product that normally *inhibits* passage through a size checkpoint.

Since a mutant that cannot complete a division cycle cannot be propagated, *cdc* mutants can be selected and maintained only if their phenotype is *conditional,* that is, if the gene product fails to function only in certain specific conditions. Most conditional cell-cycle mutants are *temperature-sensitive mutants* in which the mutant protein fails to function at high temperatures but functions well enough to allow cell division at low temperatures. A temperature-sensitive *cdc* mutant strain of cells can be grown at low temperature (the *permissive condition*) and then raised to a higher temperature (the *restrictive condition*) to switch off the function of the affected gene. All of the cells will continue their cycling until they reach the point where the function of the mutant gene is required for further progress, and at this point they will all stop (Figure17-25). In budding yeast a uniform cell-cycle arrest of this type can be detected just by looking at the cells; the presence or absence of a bud and its size provide a simple indication of the point in the cycle where the mutants are blocked. In the fission yeast, more laborious tests must be used to identify the process in the cell cycle that has failed.

There are now about 70 known cell-division-cycle genes, many of which have been cloned and sequenced. Several of them encode already familiar proteins involved in the downstream processes of the cell cycle, such as DNA polymerases and enzymes that synthesize the precursors for DNA synthesis, which are required for passage through S phase. A substantial number of other *cdc* genes, however, together with one key *wee* gene, code for components and regulators of the cell-cycle control system itself.

The Subunits of MPF in Yeasts Are Homologous to Those of MPF in Animals 17

As mentioned earlier, the most important size checkpoint in the cell cycle of *S. pombe* is the mitotic entry checkpoint located late in G_2. This is where the fission yeast cell-cycle control system normally pauses to allow time for growth when the cell is smaller than it should be: once past this checkpoint, the cell is committed to mitosis. Thus studies of the fission yeast provide a natural route toward identifying the genes encoding the components of the cell-cycle control system that drive a cell into mitosis, as well as the regulators that act on the system at this point. The mitotic entry point is also the point at which MPF is activated in the early embryonic cell cycles of *Xenopus,* and we shall now see how genetic studies on fission yeast converged with the biochemical studies in *Xenopus* and enabled the gene encoding the Cdk subunit of MPF to be identified and the mechanism of MPF activation to be clarified.

The fission yeast homolog of the protein kinase subunit of MPF is encoded by a gene called *cdc*2. Investigations of fission yeast cell-cycle mutants revealed the *cdc*2 gene product as a pivotal, decisive component for driving the cell into mitosis: when it is defective, mitosis fails to occur; when it is released from normal control, mitosis occurs prematurely. Genetic tests identified three other genes, *wee*1, *cdc*25, and *cdc*13, whose products regulate the function of the *cdc*2 gene product (Figure 17-26). The characterization of these regulatory gene products has led to our present understanding of the regulation of MPF, as we discuss below.

The discovery of the relationship between MPF and the *cdc*2 gene product depended on the cloning of *cdc*2. There is a simple and powerful strategy for cloning the normal counterpart of any mutant *cdc* gene. The mutant cells, which are incapable of

dividing at high temperature (the restrictive condition), are transfected with plasmids containing random fragments of DNA from normal cells. Occasional mutant cells will receive a DNA fragment that includes a copy of the normal *cdc* gene that the mutant lacks, and these few cells will be able to divide under the restrictive conditions. By recovering the plasmid DNA from their progeny, one obtains the *cdc* gene. It can then be sequenced and characterized, and antibodies can be made against its protein product.

Sequencing revealed that the fission yeast *cdc*2 gene encodes a protein kinase. Antibodies against this kinase recognized the cyclin-dependent kinase subunit of purified MPF from a frog. Further gene sequencing showed that the fission yeast Cdc13 protein is homologous to mitotic cyclin (cyclin B) of animals. The fundamental similarity between yeasts and vertebrates was even more dramatically emphasized by a third finding: when mutant yeast cells deficient in *cdc*2 were transfected with plasmids containing fragments of human DNA, some were rescued and divided normally. The rescuing fragment, when cloned and sequenced, contained a human gene homologous to the fission yeast *cdc*2 gene . From all this and other evidence, it is clear that in both yeasts and vertebrates entry into mitosis is driven by essentially the same kinase and that, to become active as MPF, this kinase has to be complexed with cyclin. For historical reasons the cyclin-dependent kinase subunit of MPF is commonly referred to as Cdc2 both in the fission yeast and in animal cells.

MPF Activity Is Regulated by Phosphorylation and Dephosphorylation [18], [19]

We now return to the regulatory proteins identified by *cdc* and *wee* mutations and examine how they control the activation of MPF. We saw earlier that cyclin by itself, although necessary, is not sufficient to activate Cdc2; however, once bound to cyclin B during interphase, Cdc2 becomes a substrate for two protein kinases. The first kinase is the Wee1 protein, which phosphorylates a tyrosine residue close to the catalytic site of Cdc2, blocking its kinase activity and preventing it from acting prematurely as MPF. The second kinase, called MO15 (identified in the frog), phosphorylates a threonine residue in another region of the Cdc2 molecule. This phosphorylation will ultimately activate MPF, but as long as the tyrosine residue is also phosphorylated, the cyclin-Cdc2 complex is inactive. In both frogs and yeasts it is the removal of the inhibitory tyrosine phosphate that finally activates MPF. In fission yeasts this removal is catalyzed by Cdc25 protein, which is a protein phosphatase (Figure17-27). The series of conformational changes in the Cdc2 protein molecule underlying this activation mechanism is shown in Figure 5-16.

The balance of Wee1 activity and Cdc25 activity is presumably such that at first only a small amount of active MPF is generated. But this active MPF is thought to stimulate further MPF activation, probably through stimulation of the Cdc25 phosphatase activity, inhibition of the Wee1 kinase activity, or both, creating a positive feedback effect. Thus, during G_2 phase, cyclin gradually accumulates, causing a slowly increasing level of MPF activity that eventually undergoes an autocatalytic explosion and, by rising above a critical point, drives the cell irreversibly into mitosis.

The MPF-Activation Mechanism Controls Size in Fission Yeast [15], [18], [19], [20], [21]

Although the above account of MPF activation appears to apply to all eucaryotes, there are variations. The timing of MPF activation, for example, may depend in some organisms chiefly on the timing of cyclin accumulation but in others on the timing of Cdc25 activity. Moreover, the MPF-activation mechanism is exploited for different regulatory purposes in different organisms and in different cell types within an organism. In the early embryo it serves simply to set the time between one mitosis and the next. In fission yeast, by contrast, it gives both a delay between the end of S phase and the onset of mitosis and an opportunity for cell-size control.

The precise mechanism of cell-size control in fission yeast is not yet known, but one can imagine in a general way how it might work. The activation of MPF is governed by the balance of inhibition by Wee1 protein and activation by Cdc25 protein, as well as by other possible regulators. The concentrations and activities of these molecules will change in different ways as the cell gets bigger. If, for example, Wee1 protein were to become diluted relative to Cdc25 protein as a result of cell growth, growth would swing the regulatory balance in favor of MPF activation, and growth beyond a critical size would trigger an autocatalytic MPF explosion. Whether cell size is a crucial regulator of MPF activation (as in fission yeast) or not (as in most other cells) will depend on the quantitative details of the activation mechanism and the regulators impinging on it rather than on its basic mode of operation.

Although there is evidence for a size control in many other types of cells, the mechanism is even more obscure than in fission yeast. A possible clue comes from comparisons of cells that differ in ploidy (that is, in the number of copies of the genome that they contain) but are otherwise biochemically and genetically similar (see Figure 17-49). It seems to be a general rule that cell

size is roughly proportional to ploidy, suggesting that the control mechanism depends on some sort of titration - direct or indirect - of the quantity of a cytoplasmic component against the quantity of DNA.

For Most Cells the Major Cell-Cycle Checkpoint Is in G_1 at Start <u>14</u>, <u>15</u>

For budding yeast and for the standard division cycles of most of the commonly studied cell types of multicellular eucaryotes, the major checkpoint where the cell-cycle control system pauses to allow time for growth is not in G_2, as it is in fission yeast, but in late G_1. This G_1 checkpoint is called Start. If the budding yeast cell can pass Start, it will generally pass the mitotic entry checkpoint once it has completed S phase. Thus, for budding yeast, as for most animal cells, the G_1 checkpoint is the point of no return beyond which the cell will complete the cycle even if conditions change. Genetic studies on budding yeast have shown that passage through this checkpoint, like passage through the G_2 checkpoint, hinges on the activity of a cyclin-dependent protein kinase.

The Cdc2 Protein Associates with G_1 Cyclins to Drive a Cell Past Start <u>14</u>, <u>18</u>, <u>22</u>

For a cell colony to thrive in the wild it is not enough simply to pass Start: it is essential to pass it at the right moment. For budding yeast at least three conditions are crucial - cell size, the availability of nutrients, and the demands of sex. If the cell is too small, the control system pauses to give time for growth. If the cell is starved, the control system also pauses, delaying the cell's attempt to duplicate itself. And when the cell is required to mate, a peptide mating factor secreted by a neighboring yeast cell arrests the cell cycle in G_1 and prepares the cell for fusion with a haploid partner (see <u>Figure 17-22</u>). Thus size, food, and sex together govern a three-way choice that the cell faces as it approaches Start (<u>Figure 17-28</u>). Mutations affecting the response of budding yeast cells to these influences have identified the cell-cycle control components that govern progress from G_1 to S.

The search for *cdc* genes in budding yeast revealed several that are necessary for a cell to pass Start. A mutant with a defect in any of these genes comes to a halt in G_1 despite being large enough to pass Start. One of the *cdc* genes identified in this way, named *CDC*28 in budding yeast, turned out to be homologous to the fission yeast *cdc*2: the two genes have similar sequences and are functionally interchangeable. This discovery exposed a remarkable link between Start (the predominant checkpoint in budding yeast) and mitotic entry (the predominant checkpoint in fission yeast). We now know that the cell cycles of both types of yeast include both types of checkpoint, and in both types of yeast the product of the same gene serves both to drive the cell into mitosis and to drive it past Start so as to initiate the replication of DNA. In this chapter, for clarity and to emphasize its universal role, we call this gene *cdc*2 regardless of species.

The Cdc2 protein has distinct activities at the two different checkpoints and is associated with different cyclins. In G_2, as we have seen, it associates with mitotic cyclin to form MPF; in G_1 it associates with G_1 cyclin to form a complex that we shall refer to as Start kinase. Start kinase and MPF presumably phosphorylate different sets of target proteins, or phosphorylate them differently, or both. The specificity of Cdc2 action, therefore, appears to depend on the type of cyclin that is associated with it (<u>Figure 17-29</u>).

The G_1 cyclin class of proteins was discovered in budding yeast through studies of mutant cells that passed Start either prematurely or under conditions where nonmutant cells would not. Three genes identified by these mutations turned out to code for proteins distantly related to mitotic cyclins. This earned the proteins the name of "G1 cyclins" and immediately suggested that the gene products might play an activating role at Start analogous to the role of mitotic cyclins at the G_2 checkpoint (<u>Figure17-30</u>).

The mutant phenotypes could be shown to result from an excess of G_1-cyclin activity. Surprisingly, however, *deletion* of any single one of the G_1-cyclin genes had practically no effect; only when all three of the identified genes were simultaneously deleted did the cells become arrested in G_1, unable to pass Start. It seems therefore that there are at least three G_1 cyclins in the normal yeast cell, that their function is required for the cell to get past Start, and that they are, to some extent at least, functionally interchangeable so that the cell cycle can still continue if one or two of the three are missing.

In a normal cycle the three G_1 cyclins are thought to collaborate to ensure that cells pass Start briskly, decisively, and irreversibly by an explosive activation of Start kinase analogous to the explosive activation of MPF at the onset of mitosis. Although many uncertainties remain, the mechanism is again thought to depend on positive feedback, although by a different

pathway: the Cdc2 kinase when bound to one of the G_1 cyclins is believed to form an active complex that induces transcription of the genes encoding the other two G_1 cyclins, which bind to Cdc2 in turn and further increase their own production until a threshold level of the active complex is reached.

After the cell has passed Start, the G_1 cyclins, like the G_2 cyclins at mitosis, disappear from the cell, and, so far as is known, they then play no further part until the G_1 phase of the next cycle.

The G_1 Cyclins Mediate Multiple Controls That Operate at Start [15], [22], [23]

The budding yeast cell-cycle control system appears to be regulated at Start largely through brakes and accelerators that control the production of the various G_1 cyclins.

Budding yeast cells regulate their size by making the attainment of a certain size a precondition for passing Start - a strategy that probably is also used by many other cells. Thus cells that begin G_1 when they are abnormally small take extra time to grow before passing Start, while those that begin G_1 when they are abnormally large will pass Start sooner than usual. We have already discussed how cell size may govern passage past the G_2 checkpoint in fission yeast by affecting the relative concentrations or activities of regulatory molecules. Similar principles may apply to how cell size governs passage through Start.

The mechanisms by which environmental factors regulate passage through Start are somewhat better understood. A shortage of nutrients reduces the rates of synthesis of cyclins relative to their rates of degradation and thereby reduces their concentrations in the cell. As a result, the cell may fail to attain the threshold concentrations of G_1 cyclins required to trigger the Start kinase explosion. Mating pheromones are also thought to block progress past Start by decreasing the levels of G_1 cyclins, but in this case they do so by causing the G_1 cyclins to be held inactive and degraded.

Start Kinase Triggers Production of Components Required for DNA Replication [2], [24]

Directly or indirectly, the activity of Start kinase at Start has to induce chromosome replication, just as the activity of MPF at the end of G_2 has to induce mitosis. Chromosome replication requires complex equipment - enzymes such as DNA polymerase, ligase, and topoisomerase, as well as enzymes for nucleotide synthesis, structural proteins such as histones, and initiation factors that act at origins of replication to start the process of DNA synthesis (discussed in Chapter 6). The genes for at least some of these proteins are transcribed cyclically during each S phase, and there is strong circumstantial evidence that Start kinase activates their transcription. With the exception of the histones, however, most of these proteins appear to persist (in yeast, at least) throughout the cycle. It is not clear, therefore, whether Start kinase triggers S phase by phosphorylating regulatory components so as to allow activity of a replication machine that is already present or triggers the S phase by causing production of parts of the machine that were previously missing.

In early embryonic cell cycles the situation is much simpler. The embryo is provided with an abundant store of maternally derived RNA transcripts, and all the apparatus for chromosome replication, including, apparently, Start kinase, remains available throughout the cycle. Passage through M phase, by lifting the re-replication block, is sufficient to permit a new round of DNA replication.

Feedback Controls Ensure That Cells Complete One Cell-Cycle Process Before They Start the Next [3], [25]

Each of the major actions of the cell-cycle control system - the activation of MPF at the onset of mitosis, its inactivation at the metaphase-anaphase transition, the activation of Start kinase at Start - triggers a complex downstream process that takes time to complete. If the control system proceeds to its next action before the downstream process is completed, the consequences are likely to be fatal or mutagenic to the cell. Thus, if the cell is driven into mitosis before it has finished replicating its DNA, it will pass on broken and incomplete sets of chromosomes to its daughters; if it progresses into anaphase and starts to divide in two before all the chromosomes are aligned on the mitotic spindle, the chromosomes will not be allocated equally between the daughter cells. Such disasters are avoided in most cells by feedback controls that operate at certain checkpoints to arrest the cell-cycle control system until the requisite process is completed.

The best-studied feedback control is the one that delays mitosis until DNA replication is complete. The phenomenon is easily

demonstrated in mammalian cells undergoing standard cell cycles. If these cells are treated while in S phase with an inhibitor of DNA synthesis, such as *aphidicolin* (which specifically inhibits DNA polymerase) or *hydroxyurea* (which blocks the synthesis of deoxy-ribonucleotides), the cells halt in S phase and will not progress to mitosis until the inhibitor is removed and DNA replication has been completed. If cells in which DNA synthesis is inhibited receive *caffeine* together with the inhibitor, however, the cells progress suicidally into mitosis with their DNA incompletely replicated. In the absence of an inhibitor of DNA synthesis, caffeine does no harm: the control system still follows the standard timetable, and this gives the cells time to finish DNA replication before mitosis begins (Figure17-31). Apparently, therefore, the cells possess a feedback control mechanism that is inactivated (in an unknown way) by caffeine. This feedback control acts as a safety device. In normal circumstances the safety device does not have to be called into play, for there is sufficient time for the DNA to replicate completely before mitosis begins. Indeed, as we noted earlier, in the early cell cycles of the frog embryo there is no such safety device, and inhibiting DNA replication does not delay the entry into mitosis.

Damaged DNA Generates a Signal to Delay Mitosis [25], [26]

Several other feedback controls operate to restrain the cell-cycle control system until particular conditions are satisfied. As already mentioned, chromosomes that are not attached to the mitotic spindle generate a feedback signal that blocks the inactivation of MPF (discussed in Chapter 18). Another well-characterized feedback control operates at the mitotic entry checkpoint to prevent cells with damaged DNA from entering mitosis until the damage is repaired.

The response to DNA damage is usually studied using experimentally induced lesions in DNA, such as those created by x-rays. Many radiation-sensitive (*rad*) mutations have been isolated in budding yeast, and at least one, called *rad*9, has been shown to code for an essential component of the feedback control mechanism. Mutants lacking *rad*9 still possess the machinery for DNA repair, but they fail to delay in G_2 when they have been irradiated. As a result, they proceed into mitosis with damaged chromosomes; not surprisingly, they are killed by doses of radiation that normal cells would survive. Some of the genes involved in regulating the cell cycle in yeasts are summarized in Table 17-1.

An additional safety device operates in mammalian cells to restrain them from entering S phase with damaged DNA. The mechanism seems to depend on a protein called p53, which accumulates in the cell in response to DNA damage and halts the cell-cycle control system in G_1. Mutations in the p53 gene play a crucial part in the genesis of a large proportion of human cancers, apparently by disabling the feedback control and thereby increasing the frequency of cancer-promoting genetic alterations, as we discuss in Chapter 24.

Feedback Controls in the Cell Cycle Generally Depend on Inhibitory Signals [27]

A general argument suggests why feedback controls such as those we have mentioned are based on a negative signal that arrests the cell-cycle control system rather than on a positive signal that moves the control system forward when a downstream process is completed.

Consider, for example, the monitoring of the attachment of chromosomes to the mitotic spindle. A cell needs to be able to detect the attachment of the last unattached chromosome to the microtubules of the spindle: if it proceeds into anaphase and starts to segregate its chromosomes into separate daughter cells before this has occurred, one daughter will receive an incomplete chromosome set, while the other daughter will receive a surplus. In a cell with many chromosomes, if each sent a positive signal to the cell-cycle control system once it was attached, the attachment of the last one would be hard to detect because it would be signaled by only a small fractional change in the total intensity of the "go" signal. On the other hand, if each unattached chromosome sends a negative signal to inhibit progress of the cell-cycle control system, the attachment of the last chromosome will be easily detected because it will mean a change from some "stop" signal to none. A similar argument would imply that mitosis is dependent on completion of DNA replication, not because of a requirement for a positive signal from fully replicated DNA but because of an inhibitory signal from unreplicated DNA or from the replication forks that are necessarily present as long as the chromosomes are still being replicated.

Some of the controls that operate on the cell cycle are summarized in Figure 17-32.

Summary

Yeasts are genetically tractable model organisms for the study of standard cell cycles in which cells grow as well as divide.

Normal cells keep their division cycle in step with growth, so as to maintain a standard average size, by controls that operate at two size checkpoints in the cell cycle - one in G_1, called Start (most important in budding yeast and in cells of higher animals), the other in G_2, called the mitotic entry checkpoint (most important in fission yeast). At these points the cell-cycle control system is halted if the yeast cell has not yet reached a critical size. Genes coding for components of the cell-cycle control system can be identified through mutations that make the cell halt at a specific point in the cycle or allow it to proceed past a checkpoint and divide at an abnormally small size. One of these genes, identified in fission yeast as cdc 2, encodes a protein that is homologous to, and functionally interchangeable with, the cyclin-dependent kinase subunit of vertebrate MPF. It plays a central role throughout the yeast cell cycle: in G_2 it associates with mitotic cyclin to form MPF and drive the cell past the mitotic entry checkpoint into mitosis; in G_1 it associates with G_1 cyclin to form Start kinase and drive the cell past Start. Each of these kinase activations is thought to occur by an explosive autocatalytic mechanism involving several other regulatory components, making the cell-cycle control system responsive to multiple controls. These controls include feedback signals from incompletely replicated or damaged DNA that prevent the control system from passing the next checkpoint until replication is complete or the damage is repaired.

BUDDING YEAST LIFE CYCLE

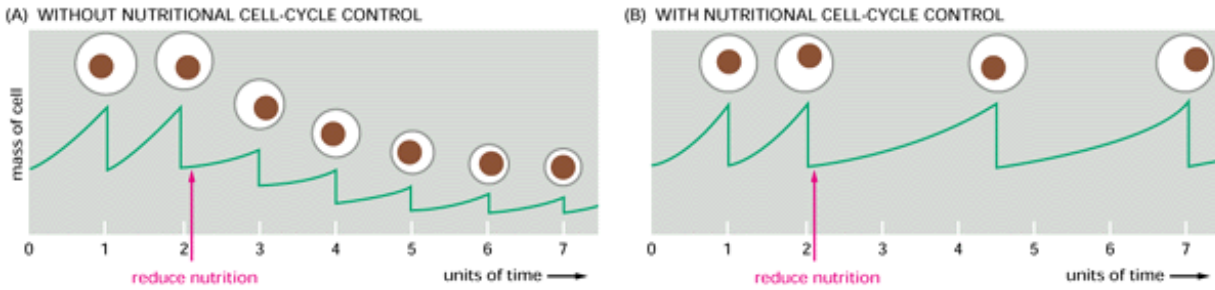
FISSION YEAST LIFE CYCLE
Figure 17-22. The life cycles of a budding yeast (*Saccharomyces cerevisiae*) and a fission yeast (*Schizosaccharomyces pombe*). The proportion of the life cycle spent in the diploid or haploid state varies with the species and according to the environment. When nutrients are plentiful, normal wild-type varieties of budding yeast proliferate as diploid cells, with a cell-cycle time of about 2 hours. If starved, they go through meiosis to form haploid spores, which germinate when conditions improve to become haploid cells that can either proliferate or fuse sexually (conjugate) in G_1 phase to re-form diploid cells, depending on the environment and other factors. Fission yeasts, by contrast, typically proliferate as haploid cells, which fuse in response to starvation to form diploid cells that promptly go through meiosis and sporulation to regenerate haploid cells. The most widely used laboratory strains of budding yeasts are mutants that can proliferate, like fission yeasts, as haploids.


Figure 17-23. Control of cell size through control of the cell cycle. The diagrams show the relationship between growth rate, cell size, and the cell-division cycle in a free-living organism such as a yeast. (A) If cell division continued at an unchanged rate when cells were starved, the daughter cells produced at each division would become progressively smaller, the size of the daughter being reduced to the small amount of material its parent cell could synthesize in one cycle time. (B) Yeast cells actually respond to poor nutritional conditions by slowing the rate of cell division: because a cell cannot proceed past a certain point in the division cycle until it has attained a certain standard size, the rate of cell division slows down and cell size remains more or less unchanged. (One unit of time in the diagram is the cycle time observed when nutrients are in excess.)
Figure 17-24. A comparison of the cell cycles of fission yeast and budding yeast. The *fission yeast* shown in the upper panel has a typical eucaryotic cell cycle with G_1, S, G_2, and M phases. Unlike that of higher eucaryotic cells, however, the nuclear envelope of the yeast cells does not break down: the microtubules of the mitotic spindle (*green*) form inside the nucleus and are attached to *spindle pole bodies* (*dark green*) at its periphery. The cell divides by forming a partition (known as the cell plate) and splitting in two. The *budding yeast* has normal G_1 and S phases. However, a microtubule-based spindle begins to form very early in the cycle, during S phase; thus there does not appear to be a normal G_2 phase. In contrast with fission yeasts, the cell divides by budding. As in fission yeasts, but in contrast with higher eucaryotic cells, the nuclear envelope remains intact during mitosis. The condensed mitotic chromosomes (*red*) are readily visible in fission yeasts, but are less easily seen in budding yeasts.
Figure 17-25. Behavior of a temperature-sensitive cell-division-cycle (*cdc*) mutant. At the permissive (low) temperature the cells divide more or less normally and are found in all phases of the cycle (the phase of the cell is indicated by its color). On warming to the restrictive (high) temperature, where the mutant gene product functions abnormally, the mutant cells continue progress through the cycle until they come to the specific step that they are unable to complete (initiation of S phase, in this example). Because the *cdc*mutants nevertheless continue growing, they become abnormally large (not shown). By contrast, non-*cdc* mutants, if deficient in processes (such as ATP production) necessary throughout the cycle for biosynthesis and growth, halt haphazardly at any stage of the cycle as soon as their biochemical reserves run out.
Figure 17-26. Some fission yeast cell-division-cycle mutants compared with a normal cell. In the *cdc2*⁻ mutant, which has a recessive phenotype, the *cdc2* gene is inactivated, and the cell fails to pass the mitotic entry checkpoint, continues growing, and so becomes enormously large. Conversely, the dominant *cdc2* mutant, *cdc2D*, in which the *cdc2* gene product is hyperactive, has a *wee* phenotype: it passes the checkpoint prematurely, at an abnormally small size. The *cdc25* mutant behaves like a *cdc2*⁻ mutant, and the *wee*1 mutant behaves like a *cdc2D* mutant: *cdc25 and wee*1 affect the activation of the kinase encoded by *cdc2* (Photographs courtesy of Sergio Moreno.)
Figure 17-27. Genesis of MPF activity. Cdc2 becomes associated with cyclin as the level of cyclin gradually increases; this enables Cdc2 to be phosphorylated by an activating kinase on an "activating" site as well by Wee1 kinase on Cdc2's catalytic site. The latter phosphorylation inhibits Cdc2 activity until this phosphate group is removed by the Cdc25 phosphatase. Active MPF is thought to stimulate its own activation by activating Cdc25 and inhibiting Wee1, either directly or indirectly.

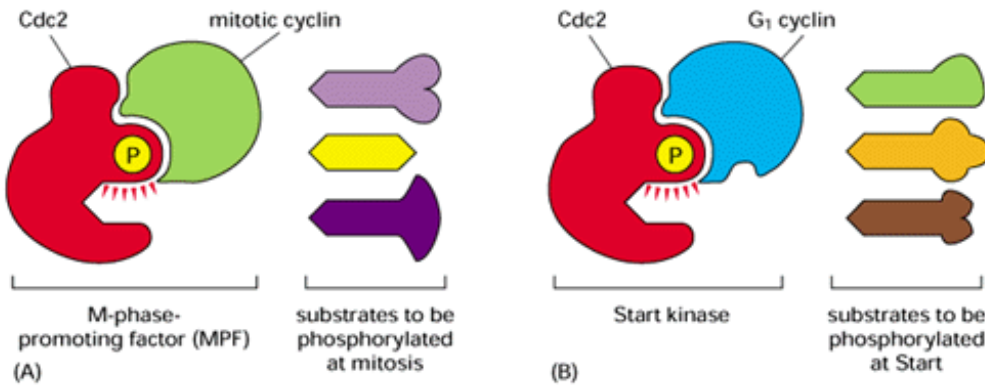
Figure 17-49. Drawings of representative sections of kidney tubules from salamander larvae of different ploidy.
Pentaploid salamanders have cells that are bigger than those of haploid salamanders, but the animals and their individual organs
are the same size because each tissue in the pentaploid animal contains fewer cells. This indicates that the number of cells is
regulated by some mechanism based on size and distance rather than on the counting of cell divisions or of cell numbers. (After
G. Fankhauser, in Analysis of Development [B.H. Willier, P.A. Weiss, and V. Hamburger, eds.], pp. 126-150. Philadelphia:
Saunders, 1955.)
Figure 17-28. The three options open to a haploid budding yeast cell as it approaches Start. Note that a diploid cell, instead
of mating, would have the option of entering meiosis and forming spores.


Figure 17-29. MPF and Start kinase contrasted. Both include Cdc2, but it is associated with different types of cyclin. This
suggests that the cyclin determines which proteins the Cdc2 will phosphorylate, either because it binds the specific substrates (as
shown) or because it directs the kinase to the appropriate location in the cell (not shown).
Figure 17-30. The Cdc2 cycle in yeast. Cdc2 is permanently present, but its state of association with cyclins changes, defining the division-cycle phase of the cell.
Figure 17-31. Incompletely replicated DNA blocks onset of mitosis. In the experiments schematized here mammalian cells in culture were treated with caffeine and hydroxyurea, either alone or in combination. Hydroxyurea blocks DNA synthesis, arresting the cells in S phase and delaying mitosis. But if caffeine is added as well as hydroxyurea, the delaying mechanism fails, and the cells proceed into mitosis according to their normal schedule with incompletely replicated DNA.

Table 17-1. Some Yeast Cell-Division-Cycle Genes and Their Functions

Gene Name in Budding Yeast	Gene Name in Fission Yeast	Gene Product	Phenotype of Loss-of-Function Mutant
CDC2	pol3	catalytic subunit of DNA polymerase d	arrest in S phase
CDC9	cdc17	DNA ligase	arrest in G_2 with imperfectly replicated DNA
CDC28	cdc2	serine/threonine protein kinase	arrest at Start or at mitotic entry (G_2) checkpoint
SWI6	cdc10	gene regulatory protein required for transcription of G_1 cyclins	failure to enter S phase

CLN1,2,3	?	G$_1$ cyclins	arrest at Start (if all three genes inactive)
CLB1,2,3,4	cdc13	mitotic cyclins	arrest at mitotic entry (G$_2$) checkpoint
WEE1	wee1	tyrosine protein kinase	premature passage past mitotic entry (G$_2$) checkpoint, hence small size
	cdc25	tyrosine protein phosphatase	arrest at mitotic entry (G$_2$) checkpoint
RAD9	?	protein of unknown function	failure to delay mitosis when DNA is damaged (loss of feedback control)
DIS2 S1	dis2	protein phosphatase I	arrest in mitosis

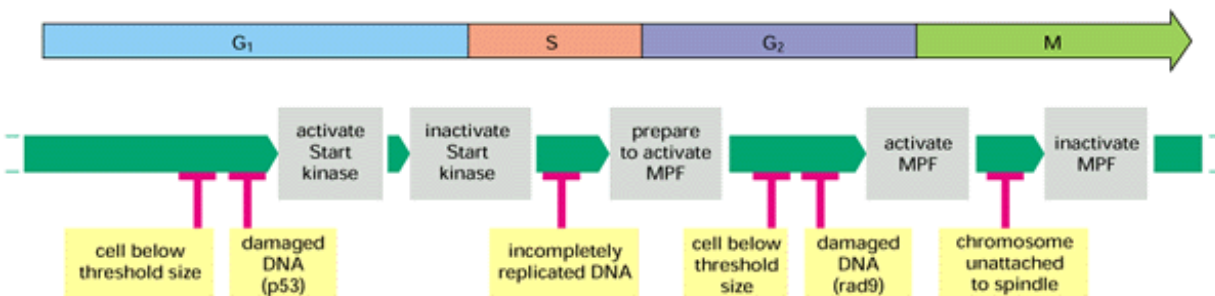
The table shows only a small selection of the *cdc* and related genes that have been identified. The terminology is confusing. In each species of yeast, the *cdc* genes were numbered roughly in order of their discovery - *CDC*1, *CDC*2, *CDC*3, ... in budding yeast; *cdc*1, *cdc*2, *cdc*3, ... in fission yeast. The numbering sequences, consequently, do not correspond, so that, for example, the counterpart of the fission yeast gene *cdc*2 is called *CDC*28 in budding yeast (both genes encode the key cyclin-dependent kinase of the cell-cycle control system). To make matters worse, there is no regular convention for naming the homologs of these genes in other organisms.


Figure 17-32. Summary of feedback, size, and damage controls in the cell cycle. The *red* T bars represent checks on progress of the cell-cycle control system arising from intracellular processes that are uncompleted or deranged.

Cell-Division Controls in Multicellular Animals

Introduction

For unicellular organisms, where each cell division generates a new individual, natural selection favors the cells that grow and divide the fastest and survive hard times the best. Their proliferation is typically restrained only by the availability of nutrients and by the occasional demands of sex. In multicellular species, by contrast, natural selection acts not on each individual cell but on the organism as a whole. To produce and maintain the intricate organization of the body, the component cells must obey strict controls that limit their proliferation. At any instant most cells in the adult are not growing or dividing but instead are in a resting state, performing their specialized function while retired from the division cycle. Because nutrients are plentiful in the tissues of the body, the cells must refrain from proliferating in circumstances where a yeast or bacterium would proliferate readily. What accounts for this difference?

We shall see that for the cells of a multicellular animal, nutrients are not enough: in order to grow and divide, a cell must receive specific positive signals from other cells. Many of these signals are protein *growth factors,* which bind to complementary receptors in the plasma membrane to stimulate cell proliferation. These positive signals act by overriding intracellular negative controls that otherwise restrain growth and block progress of the cell-cycle control system. Thus, while a well-fed yeast cell proliferates unless it gets a negative signal (such as a mating factor) to halt, an animal cell halts unless it gets a positive signal to

proliferate.

In this section we focus on mammalian cells and address four questions: (1) What is the nature of the mammalian cell-cycle control system? (2) How is proliferation in mammalian cells regulated, and how is it studied? (3) What are the extracellular signals that determine whether the cell will grow and divide? (4) How do those signals override the intracellular restraints and exert their effect on the cell-cycle control system? The last question is much the hardest. We shall therefore leave it until last and begin by examining how closely the components of the mammalian cell-cycle control system resemble those of the yeast cell-cycle control system.

The Mammalian Cell-Cycle Control System Is More Elaborate Than That of the Yeast [28]

All of the cell-cycle genes that we have discussed in yeasts, including *cdc*2, the cyclins, *cdc*25, and *wee*1, are present in mammals too. All of these have been shown to be functionally similar to their yeast counterparts, to the extent that a mutant yeast lacking its own functional gene copy can be rescued by transfection with the mammalian gene. As we noted previously, this has provided an efficient way to clone the mammalian cell-cycle genes.

The cell-cycle control system of most multicellular organisms, however, is more complex than that of yeasts. Gene duplication and divergence apparently has generated multiple variants of the basic cell-cycle genes, and these variants, existing side by side in a single cell, are specialized to function in slightly different ways. Thus, whereas in yeasts one cyclin-dependent kinase gene is sufficient for all the steps in the cell cycle, human cells depend on at least two and probably more. Two of these - *cdc*2 and a related gene called *cdk*2 - are known to be present in *Xenopus* and *Drosophila* as well; both encode kinases whose activation depends on binding to cyclins. Like yeasts, higher animals also have multiple cyclins: at least six types have been found so far, named cyclins A, B, C, D, E, and F; some of these are themselves families of closely related molecules. Induction of mitosis in the vertebrate cell depends on Cdc2 protein complexed with cyclin B; there is evidence that Cdk2 protein complexed with cyclin E may induce passage past the G_1 checkpoint (the vertebrate counterpart of Start), and cyclin A complexed to Cdk2 protein may be required subsequently to activate the DNA replication machinery (Figure 17-33). It seems, therefore, that separate mammalian Cdk proteins perform the various functions that in yeast can be carried out by a single one.

In cells that are steadily cycling, the concentrations of most of the various cyclins rise and fall at different times in the cell cycle, while the concentrations of the cyclin-dependent kinases stay roughly constant, as in yeast. The precise functions of most of the proteins of the cell-cycle control system in the mammalian cell, however, are not yet understood in detail.

The Regulation of Mammalian Cell Growth and Proliferation Is Commonly Studied in Cultured Cell Lines [29]

Mammalian cells are not easily accessible to detailed observation in the intact animal. Most studies on mammalian cell proliferation therefore use cells that are growing in culture (Figure 17-34). This gives rise to a complication, however. When cells from normal mammalian tissues are cultured in standard conditions, they usually can be propagated only for a limited number of division cycles - about 50 for typical cells derived from humans, for example; after this they cease dividing and eventually die - a process called *cell senescence,*which we discuss later. But during the propagation of some cell cultures, especially those derived from rodents, a few cells often arise that escape senescence and divide indefinitely as *cell lines.* Although these cells resemble normal cells in most respects, their immortality reflects the presence of one or more mutations that have altered their proliferative properties. Nevertheless, in spite of their slight abnormalities, cell lines are used widely for cell-cycle studies - and for cell biology generally - because they provide an unlimited source of cells of a standardized, genetically homogeneous type.

Growth Factors Stimulate the Proliferation of Mammalian Cells [30]

Mammalian cells were first cultured in blood clots, and for many decades all efforts to define the minimal requirements for cell proliferation failed; even in a medium containing all the obvious chemically defined nutrients, including glucose, amino acids, and vitamins, cells would only grow if the medium was supplemented with *serum,* the blood-derived fluid that remains after blood has clotted. Like yeast cells deprived of nutrients, mammalian cells deprived of serum stop growing and become arrested, usually between mitosis and S phase, in a quiescent state called G_0. It was eventually shown that the essential components provided by serum are certain highly specific proteins called growth factors, most of which are required only in very low concentrations (on the order of 10^{-9} to 10^{-11} M).

One of the first such factors to be identified was platelet-derived growth factor, or PDGF, and it is typical of many others discovered since. The path to its isolation began with the observation that cultured fibroblasts proliferate when provided with serum but not when provided with *plasma-* the liquid prepared by removing the cells from blood without allowing clotting to occur. When blood clots, platelets incorporated in the clot are triggered to release the contents of their secretory vesicles (Figure 17-35). The superior ability of serum to support proliferation suggested that platelets contain one or more growth factors. This hypothesis was confirmed by showing that extracts of platelets could serve instead of serum to support fibroblast proliferation. A crucial growth factor in the extracts was shown to be a protein, which was subsequently purified and named PDGF. In the body PDGF liberated from blood clots probably plays a major role in stimulating cell division (and other processes) during wound healing.

PDGF is only 1 of about 50 known proteins that act as growth factors. For each type of growth factor there is a specific receptor or set of receptors, which some cells express on their surface and others do not. Cells respond to a given protein growth factor only if they display the appropriate receptor protein (discussed in Chapter 15). Other classes of molecules besides proteins can also function as growth factors; steroid hormones, which act on intracellular receptor proteins, are an example. The growth factors can be divided into broad- and narrow-specificity classes. The broad-specificity factors, like PDGF and *epidermal growth factor (EGF),* affect many classes of cells. Thus PDGF acts on a range of target cells including fibroblasts, smooth muscle cells, and neuroglial cells, while EGF acts not only on epidermal cells but also on many other cell types, both epithelial and nonepithelial. At the opposite extreme lie narrow-specificity factors such as *erythropoietin,* which induces proliferation only of red blood cell precursors.

Because they are present in such small amounts, growth factors are difficult to isolate; once the DNA encoding a growth factor has been identified and cloned, however, it can often be used as a probe to identify and isolate a whole family of related genes that encode other members of the same growth-factor family. An example is the *fibroblast growth factor (FGF)* family, which includes at least seven members. Today, when a new growth factor is isolated by a biological assay, it is frequently found to be identical, or closely related, to an already known growth factor.

In intact animals proliferation of most cell types depends on a specific *combination* of growth factors rather than a single growth factor. Thus a fairly small number of growth factor families may serve, in different combinations, to regulate selectively the proliferation of each of the many types of cells in a higher animal.

Although some growth factors are present in the circulation, most originate from cells in the neighborhood of the affected cell and act as local mediators. In addition to growth factors that stimulate cell division, there are factors, such as some members of the *transforming growth factor beta (TGF-β)* family, that act on some cells to stimulate cell proliferation and others to inhibit it, or stimulate at one concentration and inhibit at another. Indeed, most growth factors have a multitude of other actions besides the regulation of cell growth and division: they can control the proliferation, survival, differentiation, migration, or function of cells depending on the circumstance.

A sampling of some of the many growth factors discussed in this book is given in Table 17-2.

Cell Growth and Cell Division Can Be Independently Regulated 31

One important function of growth factors is to regulate protein synthesis and thus the rate at which cells grow. Most factors that stimulate cell proliferation also stimulate cell growth, but the correspondence is not always exact. Some factors will make cells of a given type grow but do not get them past the G_1 checkpoint in their cycle, while other factors will get them past the G_1 checkpoint but do not make them grow. It seems that in a mammal there is not so rigid a rule coupling cell size and cell division as there is in yeasts.

Growth factors that act independently on cell growth and proliferation are important in the whole animal. Differently specialized cells vary enormously in their ratio of cytoplasm to DNA, and some cells in G_0, such as neurons, can grow very large without ever dividing (Figure 17-36). Such variation in cell size is controlled partly by external factors and partly by intracellular mechanisms that depend on the cell type. The growth of certain types of neurons, for example, depends on the *nerve growth factor (NGF)* that is secreted by the target cells the neurons innervate: the greater the amount of NGF that a neuron has access to, the larger it becomes.

Cells Can Delay Division by Entering a Specialized Nongrowing State 32

When proliferating cells in culture are deprived of serum, they stop growing but continue to pass through the cell cycle until they reach the G_1 phase. On reaching this part of the cycle, they come to a halt in a specialized, nongrowing state - the G_0 ("G zero") resting state we referred to earlier. The G_0 state is distinct from the state of proliferating cells in any phase of their cycle. The rate of protein synthesis, for example, is drastically reduced, often to as little as 20% of its value in proliferating cells. Thus, the absence of appropriate growth factors sends cells into a sort of cell-cycle sleep, where the cell-cycle control system is disabled from progressing past the G_1 checkpoint. Depriving a cell of nutrients, such as amino acids, also stops growth and blocks passage past a G_1 checkpoint, but from the point of view of the cell such starvation is a very different experience from that of failing to receive the wakening signal that growth factors provide. In fact, it is debatable whether the same checkpoint mechanism is involved in the two situations and uncertain how closely either type of arrest in mammalian cells resembles the Start checkpoint mechanism of yeast (which is why different names, such as "restriction point" or "commitment point," have been used to refer to the G_1 checkpoint in mammalian cells). In the tissues of the body nutrients are generally plentiful but growth factors are in short supply; thus growth factors are thought to exert the critical control.

It is the ability to enter G_0 that accounts for the enormous variability of the length of the cell cycle in multicellular organisms. In the human body, for example, some cells, such as neurons and skeletal muscle cells, do not divide at all; others, such as liver cells, normally divide only once every year or two; while certain epithelial cells in the gut divide more than twice a day in order to renew the lining of the gut continually (Figure17-37). Most cells in vertebrates fall somewhere between these extremes: they can divide if need arises but normally do so infrequently. The rate at which a cell divides varies according to external circumstances as well as the internal character of the particular cell type. Blood loss stimulates proliferation of blood cell precursors. Acute liver damage provokes surviving liver cells to proliferate with a cycle time of only a day or two until the loss is made good, and cells in the neighborhood of a wound are stimulated to divide to repair the lesion.

Almost all the variation in proliferation rates in the adult body lies in the time cells spend delayed between mitosis and the G_1 checkpoint, with slowly dividing cells remaining parked in a G_0 state for weeks or even years. By contrast, the time taken for a cell to progress from the beginning of S phase through mitosis is usually brief (typically 12 to 24 hours in mammals) and remarkably constant, irrespective of the interval from one division to the next. We must now turn to the experimental evidence that identified the G_1 checkpoint as a specific point in the cycle and consider what entry into G_0 means in molecular terms.

Serum Deprivation Prevents Passage Through the G_1 Checkpoint [32], [33]

Cells in culture can be observed under the microscope by time-lapse cinematography. In this way the time each cell takes between one division and the next is easily monitored. If the culture is filmed for at least one cell cycle before applying an experimental treatment, it is also possible to establish the time elapsed since the last mitosis for each cell at the time of the treatment. In this way one can test the effects of tampering with external conditions at different stages in the division cycle. Such studies have been done mainly with fibroblast cells. A simple experiment of this kind showed that depriving the cells of serum (that is, growth factors) for just 1 hour has dramatic effects. All cells less than 3.5 hours past mitosis when serum was withdrawn took an extra 8 hours to reach mitosis after serum was added back to the medium. Cells more than 3.5 hours old, by contrast, showed no such delay but continued with the current cycle (Figure17-38). This behavior defines the G_1 checkpoint as lying 3.5 hours after mitosis for the chosen line of cells. Cells past this point are irrevocably committed to replicate their DNA and complete the current division cycle, but cells between mitosis and the checkpoint stop at the checkpoint if appropriate growth factors are absent. The extra delay before these arrested cells could undergo mitosis after serum was returned to the medium suggests that a 1-hour serum deprivation between 0 and 3.5 hours induces them to enter an altered state - G_0- from which they require 8 hours to emerge.

The effect of serum deprivation is to depress protein synthesis and cell growth and can be mimicked with low doses of inhibitors of protein synthesis, such as cycloheximide. Experiments using either serum deprivation or cycloheximide have shown that depressing protein synthesis briefly in late G_2 can also induce entry into G_0, but in this case the cells first undergo mitosis and come to a G_0 halt when they reach the G_1 checkpoint. On the other hand, cells that are briefly deprived during S phase or early G_2 proceed through the G_1checkpoint with little or no delay, presumably because they are already more than 8 hours away from the checkpoint. The machinery that responds so dramatically to a brief withdrawal of serum must therefore have the following properties: it must be needed to pass the G_1 checkpoint but not to enter mitosis, and although it can be rapidly disabled, it must require on the order of 8 hours to be regenerated once growth factors, or protein synthesis, are restored.

The Cell-Cycle Control System Can Be Rapidly Disassembled But Only Slowly Reassembled <u>34</u>

How are these phenomena related to the behavior of the cell-cycle control system? A simple interpretation would be that some molecular component of the cell-cycle control system disappears from the cell rapidly - within an hour - when serum is withdrawn but takes a long time - 8 hours - to reappear when serum is restored. The disappearance and reappearance can occur at any time in the division cycle, it seems, but it is only at the G_1 checkpoint that the component is required.

An obvious speculation is that a Cdk protein itself is the critical component and that mammalian cells require this protein to pass the G_1 checkpoint, just as yeast cells require Cdc2 protein to pass Start. In fact, when quiescent G_0 cells are compared with cycling cells, it is found that they are severely depleted both in Cdk protein (or at least in one or more types of Cdk protein) and in all of the G_1 cyclins, even though the Cdk proteins and some of the G_1 cyclins (cyclins C and D) are present at a nearly constant level during all the phases of the cycle in the cycling cells. The G_0 cells, therefore, have not merely halted their cell-cycle control system: they have dismantled it.

When serum is supplied to G_0 cells, there is a lag of several hours before the concentrations of Cdk and G_1 cyclins are returned to their cycling levels, corresponding to the delay before the cells resume cycling. If serum deprivation halts cell proliferation by rapidly dismantling the cell-cycle control system rather than simply stopping it, it is not surprising that, when the environment becomes favorable again, cells must spend time slowly reassembling the control system in order to begin cycling again.

Having considered how the cell-cycle control system of the individual cell responds to growth factors, we next discuss how growth factors and other influences adjust the proliferative behavior of cells in tissues to maintain the form and function of the body.

Neighboring Cells Compete for Growth Factors <u>35</u>

Cell proliferation in the body has to be regulated so as to maintain both the numbers of cells and their spatial organization. This regulation depends on interactions of cells with one another and with the extracellular matrix. Consider an epithelial sheet in an adult mammal, for example. As cells die, new cells must be produced to take their places. Cell proliferation must be precisely controlled to balance the cell loss, so that the epithelial sheet neither grows nor shrinks. The new cells must be fitted into the structure correctly, so that the architecture of the sheet is not disrupted. In fact, in most epithelia it is only cells retaining contact with the underlying basal lamina that divide. These cells on the basal lamina are sensitive to at least two sorts of signals that govern their readiness to divide: those that carry information about the local cell population density, and those that reflect a cell's attachments to other cells and to the basal lamina. Both types of controls can be demonstrated and analyzed in the simplified conditions of cell culture, although most of the work has been done with fibroblasts and it is not clear how these findings relate to organized arrays of cells such as those in epithelia or in a three-dimensional organ.

Dissociated cells plated on a dish in the presence of serum will adhere to the surface, spread out, and divide until a *confluent monolayer* is formed in which each cell is attached to the dish and contacts its neighbors on all sides. At this point normal cells, unlike cancerous ("transformed") cells, stop dividing - a phenomenon known as *density-dependent inhibition of cell division*. If such a monolayer is "wounded" with a needle so as to create a cell-free strip on the dish, the cells at the edges of the strip spread into the empty space and divide (<u>Figure17-39</u>). Such phenomena were originally described in terms of "contact inhibition" of cell division, but it is probably misleading to imply that cell-cell contact interactions are solely responsible. The cell population density at which cell proliferation ceases in the confluent monolayer increases with increasing concentration of growth factors in the medium. Passing a stream of fresh medium over a confluent layer of fibroblasts reduces the diffusional limitation to the supply of growth factors and induces the cells under the stream of medium to divide at densities where they would normally be inhibited from doing so (<u>Figure17-40</u>). Thus density-dependent inhibition of cell proliferation seems to reflect, in part at least, the ability of a cell to deplete the medium locally of growth factors, thereby depriving its neighbors.

Calculations using the known concentrations of growth factors in serum and the rate at which cells remove the factors from the culture medium support this suggestion. PDGF, for example, is typically present in the medium at concentrations of about 10^{-10} M (about one molecule in a sphere of 3 µm diameter). A fibroblast has about 10^5 PDGF receptors, each with a very high affinity for the growth factor. Each cell therefore has enough receptors to bind all the PDGF molecules within a sphere of diameter ~150 µm. Thus it is clear that neighboring cells compete for minute quantities of growth factors. This type of competition could be important for cells in tissues as well as in culture, preventing them from proliferating beyond a certain population density, which

is determined by the amount of growth factor available.

Normal Animal Cells in Culture Need Anchorage in Order to Pass Start <u>36</u>

Competition for growth factors is not the only influence on the rate of cell division observed in cell culture. The shape of a cell as it spreads and crawls out over a substratum to occupy vacant space also strongly affects its ability to divide. When normal fibroblast or epithelial cells are cultured in suspension, unattached to any solid surface and therefore rounded up, they almost never divide - a phenomenon known as *anchorage dependence* of cell division. The relationship of cell spreading to proliferation can be demonstrated by culturing cells on substrata of varying stickiness or by allowing them to settle on a nonsticky surface that is dotted with minute sticky patches on which an individual cell may adhere but beyond which it cannot spread. The frequency with which a cell divides increases as the cell becomes more spread out. Perhaps well-spread cells can capture more molecules of growth factor and take up larger quantities of nutrients because of their larger surface area. But some fibroblast cell lines, although scarcely able to proliferate at all in suspension, will divide readily once they have touched down and formed a *focal contact,* even if the site of adhesion is a tiny patch on which there is no space for a cell to spread (<u>Figure17-41</u>). Focal contacts are sites of anchorage for intracellular actin filaments and extracellular matrix molecules, and these and other observations strongly hint that the control of cell division is somehow coupled to the organization of the cytoskeleton or is dependent on intracellular signals generated at sites of adhesion, or both (<u>Figure17-42</u>). In fact, for some cell types specific extracellular matrix molecules, such as laminin or fibronectin, may act as growth factors. The basal epidermal cells of the skin provide an example, discussed in <u>Chapter 22</u>.

Like other controls of cell proliferation, anchorage control operates at the G_1 checkpoint: cells require anchorage to pass this point but then do not require it to complete the cycle. In fact, they commonly loosen their attachments and round up as they pass through M phase. This cycle of attachment and detachment presumably allows cells to rearrange their contacts with other cells and with the extracellular matrix so as to accommodate the daughter cells produced by cell division and then bind them securely into the tissue before they are allowed to begin the next division cycle.

Although the mechanism of anchorage dependence is uncertain and some of the details of the phenomena just described may be peculiarities of fibroblasts in culture, it is likely that intracellular signals generated at adhesion sites play an important part in controlling the cell-cycle control system in many different cell types.

Studies of Cancer Cells Reveal Genes Involved in the Control of Cell Proliferation <u>37</u>

How do the various external influences we have examined affect the interior of the cell so as to regulate cell proliferation? In particular, how does the binding of a growth factor to cell-surface receptors influence the operation of the cell-cycle control system? Much of what we know on this topic has come from studies of cancer cells, where the control of cell proliferation is disrupted. These cells are mutants, and because they proliferate excessively and give rise to tumors, they bring their mutant genes to our attention.

As discussed in <u>Chapter 24</u>, analysis of the genetic alterations in cancer cells has revealed a large number of genes that encode proteins involved in the control of cell proliferation. These genes can be crudely classified as *proliferation genes* and *antiproliferation genes.* The products of the former help to promote cell growth and the assembly of the cell-cycle control system and to drive the cell past the G_1 checkpoint; the products of the latter help to apply the brakes that halt the control system and cause it to be dismantled. A mutation in a proliferation gene that causes its product to be overexpressed or hyperactive results in the excessive cell proliferation characteristic of cancer. The mutant gene is then classified as an oncogene (that is, a cancer-causing gene), and the normal proliferation gene is called a proto-oncogene. Conversely, a cell may be released from the normal proliferation restraints and enabled to divide as a cancer cell if an antiproliferation gene undergoes a mutation that makes it inactive. Thus the antiproliferation genes found in normal cells are often referred to as tumor-suppressor genes. For an ordinary diploid cell both copies of a tumor-suppressor gene must typically be lost or inactivated to bring about the loss of growth control (that is, the mutant phenotype is recessive), whereas only one copy of a proto-oncogene need be activated to bring about a similar effect (that is, the mutant phenotype is dominant) (<u>Figure 17-43</u>).

Because they have been easier to isolate, the set of known proliferation genes is much larger than the set of known antiproliferation genes and probably includes genes that encode representatives of all the major classes of proteins involved in relaying the stimulatory signals from the growth factor receptors to the interior of the cell.

Growth Factors Trigger Cascades of Intracellular Signals [30], [38]

The first step in the action of a protein growth factor is its binding to a transmembrane receptor at the surface of the target cell. The intracellular portion of the receptor then catalyzes the production of molecules that act as intracellular signals, relaying the stimulus to yet other molecules. The details of the initial steps in several of these signaling cascades have been well worked out for several classes of receptors and are described in Chapter 15. The complexities arise because the cascades generally are not simple linear relay chains but instead branch to activate many interacting components that operate in parallel, forming a highly interconnected signaling network.

We saw in Chapter 15 that growth-factor receptors activate intracellular phosphorylation cascades that lead to changes in gene expression. The genes that growth factors induce fall into two classes: early-response genes are induced within 15 minutes of growth factor treatment, and their induction does not require protein synthesis; delayed-response genes, by contrast, are not induced until at least 1 hour after growth factor treatment, and their induction requires protein synthesis. It seems that the delayed-response genes are induced by the products of the early-response genes, several of which are known to be gene regulatory proteins (Figure 17-44).

Both classes of genes are silent and not transcribed in cells in G_0 but are induced to high levels when growth factors are added to the medium. If the exposure to growth factors is then maintained, the level of expression of the genes gradually falls back - for some genes apparently to zero, for certain others to a new non-zero steady value. Products of the latter class of genes are therefore present at a constant low level in steadily cycling cells (Figure17-45). Thus the transcription of these genes indicates the presence of growth factors in the medium, and a high level of expression indicates a sudden increase in growth factor concentration. The signals we get from our own senses (of smell, for example) behave in much the same way.

The best-studied early-response genes are the *myc, fos,* and *jun* proto-oncogenes. All three genes encode gene regulatory proteins that act as homo- or heterodimers (discussed in Chapter 9). When overexpressed or hyperactivated by mutation in certain types of cells, all of them can cause uncontrolled proliferation. There is evidence suggesting that *myc*in particular may have a critical role in the normal control of cell proliferation. Cells in which *myc* expression is specifically prevented will not divide even in the presence of growth factors. Conversely, cells in which *myc* expression is specifically switched on independently of growth factors cannot enter G_0, and if they are in G_0 when Myc protein is provided, they will leave G_0 and begin to divide even in the absence of growth factors - a behavior that ultimately causes them to undergo programmed cell death.

Cyclins and Cdk Are Induced by Growth Factor After a Long Delay [34]

The delayed-response genes do not begin to be transcribed until well after the addition of growth factor, and their transcription requires the products of the early-response genes such as *myc.* Among the products of the delayed-response genes are some of the essential components of the cell-cycle control system itself, including Cdk proteins and several cyclins, which, from the timing of their expression, are suspected to be involved with Cdk proteins in driving the cells past the G_1 checkpoint, in initiating S phase, or both.

Thus one can tentatively trace a chain of stimulatory effects that leads from the binding of growth factor to the initiation of DNA replication. These stimulatory signals are thought to act by overcoming specific inhibitory devices that ensure that the cell refrains from proliferating in the absence of a positive signal to do so. The inhibitory devices are proteins encoded by the antiproliferation genes discussed earlier, which were originally discovered as tumor-suppressor genes in human cancers. The best-understood antiproliferation gene is the *retinoblastoma* gene.

The Retinoblastoma Protein Acts to Hold Proliferation in Check [39]

The retinoblastoma (Rb) gene was identified originally through studies of an inherited predisposition to a rare cancer that occurs in the eyes of children, as discussed in Chapter 24. Loss of both copies of this gene leads to excessive cell proliferation in the immature retina, suggesting that the gene product normally helps keep proliferation in check. Cloning of the retinoblastoma gene made it possible to explore how the gene product exerts this effect.

The Rb protein is an abundant molecule in the nucleus of mammalian cells. It binds to many other proteins, including several important gene regulatory proteins, but its binding capacity depends on its state of phosphorylation. When Rb is dephosphorylated, it binds a set of regulatory proteins that favor cell proliferation, holding them sequestered and out of action;

the phosphorylation of Rb makes it release these proteins, allowing them to act (Figure17-46). In normal cells the Rb protein is permanently present, no matter whether the cells are in G_0 or cycling, but its state of phosphorylation changes. In the G_0 cell it contains little phosphate and appears to hinder the transcription of genes, such as *fos* and *myc*, that are required for proliferation. These genes are transcribed at a high level in mutant cells that lack a functional copy of the *Rb* gene and at a much lower level in these cells when a functional copy of the *Rb* gene is put back into them by transfection.

Growth factors relieve the inhibition exerted by Rb by causing the protein to become phosphorylated on multiple serines and threonines. The cells now begin to express Cdk protein, pass the G_1 checkpoint, and embark on DNA synthesis. In proliferating cells the phosphorylation of the Rb protein increases and decreases in every cycle: it rises late in G_1, remains high in S and G_2, then falls back to a dephosphorylated state as the cell goes through mitosis (Figure17-47). *In vitro* the Rb protein is a good substrate for phosphorylation by protein kinases of the Cdk family, suggesting a possible way in which the state of Rb phosphorylation could be tightly linked to the state of the cell-cycle control system.

The dephosphorylated (active) Rb protein is thought to function in G_1 as part of the braking mechanism to inhibit passage past Start; it may also enable the cell to enter G_0 by shutting off the production of key components of the cell-cycle control system - as well as of other proteins - when the environment becomes unfavorable for proliferation. But in most cells the situation is complicated by the presence of more than one Rb-like protein, and many cell types appear to behave normally even when Rb itself is missing. (Transgenic mice that lack the *Rb* gene progress almost normally through the first half of embryonic development, but then die, showing defects only in certain specific tissues.) Improving our understanding of anti-proliferation genes such as Rb is an important task, for deficiencies in these genes play a part in a remarkably large proportion of human cancers.

The Probability of Entering G_0 Increases with the Number of Times That a Cell Divides: Cell Senescence [40]

Cell proliferation in a higher animal is not simply governed by the environment of the cell but depends on the cell's long-term history in complex ways: each differentiated cell type, at each stage of animal development, is obedient to slightly different rules, reflecting differences in its internal control machinery. Perhaps the simplest, but also the most mysterious, example of long-term effects on cell division is seen in the phenomenon of cell senescence.

Most normal cells in the body of a mammal or bird show a striking reluctance to continue proliferating forever, even when carefully nourished *in vitro*. This distinguishes them from germ-line cells and from established cultured cell lines, which are thought to have undergone a genetic change that makes them "immortal." Fibroblasts taken from a normal human fetus, for example, will go through only about 50 population doublings when cultured in a standard growth medium. Toward the end of this time, proliferation slows down and finally halts, and the cells enter a G_0 state from which they never recover. Similar cells taken from a 40-year-old stop dividing after about 40 doublings, while cells from an 80-year-old stop after about 30 doublings. Fibroblasts from animals with a shorter life-span cease dividing after a smaller number of division cycles in culture. This phenomenon has been called cell senescence because of the correspondence with aging of the body as a whole. Its relationship to the aging of the organism, however, is obscure.

Cell senescence is puzzling in several ways, and neither its function, if it has one, nor its mechanism is clear. Many theories have been proposed to explain the phenomenon. Some suggest, for example, that it results from an accumulation of deleterious random mutations, reflecting merely imprecision in the machinery of cell reproduction; others suggest that it is the effect of a mechanism that has evolved to protect us against cancer by limiting the growth of tumors. But there are good arguments against both of these interpretations. It is known, however, that the rate of senescence for at least some cell types is strongly dependent on the concentrations of growth factors in the medium. The process apparently reflects changes of proliferative potential that can be regulated by the cell's environment.

Short programmed sequences of cell divisions terminating in differentiation are a familiar feature of embryonic development, but it is hard to imagine how a cell could keep a long-term account of its division cycles and halt after completing 50. In fact, although senescence occurs at a predictable time for a given cell population, it is not strictly programmed at the level of the individual cell. In a clone of apparently identical normal fibroblasts monitored under standard culture conditions, some cells divide many times, others only a few times. Individual cells seem to stop dividing as a result of a random transition. This transition occurs with an increasing probability in each successive cell generation until there are no proliferating cells left in the population (Figure 17-48).

A possible interpretation lies in the behavior of the *telomeres*- the special repetitive DNA sequences required at the ends of chromosomes. As discussed in Chapter 8, when a cell divides these sequences are not replicated in the same manner as the rest of the genome but are synthesized by an enzyme, *telomerase,* that operates less exactly, creating random variation in the number of repeats of the telomeric DNA sequence. Cell senescence is closely correlated with a progressive reduction in the number of these repeats, suggesting that senescence may be caused by failure to maintain the length of telomeres, perhaps because the somatic cells (in contrast with germ-line cells) are deficient in telomerase.

Intricately Regulated Patterns of Cell Division Generate and Maintain the Body 41

While life may end with a haphazard process of senescence, it begins with a series of division cycles that are controlled according to precise and intricate rules. This is true of multicellular organisms in general but is most strikingly illustrated by the nematode worm *Caenorhabditis elegans.* The fertilized egg of *C. elegans* divides to produce an adult with precisely 959 somatic cell nuclei, each one of which is generated by its own characteristic and absolutely predictable sequence of cell divisions. In general such phenomena are not merely a matter of counting out cell divisions according to a clocklike schedule. Salamanders of different ploidy, for example, are the same size but have different numbers of cells; individual cells in a pentaploid animal are five times the volume of those in a haploid animal, and in each organ the pentaploids have generated only one-fifth as many cells as their haploid cousins, so that the organs are about the same size in the two animals (Figures 17-49 and 17-50). Evidently, in this case (and, in fact, in most others) the size of organs is not controlled by counting cells or cell cycles but by some mechanism that can actually measure distances. Such mechanisms require complex positional controls in which growth factors may play an important part. As we shall see in Chapter 21, some of the genes that govern programs of cell proliferation in the embryo are beginning to be characterized. In the early *Drosophila* embryo it is beginning to be possible to explain the patterns of cell division in terms of the activities of identified components of the cell-cycle control system. But developmental biologists are far from understanding in detail how cyclin-dependent kinases, cyclins, growth factors, cell contacts, proliferation genes, and antiproliferation genes - all the nuts and bolts of cell-division control that we have discussed so far - fit together to implement the complex programs of cell division in development.

In the same way, we have as yet only a fragmentary understanding of the complex network of controls that govern cell division in the society of cells that form an adult body. When a skin wound heals in a vertebrate, for example, about a dozen cell types, ranging from fibroblasts to Schwann cells, must be regenerated in appropriate numbers and in appropriate positions to reconstruct the lost tissue. These questions of cell-division control in tissues, which will be discussed further in Chapter 22, are central to the understanding of cancer, where the social controls go wrong, and of innumerable other diseases. At the heart of the matter is the operation of the cell cycle itself - the fundamental mechanism of cell reproduction on which all life depends. The revelations that have come from studies in frogs and yeasts are already beginning to cast new light on urgent human problems.

Summary

The cells of multicellular animals, such as mammals, appear to have the same basic cell-cycle control system as is found in yeasts, with a major checkpoint in G_1. But, unlike yeasts, they normally refrain from proliferating unless they receive specific signals from other cells to do so. If deprived of these signals, a typical mammalian cultured cell will come to a halt in a quiescent, nongrowing variant of the G_1 state called G_0, in which the production of components of the cell-cycle control system - and of many other proteins - is switched off. Important extracellular cues for cell proliferation are provided by protein growth factors. These are present at very low concentrations, and competition for them appears to limit cell population densities. Most cells, in addition to a requirement for specific growth factors, must be anchored to a substratum before they will divide.

Growth factors regulate cell proliferation through a complex network of intracellular signaling cascades, which ultimately regulate gene transcription and the assembly and activation of the cell-cycle control system. Many of the protein components of these signaling pathways have been identified through studies of cancer cells, where mutations have occurred either to activate genes whose products promote proliferation (proto-oncogenes) or to inactivate genes whose products normally restrain proliferation (tumor-suppressor genes). Among the proto-oncogenes are some gene regulatory proteins, such as Myc, that in some cell types are necessary and sufficient to induce cell proliferation. Conversely, there are tumor-suppressor genes, such as Rb, whose products block proliferation by binding to and sequestering gene regulatory proteins. In addition to these short-term controls on cell proliferation in multicellular organisms, there are long-term controls, such as those responsible for the progressive loss of proliferation potential when cells senesce or for the elaborate programs of cell division required during embryonic development. As yet, these are poorly understood.
Figure 17-33. Cyclins and Cdk proteins in the standard vertebrate cell cycle. Vertebrates have many different cyclin genes and many different *cdk* genes. Their products act in different cyclin/Cdk combinations at different stages of the cycle. The diagram shows only a few of these molecules and is speculative. The roles of Cdk2 and cyclin A, in particular, are still uncertain.

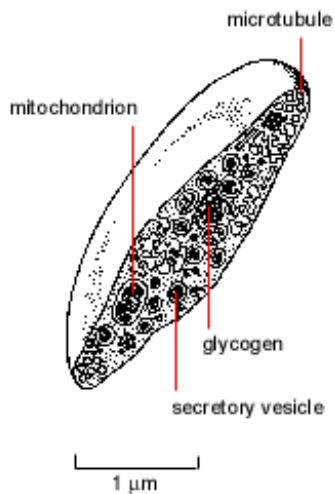
10 µm
Figure 17-34. Scanning electron micrograph of mammalian cells proliferating in culture. The cells are rat fibroblasts. (Courtesy of Guenter Albrecht-Buehler.)


Figure 17-35. A platelet. Platelets are miniature cells without a nucleus that circulate in the blood and help to mediate blood

clotting at sites of damage. They also release various factors that stimulate healing. The platelet in the diagram is cut open to show the secretory vesicles it contains; some of these contain platelet-derived growth factor (PDGF).

Table 17-2. Some Protein Growth Factors and Their Actions

Factor	Related Family Members	Broad or Narrow Specificity	Representative Actions
Platelet-derived growth factor (PDGF) - three subtypes		broad	stimulate proliferation of connective-tissue cells and some neuroglial cells
Epidermal growth factor (EGF)	transforming growth factor a (TGF-a); Lin-3 protein (in *C. elegans*)	broad	stimulate proliferation of many cell types; act as inductive signal in embryonic development
Insulinlike growth factor I (IGF-I)	insulinlike growth factor II (IGF-II); insulin	broad	promote cell survival; stimulate cell metabolism; collaborate with other growth factors to stimulate cell proliferation
Transforming growth factor b (TGF-b) - multiple subtypes	activins; bone morphogenetic proteins (BMPs); Decapentaplegic protein (in *Drosophila*); Vg1 protein (in *Xenopus*)	broad	potentiate or inhibit responses of most cells to other growth factors, depending on cell type; regulate differentiation of some cell types; act as inductive signals in embryonic development
Fibroblast growth factor (FGF) - multiple subtypes		broad	stimulate proliferation of many cell types; inhibit differentiation of various types of stem cells; act as inductive signals in embryonic development
Interleukin-2 (IL-2)		narrow	stimulate proliferation of activated T lymphocytes
Nerve growth factor	brain-derived neurotrophic factor (BDNF); neurotrophin-3 (NT-3); neurotrophin-4 (NT-4)	narrow	promote survival and nerve process outgrowth of (NGF) of specific classes of neurons
Erythropoietin		narrow	promote proliferation, differentiation, and survival of red blood cell precursors
Interleukin-3 (IL-3)	hemopoietic colony stimulating factors (CSFs) - multiple types	narrow	stimulate proliferation and survival of various types of blood cell precursors

Figure 17-36. A mammalian neuron (from the retina) and a lymphocyte compared for size. Both of these cells contain the same amount of DNA. A neuron grows progressively larger during its development while remaining in a G_0 state. During this time the ratio of cytoplasm to DNA increases enormously (by a factor of more than 10^5 for some neurons). (Neuron from B.B. Boycott in Essays on the Nervous System [R. Bellairs and E.G. Gray, eds.]. Oxford, U.K.: Clarendon Press, 1974.)
Figure 17-37. Cell division and migration in the epithelium lining the small intestine of the mouse. All cell division is confined to the bottom portion of the tube-shaped epithelial infoldings known as *crypts*. Newly generated cells move upward to form the epithelium that covers the villi, where they function in the digestion and absorption of foodstuffs from the lumen of the gut. Most epithelial cells have a very short lifetime, being shed from the tip of a villus within 5 days after emerging from the crypt. A ring of about 20 slowly dividing "immortal" cells (shown in *red*), however, remains anchored near the base of each crypt. These *stem cells* will divide to give rise to two daughter cells. On average, one daughter remains in place as an undifferentiated stem cell, while the other usually migrates upward to differentiate and join the villus epithelium. (Adapted from C.S. Potten, R. Schofield, and L.G. Lajtha, *Biochim. Biophys. Acta* 560:281-299, 1979.)
Figure 17-38. Effect of brief serum deprivation at different points in the cell cycle. Fibroblast cells deprived for 1 hour during the interval between mitosis and the G_1 checkpoint (*yellow bar*) are delayed by approximately 8 hours in their journey to the next mitosis; cells deprived in a similar way after the G_1 checkpoint (*dark green bar*) suffer no such delay (although they may be delayed in the following cycle).
Figure 17-39. Regulation of cell division in a "wounded" cell monolayer. Cells scattered on the surface of a culture dish normally proliferate until they touch one another, forming a confluent monolayer. The diagrams show the consequences of scraping away a strip of cells. The remaining cells at the margins of the vacant "wound" area flatten out and resume growth and division, which continue until the "wound" is "healed." Once the monolayer is again confluent, cell proliferation ceases almost entirely.
Figure 17-40. Effect of fresh medium on a confluent cell monolayer. Cells in a confluent monolayer do not divide (indicated in *gray*). The cells resume dividing (indicated in *green*) when exposed directly to fresh medium. Apparently, in the undisturbed

confluent monolayer proliferation has halted because the medium close to the cells is depleted of growth factors, for which the cells compete.

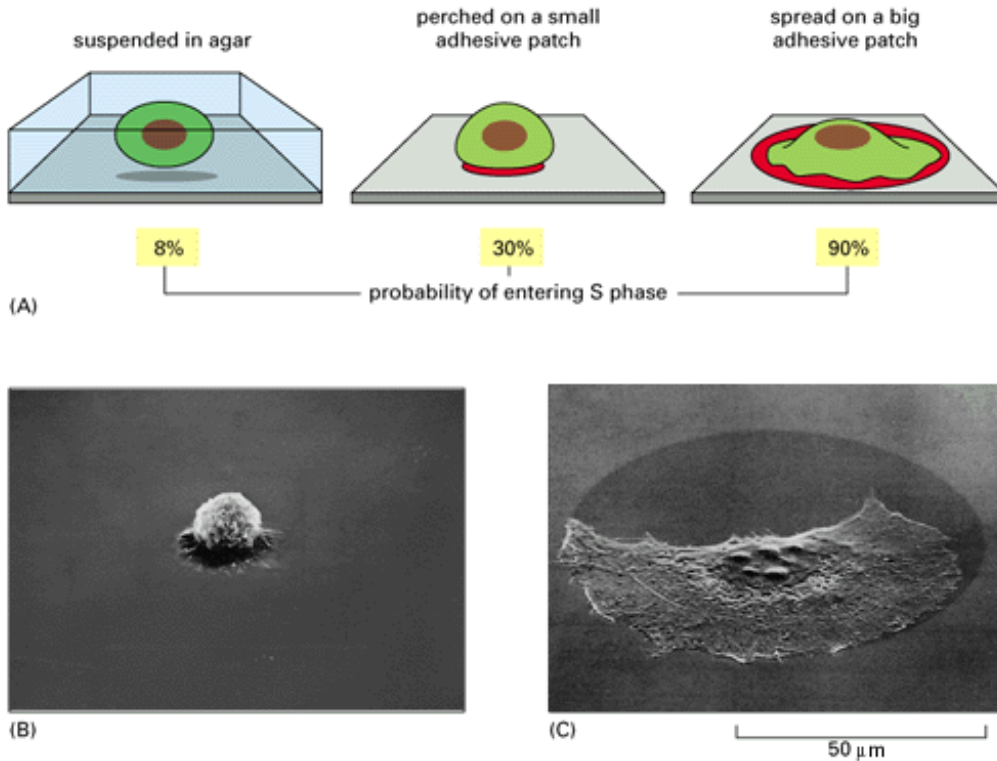
(A)


Figure 17-41. The dependence of cell division on cell shape and anchorage. In the experiment shown here, cells are either held in suspension or allowed to settle on patches of an adhesive material (palladium) on a nonadhesive substratum; the patch diameter, which is variable, determines the extent to which an individual cell spreads and the probability that it will divide.[3]H-thymidine is added to the culture medium, and after 1 or 2 days the culture is fixed and autoradiographed to discover the percentage of cells that have entered S phase. (A) Cells of the 3T3 cell line divide rarely when held rounded up in suspension, but adherence even to a very tiny patch - one that is too small to allow spreading - enables them to divide much more frequently. (B, C) Scanning electron micrographs showing a cell perched on a small patch as compared with a cell spread on a large patch. Note that, in contrast to fibroblasts, some cell types in the body (in particular, blood-cell precursors) will divide readily in suspension. (B and C from C. O'Neill, P. Jordan, and G. Ireland, *Cell*44:489-496, 1986. © Cell Press.)
Figure 17-42. Focal contacts as sites of production of intracellular signals. This fluorescence micrograph shows a fibroblast cultured on a substratum coated with the extracellular matrix molecule fibronectin. Actin filaments have been labeled so as to fluoresce green, while proteins containing phosphotyrosine have been labeled with an antibody that is tagged so as to fluoresce red. Where the two components overlap, the resulting color is yellow. The actin filaments terminate at focal contacts, where the

cell adheres to the substratum. Proteins containing phosphotyrosine are also concentrated at these sites. This is thought to reflect the operation of a tyrosine-kinase intracellular signaling mechanism activated by trans-membrane integrin proteins that bind to fibronectin extracellularly and (indirectly) to actin filaments intracellularly (see p. 999). Signals generated at such adhesion sites are thought to help regulate cell proliferation, both in fibroblasts and in epithelial cells. (Courtesy of Keith Burridge.)
Figure 17-43. Tumor-suppressor genes versus proto-oncogenes. The product of a tumor-suppressor gene inhibits assembly and activation of the cell-cycle control system; the product of a proto-oncogene does the opposite. Unrestrained proliferation can result from mutations that either inactivate both copies of the tumor-suppressor gene or strongly overactivate one copy of the proto-oncogene.
Figure 17-44. Typical signaling pathway for stimulation of cell proliferation by a growth factor. This greatly simplified diagram shows some of the major steps. It omits many of the intermediate steps in the relay system. Intracellular signaling pathways are discussed in detail in Chapter 15.
Figure 17-45. The response of Myc to a growth factor. Myc is the product of the early-response gene *myc*. The graph shows the changes in the concentration of Myc protein following a sudden increase in growth factor concentration to a new steady value, which causes the cell to exit G_0 and to proliferate. The changes in Myc concentration reflect changes in *myc* gene transcription, stimulated by exposure of the cell to the growth factor. Myc protein itself inhibits *myc* transcription, and this negative feedback is thought to explain why the level of Myc declines from its initial peak to a lower steady value.
Figure 17-46. Action of the retinoblastoma (Rb) protein. Dephosphorylated Rb binds to, and holds inactive, gene regulatory proteins that stimulate transcription of target genes (such as *myc*) required for cell proliferation. Phosphorylated Rb detaches, releasing the stimulatory proteins that activate proliferation.
Figure 17-47. Changes of Rb phosphorylation in a cycling cell. Rb becomes dephosphorylated as the cell exits from mitosis and is then rephosphorylated late in G_1 as the cell prepares to go past Start.
Figure 17-48. Evidence for cell variation in a heritable ability to divide. Individual cells in a clone vary in the number of division cycles they will undergo. Here, different pairs of sister cells from the same clone have been studied, and histograms have been drawn to show the numbers of cells that divide a given number of times. If one sister fails to divide at all, the other sister usually does likewise or divides only a few times (*left side*); and if one sister undergoes eight or more doublings, the other also usually undergoes eight or more doublings (*right side*). This shows that there are heritable differences between cells of the clone in the numbers of division cycles of which they are capable. The different heritable states are not perfectly stable, however, so sister cells sometimes behave differently. Further studies show that, as the cell population ages, the cells undergo random transitions toward states of reduced division capability. (Data from J.R. Smith and R.G. Whitney, *Science* 207:82-84, 1980.)
Figure 17-50. Micrographs comparing cells in the brains of haploid and tetraploid salamanders. (A) Cross-section of the hindbrain of a haploid salamander. (B) Corresponding cross-section through the hindbrain of a tetraploid salamander showing how reduced cell numbers compensate for increased cell size. (From G. Fankhauser, *Int. Rev. Cytol.* 1:165-193, 1952.)

18. The Mechanics of Cell Division

➡ ➡

Introduction

In this chapter we discuss the mechanical events of the M phase (or cell-division phase) of the cell cycle. This phase, which includes the various stages of nuclear division (*mitosis*) and cytoplasmic division (*cytokinesis*), is the culmination of the cell cycle. In a comparatively brief period, the contents of the parental cell, which were doubled by the biosynthetic activities of the preceding interphase, are segregated into two daughter cells (Figure 18-1).

At the molecular level M phase is initiated by a cascade of protein phosphorylations triggered by the activation of the mitosis-inducing protein kinase *MPF,* and it is terminated by the dephosphorylations that follow the inactivation of MPF through proteolysis of its cyclin subunits (discussed in Chapter 17). The protein phosphorylations that occur during M phase are responsible for the many morphological changes that accompany mitosis: the chromosomes condense, the nuclear envelope breaks down, the endoplasmic reticulum and Golgi apparatus fragment, the cell loosens its adhesions to other cells and the extracellular matrix, and the cytoskeleton is transformed to bring about the highly organized movements that will segregate the chromosomes and partition the cell. Because M phase involves a complete reorganization of the cell interior, the number of proteins that become phosphorylated is thought to be large, and essentially every part of the cell is affected in some way.
Figure 18-1. The M phase of the cell cycle. M phase starts at the end of G_2 phase and ends at the start of the next G_1 phase. It includes the five stages of nuclear division (mitosis), as well as cytoplasmic division (cytokinesis).

➤ ➤

An Overview of M Phase [1]

Introduction

With minor variations, the processes that occur in M phase to divide one cell into two follow the same sequence in all eucaryotes. They are dominated by cytoskeletal rearrangements as the cells assemble, use, and dismantle the machinery required to pull the duplicated chromosome sets apart and to split the cytoplasm into two halves.

Three Features Are Unique to M Phase: Chromosome Condensation, the Mitotic Spindle, and the Contractile Ring

The first readily visible manifestation of an impending M phase is a progressive compaction of the dispersed interphase chromatin into threadlike chromosomes. This chromosome condensation is required for the subsequent organized segregation of the chromosomes into daughter cells, and it is accompanied by extensive phosphorylation of histone H1 molecules (up to six phosphates per molecule). Since histone H1 is present at a concentration of about one molecule per nucleosome and is known to be involved in packing nucleosomes together, its phosphorylation by MPF at the onset of the M phase is thought to contribute to chromosome condensation.

Chromosome condensation is the prelude to two distinct mechanical processes: (1) *mitosis* - the segregation of the chromosomes and the formation of two nuclei in place of one - and (2) *cytokinesis* - the splitting of the cell as a whole into two. These processes are carried out by two distinct cytoskeletal structures that appear transiently in M phase. The first to form is a bipolar mitotic spindle, composed of microtubules and their associated proteins. The mitotic spindle aligns the replicated chromosomes in a plane that bisects the cell; each chromosome then separates into two daughter chromosomes, which are moved by the

spindle to opposite spindle poles. The second cytoskeletal structure required in M phase in animal cells is a contractile ring of actin filaments and myosin-II that forms slightly later, just beneath the plasma membrane in a plane perpendicular to the axis of the spindle (Figure18-2); as the ring contracts it pulls the membrane inward so as to divide the cell in two, thereby ensuring that each daughter cell receives not only one complete set of chromosomes but also half of the cytoplasmic constituents in the parental cell. The two cytoskeletal structures contain different sets of proteins and can be formed independently of each other in some specialized cells. Their formation is usually closely coordinated, however, so that cytoplasmic division (cytokinesis) occurs immediately after the end of nuclear division (mitosis). The same sequence occurs in plant cells, even though their rigid walls necessitate a different mechanism for cytokinesis, as we discuss later.

The description of M phase just given applies only to eucaryotic cells. Bacterial cells do not contain either actin filaments or microtubules. They generally have only one chromosome, whose replicated copies are segregated to daughter cells without special condensation by a mechanism that involves chromosome attachment to the bacterial plasma membrane. The need for complex mitotic machinery probably arose only with the evolution of cells that contained greatly increased amounts of DNA packaged in a number of discrete chromosomes. The primary function of this machinery is to divide the replicated chromosomes precisely between the two daughter cells: in yeast cells, where its accuracy has been determined, it makes an error in chromosome segregation only about once every 10^5 cell divisions.

Cell Division Depends on the Duplication of the Centrosome 2

As discussed in Chapter 16 the principal *microtubule organizing center (MTOC)* in most animal cells is the centrosome, a cloud of poorly defined pericentriolar material (the *centrosome matrix*) associated with a pair of *centrioles* (Figure 18-3). During interphase the centrosome matrix nucleates a cytoplasmic array of microtubules, which project outward toward the cell perimeter with their minus ends attached to the centrosome. Before a eucaryotic cell divides, it must duplicate its centrosome to provide one for each of its two daughter cells. In fact, duplicated centrosomes are required to create the two daughter cells, for centrosomes form the two poles of the mitotic spindle.

Centrosomes in most animal species share a remarkable and distinctive structural feature in the form of a pair of centrioles (discussed in Chapter 16). The centrioles, however, which are associated with the centrosome matrix, are not required for the nucleation of microtubules: plant centrosomes lack centrioles altogether, and centrioles are also missing during the early divisions of the cleaving mouse egg; moreover, drug treatments of cultured mammalian cells can create tripolar mitotic spindles, in which one spindle pole lacks centrioles yet appears to function normally. It is therefore thought that the centrosome matrix, which contains a set of centrosome-specific proteins, is the most fundamental part of the centrosome. When present, the centrioles associated with the matrix are duplicated in a strictly ordered manner, and their behavior may help in the creation of precisely two centrosomes as the cell enters each M phase (Figure18-4).

The process of centrosome duplication and separation is known as the *centrosome cycle*. During interphase of each cell cycle, the centrioles and other components of the centrosome are duplicated but remain together as a single complex on one side of the nucleus. As mitosis begins, this complex splits in two and each centriole pair becomes part of a separate microtubule organizing center that nucleates a radial array of microtubules called an aster. The two asters move to opposite sides of the nucleus to form the two poles of the mitotic spindle. As mitosis ends and the nuclear envelope re-forms around the separated chromosomes, each daughter cell receives a centrosome (the former spindle pole) in association with its chromosomes (Figure 18-5).

The centrosome cycle can operate with a surprising degree of independence from other processes of the cell cycle. Thus, if the nucleus is physically removed from a sea urchin egg, or if nuclear DNA replication is blocked by the DNA synthesis inhibitor aphidicolin, cycles of centrosome doubling and division proceed almost normally, giving first two centrosomes, then four, then eight. And in early *Drosophila* embryos similarly treated with aphidicolin, the proliferating centrosomes in the interior of the embryo dissociate from their blocked nuclei and march stepwise through the cytoplasm toward the plasma membrane; once they reach this membrane the centrosomes, through their asters, can reshape the membrane and its underlying cortex, generating cells that contain centrosomes but no nuclei (Figure 18-6). Cleaving eggs, with their stockpiles of cell components that free them from dependence on gene transcription, are admittedly exceptional in their behavior; in other cells the centrosome cycle depends on the presence of a functional cell nucleus. Yet it is clear that the division cycle of the cell as a whole depends on - and is at least in part organized by - the microtubule aster, which is in turn organized by the centrosome.

Centrosomes, and the centrioles usually associated with them, have perplexed and tantalized cell biologists for more than a hundred years. What are they made of, how are they replicated, and how did they originate in the course of evolution? These fundamental questions remain to be answered.

M Phase Is Traditionally Divided into Six Stages

The basic strategy of cell division is remarkably constant among eucaryotic organisms. The first five stages of the M phase constitute mitosis (originally defined as the period in which the chromosomes are visibly condensed); the sixth stage, overlapping with the end of mitosis, is cytokinesis. These six stages form a dynamic sequence, the complexity and beauty of which are hard to appreciate from written descriptions or from a set of static pictures.

The description of cell division is based on observations from two sources: light microscopy of living cells (often combined with microcinematography) and light and electron microscopy of fixed and stained cells. A brief summary of the various stages of cell division is given in Panel18-1. The five stages of mitosis - *prophase, prometaphase, metaphase, anaphase,* and *telophase* - occur in strict sequential order, while cytokinesis begins during anaphase and continues through the end of M phase (Figure18-7). Light micrographs of cell division in a typical animal and a typical plant cell are shown in Figures18-8 and 18-9, respectively. Innumerable variations in all of the stages of cell division shown schematically in Panel 18-1 occur in the animal and plant kingdoms. We shall mention some of these after we have looked more closely at the general mechanisms of cell division.

Large Cytoplasmic Organelles Are Fragmented During M Phase to Ensure That They Are Faithfully Inherited 3

The process of cell division must ensure that all the essential classes of cell components are inherited by each daughter cell. As discussed in Chapter 12organelles like mitochondria and chloroplasts, for example, cannot assemble spontaneously from their individual components; they can arise only from the growth and fission of the corresponding preexisting organelle, and a daughter cell cannot contain any unless it has inherited one or more. Likewise, it may not be possible to make new copies of the Golgi apparatus and endoplasmic reticulum without the prior presence of at least part of the corresponding structure. How are the various membrane-bounded organelles segregated when a higher eucaryotic cell divides? Organelles present in very large numbers will be safely inherited if, on average, their numbers simply double once each cell generation. Other organelles, such as the Golgi apparatus and the endoplasmic reticulum (ER), break up into a set of smaller fragments and vesicles during mitosis, presumably because in this highly vesiculated form they can be more evenly distributed when a cell divides. The ER vesicles seem to associate with microtubules of the mitotic spindle, which may help distribute them evenly between the two daughter cells.

Summary

The process of cell division (M phase of the cell cycle) consists of nuclear division (mitosis) followed by cytoplasmic division (cytokinesis). The nuclear division is mediated by a microtubule-based mitotic spindle, which separates the chromosomes, while the cytoplasmic division is mediated by an actin-filament-based contractile ring. Mitosis is largely organized by the microtubule asters that form around each of the two centrosomes produced when the centrosome duplicates. Centrosome duplication begins during the S and G_2 phases of the cell cycle, and the duplicated centrosomes separate and move to opposite sides of the nucleus at the onset of M phase to form the two poles of the mitotic spindle. Large membrane-bounded organelles, such as the Golgi apparatus and the endoplasmic reticulum, break up into many smaller fragments during M phase, which ensures their even distribution into daughter cells during cytokinesis.
Figure 18-2. The cytoskeleton in M phase. The mitotic spindle assembles first and segregates the chromosomes. The contractile ring assembles later and divides the cell in two.
Figure 18-3. A centrosome. An electron micrograph of a thick section of a centrosome in a mammalian cell in culture. (Courtesy of P. Witt and G. Borisy.)
Figure 18-4. Centriole replication. The centriole pair is associated with the centrosome matrix (*green*). At a certain point in G_1 phase the two centrioles separate by a few micrometers. During S phase a daughter centriole begins to grow near the base of each old centriole and at a right angle to it. The elongation of the daughter centriole is usually completed by G_2 phase. The two centriole pairs remain close together in a single centrosomal complex until the beginning of M phase, when the centrosome splits in two and the two halves begin to separate. The structure of a centriole is shown in Figures16-45 and 16-47.
Figure 18-5. The centrosome cycle of an animal cell. The centrosome in an interphase cell duplicates to form the two poles of a mitotic spindle. In most animal cells a centriole pair (shown here as a pair of *dark green bars*) is associated with the centrosome matrix (*light green*) that nucleates microtubule outgrowth. (The volume of centrosome matrix is exaggerated in this diagram for clarity; Figure18-4 gives a more accurate representation.) Centriole duplication begins in G_1 and is completed by G_2 (see Figure 18-4). Initially, the two centriole pairs and associated centrosome matrix remain together as a single complex. In early M phase this complex separates into two and each centrosome nucleates a radial array of microtubules, called an aster. The two asters, which initially lie side by side and close to the nuclear envelope, move apart. By late prophase the bundles of *polar microtubules* that interact between the two asters preferentially elongate as the two centers move apart along the outside of the nucleus. In this way a mitotic spindle is rapidly formed. At metaphase the nuclear envelope breaks down, enabling the spindle microtubules to interact with the chromosomes; at cytokinesis the nuclear envelope re-forms around the two sets of segregated chromosomes, excluding the centrosomes.
Figure 18-6. Cytoplasmic organization by centrosomes and their asters. If an early *Drosophila* embryo is injected with aphidicolin to block nuclear division, the centrosomes and the asters they nucleate detach from the nuclei in this large syncytial cell and migrate to the cell surface. At the posterior pole, where germ cells would normally form, membrane buds are organized by the detached centrosomes, resulting in the formation of germ "cells" without nuclei. (A) Schematic illustration of the budding process that is caused by the aster. (B-D) Fluorescence micrographs of germ "cells" with no nuclei: (B) is stained for DNA, showing that no nuclei are present; (C) is stained with an antibody to centrosomes; (D) is stained to show the microtubules associated with the centrosomes. (B-D, courtesy of Jordan Raff.)
Figure 18-7. A typical time course for mitosis and cytokinesis (M phase) in a mammalian cell. The times vary for different cell types and are much shorter in embryonic cell cycles. Note that cytokinesis begins before mitosis ends. The beginning of prophase (and therefore of M phase as a whole) is defined as the point in the cell cycle at which condensed chromosomes first become visible - a somewhat arbitrary criterion, since the extent of chromosome condensation appears to increase continuously during late G_2. The beginning of prometaphase is defined as the time when the nuclear envelope breaks down.
Figure 18-8. The course of mitosis in a typical animal cell. In these micrographs of cultured newt lung cells, the microtubules have been visualized by indirect immunofluorescence, while chromatin is stained with a blue fluorescent dye. During *interphase* the centrosome, consisting of matrix associated with a centriole pair, forms the focus for the interphase microtubule array. By *early prophase* the single centrosome contains two centriole pairs (not visible); at *late prophase* the centrosome divides and the resulting two asters move apart. The nuclear envelope breaks down at *prometaphase*, allowing the spindle microtubules to interact with the chromosomes. At *metaphase* the bipolar spindle structure is clear and all the chromosomes are aligned across the middle of the spindle. The paired daughter chromosomes, called *chromatids*, all separate synchronously at *early anaphase* and, under the influence of the microtubules, begin to move toward the poles. By *late anaphase* the spindle poles have moved farther apart, increasing the separation of the two groups of chromosomes. At *telophase* the daughter nuclei re-form, and by *late telophase* cytokinesis is almost complete, with the midbody persisting between the daughter cells. (Photographs courtesy of C.L. Rieder, J.C. Waters, and R.W. Cole.)
Figure 18-9. The course of mitosis in a typical plant cell. These micrographs of a living *Haemanthus* (lily) cell were taken at the times indicated using differential-interference-contrast microscopy. The cell has unusually large chromosomes that are easy to see. At the light microscope level shown here, the major events of cell division have been known for more than 100 years. (A) *Prophase:* the chromosomes have condensed and are clearly visible in the cell nucleus. (B) and (C) *Prometaphase:*the nuclear envelope has broken down and the chromosomes are interacting with microtubules that emanate from the two spindle poles. Plants do not have centrioles, but their spindle poles contain proteins related to those found in the centrosomal matrix of animal cells. Note that only 2 minutes have elapsed between the stages shown in (B) and (C). (D) *Metaphase:* the chromosomes have lined up at the metaphase plate with their kinetochores located halfway between the two spindle poles. (E) *Anaphase:* the chromosomes have separated into their two sister chromatids, which are moving to opposite poles. (F) *Telophase:* the chromosomes are decondensing to form the two nuclei that are seen later [marked N in (G)]. (G) and (H) *Cytokinesis:* two successive stages in the formation of the *cell plate*(a new cell wall) are shown; the cell plate appears as a line whose direction of outgrowth is indicated by arrows in (H). SUDDEN SEPARATION OF SISTER KINETOCHORES BEGINS ANAPHASE

1 PROPHASE

As viewed in the microscope, the transition from the G_2 phase to the M phase of the cell cycle is not a sharply defined event. The chromatin, which is diffuse in interphase, slowly condenses into well-defined chromosomes. Each chromosome has duplicated during the preceding S phase and consists of two sister *chromatids;* each of these contains a specific DNA sequence known as a *centromere,* which is required for proper segregation. Toward the end of prophase, the cytoplasmic microtubules that are part of the interphase cytoskeleton disassemble and the main component of the mitotic apparatus, the *mitotic spindle,* begins to form. This is a bipolar structure composed of microtubules and associated proteins. The spindle initially assembles outside the nucleus between separating centrosomes.

2 PROMETAPHASE

Prometaphase starts abruptly with disruption of the nuclear envelope, which breaks into membrane vesicles that are indistiguishable from bits of endoplasmic reticulum. These vesicles remain visible around the spindle during mitosis. The spindle microtubules, which have been lying outside the nucleus, can now enter the nuclear region. Specialized protein complexes called *kinetochores* mature on each centromere and attach to some of the spindle microtubules, which are then called *kinetochore microtubules.* The remaining microtubules in the spindle are called *polar microtubules,* while those outside the spindle are called *astral microtubules.* The kinetochore microtubules exert tension on the chromosomes, which are thereby thrown into agitated motion.

3 METAPHASE

The kinetochore microtubules eventually align the chromosomes in one plane halfway between the spindle poles. Each chromosome is held in tension at this *metaphase plate* by the paired kinetochores and their associated microtubules, which are attached to opposite poles of the spindle.

4 ANAPHASE

kinetochore microtubules shorten as the chromatid (chromosome) is pulled toward the pole

elongating polar microtubule

shortening kinetochore microtubule

astral microtubule

increasing separation of the spindle poles
ANAPHASE

Triggered by a specific signal, anaphase begins abruptly as the paired kinetochores on each chromosome separate, allowing each chromatid (now called a chromosome) to be pulled slowly toward the spindle pole it faces. All of the newly separated chromosomes move at the same speed, typically about 1 μm per minute. Two catagories of movement can be distinguished. During *anaphase A*, kinetochore microtubules shorten as the chromosomes approach the poles. During *anaphase B*, the polar microtubules elongate and the two poles of the spindle move farther apart. Anaphase typically lasts only a few minutes.

NUCLEAR ENVELOPE RE-FORMS

5 TELOPHASE

decondensing chromosomes without kinetochore microtubules

polar microtubules

nuclear envelope re-forming around individual chromosomes
TELOPHASE

In telophase (*telos*, end) the separated daughter chromosomes arrive at the poles and the kinetochore microtubules disappear. The polar microtubules elongate still more, and a new nuclear envelope re-forms around each group of daughter chromosomes. The condensed chromatin expands once more, the nucleoli—which had disappeared at prophase—begin to reappear, and mitosis is at an end.

centriole pair marks location of centrosome
CYTOKINESIS

The cytoplasm divides by a process known as *cleavage*, which usually starts sometime during anaphase. The process is illustrated here as it occurs in animal cells. The membrane around the middle of the cell, perpendicular to the spindle axis and between the daughter nuclei, is drawn inward to form a *cleavage furrow*, which gradually deepens until it encounters the narrow remains of the mitotic spindle between the two nuclei. This thin bridge, or *midbody*, may persist for some time before it narrows and finally breaks at each end, leaving two separate daughter cells.

Mitosis [4]

Introduction

The segregation of the chromosome is brought about by a complex machine with many moving parts. This machine, the mitotic spindle, is built mainly from microtubules, which are used both to push and to pull: pushing drives the poles of the spindle apart, while pulling draws the chromosomes toward those poles.

As we have seen, the spindle starts to form outside the nucleus while the chromosomes are condensing during prophase. When the nuclear envelope breaks down at prometaphase, the microtubules of the spindle are able to capture the chromosomes, which eventually become aligned at its midpoint, forming the so-called *metaphase plate*(see Panel18-1). At anaphase the sister chromatids abruptly split apart and are drawn to opposite poles of the spindle, while elongation of the spindle increases the separation between the poles. The spindle continues to elongate during telophase as the chromosomes arriving at the poles are released from the spindle microtubules and the nuclear envelope re-forms around them.

The assembly of the spindle, the capture of the chromosomes and their alignment at the metaphase plate, and the subsequent elongation of the spindle with the movement of the chromosomes to the poles are all critically dependent on processes occurring at or near the ends of microtubules: these are not only sites of microtubule assembly and disassembly but are also sites of force production. We shall see that three sets of spindle microtubules can be distinguished: the polar microtubules, which overlap at the midline of the spindle and are responsible for pushing the poles of the spindle apart; the kinetochore microtubules, which attach to the specialized *kinetochore* that forms at the centromere of each duplicated chromosome and maneuver the chromosomes in the spindle; and the astral microtubules, which radiate in all directions from the centrosomes and are thought to contribute to the forces that separate the poles and position them in relation to the rest of the cell (Figure18-10). The behavior of each of these sets of microtubules is different because of the different structures that their ends engage with and the different types of processes that consequently occur there.

Formation of the Mitotic Spindle in an M-Phase Cell Is Accompanied by Striking Changes in the Dynamic Properties of Microtubules [5]

The *interphase microtubule array* radiating from the centrosome is in a state of dynamic instability in which microtubules are continually polymerizing and depolymerizing and fresh microtubules are continually being nucleated to balance the loss of those that disappear completely by depolymerization (discussed in Chapter 16). During late prophase the rates of these processes change dramatically. The half-life of an average microtubule decreases about twentyfold (from about 5 minutes to as little as 15 seconds) (Figure18-11), and this is thought to reflect a steep increase in the probability that a typical growing microtubule will convert to a shrinking one by a change at its plus end (see p. 810). At the same time there is a large increase in the number of microtubules radiating from the centrosome, apparently because of an alteration in the centrosome itself, boosting the rate at which fresh microtubules are nucleated there: prophase centrosomes can be shown *in vitro* to have a greatly increased capacity for nucleating the growth of microtubules. These two changes are sufficient to explain why the onset of M phase is characterized by a rapid transition from relatively few long microtubules that extend from the centrosome to the cell periphery (the interphase microtubule array) to large numbers of short microtubules that surround each centrosome (the astral microtubules). In some cells a third mechanism may operate in addition: the breakdown of the interphase microtubules may be accelerated by proteins that sever them. The molecular basis for these changes in microtubule dynamics is uncertain, but it seems likely to involve the phosphor-ylation by MPF of one or more proteins that interact with microtubules.

The rapidly growing and shrinking microtubules emanate in all directions from the prophase centrosomes. Subsets of these astral microtubules become selectively stabilized in different ways to form an organized mitotic spindle.

Interactions Between Oppositely Oriented Microtubules Drive Spindle Assembly [6]

During prophase, while the nuclear envelope is still intact, some of the elongating microtubules that radiate from each centrosome appear to engage with microtubules of opposite polarity growing from the other centrosome (Figure18-12). In the region of overlap, midway between the two centrosomes, cross-links are thought to form, stabilizing the ends of these *polar microtubules* against disassembly and binding the two oppositely oriented sets together to form the basic framework of the characteristic bipolar spindle. The proteins that cross-link the polar microtubules are thought to be plus-end-directed

microtubule motor molecules that not only serve to stabilize the bipolar spindle but act to push the antiparallel, overlapping microtubules past each other in a direction that tends to force the two poles apart. Thus, although the polar microtubules are stabilized against catastrophic disassembly, they are not static; indeed, we shall see later that, even in the metaphase spindle (Figure18-13), which gives the appearance of stability, the polar microtubules continuously undergo net addition of monomers at their plus ends and net loss at their minus ends at the poles.

The polar microtubules presumably serve to separate the centrosomes as the spindle assembles during prophase. Later they will drive the elongation of the spindle at anaphase. In the meantime, however, during the middle stages of mitosis elongation of the spindle is held in check; while the polar microtubules exert a push, holding the spindle poles apart, the kinetochore microtubules, attaching the spindle poles to the chromosomes, exert a counterbalancing pull, as we shall now see.

Replicated Chromosomes Attach to Microtubules by Their Kinetochores 7

At the start of M phase, each chromosome has replicated and consists of two *sister chromatids* joined together along their length, with a constriction in a unique region called the centromere, where the chromatin seems to be especially condensed (Figure 18-14). During late prophase specialized protein complexes known as kinetochores assemble on each centromere, with the two kinetochores on each chromosome (one on each sister chromatid) facing in opposite directions. Through their kinetochores the replicated chromosomes will bind to a distinct subset of the microtubules of the mitotic spindle (Figure18-15). These kinetochore microtubules will serve eventually, at anaphase, to pull the two sister chromatids toward opposite poles of the spindle. But before that stage, while the sister chromatids are still linked, there is already a tension generated in the kinetochore microtubules, tugging outward on the chromosomes and inward on the spindle poles.

In most organisms the kinetochore is a large multiprotein complex that can be seen in the electron microscope as a platelike multilaminar structure (Figure 18-16). We shall see that it is not just a passive anchorage site for microtubules: it plays a central role in controlling the assembly and disassembly of the kinetochore microtubules, generating tension in them and, ultimately, driving chromosome movement.

Kinetochore Protein Complexes Assemble on Specific Centromeric DNA Sequences in Yeast Chromosomes 8

The information that specifies the construction of a kinetochore at a specific site on a chromosome is contained in the DNA sequence at the centromere. In budding yeasts centromeric DNA can be readily identified genetically by its effect on the propagation of plasmids that contain it: a plasmid including centromeric DNA can be stably inherited in mitosis and meiosis in the same way as a chromosome, whereas a plasmid that lacks this DNA (and is present in low numbers) will segregate irregularly to daughter cells and be lost within a few cell divisions. (We discuss in Chapter 7 how this property of centromeres has been exploited in the construction of vectors for cloned DNA.) Molecular genetic experiments show that each of the 17 chromosomes of the yeast *Saccharomyces cerevisiae* contains a different centromeric sequence about 110 base pairs long (Figure 18-17). Although each sequence is unique, they all contain substantial regions of homology and can be inverted or swapped from chromosome to chromosome without loss of function.

Some of the proteins that form the yeast kinetochore have been identified by their ability to bind to centromeric DNA. Element III of the yeast centromere (see Figure 18-17), for example, binds a complex of three proteins. This protein complex is thought to initiate formation of a simple kinetochore that latches onto the end of a single microtubule. One of the purified centromere-binding proteins is a minus-end-directed microtubule motor, which seems sufficient to propel the yeast kinetochore along its attached microtubule toward the mitotic pole. Other proteins bind to other sequences of the centromere and stabilize its interaction with the microtubule.

Mammalian centromeres consist of different and much longer DNA sequences, many of them repetitive, and they form much larger kinetochores, which bind 30 or 40 microtubules instead of one. It is thought that much of the repetitive sequence (called satellite DNA) in mammalian centromeres is required for the special chromatin organization at the centromere. It seems likely, however, that there are DNA sequences embedded in this structural DNA that bind protein complexes similar to those bound to the yeast centromere.

An unexpected opportunity to study the proteins of mammalian kinetochores has come from the finding that human patients suffering from certain types of *scleroderma* (a disease of unknown cause that is associated with a progressive fibrosis of connective tissue in skin and other organs) produce autoantibodies that react specifically with kinetochores. When these antibodies are used to stain dividing cells by immunofluorescence, a pattern of fluorescent spots is seen, with each spot marking

the position of a kinetochore. Unexpectedly, a similar pattern is obtained if nondividing cells are stained, with the number of spots per cell corresponding to the number of chromosomes, suggesting that a kinetochore precursor is attached to each centromere even in interphase nuclei (Figure18-18). Scleroderma autoantibodies have also made it possible to clone the genes that encode several of the many proteins associated with mammalian kinetochores, so that these normally rare proteins can now be produced in large quantities by recombinant DNA technologies. In this way their interactions with one another, with DNA, and with microtubules are being characterized.

Kinetochores Capture Microtubules Nucleated by the Spindle Poles 9

In prophase, as the polar microtubules form and the spindle lengthens, many microtubules are still growing and shrinking rapidly from the centrosome at each pole, with their plus ends constantly probing at random through the cell. Prophase ends and prometaphase begins when the rapid phosphorylation of the nuclear lamina triggers the breakdown of the nuclear envelope and the microtubules gain access to the chromosomes. By a process that has been likened to a fisherman casting a line, a randomly probing microtubule every so often passes close enough to a kinetochore to capture the chromosome. In newt cells, where the initial capture event can be visualized, the kinetochore can be seen first to bind to the side of the microtubule and then to slide rapidly along it toward the spindle pole (Figure 18-19). The lateral attachment to the microtubule and poleward sliding movement probably reflect the action of dynein (which is discussed in Chapter 16), a minus-end-directed microtubule motor protein, which can be shown by staining with antidynein antibodies to be present in kinetochores.

Each kinetochore quickly seizes hold of more microtubules as it is dragged toward the spindle pole, where the microtubule density is high. During this process the initial side-on interactions with microtubules are converted into end-on interactions, with the kinetochore bound to the plus end of each microtubule. Eventually, the opposite kinetochore, on the other sister chromatid, will be captured by the free end of a microtubule from the opposite spindle pole, positioning the chromatids for segregation and establishing tension in the kinetochore microtubule system. This tension is due to the special properties of the linkage between the microtubules and the kinetochores, which we now discuss.

The Plus Ends of Kinetochore Microtubules Can Add and Lose Tubulin Subunits While Attached to the Kinetochore 10

Just as the polar microtubules continue to add subunits at one end and lose them at the other after they have established their cross-linking connections at the spindle equator, so the kinetochore microtubules are also in a state of dynamic flux. If chemically marked tubulin is injected into mitotic cells during metaphase, it is found to be incorporated continually into these microtubules near their point of attachment to the kinetochore (Figure18-20). We shall see shortly that during anaphase the reverse reaction occurs, and tubulin molecules are lost from these microtubules at the kinetochore as it moves toward a spindle pole. This requires that both the addition and the loss of tubulin molecules take place while the kinetochore maintains a firm mechanical attachment to the microtubules. This attachment remains under tension throughout, whether tubulin molecules are being added or removed. The kinetochore thus seems to act like a sliding collar, maintaining a lateral association with polymerized tubulin subunits near the end of the microtubule while allowing the addition or loss of tubulin molecules to occur at that end (see Figure 18-28). When tubulin molecules are added the collar remains at the end of the microtubule by slipping back; when tubulin molecules are lost the collar remains at the end by traveling forward.

Spindle Poles Repel Chromosomes 11

While the kinetochore microtubules tend to pull the chromosomes poleward, another, more mysterious force acts in an opposite direction, repelling any large object that approaches the poles too closely. This can be seen if the arms of a chromosome are cut free from the kinetochore by laser microsurgery. While the kinetochore is drawn to the nearest pole, the arms tend to move away from it (Figure 18-21). The origin of this "astral exclusion force," or "polar wind," is not known. It may be the result of pushing by the growing ends of the free microtubules that are nucleated continually at the pole; alternatively, the freed chromosome arms may bind plus-end-directed microtubule motors and migrate along such microtubules; or some other cell components may be moving in that way and sweeping the chromosome arms along with them. The astral exclusion force has been proposed to play an important part in aligning chromosomes at the spindle equator in metaphase, as discussed below.

Sister Chromatids Attach by Their Kinetochores to Opposite Spindle Poles 12

The eventual outcome of the interaction between kinetochores and microtubules is the faithful segregation of the two sister chromatids of each chromosomal pair to opposite sides of the cell. This requires that sister kinetochores bind microtubules coming from opposite poles; if sister kinetochores both moved to the same pole, the resulting cell division would produce two

defective cells, one missing a chromosome and one with an extra copy. Much of the complexity of mitosis reflects this requirement for accurate segregation, and the most common mitotic error is for both sister chromatids to end up in one of the two daughter cells. This error can occur if a replicated chromosome fails to attach to the spindle, if it attaches to only one half of the spindle, or if the two sister chromatids fail to separate at anaphase.

Since sister kinetochores face in opposite directions, they will naturally tend to attach to opposite poles, but mistakes do occur. In early prometaphase the two sister kinetochores on a chromosome can become attached to the same spindle pole. This and other incorrect configurations, which would cause a failure of the chromosome to segregate properly if they persisted, are almost always corrected, however. It seems that a balanced arrangement, in which each sister kinetochore is attached to a different spindle pole and only to that spindle pole, has the greatest stability. Why this might be is suggested by an experiment designed to test how chromosomes are attached to the spindle.

Extremely fine glass needles are used to poke and pull at chromosomes inside a living cell, in this case a grasshopper spermatocyte in meiosis, whose unusually flexible plasma membrane tolerates the manipulation. By micromanipulating chromosomes during prometaphase, it is possible to force the two kinetochores on a single chromosome to engage with the same spindle pole. This arrangement is normally unstable, but it can be made stable and will persist until anaphase if the needle is used to keep the kinetochore microtubules on the incorrectly associated chromosome under tension by gently tugging on the chromosome in the direction away from the pole to which both its kinetochores are attached. It therefore appears that kinetochore microtubules are stabilized by tension and that, normally, only chromosomes attached to *both* poles will be stably attached to the spindle.

Balanced Bipolar Forces Hold Chromosomes on the Metaphase Plate [13]

During prometaphase the chromosomes can be seen to move about as if jerked first this way and then that before they align at an equal distance from the two spindle poles, thereby forming the *metaphase plate* and defining the beginning of metaphase. But what brings them to this precise position? If acted on simply by equal and opposite constant pulls toward the two poles of the spindle, the chromosomes could be held in equilibrium at any position along the spindle axis. There has to be some change in the forces acting according to the distances from the spindle poles such that any chromosome displaced away from the equatorial plane experiences a net force to bring it back there.

One hypothesis proposes that the pull exerted by a kinetochore microtubule increases as the microtubule gets longer; the net force on a chromosome then will be toward whichever pole is the more distant, with zero net force only when the chromosome lies equidistant from both poles (Figure18-22A). A plausible mechanism for generating a force proportional to microtubule length would be to have plus-end-directed microtubule motors immobilized in a matrix associated with the spindle: the longer the kinetochore microtubule, the more of these motors would be engaged, propelling the microtubule back toward its spindle pole. The position-dependent component of the force on the chromosome would be supplementary to the force developed by the activity of the motor proteins at the kinetochore itself.

Another hypothesis (Figure18-22B) proposes that the astral exclusion force is responsible for centering each chromosome on the spindle by pushing the chromosome more strongly away from the spindle pole the more closely it approaches (as would be expected, for example, if the force is due to free microtubules growing out from the pole). In this way too, a balance would be achieved only when the chromosome is equidistant from both poles. The two hypotheses are not mutually exclusive, and it is possible that both mechanisms, and/or some other mechanism, may operate in some spindles.

The forces that bring the chromosomes to the metaphase plate continue to operate throughout metaphase, and the chromosomes can be seen to oscillate back and forth, continually adjusting their positions. If one of a pair of kinetochore attachments is severed with a laser beam during metaphase, the entire chromosome immediately moves toward the one pole to which it remains attached. Similarly, if the attachment between the two chromatids is severed, the two chromatids separate and move toward opposite poles, just as they do in anaphase. Thus the forces that will pull the chromatids poleward in anaphase are not suddenly switched on at the metaphase-anaphase transition: they are present as soon as microtubules attach to the kinetochores.

Microtubules Are Dynamic in the Metaphase Spindle [14]

The metaphase spindle is a complex and beautiful assembly suspended in a state of dynamic equilibrium and is already tensed for the actions that will begin at anaphase. All of the spindle microtubules, despite their appearance of stability, are continually exchanging subunits with the pool of soluble free tubulin: treatment with the drug colchicine, which blocks tubulin assembly

into microtubules, causes the whole spindle to disassemble rapidly. The dynamic behavior of kinetochore and polar microtubules has been studied directly by allowing the microtubules to incorporate tubulin that has been covalently coupled to photoactivatable "caged" fluorescein (see p. 184). When such meta-phase spindle microtubules are marked with a bar of fluorescence (by illumination with a laser beam), the marks move continuously poleward (Figure 18-23). This experiment shows that in both the kinetochore and polar microtubules the tubulin subunits are moving continually toward the poles - a process referred to as *treadmilling* (Figure 18-24, and see p.823). The marks get dimmer with time, indicating that many individual microtubules depolymerize completely and are replaced. Since the polar and kinetochore microtubules of the metaphase spindle stay at a constant length, there must be an exact balance between the addition of tubulin subunits at the plus ends at the spindle equator and the removal of tubulin subunits at the minus ends attached to the poles (Figure18-25A).

The continuous treadmilling of tubulin subunits toward the poles of the metaphase spindle has profound implications for how the spindle is constructed. It is thought that many of the bonds between the polar microtubules in the spindle, and between microtubules and other structures such as kinetochores and centrosomes, are made by microtubule motor proteins. Because motor proteins continually associate and dissociate from the microtubule as they go through their catalytic cycle, they are ideally designed to hold onto a microtubule whose subunits are moving. They can sustain a tension even when the microtubule is lengthening by addition of subunits, and they can sustain a compression even when the microtubule is shortening by subunit loss.

Sister Chromatids Separate Suddenly at Anaphase 15

As discussed in Chapter 17, anaphase is triggered by the degradation of cyclin and the consequent inactivation of MPF. This leads abruptly to the synchronous splitting of each chromosome into its sister chromatids, each with one kinetochore. The separation of the sister chromatids frees them from the bond that holds them at the metaphase plate, and the kinetochores can begin to move toward the spindle pole to which they are attached by their kinetochore microtubules (Figure 18-25B). It is thought that the chromatids are held together along their length by chromosomal proteins that are suddenly altered in some way at the start of anaphase, allowing the chromatids to separate and begin their journey poleward (Figure 18-26).

Anaphase Is Delayed Until All Chromosomes Are Positioned at the Metaphase Plate 16

Metaphase occupies a substantial portion of the mitotic period (see Figure18-7), partly because cells pause here until all of their chromosomes are lined up appropriately at the metaphase plate. Cells arrest in metaphase for hours or days, for example, if the mitotic spindle is disassembled by treatment with colchicine. (This method of cell-cycle arrest is commonly used to collect large numbers of cells in mitosis so that their condensed chromosomes can be analyzed.) The normal inactivation of MPF that signals the metaphase-to-anaphase transition is blocked so long as the spindle is disassembled in this way. It is thought that any kinetochore that is not attached to microtubules generates a diffusible signal that somehow stabilizes MPF and that this normally guarantees that all of the chromosomes are aligned before progression into anaphase is allowed. Thus, disrupting the spindle with drugs would be expected to produce a strong signal that greatly prolongs metaphase.

Two Distinct Processes Separate Sister Chromatids at Anaphase 17

Once each chromosome has split in response to the anaphase trigger, its two chromatids move to opposite spindle poles, where they will assemble into the nucleus of a new cell. Their movement is the consequence of two independent processes mediated by the spindle. The first, referred to as anaphase A, consists of the poleward movement of chromatids, accompanied by the shortening of the kinetochore microtubules (see Figure 18-25B). The second, referred to as anaphase B, consists of the separation of the poles themselves, accompanied by the elongation of the polar microtubules (Figure18-27). Historically, these two processes were distinguished by their differential sensitivities to drugs, and it is now clear that they occur by different mechanisms.

The relative contributions of anaphase A and anaphase B to the final separation of the chromosomes vary considerably depending on the organism. In mammalian cells anaphase B begins shortly after the chromatids have begun their voyage to the poles and stops when the spindle is about 1.5-2 times its metaphase length. In some other cells, such as yeasts and certain protozoa, anaphase B predominates and the spindle elongates to 15 times its metaphase length.

Kinetochore Microtubules Disassemble During Anaphase A 18

A surprisingly large force acts on a chromosome as it moves from the metaphase plate to the spindle pole. Measurements using

the deflection of fine glass needles give an estimate of 10^{-5} dynes per chromosome, which is more than 10,000 times greater than the force required simply to move chromosomes at their observed rate through the cytoplasm. Evidently, powerful motors are responsible for moving the chromosomes, and the speed of chromosome movement must be limited by something other than viscous drag. As discussed above, the same motors may generate the tension on chromosomes at the metaphase plate.

As each chromosome moves poleward, its kinetochore microtubules depolymerize, so that they have nearly disappeared at telophase. The site of subunit loss can be determined by making marks on the kinetochore microtubules using fluorescent tubulin subunits and laser beams, as described earlier. In such experiments, kinetochore microtubules are seen to depolymerize at both ends during anaphase, with most of the depolymerization occurring at the kinetochores, where they previously polymerized. In a cultured newt cell, for example, anaphase A movement occurs at 2 microns per minute, which is equivalent to microtubules depolymerizing at about 50 subunits per second. Of this depolymerization, 60% to 80% occurs at the kinetochores, while the remainder occurs at the poles, at the same rate as observed during metaphase (see Figure18-25). The finding that the kinetochore is the major site of microtubule depolymerization in anaphase suggests that it is also the main site where the force for chromosome movement is generated.

The mechanism by which the kinetochore, and thus the chromosome, moves toward the spindle pole during anaphase A is, however, unknown. Two possible models are presented schematically in Figure18-28. In one, a minus-end-directed motor protein in the kinetochore hydrolyzes ATP to move along its attached microtubule, with the plus end of the microtubule depolymerizing as it becomes exposed. In the other model depolymerization of the microtubule itself causes the kinetochore to move passively because the kinetochore remains attached to the end of the microtubule as depolymerization proceeds. The recent finding of minus-end-directed motor proteins in the kinetochore has shifted the balance of opinion in favor of the first model, although microtubule depolymerization probably contributes to the movement, perhaps by acting as a "governor" that limits the rate of poleward migration.

Two Separate Forces May Contribute to Anaphase B [19]

Anaphase B increases the distance between the two spindle poles and, in contrast to anaphase A, is accompanied by the *elongation* of microtubules. The movement is thought to be driven by the same mechanism that pushes the centrosomes apart in prometaphase. As the two poles move apart, the polar microtubules between them lengthen, apparently by polymerization at their distal, plus ends.

Both the extent of spindle pole separation at anaphase and the degree of overlap of the polar microtubules in the midzone vary greatly from species to species. In many diatoms, which have the distinctive feature that mitosis occurs within the nuclear envelope, the overlapping arrays of spindle microtubules are especially prominent (Figure 18-29). Painstaking reconstruction of the three-dimensional architecture of complete diatom spindles from hundreds of serial thin sections examined in the electron microscope shows that the polar microtubules from each half-spindle overlap in a central region near the spindle equator and that microtubules of opposite polarity are arranged with regular spacing between them. During anaphase these two sets of antiparallel polar microtubules appear to slide away from each other in the region of overlap.

Anaphase movements can also be studied in lysed diatom cells. In this model system the prominent mitotic spindle is freely accessible to macromolecules, so that the effects of various macromolecular probes (including specific antibodies) can be tested. Anaphase B movement in diatoms is blocked by an antibody that recognizes microtubule motor proteins of the kinesin family, suggesting that the movement is probably driven by a motor protein of this family. The motor protein is thought to reside in the overlap zone, where it serves to push the half-spindles apart (Figure 18-30A).

The astral microtubules, which elongate in all directions from the spindle poles during anaphase, are thought to play an additional role in anaphase B movement. In both fungi and animal spindles, severing the central spindle does not block the separation of the spindle poles but in fact accelerates it. This suggests that the astral microtubules that point away from the spindle generate a pulling force that assists the separation of poles during anaphase B, possibly by interacting with minus-end-directed motor proteins attached to the cell cortex or other cytoplasmic structures (Figure18-30B). Consistent with this suggestion, the injection of antibodies against the minus-end-directed motor protein dynein causes the spindle in cultured cells to collapse. This pulling force is believed to operate also during spindle assembly in prophase, and similar forces are thought to guide the specific positioning of spindles prior to asymmetric cell cleavages, as we discuss later.

At Telophase the Nuclear Envelope Initially Re-forms Around Individual Chromosomes [20]

By the end of anaphase the chromosomes have separated into two equal groups, one at each pole of the spindle. In telophase, the final stage of mitosis, a nuclear envelope reassembles around each group of chromosomes to form the two daughter interphase nuclei.

At least three parts of the nuclear-envelope complex (discussed in Chapter 12) must be considered during its breakdown and reassembly in mitosis: (1) the *outer and inner nuclear membranes,* which are continuous with the endoplasmic reticulum membrane; (2) the underlying *nuclear lamina* (a thin sheetlike network of intermediate filaments formed from the nuclear lamins), which interacts with the inner nuclear membrane, chromatin, and nuclear pores; and (3) the *nuclear pores,* which are formed by large protein complexes. At prophase the phosphorylation of the lamins occurs at many sites in each polypeptide chain and causes them to disassemble, thereby disrupting the nuclear lamina. Subsequently, perhaps in response to a different signal, the nuclear envelope membranes break up into small membrane vesicles.

The sudden transition from metaphase to anaphase initiates dephosphorylation of the many proteins that were phosphorylated at prophase: although the relevant phosphatases are active throughout mitosis, it is not until MPF is switched off that the phosphatases can act unopposed. Shortly thereafter, at telo-phase, nuclear membrane vesicles associate with the surface of individual chromosomes and fuse to re-form the nuclear membranes, which partially enclose clusters of chromosomes before coalescing to re-form the complete nuclear envelope (see Figure 12-18). During this process the nuclear pores reassemble and the dephosphorylated lamins reassociate to form the nuclear lamina; one of the lamina proteins (lamin B) remains with the nuclear membrane fragments throughout mitosis and may help nucleate reassembly. After the nucleus re-forms, the pores pump in nuclear proteins, the chromosomes decondense, and RNA synthesis resumes, causing the nucleolus to reappear. Chromatin decondensation is thought to be triggered, in part, by the dephosphorylation of histone H1 molecules.

Both nuclear disassembly and nuclear assembly will occur in crude extracts of *Xenopus* eggs, provided that these extracts are prepared from cells at the correct stage of the cell cycle (mitotic cells for disassembly and interphase cells for assembly). In these extracts the entire process involving the lamina, nuclear pores, and nuclear membranes appears to progress normally in response to phosphorylation and dephosphorylation cycles. *In vitro* systems of this type provide an assay for the identification and purification of the proteins that catalyze nuclear envelope assembly and disassembly in the cell, including the proteins (such as MPF) that regulate these processes. While DNA must be added to these extracts for a nucleus to assemble, a complete nuclear envelope will form around purified DNA molecules from virtually any organism, including a bacterial virus. Therefore, while DNA-binding proteins must be involved, it is unlikely that specific DNA sequences are recognized during nuclear reassembly.

Surprisingly, nuclear-envelope breakdown is not a requirement for mitosis. In fact, we shall see below that in lower eucaryotes the nuclear envelope does not disassemble during mitosis. These organisms are said to have a closed, rather than an open, spindle.

Summary

Mitosis begins with prophase, which is marked by an increase in the phosphorylation of specific proteins, triggered by the activity of the mitosis-inducing protein kinase MPF. One consequence of this phosphorylation is an unusually dynamic microtubule array nucleated on the duplicated centrosomes that form the spindle poles. One subset of the microtubules from each centrosome becomes stabilized, apparently by cross-linking to microtubules from the opposite centrosome, to form the polar microtubules, which are thought to push the poles apart. After the nuclear envelope breaks down in pro-metaphase, the kinetochores on condensed chromosomes can capture and stabilize other subsets of microtubules from the large numbers that continually grow out from each spindle pole. Kinetochore microtubules from opposite spindle poles pull in opposite directions on the two kinetochores on each duplicated chromosome, creating a tension that stabilizes the kinetochore attachment. Balanced forces on the kinetochores also bring the chromosomes to the spindle equator to form the metaphase plate. The tubulin subunits in the spindle microtubules at metaphase undergo a continuous treadmilling from the spindle equator toward the poles. At anaphase sister chromatids suddenly detach from each other and are pulled to opposite poles (the anaphase A movement). Meanwhile, the two spindle poles move apart (the anaphase B movement). In telophase, the final stage of mitosis, the nuclear envelope re-forms on the surface of each group of separated chromosomes as the proteins phosphorylated at the onset of M phase are dephosphorylated.
Figure 18-10. The three classes of microtubules of the fully formed mitotic spindle. (A) A confocal image of a mitotic spindle at metaphase from a *Drosophila* embryo, with the microtubules fluorescently labeled. (B) A schematic diagram identifying the three classes of microtubules in a spindle. In reality, the chromosomes are much larger than shown, and multiple microtubules are attached to each kinetochore. (A, courtesy of William Theurkauf.)
Figure 18-11. Microtubules in an M-phase cell are much more dynamic, on average, than the microtubules at interphase. Mammalian cells in culture were injected with tubulin that had been covalently linked to a fluorescent dye. After the fluorescent tubulin had become incorporated into the cell's microtubules, all of the fluorescence in a small region was bleached by an intense laser beam. The recovery of fluorescence in the bleached region of microtubules, caused by their replacement by microtubules formed from unbleached fluorescent tubulin from the soluble pool, was then monitored as a function of time. The time for 50% recovery of fluorescence ($t_{1/2}$) is thought to be equal to the time required for half of the microtubules in the region to depolymerize and re-form. (Data from W.M. Saxton et al., *J. Cell Biol.* 99:2175-2187, 1984, by copyright permission of the Rockefeller University Press.)

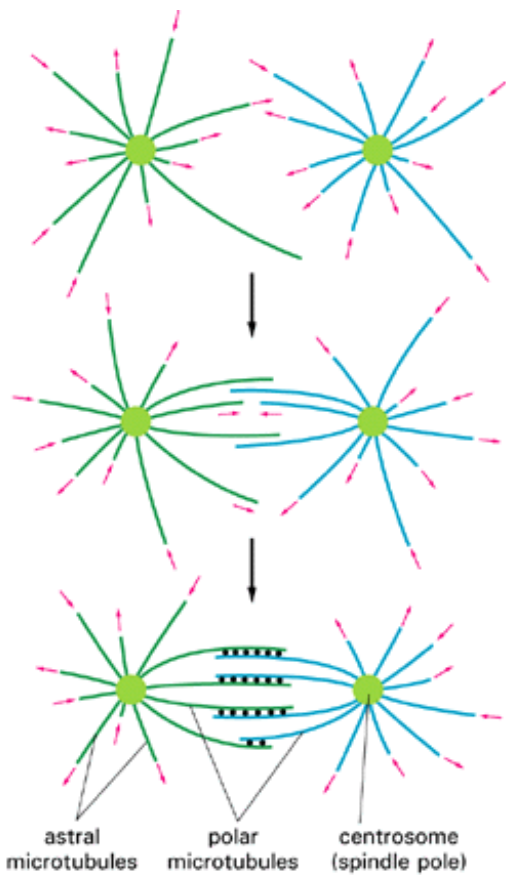

Figure 18-12. A model for how a bipolar mitotic spindle may form by the selective stabilization of interacting microtubules. New microtubules grow out in random directions from two nearby centrosomes. The microtubules are anchored to the centrosome by their minus ends. Their plus ends are "dynamically unstable" and switch suddenly from uniform growth (*outward-pointing red arrows*) to rapid shrinkage (*inward-pointing red arrows*), during which the entire microtubule often depolymerizes. When two microtubules from opposite centrosomes interact in an overlap zone, microtubule-associated proteins are thought to cross-link the microtubules together (*black beads*) in a way that caps their plus ends, stabilizing them by decreasing their probability of depolymerizing. There is evidence that the cross-linking proteins are plus-end-directed microtubule motor molecules that tend to drive the microtubules in the directions that push the poles of the spindle apart.

Figure 18-15. Kinetochore microtubules. Schematic drawing of a metaphase chromosome showing its two sister chromatids attached to kinetochore microtubules. Each kinetochore forms a plaque on the surface of the centromere. The plus ends of the microtubules bind to the kinetochores (not shown).
Figure 18-16. The kinetochore. (A) A metaphase chromosome stained with a DNA-binding fluorescent dye. (B) A metaphase chromosome stained with human autoantibodies that react with specific kinetochore proteins, showing two kinetochores, one associated with each chromatid. (C) Electron micrograph of an anaphase chromatid with microtubules attached to its kinetochore. While most kinetochores have a trilaminar structure, the one shown (from a green alga) has an unusually complex structure with additional layers. (A and B, courtesy of Bill Brinkley; C, from J.D. Pickett-Heaps and L.C. Fowke, *Aust. J. Biol. Sci.* 23:71-92, 1970, reproduced by permission of CSIRO.)
Figure 18-17. The DNA sequence of a typical centromere in the yeast *Saccharomyces cerevisiae*. The DNA sequence shown is both necessary and sufficient to cause faithful chromosome segregation. It serves to assemble the kinetochore proteins that attract a single microtubule (shown in *green*) to the kinetochore.
Figure 18-18. Immunofluorescence staining of kinetochores in cultured cells. The marsupial cells (PtK cells) shown in (A) and (B) contain relatively few chromosomes and are in G_1 phase in (A), where there is one kinetochore stained per chromosome, and in G_2 phase in (B), where there are two kinetochores stained per chromosome. The same auto-antibodies were used to label the kinetochores as were used in Figure 18-16B. A different type of cell, which is in metaphase, is shown in (C); the kinetochores are stained with antibody against a kinetochore protein, and the DNA is stained with a *red* dye. (Courtesy of B. R. Brinkley and D. He.)
Figure 18-19. Capture of kinetochores by microtubules. The kinetochore binds to the side of a growing microtubule and slides along it toward the spindle pole. On the left, the *red arrow* indicates the direction of microtubule growth, while the *gray arrow* indicates the direction of chromosome sliding. On the right is shown a computer-aided three-dimensional reconstruction, from several thin-sections, of a prometaphase chromosome from a newt. This chromosome (*blue*) had just started to move toward the spindle pole after its kinetochore (*orange*) had attached to a single mictotubule (*white*). (From C.L. Rieder and S.P. Alexander, *J. Cell Biol.* 110:81-95, 1990, by copyright permission of the Rockefeller University Press.)
Figure 18-20. Experiment demonstrating that metaphase kinetochore molecules add subunits at their kinetochore-attached (plus) end. In this experiment fluoroscein-labeled tubulin was injected into a living cell, where it became incorporated into the spindle microtubules (*green*). Rhodamine-labeled tubulin was then introduced into the cell at metaphase, where it became incorporated into kinetochore microtubules at the kinetochore-attached (plus) end (*orange*). Some incorporation is also seen at the centrosome. (Courtesy of G. Borisy.)
Figure 18-28. Two alternative models of how the kinetochore may generate a poleward force on its chromosome during anaphase. (A) Microtubule motor proteins are part of the kinetochore and use the energy of ATP hydrolysis to pull the chromosome along its bound microtubules. (B) Chromosome movement is driven by microtubule disassembly: as tubulin subunits dissociate, the kinetochore is obliged to slide poleward in order to maintain its binding to the walls of the microtubule.
Figure 18-21. Demonstration of the astral exclusion force. In this experiment prometaphase chromosomes that are temporarily attached to a single pole by kinetochore microtubules are cut in half with a laser beam. The half that is freed from the kinetochore is pushed rapidly away from the pole, whereas the half that remains attached to the kinetochore moves toward the pole, reflecting a decreased repulsion.

(A) "PULL" pulling force proportional
to length of kinetochore microtubules

(B) "PUSH" astral exclusion force decreases
with distance from pole
Figure 18-22. Two hypotheses for how chromosomes line up at the metaphase plate. In both cases the chromosomes enter the spindle randomly during prometaphase. In (A) the chromosomes eventually line up at the equator (the metaphase plate) because a *pulling* force on each kinetochore increases as it gets farther from a pole. In (B) the chromosomes end up at the equator because the astral exclusion forces *push* them there. In both cases the chromosomes are held under tension at the equator by balanced forces.

Figure 18-23. The dynamic behavior of microtubules in the metaphase spindle studied by photoactivation of fluorescence. A metaphase spindle formed *in vitro* from an extract of *Xenopus* eggs has incorporated three fluorescent markers: rhodamine-labeled tubulin (*red*) to mark all of the microtubules, a *blue* DNA-binding dye that labels the chromosomes, and caged-fluorescein-labeled tubulin, which is also incorporated into all of the microtubules but is invisible because it is

nonfluorescent until activated by ultraviolet light. The distribution of the chromosomes and microtubules in the spindle is shown in (A). In (B) a beam of ultraviolet light is used to uncage the caged-fluorescein-labeled tubulin locally, mainly just to the left side of the metaphase plate. Over the next few minutes (after 1 $^1/2$ minutes in C, after $2^1/2$ minutes in D) the uncaged fluorescein-tubulin signal is seen to move toward the left spindle pole, indicating that tubulin is continuously moving poleward even though the spindle (visualized by the *red* rhodamine-tubulin fluorescence) remains largely unchanged. The caged fluorescein signal also diminishes in intensity, indicating that the individual microtubules are continually depolymerizing and being replaced. (From K.E. Sawin and T.J. Mitchison, *J. Cell Biol.* 112:941-954, 1991, by copyright permission of the Rockefeller University Press.)
Figure 18-24. Simplified diagram of the mitotic spindle at metaphase. The spindle is constructed from two half-spindles (*green* and *orange*), each composed of kinetochore, polar, and astral microtubules. The polarity of the microtubules is indicated by the arrowheads, which point toward the plus end. The polar microtubules emanating from opposite spindle poles have a region of overlap (*shaded gray*), where microtubule-associated proteins may cross-link them. Note that the microtubules are antiparallel in the overlap zone.
Figure 18-25. The behavior of kinetochore microtubules at metaphase and anaphase. (A) During metaphase, subunits are added to the plus end of a microtubule at the kinetochore and are removed from the minus end at the spindle pole. Thus a

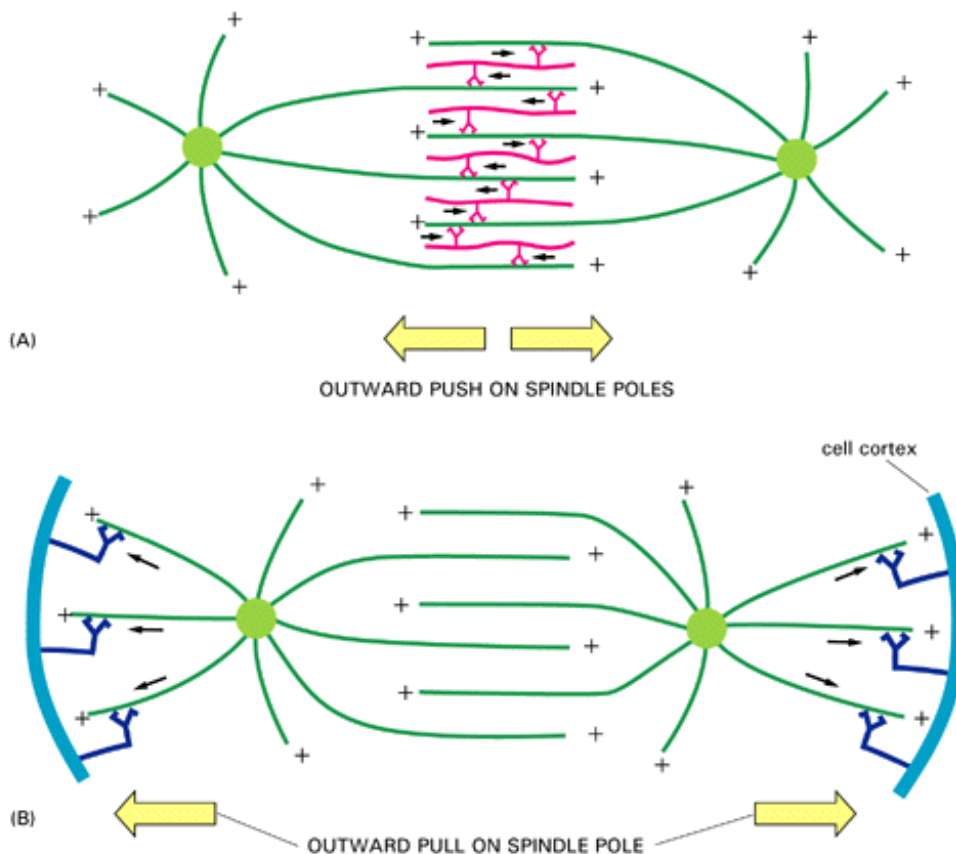
constant poleward flux of tubulin subunits occurs, while the microtubules maintain a constant length and remain under tension. (B) At anaphase the chromatid is released from attachment to its sister at the metaphase plate and the kinetochore moves rapidly up the microtubule, removing subunits from its plus end as it goes. Its attached chromatid is thereby carried to the spindle pole. Part of the chromatid movement is due to the simultaneous loss of tubulin subunits from the minus end of the microtubules at the pole.
Figure 18-26. Chromatid separation at anaphase. In the transition from metaphase (A) to anaphase (B), sister chromatids are pulled apart by spindle microtubules - as seen in these *Haemanthus* (lily) endosperm cells stained with gold-labeled antibodies to tubulin. (Courtesy of Andrew Bajer.)
Figure 18-27. The two processes that separate sister chromatids at anaphase. In *anaphase A* the chromatids are *pulled* toward opposite poles by forces associated with shortening of their kinetochore microtubules. The force driving this movement is thought to be generated mainly at the kinetochore. In *anaphase B* the two spindle poles move apart. It is likely that the forces driving anaphase B are similar to those that cause the centrosome to split and separate into two spindle poles at prophase (see Figure 18-5). There is evidence that two separate forces are responsible for anaphase B: the elongation and sliding of the polar microtubules past one another *pushes* the two poles apart, and outward forces exerted by the astral microtubules at each spindle pole act to *pull* the poles away from each other, toward the cell surface.
Figure 18-29. Sliding of overlap microtubules at anaphase. Electron micrographs showing spindle elongation and the reduction in the degree of polar microtubule overlap during mitosis in a diatom. (A) Metaphase. (B) Late anaphase. (Courtesy of Jeremy D. Pickett-Heaps.)


Figure 18-30. Model of how microtubule motor proteins are thought to act in anaphase B. In (A) plus-end-directed motor proteins of the kinesin family cross-link adjacent, overlapping, antiparallel polar microtubules and slide the microtubules past each other, thereby *pushing* the spindle poles apart. The *black arrows* indicate the direction of microtubule sliding. In (B) minus-end-directed motor proteins bind to the cell cortex and to those astral microtubules that point away from the spindle and *pull* the spindle poles apart.

Cytokinesis 21

Introduction

During cytokinesis the cytoplasm divides by a process called *cleavage*. Although nuclear and cytoplasmic division are generally linked, they are separable events, and in some normal circumstances, nuclear division is not followed by cytokinesis. The early *Drosophila* embryo, for example, undergoes 13 rounds of nuclear division without cytoplasmic division, forming a single large cell containing 6000 nuclei arranged in a monolayer near the surface. Uninucleated cells are then generated by cytoplasmic cleavage around all of these nuclei (see Figure21-51). In a typical cell, however, cytokinesis accompanies every mitosis, beginning in anaphase, continuing in telophase, and reaching completion as the following interphase begins.

The Mitotic Spindle Determines the Site of Cytoplasmic Cleavage During Cytokinesis 22

Normally, the mitotic spindle determines where cleavage occurs as well as when. The first visible sign of cleavage in animal cells is a puckering and *furrowing* of the plasma membrane during anaphase (Figure18-31). The furrowing invariably occurs in the plane of the metaphase plate, at right angles to the long axis of the mitotic spindle. This ensures that the cleavage furrow cuts between the two groups of separating chromatids and thus that the two daughter cells receive identical copies of the genetic material. If the spindle is moved by micromanipulation early enough in anaphase, the incipient furrow disappears and a new one develops in accord with the new spindle site. Ingenious experiments with fertilized sand dollar eggs show that a cleavage furrow will form midway between the asters originating from two centrosomes even when the centrosomes are not connected by a mitotic spindle (Figure 18-32). Thus, the microtubule asters, and not the chromosomes, signal to the cortex to initiate a furrow. Later, once the furrowing process is well underway, cleavage proceeds even if the spindle and its asters are removed by suction or destroyed by colchicine.

The mechanism by which a pair of microtubule asters signals the site of cleavage at the cortex is not known, but it is a classic example of communication between the microtubule and actin filament systems of the cytoskeleton. One hypothesis is that the two sets of astral microtubules contact the cell cortex and set the future cleavage site, possibly by moving actin filaments. Another is that the cortex senses a gradient of Ca^{2+}, which is set up by Ca^{2+}-sequestering vesicles that are known to be present at the spindle poles. Whatever the signal, it is clear that the cortex is poised to detect and amplify it. The whole cortex is under tension (see Figure 16-80), and if this tension is locally increased at the site of furrow initiation or decreased at the poles, actin filaments will locally align and new filaments will be drawn in, along with myosin-II, from the surrounding cortex. Thus, the furrow may be a self-amplifying system, which self-organizes on the basis of a subtle initial cue.

The Spindle Is Specifically Repositioned to Create Asymmetric Cell Divisions 23

Most cells divide symmetrically. The cleavage furrow forms around the equator of the parent cell, so that the two daughter cells produced are of equal size and have similar properties. This cleavage symmetry results from the prior placement of the spindle, which tends to center itself in the cytoplasm, with the spindle axis lined up along a particular axis of the cell. This position is thought to be established by pulling forces exerted on astral microtubules by minus-end-directed motor proteins in the cytoplasm (see Figure18-30B).

There are many instances during embryonic development, however, in which cells divide asymmetrically. In these cases the furrow creates two cells that are different in size and are destined to develop along divergent paths. Divisions of this kind are often precisely defined spatially. They may bear a precise relationship to the surface of an epithelial sheet, for example, or segregate regions of cytoplasm that have a different complement of organelles. Asymmetric positioning of the furrow is always anticipated by asymmetric positioning of the mitotic spindle. To orient the plane of division, the spindle rotates in a controlled manner to adopt a suitable position in the cell. It seems likely that these spindle movements are directed by programmed changes in local regions of the cell cortex and that the cortex then moves the spindle poles via their astral microtubules (Figure 18-33). A similar mechanism is thought to position the centrosome in a polarized cell (see p. 792).

Asymmetric cell division is particularly important in plant cells, since these cells cannot move after division, so that division planes alone determine tissue morphology. Plants use a different mechanism for establishing their cleavage plane, as we discuss later.

Actin and Myosin Generate the Forces for Cleavage [24]

Cleavage is accomplished by the contraction of a thin ring composed mainly of an overlapping array of actin filaments and bipolar myosin-II filaments. This contractile ring defines the cleavage furrow. It consists of circumferentially oriented filaments bound to the cytoplasmic face of the plasma membrane by uncharacterized attachment proteins (Figure18-34). The contractile ring assembles in early anaphase. Once assembled, it develops a force large enough to bend a fine glass needle inserted into the cell. There is compelling evidence that musclelike sliding of actin and myosin filaments in the contractile ring generates this force. In lysed mitotic cells, for example, cleavage is stopped by the addition of an inactivated myosin subfragment that blocks sites on actin that normally bind myosin. Similarly, an injection of antimyosin antibodies into fertilized sea urchin eggs causes the cleavage furrow to relax without affecting nuclear division.

At each point on its circumference, the contractile ring contains a bundle of about 20 actin filaments. During a normal cell division the ring does not get thicker as the furrow invaginates, suggesting that it continuously reduces its volume by losing filaments. Thus, like other cytoskeletal structures and unlike skeletal muscle, the furrow is dynamic. The contractile ring is finally dispensed with altogether when cleavage ends, as the plasma membrane of the cleavage furrow narrows to form the midbody, which remains as a tether between the two daughter cells. The midbody contains the remains of the two sets of polar microtubules packed tightly together with a dense matrix material (Figure18-35).

The process of cytokinesis requires wholesale reorganization of actin and myosin filaments in the cortex to allow the assembly of the contractile ring. Other functions of the cortex, most notably cell adhesion, are also affected in M phase. Tissue culture cells that are spread out in interphase due to strong adhesive contacts with extracellular matrix molecules on the substratum, for example, round up when they enter M phase; following cytokinesis the daughter cells flatten out again. It is thought that the activities of transmembrane adhesion proteins such as the integrins (discussed in Chapter 19) are in some way down-regulated during M phase or that the attachment proteins that connect these proteins to actin filaments in the cortex are modified. Like other manifestations of M phase, these changes are presumably mediated by protein phosphorylation.

In Special Cases, Selected Cell Components Can Be Segregated to One Daughter Cell Only [25]

Whereas most cell divisions produce two similar daughter cells, some produce daughter cells that are manifestly unequal. This is especially true of the initial cleavages in which a large fertilized egg is subdivided into smaller cells destined to form different parts of the body. We have already discussed how the asymmetric positioning of the spindle during cell division can produce two cells of unequal size, but the genesis of biochemically different daughter cells is a special problem.

A striking example of this process is provided by the behavior of a set of distinctive granules in the egg of the nematode worm *C. elegans*. These "P-granules" are spread evenly throughout the cytoplasm of the unfertilized egg, but they move to the posterior end of the cell just before the first cleavage and are therefore inherited by only one of the two daughter cells. The same type of segregation process is repeated in several subsequent cell divisions, so that the granules end up in only the primordial germ cells, which give rise to the eggs and sperm (Figure 18-36). It is possible that the granules play a part in controlling the distinctive fate of these cells.

The P-granules will still move to the posterior end of the cell even in mutants where the mitotic spindle is disoriented and turned at right angles to its normal position. Moreover, segregation of the granules is blocked by the drug cytochalasin D, which inhibits actin-filament polymerization, but not by colchicine, suggesting that the oriented movement of P-granules is dependent on actin filaments but not on microtubules. Although the unequal segregation of these components thus seems to be based on some asymmetric property of the actin-based cytoskeleton, the molecular mechanism for their oriented movement is unknown.

Cytokinesis Occurs by a Special Mechanism in Higher Plant Cells [26]

Most higher plant cells are enclosed by a rigid *cell wall,* and the mechanism of cytokinesis in these cells is different from the one we have just described for animal cells. Rather than pinching off the two daughter cells by means of a contractile ring at the cell surface, the cytoplasm of the plant cell is partitioned by the construction of a new cell wall inside the cell (Figure18-37). This cross-wall precisely determines the positions of the two daughter cells relative to neighboring cells. It follows that the planes of cell division, together with cell enlargement, determine plant form.

The new cross-wall, or cell plate, starts to assemble in a plane between the two daughter nuclei and in association with the residual polar spindle microtubules, which form a cylindrical structure called the phragmoplast. The phragmoplast,

corresponding to the microtubules in the animal cell midbody, contains two sets of microtubules that interdigitate at their growing (plus) ends (Figure18-38). The microtubules have their plus ends embedded in an electron dense disc in the equatorial plane. As outlined in Figure18-39, small membrane-bounded vesicles, largely derived from the Golgi apparatus and filled with cell-wall precursors, seem to contact the microtubules on each side of the phragmoplast and to be transported along them until they reach the equatorial region. Here they fuse to form a disclike membrane-bounded structure, the *early cell plate*. The polysaccharide molecules delivered by these vesicles assemble within the early cell plate to form the matrix material of the primary cell wall. This disc now has to expand laterally to reach the original parent cell wall. To make this possible the microtubules of the early phragmoplast are continuously reorganized at the periphery of the early cell plate. There they attract more vesicles, which fuse at the equator to extend the edge of the plate. This process is repeated until the growing cell plate reaches the plasma membrane of the parent cell. The plasma membrane and the membrane surrounding the cell plate fuse, completely separating the two new daughter cells (see Figure 18-37). Actin filaments are also abundant in the phragmoplast, aligned with the microtubules, but their functional role in cell plate formation is unclear. Sometime later, cellulose microfibrils are laid down within the cell plate to complete the new cell wall.

A Cytoskeletal Framework Determines the Plane of Plant Cell Division 27

The mitotic spindle by itself is generally not sufficient to determine the exact position and shape of the cell plate. The plate's future site of junction with the mother cell wall seems to be defined at some point in G_2, before mitosis has begun. Thus, the first visible sign that a higher plant cell has become committed to divide in a particular plane is seen just after the interphase cortical array of microtubules disappears in preparation for mitosis. At this time a circumferential band of microtubules appears and forms a ring around the entire cell just beneath the plasma membrane. Because this array of microtubules appears in G_2 before prophase begins, it is called the preprophase band (see Figure 18-39). The band becomes narrower as the cell progresses to prophase, and it disappears before metaphase is reached, yet the boundary of the division plane has somehow been imprinted: when the new cell plate forms later during cytokinesis, it grows outward to fuse with the parental wall precisely at the zone that was formerly occupied by the preprophase band (see Figure18-39). Even if the cell contents are displaced by centrifugation after the preprophase band has disappeared, the growing cell plate will tend to find its way back to the plane defined by the former preprophase band.

It is now known that the preprophase band contains numerous actin filaments in addition to microtubules. The actin filaments are not confined to the cell cortex; in vacuolated cells they also form a radial, disclike array of strands, which crosses the cell and connects to and supports the central dividing nucleus. After the microtubules in the preprophase band depolymerize, the radial actin strands remain and provide a "memory" of the predetermined division plane. During cytokinesis, as the phragmoplast grows out centrifugally like a circular ripple in a pond, the edges of the growing cell plate are connected to the site of the preprophase band by actin filaments. Thus, actin seems to have an important function in the division of walled cells even though contraction plays no obvious part. Actin is also associated with septum formation in fungal cells, which suggests that it may help guide cytokinesis in all eucaryotes.

The Elaborate M Phase of Higher Organisms Evolved Gradually from Procaryotic Fission Mechanisms 28

In procaryotic cells, division of the DNA and of the cytoplasm are coupled in a very direct way. When DNA replicates, the two copies of the chromosome are attached to specialized regions of the plasma membrane, which are thought to be separated gradually by the growth of the membrane between them. Fission takes place between the two attachment sites, so that each daughter cell captures one chromosome (Figure 18-40). With the evolution of the eucaryotes, the genome increased in complexity and the chromosomes increased in number and in size. For these organisms a more elaborate mechanism for dividing the chromosomes between daughter cells was apparently required.

Clearly, the mitotic apparatus could not have evolved all at once. In many primitive eucaryotes, such as the dinoflagellate *Cryphthecodinium cohnii*, mitosis still depends on a membrane-attachment mechanism, with the nuclear membrane taking over the part played by the plasma membrane in procaryotes. The intermediate status of this large single-celled alga is also reflected in the biochemistry of its chromosomes, which, like those of procaryotes, have relatively little associated protein. The nuclear membrane in *C. cohnii* remains intact throughout mitosis, and the spindle microtubules remain entirely outside the nucleus. Where these spindle microtubules press on the outside of the nuclear envelope, the envelope becomes indented in a series of parallel channels (see Figure18-40). The chromosomes become attached to the inner membrane of the nuclear envelope opposite these channels, and the separation of the chromosomes is entirely mediated on the inside of this channeled nuclear membrane. Thus the extranuclear "spindle" is used to order the nuclear membrane and thereby define the plane of division. Kinetochores in these species seem to be integrated into the nuclear membrane and may therefore have evolved from some membrane

component. The evolutionary origin of microtubules themselves is mysterious. They are important for chromosome segregation in even the most primitive eucaryotes, but they are also present in flagellar axonemes (see p. 816). Whether the flagellum or the spindle came first is unclear.

A somewhat more advanced, although still extranuclear, spindle is seen in *hypermastigotes,* in which the nuclear envelope again remains intact throughout mitosis. These large protozoa from the guts of insects provide a particularly clear illustration of the independence of spindle elongation and the chromosome movements that separate the chromatids, since the sister kinetochores become separated by the growth of the nuclear membrane (to which they are attached) before becoming attached to the spindle. Only when the kinetochores are near the poles of the spindle do they acquire the kinetochore fibers needed to attach them to the spindle. Because the spindle fibers remain separated from the chromosomes by the nuclear envelope, the kinetochore fibers, which are formed outside the nucleus, must somehow attach to the chromosomes through the nuclear membranes. After this attachment has occurred, the kinetochores are drawn poleward in a conventional manner (see Figure18-40).

A further stage in the evolution of mitotic mechanisms may be represented by organisms that form spindles inside an intact nucleus. In both yeasts and diatoms the spindle is attached to chromosomes by their kinetochores and the chromosomes are segregated in a way closely similar to that described for mammalian cells - except that the entire process generally occurs within the confines of the nuclear envelope (see Figure18-40). It is thought that the "open" mitosis of higher organisms and the "closed" mitosis of yeasts and diatoms evolved separately from a common ancestor resembling the modern hypermastigote spindle.

At present, there is no convincing explanation for why higher plants and animals have evolved a mitotic apparatus that requires the controlled and reversible dissolution of the nuclear envelope.

Summary

Cell division ends as the cytoplasmic contents are divided by the process of cytokinesis and the chromosomes decondense and resume RNA synthesis. Cytokinesis appears to be guided by organized bundles of actin filaments in eucaryotic cells as diverse as animals, plants, and fungi. In animal cells the mitotic spindle determines when and where cytokinesis occurs, with the contractile ring of actin and myosin filaments forming midway between the spindle pole asters. Whereas most cells divide symmetrically, in some cases the spindle is specifically positioned to create an asymmetric cell division: a particular cell can divide into one small cell and one large one, for example, or a specific cytoplasmic component can be moved to one side of a cell prior to cytokinesis so that it is inherited by only one of the two otherwise equal daughter cells. Cytokinesis occurs by a special mechanism in higher plant cells, where the cytoplasm is partitioned by the construction of a new cell wall, the cell plate, inside the cell. The position of the cell plate is determined by the position of a preprophase band of microtubules and actin filaments. The organization of mitosis in some protozoa and in fungi differs from that in animals and plants, suggesting how the complex process of eucaryotic cell division may have evolved.

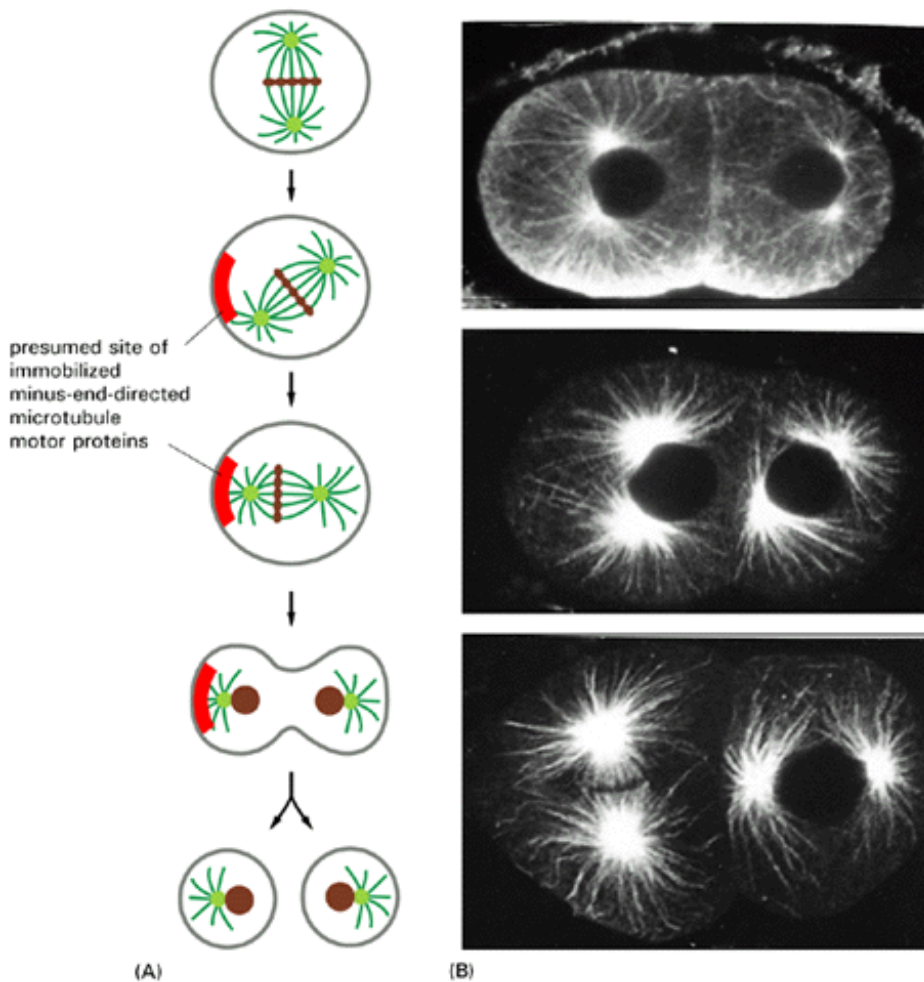
Figure 18-31. Scanning electron micrographs of early cleavage in a fertilized frog egg. The furrowing of the cell membrane is caused by the activity of the *contractile ring*underneath it. The cleavage furrow is unusually obvious and well defined in this giant spherical cell. (A) Low-magnification view of egg surface. (B) Surface of furrow at higher mag-nification. (From H.W. Beams and R.G. Kessel, *Am. Sci.* 64:279-290, 1976. Reprinted by permission of *American Scientist*, journal of Sigma Xi.)
Figure 18-32. An experiment that shows the influence of the position of microtubule asters on the subsequent plane of cleavage. If a mitotic spindle is mechanically pushed to one side of the cell, the membrane furrowing is incomplete, failing to occur on the opposite side of the cell. Subsequent cleavages occur not only in the conventional relation to each of the two subsequent mitotic spindles (*yellow arrowheads*) but also between the two adjacent asters that are not linked by a mitotic spindle (but in this abnormal cell share the same cytoplasm)(*red arrowhead*). Apparently, the contractile bundle of actin filaments that produces the cleavage furrow always forms in the region midway between two asters, which implies that the asters somehow alter the adjacent region of cell cortex.


Figure 18-33. Spindle rotation. (A) Diagram showing a possible mechanism underlying the controlled rotation of a mitotic spindle. The *red bar* represents a specialized region of cortex toward which one spindle pole is pulled by its astral microtubules. (B) Light micrographs showing a precisely programmed rotation of a mitotic spindle in an embryo of the nematode worm *C. elegans* at the two-cell stage in preparation for cleavage to form four cells in a specific pattern. The spindle in the cell on the right rotates almost 90° clockwise. (Courtesy of Tony Hyman and John White.)

Figure 18-34. The contractile ring. (A) A schematic drawing of a cleavage furrow in a dividing cell. (B) Electron micrograph of the ingrowing edge of the cleavage furrow of a dividing animal cell. (C) A dividing slime mold amoeba stained for actin (*red*) and myosin-II (*green*). The myosin staining in the contractile ring somewhat masks the actin that is also present there. (B, from H.W. Beams and R.G. Kessel, *Am. Sci.* 64:279-290, 1976, reprinted by permission of *American Scientist*, journal of Sigma Xi; C, courtesy of Yoshio Fukui.)
Figure 18-35. Cytokinesis. (A) Scanning electron micrograph of an animal cell in culture in the process of dividing; the midbody still joins the two daughter cells. (B) Electron micrograph of the midbody of a dividing animal cell. Cleavage is virtually complete, but the daughter cells remain attached by this thin strand of cytoplasm. (A, courtesy of Guenter Albrecht-Buehler; B, courtesy of J.M. Mullins.)
Figure 18-36. Asymmetric segregation. These micrographs illustrate the controlled asymmetric segregation of a cytoplasmic component to one daughter cell during each of the first few cell divisions of a fertilized egg of the nematode *C. elegans*. Above are cells viewed by differential-interference-contrast light microscopy and stained with a *blue* DNA-specific fluorescent dye to show cell nuclei; below are the same cells stained with an antibody against P-granules. These small granules of unknown function (0.5-1 microns in diameter) are distributed randomly throughout the cytoplasm in the unfertilized egg. (Courtesy of Susan Strome.)
Figure 18-37. Sequential light micrographs of a dividing plant cell. The elapsed time in minutes is shown at the bottom left corner of each photograph. The vesicles that align to form the cell plate can be seen after 42 minutes. The plate then extends sideways until it reaches and fuses with the mother cell wall. (Courtesy of Peter Hepler.)
Figure 18-38. Light micrograph of cytokinesis in a plant cell in telophase. The early cell plate (between the two *arrows*) is forming in a plane perpendicular to the plane of the page. The two arrays of microtubules that contribute to the phragmoplast are stained using gold-labeled antibodies to tubulin, while the DNA in the two sets of daughter chromosomes is stained with a fluorescent dye. (Courtesy of Andrew Bajer.)

G₂
Golgi apparatus
mother cell wall

At some point in G₂ the cortical microtubules rearrange to form a band that encircles the cell, just below the plasma membrane. This preprophase band of microtubules gradually narrows and exactly predicts where the new cell wall will join the mother cell wall when the cell divides.

preprophase band of microtubules

telophase

Phragmoplast is formed by two sets of polar spindle microtubules at telophase. Golgi-derived vesicles carrying cell wall precursors associate with microtubules, accumulate in the equatorial region, and fuse to form the early cell plate.

Golgi-derived vesicles
remains of polar spindle microtubules

cytokinesis

Phragmoplast microtubules re-form at the periphery of the early cell plate. New Golgi-derived vesicles are recruited into this region, fuse with edge of the cell plate, and extend it outward.

early cell plate
phragmoplast microtubules

G₁

The membrane of the extending cell plate fuses with the plasma membrane of the mother cell, completing the new cell wall. The cortical array of interphase microtubules is reestablished in each of the two daughter cells.

IV. Cells in Their Social Context

➜

19. Cell Junctions, Cell Adhesion, and the Extracellular Matrix

➜ ➜

Introduction

Most of the cells in multicellular organisms are organized into cooperative assemblies called *tissues,* which in turn are associated in various combinations to form larger functional units called *organs*. The cells in tissues are usually in contact with a complex network of secreted extracellular macromolecules referred to as the *extracellular matrix.* This matrix helps to hold cells and tissues together, and in animals it provides an organized lattice within which cells can migrate and interact with one another. In many cases the cells in a tissue are also held in place by direct cell-cell adhesions.

In vertebrates the major types of tissues are *nerve, muscle, blood, lymphoid, epithelial,*and *connective tissues.* Connective tissues and epithelial tissues represent two extremes in which the structural roles played by the matrix and by cell-cell adhesions are radically different (Figure 19-1). In connective tissues (discussed in Chapter 22) extracellular matrix is plentiful and cells are sparsely distributed within it. The matrix is rich in fibrous polymers, especially collagen, and it is the matrix - rather than the cells - that bears most of the mechanical stress to which the tissue is subjected. The cells are attached to components of the matrix, on which they may exert force, but direct attachments between one cell and another are relatively unimportant. In epithelial tissues, by contrast, cells are tightly bound together into sheets (called *epithelia*). Extracellular matrix is scanty and consists mainly of a thin mat called the *basal lamina,* which underlies the cellular sheet; most of the volume is occupied by cells. Here the cells themselves, rather than the matrix, bear most of the mechanical stresses, by means of strong intracellular protein filaments (components of the cytoskeleton) that criss-cross the cytoplasm of each epithelial cell; to transmit mechanical stress from one cell to the next, the filaments are directly or indirectly attached to transmembrane proteins in the plasma membrane, where specialized junctions are formed between the surfaces of adjacent cells and with the underlying basal lamina.

Epithelial cell sheets line all the cavities and free surfaces of the body, and the specialized junctions between the cells enable these sheets to form barriers to the movement of water, solutes, and cells from one body compartment to another. As illustrated in Figure 19-1, epithelial sheets almost always rest on a supporting bed of connective tissue, which may attach them to other tissues (such as muscle) that do not themselves have either strictly epithelial or strictly connective-tissue organization.

In this chapter we first discuss the structure and function of specialized cell-cell and cell-matrix junctions (collectively called *cell junctions*). We then consider how animal cells recognize one another and initiate the formation of cell junctions in the

process of assembling into tissues and organs. Finally, we discuss the structure and organization of the extracellular matrix in animals and of the cell wall in plants.
Figure 19-1. Simplified drawing of a cross-section through part of the wall of the intestine. This long, tubelike organ is constructed from epithelial tissues (*red*), connective tissues (*green*), and muscle tissues (*yellow*). Each tissue is an organized assembly of cells held together by cell-cell adhesions, extracellular matrix, or both.

➜ ➜

Cell Junctions 1

Introduction

Specialized cell junctions occur at many points of cell-cell and cell-matrix contact in all tissues, but they are particularly important and plentiful in epithelia. Most of these junctions are too small to be resolved by light microscopy. They can be visualized, however, using either conventional or freeze-fracture electron microscopy, both of which show that the interacting plasma membranes (and often the underlying cytoplasm and the intervening intercellular space as well) are highly specialized in these regions. Cell junctions can be classified into three functional groups: (1) occluding junctions, which can seal cells together in an epithelial cell sheet in a way that prevents even small molecules from leaking from one side of the sheet to the other; (2) anchoring junctions, which mechanically attach cells (and their cytoskeletons) to their neighbors or to the extracellular matrix; and (3) communicating junctions, which mediate the passage of chemical or electrical signals from one interacting cell to its partner.

The major kinds of intercellular junctions within each class are listed in Table 19-1. We shall discuss each of them in turn, except for chemical synapses, which are formed exclusively by nerve cells and are discussed in Chapters 11 and 15.

Tight Junctions Form a Selective Permeability Barrier Across Epithelial Cell Sheets 2

Despite the many structural and biochemical differences among various types of epithelia, all have at least one important function in common: they serve as selective permeability barriers, separating fluids on each side that have different chemical compositions. Tight junctions play two distinct roles in this selective-barrier function, as we shall illustrate by considering the epithelium of the mammalian small intestine, or gut.

The epithelial cells lining the small intestine keep most of the gut contents in the inner cavity (the lumen). At the same time, however, the cells must transport selected nutrients across the cell sheet from the lumen into the extracellular fluid permeating the connective tissue on the other side (see Figure 19-1), from where the nutrients diffuse into small blood vessels. This *transcellular transport* depends on two sets of membrane-bound carrier proteins: one is confined to the *apical surface* of the epithelial cell (the surface facing the lumen) and actively transports selected molecules into the cell from the lumen of the gut; the other, which is confined to the *basolateral* (basal and lateral) *surface,* allows the same molecules to leave the cell by

facilitated diffusion into the extracellular fluid on the other side. If this directional transport is to be maintained, the apical set of carrier proteins must not be allowed to migrate to the basolateral surface of the cell, and the basolateral set must not be allowed to migrate to the apical surface. Furthermore, the spaces between epithelial cells must be sealed so that the transported molecules cannot diffuse back into the gut lumen through the intercellular space (Figure 19-2).

The tight junctions between the epithelial cells are thought to block both these kinds of diffusion. First, they function as barriers to the diffusion of membrane proteins between apical and basolateral domains of the plasma membrane (see Figure 19-2). This undesirable diffusion of membrane constituents occurs if tight junctions are disrupted, for example, by removing the extracellular Ca^{2+} required for tight-junction integrity. Second, they seal neighboring cells together so that water-soluble molecules cannot leak between the cells: if a low-molecular-weight tracer is added to one side of an epithelial cell sheet, it will usually not pass beyond the tight junction (Figure 19-3). The seal is not absolute or invariable, however. Although all tight junctions are impermeable to macromolecules, their permeability to small molecules varies greatly in different epithelia. Tight junctions in the epithelium lining the small intestine, for example, are 10,000 times more leaky to inorganic ions such as Na^+ than those in the epithelium lining the urinary bladder. Epithelial cells can transiently alter their tight junctions in order to permit an increased flow of solutes and water through breaches in the junctional barriers. This pathway (called *paracellular transport*) is especially important in the absorption of amino acids and monosaccharides from the lumen of the intestine (where their concentration is sometimes high enough to drive passive transport in the desired direction).

The molecular structure of tight junctions is still uncertain, but freeze-fracture electron microscopy shows them to be composed of an anastomosing network of strands that completely encircles the apical end of each cell in the epithelial sheet (Figure 19-4A and B). In conventional electron micrographs they are seen as a series of focal connections between the outer leaflets of the two interacting plasma membranes (Figure 19-4C).The ability of tight junctions to restrict the passage of ions through the spaces between cells increases logarithmically with increasing numbers of strands in the network, as if each strand acts as an independent barrier. The strands are thought to be composed of long rows of specific transmembrane proteins in each of the two interacting plasma membranes, which join directly to each other to occlude the intercellular space (Figure 19-5).

Anchoring Junctions Connect the Cytoskeleton of a Cell to Those of Its Neighbors or to the Extracellular Matrix

Anchoring junctions are widely distributed in animal tissues. They enable groups of cells, such as those in an epithelium, to function as robust structural units by connecting the cytoskeletal elements of a cell either to those of another cell or to the extracellular matrix (Figure 19-6). They are most abundant in tissues that are subjected to severe mechanical stress, such as heart muscle and skin epithelium (epidermis). They occur in three structurally and functionally different forms: (1) *adherens junctions,* (2) *desmosomes,* and (3) *hemidesmosomes.* Adherens junctions are connection sites for actin filaments; desmosomes and hemidesmosomes are connection sites for intermediate filaments (see Table 19-1).

Before we discuss the different classes of anchoring junctions, it is worth considering briefly the general principles of their construction. As illustrated in Figure 19-7, these junctions are composed of two classes of proteins: (1) *intracellular attachment proteins,* which form a distinct *plaque* on the cytoplasmic face of the plasma membrane and connect the junctional complex to either actin filaments or intermediate filaments; and (2) *transmembrane linker proteins,* whose cytoplasmic domains bind to one or more intracellular attachment proteins, while their extracellular domains interact either with the extracellular matrix or with the extracellular domains of transmembrane linker proteins on another cell.

Much less is known about *septate junctions,* which are unique to invertebrates. They are probably best classified as anchoring junctions, for they act as connection sites for actin filaments; but it has been suggested that they can function as permeability barriers in some cases.

Adherens Junctions Connect Bundles of Actin Filaments from Cell to Cell or from Cell to Extracellular Matrix 3

Cell-cell adherens junctions occur in various forms. In many nonepithelial tissues they take the form of small punctate or streaklike attachments that connect actin filaments in the cortical cytoplasm of adjacent cells. In epithelial sheets they often form a continuous adhesion belt (or *zonula adherens*) around each of the interacting cells in the sheet, located near the apex of each cell just below the tight junction. The adhesion belts in adjacent epithelial cells are directly apposed, and the interacting plasma membranes are held together by transmembrane linker proteins that are members of a large family of Ca^{2+}-dependent cell-cell adhesion molecules called *cadherins,* which we discuss later. At one time an adhesion belt was called a belt desmosome, a misleading name because the adhesion belt is chemically and functionally very different from a real desmosome.

Within each cell a contractile bundle of actin filaments lies adjacent to the adhesion belt, running parallel to the plasma membrane, to which it is attached through a set of intracellular attachment proteins that includes α-, β-,and γ-*catenin* (discussed later), *vinculin,* α-*actinin,*and *plakoglobin*. The actin bundles in adjacent cells are thus linked, via the cadherins and attachment proteins, into an extensive transcellular network (Figure 19-8). The contraction of this network, which depends on myosin motor proteins, is thought to help mediate a fundamental process in animal morphogenesis - the folding of epithelial cell sheets into tubes and other related structures (Figure 19-9).

Cell-matrix adherens junctions enable cells to get a hold on the extracellular matrix by connecting their actin filaments to the matrix. Cultured fibroblasts migrating on an artificial substratum coated with extracellular matrix molecules, for example, grip the substratum at specialized regions of the plasma membrane called focal contacts, or *adhesion plaques,* where bundles of actin filaments terminate. Many cells in tissues make analogous focal contacts with the surrounding extracellular matrix. The transmembrane linker proteins that mediate these adhesions and serve as links between the matrix and the actin filament bundles in these plaques are members of a large family of cell-surface matrix receptors called *integrins,* which we discuss later. The extracellular domain of the integrin at a focal contact binds to a protein component of the extracellular matrix, while its intracellular domain binds indirectly to bundles of actin filaments via a complex of attachment proteins, including *talin,* α-actinin, and vinculin (Figure 19-10).

Septate junctions are widespread in invertebrate tissues. They share a number of features with adhesion belts, with which they sometimes coexist: (1) they form a continuous band around the apical borders of epithelial cells, (2) they are thought to help hold cells together, and (3) they serve as sites of attachment for actin filaments. They have a highly distinctive morphology, for the interacting plasma membranes are joined by poorly characterized junctional proteins that are arranged in parallel rows with a regular periodicity (Figure 19-11).

Desmosomes Connect Intermediate Filaments from Cell to Cell; Hemidesmosomes Connect Them to the Basal Lamina 4

Desmosomes and *hemidesmosomes* act as rivets to distribute tensile or shearing forces through an epithelium and its underlying connective tissue.

Desmosomes are buttonlike points of intercellular contact that rivet cells together (Figure 19-12A). Inside the cell they serve as anchoring sites for ropelike intermediate filaments, which form a structural framework for the cytoplasm of great tensile strength (Figure 19-12B). Thus, through desmosomes, the intermediate filaments of adjacent cells are connected indirectly to form a continuous network throughout the tissue. The particular type of intermediate filaments attached to the desmosomes depends on the cell type: they are *keratin filaments* in most epithelial cells, for example, and *desmin filaments* in heart muscle cells.

The general structure of a desmosome is illustrated in Figure 19-12C. It has a dense cytoplasmic plaque composed of a complex of intracellular attachment proteins responsible for connecting the cytoskeleton to the transmembrane linker proteins, which interact through their extracellular domains to hold the adjacent plasma membranes together. As in adhesion belts, the transmembrane linker proteins belong to the cadherin family of Ca^{2+}-dependent cell-cell adhesion molecules. The importance of desmosomes in holding cells together is demonstrated by some forms of the potentially fatal skin disease *pemphigus,* in which individuals make antibodies against one of their own desmosomal cadherin proteins; these antibodies bind to and disrupt desmosomes between skin epithelial cells (keratinocytes), causing severe blistering as a result of the leakage of body fluids into the loosened epithelium. The antibodies disrupt desmosomes only in skin, suggesting that these desmosomes are biochemically different from those in other tissues.

Hemidesmosomes, or half-desmosomes, resemble desmosomes morphologically but are both functionally and chemically distinct. Instead of joining adjacent epithelial cell membranes, they connect the basal surface of epithelial cells to the underlying *basal lamina*- a specialized mat of extracellular matrix at the interface between the epithelium and connective tissue. Moreover, whereas the keratin filaments associated with desmosomes make lateral attachments to the desmosomal plaques (see Figure 19-12C), many of those associated with hemidesmosomes have their ends buried in the plaque (Figure 19-13). As in focal contacts, the transmembrane linker proteins in hemidesmosomes belong to the integrin family of extracellular matrix receptors, rather than to the cadherin family of cell-cell adhesion proteins used in desmosomes. The intracellular attachment proteins in hemidesmosomes are also different from those in desmosomes.

Thus, although the terminology for the various anchoring junctions is a muddle, the molecular principles (for vertebrates at

least) are simple (Table 19-2). Integrins in the plasma membrane anchor a cell to extracellular matrix molecules; cadherins in the plasma membrane anchor it to cadherins in the membrane of an adjacent cell. In both cases there is an intracellular coupling to cytoskeletal filaments, which can be either actin or intermediate filaments depending on the types of intracellular attachment proteins employed. Moreover, for all these classes of anchoring junctions, the adhesion depends on extracellular divalent cations, although the significance of this dependence is unknown.

Gap Junctions Allow Small Molecules to Pass Directly from Cell to Cell [5]

Perhaps the most intriguing cell junction of all is the gap junction. It is one of the most widespread, being found in large numbers in most animal tissues and in practically all animal species. It appears in conventional electron micrographs as a patch where the membranes of two adjacent cells are separated by a uniform narrow gap of about 2-4 nm. This gap, however, is spanned by channel-forming protein molecules that allow inorganic ions and other small water-soluble molecules to pass directly from the cytoplasm of one cell to the cytoplasm of the other, thereby coupling the cells both electrically and metabolically. Such *cell coupling* has important functional implications, many of which are only beginning to be understood.

Cell-cell communication of this type was first demonstrated physiologically in 1958, but it took more than 10 years to show that the physiological coupling correlates with the presence of gap junctions seen in the electron microscope. The initial evidence for cell coupling came from electrophysiological studies of specific pairs of interacting nerve cells in the nerve cord of a crayfish. When a voltage gradient was applied across the junctional membrane through electrodes inserted into each of the two interacting cells, an unexpectedly large current flowed, indicating that inorganic ions (which carry current in living tissues) could pass freely from one cell interior to the other. Later experiments showed that small fluorescent dye molecules injected into one cell can likewise pass readily into adjacent cells without leaking into the extracellular space, provided that the molecules are no bigger than about 1000 daltons (Figure 19-14). This suggests a maximal functional pore size for the connecting channels of about 1.5 nm, implying that coupled cells share their small molecules (such as inorganic ions, sugars, amino acids, nucleotides, and vitamins) but not their macromolecules (proteins, nucleic acids, and polysaccharides).

The evidence that gap junctions mediate electrical and chemical coupling between cells in contact with each other comes from several sources. Gap-junction structures can almost always be found where coupling can be demonstrated by electrical or chemical criteria. Conversely, coupling between vertebrate cells is not found where there are no gap junctions. Moreover, dye and electrical coupling can be blocked by a microinjection of antibodies directed against a major gap-junction protein. More recently, molecular methods have provided direct proof: when a gap-junction protein is reconstituted in synthetic lipid bilayers or when mRNA encoding the protein is injected into either a frog oocyte or a gap-junction-deficient cell line, channels with the properties expected of gap-junction channels can be demonstrated electrophysiologically.

Gap-Junction Connexons Are Composed of Six Subunits [6]

Gap junctions are constructed from transmembrane proteins that form structures called *connexons.* When the connexons in the plasma membranes of two cells in contact are aligned, they form a continuous aqueous channel, which connects the two cell interiors (Figure 19-15). The connexons protrude from each cell surface, holding the interacting plasma membranes at a fixed distance from each other - hence the term gap junction, emphasizing the contrast with a tight junction, where the lipid bilayers appear to be in direct contact (compare Figures 19-5 and 19-15). Each connexon is seen as an intramembrane particle in freeze-fracture electron micrographs, and each gap junction can contain a cluster of up to several hundred connexons (19-16).

A connexon is composed of a ring of six identical protein subunits called *connexins,* each of which contains four putative membrane-spanning α helices. The six subunits are thought to associate to form a connexon with a central aqueous pore that is lined by one transmembrane α helix from each subunit. The six connexins form a larger and more permeable channel than do either the five subunits of the neurotransmitter-gated ion channels or the four subunits (or domains) of the voltage-gated cation channels, which are discussed in Chapter 11 (see Figure 11-33).

Gap junctions in different tissues can have somewhat different properties. The permeability of their individual channels can vary, for example. This is now known to reflect differences in the connexins that form the junctions. In rats, for instance, there are at least 11 distinct connexins, each encoded by a separate gene and each having a distinctive, but sometimes overlapping, tissue distribution. Some cell types express more than one type of connexin, but it is unclear whether different connexin proteins ever assemble into the same connexon. Despite the differences between various connexin proteins, their basic structure and function have been highly conserved in evolution. Thus, in cell culture at least, a cell expressing one type of connexin can often form a functional gap junction with a cell expressing a different connexin, even if the two cells are from different vertebrates.

Most Cells in Early Embryos Are Coupled by Gap Junctions 7

In tissues containing electrically excitable cells, coupling via gap junctions serves an obvious function. Electrical coupling between nerve cells, for example, allows action potentials to spread rapidly from cell to cell without the delay that occurs at chemical synapses; this is advantageous where speed and reliability are crucial, as in certain escape responses in fish and insects. Similarly, in higher vertebrates, electrical coupling synchronizes the contractions of heart muscle cells and of smooth muscle cells responsible for the peristaltic movements of the intestine.

It is less obvious why gap junctions occur in tissues that do not contain electrically excitable cells. In principle, the sharing of small metabolites and ions provides a mechanism for coordinating the activities of individual cells in such tissues and for smoothing out random fluctuations from cell to cell. The activities of cells in an epithelial cell sheet, for example, such as the beating of cilia, might be coordinated via gap junctions. More generally, since intracellular mediators such as cyclic AMP and Ca^{2+} can pass through gap junctions, responses of coupled cells to extracellular signaling molecules might be propagated and coordinated in this way.

Cell coupling via gap junctions appears to be important in embryogenesis. In early vertebrate embryos (beginning with the late eight-cell stage in mouse embryos) most cells are electrically coupled to one another. As specific groups of cells in the embryo develop their distinct identities and begin to differentiate, however, they commonly uncouple from surrounding tissue. As the neural plate folds up and pinches off to form the neural tube, for instance (see Figure 19-9), its cells uncouple from the overlying ectoderm. Meanwhile the cells within each group remain coupled with one another and so tend to behave as a cooperative assembly, all following a similar developmental pathway in a coordinated fashion.

It is possible that the coupling of cells in embryos provides a pathway for long-range cell signaling within a developing epithelium. A small molecule, for example, could pass through gap junctions from a region of the tissue where its intracellular concentration is kept high to a region where it is kept low, thereby setting up a smooth concentration gradient. The local concentration could then provide cells with "positional information" to control their differentiation according to their location in the embryo (discussed in Chapter 21). Whether gap junctions actually serve this purpose is not known.

The Permeability of Gap Junctions Is Regulated 8

Like conventional ion channels, individual gap-junction channels do not remain continuously open; instead, they flip between open and closed states. Moreover, the permeability of gap junctions is rapidly (within seconds) and reversibly decreased by experimental manipulations that decrease cytosolic pH or increase the cytosolic concentration of free Ca^{2+}. These observations indicate that gap-junction channels are dynamic structures that, like conventional ion channels, are *gated*: they can undergo a reversible conformational change that closes the channel in response to changes in the cell. An attractive model for the type of conformational change that might be involved is shown in Figure 19-17.

The physiological role of pH regulation of gap-junction permeability is unknown. There is one case, however, where the reason for the Ca^{2+} control seems clear. When a cell is damaged, its plasma membrane can become leaky. Ions present at high concentration in the extracellular fluid, such as Ca^{2+} and Na^{+}, then move into the cell, and valuable metabolites leak out. If the cell were to remain coupled to its healthy neighbors, these too would suffer a dangerous disturbance of their internal chemistry. But the influx of Ca^{2+} into the sick cell causes its gap-junction channels to close immediately, effectively isolating the cell and preventing damage from spreading in this way.

Figure 19-18 summarizes the various types of junctions formed by vertebrate cells in an epithelium. In the most apical portion of the cell, the relative positions of the junctions are the same in nearly all epithelia: the tight junction occupies the most apical portion of the cell, followed by the adhesion belt and then by a special parallel row of desmosomes; together these form a structure called a *junctional complex.* Gap junctions and additional desmosomes are less regularly organized.

In Plants, Plasmodesmata Perform Many of the Same Functions as Gap Junctions 9

The tissues of a plant are organized on different principles from those of an animal. This is because the plant cells are imprisoned within rigid *cell walls,* consisting of an extracellular matrix rich in cellulose, as we discuss later. The system of cell walls eliminates the need for anchoring junctions to hold the cells in place, but the need for direct cell-cell communication

remains. Thus, in contrast to animal cells, plant cells have only one class of intercellular junctions, *plasmodesmata,* which, like gap junctions, directly connect the cytoplasms of adjacent cells.

In plants, however, the cell wall between a typical pair of adjacent cells is at least 0.1 microns thick, so a structure very different from a gap junction is required to mediate communication across it. Plasmodesmata (singular, *plasmodesma*) solve the problem. With a few specialized exceptions, every living cell in a higher plant is connected to its living neighbors by plasmodesmata, which form fine cytoplasmic channels through the intervening cell walls. As shown in Figure 19-19A, the plasma membrane of one cell is continuous with that of its neighbor at each plasmodesma, and the cytoplasms of the two cells are connected by a roughly cylindrical channel with a diameter of 20 to 40 nm. Thus the cells of a plant can be viewed as forming a syncytium in which many cell nuclei share a common cytoplasm. Running through the center of the channel in most plasmodesmata is a narrower cylindrical structure, the *desmotubule,* which is continuous with elements of the smooth endoplasmic reticulum in each of the connected cells (Figures 19-19Band 19-20). Between the outside of the desmotubule and the inner face of the cylindrical channel formed by plasma membrane is an annulus of cytosol through which small molecules can pass from cell to cell. Plasmodesmata are normally created in all new cell walls as they are assembled during the cytokinesis phase of a cell division; they form around elements of smooth endoplasmic reticulum that become trapped across the developing cell plate (discussed in Chapter 18).

In spite of the radical difference of structure between plasmodesmata and gap junctions, they seem to function in remarkably similar ways. Evidence obtained by injecting tracer molecules of different sizes suggests that plasmodesmata allow the passage of molecules with a molecular weight of less than about 800, which is similar to the molecular-weight cutoff for gap junctions. As with gap junctions, transport through plasmodesmata is regulated. Dye-injection experiments, for example, show that there can be barriers to the movement of even low-molecular-weight molecules between certain cells that are connected by apparently normal plasmodesmata; the mechanisms that restrict communication in these cases are not understood. Conversely, certain plant viruses can enlarge plasmodesmata and use this route to pass from cell to cell, thereby spreading the infection. These viruses produce special proteins that bind to components of the plasmodesmata and dramatically increase the effective pore size of the channel. It is not clear, however, how these proteins work.

Summary

Many cells in tissues are linked to one another and to the extracellular matrix at specialized contact sites called cell junctions. Cell junctions fall into three functional classes: occluding junctions, anchoring junctions, and communicating junctions. Tight junctions are occluding junctions that play a critical part in maintaining the concentration differences of small hydrophilic molecules across epithelial cell sheets by (1) sealing the plasma membranes of adjacent cells together to create a continuous, impermeable, or semipermeable barrier to diffusion across the cell sheet and (2) acting as barriers in the lipid bilayer to restrict the diffusion of membrane transport proteins between the apical and the basolateral domains of the plasma membrane in each epithelial cell.

The main types of anchoring junctions in vertebrate tissues are adherens junctions, desmosomes, and hemidesmosomes. Adherens junctions are connecting sites for bundles of actin filaments, whereas desmosomes and hemidesmosomes are connecting sites for intermediate filaments. Septate junctions also serve as connecting sites for actin filaments, but only in invertebrate tissues. Gap junctions are communicating junctions composed of clusters of channel proteins that allow molecules smaller than about 1000 daltons to pass directly from the inside of one cell to the inside of the other. Cells connected by such junctions share many of their inorganic ions and other small molecules and are therefore chemically and electrically coupled. Gap junctions are important in coordinating the activities of electrically active cells, and they are thought to play a coordinating role in other groups of cells as well. Plasmodesmata are the only intercellular junctions in plants; they function like gap junctions even though their structure is entirely different.

Table 19-1. A Functional Classification of Cell Junctions

---

1. **Occluding junctions** (tight junctions)
2. **Anchoring junctions**
   a. actin filament attachment sites
      i. cell-cell adherens junctions (e.g., adhesion belts)
      ii. cell-matrix adherens junctions (e.g., focal contacts)
      iii. septate junctions (invertebrates only)
   b. intermediate filament attachment sites
      i. cell-cell (desmosomes)
      ii. cell-matrix (hemidesmosomes)
3. **Communicating junctions**
   a. gap junctions
   b. chemical synapses
c. plasmodesmata (plants only)
Figure 19-2. The role of tight junctions in transcellular transport. Transport proteins are confined to different regions of the plasma membrane in epithelial cells of the small intestine. This segregation permits a vectorial transfer of nutrients across the epithelial sheet from the gut lumen to the blood. In the example shown, glucose is actively transported into the cell by Na^+-driven glucose symports at the apical surface, and it diffuses out of the cell by facilitated diffusion mediated by glucose carriers in the basolateral membrane. Tight junctions are thought to confine the transport proteins to their appropriate membrane

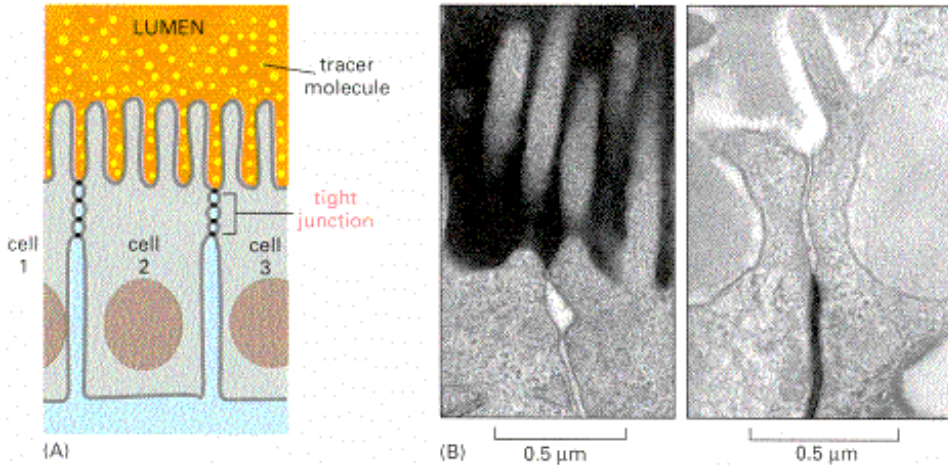
domains by acting as diffusion barriers within the lipid bilayer of the plasma membrane; these junctions also block the backflow of glucose from the basal side of the epithelium into the gut lumen.


Figure 19-3. Tight junctions allow cell sheets to serve as barriers to solute diffusion. (A) Schematic drawing showing how a small extracellular tracer molecule added on one side of an epithelial cell sheet cannot traverse the tight junctions that seal adjacent cells together. (B) Electron micrographs of cells in an epithelium where a small, extracellular, electron-dense tracer molecule has been added to either the apical side (on the *left*) or the basolateral side (on the *right*); in both cases the tracer is stopped by the tight junction. (B, courtesy of Daniel Friend.)
Figure 19-4. Structure of a tight junction between epithelial cells of the small intestine. The junctions are shown schematically in (A) and in freeze-fracture (B) and conventional (C) electron micrographs. Note that the cells are oriented with their apical ends down. In (B) the plane of the micrograph is parallel to the plane of the membrane, and the tight junction appears as a beltlike band of anastomosing *sealing strands* that encircle each cell in the sheet. The sealing strands are seen as ridges of intramembrane particles on the cytoplasmic fracture face of the membrane (the P face) or as complementary grooves on the external face of the membrane (the E face) (see Figure 19-5). In (C) the junction is seen as a series of focal connections between the outer leaflets of the two interacting plasma membranes, each connection corresponding to a sealing strand in cross-section. (B and C, from N.B. Gilula, in Cell Communication [R.P. Cox, ed.], pp. 1-29. New York: Wiley, 1974. Reprinted by permission of John Wiley & Sons, Inc.)
Figure 19-5. A current model of a tight junction. It is postulated that the sealing strands that hold adjacent plasma membranes together are formed by continuous strands of transmembrane junctional proteins, which make contact across the intercellular space and create a seal. In this schematic the cytoplasmic half of one membrane has been peeled back by the artist to expose the protein strands. Two peripheral proteins associated with the cytoplasmic side of tight junctions have been characterized, but the putative transmembrane protein has not yet been identified. In freeze-fracture electron microscopy the tight-junction proteins would remain with the cytoplasmic (P face) half of the lipid bilayer to give the pattern of intramembrane particles seen in Figure 19-4B, instead of staying in the other half as shown here.
Figure 19-6. Anchoring junctions in an epithelial tissue. Highly schematized drawing of how such junctions join cytoskeletal filaments from cell to cell and from cell to extracellular matrix.
Figure 19-7. Construction of an anchoring junction. Highly schematized drawing showing the two classes of proteins that constitute such a junction: intracellular attachment proteins and transmembrane linker proteins.
Figure 19-8. Adhesion belts between epithelial cells in the small intestine. This beltlike anchoring junction encircles each of the interacting cells. Its most obvious feature is a contractile bundle of actin filaments running along the cytoplasmic surface of the junctional plasma membrane. The actin filaments are joined from cell to cell by transmembrane linker proteins (cadherins), whose extracellular domain binds to the extracellular domain of an identical cadherin molecule on the adjacent cell (see Figure 19-7).
Figure 19-9. The folding of an epithelial sheet to form an epithelial tube. It is thought that the oriented contraction of the bundle of actin filaments running along adhesion belts causes the epithelial cells to narrow at their apex and that this plays an important part in the rolling up of the epithelial sheet into a tube (although cellular rearrangements are also thought to play an important part). An example is the formation of the neural tube in early vertebrate development (discussed in Chapter 21).
Figure 19-10. The localization of vinculin at a focal contact. In these immunofluorescence micrographs, cells in culture have been double-labeled with antibodies against actin (*green*) and vinculin (*red*). Note that vinculin is located at focal contacts, where bundles of actin filaments terminate at the plasma membrane. (From B. Geiger, E. Schmid, and W. Franke, *Differentiation* 23:189-205, 1983.)

Figure 19-11. A septate junction. Electron micrograph of a septate junction between two epithelial cells of a mollusk. The interacting plasma membranes, seen in cross-section, are connected by parallel rows of junctional proteins. The rows, which have a regular periodicity, are seen as dense bars or septa. (From N.B. Gilula, in Cell Communication [R.P. Cox, ed.], pp. 1-29. New York: Wiley, 1974. Reprinted by permission of John Wiley & Sons, Inc.)
Figure 19-12. Desmosomes. (A) An electron micrograph of three desmosomes between two epithelial cells in the intestine of a rat. (B) An electron micrograph of a single desmosome between two epidermal cells in a developing newt, showing clearly the attachment of intermediate filaments. (C) A schematic drawing of a desmosome. On the cytoplasmic surface of each interacting plasma membrane is a dense plaque composed of a mixture of intracellular attachment proteins (including *plakoglobin* and *desmoplakins*). Each plaque is associated with a thick network of keratin filaments, which are attached to the surface of the plaque. Transmembrane linker proteins, which belong to the cadherin family of cell-cell adhesion molecules, bind to the plaques and interact through their extracellular domains to hold the adjacent membranes together by a Ca^{2+}-dependent mechanism. (A, from N.B. Gilula, in Cell Communication [R.P. Cox, ed.], pp. 1-29, New York: Wiley, 1974. Reprinted by permission of John Wiley & Sons, Inc.; B, from D.E. Kelly, *J. Cell Biol.* 28:51-59, 1966, by copyright permission of the Rockefeller University Press.)

Cell-Cell Adhesion [10]

Introduction

To form an anchoring junction, cells must first adhere. A bulky cytoskeletal apparatus must then be assembled around the molecules that directly mediate the adhesion. The result is a well-defined structure - a desmosome, a hemidesmosome, or an adherens or septate junction - that is easily identified in the electron microscope. Indeed, electron microscopy provided the basis for the original classification of cell junctions. In the early stages of development of a cell junction, however, before the cytoskeletal apparatus has assembled, and especially in embryonic tissues, the cells often adhere to one another without clearly displaying these characteristic structures: in the electron microscope one may simply see two plasma membranes separated by a small gap of a definite width. Functional tests may show, nevertheless, that the two cells are sticking to one another, and biochemical analysis can reveal the molecules responsible for the adhesion.

Thus, while cell-cell junctions and cell-cell adhesion might seem to be two names for the same phenomenon, they correspond in practice to two different experimental approaches - one through electron microscopic description, the other through functional tests and biochemistry - and two different emphases - one on mature, adult structure, the other on developmental function. It is only in recent years that these two approaches have begun to converge in a unified view of the molecular basis of cell junctions and cell adhesion. In the previous section we concentrated on the structures of mature cell junctions. In this section we turn to functional and biochemical studies of the cell-cell adhesion mechanisms that have to operate before a full-blown cell-cell anchoring junction can be constructed; later in the chapter we discuss functional and biochemical studies of cell-matrix adhesion mechanisms. We begin with a developmental question: what mechanisms ensure that an embryonic cell will attach to appropriate neighbors at the right time?

There Are Two Basic Ways in Which Animal Cells Assemble into Tissues [11]

Many simple tissues, including most epithelia, derive from precursor cells whose progeny are prevented from wandering away by being attached to the extracellular matrix or to other cells or to both (Figure 19-21). But the cells, as they accumulate, do not simply remain passively stuck together as a disorderly pile; instead, as we shall see, the tissue architecture is actively maintained by selective adhesions that the cells make and progressively adjust. Thus, if cells of different embryonic tissues are artificially mingled, they will often spontaneously sort out to restore a more normal arrangement.

Such selective adhesion is even more essential for the development of tissues that have more complex origins involving cell migration, whereby one population of cells invades another and assembles with them, and perhaps with other migrant cells, to form an orderly structure. In vertebrate embryos, for example, cells from the *neural crest* break away from the epithelial neural tube with which they are initially associated and migrate along specific paths to many other regions. There they assemble with other cells and with one another and differentiate into a variety of tissues, including those of the peripheral nervous system (Figure 19-22). Such a process requires, first, some mechanism for directing the cells to their final destination, such as the secretion of a soluble chemical that attracts migrating cells (by *chemotaxis*) or the laying down of adhesive molecules in the extracellular matrix or on cell surfaces to guide the migrating cells along the right paths (by *pathway guidance*). Once a migrating cell reaches its destination, it must recognize and join other cells of the appropriate type in order to assemble into a tissue.

Dissociated Vertebrate Cells Can Reassemble into Organized Tissues Through Selective Cell-Cell Adhesion [12]

Unlike adult vertebrate tissues, which are difficult to dissociate, embryonic vertebrate tissues are easily dissociated by treatment with low concentrations of a proteolytic enzyme such as trypsin, sometimes combined with the removal of extracellular Ca^{2+} and Mg^{2+} with a divalent-cation chelator (such as EDTA). These reagents disrupt the protein-protein interactions (many of which are divalent-cation-dependent) that hold cells together. Remarkably, such dissociated cells often reassemble *in vitro* into structures that resemble the original tissue. Such findings suggest that tissue structure is not just a product of history; it is actively maintained and stabilized by the system of affinities that cells have for one another and for the extracellular matrix. Thus, by studying the reassembly of dissociated cells in culture, one can hope to illuminate the role of cell-cell and cell-matrix adhesion in creating and maintaining the organization of tissues in the body.

Experiments on cultured cells from the *epidermis* (the epithelium of the skin) provide an instructive example. The epidermal

cells, known as *keratinocytes*, adhere tightly to one another and form a multilayered sheet that rests on a basal lamina. The keratinocytes in the basal layer are relatively undifferentiated and proliferate steadily, releasing progeny into the upper layers. There cell division halts and terminal differentiation occurs (see Figure 22-21). Given a suitable substratum, dissociated keratinocytes in culture will likewise proliferate and differentiate. If the concentration of Ca^{2+} in the culture medium is kept abnormally low, however, so that Ca^{2+}-dependent cell-cell adhesion systems cannot operate, the keratinocytes grow as a monolayer in which proliferating and differentiating cells are intermingled. If the Ca^{2+} concentration is then raised, the spatial organization of the cells is soon transformed: the monolayer is converted into a multilayered epithelium in which the proliferating cells form the basal layer adherent to the substratum and the differentiating cells are segregated into the upper layers, just as in normal skin. This result suggests that the normal stratified arrangement of keratinocytes, ordered according to their state of differentiation, is maintained by Ca^{2+}-dependent cell adhesion mechanisms. One such mechanism involves integrin matrix receptors, which we discuss later; these are absent from differentiated epidermal cells but are present on basal cells, which use the integrins to adhere to the basal lamina. Others involve cadherin cell-cell adhesion molecules, which we discuss below.

A still more striking example of the same phenomenon is seen when dissociated cells from two embryonic vertebrate organs such as liver and retina are mixed together and artificially formed into a pellet: the mixed aggregates gradually sort out according to their organ of origin. Similarly, disaggregated cells are found to adhere more readily to aggregates of their own organ than to aggregates of other organs (Figure 19-23). Evidently there are cell-cell recognition systems that make cells of the same differentiated tissue preferentially adhere to one another; these adhesive preferences are presumably important in stabilizing tissue architecture.

What is the molecular basis of this selective cell-cell adhesion in vertebrates? Two distinct classes of cell-cell adhesion molecules (CAMs) operate in most multicellular animals, one Ca^{2+}-dependent and the other Ca^{2+}-independent, and it is the Ca^{2+}-dependent molecules that seem to be primarily responsible for the tissue-specific cell-cell adhesion seen in early vertebrate embryos. Both classes of adhesion molecules were initially identified by making antibodies against cell-surface molecules and then testing the antibodies for their ability to inhibit cell-cell adhesion in a test tube. Those rare antibodies that inhibit are then used to characterize and isolate the adhesion molecule recognized by the antibodies.

The Cadherins Mediate Ca^{2+}-dependent Cell-Cell Adhesion in Vertebrates 13

The cadherins are responsible for Ca^{2+}-dependent cell-cell adhesion in vertebrate tissues, as mentioned in our account of cell-cell junctions. The first three cadherins that were discovered were named according to the main tissues in which they were found: *E-cadherin* is present on many types of epithelial cells; *N-cadherin* on nerve, muscle, and lens cells; and *P-cadherin* on cells in the placenta and epidermis. All are also found transiently on various other tissues during development. In addition, new types of cadherins are continually being discovered, and at least a dozen are currently known. Virtually all vertebrate cells seem to express one or more cadherins, each encoded by a separate gene, the particular set expressed being characteristic of the cell type. Experiments *in vitro* and *in vivo* demonstrate that cadherins are the main adhesion molecules holding cells together in early embryonic tissues. *In vitro*, the removal of extracellular Ca^{2+} or treatment with anti-cadherin antibodies disrupts the tissue, and if cadherin-mediated adhesion is left intact, antibodies against other adhesion molecules are without effect; *in vivo*, mutations that inactivate the function of cadherins cause embryos to fall apart early in development.

Most cadherins are single-pass transmembrane glycoproteins composed of about 700-750 amino acid residues. The large extracellular part of the polypeptide chain is usually folded into five domains, each containing about 100 amino acid residues; four of these domains are homologous and contain presumptive Ca^{2+}-binding sites (Figure 19-24). In the absence of Ca^{2+}, the cadherins undergo a large conformational change and, as a result, are rapidly degraded by proteolytic enzymes. The biological significance of the striking Ca^{2+} dependence of cadherin protein function is unknown.

E-cadherin (also called *uvomorulin*) is the best-characterized cadherin. We encountered it earlier when we discussed cell junctions, since it is usually concentrated in *adhesion belts* in mature epithelial cells, where it connects the cortical actin cytoskeletons of the cells it holds together. E-cadherin is also the first cadherin expressed during mammalian development, where it helps to cause *compaction*, an important morphological change that occurs at the eight-cell stage of mouse embryo development. During compaction the loosely attached cells, called *blastomeres*, become tightly packed together and joined by intercellular junctions. Antibodies against E-cadherin block blastomere compaction, whereas antibodies that react with various other cell-surface molecules on these cells do not.

It seems likely that cadherins also play crucial roles in later stages of vertebrate development, since their appearance and disappearance correlate with major morphogenetic events in which tissues segregate from one another. As the neural tube forms and pinches off from the overlying ectoderm, for example, the neural tube cells lose E-cadherin and acquire N-cadherin, while the cells in the overlying ectoderm continue to express E-cadherin (Figure 19-25). Moreover, the neural crest cells that form the peripheral nervous system have large amounts of N-cadherin on their surface when they are associated with the neural tube, lose it while they are migrating, and then reexpress it when they aggregate to form a ganglion (see Figure 19-22). Thus three cell groups that originate from one cell-layer exhibit distinct patterns of cadherin expression when separating from one another, suggesting that the switches in cadherin expression are involved in the separation process.

Cadherins Mediate Cell-Cell Adhesion by a Homophilic Mechanism [14]

How do cell-cell adhesion molecules such as the cadherins bind cells together? Three possibilities are illustrated in Figure 19-26: (1) molecules on one cell might bind to other molecules of the same kind on adjacent cells (so-called *homophilic* binding); (2) molecules on one cell might bind to molecules of a different kind on adjacent cells (so-called *heterophilic* binding); and (3) cell-surface receptors on adjacent cells might be linked to one another by secreted multivalent linker molecules. All of these mechanisms have been found to operate in animals. Cadherins, however, usually utilize a homophilic mechanism. This has been shown by using a line of cultured fibroblasts called *L cells,* which do not express cadherins and do not adhere to one another. When L cells are transfected with DNA encoding E-cadherin, the transfected cells now adhere to one another by a Ca^{2+}-dependent mechanism and the adhesion is inhibited by anti-E-cadherin antibodies. Since the transfected cells do not bind to untransfected L cells, E-cadherin must bind cells together by the interaction of two E-cadherin molecules on different cells.

If L cells expressing different cadherins are mixed together, they sort out and aggregate separately, indicating that different cadherins preferentially bind to their own type. A similar segregation of cells occurs if L cells expressing different amounts of the same cadherin are mixed together. It seems likely, therefore, that both qualitative and quantitative differences in the expression of cadherins play a crucial part in forming tissues; differences in cadherins probably also explain most of the classical experiments demonstrating organ- and tissue-specific adhesion in a test tube.

Most cadherins, such as E, N, and P-cadherins, function as transmembrane linker proteins that mediate interactions between the actin cytoskeletons of the cells they join together. They are, as we have seen, the adhesion proteins around which cell-cell adherens junctions are constructed. A highly conserved cytoplasmic domain of these cadherins interacts with the actin cortex by means of at least three intracellular attachment proteins called *catenins* (see Figure 19-24). This interaction is required for cell-cell adhesion: E-cadherin molecules lacking their cytoplasmic domain are unable to hold cells together. Those cadherins that are localized in desmosomes interact with intermediate filaments rather than actin filaments; their cytoplasmic domain is different and binds to a different set of attachment proteins, which in turn bind to intermediate filaments.

Cadherins are not the only proteins that mediate Ca^{2+}-dependent cell-cell adhesion: some integrins can also bind cells together through heterophilic interactions with other cell-surface proteins, although most integrins mediate the attachment of cells to the extracellular matrix, as we discuss later. In addition, a family of cell-surface carbohydrate-binding proteins (*lectins*) called selectins function in a variety of transient cell-cell adhesion interactions in the bloodstream; they enable white blood cells, for example, to bind transiently to endo-thelial cells lining small blood vessels and thereby to migrate out of the blood into tissues at sites of inflammation. Selectins contain a highly conserved lectin domain that, in the presence of Ca^{2+}, binds to a specific oligosaccharide on another cell - another example of heterophilic cell-cell adhesion (see Figure 10-42). Since selectins have been discussed in Chapter 10, they will not be considered further here.

We discuss later how cells can regulate the adhesive activity of their integrins. In a similar way it seems likely that some cells, at least, can regulate the adhesive activity of their cadherins, although much less is known about cadherin regulation than integrin regulation. Such regulation may be important for the cellular rearrangements that occur within epithelia when these cell sheets change their shape and organization during animal development.

Ca^{2+}-independent Cell-Cell Adhesion Is Mediated Mainly by Members of the Immunoglobulin Superfamily of Proteins [15]

The molecules responsible for Ca^{2+}-independent cell-cell adhesion belong mainly to the large and ancient immunoglobulin (Ig) superfamily of proteins, so-called because they contain one or more Ig-like domains that are characteristic of anti-body molecules (discussed in Chapter 23). The best-studied example is the neural cell adhesion molecule (N-CAM), which is

expressed by a variety of cell types, including most nerve cells. It is the most prevalent of the Ca^{2+}-independent cell-cell adhesion molecules in vertebrates, and, like cadherins, it is thought to bind cells together by a homophilic interaction (between N-CAM molecules on adjacent cells). Some Ig-like cell-cell adhesion proteins, however, use a heterophilic mechanism; some of these, called *intercellular adhesion molecules (ICAMs),* are expressed on activated endothelial cells, where they bind to integrins on the surface of white blood cells and thereby help to trap these blood cells at sites of inflammation.

There are at least 20 forms of N-CAM. Unlike the cadherins, each of which is encoded by a separate gene, the different N-CAM mRNAs are generated by alternative splicing of an RNA transcript produced from a single gene. The large extracellular part of the polypeptide chain in all forms of N-CAM is folded into five Ig-like domains. Most N-CAMs are single-pass transmembrane proteins with variable-sized intracellular domains, which are thought to be involved in cell signaling or binding to the cytoskeleton. One form does not cross the lipid bilayer and is attached to the plasma membrane by a glycosylphosphatidylinositol (GPI) anchor, while another is secreted and may become incorporated into the extracellular matrix (Figure 19-27). Further variation arises from the glycosylation of N-CAM: some forms carry a large quantity of sialic acid (in the highly unusual form of several chains, each containing hundreds of repeating sialic acid residues), while others carry very much less. By virtue of their negative charge, the long sialic acid chains hinder cell adhesion, thereby modifying the adhesive function of the N-CAM. Indeed, it is possible that N-CAM that is heavily loaded with sialic acid may, in some cases, serve to prevent adhesion rather than cause it. In some neurons, for example, the presence of these polysialic acid chains promotes nerve process outgrowth, presumably by making it easier for the growing tips of the processes to let go of the cells to which they are stuck.

There is substantial evidence that N-CAM and its Ig-like relatives play an important part in vertebrate development. When antibodies against either N-CAM or another Ig-related neural cell-cell adhesion molecule called *L1* are injected along the pathway of nerve processes growing from the retina to the brain, they disturb the normal growth pattern of the nerve processes. When used in culture, these antibodies inhibit the tendency of developing nerve cell processes to adhere to one another to form bundles (fascicles). Like N-cadherin, N-CAM is expressed in large amounts on cells of the developing neural tube, but when neural crest cells dissociate from the neural tube and migrate away, they lose N-CAM, only to reexpress it later when they reaggregate to form a neural ganglion (see Figure 19-22). As in the case of cadherins, N-CAM is also expressed transiently during critical stages in the development of many non-neural tissues.

Although cadherins and Ig family members are frequently expressed on the same cells, the adhesions mediated by the cadherins are much stronger, and they almost certainly play the major role in holding cells together, segregating cell collectives into discrete tissues, and maintaining tissue integrity. N-CAM and other members of the Ig family seem to contribute more to the regulation or fine-tuning of these adhesive interactions during development and regeneration. Thus an injection of N-cadherin mRNA into a fertilized frog egg results in the overexpression of N-cadherin in places where it is not normally expressed and leads to a gross disruption of normal tissue architecture. By contrast, the same experiment performed with N-CAM mRNA leads to relatively minor disturbances in development even though N-CAM is overexpressed in many abnormal locations.

The most critical test of the requirement for a protein in a particular biological process is not to overexpress it but instead to inhibit its production by disrupting the gene. While this can now be done in some vertebrates, it is most readily done in genetically tractable invertebrates such as *Drosophila* and the nematode *C. elegans.* A number of Ig-like proteins that mediate Ca^{2+}-independent cell-cell adhesion have been defined in *Drosophila.* One of these, fasciclin II, is a close relative of N-CAM: like N-CAM, it has five Ig-like domains and operates by homophilic binding. It is expressed mainly on a subset of nerve cell processes and on some of the glial cells they contact during development. If both copies of the fasciclin II gene are inactivated by mutation, the gross structure of the nervous system is normal. However, at least two of the nerve cell processes that normally express fasciclin II and adhere together now fail to recognize each other and therefore do not form a bundle. This observation is consistent with the view that Ig-like cell-cell adhesion molecules play subtle but important roles in development.

Multiple Types of Cell-Surface Molecules Act in Parallel to Mediate Selective Cell-Cell and Cell-Matrix Adhesion [16]

Morphological, cell biological, and biochemical studies all indicate that even a single cell type utilizes multiple molecular mechanisms in adhering to other cells and to the extracellular matrix. Some of these mechanisms involve organized cell junctions; others do not (Figure 19-28). Just as each cell in a multicellular animal contains an assortment of cell-surface receptors that enables the cell to respond specifically to a complementary assortment of soluble chemical signals such as hormones and growth factors, so each cell in a tissue has a particular combination (and concentration) of cell-surface receptors (cell adhesion molecules) that enables it to bind in its own characteristic way to other cells and to the extracellular matrix. And just as receptors for soluble chemical signals generate intracellular signals that alter the cell's behavior, so too can cell adhesion

molecules, although the signaling mechanisms are less well understood for these molecules.

Unlike receptors for soluble chemical signals, which bind their specific ligand with high affinity, the receptors that bind to molecules on cell surfaces or in the extracellular matrix usually do so with relatively low affinity. The latter receptors therefore rely on the enormous increase in binding strength gained through simultaneous binding of multiple receptors to multiple ligands on an opposing cell or in the adjacent matrix. One could call this the "Velcro principle." We have seen, however, that the interaction of the extracellular binding domains of these cell-surface molecules is not enough to ensure cell adhesion: at least in the case of cadherins and, as we shall see, integrins, the adhesion molecules must also attach (via attachment proteins) to the cortical cytoskeleton inside the cell. The cytoskeleton is thought to assist and stabilize the lateral clustering of the adhesion molecules so as to facilitate multipoint binding, and it is also required to enable the adhering cell to exert traction on the adjacent cell or matrix (and vice versa) (Figure 19-29). Thus the mixture of specific types of cell-cell adhesion molecules and matrix receptors present on any two cells, as well as their concentration, cytoskeletal linkages, and distribution on the cell surface, will determine the total affinity with which the two cells bind to each other and to the matrix.

Nonjunctional Contacts May Initiate Tissue-specific Cell-Cell Adhesions That Junctional Contacts Then Orient and Stabilize 16

Which, if any, of the several types of intercellular junctions discussed earlier in this chapter are involved as cells migrate and recognize one another during the formation of tissues and organs? One way to find out is to use an electron microscope to examine the contacts between adjacent cells when they are migrating over each other in developing embryos or in adult tissues undergoing repair after injury. Such studies show that, with the exception of cells reorganizing within an epithelium, these contacts generally do not involve the formation of organized intercellular junctions. Nevertheless, the interacting plasma membranes often come close together and run parallel, separated by a space of 10-20 nm. As several known transmembrane proteins extend above the plasma membrane by 10-20 nm or more, two cell-surface proteins could readily interact directly with each other across the 10-20-nm gap to mediate the adhesion. This type of nonjunctional contact may be optimal for cell locomotion - close enough to give traction but not tight enough to immobilize the cell.

As anchoring junctions (adherens junctions, desmosomes, hemidesmo-somes, and, in insects, septate junctions) are generally not seen between migrating embryonic cells, the formation of such junctions might be an important mechanism for immobilizing cells within an organized tissue once it has formed. In addition, within epithelia the formation of intercellular junctions is thought to be necessary for mechanical strength and to help polarize and orient the constituent cells. A reasonable hypothesis is that nonjunctional cell-cell adhesion proteins initiate tissue-specific cell-cell adhesions, which are then oriented and stabilized by the assembly of full-blown intercellular junctions. As many of the transmembrane proteins involved can diffuse in the plane of the plasma membrane, they can accumulate at sites of cell-cell (and cell-matrix) contact and therefore be used for junctional as well as nonjunctional adhesions. This has been demonstrated to occur for some integrins and cadherins, which help initiate cell adhesion and then later become integral parts of cell junctions.

As an increasing number of monoclonal antibodies and peptide fragments are characterized, each of which blocks a single type of cell-cell adhesion molecule or matrix receptor - and as the genes that encode these cell-surface proteins become available for manipulation in cells in culture and in experimental animals - it should be possible to inactivate the various types of cell-cell adhesion proteins and matrix receptors individually and in different combinations in order to decipher the rules of recognition and binding used in the morphogenesis of complex tissues.

Summary

Cells dissociated from various tissues of vertebrate embryos preferentially reassociate with cells from the same tissue when they are mixed together. This tissue-specific recognition process in vertebrates is mainly mediated by a family of Ca^{2+}-dependent cell-cell adhesion proteins called cadherins, which hold cells together by a homophilic interaction between transmembrane cadherin proteins on adjacent cells. In order to hold cells together, the cadherins must be attached to the cortical cytoskeleton. Most animal cells also have Ca^{2+}-independent cell-cell adhesion systems that mainly involve members of the immunoglobulin superfamily, which includes the neural cell adhesion molecule N-CAM. As even a single cell type uses multiple molecular mechanisms in adhering to other cells (and to the extracellular matrix), the specificity of cell-cell adhesion seen in embryonic development must result from the integration of a number of different adhesion systems, some of which are associated with specialized cell junctions while others are not.
Figure 19-21. The simplest mechanism by which cells assemble to form a tissue. The progeny of the founder cell are retained in the epithelial sheet by the basal lamina and by cell-cell adhesion mechanisms, including the formation of intercellular junctions.

peripheral ganglia
Figure 19-22. An example of a more complex mechanism by which cells assemble to form a tissue. Neural crest cells escape from the epithelium forming the upper surface of the neural tube and migrate away to form a variety of cell types and tissues throughout the embryo. Here they are shown assembling and differentiating to form two collections of nerve cells in the peripheral nervous system. Such a collection of nerve cells is called a *ganglion.* Other neural crest cells differentiate in the ganglion to become supporting (satellite) cells surrounding the neurons. Although it is not shown, the neural crest cells proliferate rapidly as they migrate.

MIXING OF RADIOACTIVELY LABELED CELLS WITH CELL AGGREGATES
Figure 19-23. Organ-specific adhesion of dissociated vertebrate embryo cells determined by a radioactive cell-binding assay. The rate of cell adhesion can be measured by determining the number of radioactively labeled cells bound to the cell aggregates after various periods of time. The rate of adhesion is greater between cells of the same kind. In a commonly used modification of this assay, cells labeled with a fluorescent or radioactive marker are allowed to bind to a monolayer of unlabeled cells in culture.
Figure 19-24. Schematic drawing of a typical cadherin molecule. The extracellular part of the protein is folded into five similar domains, three of which contain Ca^{2+}-binding sites. The extracellular domain farthest from the membrane is thought to mediate cell-cell adhesion; the sequence His-Ala-Val in this domain seems to be involved, as peptides with this sequence inhibit cadherin-mediated adhesion. The cytoplasmic tail interacts with the actin cytoskeleton via a number of intracellular attachment proteins, including three catenin proteins. a-catenin is structurally related to vinculin. X represents uncharacterized attachment proteins involved in coupling cadherins to actin filaments.
Figure 19-25. Distribution of E- and N-cadherin in the developing nervous system. Immuno-fluorescence micrographs of a cross-section of a chick embryo showing the developing neural tube labeled with antibodies against E-cadherin (A) and N-cadherin (B). Note that the overlying ectoderm cells express only E-cadherin, while the cells in the neural tube have lost E-cadherin and have acquired N-cadherin. (Courtesy of Kohei Hatta and Masatoshi Takeichi.)

BINDING THROUGH
AN EXTRACELLULAR
LINKER MOLECULE

Figure 19-26. Three mechanisms by which cell-surface molecules can mediate cell-cell adhesion. Although all of these mechanisms can operate in animals, the one that depends on an extracellular linker molecule seems to be least common.
Figure 19-27. Schematic drawing of four forms of N-CAM. The extracellular part of the polypeptide chain in each case is folded into five immunoglobulinlike domains (and one or two other domains called fibronectin type III repeats for reasons that will become clear later). Disulfide bonds (shown in *red*) connect the ends of each loop forming each Ig-like domain.
Figure 19-28. A summary of the junctional and nonjunctional adhesive mechanisms used by animal cells in binding to one another and to the extracellular matrix. The junctional mechanisms are shown in epithelial cells, while the nonjunctional mechanisms are shown in nonepithelial cells. A junctional interaction is operationally defined as one that can be seen as a specialized region of contact by conventional and/or freeze-fracture electron microscopy. Note that the integrins and cadherins are involved in both nonjunctional and junctional cell-cell (cadherins) and cell-matrix (integrins) contacts. The cadherins generally mediate homophilic interactions, whereas the integrins mediate heterophilic interactions (see Figure 19-26). Both the cadherins and integrins act as transmembrane linkers and depend on extracellular divalent cations to function; for this reason, most cell-cell and cell-matrix contacts are divalent-cation-dependent. The selectins and integrins can also act as heterophilic cell-cell adhesion molecules: the selectins bind to carbohydrate, while the cell-binding integrins bind to members of the immunoglobulin superfamily. The integrins and integral membrane proteoglycans that mediate nonjunctional adhesion to the extracellular matrix are discussed later.
Figure 19-29. Importance of the cytoskeleton in cell adhesion. This drawing illustrates why cell-adhesion molecules must be linked to the cytoskeleton in order to mediate robust cell-cell or cell-matrix adhesion. In reality, many adhesion proteins would probably be pulled from the cell with bits of attached membrane, and the holes left in the membrane would immediately reseal. ➜ ➜

The Extracellular Matrix of Animals 17

Introduction

Tissues are not made up solely of cells. A substantial part of their volume is *extracellular space,* which is largely filled by an intricate network of macromolecules constituting the extracellular matrix (Figure 19-30). This matrix is composed of a variety of versatile proteins and polysaccharides that are secreted locally and assembled into an organized meshwork in close association with the surface of the cell that produced them. Whereas we discussed cell junctions chiefly in the context of epithelial tissues, our account of extracellular matrix concentrates chiefly on connective tissues (Figure 19-31). In these tissues the matrix is frequently more plentiful than the cells that it surrounds, and it determines the tissue's physical properties. Connective tissues form the architectural framework of the vertebrate body, but the amounts found in different organs vary greatly: from skin and bone, in which they are the major component, to brain and spinal cord, in which they are only minor constituents.

Variations in the relative amounts of the different types of matrix macromolecules and the way they are organized in the extracellular matrix give rise to an amazing diversity of forms, each adapted to the functional requirements of the particular tissue. The matrix can become calcified to form the rock-hard structures of bone or teeth, or it can form the transparent matrix of the cornea, or it can adopt the ropelike organization that gives tendons their enormous tensile strength. At the interface between an epithelium and connective tissue, the matrix forms a *basal lamina,* a thin but tough mat that plays an important part in controlling cell behavior. We shall focus on the extracellular matrix of vertebrates, but other organisms make many unique and interesting related materials, as in the cell walls of bacteria, the cuticles of worms and insects, the shells of mollusks, and, as we discuss later, the cell walls of plants.

Until recently the vertebrate extracellular matrix was thought to serve mainly as a relatively inert scaffolding to stabilize the physical structure of tissues. But now it is clear that the matrix plays a far more active and complex role in regulating the behavior of the cells that contact it - influencing their development, migration, proliferation, shape, and function. The extracellular matrix has a correspondingly complex molecular composition. Although our understanding of its organization is still fragmentary, there has been rapid progress in characterizing many of its major components.

The Extracellular Matrix Is Made and Oriented by the Cells Within It 17

The macromolecules that constitute the extracellular matrix are mainly produced locally by cells in the matrix. As we discuss later, these cells also help to pattern the matrix, in that the orientation of their cytoskeleton influences the orientation of the matrix they produce. In most connective tissues the matrix macromolecules are secreted largely by cells called fibroblasts (Figure 19-32). In some specialized connective tissues such as cartilage and bone, however, they are secreted by cells of the fibroblast family that have more specific names: *chondroblasts,* for example, form cartilage, and *osteoblasts* form bone. The two main classes of extracellular macromolecules that make up the matrix are (1) polysaccharide chains of the class called *glycosaminoglycans (GAGs),* which are usually found covalently linked to protein in the form of *proteoglycans,* and (2) fibrous proteins of two functional types: mainly structural (for example, *collagen* and *elastin*) and mainly adhesive (for example, *fibronectin* and *laminin*). We shall see (in Figure 19-57) that the members of both classes come in a great variety of shapes and sizes. Glycosaminoglycan and proteoglycan molecules in connective tissue form a highly hydrated, gel-like "ground substance" in which the fibrous proteins are embedded; the polysaccharide gel resists compressive forces on the matrix, and the collagen fibers provide tensile strength. The aqueous phase of the polysaccharide gel permits the rapid diffusion of nutrients, metabolites, and hormones between the blood and the tissue cells; the collagen fibers both strengthen and help to organize the matrix, and rubberlike elastin fibers give it resilience. The adhesive proteins help cells attach to the appropriate part of the extracellular matrix: fibronectin, for example, promotes the attachment of fibroblasts and various other cells to the matrix in connective tissues, while laminin promotes the attachment of epithelial cells to the basal lamina.

Glycosaminoglycan (GAG) Chains Occupy Large Amounts of Space and Form Hydrated Gels 18

Glycosaminoglycans (GAGs) are unbranched polysaccharide chains composed of repeating disaccharide units. They are called

GAGs because one of the two sugar residues in the repeating disaccharide is always an amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine), which in most cases is sulfated. The second sugar is usually a uronic acid (glucuronic or iduronic). Because there are sulfate or carboxyl groups on most of their sugar residues, GAGs are highly negatively charged (Figure 19-33). Four main groups of GAGs have been distinguished by their sugar residues, the type of linkage between these residues, and the number and location of sulfate groups: (1) *hyaluronan,* (2) *chondroitin sulfate* and *dermatan sulfate,* (3) *heparan sulfate* and *heparin,* and (4) *keratan sulfate.*

Polysaccharide chains are too inflexible to fold up into the compact globular structures that polypeptide chains typically form. Moreover, they are strongly hydrophilic. Thus GAGs tend to adopt highly extended conformations that occupy a huge volume relative to their mass (Figure 19-34), and they form gels even at very low concentrations. Their high density of negative charges attracts a cloud of cations, such as Na^+, that are osmotically active, causing large amounts of water to be sucked into the matrix. This creates a swelling pressure, or turgor, that enables the matrix to withstand compressive forces (in contrast to collagen fibrils, which resist stretching forces). The cartilage matrix that lines the knee joint, for example, can support pressures of hundreds of atmospheres by this mechanism.

The amount of GAGs in connective tissue is usually less than 10% by weight of the amount of the fibrous proteins. Because they form porous hydrated gels, however, the GAG chains fill most of the extracellular space, providing mechanical support to tissues while still allowing the rapid diffusion of water-soluble molecules and the migration of cells. The importance of GAGs is illustrated by a rare human genetic disease in which there is a severe deficiency in the synthesis of the dermatan sulfate disaccharide shown in Figure 19-33. The affected individuals are dwarves, have a prematurely aged appearance, and have generalized defects in their skin, joints, muscles, and bones.

It should be emphasized, however, that in invertebrates and in plants other types of polysaccharides often dominate the structure of the extracellular matrix. Thus in higher plants, as we discuss later, cellulose (polyglucose) chains are packed tightly together in ribbonlike crystalline arrays to form the microfibrillar component of the cell wall. In insects, crustaceans, and other arthropods, *chitin* (poly- *N*-acetylglucosamine) similarly forms the main component of the exoskeleton. Together, cellulose and chitin are the most abundant biopolymers on earth.

Hyaluronan Is Thought to Facilitate Cell Migration During Tissue Morphogenesis and Repair [19]

Hyaluronan (also called *hyaluronic acid* or *hyaluronate*) is the simplest of the GAGs. It consists of a regular repeating sequence of up to 25,000 nonsulfated disaccharide units (Figure 19-35). It is found in variable amounts in all tissues and fluids in adult animals and is especially abundant in early embryos. Because of its simplicity, hyaluronan is thought to represent the earliest evolutionary form of GAG, but it is not typical of the majority of GAGs. All of the others (1) contain sulfated sugars, (2) tend to contain a number of different disaccharide units arranged in more complex sequences, (3) have much shorter chains, consisting of fewer than 300 sugar residues, and (4) are covalently linked to protein to form proteoglycans. Moreover, whereas other GAGs are synthesized inside the cell and released by exocytosis, hyaluronan is spun out directly from the cell surface by an enzyme complex that is embedded in the plasma membrane.

Hyaluronan is thought to play a part in resisting compressive forces in tissues and joints. It also has an important role as a space filler during embryonic development, where it can be used to force a change in the shape of a structure. Like styrofoam, it can be quickly and cheaply produced: a small quantity expands with water to occupy a large volume (see Figure 19-34). Hyaluronan synthesized from the basal side of an epithelial sheet, for example, often serves to create a cell-free space into which cells subsequently migrate; this occurs in the formation of the heart, the cornea, and several other organs. When cell migration ends, the excess hyaluronan is generally degraded by the enzyme *hyaluronidase.* Hyaluronan is also produced in large quantities during wound repair, and it is an important constituent of joint fluid, where it serves as a lubricant.

Many of the functions of hyaluronan depend on specific hyaluronan-binding proteins and proteoglycans, some of which are constituents of the extracellular matrix, while others are integral components of the surface of cells. A number of these molecules (sometimes referred to as *hyaladherins*) have been shown to have homologous hyaluronan-binding domains containing a characteristic cluster of positively charged amino acid residues.

Proteoglycans Are Composed of GAG Chains Covalently Linked to a Core Protein [20]

Except for hyaluronan, all GAGs are found covalently attached to protein in the form of proteoglycans, which are made by most

animal cells. As is the case for almost all glycoproteins, the polypeptide chain, or *core protein,* of a proteoglycan is made on membrane-bound ribosomes and threaded into the lumen of the endoplasmic reticulum. The polysaccharide chains are assembled on the core protein mainly in the Golgi apparatus: first a special *link tetrasaccharide* is attached to a serine residue on the core protein to serve as a primer for polysaccharide growth; then one sugar residue at a time is added by specific glycosyl transferases (Figure 19-36). While still in the Golgi apparatus, many of the polymerized sugar residues are covalently modified by a sequential and coordinated series of sulfation reactions and epimerization reactions. The epimerizations alter the configuration of the substituents around individual carbon atoms in the sugar molecule; the sulfations greatly increase the negative charge of the proteoglycans.

The proteoglycans are usually easily distinguished from other glycoproteins by the nature, quantity, and arrangement of their sugar side chains: by definition, at least one of the sugar side chains of a proteoglycan must be a GAG. Glycoproteins contain from 1% to 60% carbohydrate by weight in the form of numerous relatively short, branched oligosaccharide chains. The core protein in a proteoglycan is usually a glycoprotein, but it can contain as much as 95% carbohydrate by weight, mostly in the form of long unbranched GAG chains, each typically about 80 sugar residues long. Proteoglycans can thus be much larger than glycoproteins. The *aggrecan* proteoglycan, for example, which is a major component of cartilage, has a mass of about 3×10^6 daltons; it has over 100 GAG chains, approximately 1 for every 20 amino acid residues. On the other hand, many proteoglycans are much smaller and have only 1 to 10 GAG chains; an example is *decorin,* which is secreted by fibroblasts and has a single GAG chain (Figure 19-37).

In principle, proteoglycans have the potential for almost limitless heterogeneity. Core proteins range in molecular weight from 10,000 to more than 600,000 daltons and vary greatly in the number and types of their attached GAG chains. Moreover, the underlying repeating pattern of disaccharides in each GAG can be modified by a complex pattern of sulfate groups. The heterogeneity of these GAGs makes it difficult to identify and classify proteoglycans in terms of their sugars. The sequences of many core proteins have been determined with the aid of recombinant DNA techniques, and they too are extremely diverse. Although a few small families have been recognized, there is no common structural feature that clearly distinguishes proteoglycan core proteins from other proteins, and many have one or more domains that are homologous to domains found in other proteins of the extracellular matrix or plasma membrane. Thus it is probably best to regard proteoglycans as a diverse group of highly glycosylated glycoproteins whose functions are mediated by both their core proteins and GAG chains.

Proteoglycans Can Regulate the Activities of Secreted Signaling Molecules [21]

Given the structural diversity of proteoglycan molecules, it would be surprising if their function in the extracellular matrix were limited to providing hydrated space around and between cells. Their GAG chains, for example, can form gels of varying pore size and charge density, and they could therefore serve as selective sieves to regulate the traffic of molecules and cells according to their size, charge, or both. There is evidence that a heparan sulfate proteoglycan called *perlecan* has this role in the basal lamina of the kidney glomerulus, which filters molecules passing into the urine from the bloodstream (discussed below).

Proteoglycans are thought to play a major part in chemical signaling between cells. They bind various secreted signaling molecules, such as certain protein growth factors, in a test tube, and it is likely that they do so in tissues. Such binding can enhance or inhibit the activity of the growth factor. *Fibroblast growth factor (FGF),* for example, which stimulates a variety of cell types to proliferate, binds to heparan sulfate chains of proteoglycans both *in vitro* and in tissues; for some cells, this binding seems to be a required step for FGF to activate its cell-surface receptor (which is a transmembrane tyrosine kinase, discussed in Chapter 15). Whereas in most cases the signaling molecules bind to the GAG chains of the proteoglycan, this is not always so: the ubiquitous growth regulatory protein *transforming growth factor* β *(TGF-β)* binds to the core proteins of several matrix proteoglycans, including decorin; binding to decorin inhibits the activity of the TGF-β.

Proteoglycans also bind and regulate the activities of other types of secreted proteins, such as proteolytic enzymes (proteases) and protease inhibitors. Binding to a proteoglycan could control the activity of a protein in any of the following ways: (1) it could immobilize the protein close to the site where it is produced, thereby restricting its range of action; (2) it could sterically block the activity of the protein; (3) it could provide a reservoir of the protein for delayed release; (4) it could protect the protein from proteolytic degradation, thereby prolonging its action; and (5) it could alter or concentrate the protein for more effective presentation to cell-surface receptors. Proteoglycans are thought to act in all these ways to help regulate the activities of secreted proteins.

GAG Chains May Be Highly Organized in the Extracellular Matrix [20], [22]

GAGs and proteoglycans associate to form huge polymeric complexes in the extracellular matrix. Molecules of *aggrecan,* for example, the major proteoglycan in cartilage, shown in Figure 19-37, assemble with hyaluronan in the extracellular space into aggregates that are as big as a bacterium (Figure 19-38).

Moreover, besides associating with one another, GAGs and proteoglycans associate with fibrous matrix proteins such as collagen and with protein meshworks such as the basal lamina, creating extremely complex structures. The arrangement of proteoglycan molecules in living tissues is generally hard to determine. As they are highly water soluble, they may be washed out of the extracellular matrix when tissue sections are exposed to aqueous solutions during fixation; and changes of pH, ionic, or osmotic conditions can drastically alter their conformation. Thus specialized methods have to be used to visualize them *in vivo* (Figure 19-39).

Cell-Surface Proteoglycans Act as Co-Receptors

Not all proteoglycans are secreted components of the extracellular matrix. Some, such as *serglycin,* are constituents of intracellular secretory vesicles, where they help to package and store secretory molecules. Others are integral components of plasma membranes and have their core protein either inserted across the lipid bilayer or attached to the lipid bilayer by a glycosylphosphatidylinositol (GPI) anchor.

Among the best-characterized plasma membrane proteoglycans are the *syndecans,* which have a membrane-spanning core protein. The extracellular domain of this transmembrane proteoglycan carries a variable number of chondroitin sulfate and heparan sulfate GAG chains, while its intracellular domain is thought to interact with the actin cytoskeleton in the cell cortex. Syndecans are found on the surface of many types of cells, including fibroblasts and epithelial cells, where they serve along with integrins as receptors for collagen, fibronectin, and other matrix proteins to which the syndecans bind. As discussed above, syndecans also bind fibroblast growth factor (FGF) and present it to FGF receptor proteins on the same cell. Similarly, another plasma membrane proteoglycan, called *betaglycan,* binds transforming growth factor β (TGF-β) and presents it to TGF-β receptors.

Thus plasma membrane proteoglycans act as *co-receptors* that collaborate with conventional cell-surface receptor proteins, both in binding cells to the extracellular matrix and in initiating the response of cells to some growth factors. The proteoglycans that are discussed in this chapter are summarized in Table 19-3.

Collagens Are the Major Proteins of the Extracellular Matrix [23]

The collagens are a family of highly characteristic fibrous proteins found in all multicellular animals. They are secreted by connective tissue cells, as well as by a variety of other cell types. As a major component of skin and bone, they are the most abundant proteins in mammals, constituting 25% of the total protein mass in these animals. The characteristic feature of a typical collagen molecule is its long, stiff, triple-stranded helical structure, in which three collagen polypeptide chains, called α *chains,* are wound around one another in a ropelike superhelix. Collagens are extremely rich in proline and glycine, both of which are important in the formation of the triple-stranded helix. Proline, because of its ring structure, stabilizes the helical conformation in each a chain, while glycine is regularly spaced at every third residue throughout the central region of the a chain. Being the smallest amino acid (having only a hydrogen atom as a side chain), glycine allows the three helical α chains to pack tightly together to form the final collagen superhelix (Figure 19-40).

So far, about 25 distinct collagen α chains have been identified, each encoded by a separate gene. Different combinations of these genes are expressed in different tissues. Although in principle more than 10,000 types of triple-stranded collagen molecules could be assembled from various combinations of the 25 or so α chains, only about 15 types of collagen molecules have been found. The main types of collagen found in connective tissues are types I, II, III, V, and XI - type I being the principal collagen of skin and bone and by far the most common. These are the fibrillar collagens and have the ropelike structure we have described for a typical collagen molecule. After being secreted into the extracellular space, these collagen molecules assemble into ordered polymers called *collagen fibrils,* which are thin (10-300 nm in diameter) structures, many hundreds of micrometers long in mature tissues and clearly visible in electron micrographs (Figure 19-41, and see Figure 19-39). The collagen fibrils often aggregate into larger, cablelike bundles, which can be seen in the light microscope as *collagen fibers* several micrometers in diameter. Types IX and XII are called *fibril-associated collagens* as they decorate the surface of collagen fibrils; they are thought to link these fibrils to one another and to other components in the extracellular matrix. Types IV and VII are *network-forming collagens*: type IV molecules assemble into a feltlike sheet or meshwork that constitutes a major part of mature basal

laminae, while type VII molecules form dimers that assemble into specialized structures called *anchoring fibrils,* which help attach the basal lamina of multilayered epithelia to the underlying connective tissue and therefore are especially abundant in the skin. The collagen types that we discuss are listed in Table 19-4.

Many proteins that contain a repeated pattern of amino acids have evolved by duplications of DNA sequences. The fibrillar collagens apparently arose in this way. Thus the genes that encode the α chains of most of these collagens are very large (up to 44 kilobases in length) and contain about 50 exons. Most of the exons are 54, or multiples of 54, nucleotides long, suggesting that these collagens arose by multiple duplications of a primordial gene containing 54 nucleotides and encoding exactly 6 Gly-X-Y repeats (see Figure 19-40).

Collagens Are Secreted with a Nonhelical Extension at Each End 23, 24

The individual collagen polypeptide chains are synthesized on membrane-bound ribosomes and injected into the lumen of the endoplasmic reticulum (ER) as larger precursors, called *pro-α chains.* These precursors not only have the short amino-terminal signal peptide required to direct the nascent polypeptide to the ER, they also have additional amino acids, called *propeptides,* at both their amino- and carboxyl-terminal ends. In the lumen of the ER selected proline and lysine residues are hydroxylated to form hydroxyproline and hydroxylysine, respectively, and some of the hydroxylysine residues are glycosylated. Each pro-α chain then combines with two others to form a hydrogen-bonded, triple-stranded helical molecule known as *procollagen.* The secreted forms of fibrillar collagens (but not the other types of collagen) are converted to *collagen molecules* in the extracellular space by the removal of the propeptides (see Figure 19-43).

Hydroxylysine and *hydroxyproline* residues (Figure 19-42) are infrequently found in other animal proteins, although hydroxyproline is abundant in some proteins found in the plant cell wall. In collagen the hydroxyl groups of these amino acids are thought to form interchain hydrogen bonds that help stabilize the triple-stranded helix, and conditions that prevent proline hydroxylation, such as a deficiency of ascorbic acid (vitamin C), have serious consequences. In scurvy, the disease caused by a dietary deficiency of vitamin C that was common in sailors until the last century, the defective pro-α chains that are synthesized fail to form a stable triple helix and are immediately degraded within the cell. Consequently, with the gradual loss of the preexisting normal collagen in the matrix, blood vessels become extremely fragile and teeth become loose in their sockets. This implies that in these particular tissues degradation and replacement of collagen is relatively rapid. In many other adult tissues, however, the turnover of collagen (and other extracellular matrix macromolecules) is thought to be very slow: in bone, to take an extreme example, collagen molecules persist for about 10 years before they are degraded and replaced. By contrast, most cellular proteins have half-lives of hours or days.

After Secretion Fibrillar Procollagen Molecules Are Cleaved to Collagen Molecules, Which Assemble into Fibrils 23, 24, 25

After secretion the propeptides of the fibrillar procollagen molecules are removed by specific proteolytic enzymes outside the cell. This converts the procollagen molecules to collagen molecules, which assemble in the extracellular space to form much larger collagen fibrils. The propeptides have at least two functions: (1) they guide the intracellular formation of the triple-stranded collagen molecules, and (2) because they are removed only after secretion, they prevent the intracellular formation of large collagen fibrils, which could be catastrophic for the cell. The process of fibril formation is driven, in part, by the tendency of the collagen molecules, which are more than 1000-fold less soluble than procollagen molecules, to self-assemble. The fibrils begin to form close to the cell surface, often in deep infoldings of the plasma membrane formed by the tandem fusion of secretory vesicles with the cell surface. The underlying cortical cytoskeleton can therefore influence the sites, rates, and orientation of fibril assembly.

Figure 19-43 summarizes the various steps in the synthesis and assembly of collagen fibrils. Given the large number of enzymatic steps involved in forming a collagen fibril, it is not surprising that there are many human genetic diseases that affect fibril formation. Mutations affecting type I collagen cause *osteogenesis imperfecta,* characterized by weak bones that easily fracture. Mutations affecting type II collagen cause *chondrodysplasias,* characterized by abnormal cartilage, which leads to bone and joint deformities. Mutations affecting type III collagen cause Ehlers-Danlos syndrome, characterized by fragile skin and blood vessels and hypermobile joints.

When viewed in an electron microscope, collagen fibrils have characteristic cross-striations every 67 nm, reflecting the regularly staggered packing of the individual collagen molecules in the fibril (Figure 19-44). After the fibrils form in the extracellular

space, they are greatly strengthened by the formation of covalent cross-links between lysine residues of the constituent collagen molecules (Figure 19-45). The types of covalent bonds involved are found only in collagen and elastin. If cross-linking is inhibited, the tensile strength of the fibrils is drastically reduced; collagenous tissues become fragile, and structures such as skin, tendons, and blood vessels tend to tear. The extent and type of cross-linking varies from tissue to tissue: collagen is especially highly cross-linked in the Achilles tendon, for example, where tensile strength is crucial.

Fibril-associated Collagens Help Organize the Fibrils 26

In contrast to GAGs, which resist compressive forces, collagen fibrils form structures that resist tensile forces. The fibrils come in a variety of diameters and are organized in different ways in different tissues. In mammalian skin, for example, they are woven in a wickerwork pattern so that they resist tensile stress in multiple directions. In tendons they are organized in parallel bundles aligned along the major axis of tension. And in mature bone and in the cornea they are arranged in orderly plywoodlike layers, with the fibrils in each layer lying parallel to each other but nearly at right angles to the fibrils in the layers on either side. The same arrangement occurs in tadpole skin, which serves to illustrate this organization (Figure 19-46).

The connective tissue cells themselves must determine the size and arrangement of the collagen fibrils. The cells can express one or more of the genes for the different types of fibrillar procollagen molecules. But even fibrils composed of the same mixture of fibrillar collagen molecules have different arrangements in different tissues. How is this achieved? Part of the answer may be that cells can regulate the disposition of the collagen molecules after secretion by guiding collagen fibril formation in close association with the plasma membrane (see Figure 19-43). In addition, as the spatial organization of collagen fibrils at least partly reflects their interactions with other molecules in the matrix, cells can influence this organization by secreting, along with their fibrillar collagens, different kinds and amounts of other matrix macromolecules. The fibril-associated collagens, such as *type IX* and *XII* collagen molecules, are thought to be especially important in this regard. They differ from the fibrillar collagens in several ways. (1) Their triple-stranded helical structure is interrupted by one or two short nonhelical domains, which makes the molecules more flexible than fibrillar collagen molecules. (2) They are not cleaved after secretion and so retain their propeptides. (3) They do not aggregate with one another to form fibrils in the extracellular space. Instead, they bind in a periodic manner to the surface of fibrils formed by the fibrillar collagens: type IX molecules bind to type-II-collagen-containing fibrils in cartilage, the cornea, and the vitreous of the eye (Figure 19-47), whereas type XII molecules bind to type-I-collagen-containing fibrils in tendons and various other tissues. The fibril-associated collagens are thought to mediate interactions of collagen fibrils with one another and with other matrix macromolecules. In this way they play a part in determining the organization of the fibrils in the matrix.

Cells Help Organize the Collagen Fibrils They Secrete by Exerting Tension on the Matrix 27

There is yet another way that collagen-secreting cells determine the spatial organization of the collagen matrix they produce. Fibroblasts work on the collagen they have secreted, crawling over it and tugging on it - helping to compact it into sheets and draw it out into cables. This mechanical role of fibroblasts in shaping collagen matrices has been demonstrated dramatically in culture. When fibroblasts are mixed with a meshwork of randomly oriented collagen fibrils that form a gel in a culture dish, the fibroblasts tug on the meshwork, drawing in collagen from their surroundings and causing the gel to contract to a small fraction of its initial volume; by similar activities, a cluster of fibroblasts will surround itself with a capsule of densely packed and circumferentially oriented collagen fibers.

If two small pieces of embryonic tissue containing fibroblasts are placed far apart on a collagen gel, the intervening collagen becomes organized into a compact band of aligned fibers that connect the two explants (Figure 19-48). The fibroblasts subsequently migrate out from the explants along the aligned collagen fibers. Thus the fibroblasts influence the alignment of the collagen fibers, and the collagen fibers in turn affect the distribution of the fibroblasts. Fibroblasts presumably play a similar role in generating long-range order in the extracellular matrix inside the body - in helping to create tendons and ligaments, for example, and the tough, dense layers of connective tissue that ensheathe and bind together most organs.

Elastin Gives Tissues Their Elasticity 28

Many vertebrate tissues, such as skin, blood vessels, and lungs, need to be both strong and elastic in order to function. A network of elastic fibers in the extracellular matrix of these tissues gives them the required resilience so that they can recoil after transient stretch. Elastic fibers are at least five times more extensible than a rubber band of the same cross-sectional area. Long, inelastic collagen fibrils are interwoven with the elastic fibers to limit the extent of stretching and prevent the tissue from tearing.

The main component of elastic fibers is elastin, a highly hydrophobic protein (about 750 amino acid residues long), which, like collagen, is unusually rich in proline and glycine but, unlike collagen, is not glycosylated and contains little hydroxyproline and no hydroxylysine. Elastin molecules are secreted into the extracellular space and assemble into elastic fibers close to the plasma membrane, generally in cell-surface infoldings. After secretion the elastin molecules become highly cross-linked to one another to generate an extensive network of fibers and sheets (Figure 19-49). The cross-links are formed between lysine residues by a mechanism similar to the one that operates in cross-linking collagen molecules.

The elastin protein is composed largely of two types of short segments that alternate along the polypeptide chain - hydrophobic segments, which are responsible for the elastic properties of the molecule, and alanine- and lysine-rich α-helical segments, which form cross-links between adjacent molecules. Each segment is encoded by a separate exon. There is still controversy, however, about the conformation of elastin molecules in elastic fibers and about how the structure of these fibers accounts for their rubberlike properties. In one view the elastin polypeptide chain, like the polymer chains in ordinary rubber, adopts a loose "random coil" conformation, and it is the random-coil structure of the component molecules cross-linked into the elastic fiber network that allows the network to stretch and recoil like a rubber band (Figure 19-50).

Elastic fibers are not composed solely of elastin, however. The elastin core is covered with a sheath of *microfibrils,* each microfibril having a diameter of about 10 nm. While elastic fibers always contain microfibrils, the same microfibrils can be found in extracellular matrices that do not contain elastin. Microfibrils are composed of a number of distinct glycoproteins, including the large glycoprotein *fibrillin,* which seems to be essential for the integrity of elastic fibers. Mutations in the fibrillin gene result in *Marfan's syndrome,* a relatively common human genetic disease that affects connective tissues that are rich in elastic fibers; in the most severely affected individuals, the aorta (whose wall is normally full of elastin - see Figure 19-49) is prone to rupture. Microfibrils are thought to play an important part in the assembly of elastic fibers. They appear before elastin in developing tissues and seem to form a scaffold on which the secreted elastin molecules are deposited. As the elastin is deposited, the microfibrils become displaced to the periphery of the growing fiber.

Fibronectin Is an Extracellular Adhesive Protein That Helps Cells Attach to the Matrix 29

The extracellular matrix contains a number of noncollagen *adhesive proteins* that typically have multiple domains, each with specific binding sites for other matrix macromolecules and for receptors on the surface of cells. These proteins thus contribute to both organizing the matrix and helping cells attach to it. The first of them to be well characterized was fibronectin, a large glycoprotein found in all vertebrates. Fibronectin is a dimer composed of two very large subunits joined by a pair of disulfide bonds near their carboxyl termini. Each subunit is folded into a series of functionally distinct rodlike domains separated by regions of flexible polypeptide chain (Figure 19-51A and B). The domains in turn consist of smaller modules, each of which is serially repeated and usually encoded by a separate exon, suggesting that the fibronectin gene, like the collagen genes, evolved by multiple exon duplications. The main type of module, called the type III fibronectin repeat, is about 90 amino acid residues in length, and it occurs at least 15 times in each subunit (Figure 19-51C). It is also found in some other matrix proteins, as well as in some plasma membrane and cytoplasmic proteins.

One way to analyze a complex multifunctional protein molecule like fibronectin is to chop it into pieces and determine the function of its individual domains. The protein is treated with low concentrations of a proteolytic enzyme, which cuts the polypeptide chain in the connecting regions between the rodlike domains, leaving the domains themselves intact, so that their binding activity can be tested. In this way it was shown that one domain binds to collagen, another to heparin, another to specific receptors on the surface of various types of cells, and so on (see Figure 19-51). Once a domain with cell-binding activity had been isolated, for example, its amino acid sequence could be determined and synthetic peptides corresponding to different segments of the domain prepared. These peptides were used to localize the main region responsible for cell binding and then to identify a specific tripeptide sequence (Arg-Gly-Asp, or RGD), which is found in one of the type III repeats (see Figure 19-51C), as a central feature of the binding site. Even very short peptides containing this RGD sequence will compete with fibronectin for the binding site on cells and so will inhibit the attachment of the cells to a fibronectin matrix. If these peptides are coupled to a solid surface, they cause cells to adhere to it. The RGD sequence is not confined to fibronectin. It is found in a number of extracellular matrix proteins, and it is recognized by several members of the integrin family of cell-surface matrix receptors that bind these proteins (discussed below). Each receptor, however, specifically recognizes its own small set of matrix molecules, indicating that tight receptor binding requires more than just the RGD sequence.

Multiple Forms of Fibronectin Are Produced by Alternative RNA Splicing 29, 30

There are multiple forms (isoforms) of fibronectin, including one called *plasma fibronectin,* which is soluble and circulates in

the blood and other body fluids, where it is thought to enhance blood clotting, wound healing, and phagocytosis. All of the other forms assemble on the surface of cells and are deposited in the extracellular matrix as highly insoluble *fibronectin filaments.* In these cell-surface and matrix forms, fibronectin dimers are cross-linked to one another by additional disulfide bonds; unlike fibrillar collagen molecules, which can be made to self-assemble into fibrils in a test tube, fibronectin molecules assemble into filaments only on the surface of certain cells, suggesting that additional proteins are needed for filament formation.

All forms of fibronectin are encoded by a single large gene that is about 50 kilobases long and contains about 50 exons of similar size. Transcription produces a single large RNA molecule that can be alternatively spliced in three regions, depending on the cell type and stage of development. In humans about 20 different messenger RNAs are produced, each encoding a somewhat different fibronectin subunit. Plasma fibronectin, for example, which is secreted mainly by liver cells, lacks two of the type III repeats that are found in cell- and matrix-associated forms of fibronectin. In some cases alternative splicing adds or deletes a cell-type-specific cell binding site: one such site is used by lymphocytes to adhere to fibronectin.

Alternative splicing presumably allows a cell to produce the type of fibronectin that is most suitable for the needs of the tissue. The pattern of fibronectin RNA splicing in the early embryo is different from that seen later in development; but if adult skin is injured, the pattern of fibronectin RNA splicing in the base of the wound switches back to the pattern seen in early development. These observations suggest that the forms of fibronectin produced in the early embryo and in wound healing are especially appropriate for promoting the cell migrations and proliferation required for tissue development and repair.

The crucial importance of fibronectin in animal development has been dramatically demonstrated by gene "knockout" experiments. Mice with both copies of their fibronectin gene inactivated by mutation, for example, die early in embryogenesis. The mutant mice have multiple morphological defects, including abnormalities in the formation of the notochord, somites, heart, blood vessels, neural tube, and extraembryonic membranes.

Glycoproteins in the Matrix Help Define Cell Migration Pathways 31

Fibronectin is important not only for cell adhesion to the matrix but also for guiding cell migrations in vertebrate embryos. Large amounts of fibronectin, for example, are found along the pathway followed by migrating prospective mesodermal cells during amphibian gastrulation (discussed in Chapter 21). The migration of these cells can be inhibited by injecting into the developing amphibian embryo various ligands that disrupt the ability of the cells to bind to fibronectin: antibodies against fibronectin, peptides containing the RGD cell-binding tripeptide but lacking the matrix-binding domains of fibronectin, and antibodies against an integrin that serves as a fibronectin receptor on these cells all inhibit the migration. Fibronectin presumably promotes cell migration by helping cells attach to the matrix. The effect must be delicately balanced so that the migrating cells can grip the matrix without becoming immobilized on it.

Many types of adhesive molecules in the matrix are believed to play a part in guiding morphogenetic cell movements, and new ones are continually being discovered. Tenascin, for example, is a large glycoprotein complex of six identical or similar disulfide-linked polypeptide chains, which radiate from a center like the spokes of a wheel (see Figure 19-57). As in fibronectin, each of the polypeptide chains is composed of several types of short amino acid sequences that are repeated many times; a fibronectin type III repeat, for instance, occurs eight or more times in each chain. Each polypeptide chain is folded into a number of functionally distinct domains, one of which binds the cell-surface transmembrane proteoglycan syndecan, while another binds fibronectin. Tenascin has a much more restricted distribution than fibronectin and is most abundant in the extracellular matrix of embryonic tissues. Unlike fibronectin, it can either promote or inhibit cell adhesion, depending on the cell type; the adhesive and anti-adhesive functions are thought to be mediated by different protein domains. There is increasing evidence that anti-adhesive interactions, like adhesive ones, play an important part in guiding cell migration, as we discuss in Chapter 21.

Type IV Collagen Molecules Assemble into a Sheetlike Meshwork to Help Form Basal Laminae 32

Our discussion of extracellular matrix thus far has focused on the volume-filling material between cells. But in certain places, especially beneath epithelia, extracellular matrix can also be organized as a thin tough sheet - a *basal lamina.* The construction of basal laminae depends on some specialized types of extracellular matrix molecules, including a specialized variety of collagen, to which we now turn.

Type IV collagen molecules have a more flexible structure than the fibrillar collagens: their triple-stranded helix is interrupted in 26 regions, allowing multiple bends. Like the fibril-associated collagens, they are not cleaved after secretion but retain the

terminal regions that hinder side-to-side packing into long fibrils. Instead, they interact via their uncleaved terminal domains to assemble extracellularly into a flexible, sheetlike, multilayered network. Electron microscopic studies of preparations of assembling type IV collagen molecules suggest that these molecules associate by their carboxyl termini to form head-to-head dimers, which then form an extended lattice via amino-terminal associations with three other molecules and the further lateral associations shown in Figure 19-52. Disulfide and other covalent cross-links between the collagen molecules stabilize these associations. The resulting meshwork forms an insoluble scaffolding to which other components of the basal lamina bind via their specific associations with type IV collagen molecules.

Basal Laminae Are Composed Mainly of Type IV Collagen, Heparan Sulfate Proteoglycan, Laminin, and Entactin 33

Basal laminae are flexible thin (40-120 nm thick) mats of specialized extracellular matrix that underlie all epithelial cell sheets and tubes; they also surround individual muscle cells, fat cells, and Schwann cells (which wrap around peripheral nerve cell axons to form myelin). The basal lamina thus separates these cells and cell sheets from the underlying or surrounding connective tissue. In other locations, such as the kidney glomerulus and lung alveolus, a basal lamina lies between two cell sheets and functions as a highly selective filter (Figure 19-53). Basal laminae serve more than simple structural and filtering roles, however. They are able to determine cell polarity, influence cell metabolism, organize the proteins in adjacent plasma membranes, induce cell differentiation, and serve as specific highways for cell migration.

The basal lamina is largely synthesized by the cells that rest on it (Figure 19-54). As seen in the electron microscope after conventional fixation and staining, most basal laminae consist of two distinct layers: an electron-lucent layer (*lamina lucida* or *rara*) adjacent to the basal plasma membrane of the cells that rest on the lamina - typically epithelial cells - and an electron-dense layer (*lamina densa*) just below. In some cases a third layer containing collagen fibrils (*lamina fibroreticularis*) connects the basal lamina to the underlying connective tissue. Some cell biologists use the term *basement membrane* to describe the composite of all three layers, which is usually thick enough to be seen in the light microscope; others use the terms basal lamina and basement membrane interchangeably. In the basal lamina of some multilayered epithelia, such as the stratified squamous epithelium that forms the epidermis of the skin, the lamina densa is tethered to the underlying connective tissue by specialized *anchoring fibrils* made of *type VII* collagen molecules. In one type of skin-blistering disease these connections are either absent or destroyed, and the epidermis and its basal lamina become detached from the underlying connective tissue.

Although its precise composition varies from tissue to tissue and even from region to region in the same lamina, most mature basal laminae contain type IV collagen (see Figure 19-52), the large heparan sulfate proteoglycan *perlecan,* and the glycoproteins *laminin* and *entactin.* Laminin is one of the first extracellular matrix proteins synthesized in a developing embryo, and early in development basal laminae contain little or no type IV collagen and consist mainly of a laminin network. Laminin is a large (~850,000 daltons) flexible complex of three very long polypeptide chains arranged in the shape of an asymmetric cross and held together by disulfide bonds (Figure 19-55). Like many other proteins in the extracellular matrix, it consists of a number of functional domains: one binds to type IV collagen, one to heparan sulfate, one to entactin, and two or more to laminin receptor proteins on the surface of cells. Like type IV collagen, laminin molecules can self-assemble *in vitro* into a feltlike sheet, largely through interactions between the ends of the laminin arms. A single dumbbell-shaped *entactin* molecule binds tightly to each laminin molecule where the short arms meet the long one; as entactin also binds to type IV collagen, it is thought to act as an additional bridge between the type IV collagen and laminin networks in basal laminae (Figure 19-56).

The shapes and sizes of some of the extracellular matrix molecules discussed in this chapter are compared in Figure 19-57.

Basal Laminae Perform Diverse and Complex Functions 34

In the kidney glomerulus an unusually thick basal lamina acts as a molecular filter, preventing the passage of macromolecules from the blood into the urine as urine is formed (see Figure 19-53). The heparan sulfate proteoglycan seems to be important for this function: when the GAG chains are removed by specific enzymes, the filtering properties of the lamina are destroyed. The basal lamina can also act as a selective barrier to the movement of cells. The lamina beneath an epithelium, for example, usually prevents fibroblasts in the underlying connective tissue from making contact with the epithelial cells. It does not, however, stop macrophages, lymphocytes, or nerve processes from passing through it. The basal lamina plays an important part in tissue regeneration after injury. When tissues such as muscles, nerves, and epithelia are damaged, the basal lamina survives and provides a scaffolding along which regenerating cells can migrate. In this way the original tissue architecture is readily reconstructed. In some cases, as in the skin or cornea, the basal lamina becomes chemically altered following injury - for example, by the addition of fibronectin, which promotes the cell migration required for wound repair.

A particularly striking example of the instructive role of the basal lamina in regeneration comes from studies on the *neuromuscular junction,* the site where a nerve cell transmits its stimulus to a skeletal muscle cell. At the neuromuscular junction the nerve terminals of a motor neuron form a *synapse* with a muscle cell. The basal lamina that surrounds the muscle cell separates the nerve and muscle cell plasma membranes at the synapse. The synaptic region of the basal lamina has a distinctive chemical character: special isoforms of type IV collagen and laminin are found there, for example. This *junctional basal lamina* plays a central role in reconstructing a synapse after nerve or muscle injury. The evidence comes mainly from experiments in frogs. If a frog muscle and its motor nerve are destroyed, the basal lamina around each muscle cell remains and the sites of the old neuromuscular junctions are still recognizable. If the motor nerve but not the muscle is allowed to regenerate, the nerve axons regularly seek out the original synaptic sites on the empty basal laminae and differentiate there to form normal-looking nerve terminals. Thus the junctional basal lamina by itself can guide the regeneration of motor nerve terminals.

Similar experiments show that the basal lamina also controls the localization of the acetylcholine receptors that cluster in the muscle cell plasma membrane at a neuromuscular junction (discussed in Chapter 11). If the muscle and nerve are both destroyed but now the muscle is allowed to regenerate while the nerve is prevented from doing so, the acetylcholine receptors synthesized by the regenerated muscle localize predominantly in the region of the old junctions, even though the nerve is absent (Figure 19-58).

Thus the junctional basal lamina apparently coordinates the local spatial organization of the components in each of the two cells that form a neuromuscular junction. Extracts prepared from junctional basal lamina contain a novel matrix protein called *agrin,* which, when added to cultured muscle cells, initiates the assembly of synaptic structures in their plasma membrane. Motor neurons have been shown to make agrin, and it is thought that they deposit it (and other specialized macromolecules) in the basal lamina at the developing neuromuscular junction and that these matrix-localized molecules help assemble and stabilize the synaptic connection. Agrin is also made by many other types of neurons, raising the possibility that it directs the assembly of receptors and other postsynaptic macromolecules in synapses throughout the nervous system.

It is likely that basal laminae also play a sophisticated part in guiding cell migrations during embryonic development. Thus, in the nematode worm *Caenorhabditis elegans* mutation of a gene coding for a lamininlike protein selectively disrupts the paths taken by certain of the mesoderm cells and nerve axons that migrate over the basal lamina underlying the epidermis. Remarkably, only migrations along the dorsoventral axis of the embryo are affected; migrations along the anteroposterior axis of the same basal lamina occur normally. Such findings, and those on the regeneration of the frog neuromuscular junction, suggest that we still have much to learn about the chemistry and functional specializations of basal laminae.

The Degradation of Extracellular Matrix Components Is Tightly Controlled 35

The regulated turnover of extracellular matrix macromolecules is critical to a variety of important biological processes. Rapid degradation occurs, for example, when the uterus involutes following childbirth or when the tadpole tail is resorbed during metamorphosis. A more localized degradation of matrix components is required when cells migrate through a basal lamina, as when white blood cells migrate across the vascular basal lamina into tissues in response to infection or injury, or when cancer cells migrate from their site of origin to distant organs via the bloodstream or lymphatic vessels, a process known as *metastasis.* Even in the seemingly static extracellular matrix of adult animals there is a slow continual turnover due to degradation and resynthesis.

In each of these cases matrix components are degraded by extracellular proteolytic enzymes that are secreted locally by cells. Most of these proteases belong to one of two general classes: many are metalloproteases, which depend on bound Ca^{2+} or Zn^{2+} for activity, while the others are serine proteases, which have a highly reactive serine residue in their active site. Together, metalloproteases and serine proteases cooperate to degrade matrix proteins such as collagen, laminin, and fibronectin. Some of the metalloproteases, such as the *collagenases,* are highly specific, cleaving particular proteins at a small number of sites, which are often positioned in such a fashion that the structural integrity of the matrix is destroyed by relatively limited proteolysis; in this way cell migration can be greatly facilitated by a relatively small amount of proteolysis.

An important serine protease involved in matrix degradation is *urokinase-type plasminogen activator (U-PA).* This acts as the specific trigger in a proteolytic cascade: its immediate target is *plasminogen,* an inactive serine protease precursor that is abundant in the bloodstream and accumulates at sites of tissue remodeling such as wounds, tumors, and sites of inflammation. U-PA cleaves a single bond in plasminogen to yield the active protease *plasmin.* In contrast to U-PA, plasmin has a broad specificity, cleaving a variety of proteins, including fibrin (a component of blood clots), fibronectin, and laminin.

Several mechanisms operate to ensure that the degradation of matrix components is tightly controlled. First, like plasminogen, many proteases are secreted as inactive precursors that can be activated locally. Second, the action of proteases is confined to specific areas by various secreted protease inhibitors, such as the *tissue inhibitors of metalloproteases (TIMPs)* and the serine protease inhibitors known as *serpins.* These inhibitors are specific for particular proteases and bind tightly to the activated enzyme to block its activity. An attractive idea is that inhibitors are secreted by cells at the margins of areas of active degradation in order to protect uninvolved matrix; they may also protect cell-surface proteins that are required for cell adhesion or migration. Third, many cells have receptors on their surface that bind proteases such as U-PA, thereby confining the enzyme to where it is needed: receptor-bound U-PA is found on nerve growth cones and at the leading edge of migrating white blood cells, for example, where it may serve to clear a pathway for their migration, and it seems to be required for some types of cancer cells to metastasize (Figure 19-59).

Summary

Cells in connective tissues are embedded in an intricate extracellular matrix that not only binds the cells together, but also influences their development, polarity, and behavior. The matrix contains various protein fibers interwoven in a hydrated gel composed of a network of glycosaminoglycan (GAG) chains.

The GAGs are a heterogeneous group of negatively charged polysaccharide chains, which (except for hyaluronan) are covalently linked to protein to form proteoglycan molecules. They occupy a large volume and form hydrated gels in the extracellular space. Proteoglycans are also found on the surface of cells, where they function as co-receptors to help cells bind to the matrix and respond to growth factors.

The fiber-forming proteins can be divided roughly into two functional types: mainly structural (collagens and elastin) and mainly adhesive (such as fibronectin and laminin). The fibrillar collagens (types I, II, III, V, and XI) are ropelike, triple-stranded helical molecules that aggregate into long fibrils in the extracellular space; these in turn can assemble into a variety of highly ordered arrays. Fibril-associated collagen molecules, such as types IX and XII, decorate the surface of collagen fibrils and influence the interactions of the fibrils with one another and with other matrix components. Type IV collagen molecules assemble into a sheetlike meshwork that is a crucial component of all mature basal laminae, which also contain the proteins laminin and entactin, as well as the heparan sulfate proteoglycan perlecan. Elastin molecules form an extensive cross-linked network of fibers and sheets that can stretch and recoil, imparting elasticity to the matrix. Fibronectin and laminin are examples of large, multidomain, adhesive glycoproteins in the matrix; fibronectin is widely distributed in connective tissues, whereas laminin is found mainly in basal laminae. By means of their multiple binding domains, such proteins help organize the extracellular matrix and help cells adhere to it.

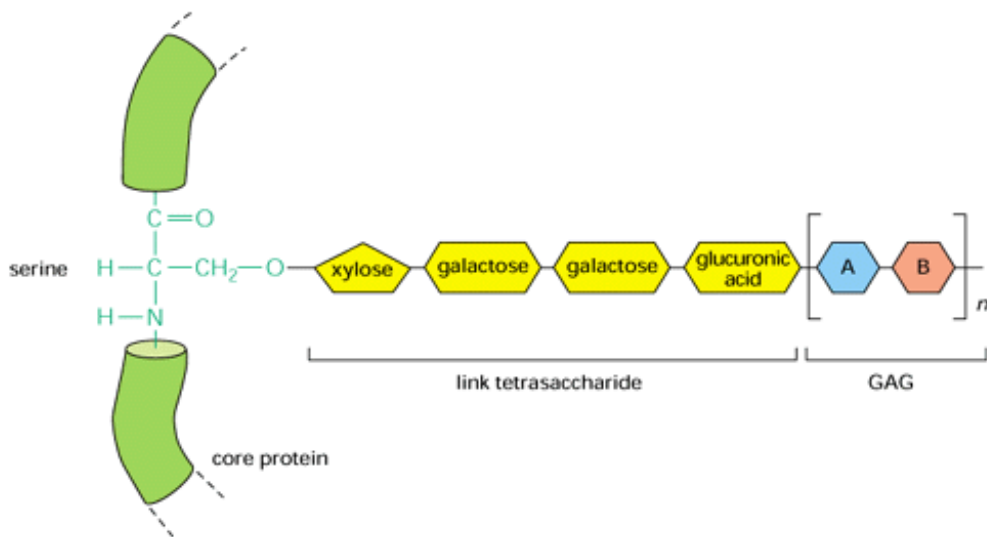
Figure 19-31. The connective tissue underlying an epithelial cell sheet. It consists largely of extracellular matrix that is secreted by the fibroblasts.
Figure 19-32. Scanning electron micrograph of fibroblasts in connective tissue. The tissue is from the cornea of a rat. The extracellular matrix surrounding the fibroblasts is composed largely of collagen fibrils (there are no elastic fibers in the cornea). The glycoproteins, glycosaminoglycans, and proteoglycans, which normally form a hydrated gel filling the interstices of the fibrous network, have been removed by enzyme and acid treatment. (From T. Nishida et al. *Invest. Ophthalmol. Vis. Sci.* 29:1887-1890, 1988.)
Figure 19-57. The comparative shapes and sizes of some of the major extracellular matrix macromolecules. Protein is shown in *green,* glycosaminoglycan in *red.*
Figure 19-33. The repeating disaccharide sequence of a dermatan sulfate glycosaminoglycan (GAG) chain. These chains are typically 70 to 200 sugar residues long. There is a high density of negative charges along the chain resulting from the presence of both carboxyl and sulfate groups.
Figure 19-34. The relative dimensions and volumes occupied by various macromolecules. Several proteins, a glycogen granule, and a single hydrated molecule of hyaluronan are shown.
Figure 19-35. The repeating disaccharide sequence in hyaluronan, a relatively simple GAG. It consists of a single long chain of up to 25,000 sugar residues. Note the absence of sulfate groups.


Figure 19-36. The linkage between a GAG chain and its core protein in a proteoglycan molecule. A specific link tetrasaccharide is first assembled on a serine residue. In most cases it is not clear how the serine residue is selected, but it seems to be a specific local conformation of the polypeptide chain, rather than a specific linear sequence of amino acids, that is recognized. The rest of the GAG chain, consisting mainly of a repeating disaccharide unit, is then synthesized, with one sugar residue being added at a time. In *chondroitin sulfate* the disaccharide is composed of D-glucuronic acid and *N*-acetyl- D-galactosamine; in *heparan sulfate* it is D-glucosamine (or L-iduronic acid) and *N*-acetyl- D-glucosamine; in *keratan sulfate* it is D-galactose and *N*-acetyl- D-glucosamine.
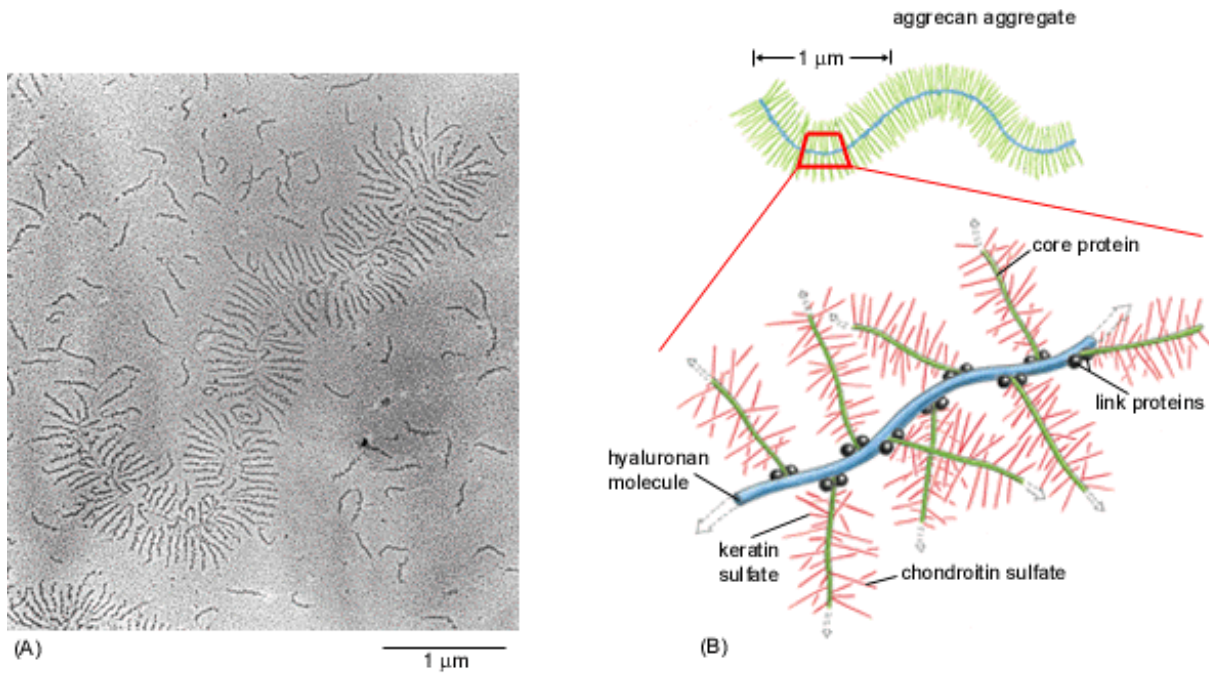
Figure 19-37. Examples of a large (aggrecan) and a small (decorin) proteoglycan found in the extracellular matrix. They are compared to a typical secreted glycoprotein molecule (pancreatic ribonuclease B). All are drawn to scale. The core proteins of both aggrecan and decorin contain oligosaccharide chains as well as the GAG chains, but these are not shown. Aggrecan typically consists of about 100 chondroitin sulfate chains and about 30 keratan sulfate chains linked to a serine-rich core protein of almost 3000 amino acids. Decorin "decorates" the surface of collagen fibrils, hence its name.


Figure 19-38. An aggrecan aggregate from fetal bovine cartilage. (A) Electron micrograph of an aggrecan aggregate shadowed with platinum. Many free aggrecan molecules are also seen. (B) Schematic drawing of the giant aggrecan aggregate shown in (A). It consists of about 100 aggrecan monomers (each like the one shown in Figure 19-37) noncovalently bound to a single hyaluronan chain through two link proteins that bind to both the core protein of the proteoglycan and to the hyaluronan chain, thereby stabilizing the aggregate; the link proteins are members of the hyaladherin family of hyaluronan-binding proteins discussed previously. The molecular weight of such a complex can be 10^8 or more, and it occupies a volume equivalent to that of a bacterium, which is about 2 x 10^{-12} cm $\underline{3}$. (A, courtesy of Lawrence Rosenberg.)
Figure 19-39. Electron micrograph of proteoglycans in the extracellular matrix of rat cartilage. The tissue was rapidly frozen at -196°C and fixed and stained while still frozen (a process called *freeze substitution*) to prevent the GAG chains from collapsing. The proteoglycan molecules are seen to form a fine filamentous network in which a single striated collagen fibril is embedded. The more darkly stained parts of the proteoglycan molecules are the core proteins; the faintly stained threads are the GAG chains. (Reproduced from E.B. Hunziker and R.K. Schenk, *J. Cell Biol.* 98:277-282, 1985, by copyright permission of the Rockefeller University Press.)

Table 19-3. Some Common Proteoglycans

Proteoglycan	Approximate Molecular Weight of Core Protein	Type of GAG Chains	Number of GAG Chains	Location	Functions
Aggrecan	210,000	chondroitin sulfate + keratan sulfate	~130	cartilage	mechanical support; forms large aggregates with hyaluronan
Betaglycan	36,000	chondroitin sulfate/ dermatan sulfate	1	cell surface and matrix	binds TGF-b
Decorin	40,000	chondroitin sulfate/ dermatan sulfate	1	widespread in connective tissues	binds to type I collagen fibrils and TGF-b
Perlecan	600,000	heparan sulfate	2-15	basal laminae	structural and filtering function in basal lamina
Serglycin	20,000	chondroitin sulfate/ dermatan sulfate	10-15	secretory vesicles in white blood cells	helps to package and store secretory molecules
Syndecan-1	32,000	chondroitin sulfate + heparan sulfate	1-3	fibroblast and epithelial cell surface	cell adhesion; binds FGF
Figure 19-40. The structure of a typical collagen molecule. (A) A model of part of a single collagen a chain in which each

amino acid is represented by a sphere. The chain contains about 1000 amino acid residues and is arranged as a left-handed helix with three amino acid residues per turn and with glycine as every third residue. Therefore an a chain is composed of a series of triplet Gly-X-Y sequences in which X and Y can be any amino acid (although X is commonly proline and Y is commonly hydroxyproline). (B) A model of a part of a collagen molecule in which three a chains, each shown in a different color, are wrapped around one another to form a triple-stranded helical rod. Glycine is the only amino acid small enough to occupy the crowded interior of the triple helix. Only a short length of the molecule is shown; the entire molecule is 300 nm long. (From model by B.L. Trus.)

Table 19-4. Some Types of Collagen and Their Properties

	Type	Molecular Formula	Polymerized Form	Tissue Distribution
FIBRIL-FORMING (FIBRILLAR)	I	[a 1(I)]$_2$a2(I)	fibril	bone, skin, tendon, ligaments, cornea, internal organs (accounts for 90% of body collagen)
	II	[a 1(II)]$_3$	fibril	cartilage, intervertebral disc, notochord, vitreous humor of the eye
	III	[a 1(III)]$_3$	fibril	skin, blood vessels, internal organs
	V	[a 1(V)]$_2$a2(V)	fibril (with type I)	as for type I
	XI	a1(XI) a2(XI) a3(XI)	fibril (with type II)	as for type II
FIBRIL-ASSOCIATED	IX	a1(IX) a2(IX) a3(IX) with type II fibrils	lateral association	cartilage
	XII	[a 1(XII)]$_3$ with some type I fibrils	lateral association	tendon, ligaments, some other tissues
NETWORK-FORMING	IV	[a 1(IV)$_2$a2(IV)	sheetlike network	basal laminae
	VII	[a 1(VII)]$_3$	anchoring fibrils	beneath stratified squamous epithelia

Note that types I, IV, V, and XI are each composed of 2 or 3 types of a chain, whereas types II, III, VII, and XII are composed of only 1 type of a chain each. Only 9 types of collagen are shown, but about 15 types of collagen and about 25 types of a chain have been defined so far.
1 μm

Figure 19-41. Electron micrograph of fibroblasts surrounded by collagen fibrils in the connective tissue of embryonic chick skin. The fibrils, which are organized into bundles that run approximately at right angles to one another, are produced by the fibroblasts. These cells contain abundant endoplasmic reticulum, where secreted proteins such as collagen are synthesized. (From C. Ploetz, E.I. Zycband, and D.E. Birk, *J. Struct. Biol.* 106:73-81, 1991.)
Figure 19-43. The intracellular and extracellular events involved in the formation of a collagen fibril. Note that collagen fibrils are shown assembling in the extracellular space contained within a large infolding in the plasma membrane. As one example of how the collagen fibrils can form ordered arrays in the extracellular space, they are shown further assembling into large collagen fibers, which are visible in the light microscope. The covalent cross-links that stabilize the extracellular assemblies are not shown.

hydroxylysine
in protein

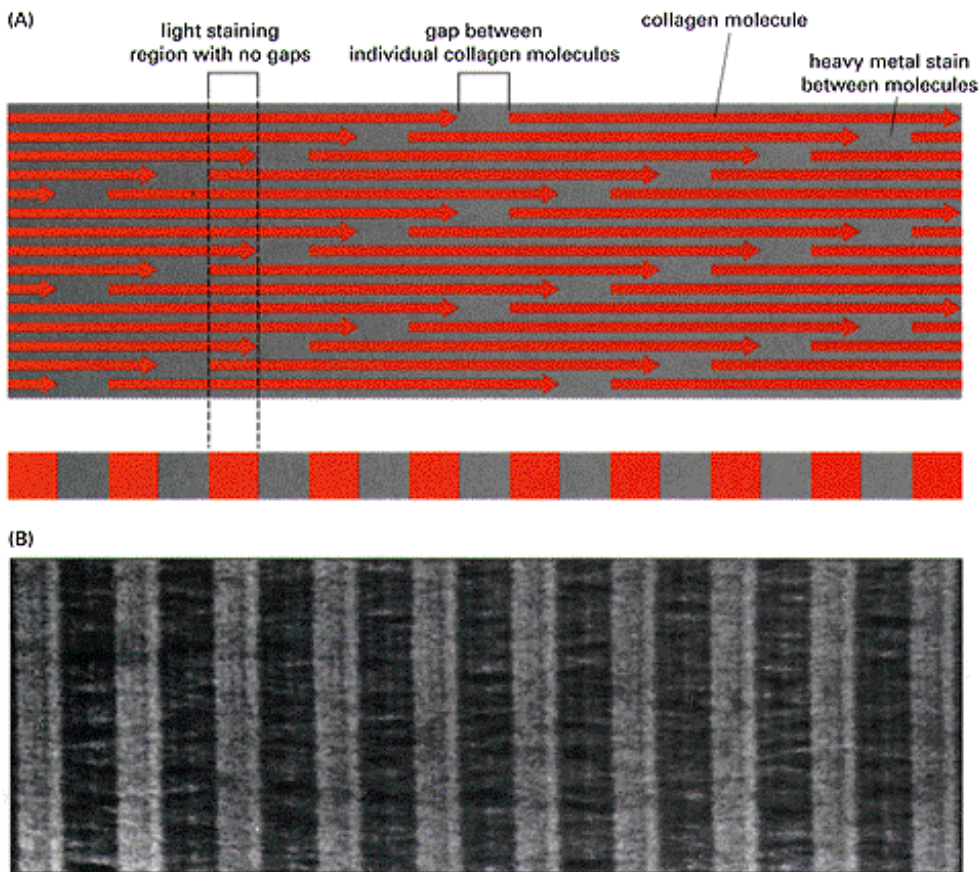
hydroxyproline
in protein
Figure 19-42. Hydroxylysine and hydroxyproline residues. These modified amino acids are common in collagen; they are formed by enzymes that act after the lysine and proline are incorporated into procollagen molecules.


Figure 19-44. How the staggered arrangement of collagen molecules gives rise to the striated appearance of a negatively stained fibril. (A) Since the negative stain fills only the space between the molecules, the stain in the gaps between the individual molecules in each row accounts for the dark staining bands. An electron micrograph of a portion of a negatively stained fibril is shown below (B). The staggered arrangement of the collagen molecules maximizes the tensile strength of the aggregate. (B, courtesy of Robert Horne.)
Figure 19-45. The covalent intramolecular and intermolecular cross-links formed between modified lysine side chains within a collagen fibril. The cross-links are formed in several steps. First, certain lysine and hydroxylysine residues are deaminated by the extracellular enzyme lysyl oxidase to yield highly reactive aldehyde groups. The aldehydes then react spontaneously to form covalent bonds with each other or with other lysine or hydroxylysine residues. Most of the cross-links form between the short nonhelical segments at each end of the collagen molecules.
Figure 19-46. Electron micrograph of a cross-section of tadpole skin. Note the plywoodlike arrangement of collagen fibrils, in which successive layers of fibrils are laid down nearly at right angles to each other. This arrangement is also found in mature bone and in the cornea. (Courtesy of Jerome Gross.)
Figure 19-47. Type IX collagen. (A) Schematic drawing of type IX collagen molecules binding in a periodic pattern to the surface of a type-II-collagen-containing fibril. (B) Electron micrograph of a rotary-shadowed type-II-collagen-containing fibril in cartilage sheathed in type IX collagen molecules; an individual type IX collagen molecule is shown in (C). (B and C, from L. Vaughan et al., *J. Cell Biol.* 106:991-997, 1988, by copyright permission of the Rockefeller University Press.)
Figure 19-48. The shaping of the extracellular matrix by cells. This micrograph shows a region between two pieces of embryonic chick heart (rich in fibroblasts as well as heart muscle cells) that has grown in culture on a collagen gel for four days. A dense tract of aligned collagen fibers has formed between the explants, presumably as a result of the fibroblasts in the explants tugging on the collagen. (From D. Stopak and A.K. Harris, *Dev. Biol.* 90:383-398, 1982.)

Figure 19-49. A network of elastic fibers. These scanning electron micrographs show a low-power view of a segment of a dog's aorta (A) and a high-power view of the dense network of longitudinally oriented elastic fibers in the outer layer of the same blood vessel (B). All of the other components have been digested away with enzymes and formic acid. (From K.S. Haas, S. J. Phillips, A.J. Comerota, and J.W. White, *Anat. Rec.* 230:86-96, 1991.)
Figure 19-50. Stretching a network of elastin molecules. The molecules are joined together by covalent bonds (indicated in *red*) to generate a cross-linked network. In the model shown each elastin molecule in the network can expand and contract as a random coil, so that the entire assembly can stretch and recoil like a rubber band.
Figure 19-51. The structure of a fibronectin dimer. As shown schematically in (A), the two polypeptide chains are similar but generally not identical (being made from the same gene but from differently spliced mRNAs). They are joined by two disulfide bonds near the carboxyl terminus. Each chain is almost 2500 amino acid residues long and is folded into five or six rodlike domains connected by flexible polypeptide segments. Individual domains are specialized for binding to a particular molecule or to a cell, as indicated for three of the domains. For simplicity, not all of the known binding sites are shown (there are other cell-binding sites, for example). (B) Electron micrographs of individual molecules shadowed with platinum; *arrows* mark the carboxyl termini. (C) The three-dimensional structure of a type III fibronectin repeat, as determined by nuclear magnetic resonance studies. It is the main type of repeating module in fibronectin and is also found in many other proteins. The Arg-Gly-Asp (RGD) sequence shown is part of the major cell-binding site (shown in *blue* in [A]) that we discuss in the text. (B, from J.
Figure 19-52. How type IV collagen molecules are thought to assemble into a multilayered network. The model is based on electron micrographs of rotary-shadowed preparations of these molecules assembling *in vitro.* (Based on P.D. Yurchenco, E. C. Tsilibary, A.S. Charonis, and H. Furthmayr, *J. Histochem. Cytochem.* 34:93-102, 1986.)
Figure 19-53. Three ways in which basal laminae (*yellow lines*) are organized. They surround certain cells (such as muscle cells), underlie epithelial cell sheets, and are interposed between two cell sheets (as in the kidney glomerulus). Note that in the kidney glomerulus both cell sheets have gaps in them, so that the basal lamina serves as the permeability barrier determining which molecules will pass into the urine from the blood.
Figure 19-54. Scanning electron micrograph of a basal lamina in the cornea of a chick embryo. Some of the epithelial cells (E) have been removed to expose the upper surface of the matlike basal lamina (BL). A network of collagen fibrils (C) in the underlying connective tissue interacts with the lower face of the lamina. (Courtesy of Robert Trelstad.)
Figure 19-55. The structure of laminin. A schematic drawing of a laminin molecule is shown in (A), and electron micrographs of laminin molecules shadowed with platinum are shown in (B). This multidomain glycoprotein is composed of three polypeptides (A, B_1, and B_2) that are disulfide bonded into an asymmetric crosslike structure. Each of the polypeptide chains is more than 1500 amino acid residues long. Three types of a chains, three types of B_1 chains, and two types of B_2 chains have been identified, which in principle can associate to form 18 different laminin isoforms. Several such isoforms have been found, each with a characteristic tissue distribution. There are also several isoforms of type IV collegen, each with a distinctive tissue distribution. Thus basal laminae are chemically diverse, which is not surprising in view of their functional diversity. (B, from J. Engel et al., *J. Mol. Biol.* 150:97-120, 1981. © Academic Press Inc. [London] Ltd.)

Figure 19-56. A current model of the molecular structure of a basal lamina. The basal lamina (A) is formed by specific interactions between the proteins type IV collagen, laminin, and entactin plus the proteoglycan perlecan (B). Arrows in (B) connect molecules that can bind directly to each other. (Based on P.D. Yurchenco and J.C. Schittny, *FASEB J.* 4:1577-1590, 1990.)
Figure 19-58. Regeneration experiments indicating the special character of the junctional basal lamina at a neuromuscular junction. When the nerve, but not the muscle, is allowed to regenerate after both the nerve and muscle have been damaged (*upper* part of figure), the junctional lamina directs the regenerating nerve to the original synaptic site. When the muscle, but not the nerve, is allowed to regenerate (*lower* part of figure), the junctional lamina causes newly made acetylcholine receptors to accumulate at the original synaptic site (the muscle regenerates from satellite cells located between the basal lamina and the original muscle cell - not shown, but see p. 1178). These experiments show that the junctional basal lamina controls the localization of other components of the synapse - on both sides of the lamina.
Figure 19-59. Importance of cell-surface-receptor-bound protease. In (A) human prostate cancer cells make and secrete the serine protease U-PA, which binds to cell-surface U-PA receptor proteins. In (B) the same cells have been transfected with DNA that encodes an excess of an inactive form of U-PA, which binds to the U-PA receptors but has no protease activity; by

occupying most of the U-PA receptors, the inactive U-PA prevents the active protease from binding to the cell surface. Both types of cells secrete active U-PA, grow rapidly, and produce tumors when injected into experimental animals. But the cells in (A) metastasize widely, whereas the cells in (B) do not. In order to metastasize, tumor cells have to crawl through basal laminae and other extracellular matrices on the way into and out of the bloodstream. This experiment therefore suggests that proteases must be cell-surface bound to mediate migration through the matrix.

Extracellular Matrix Receptors on Animal Cells: The Integrins

Introduction

To understand how the extracellular matrix interacts with cells, one has to identify the cell-surface molecules (*matrix receptors*) that bind the matrix components as well as the extracellular matrix components themselves. Because of the multiple interactions among matrix macromolecules in the extracellular space, it is largely a matter of semantics where the plasma membrane components end and the extracellular matrix begins. The ultimate link to the cell, however, requires a transmembrane protein that ties the matrix to the cell's cortical cytoskeleton. Although we have seen that some proteoglycans with transmembrane core proteins function as co-receptors for matrix components, the principal receptors on animal cells for binding most extracellular matrix proteins, including collagen, fibronectin, and laminin, are the integrins, a large family of homologous transmembrane linker proteins.

Integrins differ from cell-surface receptors for hormones and for other soluble signaling molecules in that they bind their ligand with relatively low affinity ($K_a = 10^6$- 10^9 liters/mole) and are usually present at about 10- to 100-fold higher concentration on the cell surface. This arrangement makes sense, as binding simultaneously but weakly to large numbers of matrix molecules allows cells to explore their environment without losing all attachment to it. If the binding were too tight, cells would presumably become irreversibly glued to the matrix and be unable to move - a problem that does not arise if attachment depends on multiple weak adhesions. This is an example of the "Velcro principle" mentioned earlier.

Integrins Are Transmembrane Heterodimers [36]

Integrins are crucially important receptor proteins because they are the main way that cells both bind to and respond to the extracellular matrix. They are composed of two noncovalently associated transmembrane glycoprotein subunits called α and β, both of which contribute to the binding of the matrix protein (Figure 19-60). Whereas some integrins seem to bind only one matrix macromolecule such as fibronectin or laminin, others bind more than one: an integrin that is present on fibroblasts, for example, binds collagen, fibronectin, and laminin. One subfamily of integrins recognizes the RGD sequence present in these and other matrix proteins, while other integrins recognize various other sequences or domains. Since the same integrin molecule in different cell types can have different ligand-binding activities, it seems that additional cell-type-specific factors can interact with integrins to modulate their binding activity.

The binding of integrins to their ligands depends on extracellular divalent cations (Ca^{2+} or Mg^{2+}, depending on the integrin), reflecting the presence of three or four divalent-cation-binding domains in the large extracellular part of the a chain. This property can be used to purify integrins: detergent-solubilized plasma membrane proteins are passed over an affinity column that contains an extracellular matrix protein or an RGD-containing peptide, and the bound integrins are then eluted from the column by washing in a divalent-cation-free solution. The type of divalent cation can influence both the affinity and specificity of the binding of an integrin to its ligands, but, as in the case of the cadherins, the physiological significance of this cation regulation is unknown.

Many matrix proteins in vertebrates are recognized by multiple integrins: for example, at least 8 integrins bind fibronectin, and at least 5 bind laminin. About 20 integrin heterodimers, made from 9 types of β subunits and 14 types of α subunits, have been defined, and new ones are still being discovered. This diversity is further increased by the alternative splicing of some integrin RNAs. The β_1 chains, which form dimers with at least 9 distinct α chains, are found on almost all vertebrate cells; $\alpha_5\beta_1$, for example, is a fibronectin receptor, and $\alpha_6\beta_1$ is a laminin receptor on many types of cells. β_2 chains, by contrast, which form dimers with 3 types of α chains, are expressed exclusively on the surface of white blood cells, and they play an essential role in enabling these cells to fight infection. One of these β_2 integrins ($\alpha_L\beta_2$) is called *LFA1* (for lymphocyte function associated); another ($\alpha_M\beta_2$) is called *Mac1* because it is found mainly on macrophages. The β_2 integrins mainly mediate cell-cell, rather than cell-matrix, interactions by binding to specific ligands on another cell, such as an endothelial cell lining a blood vessel; the

ligands, sometimes referred to as *counterreceptors,* are members of the immunoglobulin superfamily of cell adhesion molecules discussed earlier. The β_2 integrins enable white blood cells, for example, to attach firmly to and cross the endothelial lining of blood vessels at sites of infection. Humans with the genetic disease called *leucocyte adhesion deficiency* are unable to synthesize the β_2 subunit; as a consequence, their white blood cells lack the entire family of β_2 receptors, and they suffer repeated bacterial infections. β_3 integrins are found on a variety of cells, including blood platelets, and they bind several matrix proteins, including *fibrinogen;* platelets interact with fibrinogen during blood clotting, and humans with *Glanzmann's disease,* who are genetically deficient in β_3 integrins, bleed excessively.

Two integrins that share a common β subunit have been described in *Drosophila.* If both copies of the *Drosophila* gene encoding this β subunit are mutated, the flies die as embryos; they develop normally until the first muscle contractions begin, at which point the muscles tear away from their extracellular matrix attachment sites.

Integrins Must Interact with the Cytoskeleton in Order to Bind Cells to the Extracellular Matrix <u>37</u>

Integrins function as transmembrane linkers (or "integrators") mediating the interactions between the cytoskeleton and the extracellular matrix that are required for cells to grip the matrix. Most integrins connect to bundles of actin filaments. (The integrin found in hemidesmosomes -$\alpha_6\beta_4$- is an exception in that it connects to intermediate filaments.) Following the binding of a typical integrin to its ligand in the matrix, the cytoplasmic tail of the β chain binds to both *talin* and α-actinin and thereby initiates the assembly of a complex of intracellular attachment proteins that link the integrin to actin filaments in the cell cortex; this is thought to be how *focal contacts* form between cells and the extracellular matrix, as discussed earlier. If the cytoplasmic domain of the β chain is deleted using recombinant DNA techniques, the mutant integrins still bind to their ligands but no longer mediate robust cell adhesion or cluster at focal contacts. It seems that integrins must interact with the cytoskeleton in order to bind cells to the matrix, just as cadherins must interact with the cytoskeleton in order to hold cells together. As discussed earlier, a transmembrane attachment to the cytoskeleton appears to be an important general requirement for both cell-matrix and cell-cell adhesions: without such internal anchorage the attachment site is liable to be ripped out of the cell (see <u>Figure 19-29</u>). The cytoskeletal attachments may also help to cluster the integrins together to give a strong aggregate bond (the Velcro principle again).

As we shall discuss next, the interactions that integrins mediate between the extracellular matrix and the cytoskeleton operate in both directions and play an important part in orienting both the cells and the matrix in a tissue.

Integrins Enable the Cytoskeleton and Extracellular Matrix to Communicate Across the Plasma Membrane <u>37</u>, <u>38</u>

The matrix can influence the organization of a cell's cytoskeleton. This can be vividly demonstrated with transformed (cancerlike) fibroblasts in culture (discussed in <u>Chapter 24</u>). Transformed cells often make less fibronectin than normal cultured cells and behave differently. They adhere poorly to the substratum, for example, and fail to flatten out or develop the organized intracellular actin filament bundles known as *stress fibers.* This may contribute to the tendency of cancer cells to break away from the primary tumor and spread to other parts of the body. In some cases the fibronectin deficiency seems to be at least partly responsible for this abnormal morphology: if the cells are grown on a matrix of organized fibronectin filaments, they flatten out and assemble intracellular stress fibers that are aligned with the extracellular fibronectin filaments.

This interaction between the extracellular matrix and the cytoskeleton is reciprocal in that intracellular actin filaments can influence the orientation of secreted fibronectin molecules. Extracellular fibronectin filaments, for example, assemble on or near the surface of cultured fibroblasts in alignment with adjacent intracellular stress fibers (<u>Figure 19-61</u>). If these cells are treated with the drug cytochalasin, which disrupts actin filaments, the fibronectin filaments dissociate from the cell surface (just as they do during mitosis when a cell rounds up). These reciprocal interactions between extracellular fibronectin and intra-cellular actin filaments across the fibroblast plasma membrane are mediated mainly by integrins.

Since the cytoskeletons of cells can exert forces that orient the matrix macromolecules that the cells secrete, and the matrix macromolecules can in turn organize the cytoskeletons of cells that contact them, the extracellular matrix can in principle propagate order from cell to cell (<u>Figure 19-62</u>), creating large-scale oriented structures, as we saw earlier (see p. 984). The integrins serve as adapters in this ordering process, mediating the interactions between cells and the matrix around them.

Cells Can Regulate the Activity of Their Integrins <u>39</u>

Whereas the matrix-binding integrins of many cells in tissues are constantly in an adhesive-competent state, the integrins on blood cells often have to be activated before they can mediate cell adhesion. Such regulated adhesion presumably allows blood cells to circulate unimpeded until they are activated by an appropriate stimulus; because the integrins do not need to be synthesized *de novo,* the response can be rapid. Platelets, for example, can be activated by contact with a damaged blood vessel or any one of a number of soluble signaling molecules. The stimulus triggers intracellular signaling pathways, which in turn rapidly and permanently activate a β_3 integrin in the platelet membrane, altering its conformation so that its extracellular domain becomes able to bind the blood-clotting protein fibrinogen with high affinity, thereby promoting platelet aggregation and blood clot formation (Figure 19-63A). Similarly, the weak binding of T lymphocytes, either to their specific antigen on the surface of an antigen-presenting cell or to a virus-infected cell (discussed in Chapter 23), triggers intracellular signaling pathways in the T cells, which leads to the rapid but transient activation of an integrin (*LFA1*) on the T cells. The activated integrin enables the T lymphocytes to adhere strongly to the target cell, so that they remain in contact long enough to become stimulated; the integrin then returns to an inactive state to allow the T lymphocytes to disengage. The mechanisms by which intracellular signaling events activate the extracellular binding site of an integrin on a blood cell are largely unknown.

Other intracellular events can inactivate integrins. The phosphorylation of a serine residue on the cytoplasmic tail of a β_1 integrin during mitosis in cultured cells, for example, impairs the ability of the integrin to bind fibronectin, which may explain why these cells round up and detach from the substratum during mitosis. Similarly, in some cancer cells the phosphorylation of a tyrosine residue on the cytoplasmic tail of a fibronectin-binding integrin reduces the ability of the integrin to bind to talin, and this is thought to contribute to the relatively poor adhesion of these cells to fibronectin (Figure 19-63B).

Integrins Can Activate Intracellular Signaling Cascades [40]

Extracellular matrix macromolecules have striking effects on the behavior of cells in culture, influencing their shape, polarity, movement, metabolism, development, and differentiated functions. Many of these effects involve changes in gene expression, and almost all of them are mediated by integrins. We have already discussed how integrins function as transmembrane linkers that connect extracellular matrix molecules to actin filaments in the cell cortex and thereby regulate the shape, orientation, and movement of cells. But there is increasing evidence that the clustering of integrins at the sites of contact with the matrix (or another cell) can also activate several intracellular signaling pathways, including the inositol phospholipid pathway; in addition, several intracellular proteins, including a tyrosine kinase located in focal contacts, become phosphorylated on tyrosine residues. Although the molecular mechanisms are not known, it seems likely that clustered integrins generate intracellular signals by initiating the assembly of a signaling complex at the cytoplasmic face of the plasma membrane, in much the same way that growth factor receptor tyrosine kinases operate (discussed in Chapter 15). Signaling by both integrins and growth factor receptors frequently seems to be required for an optimal cellular response: many cells in culture, for example, will not proliferate in response to growth factors unless the cells are attached via integrins to extracellular matrix molecules. The challenge is to determine how these signaling cascades interact to influence complex cell behaviors such as gene expression and cell proliferation.

The cell adhesion molecules discussed in this chapter are summarized in Table 19-5.

Summary

Integrins are the principal receptors used by animal cells to bind to the extracellular matrix. They are heterodimers that function as transmembrane linkers that mediate bidirectional interactions between the extracellular matrix and the actin cytoskeleton. They also function as signal transducers, activating various intracellular signaling pathways when activated by matrix binding. A cell can regulate the adhesive activity of its integrins by altering either their matrix-binding site or their attachment to actin filaments.
Figure 19-60. The subunit structure of an integrin cell-surface matrix receptor. Electron micrographs of isolated receptors suggest that the molecule has approximately the shape shown, with the globular head projecting more than 20 nm from the lipid bilayer. By binding to a matrix protein outside the cell and to the actin cytoskeleton (via the attachment proteins talin and a-actinin) inside the cell, the protein serves as a transmembrane linker. The a and b chains are both glycosylated (not shown) and are held together by noncovalent bonds. In the fibronectin receptor shown, the a chain is made initially as a single 140,000-dalton polypeptide chain, which is then cleaved into one small transmembrane chain and one large extracellular chain that remain held together by a disulfide bond; this extracellular chain is folded into four divalent-cation-binding domains. The extracellular part of the b chain contains a repeating cysteine-rich region, where intrachain disulfide bonding occurs; the b chain has a mass of about 100,000 daltons.
Figure 19-61. Coalignment of extracellular fibronectin filaments and intracellular actin filament bundles. The fibronectin is visualized in two rat fibroblasts in culture by the binding of rhodamine-coupled anti-fibronectin antibodies (A). The actin is visualized by the binding of fluorescein-coupled anti-actin antibodies (B). (From R.O. Hynes and A.T. Destree, *Cell* 15:875-886, 1978. © Cell Press.)
orientation of cytoskeleton in cell ① orients the assembly of secreted extra-cellular matrix molecules in the vicinity
the oriented extracellular matrix reaches cells ② and ③ and orients the cytoskeleton of those cells
cells ② and ③ now secrete an oriented matrix in their vicinity; in this way the ordering of cytoskeletons is propagated to cells ④ and ⑤

Figure 19-62. How the extracellular matrix could propagate order from cell to cell within a tissue. For simplicity, the figure represents a hypothetical scheme in which one cell influences the orientation of its neighboring cells. It is more likely, however, that the cells would mutually affect one another's orientation.
Figure 19-63. Cells can regulate the activity of their integrins. In (A) cell activation leads to a change in the extracellular binding site of the integrin so that it can now mediate cell adhesion. In (B) the tyrosine phosphorylation of the cytoplasmic tail of the integrins impairs their ability to bind to the actin cytoskeleton. As integrins must bind to the cytoskeleton to mediate robust cell-matrix adhesion, the phosphorylation causes the integrins to relax their grip on the extracellular matrix.

Table 19-5. Cell Adhesion Molecule Families

	Some Family Members	Ca^{2+}- or Mg^{2+} - dependence	Homophilic or Heterophilic	Cytoskeleton Associations	Cell Junction Associations
CELL-CELL ADHESION					
Cadherins	E, N, P cadherins	yes	homophilic	actin filaments (via catenins)	adhesion belts
	desmosomal cadherins	yes	homophilic	intermediate filaments (via desmoplakins, plakoglobin and other proteins)	desmosomes
Ig family members	N-CAM, L1	no	homophilic or heterophilic	unknown	no
Selectins (blood cells + endothelial cells only)	P-selectin (see p. 504)	yes	heterophilic	unknown	no
Integrins on blood cells	LFA-1 ($a_L b_2$), Mac-1 ($a_M b_2$)	yes	heterophilic	actin filaments	no

CELL-MATRIX ADHESION

Integrins	many types	yes	heterophilic	actin filaments (via talin, vinculin, and other proteins)	focal contacts
	a_6b_4	yes	heterophilic	intermediate filaments	hemidesmosomes
Transmembrane Proteoglycans	syndecans	no	heterophilic	actin filaments	no

The Plant Cell Wall

Introduction

The plant cell wall is an elaborate extracellular matrix that encloses each cell in a plant. It was the thick cell walls of cork, visible in a primitive microscope, that in 1663 enabled Robert Hooke to distinguish cells clearly and to name them as such. The walls of neighboring plant cells, cemented together to form the intact plant (Figure 19-64), are generally thicker, stronger, and, most important of all, more rigid than the extracellular matrix produced by animal cells. In evolving relatively rigid walls, which can be up to many micrometers in thickness, early plant cells forfeited the ability to crawl about and adopted a sedentary life-style that has persisted in all present-day plants.

The Composition of the Cell Wall Depends on the Cell Type 41

Most newly formed cells in a multicellular plant are produced in special regions called *meristems*, as explained in Chapter 21. These new cells are generally small in comparison to their final size, and to accommodate subsequent cell growth, their walls, called primary cell walls, are thin and only semirigid. Once growth stops and the wall no longer needs to be able to expand, either the primary wall is simply retained or, far more commonly, a rigid, secondary cell wall is produced, either by thickening the primary wall or by depositing new layers with a different composition underneath the old ones. In addition to a structural or "skeletal" role, the cell wall also protects the underlying cell and functions in the transport of fluid within the plant. When plant cells become specialized, they generally produce specially adapted types of walls, according to which the different types of cells in a plant can be recognized and classified.

Although the primary cell walls of higher plants vary greatly in both composition and organization, like all extracellular matrices they are constructed according to a common principle: they derive their tensile strength from long fibers and their resistance to compression from the matrix of protein and polysaccharide in which the fibers are embedded. In the cell walls of higher plants the fibers are generally made from the polysaccharide *cellulose,* the most abundant organic macromolecule on earth. The rest of the matrix is composed predominantly of two other types of polysaccharide, *hemicellulose* and *pectin,* together with structural proteins. All of these molecules are held together by a combination of covalent and noncovalent bonds to form a highly complex structure whose composition depends on the cell type.

The Tensile Strength of the Cell Wall Allows Plant Cells to Develop Turgor Pressure 42

The aqueous extracellular environment of a plant cell consists of the fluid contained in the walls that surround the cell. Although the fluid in the plant cell wall contains more solutes than does the water in the plant's external milieu (for example, soil), it is still hypotonic in comparison to the cell interior. This osmotic imbalance causes the cell to develop a large internal hydrostatic pressure, or turgor pressure, that pushes outward on the cell wall, just as an inner tube pushes outward on a tire. The turgor pressure increases just to the point where the cell is in osmotic equilibrium, with no net influx of water despite the salt imbalance (see Panel 11-1, p. 517). This pressure is vital to plants because it is the main driving force for cell expansion during growth, and it provides much of the mechanical rigidity of living plant tissues. Compare the wilted leaf of a dehydrated plant, for example, with the turgid leaf of a well-watered one. It is the mechanical strength of the cell wall that allows plant cells to sustain this internal pressure.

The Cell Wall Is Built from Cellulose Microfibrils Interwoven with a Network of Polysaccharides and Proteins 43

The tensile strength of the primary cell wall is provided by cellulose. A cellulose molecule consists of a linear chain of at least 500 glucose residues that are covalently linked to one another to form a ribbonlike structure, which is stabilized by hydrogen bonds within the chain. In addition, intermolecular hydrogen bonds between adjacent cellulose molecules cause them to adhere strongly to one another in overlapping parallel arrays, forming a bundle of 60 to 70 cellulose chains, all of which have the same polarity. These highly ordered crystalline aggregates, many micrometers long, are called cellulose microfibrils. Sets of microfibrils are arranged in layers, or lamellae, with each microfibril about 20-40 nm from its neighbors and connected to them by long *hemicellulose* molecules that are bound by hydrogen bonds to the surface of the microfibrils. The primary cell wall consists of several such lamellae arranged in a plywoodlike network (Figure 19-65).

Hemicelluloses are a heterogeneous group of branched polysaccharides that bind tightly to the surface of each cellulose microfibril as well as to one another and thereby help to cross-link microfibrils into a complex network. Their function is analogous to that of the fibril-associated collagens discussed earlier. There are many classes of hemicelluloses, but they all have a long linear backbone composed of one type of sugar, from which short side chains of other sugars protrude. Both the backbone sugar and the side-chain sugars vary according to the plant species and its stage of development. It is the sugar molecules in the backbone that form hydrogen bonds with cellulose microfibrils.

Coextensive with this network of cellulose microfibrils and hemicelluloses is another cross-linked polysaccharide network based on *pectins* (see Figure 19-65). These are a heterogeneous group of branched polysaccharides that contain many negatively charged galacturonic acid residues. Because of their negative charge, pectins are highly hydrated and accompanied by a cloud of cations, resembling the glycosaminoglycans of animal cells in the large amount of space they occupy. When Ca^{2+} is added to a solution of pectin molecules, it cross-links them to produce a semirigid gel (it is pectin that is added to fruit juice to make jelly). Certain pectins are particularly abundant in the *middle lamella,* the specialized central region of the wall that cements together the walls of adjacent cells, and such Ca^{2+} cross-links are thought to help hold cell wall components together. Thus many plant tissues, if treated with a Ca^{2+} chelating agent, dissociate into their constituent cells. Although covalent bonds also play a part in linking the different plant cell-wall components together, very little is known about their nature.

In addition to the two polysaccharide-based networks that are present in all plant primary cell walls, there is a variable contribution from structural proteins. One class of proteins contains high levels of hydroxyproline, like collagen. These proteins are thought to strengthen the wall, and they are produced in greatly increased amounts as a local response to attack by microorganisms. During normal differentiation cells use structural proteins to modify local regions of their walls, as required to create the wide range of functionally specialized secondary walls characteristic of mature cell types (see Panel 1-1, pp. 18-19).

In order for a plant cell to grow or change its shape, the cell wall has to stretch or deform. But because of their crystalline structure, individual cellulose microfibrils are unable to stretch. Thus stretching or deformation of the cell wall must involve either the sliding of microfibrils past one another, or the separation of adjacent microfibrils, or both. As we discuss next, the direction in which the growing cell enlarges depends on the orientation of the strain-resisting cellulose microfibrils in the primary wall, which in turn depends on the orientation of microtubules in the underlying cell cortex at the time the wall was deposited.

Microtubules Orient Cell-Wall Deposition 44

The final shape of a growing plant cell, and hence the final form of the plant, is determined by controlled cell expansion. Expansion occurs in response to turgor pressure in a direction that depends on the arrangement of the cellulose microfibrils in the wall. Cells anticipate their future morphology, therefore, by controlling the orientation of microfibrils that they deposit in the wall. Unlike most other matrix macromolecules, which are made in the endoplasmic reticulum and Golgi apparatus and secreted, cellulose, like hyaluronan, is spun out from the surface of the cell by a plasma-membrane-bound enzyme complex (*cellulose synthase*), which uses sugar nucleotide precursors supplied from the cytosol. As they are being synthesized, the nascent cellulose chains spontaneously assemble into microfibrils that form on the extracellular surface of the plasma membrane - forming a layer, or lamella, in which all the microfibrils have more or less the same alignment (Figure 19-65). Each new lamella forms internally to the previous one, so that the wall consists of concentrically arranged lamellae, with the oldest on the outside. The most recently laid down microfibrils in elongating cells commonly lie perpendicular to the axis of cell elongation (Figure 19-66); although the orientation of the microfibrils in the outer lamellae that were laid down earlier might be different, it is the orientation of these inner lamellae that have a dominant influence on the direction of cell expansion (Figure 19-67).

An important clue to understanding how this orientation is brought about was provided by the discovery that most cytoplasmic microtubules are arranged in the cortex of the plant cell with the same orientation as the cellulose microfibrils that are currently

being deposited in that region. These cortical microtubules, forming what is called the *cortical array,* lie close to the cytoplasmic face of the plasma membrane, held there by poorly characterized proteins (Figure 19-68). The congruent orientation of the cortical array of microtubules (lying just inside the plasma membrane) and cellulose microfibrils (lying just outside) is seen in many types and shapes of plant cells and is present during both primary and secondary cell-wall deposition.

If the entire system of cortical microtubules is disassembled by treating a plant tissue with a microtubule-depolymerizing drug, the consequences for subsequent cellulose deposition are not as straightforward as might be expected. The drug treatment has no effect on the production of new cellulose microfibrils, and in some cases cells can continue to deposit new microfibrils in the preexisting orientation. Any developmental change in the microfibril pattern that would normally occur between successive lamellae, however, is invariably blocked. It seems that a preexisting orientation of microfibrils can be propagated even in the absence of microtubules, but any change in the deposition of cellulose microfibrils requires that intact microtubules be present to determine the new orientation.

These observations are consistent with the following model. The cellulose-synthesizing complexes embedded in the plasma membrane are thought to spin out long cellulose molecules. As the synthesis of cellulose molecules and their self-assembly into microfibrils proceeds, the distal end of each microfibril presumably forms indirect cross-links to the previous layer of wall material. At the growing, proximal end the synthesizing complexes would therefore need to move along the membrane in the direction of synthesis. Since the growing cellulose microfibrils are very stiff, each layer of microfibrils would tend to be spun out from the membrane in the same orientation as the previously laid down layer, with the cellulose synthase complex following along the preexisting tracks of oriented microfibrils outside the cell. Oriented microtubules inside the cell, however, can change this predetermined direction in which the synthase complexes move: they can create boundaries in the plasma membrane that act like the banks of a canal to constrain movement of the synthase complexes to a parallel axis (Figure 19-69). In this view, cellulose synthesis can occur independently of microtubules but is constrained spatially when cortical microtubules are present to define membrane domains within which the enzyme complex can move.

Plant cells change their direction of elongation, and thus their future plane of cell growth and division, by a sudden change in the orientation of their entire cortical array of microtubules. Inasmuch as plant cells cannot move (being constrained by their walls), the entire morphology of a multicellular plant depends on the coordinated, highly patterned control of these cortical microtubule orientations during plant development. It is not known how the organization of these microtubules is controlled, although it has been shown that they can rapidly reorient in response to extracellular stimuli, including low-molecular-weight plant growth factors such as *ethylene* and *gibberellic acid.*

Summary

Plant cells are surrounded by a rigid extracellular matrix in the form of a cell wall, which is responsible for many of the unique features of a plant's life-style. The cell wall is composed of tough cellulose microfibrils embedded in a highly cross-linked matrix of polysaccharides (mainly pectins and hemicellulose) and glycoproteins. A cortical array of microtubules can determine the orientation of newly deposited cellulose microfibrils, which in turn determines the manner in which the cell expands and therefore the cell's final shape and cell-division patterns.
Figure 19-64. Plant cell walls. (A) Electron micrograph of the root tip of a rush, showing the organized pattern of cells that results from an ordered sequence of cell divisions in cells with rigid cell walls. (B) Section of a typical cell wall separating two adjacent plant cells. The two dark transverse bands correspond to plasmodesmata that span the wall. (A, courtesy of Brian Gunning; B, courtesy of Jeremy Burgess.)
Figure 19-65. Scale model of a portion of a primary cell wall showing the two major polysaccharide networks. The orthogonally arranged layers of cellulose microfibrils (*green*) are cross-linked into a network by H-bonded hemicellulose (*red*). This network is coextensive with a network of pectin polysaccharides (*blue*). The cellulose and hemicellulose network provides tensile strength, while the pectin network resists compression. Cellulose, hemicellulose, and pectin are typically present in roughly equal quantities in a primary cell wall. The middle lamella is pectin rich and cements adjacent cells together.
Figure 19-66. The orientation of cellulose microfibrils in the primary cell wall of an elongating carrot cell. This electron micrograph of a shadowed replica from a rapidly frozen and deep-etched cell wall shows the largely parallel arrange-ments of cellulose microfibrils, oriented perpendicular to the axis of cell elongation. The microfibrils are cross-linked by, and interwoven

with, a complex web of matrix molecules (compare with Figure 19-65). (Courtesy of Brian Wells and Keith Roberts.)
Figure 19-67. How the orientation of cellulose microfibrils within the cell wall influences the direction in which the cell elongates. The cells in (A) and (B) start off with identical shapes (shown here as cubes) but with different orientations of cellulose microfibrils in their walls. Although turgor pressure is uniform in all directions, cell-wall weakening causes each cell to elongate in a direction perpendicular to the orientation of the microfibrils, which have great tensile strength. The final shape of an organ, such as a shoot, is determined by the direction in which its cells expand.
Figure 19-68. The cortical array of microtubules in a plant cell. (A) A grazing section of a root-tip cell from Timothy grass, showing a cortical array of microtubules lying just below the plasma membrane. These microtubules are oriented perpendicular to the long axis of the cell. (B) An isolated onion root-tip cell. (C) The same cell stained by immunofluorescence to show the transverse cortical array of microtubules. (A, courtesy of Brian Gunning; B and C, courtesy of Kim Goodbody.)
Figure 19-69. One model of how the orientation of newly deposited cellulose microfibrils might be determined by the orientation of cortical microtubules. The large cellulose synthase complexes are integral membrane proteins that continuously synthesize cellulose microfibrils on the outer face of the plasma membrane. The distal ends of the stiff microfibrils become integrated into the texture of the wall, and their elongation at the proximal end pushes the synthase complex along in the plane of the membrane. Because the cortical array of microtubules is attached to the plasma membrane in a way that confines this complex to defined membrane channels, the microtubule orientation determines the axis along which the microfibrils are laid down.

20. Germ Cells and Fertilization

Introduction

Sex is not absolutely necessary. Single-celled organisms can reproduce by simple mitotic division, and many plants propagate vegetatively, by forming multicellular offshoots that later detach from the parent. Likewise, in the animal kingdom, a solitary multicellular *Hydra* can produce offspring by budding (Figure 20-1). Sea anemones and marine worms can split into two half-organisms, each of which then regenerates its missing half. There are even species of lizards that consist only of females and reproduce without mating. While such asexual reproduction is simple and direct, it gives rise to offspring that are genetically identical to the parent organism. Sexual reproduction, on the other hand, involves the mixing of genomes from two individuals to produce offspring that differ genetically from one another and from both their parents. This mode of reproduction apparently has great advantages, as the vast majority of plants and animals have adopted it. Even many procaryotes and other organisms that normally reproduce asexually engage in occasional bouts of sexual reproduction, thereby creating new combinations of genes. This chapter is concerned with the cellular machinery of sexual reproduction. Before discussing in detail how the machinery works, however, we shall pause to consider why it exists and what benefits it brings.
Figure 20-1. Photograph of a *Hydra* from which two new organisms are budding (*arrows*). The offspring, which are genetically identical to their parent, will eventually detach and live independently. (Courtesy of Amata Hornbruch.)

The Benefits of Sex

Introduction

The sexual reproductive cycle involves an alternation of haploid generations of cells, each carrying a single set of chromosomes, with diploid generations of cells, each carrying a double set of chromosomes. The mixing of genomes is achieved by fusion of two haploid cells to form a diploid cell. Later, new haploid cells are generated when a descendant of this diploid cell divides by the process of *meiosis* (Figure 20-2). During meiosis the chromosomes of the double chromosome set exchange DNA by *genetic recombination* before being shared out, in fresh combinations, into single chromosome sets. In this way each cell of the new haploid generation receives a novel assortment of genes, with some genes on each chromosome originating from one ancestral cell of the previous haploid generation and some from the other. Thus, through cycles of haploidy, cell fusion, diploidy, and meiosis, old combinations of genes are broken up and new combinations are created.

In Multicellular Animals the Diploid Phase Is Complex and Long, the Haploid Simple and Fleeting

Cells proliferate by mitotic division. In most organisms that reproduce sexually, this proliferation occurs during the diploid phase. Some primitive organisms, such as fission yeasts, are exceptional in that the haploid cells proliferate mitotically and the diploid cells, once formed, proceed directly to meiosis. A less extreme exception occurs in plants, where mitotic cell divisions occur in both the haploid and the diploid phases. In all but the most primitive plants, however, the haploid phase is very brief and simple, while the diploid phase is extended into a long period of development and proliferation. For almost all multicellular animals, including vertebrates, practically the whole of the life cycle is spent in the diploid state: the haploid cells exist only briefly, do not divide at all, and are highly specialized for sexual fusion (Figure 20-3).

Haploid cells that are specialized for sexual fusion are called gametes. Typically, two types of gametes are formed: one is large and nonmotile and is referred to as the *egg* (or *ovum*); the other is small and motile and is referred to as the *sperm* (or *spermatozoon*) (Figure 20-4). During the diploid phase that follows fusion of gametes, the cells proliferate and diversify to form a complex multicellular organism. In most animals a useful distinction can be drawn between the cells of the germ line, from which the next generation of gametes will be derived, and the somatic cells, which form the rest of the body and ultimately leave no progeny. In a sense, the somatic cells exist only to help the cells of the germ line (the germ cells) survive and propagate.

Sexual Reproduction Gives a Competitive Advantage to Organisms in an Unpredictably Variable Environment [1]

The machinery of sexual reproduction is elaborate, and the resources spent on it are large. What benefits does it bring, and why did it evolve? Through genetic recombination sexual individuals beget unpredictably dissimilar offspring, whose haphazard genotypes are at least as likely to represent a change for the worse as a change for the better. Why, then, should sexual individuals have a competitive advantage over individuals that breed true, by an asexual process? This problem continues to perplex population geneticists, but the general conclusion seems to be that the reshuffling of genes in sexual reproduction helps a species survive in an unpredictably variable environment. If a parent produces many offspring with a wide variety of gene combinations, there is a better chance that at least one of the offspring will have the assortment of features necessary for survival.

Many other ideas have been proposed to explain the competitive advantages of sexual reproduction. One of these suggests how one of the first steps in the evolution of sex might have occurred. Evolution depends to a large extent on competition among individuals carrying alternative *alleles,* or variants, created by mutation of particular genes. Suppose that two individuals in a population each undergo a beneficial mutation affecting a different *genetic locus* and therefore a different function. In a strictly asexual species each of these individuals will give rise to a clone of mutant progeny, and the two clones will compete until one or the other triumphs: one of the two beneficial mutations will spread through the population, while the other will eventually be lost. But suppose that one of the original mutants has evolved a genetically determined mechanism that enables it occasionally to incorporate genes from other cells. During the period of competition acquisition of genes from a cell of the competing clone is likely to create a cell that carries both beneficial mutations. Such a cell will be the most successful of all, and its success will ensure the propagation of the trait that enabled it to incorporate genes from other cells. This rudimentary sexual capability will thus be favored by natural selection.

Whatever the origins of sex may be, it is striking that practically all complex present-day organisms have evolved largely through generations of sexual, rather than asexual, reproduction. Asexual organisms, although plentiful, seem mostly to have remained simple and primitive.

We shall now examine the detailed cellular mechanisms of sex, beginning with the events of *meiosis,* in which genetic recombination occurs and diploid cells of the germ line divide to produce haploid *gametes.* Then we shall consider the gametes themselves and, finally, the process of *fertilization,* in which the gametes fuse to form a new diploid organism.

Summary

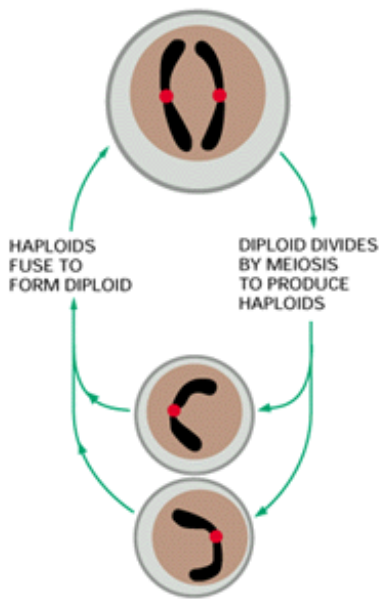
Sexual reproduction involves a cyclic alternation of diploid and haploid states: diploid cells divide by meiosis to form haploid cells, and the haploid cells from two individuals fuse in pairs at fertilization to form new diploid cells. In the process, genomes are mixed and recombined to produce individuals with novel assortments of genes. Most of the life cycle of higher plants and animals is spent in the diploid phase; the haploid phase is very brief. Sexual reproduction has probably been favored by evolution because the random recombination of genetic information improves the chances of producing at least some offspring that will survive in an unpredictably variable environment.


Figure 20-2. The sexual life cycle. It involves an alternation of haploid and diploid generations of cells.
Figure 20-3. Haploid and diploid cells in the life cycle of higher and some lower eucaryotes. Cells in higher eucaryotic organisms proliferate in the diploid phase to form a multicellular organism; only the gametes are haploid. In some lower eucaryotes, by contrast, the haploid cells proliferate, and the only diploid cell is the *zygote,* which exists transiently following mating. The haploid cells are shown in *red* and the diploid cells in *blue*.

Meiosis 2

Introduction

The realization that germ cells are haploid, and must therefore be produced by a special type of cell division, came from an observation that was also among the first to suggest that chromosomes carry genetic information. In 1883 it was discovered that, whereas the fertilized egg of a particular worm contains four chromosomes, the nucleus of the egg and that of the sperm each contain only two chromosomes. The chromosome theory of heredity therefore explained the long-standing paradox that maternal and paternal contributions to the character of the progeny seem often to be equal, despite the enormous difference in size between the egg and sperm (see Figure 20-4).

The finding also implied that germ cells must be formed by a special kind of nuclear division in which the chromosome complement is precisely halved. This type of division is called meiosis, from the Greek, meaning diminution. (There is no connection with the term mitosis, which is from the Greek *mitos,* meaning a thread, and refers to the threadlike appearance of the chromosomes as they condense during nuclear division - a process that occurs in both ordinary and meiotic divisions.) The behavior of the chromosomes during meiosis turned out to be considerably more complex than expected. Consequently, it was not until the early 1930s, as a result of painstaking cytological and genetic studies, that the essential features of meiosis were established.

Meiosis Involves Two Nuclear Divisions Rather Than One

With the exception of the chromosomes that determine sex (the *sex chromosomes*), a diploid nucleus contains two closely similar versions of each of the other chromosomes (the *autosomes*), one from the male parent (paternal chromosome) and one from the female parent (maternal chromosome). The two versions are called homologues, and in most cells they maintain a completely separate existence as independent chromosomes. When each chromosome is duplicated by DNA replication, the twin copies of the fully replicated chromosome at first remain closely associated and are called sister chromatids. In an ordinary cell division (described in Chapter 18) the sister chromatids line up on the spindle during mitosis with their kinetochore fibers pointing toward opposite poles. The sister chromatids then separate from each other at anaphase to become individual chromosomes. In this manner each daughter cell formed by ordinary cell division inherits one copy of each paternal chromosome and one copy of each maternal chromosome.

In contrast, a haploid gamete produced by the divisions of a diploid cell during meiosis must contain half the original number of chromosomes - only one chromosome in place of each homologous pair of chromosomes - so that the gamete is endowed with either the maternal or the paternal copy of each gene but not both. This requirement makes an extra demand on the machinery for cell division. The mechanism that has evolved to accomplish the additional sorting requires that homologues recognize each other and become physically paired before they line up on the spindle. This pairing of the maternal and the paternal copy of each chromosome is unique to meiosis. How the correct chromosomes recognize each other is still unclear, as will be discussed later.

Given a mechanism for pairing the maternal and paternal homologues and for their subsequent separation on the spindle, cells could, in principle, carry out meiosis by a simple modification of a single mitotic cell cycle in which chromosome duplication (S phase) was omitted: if the unduplicated homologues paired before M phase, the ensuing cell division would then produce two haploid cells directly. For unknown reasons, the actual meiotic process is more complex. Before the homologues pair, each one replicates to produce two sister chromatids as in an ordinary cell division. It is only after DNA replication has been completed that the special features of meiosis become evident. Rather than separating, the sister chromatids behave as a unit, as if chromosome duplication had not occurred: each duplicated homologue pairs with its partner, forming a structure called a *bivalent,* which contains four chromatids. The pairing, as we shall see, allows genetic recombination to occur, whereby a fragment of a maternal chromatid may be exchanged for a corresponding fragment of a homologous paternal chromatid. The bivalents line up on the spindle, and at anaphase the two duplicated homologues (each consisting of two sister chromatids) separate and move to opposite poles. Because the joined sister chromatids behave as a unit, each daughter cell inherits two copies of one of the two homologues when the meiotic cell divides; these two copies are identical except where genetic recombination has occurred (Figure 20-5). The two progeny of this division (division I of meiosis) therefore contain a diploid amount of DNA but differ from normal diploid cells in two ways: (1) both of the two DNA copies of each chromosome derive from only one of the two homologous chromosomes in the original cell (except where there has been genetic recombination), and (2) these two copies are inherited as closely associated sister chromatids, as if they were a single chromosome (see Figure 20-5).

Formation of the actual gamete nuclei can now proceed simply through a second cell division, division II of meiosis, without further DNA replication. The chromosomes align on a second spindle and the sister chromatids separate, as in normal mitosis, to produce cells with a haploid DNA content. Meiosis thus consists of two cell divisions following a single phase of DNA replication, so that four haploid cells are produced from each cell that enters meiosis. Meiosis and mitosis are compared in Figure 20-6.

Occasionally, the meiotic process occurs abnormally and homologues fail to separate - a phenomenon known as nondisjunction. In this case some of the haploid cells that are produced lack a chromosome, while others have more than one copy. Such gametes form abnormal embryos, most of which die. Some survive, however: *Down's syndrome* in humans, for example, is caused by an extra copy of chromosome 21 resulting from nondisjunction during meiotic division I or II.

Genetic Reassortment Is Enhanced by Crossing-over Between Homologous Nonsister Chromatids [3]

Unless they are identical twins, which develop from a single zygote, no two offspring of the same parents are genetically the same. This is because, long before the two gametes fuse, two kinds of randomizing genetic reassortment have occurred during meiosis.

One kind of reassortment is a consequence of the random distribution of the maternal and paternal homologues between the daughter cells at meiotic division I, as a result of which each gamete acquires a different mixture of maternal and paternal chromosomes. From this process alone, one individual could, in principle, produce 2^n genetically different gametes, where n is the haploid number of chromosomes (Figure 20-7A). In humans, for example, each individual can produce at least $2^{23} = 8.4 \times 10^6$ genetically different gametes. But the actual number of variants is very much greater than this because a second type of reassortment, called chromosomal crossing-over, occurs during meiosis. It takes place during the long prophase of meiotic division I, in which parts of homologous chromosomes are exchanged. On average, between two and three crossover events occur on each pair of human chromosomes during meiotic division I. This process scrambles the genetic constitution of each of the chromosomes in gametes, as illustrated in Figure 20-7B.

Chromosomal crossing-over involves breaking the DNA double helix in a maternal chromatid and in a homologous paternal chromatid so as to exchange fragments between the two nonsister chromatids in a reciprocal fashion by a process known as

general genetic recombination. The molecular details of this process are discussed in Chapter 6. The consequences of each crossover event can be observed cytologically at the latest stages of prophase of meiotic division I, when the chromosomes are highly condensed. At this stage the sister chromatids are tightly apposed along their entire length. The two duplicated homologues (maternal and paternal) are seen to be physically connected at specific points. Each connection, called a chiasma (plural chiasmata), corresponds to a crossover between two nonsister chromatids (Figure 20-8).

At this stage of meiosis, each pair of duplicated homologues, or *bivalent,* is held together by at least one chiasma. Many bivalents contain more than one chiasma, indicating that multiple crossovers can occur between homologues.

Meiotic Chromosome Pairing Culminates in the Formation of the Synaptonemal Complex 4

Elaborate morphological changes occur in the chromosomes as they pair (*synapse*) and then begin to unpair (*desynapse*) during the first meiotic prophase. This prophase is traditionally divided into five sequential stages - *leptotene, zygotene, pachytene, diplotene,* and *diakinesis-* defined by these morphological changes. The most striking event is the initiation of intimate chromosome synapsis at zygotene, when a complex structure called the *synaptonemal complex* begins to develop between the two sets of sister chromatids in each bivalent. Pachytene is said to begin as soon as synapsis is complete, and it generally persists for days, until desynapsis begins the diplotene stage, in which the chiasmata are first seen (Figure 20-9).

Genetic recombination requires a close apposition between the recombining chromosomes. The synaptonemal complex, which forms just before pachytene and dissolves just afterward, keeps the homologous chromosomes in a bivalent together and closely aligned, and it has been suggested that it may play a part in the recombination process. It consists of a long ladderlike protein core, on opposite sides of which the two homologues are aligned to form a long linear chromosome pair. The sister chromatids in each homologue are kept tightly packed together, and their DNA extends from the same side of the protein ladder in a series of loops (Figure 20-10).

It is not known how homologous chromosomes become aligned. It is unlikely that continuous connections all along the interacting chromosomes are involved, since the chromatin of one homologue is well separated from the chromatin of its partner in the synaptonemal complex. It has been proposed that the initial interaction between homologous chromosomes is mediated by complementary DNA base-pair interactions at discrete sites along the chromosomes. This recognition may occur at zygotene or even earlier, when the chromosomes are not very condensed; following chromosome condensation, the formation of the synaptonemal complex would then pack the remaining portions of the chromosomes together.

Recombination Nodules Are Thought to Mediate Chromatid Exchanges 5

Although the synaptonemal complex may provide the structural framework for recombination events, it probably is not the engine that brings them about. The active recombination process is thought to be mediated instead by recombination nodules, which are very large protein-containing assemblies with a diameter of about 90 nm. (For comparison, a large globular protein molecule of molecular weight 400,000 has a diameter of about 10 nm.) Recombination nodules sit at intervals on the synaptonemal complex, placed like basketballs on a ladder between the two homologous chromosomes (see Figure 20-10). They are thought to mark the site of a large multienzyme "recombination machine," which brings local regions of DNA on the maternal and paternal chromatids together across the 100-nm-wide synaptonemal complex.

The evidence that the recombination nodule serves this function is indirect: (1) The total number of nodules is about equal to the total number of chiasmata seen later in prophase. (2) The nodules are distributed along the synaptonemal complex in the same way that crossover events are distributed. Like the crossover events themselves, for example, the nodules are absent from those regions of the synaptonemal complex that hold heterochromatin together. Moreover, both genetic and cytological measurements indicate that the occurrence of one crossover event prevents a second crossover event occurring at any nearby chromosomal site; similarly, the nodules tend not to occur very near one another. (3) Some *Drosophila* mutations cause an abnormal distribution of crossover events along the chromosomes, as well as a greatly diminished recombination frequency. In these mutants correspondingly fewer recombination nodules are found, with a changed distribution that parallels the changed crossover distribution. This correlation strongly suggests that a recombination nodule determines the site of each crossover event. (4) Genetic recombination is thought to involve a limited amount of DNA synthesis at the site of each crossover event (discussed in Chapter 6). Electron microscopic autoradiography shows that radioactive DNA precursors are preferentially incorporated into pachytene DNA at or near recombination nodules.

Because there are about as many recombination nodules as crossover events, it seems that recombination nodules are extremely

efficient in causing the chromatids on opposite homologues to recombine. Little is known, however, about their structure or mechanism of action.

Chiasmata Play an Important Part in Chromosome Segregation in Meiosis

In addition to reassorting genes, chromosomal crossing-over is crucial in most organisms for the correct segregation of the two homologues to separate daughter nuclei. This is because the chiasma created by each crossover event plays a role analogous to that of the centromere in an ordinary mitotic division, holding the maternal and paternal homologues together on the spindle until anaphase I. In mutant organisms that have a reduced frequency of meiotic chromosome crossing-over, some of the chromosome pairs lack chiasmata. These pairs fail to segregate normally, and a high proportion of the resulting gametes contain too many or too few chromosomes - an example of nondisjunction.

There are at least two major differences in the way chromosomes separate in meiotic division I and in normal mitosis (see Figure 20-6). (1) During normal mitosis (and in meiotic division II, which resembles a normal mitosis) the sister chromatids are held together only at the centromere; the kinetochores (protein complexes associated with the centromeres, discussed in Chapter 18) on each sister chromatid have attached kinetochore fibers pointing in opposite directions, so that the chromatids are drawn into different daughter cells at anaphase. At metaphase I of meiosis, by contrast, the kinetochores on both sister chromatids appear to have fused so that their attached kinetochore fibers all point in the same direction and the arms of the sister chromatids are closely apposed; moreover, the homologous maternal and paternal chromosomes are held together at the chiasmata. (2) During normal mitosis (and meiotic division II) the movement of chromatids to the poles is triggered by a mechanism that detaches the two sister kinetochores from each other (thus beginning anaphase), allowing the sister chromatids to segregate into different daughter cells. In anaphase I of meiosis, however, movement to the poles is initiated by the disruption of the poorly understood forces keeping the arms of sister chromatids together and by the simultaneous dissolution of the chiasmata linking the homologous maternal and paternal chromosomes; consequently, the sister chromatids remain paired, but the maternal and paternal homologues segregate into different daughter cells. The difference between the way chromosomes separate in meiotic divisions I and II are illustrated in Figure 20-11.

Pairing of the Sex Chromosomes Ensures That They Also Segregate 6

We have explained how homologous chromosomes pair during meiotic division I so that they segregate accurately between the daughter cells. But what about the sex chromosomes, which in male mammals are not homologous? Females have two X chromosomes, which pair and segregate like other homologues. But males have one X and one Y chromosome, which must pair during the first metaphase of meiosis if the sperm are to contain either one Y or one X chromosome and not both or neither. The necessary pairing is made possible by a small region of homology between the X and the Y at one end of these chromosomes. In this region the two chromosomes pair and cross over during the first meiotic prophase. The chiasma corresponding to this small amount of genetic recombination is sufficient to keep the X and Y chromosomes paired on the spindle so that only two types of sperm are normally produced: sperm containing one Y chromosome, which will give rise to male embryos, and sperm containing one X chromosome, which will give rise to female embryos.

Meiotic Division II Resembles a Normal Mitosis

After the long prophase I (which can occupy 90% or more of meiosis) has ended, two successive cell divisions, without an intervening period of DNA synthesis, bring meiosis to an end (see Figure 20-6). The entire first meiotic cell cycle, which ends with an initial meiotic cell division, is called *meiotic division I,* and it is far more complex and requires much more time than the second meiotic cell cycle, called *meiotic division II* (Figure 20-12). Even the preparatory DNA replication during the first cell cycle tends to take much longer than a normal S phase, and cells can then spend days, months, or even years in the first meiotic prophase, depending on the species and on the gamete being formed. (Although it is traditionally called prophase, this prolonged phase of meiotic division I resembles the G_2 phase of an ordinary cell division in that the nuclear envelope remains intact and disappears only when the spindle fibers begin to form as prophase I gives way to metaphase I.)

After the end of meiotic division I, nuclear membranes re-form around the two daughter nuclei and a brief interphase begins. During this period the chromosomes may decondense somewhat, but usually they soon recondense and prophase II begins. As there is no DNA synthesis during this interval, in some organisms the chromosomes seem to pass almost directly from one division phase into the next. In all organisms prophase II is brief: the nuclear envelope breaks down as the new spindle forms, after which metaphase II, anaphase II, and telophase II usually follow in quick succession. As in an ordinary mitosis, a separate set of kinetochore fibers forms on each sister chromatid, and these two sets of fibers extend in opposite directions. Moreover,

the two sister chromatids are kept together on the metaphase plate until they are released by the sudden separation of their kinetochores at anaphase (see Figure 20-11). Thus division II, unlike division I, closely resembles a normal mitosis. The difference is that one copy of each chromosome is present instead of two homologues. After nuclear envelopes have formed around the four haploid nuclei produced at telophase II, meiosis is complete (see Figure 20-6). The principles of meiosis are the same in plants and animals and in males and females. But the production of gametes involves more than just meiosis, and the other processes required vary widely among organisms and are very different for eggs and sperm. We shall focus our discussion of gametogenesis mainly on vertebrates. As we shall see, by the end of meiosis a vertebrate egg is fully mature (and in some cases even fertilized), whereas a sperm that has completed meiosis has only just begun its differentiation.

Summary

The formation of both eggs and sperm begins in a similar way, with meiosis. In this process two successive cell divisions following one round of DNA replication give rise to four haploid cells from a single diploid cell. Meiosis is dominated by prophase of meiotic division I, which can occupy 90% or more of the total meiotic period. Each chromosome as it enters this prophase consists of two tightly joined sister chromatids. Chromosomal crossover events occur during this prolonged prophase I, when homologous chromosomes are aligned in register. Each crossover event is thought to be mediated by a recombination nodule, and it results in the formation of a chiasma, which persists until anaphase I. In the first meiotic cell division one member of each chromosome pair, still composed of linked sister chromatids, is distributed to each daughter cell. A second cell division, without DNA replication, then rapidly ensues in which each sister chromatid is segregated into a separate haploid cell.
Figure 20-5. Events through the first cell division of meiosis. For clarity, only one pair of homologous chromosomes is shown. The pairing of homologous chromosomes (homologues) is unique to meiosis. Each chromosome has been duplicated and exists as attached sister chromatids before the pairing occurs. As shown by the formation of chromosomes that are part *red* and part *black*, the chromosome pairing in meiosis involves *crossing-over* (genetic recombination) between homologous

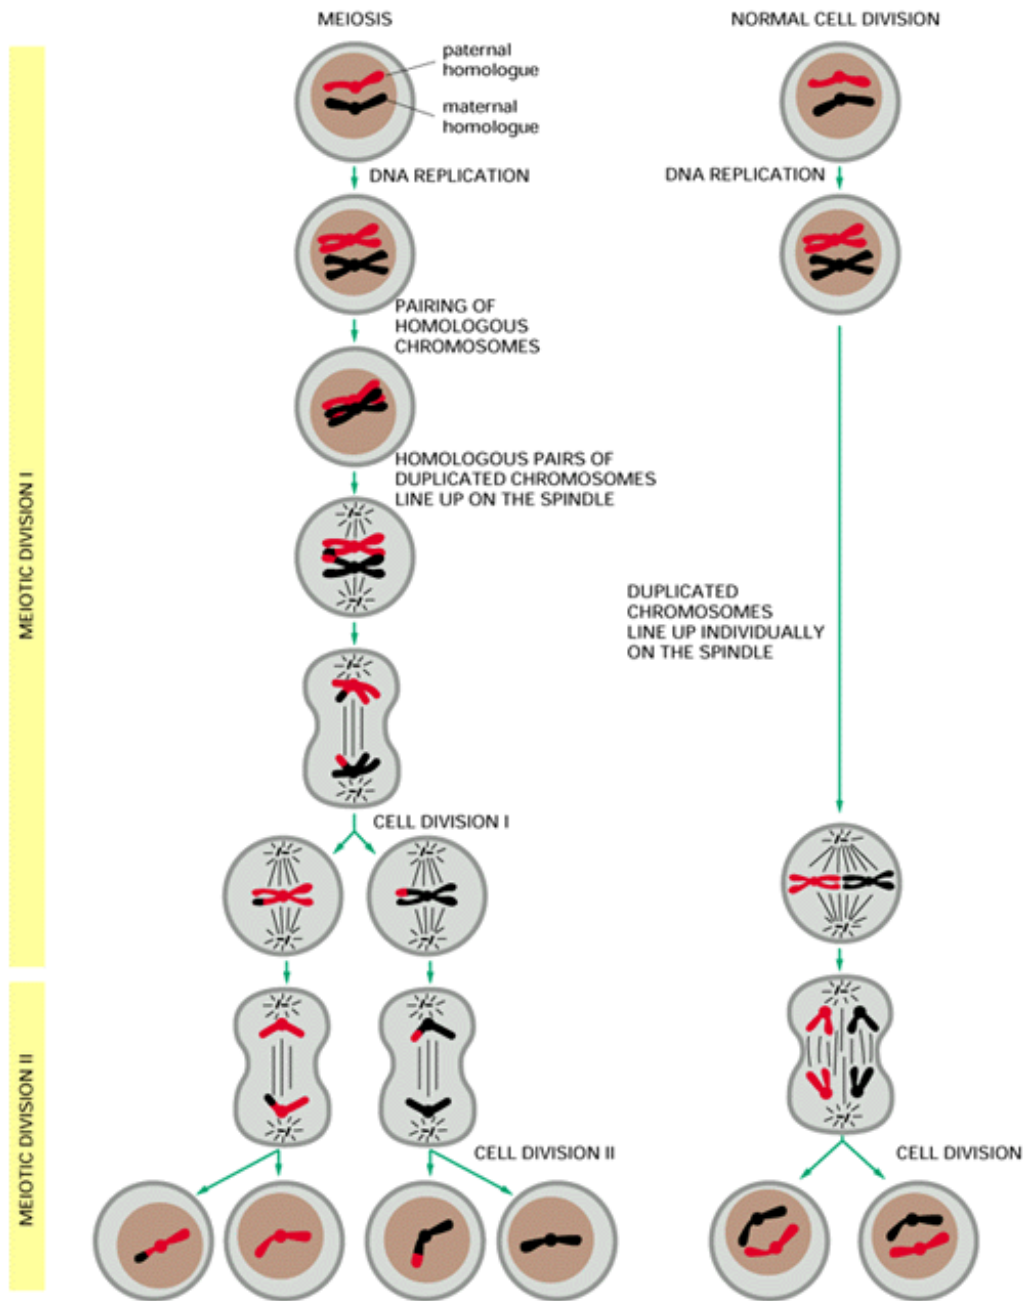
chromosomes, as explained in the text.


Figure 20-6. Comparison of meiosis and normal cell division. As in the previous figure, only one pair of homologous chromosomes is shown. In meiosis, following DNA replication, two nuclear (and cell) divisions are required to produce the haploid gametes. Each diploid cell that enters meiosis therefore produces four haploid cells, whereas each diploid cell that divides by mitosis produces two diploid cells.
Figure 20-7. Two major contributions to the reassortment of genetic material that occurs during meiosis. (A) The independent assortment of the maternal and paternal homologues during the first meiotic division produces 2^n different haploid gametes for an organism with n chromosomes. Here $n = 3$, and there are 8 different possible gametes. (B) Crossing-over during meiotic prophase I exchanges segments of homologous chromosomes and thereby reassorts genes in individual chromosomes. Because of the many small differences in DNA sequence that always exist between any two homologues, both mechanisms increase the genetic variability of organisms that reproduce sexually.
Figure 20-8. Paired homologous chromosomes during the transition to metaphase of meiotic division I. A single crossover event has occurred earlier in prophase to create one chiasma. Note that the four chromatids are arranged as two distinct pairs of sister chromatids and that the two chromatids in each pair are tightly aligned along their entire lengths as well as joined at their centromeres. The entire unit of four chromatids is referred to as a *bivalent*.
Figure 20-9. Time course of chromo-some synapsis and desynapsis during meiotic prophase I. A single bivalent is shown. The *pachytene stage* is defined as the period during which a fully formed synaptonemal complex exists. In gametes of female animals the subsequent *diplotene stage* is an enormously prolonged period of cell growth during which the chromosomes are decondensed and very active in transcription. This ends with *diakinesis*- the stage of transition to metaphase - in which the chromosomes recondense and transcription halts. In male gametes diplotene and diakinesis are briefer and less distinct.

Times differ for male and female gametes (egg and sperm) of the same species, as well as for the same gametes of different species. Meiosis in a human male, for example, lasts for 24 days, compared with 12 days in the mouse. Meiotic prophase I, however, is always much longer than all the other meiotic stages combined.
➦ ➦

Eggs

Introduction

In all vertebrate embryos certain cells are singled out early in development as progenitors of the gametes. These primordial germ cells migrate to the developing gonads, called the *genital ridges,* which will form the ovaries in females and the testes in males. After a period of mitotic proliferation, these cells undergo meiosis and differentiate into mature gametes - either eggs or sperm. Later, the fusion of egg and sperm after mating initiates embryogenesis, with the subsequent production in the embryo of new primordial germ cells, which begins the cycle again.

An Egg Is the Only Cell in a Higher Animal That Is Able to Develop into a New Individual

In one respect at least, eggs are the most remarkable of animal cells: once activated, they can give rise to a complete new individual within a matter of days or weeks. No other cell in a higher animal has this capacity. Activation is usually the consequence of *fertilization*- fusion of a sperm with the egg. The sperm itself, however, is not strictly required. An egg can be activated artificially by a variety of nonspecific chemical or physical treatments; a frog egg, for example, can be activated by pricking it with a needle. Indeed, some organisms, including even a few vertebrates such as some lizards, normally reproduce from eggs that become activated in the absence of sperm - that is, parthenogenetically.

Although an egg can give rise to every cell type in the adult organism (that is, it is *totipotent*), it is itself a highly specialized cell, uniquely equipped for the single function of generating a new individual. We shall now briefly consider some of its specialized features before discussing how it develops to the point at which it is ready for fertilization.

An Egg Is Highly Specialized for Independent Development, with Large Nutrient Reserves and an Elaborate Coat 7

The eggs of most animals are giant cells, containing stockpiles of all the materials needed for initial development of the embryo to carry it through to the stage where the new individual can begin feeding. Before this stage, the single giant cell cleaves into many smaller cells, but no net growth occurs. Mammals are an exception in that the embryo can start to grow early by taking up nutrients from the mother; thus a mammalian egg, though still a large cell, does not have to be as large as the egg of a frog or a bird, for example. In general, eggs are typically spherical or ovoid, with a diameter of about 100 microns in humans and sea urchins (whose feeding larvae are tiny), 1 microns to 2 microns in frogs and fishes, and many centimeters in birds and reptiles (Figures 20-13). A typical somatic cell, by contrast, has a diameter of only about 10 or 20 microns (Figure 20-14).

The egg cytoplasm contains nutritional reserves in the form of yolk, which is rich in lipids, proteins, and polysaccharides and is usually contained within discrete structures called *yolk granules.* In some species each yolk granule is membrane-bounded, whereas in others it is not. In eggs that develop into large animals outside the mother's body, yolk can account for more than 95% of the volume of the cell, whereas in mammals, whose embryos are largely nourished by their mothers, there is little if any.

The egg coat is another peculiarity of eggs. It is a specialized form of extracellular matrix consisting largely of glycoprotein molecules, some secreted by the egg and others by surrounding cells. In many species the major coat is a layer immediately surrounding the egg plasma membrane; in nonmammalian eggs, such as those of sea urchins or chickens, it is called the *vitelline layer*, whereas in mammalian eggs it is called the *zona pellucida*(Figure 20-15). This layer protects the egg from mechanical

damage, and in many eggs it also acts as a species-specific barrier to sperm, admitting only those of the same or closely related species (discussed below). Nonmammalian eggs often have additional layers overlying the vitelline layer that are secreted by surrounding cells. As frog eggs, for example, pass from the ovary through the oviduct (the tube that conveys them to the outside), they acquire several layers of gelatinous coating secreted by epithelial cells lining the oviduct. Similarly, the "white" (albumin) and shell of chicken eggs are added (after fertilization) as the eggs pass along the oviduct. The vitelline layer of insect eggs is covered by a thick, tough layer called the *chorion,* which is secreted by the *follicle cells* that surround each egg in the ovary.

Many eggs (including those of mammals) contain specialized secretory vesicles just under the plasma membrane in the outer region, or *cortex,* of the egg cytoplasm. When the egg is activated by a sperm, these cortical granules release their contents by exocytosis; the contents of the granules act to alter the egg coat so as to prevent more than one sperm from fusing with the egg (discussed below).

Eggs Develop in Stages 8

A developing egg is called an oocyte. Its differentiation into a mature egg (or *ovum*) involves a series of changes whose timing is geared to the steps of meiosis in which the germ cells go through their two final, highly specialized divisions. Oocytes have evolved special mechanisms for arresting progress through meiosis: they remain suspended in prophase I for prolonged periods while the oocyte grows in size, and in many cases they later arrest in metaphase II while awaiting fertilization.

While the details of oocyte development (oogenesis) vary in different species, the general stages are similar, as outlined in Figure 20-16. Primordial germ cells migrate to the forming gonad to become *oogonia,* which proliferate by ordinary cell division cycles for a period before differentiating into *primary oocytes*. At this stage the first meiotic division begins: the DNA replicates so that each chromosome consists of two chromatids, the homologous chromosomes pair along their long axes, and crossing-over occurs between the chromatids of these paired chromosomes. After these events the cell remains arrested in prophase of division I of meiosis (in a state equivalent, as we previously pointed out, to a G_2 phase of an ordinary division cycle) for a period lasting from a few days to many years, depending on the species. During this long period (or, in some cases, at the onset of sexual maturity) the primary oocytes synthesize a coat and cortical granules and, in the case of large nonmammalian oocytes, they accumulate ribosomes, yolk, glycogen, lipid, and the mRNA that will later direct the synthesis of proteins required for early embryonic growth and the unfolding of the developmental program. In many oocytes the intensive biosynthetic activities are reflected in the structure of the chromosomes, which decondense and form lateral loops, taking on a characteristic "lampbrush" appearance, signifying that they are very busily engaged in RNA synthesis (discussed in Chapter 8).

The next phase of oocyte development is called *oocyte maturation* and usually does not occur until sexual maturity, when it is stimulated by hormones. Under these hormonal influences the cell resumes its progress through division I of meiosis: the chromosomes recondense, the nuclear envelope breaks down (this is generally taken to mark the beginning of maturation), and the replicated homologous chromosomes segregate at anaphase I into two daughter nuclei, each containing half the original number of chromosomes. To end division I, the cytoplasm divides asymmetrically to produce two cells that differ greatly in size: one is a small *polar body*, and the other is a large secondary oocyte, the precursor of the egg. At this stage each of the chromosomes is still composed of two sister chromatids. These chromatids do not separate until division II of meiosis, when they are partitioned into separate cells by a process that is identical to a normal mitosis, as previously described. After this final chromosome separation at anaphase II, the cytoplasm of the large secondary oocyte again divides asymmetrically to produce the mature egg (or ovum) and a second small polar body, each with a haploid number of single chromosomes (see Figure 20-16). Because of these two asymmetrical divisions of their cytoplasm, oocytes maintain their large size despite undergoing the two meiotic divisions. Both of the polar bodies are small, and they eventually degenerate.

In most vertebrates oocyte maturation proceeds to metaphase of meiosis II and then arrests until fertilization. At ovulation the arrested secondary oocyte is released from the ovary, and if fertilization occurs, the oocyte is stimulated to complete meiosis.

Oocytes Grow to Their Large Size Through Special Mechanisms 8, 9

A somatic cell with a diameter of 10 to 20 microns typically takes about 24 hours to double its mass in preparation for cell division. At this rate of biosynthesis such a cell would take a very long time to reach the hundredfold greater mass of a mammalian egg with a diameter of 100 microns or the 10^5-fold greater mass of an insect egg with a diameter of 1000 microns. Yet some insects live only a few days and manage to produce eggs with diameters even greater than 1000 microns. It is clear that eggs must have special mechanisms for achieving their large size.

One simple strategy for rapid growth is to have extra gene copies in the cell. Thus the oocyte delays completion of the first meiotic division so as to grow while it contains the diploid chromosome set in duplicate. In this way it has twice as much DNA available for RNA synthesis as does an average somatic cell in the G_1 phase of the cell cycle. Some oocytes go to even greater lengths to accumulate extra DNA: they produce many extra copies of certain genes. We discuss in Chapter 8 how the somatic cells of most organisms require 100 to 500 copies of the ribosomal RNA genes in order to produce enough ribosomes for protein synthesis. Eggs require even greater numbers of ribosomes to support protein synthesis during early embryogenesis, and in the oocytes of many animals the ribosomal RNA genes are specifically amplified; some amphibian eggs, for example, contain 1 or 2 million copies of these genes.

Oocytes may also depend partly on the synthetic activities of other cells for their growth. Yolk, for example, is usually synthesized outside the ovary and imported into the oocyte. In birds, amphibians, and insects yolk proteins are made by liver cells (or their equivalents), which secrete these proteins into the blood. Within the ovaries oocytes take up the yolk proteins from the extracellular fluid by receptor-mediated endocytosis (see Figure 13-28). Nutritive help can also come from neighboring accessory cells in the ovary. These can be of two types. In some invertebrates some of the progeny of the oogonia become nurse cells instead of becoming oocytes. These cells usually are connected to the oocyte by cytoplasmic bridges through which macromolecules can pass directly into the oocyte cytoplasm (Figure 20-17). For the insect oocyte the nurse cells manufacture many of the products - ribosomes, mRNA, protein, and so on - that a vertebrate oocyte has to manufacture for itself.

The other accessory cells in the ovary that help nourish developing oocytes are ordinary somatic cells called follicle cells, which are found in both invertebrates and vertebrates. They are arranged as an epithelial layer around the oocyte (Figure 20-18, and see Figure 20-17), to which they are connected only by gap junctions, which permit the exchange of small molecules but not macromolecules. While these cells are unable to provide the oocyte with preformed macromolecules through these communicating junctions, they may help to supply the smaller precursor molecules from which macromolecules are made. In addition, follicle cells frequently secrete macromolecules that contribute to the egg coat, or are taken up by receptor-mediated endocytosis into the growing oocyte, or act on egg cell-surface receptors to control the spatial patterning and axial asymmetries of the egg (discussed in Chapter 21).

Summary

Eggs develop in stages from primordial germ cells that migrate into the developing gonad very early in development to become oogonia. After mitotic proliferation oogonia become primary oocytes that begin meiotic division I and then arrest at prophase for days or years, depending on the species. During this prophase-I arrest period, primary oocytes grow, synthesize a coat, and accumulate ribosomes, mRNAs, and proteins, often enlisting the help of other cells, including surrounding accessory cells. In the process of maturation primary oocytes complete meiotic division I to form a small polar body and a large secondary oocyte, which proceeds into metaphase of meiotic division II. There, in many species, the oocyte is arrested until stimulated by fertilization to complete meiosis and begin embryonic development.

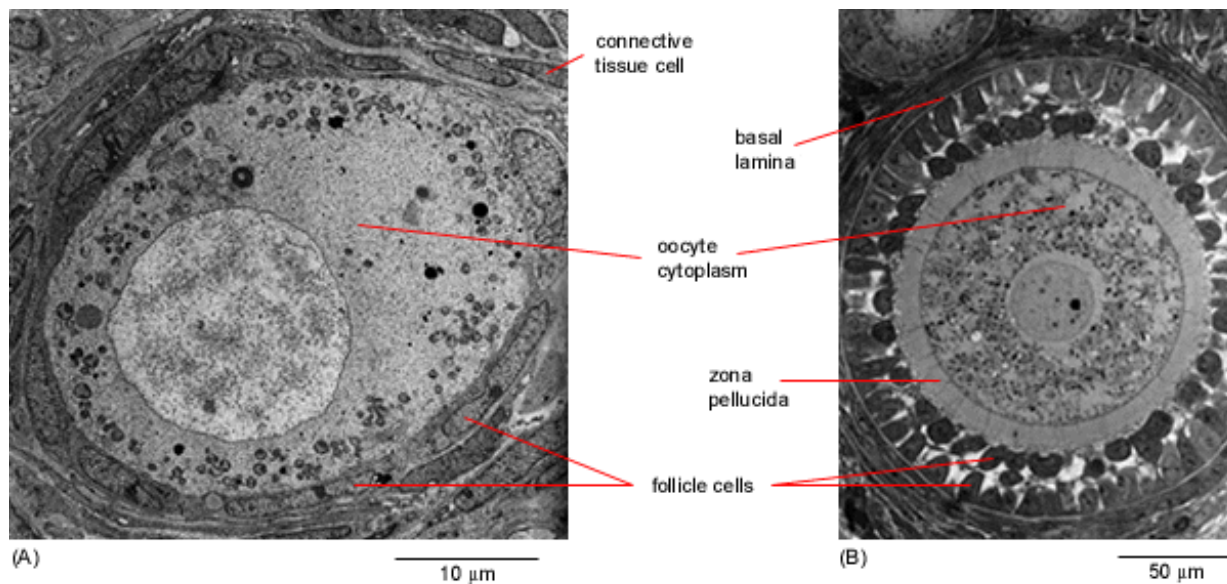
Figure 20-16. The stages of oogenesis. *Oogonia* develop from primordial germ cells that migrate into the developing gonad early in embryogenesis. After a number of mitotic divisions, oogonia begin meiotic division I, after which they are called *primary oocytes*. In mammals primary oocytes are formed very early (between 3 and 8 months of gestation in the human embryo) and remain arrested in prophase of meiotic division I until the female becomes sexually mature. At this point a small number periodically mature under the influence of hormones, completing meiotic division I to become *secondary oocytes,* which eventually undergo meiotic division II to become mature eggs (*ova*). The stage at which the egg or oocyte is released from the ovary and is fertilized varies from species to species. In most vertebrates oocyte maturation is arrested at metaphase of meiosis II and the secondary oocyte completes meiosis II only after fertilization. All of the polar bodies eventually degenerate. In most animals the developing oocyte is surrounded by specialized accessory cells that help isolate and nourish it (not shown).
Figure 20-17. Nurse cells and follicle cells associated with a *Drosophila* oocyte. The nurse cells and the oocyte arise from a common oogonium, each of which gives rise to one oocyte and 15 nurse cells (only 7 of which are seen in this plane of section). These cells remain joined by cytoplasmic bridges, which result from incomplete cell division. The follicle cells develop independently, from mesodermal cells.


Figure 20-18. Electron micrographs of developing primary oocytes in the rabbit ovary. (A) An early stage of primary oocyte development. Neither a zona pellucida nor cortical granules have developed, and the oocyte is surrounded by a single layer of flattened follicle cells. (B) A more mature primary oocyte, which is shown at a sixfold lower magnification because it is much larger than the oocyte in (A). This oocyte has acquired a thick zona pellucida and is surrounded by several layers of follicle cells and a basal lamina, which isolate the oocyte from the other cells in the ovary. The primary oocyte together with its surrounding follicle cells is called a *primary follicle*. The follicle cells are connected to one another and to the oocyte by gap junctions. (Copyright 1979. Sperm

Introduction

In most species there are just two types of gametes, and they are radically different. The egg is among the largest cells in an organism, while the sperm (spermatozoon, plural spermatozoa) is often the smallest. The egg and the sperm are optimized in opposite ways for the propagation of the genes they carry. The egg is nonmotile and aids the survival of the maternal genes by providing large stocks of raw materials for growth and development, as well as providing an effective protective wrapping. The sperm, by contrast, is optimized to propagate the paternal genes by exploiting this maternal investment: it is usually highly motile and streamlined for speed and efficiency in the task of fertilization. Competition between sperm is fierce, and the vast majority fail in their mission: of the billions of sperm released during the reproductive life of a human male, only a few ever manage to fertilize an egg.

Sperm Are Highly Adapted for Delivering Their DNA to an Egg [10]

Typical sperm are "stripped-down" cells, equipped with a strong flagellum to propel them through an aqueous medium but unencumbered by cytoplasmic organelles such as ribosomes, endoplasmic reticulum, or Golgi apparatus, which are unnecessary for the task of delivering the DNA to the egg. On the other hand, sperm contain many mitochondria strategically placed where they can most efficiently power the flagellum. Sperm usually consist of two morphologically and functionally distinct regions enclosed by a single plasma membrane: the *tail*, which propels the sperm to the egg and helps it burrow through the egg coat, and the *head*, which contains a condensed haploid nucleus (Figure 20-19). The DNA in the nucleus is extremely tightly packed, so that its volume is minimized for transport. The chromosomes of many sperm have dispensed with the histones of somatic cells and are packed instead with simple, highly positively charged proteins called *protamines.*

In the head of most animal sperm, closely apposed to the anterior end of the nuclear envelope, is a specialized secretory vesicle called the acrosomal vesicle (see Figure 20-19). This contains hydrolytic enzymes that help the sperm to penetrate the egg's outer coat. When a sperm contacts an egg, the contents of the vesicle are released by exocytosis in the so-called *acrosomal reaction;* in some sperm this reaction also exposes or releases specific proteins that help bind the sperm tightly to the egg coat.

The motile tail of a sperm is a long flagellum whose central axoneme emanates from a basal body situated just posterior to the nucleus. As described in Chapter 16, the axoneme consists of two central singlet microtubules surrounded by nine evenly spaced microtubule doublets. The flagellum of some sperm (including those of mammals) differs from other flagella in that the usual 9 + 2 pattern of the axoneme is further surrounded by nine *outer dense fibers* composed mainly of keratin (Figure 20-20). These dense fibers are stiff and noncontractile, and it is not known what part they play in the active bending of the flagellum, which is caused by the sliding of adjacent microtubule doublets past one another. Flagellar movement is driven by dynein motor proteins, which use the energy of ATP hydrolysis to slide the microtubules, as discussed in Chapter 16; the ATP is generated by highly specialized mitochondria in the anterior part of the sperm tail (called the *midpiece*), where the ATP is needed (see Figures 20-19 and 20-20).

Sperm Are Produced Continuously in Many Mammals [11]

In mammals there are major differences in the way eggs are produced (oogenesis) and the way sperm are produced (spermatogenesis). In human females, for example, oogonia proliferate only in the fetus, enter meiosis before birth, and become arrested as oocytes in the first meiotic prophase, in which state they may remain for up to 50 years. Individual oocytes mature from this strictly limited stock and are ovulated at intervals, generally one at a time, beginning at puberty. In human males, on the other hand, meiosis and spermatogenesis do not begin in the testes until puberty and then go on continuously in the epithelial lining of very long, tightly coiled tubes, called *seminiferous tubules*. Immature germ cells, called *spermatogonia*, are located around the outer edge of these tubes next to the basal lamina, where they proliferate continuously by ordinary cell division cycles. Some of the daughter cells stop proliferating and differentiate into *primary spermatocytes*. These cells enter the first meiotic prophase, in which their paired homologous chromosomes participate in crossing-over, and then proceed with division I of meiosis to produce two *secondary spermatocytes*, each containing 22 duplicated autosomal chromosomes and either a duplicated X or a duplicated Y chromosome. The two secondary spermatocytes proceed through meiotic division II to produce four *spermatids*, each with a haploid number of single chromosomes. These haploid spermatids then undergo morphological differentiation into sperm (Figure 20-21), which escape into the lumen of the seminiferous tubule (Figure 20-22). The sperm

subsequently pass into the *epididymis,* a coiled tube overlying the testis, where they are stored and undergo further maturation.

An intriguing feature of spermatogenesis is that the developing male germ cells fail to complete cytoplasmic division (cytokinesis) during mitosis and meiosis. Consequently, large clones of differentiating daughter cells descended from one maturing spermatogonium remain connected by cytoplasmic bridges, forming a *syncytium* (Figure 20-23). The cytoplasmic bridges persist until the very end of sperm differentiation, when individual sperm are released into the tubule lumen. This accounts for the observation that mature sperm arise synchronously in any given area of a seminiferous tubule. But what is the function of the syncytial arrangement?

Unlike oocytes, sperm undergo most of their differentiation after their nuclei have completed meiosis to become haploid. The presence of cytoplasmic bridges between them, however, means that each developing haploid sperm shares a common cytoplasm with its neighbors, so that it can be supplied with all the products of a complete diploid genome. Thus the diploid genome directs sperm differentiation just as it directs egg differentiation.

Summary

A sperm is usually a small, compact cell, highly specialized for the task of fertilizing an egg. Whereas in human females the total pool of oocytes is produced before birth, in males new germ cells enter meiosis continually from the time of sexual maturation, each primary spermatocyte giving rise to four mature sperm. Sperm differentiation occurs after meiosis, when the nuclei are haploid. Because the maturing spermatogonia and spermatocytes fail to complete cytokinesis, however, the progeny of a single spermatogonium develop as a large syncytium. This allows sperm differentiation to be directed by the products of both parental chromosomes.

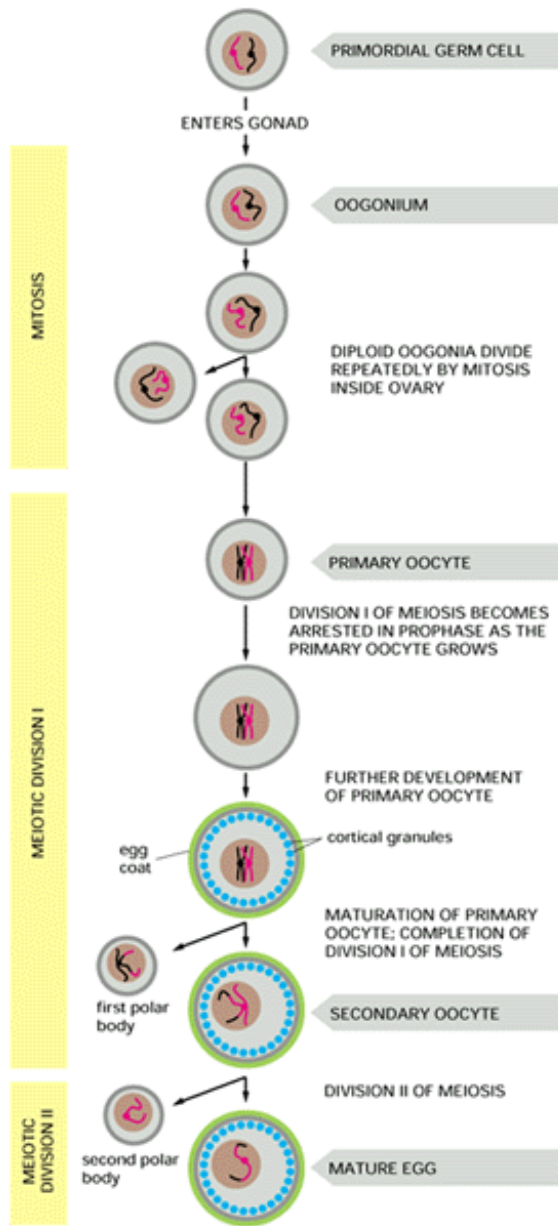
Figure 20-20. Drawing of the midpiece of a mammalian sperm as seen in cross-section in an electron microscope. The core of the flagellum is composed of an axoneme surrounded by nine dense fibers. The axoneme consists of two singlet microtubules surrounded by nine microtubule doublets. The mitochondrion (shown in *green*) is well placed for providing the ATP required for flagellar movement; its unusual spiral structure (see Figure 20-19) results from the fusion of individual mitochondria during spermatid differentiation.


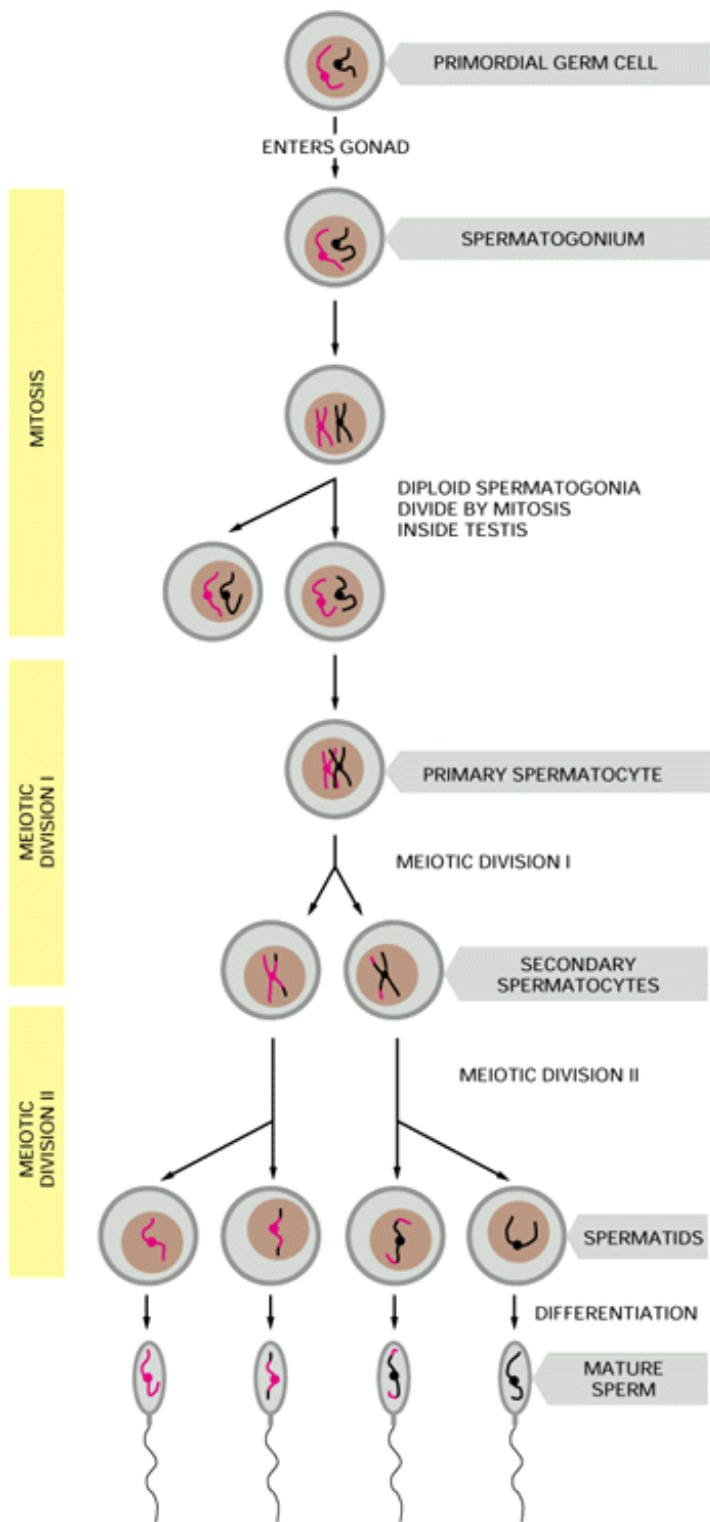


Figure 20-21. The stages of spermatogenesis. *Spermatogonia* develop from primordial germ cells that migrate into the testis early in embryogenesis. When the animal becomes sexually mature, the spermatogonia begin to proliferate rapidly, generating some progeny that retain the capacity to continue dividing indefinitely (as stem-cell spermatogonia) and other progeny (maturing spermatogonia) that will, after a limited number of further normal division cycles, embark on meiosis to become *primary spermatocytes*. These continue through meiotic division I to become *secondary spermatocytes.*After they complete meiotic division II, the secondary spermatocytes produce haploid *spermatids* that differentiate into mature sperm (*spermatozoa*). Spermatogenesis differs from oogenesis (see Figure 20-16) in several ways: (1) new cells enter meiosis continually from the time of puberty, (2) each cell that begins meiosis gives rise to four mature gametes rather than one, and (3) mature sperm form by an elaborate process of cell differentiation that begins after meiosis is complete.
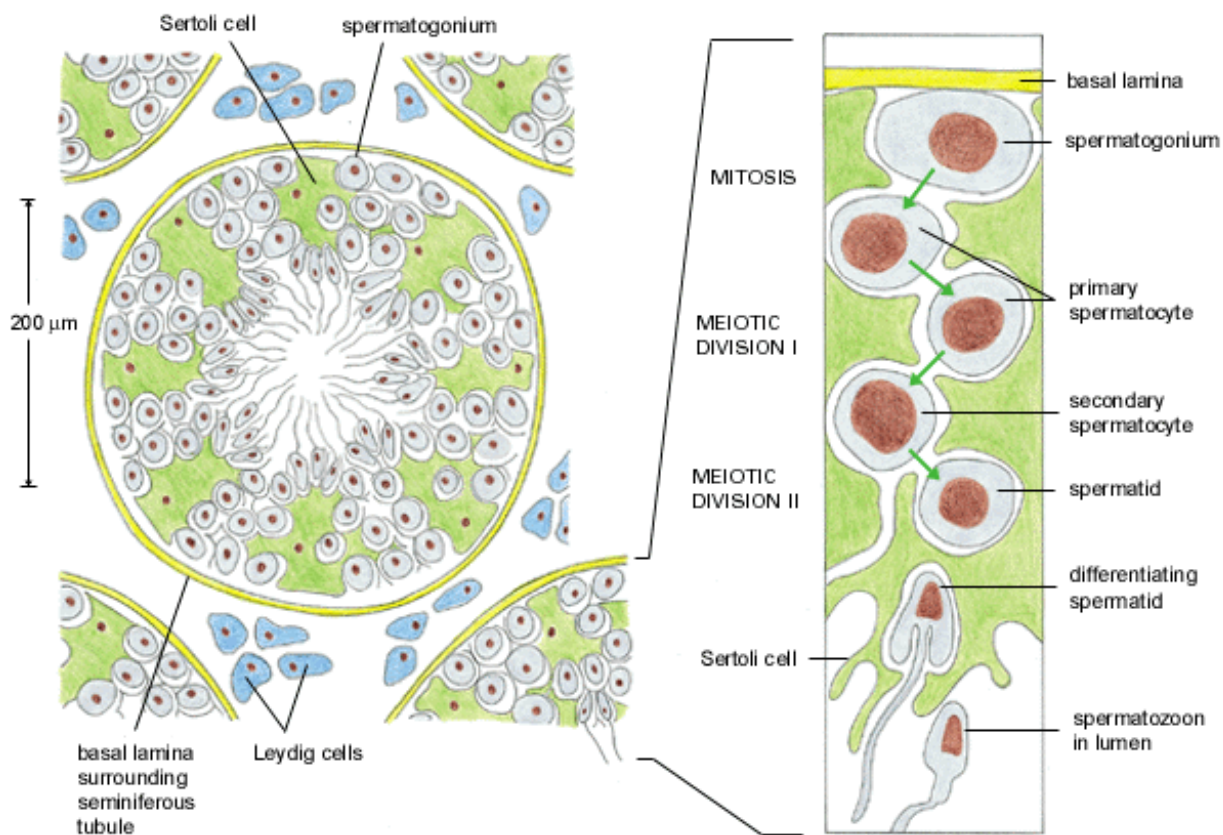

Figure 20-22. Highly simplified drawing of a cross-section of a seminiferous tubule in a mammalian testis. (A) All of the stages of spermatogenesis shown take place while the developing gametes are in intimate association with *Sertoli cells,* which are large cells that extend from the basal lamina to the lumen of the seminiferous tubule; they are analogous to follicle cells in the ovary. Spermatogenesis depends on testosterone secreted by *Leydig cells,* located between the seminiferous tubules. (B) Dividing spermatogonia are found along the basal lamina. Some of these cells stop dividing and enter meiosis to become primary spermatocytes. Eventually sperm are released into the lumen. In man it takes about 24 days for a spermatocyte to complete meiosis to become a spermatid and another 5 weeks for a spermatid to develop into a sperm. Sperm undergo further maturation and become motile in the epididymis and are only then fully mature sperm.
Figure 20-23. Cytoplasmic bridges in developing sperm cells and their precursors. The progeny of a single maturing spermatogonium remain connected to one another by cytoplasmic bridges throughout their differentiation into mature sperm. For the sake of simplicity, only two connected maturing spermatogonia are shown entering meiosis, eventually to form eight connected haploid spermatids. In fact, the number of connected cells that go through two meiotic divisions and differentiate together is very much larger than shown here.

Fertilization 12

Introduction

Once released, egg and sperm alike are destined to die within minutes or hours unless they find each other and fuse in the process of fertilization. Through fertilization the egg and sperm are saved: the egg is activated to begin its developmental program, and the nuclei of the two gametes come together to form the genome of a new organism. The mechanism of fertilization has been most intensively studied in marine invertebrates, especially sea urchins. In these organisms fertilization occurs in sea water, into which huge numbers of both sperm and eggs are released. Such *external fertilization* is more accessible to study than the *internal fertilization* of mammals, which occurs in the female reproductive tract following mating.

In the late 1950s, however, it became possible to fertilize mammalian eggs (more accurately, secondary oocytes - see Figure 20-16) *in vitro*, opening the way to an analysis of the cellular and molecular events in mammalian fertilization. Progress in

understanding mammalian fertilization has brought substantial medical benefit: mammalian eggs that have been fertilized *in vitro* can develop into normal individuals when transplanted into the uterus; in this way many previously infertile women have been able to produce normal children. We shall focus our brief discussion, then, on mammalian fertilization.

Binding to the Zona Pellucida Induces the Sperm to Undergo an Acrosomal Reaction [13]

Of the 300 million human sperm ejaculated during coitus, only about 200 reach the site of fertilization in the oviduct. Once there, the sperm must first migrate through the shell of follicular cells that surrounds the ovulated egg and then bind to and traverse the egg coat - the *zona pellucida*. Finally, it must bind and fuse with the egg plasma membrane. To become competent to accomplish these tasks, ejaculated mammalian sperm must normally be modified by secretions in the female reproductive tract, a process called capacitation, which requires about 5-6 hours in humans. Capacitation seems to involve both an alteration in the lipid and glycoprotein composition of the sperm plasma membrane and an increase in sperm metabolism and motility; its mechanism is unclear.

Once a capacitated sperm has penetrated the layer of follicle cells, it binds to the zona pellucida (see Figure 20-15). The zona pellucida usually acts as a barrier to fertilization across species, and removing it often removes this barrier. Human sperm, for example, will fertilize hamster eggs from which the zona pellucida has been removed with specific enzymes; not surprisingly, such hybrid zygotes do not develop. Zona-free hamster eggs, however, are used in fertility clinics to assess the fertilizing capacity of human sperm *in vitro* (Figure 20-24) .

The zona pellucida of mammalian eggs is composed of only three glycoproteins. Two of them, *ZP2* and *ZP3*, assemble into filaments, while the other, *ZP1*, cross-links the filaments into a three-dimensional network. ZP3 acts as a sperm receptor: the species-specific binding of sperm to the zona pellucida is mediated by a molecule (which may be the enzyme *galactosyl transferase*) on the surface of the sperm head that binds to *O*-linked oligosaccharides on ZP3 in the zona. On binding, the sperm is induced to undergo the acrosomal reaction, in which the contents of the acrosome are released by exocytosis (Figure 20-25). In the mouse, at least, the trigger for the acrosomal reaction is ZP3 in the zona, which activates a complex intracellular signaling mechanism that induces an influx of Ca^{2+} into the sperm cytosol, which is thought to initiate exocytosis.

The acrosomal reaction releases proteases and hyaluronidase, which are essential for the penetration of the sperm through the zona pellucida, and it exposes other proteins on the sperm surface that bind to ZP2 and thereby help the sperm maintain its tight binding to the zona while boring through it. In addition, the acrosomal reaction exposes a protein in the sperm plasma membrane that mediates the binding and fusion of this membrane with that of the egg, as we see below.

The Egg Cortical Reaction Helps to Ensure That Only One Sperm Fertilizes the Egg [14]

Although many sperm can bind to an egg, normally only one fuses with the egg plasma membrane and injects its nucleus and other organelles into the egg cytoplasm. If more than one sperm fuses - a condition called *polyspermy* - multipolar or extra mitotic spindles are formed, resulting in faulty segregation of chromosomes during cell division; nondiploid cells are produced, and development quickly stops. Two mechanisms operate to ensure that only one sperm fertilizes the egg. A rapid depolarization of the egg plasma membrane, which is caused by the fusion of the first sperm, is thought to prevent further sperm from fusing and thereby acts as a fast *primary block to polyspermy*. But the membrane potential returns to normal soon after fertilization, so that a second mechanism is required to ensure a longer-term, *secondary block to polyspermy*. This is provided by the egg cortical reaction.

When the sperm fuses with the egg plasma membrane, it activates the inositol phospholipid cell-signaling pathway (discussed in Chapter 15) in the egg. This, in turn, causes a local increase in cytosolic Ca^{2+}, which spreads through the cell in a wave. The rise in Ca^{2+} in the cytosol is thought to activate the egg and initiate the cortical reaction, in which the cortical granules release their contents by exocytosis. If the cytosolic concentration of Ca^{2+} is increased artificially - either directly by an injection of Ca^{2+} or indirectly by the use of Ca^{2+}-carrying ionophores (discussed in Chapter 11) - the eggs of all animals so far tested, including mammals, are activated. Conversely, preventing the increase in Ca^{2+} by injecting the Ca^{2+} chelator EGTA inhibits activation of the egg in response to fertilization. The enzymes released by the cortical reaction change the structure of the zona pellucida, which becomes "hardened," so that sperm no longer bind to it, thereby providing a slow, secondary block to polyspermy. Among the changes that occur in the zona is the proteolytic cleavage of ZP2 and the hydrolysis of sugar groups on ZP3 (Figure 20-26).

A Transmembrane Fusion Protein in the Sperm Plasma Membrane Catalyzes Sperm-Egg Fusion [15]

After a sperm penetrates the extracellular coat of the egg, it interacts with the egg plasma membrane overlying the tips of microvilli on the egg surface (see Figure 20-24). Neighboring microvilli then rapidly elongate and cluster around the sperm to ensure that it is held firmly so that it can fuse with the egg. After fusion, the entire sperm is drawn head-first into the egg as the microvilli are resorbed. In hamsters a single transmembrane protein called PH-30, which becomes exposed on the sperm surface during the acrosomal reaction, is thought to mediate both the binding of the sperm to the egg plasma membrane and the fusion of the two plasma membranes.

The protein is composed of two glycosylated transmembrane subunits called α and β, which are held together by noncovalent bonds (Figure 20-27). The extracellular domain of the alpha subunit contains a hydrophobic region of about 20 amino acid residues that resembles the fusogenic regions of viral fusion proteins, which mediate the fusion of enveloped viruses with the cells that they infect (discussed in Chapter 13). It has long been suspected that the various membrane fusions that occur within and between eucaryotic cells are catalyzed by fusion proteins resembling those present in enveloped viruses; PH-30 is the first such cellular protein to be defined.

The extracellular amino-terminal domain of the β subunit of PH-30 resembles a domain found in some proteins that bind to *integrins*, the cell-surface receptors that help animal cells to adhere to the extracellular matrix (discussed in Chapter 19). This and other indirect evidence suggest that the PH-30 β subunit binds to an integrin in the egg plasma membrane and thereby helps the sperm adhere to the surface of the egg in preparation for fusion.

As the cell biology of mammalian fertilization becomes better understood and the molecules that mediate the various steps in the process are defined, new strategies for contraception become possible. One approach currently being investigated, for example, is to immunize males or females with molecules that are required for reproduction in the hope that the antibodies produced will inhibit the activities of these molecules. In addition to the various hormones and hormone receptors involved in reproduction, ZP3 and PH-30 might be appropriate target molecules. An alternative approach would be to administer oligosaccharides or peptides corresponding to ligands, such as the postulated integrin-binding domain of PH-30, that operate in fertilization. Small molecules of this type might block fertilization by competing with the normal ligand.

The Sperm Provides a Centriole for the Zygote [16]

Once fertilized, the egg is called a zygote. Fertilization is not complete, however, until the two haploid nuclei (called *pronuclei*) have come together and combined their chromosomes into a single diploid nucleus. In fertilized mammalian eggs the two pronuclei do not fuse directly as they do in many other species: they approach each other but remain distinct until after the membrane of each pronucleus breaks down in preparation for the first mitotic division (Figure 20-28).

In most animals, including humans, the sperm contributes more than DNA to the zygote: it also donates a centriole - an organelle that is curiously lacking in the unfertilized eggs of these animals; the egg has a centrosome, but this does not contain a centriole. The sperm centriole enters the egg along with the sperm nucleus and tail, and in some species it replicates and helps organize the assembly of the first mitotic spindle in the zygote (see Figure 20-28). This explains why multipolar or extra mitotic spindles form in cases of polyspermy, where several sperm contribute centrioles to the egg.

Fertilization marks the beginning of one of the most remarkable phenomena in all of biology - the process of embryogenesis, in which the zygote develops into a new individual. This is the subject of the next chapter.

Summary

Mammalian fertilization begins when the head of a sperm binds in a species-specific manner to the zona pellucida surrounding the egg. This induces the acrosomal reaction in the sperm, which releases the contents of its acrosomal vesicle, including enzymes that help the sperm digest its way through the zona to the egg plasma membrane in order to fuse with it. Fusion is catalyzed by a transmembrane protein located in the sperm plasma membrane. This event activates the egg to undergo the cortical reaction, in which cortical granules release their contents, including enzymes that alter the zona pellucida and thereby prevent the fusion of additional sperm. Development of the zygote begins after sperm and egg haploid pronuclei have come together, pooling their chromosomes to form a single diploid nucleus.
Figure 20-24. Scanning electron micrograph of a human sperm contacting a hamster egg. The zona pellucida of the egg has been removed, exposing the plasma membrane, which contains numerous microvilli. The ability of an individual's sperm to penetrate hamster eggs is used as an assay of male fertility; penetration of more than 10-25% of the eggs is considered to be normal. (Courtesy of David M. Phillips.)
Figure 20-25. The acrosomal reaction that occurs when a mammalian sperm fertilizes an egg. In mice a single glycoprotein in the zona pellucida, ZP3, is thought to be responsible for both binding the sperm and inducing the acrosomal reaction. Note that a mammalian sperm interacts tangentially with the egg plasma membrane so that fusion occurs at the equator, rather than at the tip, of the sperm head. In mice the zona pellucida is 7 mm in diameter and sperm cross it at a rate of about 1 mm/min.
Figure 20-26. Schematic drawing of how the cortical reaction in a mouse egg is thought to prevent additional sperm from entering the egg. The released contents of the cortical granules both remove carbohydrate from ZP3 so it no longer can bind to the sperm plasma membrane and partly cleave ZP2, hardening the zona pellucida. Together these changes provide a block to polyspermy.
Figure 20-27. The PH-30 protein in the hamster sperm plasma membrane. The a and b subunits, which are both glycosylated (not shown), are noncovalently associated. Amino acid sequence similarity between the two subunits, such as the EGF-like repeat in the same location, suggests that the subunits evolved from a common progenitor protein.
Figure 20-28. The coming together of the sperm and egg pronuclei following mammalian fertilization. The pronuclei migrate toward the center of the egg. When they come together, their nuclear envelopes interdigitate. The centrioles replicate, the nuclear envelopes break down, and the chromosomes of both gametes are eventually integrated into a single mitotic spindle, which mediates the first cleavage division of the zygote. (Adapted from drawings and electron micrographs provided by Daniel Szöllösi.)

21. Cellular Mechanisms of Development

➜ ➜

Introduction

A multicellular animal or plant is an ordered clone of cells, all containing the same genome but specialized in different ways. Although the final structure may be enormously complex, it is generated by a limited repertoire of cell activities. Cells grow, divide, and die. They form mechanical attachments and generate forces for movement. They differentiate by switching on or off the production of specific sets of proteins. They produce molecular signals to influence neighboring cells, and they respond to signals that neighboring cells deliver to them. The genome, repeated identically in every cell, defines the rules according to which these various possible cell activities are called into play. Through its operation in each cell individually, it guides the whole intricate multicellular process of development by which an adult organism is generated from a fertilized egg.

In this chapter, rather than follow any one organism in detail, we illustrate the general principles of development by reference to the species that display each principle best. We discuss first how cell movements and cell divisions shape the animal embryo and how differences between cells arise in a spatially ordered fashion. We then consider how cell memory serves to perpetuate the spatial pattern of differences and allows new details to be filled in as an animal grows. In the central part of the chapter we examine the underlying genetic control mechanisms, taking the nematode worm *Caenorhabditis elegans* and the fly *Drosophila melanogaster* as examples. We shall see that molecular genetics has revealed remarkable similarities in the development of the most diverse types of animals. Because worms and flies are our cousins, what we learn from them provides a key to the development of mammals also.

The last two sections of the chapter can be read as separate modules: we review the development of flowering plants and ask how far it obeys the same principles as animal development, and then we discuss the special mechanisms by which the nervous system develops its astonishing circuitry.

➜ ➜

Morphogenetic Movements and the Shaping of the Body Plan [1]

Introduction

We begin by considering how the geometrical structure of the early vertebrate embryo is formed. The focus will be on the question of how cells move into the correct positions. Later sections will consider how cells adopt the correct differentiated characters. It is traditional to distinguish three phases in the development of a vertebrate - and indeed of many other types of animal. In the first phase the fertilized egg *cleaves* to form many smaller cells, and these become organized into an epithelium and perform a complex series of movements, called *gastrulation* and *neurulation,* that create the basic body plan, with a rudimentary gut cavity and a neural tube. In the second phase the rudiments of the various organs, such as limbs, eyes, heart, and so on, are formed - a process called *organogenesis.* In the third phase the tiny structures that have been generated in this way proceed to grow to their adult size. These phases are not sharply distinct but overlap considerably in time. To follow the course of events from the fertilized egg to the beginning of organogenesis, we take as our chief example the frog *Xenopus laevis* (Figure 21-1), whose early development has been particularly well studied. As in other amphibians, the entire process from fertilization onward takes place outside the mother, and the developing embryo is robust and easy to manipulate experimentally.

The Polarity of the Amphibian Embryo Depends on the Polarity of the Egg [2]

The *Xenopus* egg is a large cell, just over a millimeter in diameter, enclosed in a transparent extracellular capsule, or jelly coat. Most of the cell's volume is occupied by yolk platelets, which are membrane-bounded aggregates chiefly of lipid and protein. The yolk is concentrated toward the lower end of the egg, called the vegetal pole; the upper end is called the animal pole. The animal and vegetal regions contain different selections of mRNA molecules as well as different quantities of yolk and other cell components, and they have different fates. Roughly speaking, the vegetal end of the egg is destined to form internal tissues (in particular, the gut), and the animal end, external ones (such as the skin). Fertilization initiates a complex series of movements that will eventually tuck vegetal regions into the interior to form the gut and in the process will establish the three principal axes of the body: *anteroposterior,* from head to tail; *dorsoventral,* from back to belly; and *mediolateral,* from the median plane outward to the left or to the right.

The animal-vegetal asymmetry of the unfertilized egg is sufficient to define only one of the eventual body axes - the anteroposterior - but fertilization triggers a distortion of the egg contents that creates an additional asymmetry defining a dorsoventral difference: the outer, actin-rich cortex of the egg cytoplasm abruptly rotates relative to the central core of the egg, so that the animal pole of the cortex is slightly shifted to the future ventral side (Figure 21-2). The direction of the rotation is determined by the point of sperm entry - perhaps through an effect of the centrosome that the sperm brings into the egg. Because pigment granules in the egg are displaced by the rotation, a band of slightly diminished pigmentation, called the *gray crescent,* becomes visible in some amphibian species opposite the sperm entry point. In the neighborhood of the gray crescent the cortex of the vegetal hemisphere has become juxtaposed with core cytoplasm of the animal hemisphere, creating a special region that is crucial in organizing the dorsoventral axis of the body, as we discuss later.

The sperm entry point corresponds, roughly speaking, to the future belly; the opposite side will form the back and dorsal structures, including the spinal cord. Treatments that block the rotation allow cleavage to occur normally but produce an embryo with a central gut and no dorsoventral asymmetry.

Cleavage Produces Many Cells from One [3]

The cortical rotation is completed in about an hour after fertilization and sets the scene for *cleavage,* in which the single large egg cell subdivides by repeated mitosis into many smaller cells, or blastomeres, without any change in total mass (Figure 21-3). To survive, the embryo must quickly reach a stage where it can begin to feed, swim, and escape from predators, and these first cell divisions are extraordinarily rapid, with a cycle time of about 30 minutes. The very high rate of DNA replication and mitosis seems to preclude gene transcription (although protein synthesis occurs), and the cleaving embryo is almost entirely dependent on reserves of RNA, protein, membrane, and other materials that accumulated in the egg while it developed as an oocyte in the mother. The only crucial biosynthesis obviously required is that of DNA, and unusually rapid DNA replication is made possible by the use of an exceptionally large number of replication origins, closely spaced in the chromosomal DNA.

After about 12 cycles of cleavage (7 hours), the cell division rate slows down abruptly, and transcription of the embryo's genome begins. This change, known as the *mid-blastula transition,* seems to be triggered by attainment of a critical ratio of DNA to cytoplasm: the transition can be hastened or delayed by artificially increasing or decreasing the amount of DNA in the egg.

The Blastula Consists of an Epithelium Surrounding a Cavity [4]

From the outset the cells of the embryo are not only bound together mechanically, they are also coupled by *gap junctions* through which ions and other small molecules can pass, conveying messages that may help to coordinate the behavior of the cells. Meanwhile, in the outermost regions of the embryo, *tight junctions* between the blastomeres create a seal, isolating the interior of the embryo from the external medium. At about the 16-cell stage, Na^+ begins to be pumped across the cell membranes into the spaces between cells in the interior of the embryo, and water follows because of the resulting osmotic pressure gradient. As a result, the intercellular crevices deep inside the embryo enlarge to form a single cavity, the blastocoel, and the embryo is now termed a blastula (Figure 21-4). The cells that form the exterior of the blastula have become organized as an epithelial sheet, which will be crucial in coordinating their subsequent behavior.

Gastrulation Transforms a Hollow Ball of Cells into a Three-layered Structure with a Primitive Gut [5], [6]

Once the cells of the blastula have become arranged into an epithelial sheet, the stage is set for the coordinated movements of gastrulation. This dramatic process transforms the simple hollow ball of cells into a multilayered structure with a central gut tube and bilateral symmetry: by a complicated invagination, many of the cells on the outside of the embryo are moved inside it. Subsequent development depends on the interactions of the inner, outer, and middle layers of cells thus formed.

Gastrulation - the formation of a gut by tucking cells from the exterior of the early embryo into the interior - is a fundamental step in the development of practically every type of animal. The transparent embryo of the sea urchin provides one of the clearest and simplest illustrations of the process. Figure 21-5 shows the sequence of events, starting with a simple hollow blastula. Briefly, cells at the vegetal pole invaginate, forming a hollow tube that eventually makes contact with the epithelium near the opposite end of the embryo to form the mouth. Meanwhile, cells escape from the invaginating epithelium at certain sites and move into the body cavity to form embryonic connective tissue, or *mesenchyme.*

In the three-layered structure created by gastrulation, the innermost layer, the tube of the primitive gut, is the *endoderm;* the outermost layer, the epithelium that has remained external, is the *ectoderm;* and between the two, the looser layer of tissue composed of mesenchyme cells is the *mesoderm.* These are the three primary germ layers common to higher animals. The organization of the embryo into the three layers corresponds roughly to the organization of the adult - gut on the inside, epidermis on the outside, and connective tissue and muscle in between. Very crudely, these three layers of adult tissues may be said to derive from the endoderm, the ectoderm, and the mesoderm, respectively, although there are exceptions.

In *Xenopus* the geometry of gastrulation is more complex than in the sea urchin. But it is important to grasp the basic principles, for it is through the movements of gastrulation that the main axes of the vertebrate body are created. The details of the process are described in Figure 21-6. A central part is played by the tissue near the site of the gray crescent, to one side of the vegetal pole. Here, gastrulation starts with a short indentation that gradually extends to form the blastopore - a line of invagination that eventually curves around to encircle the vegetal pole. The site where the invagination starts defines the *dorsal lip* of the blastopore; this tissue plays a leading part in the ensuing complex series of movements and gives rise to the dorsal structures of the main body axis. As in the sea urchin, the end result of the whole process is a three-layered structure: an outermost sheet of ectoderm, an innermost tube of endoderm forming the rudiment of the gut, and between them a layer of mesoderm. Again, the mouth develops as a hole formed at an anterior site where endoderm and ectoderm come into direct contact without intervening mesoderm.

The transformation that is brought about by gastrulation can be summarized by plotting on the surface of the embryo at the beginning of gastrulation a *fate map* showing which regions are destined to give rise to which parts of the adult body; such a map is shown in Figure 21-6B.

Gastrulation Movements Are Organized Around the Dorsal Lip of the Blastopore 6, 7

The dorsal lip of the blastopore plays a central role not just in a geometrical sense, but also as the source of a controlling influence. If the dorsal lip of the blastopore is excised from a normal embryo at the beginning of gastrulation and grafted into another embryo but in a different position, the host embryo initiates gastrulation both at the site of its own dorsal lip and at the site of the graft (Figure 21-7). The movements of gastrulation at the second site entail the formation of a second whole set of body structures, and a double embryo (Siamese twins) results.

By carrying out such grafts between species with differently pigmented cells, so that host tissue can be distinguished from implanted tissue, it has been shown that the grafted blastopore lip recruits host epithelium into its own system of invaginating endoderm and mesoderm. Evidently, the dorsal lip of the blastopore is the source of some signal (or signals) coordinating both the movements of gastrulation and, directly or indirectly, the pattern of specialization of the tissues in its neighborhood. Because of this crucial role in organizing the formation of the main body axis, the dorsal lip of the blastopore is known as the *Organizer* (or *Spemann's Organizer,* after its co-discoverer). It is the oldest and most famous example of an *embryonic signaling center* - a function we discuss later when we consider how cell diversification is controlled.

Active Changes of Cell Packing Provide a Driving Force for Gastrulation 1, 6, 8

Gastrulation begins with changes in the shape of the cells at the site of the blastopore. In the amphibian these are called *bottle cells:* they have broad bodies and narrow necks that anchor them to the surface of the epithelium (Figure 21-8), and they may help to force the epithelium to curve and so to tuck inward, producing the initial indentation seen from outside. Once this first

tuck has formed, cells can continue to pass into the interior as a sheet to form the gut and mesoderm. Just as in the sea urchin, the movement seems to be driven by a combination of mechanisms but mainly by active repacking of the cells, especially those in the dorsal part of the *marginal zone* neighboring the blastopore lip (see Figure 21-8). Here convergent extension occurs. Small square fragments of dorsal marginal-zone tissue isolated in culture will spontaneously narrow and elongate through a rearrangement of the cells, just as they would in the embryo in the process of converging toward the dorsal midline, turning inward around the blastopore lip, and elongating to form the main axis of the body. A current view of the cellular mechanism underlying convergent extension is illustrated in Figure 21-9.

The Three Germ Layers Formed by Gastrulation Have Different Fates 9, 10, 11, 12

The endoderm forms a tube, the primordium of the digestive tract, from the mouth to the anus. It gives rise not only to the pharynx, esophagus, stomach, and intestines, but also to many associated glands. The salivary glands, the liver, the pancreas, the trachea, and the lungs, for example, all develop from extensions of the wall of the originally simple digestive tract and grow to become systems of branching tubes that open into the gut or pharynx. While the endoderm forms the epithelial components of these structures - the lining of the gut and the secretory cells of the pancreas, for example - the supporting muscular and fibrous elements arise from the mesoderm.

The differentiation of the mesoderm is guided by the Organizer at the dorsal lip of the blastopore, which is thought to be a source of signaling molecules that regulate choices between alternative mesodermal fates. Signals from the differently specialized groups of mesoderm cells in turn control the basic pattern of specializations of the endoderm and ectoderm and in particular initiate formation of the nervous system, as we shall see. The mesodermal layer is divided in the postgastrulation embryo into separate parts on the left and right of the body. Defining the central axis of the vertebrate body, and effecting this separation, is the very early specialization of the mesoderm known as the notochord. This is a slender rod of cells, about 80 μm in diameter, with ectoderm above it, endoderm below it, and mesoderm on either side (see Figure 21-12). It derives from the cells of the Organizer itself. As these pass around the dorsal lip of the blastopore and move into the interior of the embryo, they form a column of tissue that elongates dramatically by convergent extension. The cells of the notochord also become swollen with vacuoles, so that the rod elongates still further and stretches out the embryo. In the most primitive chordates, which have no vertebrae, the notochord persists as a primitive substitute for a vertebral column. In vertebrates it serves as a core around which other mesodermal cells gather to form the vertebrae. Thus the notochord is the precursor of the vertebral column, both in an evolutionary and in a developmental sense.

In general, the mesoderm gives rise to the muscles and to the connective tissues of the body - at first to the loose, space-filling, three-dimensional mesh of cells known as *mesenchyme* (see Figure 19-30) and ultimately to cartilage, bone, and fibrous tissue, including the dermis (the inner layer of the skin). In addition, the tubules of the urogenital system form from it and so does the vascular system, including the heart, the blood vessels, and the cells of the blood. These specialized mesodermal tissues derive from cells at different distances from the dorsal lip of the blastopore, with notochord having the most dorsal origin and blood cells the most ventral.

At the end of gastrulation the sheet of ectoderm covers the embryo and thus eventually forms the epidermis (the outer layer of the skin). It also gives rise to the entire nervous system. In a process known as neurulation, a broad central region of the ectoderm thickens, rolls up into a tube, and pinches off from the rest of the cell sheet (Figure 21-10). The tube thus created from the ectoderm is called the neural tube; it will form the brain and the spinal cord. The mechanics of neurulation depend, like gastrulation, on changes of cell packing and cell shape, and Figure 21-11 shows how the cytoskeleton can be organized to bring about cell shape changes that can make an epithelium roll up into a tube.

Neurulation is induced by an interaction with the underlying notochord and the mesoderm adjacent to it. If a piece of such dorsal mesoderm is taken from the area just beneath the future neural tube of one gastrulating amphibian embryo and implanted directly beneath the ectoderm of another gastrulating embryo in, say, the belly region, the ectoderm in that region will thicken and roll up to form a piece of misplaced neural tube.

Along the line where the neural tube pinches off from the future epidermis, a number of ectodermal cells break loose from the epithelium and migrate as individuals out through the mesoderm. These are the cells of the neural crest; they will form almost all of the peripheral nervous system (including most of the sensory and all of the sympathetic ganglia and the Schwann cells that make the myelin sheaths of peripheral nerves) as well as the pigment cells of the skin. In the head many of the neural crest cells will differentiate into cartilage, bone, and other connective tissues, which elsewhere in the body arise from the mesoderm. This is one of several instances that run counter to the general scheme in which the three germ layers give rise to cells in three

corresponding concentric layers of the adult body.

The sense organs, by which light, sound, smell, and so forth impinge on the nervous system, also have ectodermal origins: some derive from the neural tube, some from the neural crest, and some from the exterior layer of ectoderm (see Figure 21-102). The retina, for example, originates as an outgrowth of the brain and so is derived from cells of the neural tube, while the olfactory cells of the nose differentiate directly from the ectodermal epithelium lining the nasal cavity.

The Mesoderm on Either Side of the Body Axis Breaks Up into Somites from Which Muscle Cells Derive 13

On either side of the newly formed neural tube lies a broad expanse of mesoderm (Figure 21-12). The thicker, more medial and dorsal part of this mesoderm gives rise to the muscular and skeletal tissues of the central body axis. It consists at first of a single continuous slab of tissue on each side of the body. To form the repetitive series of vertebrae and segmental muscles, this slab soon breaks up into separate blocks, or somites (Figure 21-13). The somites form one after another, starting in the head and ending at the tail (Figure 21-13). Segmentation is accompanied by changes in the connections between the mesoderm cells, but the mechanism that controls the regular spacing of the clefts that separate one somite from the next remains a mystery (although it is known that the physical process of somite formation is foreshadowed by a segmental pattern of expression of certain genes).

Each somite corresponds to one unit in the final sequence of articulated ele-ments. The bulk of the somite forms the skeletal muscles of the segment, while a subset of its cells go to form the corresponding vertebrae and other connective tissues such as dermis. The somites are also the source of almost all skeletal muscle cells elsewhere in the body: these derive from precursors that migrate away from the somites before differentiating overtly.

Changing Patterns of Cell Adhesion Molecules Regulate Morphogenetic Movements 14

The tissue movements in the embryo go hand in hand with changes in the chemical characters of the cells. By switching on production of a cytoskeletal protein, for example, a cell may alter its shape or the way it moves. By changing the set of adhesion molecules it displays on its surface, it may break old attachments and make new ones. Cells in one region may develop surface properties that make them cohere with one another and become segregated from a neighboring group of cells whose surface chemistry is different.

Classical experiments on early amphibian embryos showed that the effects of selective cell-cell adhesion can be so powerful that they bring about an approximate reconstruction of the normal structure even after the cells have been artificially dissociated into a random mixture (Figure 21-14). As discussed in Chapter 19, studies on chick and mouse embryos suggest that this behavior depends, at least in part, on a family of homologous Ca^{2+}-dependent cell-cell adhesion glycoproteins - the *cadherins*. These molecules and other, Ca^{2+}-independent cell-cell-adhesion molecules such as N-CAM are differentially expressed in the various tissues of the early embryo, and antibodies against them interfere with the normal selective adhesion between cells of a similar type.

Changes in the patterns of expression of the various cadherins correlate closely with the changing patterns of association among cells during gastrulation, neurulation, and somite formation (Figure 21-15); these transformations of the early embryo may be regulated and driven in part by the cadherin pattern. In particular, cadherins appear to have a major role in controlling the formation and dissolution of epithelial sheets and clusters of cells. They not only glue one cell to another, but also provide anchorage for intracellular actin filaments at the sites of cell-cell adhesion (discussed in Chapter 19): in this way they help to regulate the pattern of stresses and movements in the developing tissue according to the pattern of adhesions.

Besides sticking to one another, cells can stick to components of the extracellular matrix such as fibronectin and laminin. These adhesions are typically mediated by *integrins,* which, like cadherins, serve as transmembrane linkers between sites of attachment on the outside of the cell and actin filaments inside. Cell-matrix interactions of this sort are important for the movements of certain special classes of cells that lose adhesions to their neighbors and migrate as individuals through the embryo by crawling through the spaces between other cells. As a result of such invasions, to be discussed next, most tissues in the adult vertebrate body include admixtures of cells derived from widely separate parts of the early embryo.

Embryonic Tissues Are Invaded in a Strictly Controlled Fashion by Migratory Cells 11, 15, 16

We have already mentioned two classes of migratory cells - those of the neural crest and those that leave the somites to give rise

to skeletal muscle. Other important migrants are the precursors of the blood cells, of the germ cells, and of many groups of neurons within the central nervous system.

Cell migrations can be traced by marking the cells at the beginning of their journey, using either a nontoxic dye or, better, a heritable genetic label. Much of our knowledge has come from studies in which cells are grafted from quail embryos into chick embryos. Although the quail is similar in most respects to the chick, its cells can be distinguished in histological sections by a large, strongly staining mass of heterochromatin associated with the nucleolus. This nucleolar marker makes it possible to identify grafted cells that have migrated from the site where they were implanted. For example, if quail somite tissue is substituted for the somite tissue of a very young chick embryo before the limb buds appear, all the muscle cells in the limbs that subsequently develop have a quail origin (Figure 21-16). Evidently the future muscle cells migrate from the somites into the prospective wing region and remain there, inconspicuously mixed with the connective-tissue cells of the limb bud, until the time comes for them to differentiate.

In a similar way one can trace the dispersal of cells from the neural crest. These migrate along certain specific pathways through the embryo (Figure 21-17) and settle in precisely defined locations. As a migrant cell travels through the embryo, it repeatedly extends projections that probe its immediate surroundings (Figure 21-18), testing for subtle cues to which it is particularly sensitive by virtue of its specific assortment of cell-surface receptor proteins. Inside the cell these receptor proteins are connected to the cytoskeleton, which moves the cell along. Some extracellular matrix materials, such as fibronectin, provide adhesive sites that help the cell to advance; others, such as chondroitin sulfate proteoglycan, inhibit locomotion and repel immigration. The nonmigrant cells along the pathway may likewise have inviting or repellent surfaces, or may even extend filopodia that touch the migrant cell and affect its behavior. An incessant tug-of-war between opposing tentative attachments made by the migrant cell leads to a net movement in the most favored direction until the cell finds a site where it can form a lasting attachment. Other factors such as chemotaxis and interactions among the migratory cells may also play an important part.

Yet another means of controlling the distribution of migrant cells is through regulation of their survival and proliferation. Germ cells, blood cell precursors, and pigment cells derived from the neural crest all appear to be governed in this respect by the same basic control mechanism. This involves a transmembrane receptor, called the *Kit* protein, in the membrane of the migrant cells and a ligand, called the *Steel* factor, produced by the cells of the tissue through which the cells migrate and/or in which they come to settle. Individuals with mutations in the genes for either of these proteins are deficient in their pigmentation, their supply of blood cells, and their production of germ cells (Figure 21-19). The Steel factor appears to be required in a membrane-bound form in order to activate Kit correctly and enable all these cell types to survive and proliferate.

The Vertebrate Body Plan Is First Formed in Miniature and Then Maintained as the Embryo Grows 9

The embryo at the stage when the somites are forming and neural crest cells are setting off on their migrations is typically a few millimeters long and consists of about 10^5 cells. While we have been speaking thus far mainly of *Xenopus,* the scale and general form are much the same for a fish, a salamander, a chick, or a human (see Figure 1-36). Later these species of embryo will grow to be very different in size and shape, but at this early stage they all share the basic vertebrate body plan. The central nervous system is represented by the neural tube, with an enlargement at one end for the brain; the gut and its derivatives, by a tube of endoderm; the segments of the trunk, by the somites; the other connective tissues, including the vascular system, by the more peripheral unsegmented mesoderm; and the epidermal layer of the skin, by the ectoderm. During subsequent development all of these components will enlarge, by a factor of as much as a hundred or more in length or a million or more in volume and cell number. But the same basic organization of the body will be preserved.

Summary

The eggs of most animals are large cells, containing stores of nutrients and other cell components specified by the maternal genome. In amphibians the first major movement after fertilization is a rotation of the cortex of the egg relative to its core. The asymmetry created by this rotation, together with the original asymmetry in the distribution of the contents of the egg before fertilization, defines the future antero-posterior and dorsoventral axes of the body. During the subsequent cleavage divisions the egg subdivides into many smaller cells, but no growth occurs.

A cavity soon develops in the interior of the embryo, while the surrounding cells become organized into an epithelial sheet. Part of the epithelium then invaginates, transforming the embryo into a three-layered structure with an internal epithelial tube of endoderm, an external epithelial covering of ectoderm, and a middle layer of mesodermal cells that have broken loose from the original epithelial sheet. In this process of gastrulation the epithelial cells actively change their packing, and this is thought to

provide a major driving force for the movements.

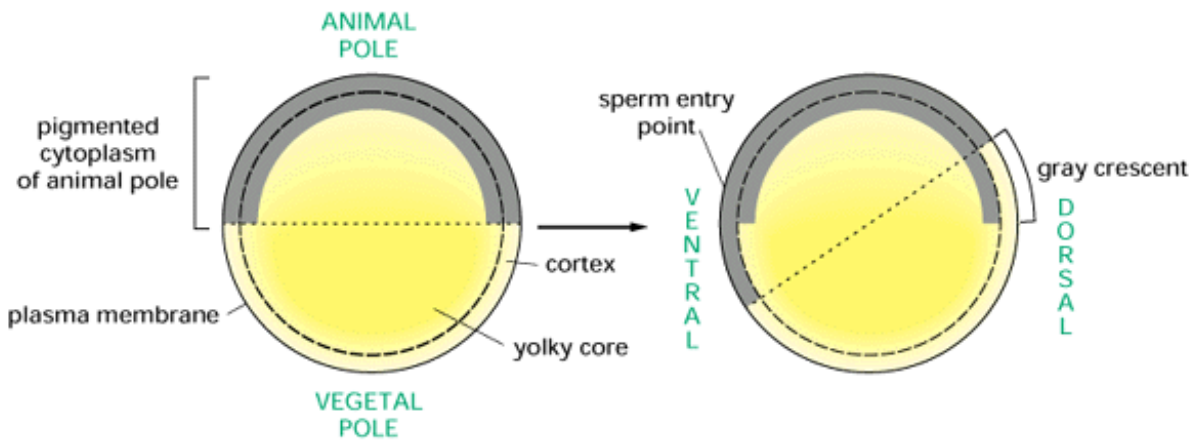
The endoderm will form the lining of the gut and its derivatives, the ectoderm will form the epidermis and the nervous system, and the mesoderm will form muscles, connective tissues, vascular system, and urogenital tract. The development of all these structures depends on interactions between the three germ layers and involves further cell movements. The dorsal mesoderm, for example, induces the overlying ectoderm to thicken, roll up, and pinch off to form the neural tube and neural crest. In the middle of the dorsal mesoderm a rod of specialized cells called the notochord elongates to form the central axis of the embryo. The long slabs of mesoderm on either side of the notochord become segmented into somites, from which the vertebrae and skeletal muscles will be derived. At several sites migrant cells, such as those of the neural crest, break loose from their original neighbors and migrate through the embryo to colonize new sites. Specific cell-adhesion molecules, such as cadherins and integrins, help to guide the migrations and control the selective cohesion of cells in epithelia.
Figure 21-1. Synopsis of the development of *Xenopus laevis* from newly fertilized egg to feeding tadpole. The adult frog is shown in the photograph at the top. The developmental stages are viewed from the side, except for the 10-hour and 19-hour embryos, which are viewed from below and from above, respectively. All stages except the adult are shown at the same scale. (Photograph courtesy of Jonathan Slack; drawings after P.D. Nieuwkoop and J. Faber, Normal Table of *Xenopus laevis* [Daudin]. Amsterdam: North-Holland, 1956.)


Figure 21-2. The first morphogenetic movement following fertilization of a frog's egg. The egg cortex (a layer a few micrometers deep) rotates through about 30° relative to the core of the egg in a direction determined by the site of sperm entry. In species where the cytoplasm capping the animal pole is appropriately pigmented, the rotation creates a visible gray crescent opposite the site of sperm entry.
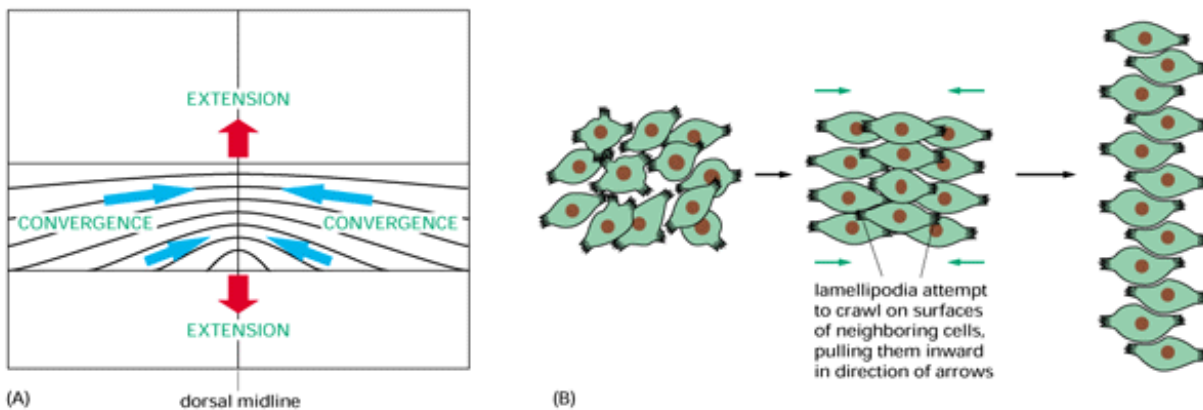
Figure 21-3. The stages of cleavage in *Xenopus*. The drawings show a series of side views. The photographs show views from above. The cleavage divisions rapidly subdivide the egg into many smaller cells. All the cells divide synchronously for the first 12 cleavages, but the divisions are asymmetric, so that the lower, vegetal cells, encumbered with yolk, are fewer and larger.The asymmetries of the egg and the detailed patterns of cleavage vary from one animal species to another. In mammals, whose small, symmetrical eggs contain little yolk, the first three cleavages divide the cell evenly into eight equal blastomeres. At the other extreme, exemplified by the very yolky bird egg, cleavage does not cut all the way through the yolk, and all the nuclei remain clustered at the animal pole; the embryo then develops from a cap of cells on top of the yolk. (Photographs courtesy of Jonathan Slack.)
Figure 21-4. The blastula. At this stage the cells are arranged to form an epithelium surrounding a fluid-filled cavity, the blastocoel. The cells are electrically coupled via gap junctions, and tight junctions close to the outer surface create a seal that isolates the interior of the embryo from the external medium. Note that in *Xenopus* the wall of the blastocoel is several cells thick, and only the outermost cells are tightly bound together as an epithelium.
Figure 21-5. Gastrulation in a sea urchin. The starting point for sea-urchin gastrulation is a very simple blastula: a sheet of about 1000 cells, one cell thick, surrounding a spherical cavity. (A) Scanning electron micrograph showing the initial intucking of the epithelium at the vegetal pole. (B) A first group of mesenchyme cells break loose from the epithelium at the vegetal pole of the blastula. (C) These cells then crawl over the inner face of the wall of the blastula. (D) Meanwhile the epithelium at the vegetal pole is continuing to tuck inward. (E and F) The invaginating epithelium extends into a long gut tube: the invaginating cells actively change their packing, without much altering their average shape, so as to convert the initial squat dome-shaped invagination into a long narrow gut tube. This type of tissue movement, in which a sheet of cells elongates along one dimension while narrowing along another, provides an important means of remodeling during animal development and is called *convergent extension.* At the same time certain cells in the rounded tip of the invaginating sheet extend long filopodia into the blastocoel cavity; these contact the walls of the cavity, adhere there, and contract, thereby helping to steer the invagination movement. (G) The end of the gut tube makes contact with the wall of the blastula at the site of the future mouth opening. Here the epithelia will fuse and a hole will form. (A, from R.D. Burke, R.L. Myers, T.L. Sexton, and C. Jackson, *Dev. Biol.* 146:542-557, 1991; B-G, after L. Wolpert and T. Gustafson, *Endeavour* 26:85-90, 1967.)
Figure 21-6. Gastrulation in *Xenopus*. (A) The external views (*above*) show the embryo as a semitransparent object, seen from the side; the cross-sections (*below*) are cut in the median plane (the plane of the dorsal and ventral midlines). The directions of cell movement are indicated by *red arrows*. Gastrulation begins when a short indentation, the beginning of the blastopore, becomes visible in the exterior of the blastula. This indentation gradually extends, curving around to form a complete circle surrounding a plug of very yolky cells (destined to be enclosed in the gut and digested). Sheets of cells meanwhile turn in around the lip of the blastopore and move deep into the interior of the embryo. At the same time the external epithelium in the region of the animal pole actively spreads to take the place of the cell sheets that have turned inward. Eventually, the epithelium of the animal hemisphere extends in this way to cover the whole external surface of the embryo, and, as gastrulation reaches completion, the blastopore circle shrinks almost to a point. (B) A fate map for the early *Xenopus* embryo (viewed from the side) as it begins gastrulation, showing the origins of the cells that will come to form the three germ layers as a result of the movements of gastrulation. The various parts of the mesoderm (lateral plate, somites, and notochord) derive from deep-lying cells that segregate from the epithelium in the cross-hatched region; the other cells, including the more superficial cells in the cross-hatched region, will give rise to ectoderm (*blue* and *red, above*) or endoderm (*yellow, below*). Roughly speaking, the first cells to turn into the interior, or *involute,* will move forward inside the embryo to form the most anterior endodermal and mesodermal structures, while the last to involute will form the most posterior structures. (After R.E. Keller, *J. Exp. Zool.* 216:81-101, 1981.)
Figure 21-7. The role of the Organizer. Diagram of an experiment showing that the dorsal lip of the blastopore (Spemann's Organizer) initiates and controls the movements of gastrulation and thereby, if transplanted, organizes the formation of a second set of body structures. The photograph shows a two-headed, two-tailed axolotl tadpole resulting from such an operation; the results are similar for *Xenopus.* (Photo courtesy of Jonathan Slack.)
Figure 21-8. Cell movements in gastrulation. A section through a gastrulating *Xenopus* embryo, cut in the same plane as in Figure 21-6, indicating the four main types of movement that gastrulation involves. The animal pole epithelium expands by cell rearrangement, becoming thinner as it spreads. Migration of mesodermal cells over fibronectin-rich matrix lining the roof of the blastocoel may help to pull the invaginated tissues forward. But the main driving force for gastrulation in *Xenopus* is convergent extension in the marginal zone. (After R.E. Keller, *J. Exp. Zool.* 216:81-101, 1981.)


Figure 21-9. Convergent extension and its cellular basis. (A) The pattern of convergent extension in the marginal zone of a gastrula as viewed from the dorsal aspect. *Blue arrows* represent convergence toward the dorsal midline, *red arrows* represent extension of the anteroposterior axis. The simplified diagram does not attempt to show the accompanying movement of involution, whereby the cells are tucking into the interior of the embryo. (B) Schematic diagram of the cell behavior that underlies convergent extension. The cells form lamellipodia, with which they attempt to crawl over one another. Alignment of the lamellipodial movements along a common axis leads to convergent extension. The process is presumably cooperative because cells that are already aligned exert forces that tend to align their neighbors in the same way. (B, after J. Shih and R. Keller, *Development* 116:901-914, 1992.)
Figure 21-12. A cross-section (schematic) through the trunk of an amphibian embryo after the neural tube has closed. (After T. Mohun, R. Tilly, R. Mohun, and J.M.W. Slack, *Cell* 22:9-15, 1980. © Cell Press.)
Figure 21-10. Neural tube formation in *Xenopus*. The external views are from the dorsal aspect. The cross-sections are cut in a plane indicated by the broken lines. (After T.E. Schroeder, *J. Embryol. Exp. Morphol.* 23:427-462, 1970. © Company of Biologists Ltd.)
Figure 21-11. The bending of an epithelium through cell shape changes mediated by microtubules and actin filaments. The diagram is based on observations of neurulation in newts and salamanders, where the epithelium is only one cell layer thick. As the apical ends of the cells become narrower, their upper-surface membrane becomes puckered.

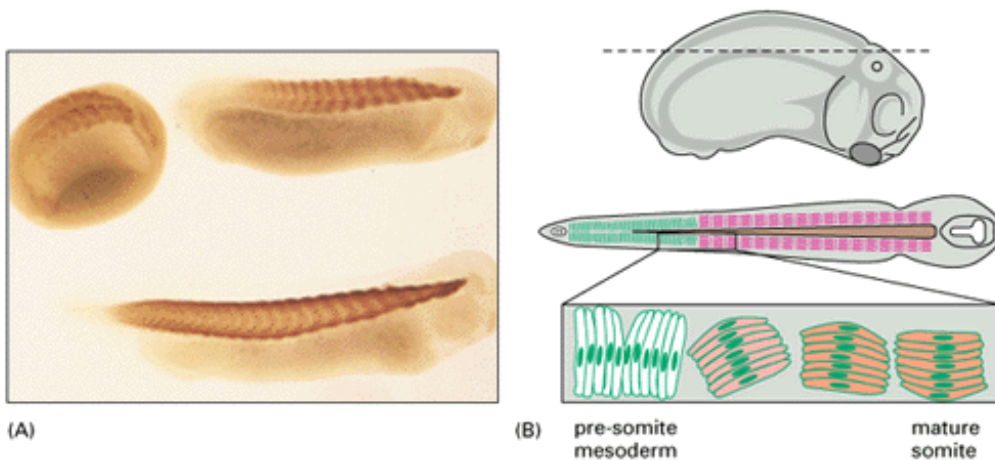
(B) pre-somite mesoderm   mature somite


Figure 21-13. Somite formation in *Xenopus*. (A) Photograph of embryos at three successive stages, seen in side view and stained with a muscle-specific antibody to show the progress of somite formation. (B) Explanatory drawings. A side view of the embryo is shown at the top; the broken line indicates the plane of the horizontal section shown below. The bottom drawing is a schematic high-magnification view of the mesoderm cells in the process of rearranging to form somites. In *Xenopus* the future somite cells are initially all oriented at right angles to the body axis and then rotate in groups during somite formation. The main part of each somite will form muscle and is called the *myotome;* the inner part facing the notochord is the source of the cells that form the vertebrae and ribs and is called the *sclerotome;* the outer, dorsal part (in higher vertebrates, though not in *Xenopus*) will contribute to the dermis (the connective tissue of the skin) and is called the *dermatome.*
Figure 21-14. (*left*) Sorting out. Cells from different parts of an early amphibian embryo will sort out according to their origins. In the classical experiment shown here mesoderm cells, neural plate cells, and epidermal cells have been disaggregated and then reaggregated in a random mixture. They sort out into an arrangement reminiscent of a normal embryo, with a "neural tube" internally, epidermis externally, and mesoderm in between. (Mod-ified from P.L. Townes and J. Holtfreter, *J. Exp. Zool.* 128:53-120, 1955.)
Figure 21-15. (*right*) **Cadherins in the early embryo.** The changing patterns of expression of three cadherins at successive stages in the early chick or mouse embryo, as seen in cross-sections through the developing neural tube and somites. Cells expressing the same type of cadherins tend to stick to each other and to segregate from other cells. The pattern of cadherins thus helps to regulate the pattern of morphogenetic movements involved in formation of the neural tube, notochord, somites, neural crest, and sclerotomes. (After M. Takeichi, *Trends Genet.* 8:213-217, 1987.)

Cell Diversification in the Early Animal Embryo [17], [18]

Introduction

A fertilized egg may develop into a daisy or an oak tree, a sea urchin or a human being. The outcome is governed by the genome: the linear sequence of A, G, C, and T nucleotides in the DNA of the organism must direct the production of a variety of chemically different cell types arranged in a precise pattern in space. Developmental biology aims to explain how. The whole discussion of this problem, in this and subsequent sections, rests on one fundamentally important fact: the cells in the body inherit the same genome from the egg. No matter how different they may appear - in muscle, bone, or nerve, in root, stem, or leaf - they all contain the same set of genetic instructions.

One of the earliest and most powerful demonstrations of this principle came from experiments on nuclear transplantation using amphibian eggs (Figure 21-20). A typical amphibian egg is so large that, using a fine glass pipette, one can readily inject into it a nucleus taken from another cell. The nucleus of the egg itself is destroyed beforehand by ultraviolet irradiation. The egg is activated to begin development by the act of pricking with the fine pipette used to inject the transplanted nucleus. Thus one can test whether the nucleus from a differentiated somatic cell contains a complete genome equivalent to that of a normal fertilized egg and equally serviceable for development. The answer is yes: a complete swimming tadpole can be produced, for example, from an egg whose own nucleus has been replaced by a nucleus derived from a keratinocyte cell from an adult frog's skin or by a nucleus from a frog red blood cell. These experiments admittedly have limitations. They have been successful only with nuclei from a limited range of differentiated cell types and in only a few species. But there is now an overwhelming body of evidence pointing to the same conclusion. With just a few exceptions (see Figure 23-37), the genome remains intact during development. Genes can be switched on or off, and the cells of the body differ not because they contain different genes but because they *express* different genes. In Chapter 9 we examine the intracellular mechanisms for regulating gene expression. In this chapter we have to consider not only how the differences between cells originate, but how they are coordinated in space and time within a multicellular organism. The present section discusses how the first steps of cell diversification are coordinated in early embryos, taking frog and mouse as examples.

Initial Differences Among *Xenopus* Blastomeres Arise from the Spatial Segregation of Determinants in the Egg [2], [17], [19]

In most animal and plant species the egg itself is chemically asymmetrical, with certain components concentrated in specific regions of the cytoplasm or membrane. As a result, there are differences from the outset between the cells that form by cleavage because they receive different portions of the localized materials. The importance of such *localized determinants* in the egg varies from species to species. It is traditional to distinguish two theoretical extremes: in *mosaic* development the whole future pattern of the body is delineated by localized determinants in the egg, and subsequent cell-cell interactions count for nothing; in *regulative* development localized determinants in the egg count for nothing, and the body pattern is generated entirely by subsequent cell-cell interactions. In reality, most higher animals and plants lie between these extremes. None, so far as is known, is truly mosaic - regulative interactions always play an important part; mammalian eggs, as we shall see, appear to be entirely regulative. *Xenopus* represents a typical intermediate case.

The asymmetries of the *Xenopus* egg are manifest in several ways - in the eccentric location of the nucleus, in the distribution of yolk and pigment granules, in the cytoskeleton, and, perhaps most significantly, in the distribution of certain specific mRNAs. The egg asymmetries endow the early blastomeres with different characters according to whether they are animal or vegetal, dorsal or ventral. Treatments such as centrifugation or ultraviolet irradiation that displace the contents of the uncleaved egg or prevent the cortical rotation that usually follows fertilization lead to drastic disturbances of the embryonic body plan, and equally drastic disturbances result if the early blastomeres are artificially rearranged.

Inductive Interactions Generate New Types of Cells in a Progressively More Detailed Pattern [20]

The initial differences between the early blastomeres define only the crude beginnings of the pattern of the embryo. To generate the full range of cell types, the blastomeres must interact with one another. If the early *Xenopus* embryo is placed in a medium

devoid of Ca^{2+} and Mg^{2+}, the blastomeres lose their cohesiveness and can then be separated and allowed to develop on their own; some go on to develop features characteristic of ectoderm, while others develop features characteristic of endoderm, but none of them switches on expression of genes characteristic of mesoderm, such as the muscle-specific actin gene. But when cells from the animal pole of a blastula are placed next to vegetal cells, some of the animal pole cells are diverted from the ectodermal pathway of development into the mesodermal pathway (Figure 21-21). The switching of cells from one pathway into another by the influence of an adjacent group of cells is called induction. During normal development, inductive interactions may occur between cells that have been adjacent from the outset - as in mesoderm induction - or between cells that are brought together through morphogenetic movements such as gastrulation. By a series of successive inductions, it is possible to generate many different kinds of cells from interactions between a few kinds (Figure 21-22).

As we emphasized earlier, asymmetries in the *Xenopus* egg define not only the animal-vegetal axis, and thereby the partitioning of the embryo into ectoderm, mesoderm, and endoderm, but also the dorsoventral and anteroposterior axes of the body. For the organization of the dorsoventral axis, an inductive mechanism again seems to operate. Grafting experiments indicate that, while all vegetal blastomeres can induce mesoderm, they do not all do so in the same way: the *dorsal* vegetal blastomeres are unique in that they induce the cells above them to take on the special character of Spemann's Organizer. The Organizer in its turn, as we saw earlier, produces a signal that induces an array of specializations in the mesoderm next to it. Later still, the pattern created in the mesoderm will induce patterns of local specialization in the ectoderm and endoderm that it contacts.

Thus there seem to be at least three inductive signals at work in the earliest stages of *Xenopus* development: from ventral vegetal blastomeres, from dorsal vegetal blastomeres, and from the Organizer (Figure 21-23). What are these signals in chemical terms? Members of at least four families of secreted signaling proteins seem to be involved. Although their precise roles in normal development are still not clear, all are thought to be present in the early *Xenopus* embryo, and all have dramatic inductive effects when supplied artificially. For at least two of the four, artificial blockade of function produces embryos with major parts of the body missing (Figure 21-24).

Such observations do not explain, however, how the localization of the inductive signals that pass between blastomeres in the *Xenopus* embryo is governed by the pattern of asymmetries in the uncleaved egg. In the case of the *Vg1 protein,* which is a member of the TGF-β superfamily of secreted signaling factors, one can glimpse how this may come about. A store of maternal mRNA coding for the protein is localized in the vegetal part of the egg before fertilization. It is thought that the protein is produced in precursor form in the vegetal regions, and that it may be activated in the dorsal vegetal region and released from dorsal vegetal blastomeres to induce the Organizer (Figure 21-25).

A Simple Morphogen Gradient Can Organize a Complex Pattern of Cell Responses 21

There are many ways in which signals passing from one part of an embryo to another can control pattern formation (Figure 21-26). The Organizer exemplifies one strategy of particular interest: a small patch of tissue in a specific region acquires a specialized character and becomes the source of a signal that spreads into neighboring tissue and controls its behavior. The signal, for example, may take the form of a diffusible molecule secreted from the signaling center. Suppose that this substance is slowly degraded as it diffuses through the neighboring tissue. The steady-state concentration then will be high near the source and decrease gradually with increasing distance, so that a concentration gradient is established (Figure 21-27). Cells at different distances from the source will be exposed to different concentrations and may become different as a result. A substance such as this, whose concentration is read by cells to discover their position relative to a certain landmark or beacon, is termed a morphogen. Morphogen gradients are thought to be a common way of providing cells with positional information or controlling their pattern of differentiation, although there are still only a few cases where a morphogen has been identified chemically.

How do cells respond to a morphogen gradient? The concentration of a diffusible morphogen should be smoothly graded, but many of the important specializations in development are discrete: there is no graded series of mature kinds of cells intermediate between cartilage and muscle, or bone and nerve, for example. In theory, sharp distinctions can arise in a population of initially uniform cells through a *threshold* in their response to a smoothly graded signal. If there is a positive feedback in each responding cell that amplifies the effect of a small increment in the signal, cells exposed to only slightly different intensities of the signal can be launched on radically different courses of development according to whether their exposure is above or below a certain threshold level. If there are several thresholds of response to one signal, a single morphogen can control the pattern of several different cell choices. It has been shown, for example, that when cells from the animal pole of an early *Xenopus* embryo are exposed to the signaling molecule activin (see Figure 21-24), they will develop as epidermis if the activin concentration is low, as muscle if it is a little higher, and as notochord if it is a little higher still. The normal role of activin in the intact *Xenopus* embryo, however, is uncertain, and the nature of the signals emanating from Spemann's Organizer is still unclear.

Cells Can React Differently to a Signal According to the Time When They Receive It: The Role of an Intracellular Clock 22

As development proceeds, embryonic cells generally change their character even if their environment is unchanged. If cells taken from the animal pole of a *Xenopus* blastula, for example, are kept in isolation *in vitro,* they will spontaneously differentiate into epidermis at roughly the normal time. In this sense, the cells behave as though governed by some sort of intracellular clock. Because cells are spontaneously changing their internal state, they may respond differently to an inductive signal according to the time when they receive it. If a fragment of animal pole epithelium is taken from an early gastrula and grafted over the eye rudiment of a later embryo, for example, it will be induced to differentiate (inappropriately) into a piece of tissue resembling neural tube; if it is allowed to age for a few hours *in vitro* before grafting into the same environment, it will be induced to differentiate (appropriately) into a lens; if it is cultured *in vitro* for a longer period still, it loses competence to respond to the inductive influence from the eye rudiment in either of these ways.

There is an important general lesson here: cellular diversity and spatial patterning can arise from a simple *unchanging* inductive signal acting on a succession of otherwise identical cells at different times (Figure 21-28). We have seen, for example, that the parts of the central body axis are formed sequentially during gastrulation, with anterior parts involuting around the blastopore lip first and posterior parts last. According to one theory, the difference in the age at which the cells pass the dorsal lip and are acted on by Spemann's Organizer could be the source of the differences of cell character between the anterior and posterior parts of the mesoderm and endoderm and therefore of the body as a whole.

Thus the general strategy of pattern formation can be summarized as follows: (1) patterns begin from simple asymmetries, (2) details are filled in sequentially through inductive cell-cell interactions, and the pattern of cell diversification that results depends both on (3) the positional signals between cells and on (4) intracellular programs that change a cell's response to these signals with time.

In different species these four basic elements may be combined in different ways. We now consider the special case of the early mammalian embryo, which has some remarkable regulative properties.

In Mammals the Protected Uterine Environment Permits an Unusual Style of Early Development 9, 23

The mammalian embryo does many things differently from other animals. Developing in the protected environment of the uterus, it does not have the same need as the embryos of most other species to complete the early stages of development rapidly. Moreover, the development of a placenta quickly provides nutrition from the mother, so that the egg does not have to contain large stores of raw materials such as yolk. The egg of a mouse has a diameter of only about 80 μm and therefore a volume about 2000 times smaller than that of a typical amphibian egg. Its cleavage divisions occur no more quickly than the divisions of many ordinary somatic cells, and gene transcription has already begun by the two-cell stage. Furthermore, while the later stages of mammalian development are fundamentally similar to those of other vertebrates such as *Xenopus,* mammals begin by taking a large developmental detour to generate a complicated set of structures - notably the amniotic sac and the placenta - that enclose and protect the embryo proper and provide for the exchange of metabolites with the mother. These structures, like the rest of the body, derive from the fertilized egg but are called *extraembryonic* because they are discarded at birth and form no part of the adult.

The early stages of mouse development are summarized in Figure 21-29. The egg is surrounded initially by a transparent cell coat, the *zona pellucida.* Upon fertilization, the egg cleaves within this coat to form a mulberry-shaped cluster of cells called the *morula.* Sometime between the 8-cell and 16-cell stages, the surface of the morula becomes smoother and more nearly spherical as the cells change their cohesiveness and become compacted together (Figure 21-30), with tight junctions forming between the outer cells and sealing off the interior of the morula from the external medium. Soon after, the internal intercellular spaces enlarge to create a central fluid-filled cavity - the blastocoel. At this stage the morula is said to have become a *blastocyst.* The cells of the blastocyst form a spherical shell enclosing the blastocoel, with one pole distinguished by a thicker accumulation of cells. As shown in Figure 21-29, the entire outer cell layer is the *trophectoderm;* the cluster of cells inside the trophectoderm at the thicker pole is called the *inner cell mass.*

The whole of the embryo proper is derived from the inner cell mass. The trophectoderm is the precursor of the placenta and is the earliest component of the system of extraembryonic structures. Once the zona pellucida has been shed, the cells of the trophectoderm come into close contact with the wall of the uterus, in which the embryo becomes implanted. Meanwhile the

inner cell mass grows and begins to differentiate. Part of it gives rise to some further extraembryonic structures, such as the yolk sac, while the rest of it goes on to form the embryo proper by processes of gastrulation, neurulation, and so on, that are largely homologous to those seen in other vertebrates, although extreme distortions of the geometry sometimes make the homology hard to discern.

All the Cells of the Very Early Mammalian Embryo Have the Same Developmental Potential [24]

Up to the eight-cell stage, each cell of the early mammalian embryo can form any part of the later embryo or adult. If the early embryo is split in two, a pair of identical twins can be produced - two complete normal individuals from a single cell. Similarly, if one of the cells in a two-cell mouse embryo is destroyed by pricking it with a needle and the resulting "half-embryo" is placed in the uterus of a foster mother to develop, in many cases a perfectly normal mouse will emerge.

Conversely, two eight-cell mouse embryos can be combined to form a single giant morula, which then develops into a mouse of normal size (Figure 21-31). Such creatures, formed from aggregates of genetically different groups of cells, are called chimeras. Chimeras can also be made by injecting cells from an early embryo of one genotype into a blastocyst of another genotype. The injected cells become incorporated into the inner cell mass of the host blastocyst, and a chimeric animal develops. It is even possible to make a chimera by injecting a single cell in this way; thus one can assay the developmental capabilities of the single cell. One of the major conclusions derived from these studies is that the cells of the very early mammalian embryo (up to the eight-cell stage) are initially identical and unrestricted in their capabilities: they are all *totipotent*. Localized determinants apparently have no part to play in the mammalian egg, and the pattern of cell diversification in the embryo is generated later, entirely through interactions of the cells with one another and with their environment.

Mammalian Embryonic Stem Cells Show How Environmental Cues Can Control the Pace as well as the Pathway of Development [25]

Mammalian early development is highly *regulative*. The fate of each cell is governed by interactions with its neighbors. The mouse experiments just described illustrate this well. The cells in a half-embryo or in a chimeric double embryo must adjust their behavior so as to generate an animal that is normal in both pattern and size. When the circumstances of development are more grossly abnormal, however, the embryonic cells can go wildly out of control. Some important lessons can be learned from these phenomena.

If a normal early mouse embryo is grafted into the kidney or testis of an adult, it rapidly becomes disorganized, and the normal controls on cell proliferation break down. The result is a bizarre growth known as a *teratoma*, which consists of a disorganized mass of cells containing many varieties of differentiated tissue - skin, bone, glandular epithelium, and so on - mixed with undifferentiated stem cells that continue to divide and generate yet more of these differentiated tissues. Teratomas with similar properties can also arise spontaneously from germ cells in the gonads as the result of various developmental accidents.

It is possible to derive transplantable cancers from teratomas. Such *teratocarcinomas* will grow without limit until they kill their host. They can be maintained indefinitely by grafting samples of the tumor cells serially from one host to another, and they always include some undifferentiated *stem cells,* together with a variety of differentiated cell types to which the stem cells give rise. The teratocarcinoma stem cells can also be maintained in culture as permanent cell lines.

One might think that teratocarcinoma stem cells originate, as in other cancers, through mutations in genes responsible for the normal controls of cell behavior (discussed in Chapter 24). The following observations, however, suggest that this is not the case. Stem cells with very similar properties can be derived by placing a normal inner cell mass in culture and dispersing the cells as soon as they proliferate. Once dispersed, some of the cells, if kept in suitable culture conditions, will continue dividing indefinitely without altering their character. The resulting *embryonic stem (ES)* cell lines are similar to teratocarcinoma-derived cell lines, but they can be generated at such high frequency from normal embryos that it is unlikely that they arise by mutation. Instead, it appears that separating the cells from their normal neighbors and placing them in the appropriate culture medium has arrested the normal program of change of cell character with time and so enabled the cells to carry on dividing indefinitely without differentiating. The presence in the medium of a protein growth factor known as *leukemia inhibitory factor (LIF)* seems to be critical for this suspension of developmental progress. With a slightly more complex cocktail of growth factors, embryonic germ cells can be induced to behave in the same way in culture.

The state in which the ES, teratocarcinoma, or germ-cell-derived stem cells are arrested seems to be equivalent to that of normal inner-cell-mass cells. This can be shown by taking the cells from their culture dish and injecting them into the blastocoel cavity

of a normal blastocyst ([Figure 21-32](#)). The injected cells become incorporated in the inner cell mass of the blastocyst and can contribute to the formation of an apparently normal chimeric mouse. Descendants of the injected stem cells can be found in practically any of the tissues of this mouse, where they differentiate in a well-behaved manner appropriate to their location and can even form viable germ cells. This capability of ES cells forms the basis for a widely used technique that allows mice to be generated with a genetically engineered mutation in any chosen gene whose DNA has been cloned. To produce such "gene-knockout" mice, mutant ES cells are made by selecting for a DNA insertion that replaces the chosen gene by an artificially altered version; the mutant ES cells are then used to produce chimeric mice that carry the mutation in their germ cells (see p. 329).

The extraordinarily adaptable behavior of ES cells shows that environmental cues not only guide choices between different pathways of differentiation, but in certain cases, they can also stop or start the developmental clock - the processes that drive a cell to progress from an embryonic to an adult state.

Summary

In the course of embryonic development many types of cells are generated from the fertilized egg. The genomes of the differentiated cells remain the same; it is the pattern of gene expression that changes. Some of the differences between cells in the early embryo generally originate from the unequal distribution of cytoplasmic determinants localized in the egg before cleavage, but most of them arise later from local differences in the environments of the cells in the embryo. In Xenopus, for example, the animal and vegetal cells of the early embryo inherit different cytoplasmic determinants from the egg, and an influence from the vegetal cells then induces some of the animal cells to develop as mesoderm instead of ectoderm. This mesoderm induction seems to be mediated by families of growth factor proteins that also help regulate growth and differentiation in the mature organism.

Mammalian eggs are exceptional in that they are essentially symmetrical. Thus all the cells in an early mammalian embryo are initially alike and become different only through their interactions with one another. Through cell-cell interactions cells from two different early mouse embryos can adjust their fates and collaborate to form a single chimeric mouse. Early mouse embryo cells removed from the normal influences of their neighbors can proliferate inappropriately to give rise to teratocarcinomas, from which embryonic stem cells can be obtained. But when implanted into a normal early embryo, such cells revert to normal behavior, and their progeny differentiate according to their environment and can contribute to the formation of a healthy chimeric animal.

Although all four classes of factors can have powerful effects on mesoderm induction, their exact roles in relation to the three-signal model (Figure 21-23) are not yet certain. The Wnt, activin, and FGF (fibroblast growth factor) families of factors are well known as cell-cell signaling molecules in other contexts; activin (like Vgl - see Figure 21-25) belongs to the TGF-b superfamily of growth factors. Reception of activin or FGF signals can be blocked by injecting mRNA coding for a defective form of the corresponding receptor protein, which lacks the intracellular domain and interferes with the function of the normal receptor. (A) *In situ* hybridization with a probe for Vgl mRNA, showing its localization in the vegetal cortical region of the oocyte (the future egg). (B) Diagrams illustrating a hypothesis as to how Vgl acts. Vgl mRNA is synthesized in the oocyte and becomes localized, by unknown mechanisms, in the vegetal cortical regions of the cell. In the same way as for other TGF-b superfamily members, the active form of Vgl protein is a fragment cleaved from the full-length precursor. The control of the activating cleavage step is not understood. When mRNA coding for full-length Vgl is injected into an early embryo, very little of the active fragment is produced and no effect on embryo patterning is seen. But if the mRNA is modified to code for a precursor that is readily cleaved to produce the Vgl active fragment, the effects are dramatic: an entire body axis can be induced, in a way that suggests that the Vgl fragment is mimicking the signal that normally comes from dorsal vegetal blastomeres and induces development of the Organizer. According to one proposal, Vgl acts as this signal in normal development, and the production of the active Vgl fragment is localized to dorsal vegetal blastomeres by a two-step process. First, the mRNA is delivered to the vegetal end of the egg; then the cortical rotation that follows fertilization creates special conditions in the dorsal part of the vegetal cortex, such that the precursor protein is cleaved there to produce the active fragment. This then is released from the dorsal vegetal blastomeres to induce formation of an Organizer. (A, courtesy of Douglas Melton.)

Cell Memory, Cell Determination, and the Concept of Positional Values

Introduction

Cells must not only become different, they must also *remain* different after the original cues responsible for cell diversification have disappeared. Despite the continual turnover and resynthesis of almost all cell components, most cell types in the adult body have at least some distinctive features that are stably and heritably maintained even when the environment is changed. Thus, when a pigment cell divides, its daughters remain pigment cells; when a keratinocyte from the skin divides, its daughters remain keratinocytes; even though a fibroblast may be convertible into some other sort of connective-tissue cell such as a cartilage cell, it never changes into a neuron or a liver cell; and so on. Such durable differences between cell types are ultimately due to the different influences that the cells have been subjected to in the embryo, but the differences are maintained because the cells somehow remember the effects of those past influences and pass them on to their descendants. As we discuss in this section, cell memory - and the types of information, especially positional information, that cells retain as a consequence - are central elements of the patterning mechanisms that make a complex multicellular organism possible.

Cells Often Become Determined for a Future Specialized Role Long Before They Differentiate Overtly [15], [26]

Cell memory is most obvious in the persistence and stability of the differentiated states of cells in the adult body (discussed in Chapter 22). But the final character of a cell has usually been decided by a complex sequence of cues delivered to its progenitors during development and is often fixed long before differentiation becomes manifest. Through a series of decisions taken before, during, and just after gastrulation, for example, certain cells in the somites of a vertebrate become specialized at a very early stage as precursors of skeletal muscle cells; they then migrate from the somites into various other regions including those where the limbs will form (see Figure 21-16). These muscle cell precursors lack the large quantities of specialized contractile proteins found in mature muscle cells; indeed, they look superficially just like the other cells of the limb rudiment. But after several days they begin manufacturing large quantities of specialized muscle proteins, whereas the other limb cells with which they are mingled differentiate into various types of connective-tissue cells. Thus the developmental choice between muscle and

connective tissue has been made by each cell long before it is expressed in overt differentiation, and it is meanwhile recorded in each cell as a molecular change that has no obvious effect on the cell's outward appearance.

A cell that has made a developmental choice in the above sense is said to be *determined.* Since the concept is a basic part of the language of developmental biology, it is useful to have a formal definition: a cell is determined if it has undergone a self-perpetuating change of internal character that distinguishes it and its progeny from other cells in the embryo and commits them to a specialized course of development. The term differentiation is generally reserved for *overt* cell specialization, that is, for a specialization of cell character that is grossly apparent. Usually, a cell becomes determined before it differentiates, although in some cases the two processes occur simultaneously. Indeed, it is possible for differentiation to occur without determination, if the overt specialization of cell character is reversible.

The Time of Cell Determination Can Be Discovered by Transplantation Experiments 27

To prove that a cell or group of cells is determined, one must show that it has a distinctive character that is maintained even when its circumstances are altered by experimental manipulation. The standard technique is to transplant the cells to a test environment (Figure 21-33).

A simple example of such an experiment comes from studies on amphibian embryos. As noted earlier, one can plot a fate map for a blastula or an early gastrula, showing which of its parts will normally develop into what. The cells in one region, for example, are fated to become epidermis if development proceeds normally, while those in another region are fated to form brain. To establish when these two groups of cells become *determined* to follow their particular modes of differentiation, a block of cells is cut from the prospective epidermal region and put in the position of prospective brain, and vice versa. If the cells are transplanted at the early gastrula stage, they show no memory of their origins and differentiate in the fashion appropriate to their new locations. If, however, the same experiment is done at a somewhat later stage, in the late gastrula, the prospective brain cells transplanted to an epidermal site will differentiate as misplaced neural tissue, and the prospective epidermal cells transplanted to a brain site will differentiate there as misplaced epidermis. This shows that both groups of cells have become determined sometime between the early and late gastrula stages.

Cell Determination and Differentiation Reflect the Expression of Regulatory Genes 28

The phenomenon of determination raises three molecular questions: what molecule or molecules define a cell's state of determination; what is the memory mechanism that maintains that state; and how is determination coupled to differentiation? In general, the character of a cell is governed by the combination of gene regulatory proteins that it contains. These control its pattern of gene expression. In the well-studied case of muscle, as discussed in Chapter 9, a critical part is played by the *MyoD family* of closely related *myogenic proteins* (MyoD, Myf5, MRF4, and myogenin). In suitable circumstances these can activate the expression of muscle-specific genes such as muscle actin and muscle myosin, and introduction of a MyoD family member into fibroblasts and various other cell types can convert them into muscle precursor cells. In normal development genes coding for proteins of the MyoD family begin to be switched on very early in the muscle precursor cells as they leave the somites, suggesting that the presence of these proteins defines the cells' state of determination. And if the myogenin gene is deleted by targeted genetic recombination, for example, muscle cells fail to develop.

The set of genes subject to activation by MyoD family members includes at least some of the genes of that family themselves. For this reason, expression of one member of the family generally leads to expression of others as well. In addition, at least some of these regulatory proteins act back directly on their own gene, so as to maintain expression of the gene once it has been turned on. The *positive feedback* resulting from mutual activation and self-activation provides a possible mechanism for cell memory, as discussed in Chapter 9.

This still leaves a problem. The muscle precursor cells do not start to manufacture large quantities of muscle-specific proteins until days, weeks, or even years after leaving the somites. How can they remain undifferentiated for so long after they have become determined? The mechanism is thought to depend on other proteins that interact with MyoD family members and regulate their action. As discussed in Chapter 9, MyoD and its relatives belong to the helix-loop-helix superfamily, whose members dimerize with one another in order to bind to DNA and activate gene expression. The efficacy in gene activation depends on the choice of partner for dimerization. By regulating the availability of appropriate dimerization partners for a protein of the MyoD family, the cell can apparently switch from a determined state, where the protein is able to maintain production of MyoD family members only, to a differentiated state, where the protein activates the full panoply of muscle-specific genes (Figure 21-34).

The State of Determination May Be Governed by the Cytoplasm or Be Intrinsic to the Chromosomes <u>29</u>

Cell memory, as manifested in the phenomenon of determination, presents one of the most challenging problems in molecular biology. In <u>Chapter 9</u> we discuss some of the molecular mechanisms by which certain patterns of gene expression can become self-sustaining. In the context of cell determination three broad categories of cell memory can be distinguished, which may be called *cytoplasmic, autocrine,* and *nuclear memory,* respectively. The mechanism that has just been outlined for the myogenic proteins is an example of cytoplasmic memory. Here, components encoded by the set of active genes are present in the cytoplasm and act back on the genome, directly or indirectly, to maintain the selective expression of that specific set of genes. An implication of this mechanism is that if a nucleus is taken from one type of differentiated cell and injected into the cytoplasm of another type, the pattern of gene expression should alter to match the character of the host cytoplasm. The nuclear transplantation experiments on amphibian eggs that we discussed earlier provide an example of this sort of behavior.

The autocrine memory mechanism is a variant of the cytoplasmic. It depends again on the synthesis of products that stimulate their own production, but with the special feature that these products are secreted into the extracellular medium and act back on the cell's exterior to keep the cell in the state where it produces them. This mechanism has an important side effect: since neighboring cells share the same extracellular environment, they will tend to behave cooperatively, adopting the same state because they are exposed to the substances that they themselves produce, and an individual cell transplanted into a new environment will tend to switch its character to match that of the cells that surround it on all sides. Thus a group of cells may behave as determined, even though an individual cell in isolation does not. Such "community effects" in cell determination seem to be common and have been especially well documented in the early *Xenopus* embryo.

In contrast with cytoplasmic and autocrine memory, nuclear memory depends on self-sustaining changes that are intrinsic to the chromosomes - changes that define the selection of genes to be expressed and yet leave the DNA sequence unaltered. X-chromosome inactivation (see p. 446) and genomic imprinting (see p. 451) are well-established examples. Nuclear memory is based on inherited modifications in the chromatin or the DNA; unlike cytoplasmic memory, it allows two identical genes to coexist in different states in a single cell, one being expressed and the other not, even though both are exposed to the same intracellular environment.

Our ignorance is still profound concerning cell memory, and it is not yet possible in most cases even to classify the memory mechanism as cytoplasmic or nuclear.

Cells in Developing Tissues Remember Their Positional Values <u>30</u>

In an animal embryo positional signals and interactions operate over small distances, on the order of a millimeter or less, and through cell memory these influences leave their mark on cell character. As the body grows, further influences act locally in each of its parts, creating new distinctions within each class of cells and embroidering progressively finer levels of detail on the original basic body plan.

Thus before cells become committed to a particular mode of differentiation, they usually become *regionally specified:* they acquire distinct biochemical address labels, or positional values, that reflect their location in the body. The positional value of a cell will guide its behavior in subsequent steps of pattern formation - the way it responds to later positional signals, the ways in which it interacts with its neighbors, and the range of modes of differentiation ultimately open to it and its progeny. The cues that control the choice of positional value are said to provide the cell with *positional information.*

The existence and nature of remembered positional values is dramatically demonstrated by grafting experiments that have been carried out between the developing leg and wing of the chick embryo. The leg and the wing of the adult both consist of muscle, bone, skin, and so on - almost exactly the same range of differentiated tissues. The difference between the two limbs lies not in the types of tissues, but in the way in which those tissues are arranged in space. So how does the difference come about? At first sight it might seem simplest to explain the difference in terms of the presence of a different spatial distribution of signals in the developing forelimb and hindlimb, which directly tells cells which differentiated state to adopt. A simple grafting experiment shows that this view is profoundly wrong.

In the chick embryo the leg and the wing originate at about the same time in the form of small tongue-shaped buds projecting from the flank (<u>Figure 21-35</u>). The cells in the two pairs of limb buds appear similar and uniformly undifferentiated at first (see <u>Figure 19-30</u>). A small block of undifferentiated tissue at the base of the leg bud, from the region that would normally give rise

to part of the thigh, can be cut out and grafted into the tip of the wing bud. Remarkably, the graft forms not the appropriate part of the wing tip, nor a misplaced piece of thigh tissue, but a toe (Figure 21-36). This experiment shows that the early leg-bud cells are already determined as leg but are not yet irrevocably committed to form a particular part of the leg: they can still respond to cues in the wing bud so that they form structures appropriate to the tip of the limb rather than the base. The signaling system that controls the differences between the parts of the limb is apparently the same for leg and wing. The difference between the two limbs results from a difference in the internal states of their cells at the outset of limb development. Even though the cells look the same and are destined to give rise to the same range of differentiated cell types, they are *nonequivalent,* with different positional values. In this way the final specification of how a limb cell should behave is built up combinatorially: first it is supplied with information as to whether it is to be leg or wing; then signals within the growing limb bud specify more fine-grained components of positional value, reflecting the precise position within the limb.

One of the most remarkable revelations of modern molecular genetics has been that almost all animals seem to use the same highly conserved molecular machinery to record positional values along the head-to-tail axis of the body, and some of these same gene products also operate to specify positional values in the limbs of vertebrates. We shall postpone the discussion of these master regulators of the body pattern until we have introduced the fruit fly, *Drosophila,* where the machinery was first discovered and characterized.

The Pattern of Positional Values Controls Cell Proliferation and Is Regulated by Intercalation 31

A crucial aspect of pattern formation is the regulation of cell proliferation, through which the parts of the pattern attain their appropriate sizes. In many cases growth and the pattern of positional values both depend in a closely coupled way on continuing cell-cell interactions. A simple rule has been deduced from studies of the regeneration that occurs in various organisms when fragments of tissue with different positional values are juxtaposed and allowed time to grow and adjust. The principles appear to be general, but they are perhaps most clearly illustrated by studies on the leg of the cockroach (Figure 21-37).

Cockroaches belong to the class of insects in which there is no radical metamorphosis from larva to adult but a gradual progression through a series of juvenile forms separated by molts, in which the old coat of cuticle is shed and a larger one is laid down. The juvenile cockroach has well-differentiated limbs, but the differentiated cells - unlike those in human limbs - are still able to respond to the cues that governed the development of the limb pattern, and they can regenerate that pattern if it is disturbed. Thus the workings of the pattern-formation system can be tested by operations done long after the period of embryonic development.

If two cockroach legs are amputated through one of their middle segments - through the tibia, say - but at different levels, the distal fragment of the one can be grafted onto the proximal stump of the other in such a way that the composite leg heals with the middle part of the tibia missing. Yet the leg that emerges after the animal has molted appears normal: the missing middle part of the pattern has regenerated (Figure 21-38A). More surprising is the result of a variant of this operation. The tibia of one cockroach leg is cut through near the proximal end and that of another leg near the distal end. The large detached portion of the first leg is then stuck onto the large remaining stump of the second leg to give an excessively long leg with a middle part present in duplicate (Figure 21-38B). The animal is left to molt. The leg that results, far from being more nearly normal, is now even longer because a third middle part of a tibia has developed between the two already present. As shown in Figure 21-38B, the bristles on this freshly formed region point in the direction opposite to that of the bristles on the rest of the tibia.

Many different operations of this type can be performed. All of them point to the existence in the insect epidermis of a system of positional values that makes the cells at different positions along the limb axis nonequivalent, and that is intimately coupled to the control of cell proliferation. It is convenient to describe the positional value by a number that goes from a maximum at one end of the limb segment to a minimum at the other. In the operations described above, cells with widely different positional values are brought together. As a result, new cells are formed by proliferation of the cells in the neighborhood of the junction. These new cells acquire positional values interpolated between those of the two sets of cells that were brought into confrontation (Figure 21-38). This behavior is summed up in the rule of intercalation: *discontinuities of positional value provoke local cell proliferation, and the newly formed cells take on intermediate positional values so as to restore continuity in the pattern.* Cell proliferation ceases only when cells with all the missing positional values have been intercalated in the initial gap and have become spread out to the normal spatial separation from one another. This process as a whole is called intercalary regeneration.

The rule of intercalation, with the corollary that cell proliferation continues until a certain spacing of positional values has been attained, is a powerful organizing principle in those systems to which it applies. Beginning with a pattern specified approximately and in miniature - for example, by a morphogen gradient - it can bring about the construction of a complete

accurate pattern of positional values and regulate the growth of each part of the pattern to a standard size: all that is necessary is that the initial pattern should be qualitatively - that is, topologically - correct. The same rule appears to govern many processes of organogenesis and regeneration not only in insects but also in crustaceans and amphibians. Even in creatures such as mammals, where lost structures generally do not regenerate in the adult, the rule of intercalation may help to regulate growth and pattern formation during embryonic development. Unfortunately, the molecular mechanisms that underlie this crucial form of growth control are unknown.

Summary

Embryonic cells must not only become different, they must also remain different even after the influence that initiated cell diversification has disappeared. This requires cell memory, which enables cells to become determined for a particular specialized role long before they differentiate overtly. The mechanisms of cell memory may be cytoplasmic, involving molecules in the cytoplasm that act back on the nucleus to maintain their own synthesis, autocrine, involving secreted molecules that act back on the cell, or nuclear, involving processes of chromatin or DNA modification. In some cases the state of determination has been related to the expression of specific regulatory genes, such as the myogenic genes for muscle cells.

The different kinds of cells in an embryo are produced in a regular spatial pattern. The formation of this pattern usually begins with asymmetries in the egg and continues by means of cell-cell interactions in the embryo. The spatial signals that coordinate pattern formation supply cells with positional information, and a cell's remembered record of this information is called its positional value. Cells in the early forelimb and hindlimb rudiments of a vertebrate embryo, for example, acquire different positional values, making forelimb and hindlimb cells nonequivalent in their intrinsic character, long before the detailed pattern of cell differentiation has been determined.

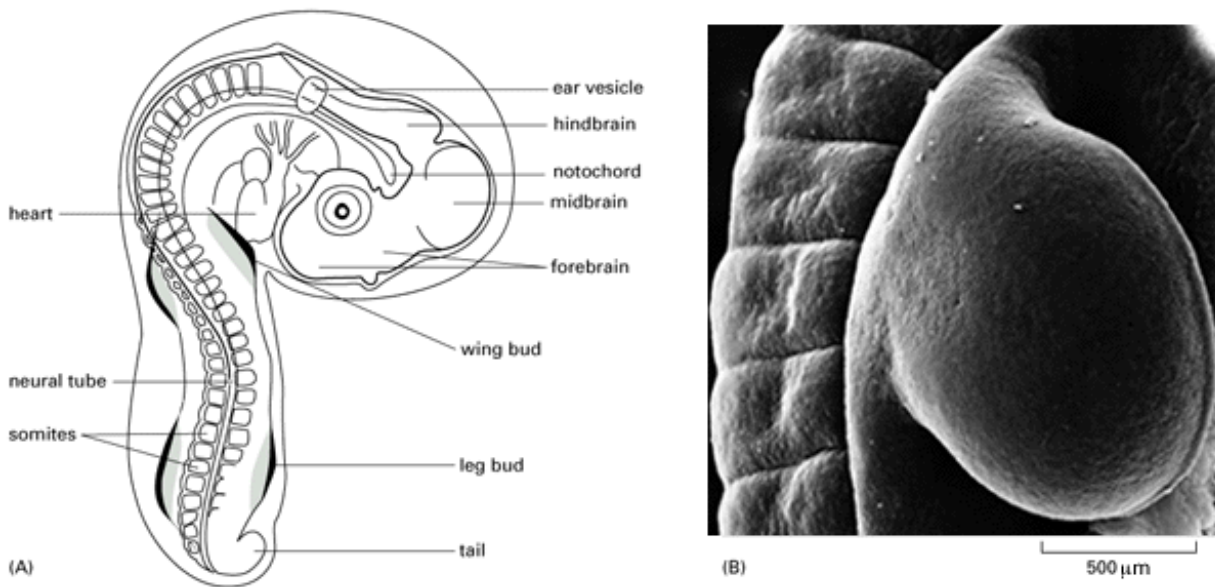
In many animals the pattern of positional values is closely coupled to the control of cell proliferation according to a simple rule of intercalation. According to the rule, discontinuities of positional value provoke local cell proliferation, and the newly formed cells take on intermediate positional values that restore continuity in the pattern. This mechanism is likely to operate in normal embryonic development to correct inaccuracies in the initial specification of positional information.
The standard test of determination.
Figure 21-34. Genetic control circuitry for muscle cell determination. In this simplified diagram only two representative members of the MyoD family of genes are shown *myoD* itself and *myogenin.* Mutual activation and self-activation of these genes by their own products create positive feedback that tends to make expression of the genes self-sustaining. Id is a helix-loop-helix protein encoded by the *inhibitor-of-DNA-binding* gene; by dimerizing with other helix-loop-helix proteins, and in particular by competing with MyoD family members for the requisite partners, it is thought to hinder expression of muscle-specific genes. The full control system for muscle differentiation is, however, certainly more complicated than this diagram suggests.


Figure 21-35. Chick limb development. (A) A chick embryo after 3 days of incubation, illustrating the positions of the early limb buds. (B) Scanning electron micrograph showing a dorsal view of the wing bud and adjacent somites 1 day later; the bud has grown to become a tongue-shaped projection about 1 mm long, 1 mm broad, and 0.5 mm thick. (A, after W.H. Freeman and B. Bracegirdle, An Atlas of Embryology. London: Heinemann, 1967; B, courtesy of Paul Martin.)
Figure 21-36. Prospective thigh tissue grafted into the tip of a chick wing bud forms toes. (After J.W. Saunders et al., *Dev. Biol.*1:281-301, 1959.)
Figure 21-37. The cockroach leg. With each successive molt the leg grows bigger (by cell proliferation) but does not change its basic structure. The leg is covered by a cuticle that is secreted by a sheet of epidermal cells and replaced at each molt. The pattern of the cuticle reflects the pattern of positional values in the underlying epidermal sheet.
Figure 21-38. Intercalary regeneration. When mismatched portions of the cockroach tibia are grafted together, new tissue (*green*) is intercalated (by cell proliferation) to fill in the gap in the pattern of positional values (numbered from 1 to 10). In case (A) intercalation restores the missing part. In case (B) intercalation generates a third middle part of a tibia between the two middle parts already present. The bristles indicate the polarity of the intercalated tissue. In both cases continuity is restored in the final pattern of positional values.

The Nematode Worm: Developmental Control Genes and the Rules of Cell Behavior <u>32</u>

Introduction

For cells, as for computers, memory makes complex programs of behavior possible, and many cells together, each one stepping through its complex developmental program, can generate a very complex adult body. Some of the steps that a cell takes in the course of development are autonomous, while others are affected by signals from other cells. Thus the cells of the embryo can be likened to an array of little computers, or *automata,* operating in parallel and exchanging information with one another. The rules that determine cell behavior are encoded in the cell's genes. Each cell contains the same genome and therefore behaves according to the same rules, but it can exist in a variety of states; the rules direct development along various alternative paths according to a combination of the past information the cell has remembered and the present environmental signals it receives. Computer modeling shows that even a very simple set of rules for the individual automata (cells) in such a system can lead to the production of astonishingly complex patterns; one cannot deduce the rules simply by observing the normal development of the pattern. The challenge, therefore, is to decipher the underlying cellular rules of development by experimentation and to find out how they are specified by the genes.

In this enterprise the nematode worm *Caenorhabditis elegans* offers some exceptional advantages, and it has become one of the foremost model systems in developmental genetics. We use it here to illustrate some general principles. A detailed discussion of the developmental genetics of pattern formation, however, is reserved for the next section, on *Drosophila,* where more years of research and a much larger army of research workers have provided a fuller picture.

Caenorhabditis elegans **Is Anatomically and Genetically Simple** <u>33</u>

As an adult, *C. elegans* is about 1 mm long and consists of only about 1000 somatic cells and 1000-2000 germ cells (exactly 959

somatic cell nuclei plus about 2000 germ cells are counted in one sex; exactly 1031 somatic cell nuclei plus about 1000 germ cells in the other) (Figure 21-39). The anatomy has been reconstructed, cell by cell, by electron microscopy of serial sections. The body plan of this simple worm is fundamentally the same as that of most higher animals in that it has a roughly bilaterally symmetrical, elongate body composed of the same basic tissues (nerve, muscle, gut, skin) organized in the same basic way (mouth and brain at the anterior end, anus at the posterior). The outer body wall is composed of two layers: the protective hypodermis, or "skin," and the underlying muscular layer. A simple tube of endodermal cells forms the intestine. A second tube, located between the intestine and the body wall, constitutes the gonad; its wall is composed of somatic cells, with the germ cells inside it. *C. elegans* has two sexes - a hermaphrodite and a male. The hermaphrodite can be viewed most simply as a female that produces a limited number of sperm: she can reproduce either by self-fertilization, using her own sperm, or by cross-fertilization after transfer of male sperm by mating. Self-fertilization allows a single heterozygous worm to produce homozygous progeny, a special feature that helps to make *C. elegans* an exceptionally convenient organism for genetic studies.

The relative simplicity of *C. elegans* anatomy is reflected in a similar simplicity of its genome. The animal has six homologous pairs of chromosomes, estimated to carry a total of 3000 "essential" genes (that is, genes in which mutations are lethal or have an easily observable effect on the phenotype) and four or five times that number of nonessential genes. The haploid genome consists of approximately 10^8 nucleotide pairs of DNA, which is about 20 times more than *E. coli,* about the same as *Drosophila,* and 30 times less than humans. Currently, more than 900 essential genes have been identified by mutation. These include genes that influence visible features such as the shape or behavior of the worm, genes that code for known proteins such as myosin, and genes that control the course of development. Nearly the entire genome has been mapped as a large set of overlapping DNA segments, represented by a library of ordered genomic clones (see p. 314), and a systematic effort has begun to determine the complete DNA sequence of the organism.

Nematode Development Is Almost Perfectly Invariant [34]

C. elegans begins life as a single cell, the fertilized egg, which gives rise, through repeated cell divisions, to 558 cells that form a small worm inside the egg shell. After hatching, further divisions result in the growth and sexual maturation of the worm as it passes through four successive larval stages separated by molts. After the final molt to the adult stage, the hermaphrodite worm begins to produce its own eggs. The entire developmental sequence, from egg to egg, takes only about three days.

Because C. *elegans* is small and transparent, its individual cells can be followed as they divide, migrate, differentiate, and die in the living embryo, and their pedigree can be traced from egg to adult organism. By this simple technique of direct observation, the behavior and lineage of all of the cells from the single-cell egg to the adult animal have been described. This has made possible a detailed lineage analysis that would be very difficult in larger animals, where individual cells at early stages usually must be specially marked if they and their progeny are to be identified later. Moreover, in larger animals the details of cell lineage show many random variations, even between genetically identical individuals. In the nematode, by contrast, the somatic structures develop by an invariant, predictable cell lineage, and each of the many cell divisions is precisely timed. This means that a given precursor cell follows the same pattern of cell divisions in every individual, and with very few exceptions the fate of each descendant cell can be predicted from its position in the lineage tree (Figure 21-40).

The full description of cell lineage in *C. elegans* leads to an immediate answer to a fundamental question. The nematode, like most animals, is formed from a relatively large number of cells that can be classified into a much smaller number of differentiated cell types. Given the importance of cell ancestry, one might be tempted to guess that all the cells of a given type are descendants of a single "founder cell" committed exclusively to that developmental pathway. Lineage analysis shows, however, that this is not generally true, either for nematodes or for other animals. Thus in *C. elegans* (with a few exceptions such as the intestinal cells and the germ-line cells) each class of differentiated cells - hypodermal, neuronal, muscular, gonadal - is derived from several founder cells originating in separate branches of the lineage tree (see Figure 21-40). Thus cells of similar character need not be close relatives. Conversely (but rarely), cells of very different character may be closely related by lineage; for example, some of the neurons in *C. elegans* are sisters of muscle cells.

The problem, then, is to understand the rules that operate in each branch of the lineage tree to generate a specific array of cell types, each in appropriate numbers.

Developmental Control Genes Define the Rules of Cell Behavior That Generate the Body Plan [35]

To explain how the genome specifies the developmental rules, one has to be able to identify the genes that control the cells' developmental choices. Mutations in such genes will disturb development, but they are not the only mutations that do so. Some

mutations, for example, will cut short all cell lineages and cause premature death of the embryo simply because they disrupt "housekeeping" genes that every cell needs in order to survive and proliferate. Other mutations will affect genes for proteins that particular types of differentiated cells require in order to carry out their specialized function; the body plan will then be essentially normal, but certain cell types, though still identifiable, will malfunction. Mutations in genes that are involved specifically in controlling developmental choices, by contrast, will disturb the body plan: they typically give rise to cells of the normal differentiated types arranged in an abnormal pattern or in abnormal numbers as a result of specific alterations in the lineage tree. Developmental control genes identified in this way can be classified according to the parts of the lineage tree that are affected and, hence, if we know the rules of cell behavior that generate that part of the lineage tree, according to the rules of cell behavior for which they are responsible.

To illustrate the principles of genetic analysis of a developmental mechanism, we discuss one example of a cell-cell interaction in the nematode - the induction of the vulva.

Induction of the Vulva Depends on a Large Set of Developmental Control Genes 36

The vulva - the egg-laying orifice in a hermaphrodite - is a ventral opening in the hypodermis (skin) formed by 22 cells that arise by specific lineages from three precursor cells in the hypodermis. A single nondividing cell in the gonad, called the *anchor cell,* attaches, or "anchors," the developing vulva to the overlying gonad (the uterus) to create a passageway through which the eggs can pass to the outside world. Microsurgical experiments show that the anchor cell is responsible for inducing the three nearest hypodermal cells to form a vulva (Figure 21-41). If the anchor cell is destroyed by focusing a laser beam on it, these cells, instead of forming a vulva, give rise to ordinary hypodermal cells. And if the anchor cell is shifted relative to the hypodermal cells, there is a corresponding shift in the site at which the vulva develops: flanking the three cells that normally give rise to the vulva lie three others that are also capable of doing so if exposed to the anchor-cell signal. Thus the anchor cell induces vulval differentiation in *C. elegans* just as the vegetal blastomeres induce mesodermal differentiation in the early *Xenopus* embryo. Only the anchor cell is necessary for this induction: if all the gonadal cells except the anchor cell are destroyed, the vulva still develops normally.

To identify genes involved in a given step of development, one searches for mutations that disrupt the process by screening the progeny of a large population of animals that have been exposed to mutagens. In this way many mutants are found that have a "vulvaless" phenotype, where none of the hypodermal cells behave as though they have received the anchor-cell signal. Another large group of mutants have a converse "multivulva" phenotype, in which all six hypodermal cells capable of responding to the anchor-cell signal behave as though they have actually received it, so that the worm forms several vulvalike structures instead of one. Individual mutations giving a similar phenotype are then tested in pairs to see whether they affect the same or different genes, as explained in Panel 21-1, pages 1072-1073. Once a set of relevant genes has been identified in this way, still more components of the system usually can be discovered by searching for mutations in other genes that will suppress the ill effects of mutations in an already identified gene. Such *extragenic suppressor mutations* can be rare, and it is only in genetically favorable organisms such as *C. elegans* that one can easily find them; but when found, they often identify genes whose protein products interact directly with those of the already identified gene (because the alteration in the shape of the one protein molecule, for example, can be compensated for by a complementary alteration in the shape of its partner). More than 30 distinct identified genes have been implicated in the control of vulval development.

Genetic and Microsurgical Tests Reveal the Logic of Developmental Control; Gene Cloning and Sequencing Help to Reveal Its Biochemistry 37

We focus here on just five of the vulval control genes, called *lin-3, let-23, sem-5, let-60,* and *lin-45.* Impairment of the function of any one of them by mutation has the same consequence - a vulvaless phenotype. Conversely, a genetic change causing excess of any of the gene products or excessive or unregulated activity - in other words, a gain of function - can have an opposite, multivulva effect. Each of the five genes therefore is needed for induction of the vulva, in a way that suggests they might all be links in a single chain of cause and effect; all of them, that is, might belong to a single *genetic pathway.* We saw in Chapter 15 how the signaling pathway that controls specialization of a particular cell type in the *Drosophila* eye has been defined by genetic analysis. A similar kind of analysis has been used to determine the order in which the vulval control genes act, as explained in Figure 21-42. The five genes do indeed appear to lie in a single genetic pathway, with *lin-3* the most upstream, then *let-23, sem-5, let-60,* and lastly *lin-45.* Thus, for example, a gain-of-function mutation in *lin-3* has no effect on the phenotype in an animal that also carries a loss-of-function mutation of *let-23;* the double mutant is vulvaless because the upstream component can do nothing when the downstream component upon which it should operate is missing.

The next problem is to relate the gene actions to specific cells in the embryo. Is *lin-3,* for example, needed in the anchor cells that produce the inductive signal or in the hypodermal cells that respond to it? For *lin-3*a simple answer has come from molecular genetics: the gene has been cloned and has been shown to be expressed in the anchor cell and nowhere else in the neighborhood (Figure 21-43). The other four genes, by contrast, appear to function in the hypodermal cells, and a gain-of-function mutation in one of them can cause a multivulva phenotype even when the anchor cell has been destroyed.

To complete the picture, we have to relate the genetically defined pathway to protein molecules and biochemistry. The five genes *lin-3, let-23, sem-5, let-60,* and *lin-45* have all been cloned and sequenced, and in each case the sequence indicates the probable function: *lin-3* codes for a protein similar to a secreted signaling molecule well known in vertebrates - epidermal growth factor (EGF); *let-23* codes for a receptor tyrosine kinase homologous to the members of the vertebrate EGF receptor family; *sem-5,* as we saw in Chapter 15, codes for a protein containing the SH2 and SH3 domains, found in many proteins that directly bind to such receptors and mediate their effects on other intracellular components; and *let-60* and *lin-45* are respectively homologous to the vertebrate *ras* and *raf* genes, whose products relay signals intracellularly from such receptors into the cell interior, as discussed in Chapter 15. Presumably, therefore, the Lin-3 protein is the signal molecule secreted by the anchor cell, the Let-23 protein is the transmembrane receptor in the hypodermal cells to which it binds, and the Sem-5, Let-60, and Lin-45 proteins are links in the intracellular signaling chain through which binding of the ligand to the receptor exerts its ultimate effects on gene expression and cell determination (Figure 21-44). In fact, the genetic analysis of this system in the developing nematode worm provides one of the clearest accounts we have of the organization of a signaling pathway that appears to have been conserved throughout most of the animal kingdom. A very similar pathway, as we saw in Chapter 15, emerges from analysis of the *seveneless* mutant in *Drosophila* (see p. 764).

Heterochronic Mutations Identify Genes That Specify Changes in the Rules of Cell Behavior as Time Goes By 38

As computer programmers know, small changes in a program can have drastic effects on the output produced when a program is executed. Likewise, a mutation in a control gene that alters a single rule of cell behavior can result in a grossly abnormal cell lineage tree. This is well illustrated by *heterochronic mutations* in *C. elegans,* which cause certain sets of cells to behave in a way that would be appropriate for normal cells at a different stage in development. A daughter cell may behave like its parent or grandparent, for example, and the offspring of the daughter may behave again in the same way, and so on, with the result that a portion of the lineage pattern is reiterated indefinitely.

Figure 21-45 shows lineage diagrams for a set of mutations in a gene called *lin-14,* illustrating this phenomenon: instead of progressing through the normal series of cell divisions characteristic of the first, second, third, and fourth larval stages and then halting, many of the cells in gain-of-function *lin-14* mutants repeatedly go through the patterns of cell divisions characteristic of the first larval stage, continuing through as many as five or six molt cycles and persisting in the manufacture of an immature type of cuticle. Loss-of-function mutations in the *lin-14* gene have the reverse effect, causing cells to adopt mature states precociously, skipping intermediate stages, so that the animal reaches its final state prematurely and with an abnormally small number of cells.

The *lin-14* gene has been cloned, and the protein it encodes has been found to be concentrated in cell nuclei. In a normal individual the protein is present in most of the somatic cells of the late embryo and early first larval stage, but its concentration then declines to near zero by the second larval stage. Those *lin-14* mutants that enter an adult state precociously are found to have a reduced level of the Lin-14 protein, whereas those mutants that carry on with repeated first larval stage cycles are found to express the Lin-14 protein for an abnormally long time (because of a mutation in a regulatory portion of the gene). Thus the effect of the Lin-14 protein is to keep the cells in an immature state, and normal maturation depends on its disappearance. This gene product is presumably only one of many whose changing concentrations in cells specify changes in the rules of cell behavior as development proceeds.

The Tempo of Development Is Not Controlled by the Cell-Division Cycle 39

The example we have just discussed brings us to a fundamental general problem in development. The genome has to define a set of rules for cell division as well as for cell specialization, and the two processes have to be coordinated. How is the division cycle regulated in development, and how is it coordinated with cell specialization?

One suggestion is that changes of internal state might be locked to passage through the division cycle: the cell would click to the next state as it went through mitosis, so to speak. This seems a tempting idea, especially when one pictures development in terms of lineage diagrams, but the evidence is largely against it. Cells in developing embryos frequently go on to differentiate in

an almost normal way even when cell division is artificially prevented. Necessarily, there are some abnormalities, if only because a single undivided cell cannot differentiate normally in two ways at once. But in most cases that have been studied, it seems clear that cell divisions are not the ticks of a clock that sets the tempo of development. Rather, the cell changes its chemical state with time regardless of cell division, and this changing state controls both the decision to divide and the decision as to when and how to specialize.

Cells Die Tidily as a Part of the Program of Development [40]

A *C. elegans* hermaphrodite generates 1030 somatic cell nuclei in the course of its development, but 131 of the cells die. These programmed cell deaths occur in an absolutely predictable pattern, and they create no mess. Whereas cells that die from damage or poisoning typically swell and burst, spilling their contents over their neighbors, these normal cell deaths occur by a process known as apoptosis, in which the cell nucleus becomes condensed, the cell itself shrivels, and the shrunken corpse is rapidly engulfed and digested by neighboring cells (Figure 21-46). Programmed cell death is a regular feature of normal animal development and is probably the fate of a substantial fraction of the cells produced in most animals.

Because apoptosis occurs quickly and leaves no trace, the deaths easily go unnoticed. Yet cell death may be as important as cell division in generating an individual with the right cell types in the right numbers and places. In vertebrates, for example, it regulates the numbers of neurons (as we discuss later), eliminates undesirable types of lymphocytes (discussed in Chapter 23), disposes of cells that have finished their job (as when a tadpole loses its tail at metamorphosis), and helps to sculpt the shapes of developing organs (creating the gaps between digits by doing away with the cells that lie between the digit rudiments in the limb bud, for example).

Normal cell deaths are thought to be suicides in which the cell activates a death program and kills itself. The best evidence that animal cells have an intrinsic death program comes from genetic studies in *C. elegans,* where two genes, called *ced-3* and *ced-4* (*ced* stands for "cell death abnormal"), have been identified that are required for the 131 normal cell deaths to occur. If either gene is inactivated by mutation, the cells that are normally fated to die survive instead, differentiating as recognizable cell types such as neurons. Conversely, overexpression or misplaced expression of *ced-3* and *ced-4* (as a result of loss-of-function mutations that inactivate another gene, *ced-9,* which normally represses the death program) causes many cells to die that would normally survive.

The amino acid sequences of these three Ced proteins are known. The Ced-4 protein is novel and is thought to act upstream of Ced-3, which is a protease. Ced-9 is 23% identical in amino acid sequence to a mammalian protein called Bcl-2 (the product of the proto-oncogene *bcl-2*), which acts like Ced-9 to suppress programmed cell death in many types of mammalian cells. Remarkably, when the human *bcl-2* gene is transferred to *C. elegans,* it acts to inhibit normal cell death in the worm and is even able to rescue *ced-9* mutants that otherwise die early in development. These important findings indicate that both the mechanism of programmed cell death and its regulation have been highly conserved in evolution from worms to humans, confirming that the ability to commit suicide in this way is a fundamental property of animal cells.

Summary

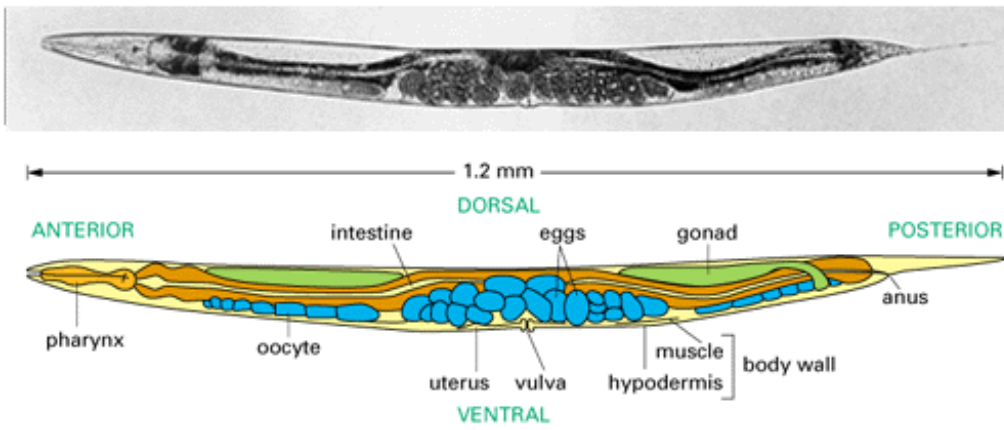
Two things make the nematode Caenorhabditis elegans an attractive organism for investigating the genetic basis of development: first, genetic analysis is easy because the generation time is short and the genome small; second, the normal course of development is extraordinarily reproducible and has been chronicled in detail, so that a cell at any given position in the body has the same lineage in every individual, and this lineage is fully known. As in other organisms, development depends on an interplay of cell-cell interactions and cell-autonomous processes. Cell-destruction experiments show, for example, that the development of the vulva depends on an inductive signal, and the genes required for this induction can be identified through mutations that disrupt vulval development. Molecular genetic analysis reveals the individual functions of these genes and shows that several of them code for components of a signaling pathway that operates in vertebrates too. Lineage analysis of mutants leads to the discovery of many other important classes of genes, including genes whose products serve to specify changes in the rules of cell behavior with time during development and genes that are responsible for programmed cell death - an invariable feature of development in all animals.


Figure 21-39. *Caenorhabditis elegans*. A side view of an adult hermaphrodite is shown. Note that the tissue called hypodermis in the nematode corresponds to the epidermis of other animals. (From J.E. Sulston and H.R. Horvitz, *Dev. Biol.* 56:110-156, 1977.)
Figure 21-40. The lineage tree for the cells that form the intestine of *C. elegans*. The egg (*top*) is drawn to the same scale as the adult (*bottom*). Note that although the intestinal cells form a single clone (as do the germ-line cells), the cells of most other tissues do not.
Figure 21-41. Induction of the vulva. (A) Experiments showing that an inductive influence from the anchor cell is required for normal development of the vulva. (B) Magnified view of the cells of the ventral hypodermis adjacent to the gonad, in the neighborhood of the anchor cell, with the normal lineage diagrams of their progeny sketched below. All six of these cells (and no others) are capable of responding to the vulva-inducing influence, but only three of them are normally exposed to it.

Panel 21-1: Review of classical genetics

GENES AND PHENOTYPES

Gene: a functional unit of inheritance, usually corresponding to the segment of DNA coding for a single protein.
Genome: an organism's set of genes.

locus: the site of the gene in the genome

alleles: alternative forms of a gene

Wild-type: the normal, naturally occurring type

Mutant: differing from the wild-type because of a genetic change (a mutation)

GENOTYPE: the specific set of alleles forming the genome of an individual

PHENOTYPE: the visible character of the individual

homozygous A/A   heterozygous a/A   homozygous a/a
allele A is dominant (relative to a); allele a is recessive (relative to A)

In the example above, the phenotype of the heterozygote is the same as that of one of the homozygotes; in cases where it is different from both, the two alleles are said to be co-dominant.

CHROMOSOMES

a chromosome at the beginning of the cell cycle, in G_1 phase; the single long bar represents one long double helix of DNA

centromere

short "p" arm   long "q" arm

a chromosome at the end of the cell cycle, in metaphase; it is duplicated and condensed, consisting of two identical sister chromatids (each containing one DNA double helix) joined at the centromere.

short "p" arm   long "q" arm

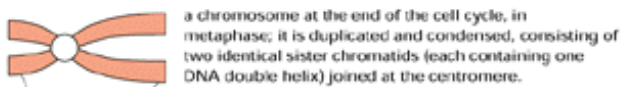
autosomes

maternal 1

paternal 1   paternal 3

maternal 3

paternal 2   maternal 2

X   Y


sex chromosomes

A normal diploid chromosome set, as seen in a metaphase spread, prepared by bursting open a cell at metaphase and staining the scattered chromosomes. In the example shown schematically here, there are three pairs of autosomes (chromosomes inherited symmetrically from both parents, regardless of sex) and two sex chromosomes—an X from the mother and a Y from the father. The numbers and types of sex chromosomes and their role in sex determination are variable from one class of organisms to another, as is the number of pairs of autosomes.

THE HAPLOID-DIPLOID CYCLE OF SEXUAL REPRODUCTION

mother   father

DIPLOID

MEIOSIS

HAPLOID

egg   sperm

SEXUAL FUSION (FERTILIZATION)

DIPLOID

zygote

maternal chromosome

paternal chromosome
For simplicity, the cycle is shown for only one chromosome/chromosome pair.

MEIOSIS AND GENETIC RECOMBINATION

maternal chromosome

A   B

paternal chromosome

a   b

diploid germ cell

genotype $\dfrac{AB}{ab}$
MEIOSIS AND RECOMBINATION

genotype Ab

A   b

site of crossing-over

genotype aB

a   B

haploid gametes (eggs or sperm)
The bigger the distance between two loci, the bigger the chance that they will be recombined by crossing-over occurring at a site between them. If they get recombined in x% of gametes, they are said to be separated by a genetic map distance of x map units (or x centimorgans).

TYPES OF MUTATIONS

point mutation: maps to a single site in the genome, corresponding to a single nucleotide pair or a very small part of a single gene
inversion: inverts a segment of a chromosome

deletion: deletes a segment of a chromosome

translocation: breaks off a segment from one chromosome and attaches it to another

lethal mutation: causes the developing organism to die prematurely.

conditional mutation: produces its phenotypic effect only under certain conditions, called the *restrictive* conditions; under other conditions—the *permissive* conditions—the effect is not seen. For a *temperature-sensitive* mutation, the restrictive condition typically is high temperature, while the permissive condition is low temperature.

loss-of-function mutation: reduces or abolishes the activity of the gene. These are the commonest class of mutations. Loss-of-function mutations are usually *recessive*—the organism can usually function normally so long as it retains at least one normal copy of the affected gene.

null mutation: completely abolishes the activity of the gene.

gain-of-function mutation: increases the activity of the gene or makes it active in inappropriate circumstances; these mutations are usually *dominant*.

dominant negative mutation: dominant-acting mutation that blocks gene activity, causing a loss-of-function phenotype even in the presence of a normal copy of the gene. The phenomenon occurs when the mutant gene product interferes with the function of the normal gene product.

suppressor mutation: suppresses the phenotypic effect of another mutation, so that the double mutant appears normal. An *intragenic* suppressor mutation lies within the gene affected by the first mutation; an *extragenic* suppressor mutation lies in a second gene—often one whose product interacts directly with the product of the first.

TWO GENES OR ONE?

Given two mutations that produce the same phenotype, how can we tell whether they are mutations in the same gene? If the mutations are recessive (as they most often are), the answer can be found by a complementation test.

In the simplest type of complementation test, an individual who is homozygous for one mutation is mated with an individual who is homozygous for the other. The phenotype of the offspring gives the answer to the question.

COMPLEMENTATION:
MUTATIONS IN TWO DIFFERENT GENES

homozygous mutant mother   homozygous mutant father
hybrid offspring shows normal phenotype:
one normal copy of each gene is present

NONCOMPLEMENTATION:
TWO INDEPENDENT MUTATIONS IN THE SAME GENE

homozygous mutant mother   homozygous mutant father
hybrid offspring shows mutant phenotype:
no normal copies of the mutated gene are present
Figure 21-42. How genes can be ordered in a genetic pathway by tests with double mutants. A gene A is said to lie *upstream* from a gene B if its product normally acts by regulating the activity of B (or of the product of B) and *downstream* if the relationship is the other way around. If the upstream gene affects the phenotype *only* by regulating the downstream gene activity, the two genes are said to be links in a single *genetic pathway*. In this case mutations of either gene will result in a similar range of phenotypes. To discover the ordering of the genes in the pathway, one uses double mutants to see which of two genes is the more direct determinant of the phenotype. The approach depends on finding specific mutations of A and B that have opposite effects on the phenotype when taken singly. In the example shown a (dominant) gain-of-function mutation in gene B, making it active independently of regulation by upstream genes, is combined with a (recessive) loss-of-function mutation in A or C: the (A,B) double mutant has a gain-of-function phenotype, implying that A lies upstream from B, while the (B,C) double mutant has a loss-of-function phenotype, implying that C lies downstream from B.

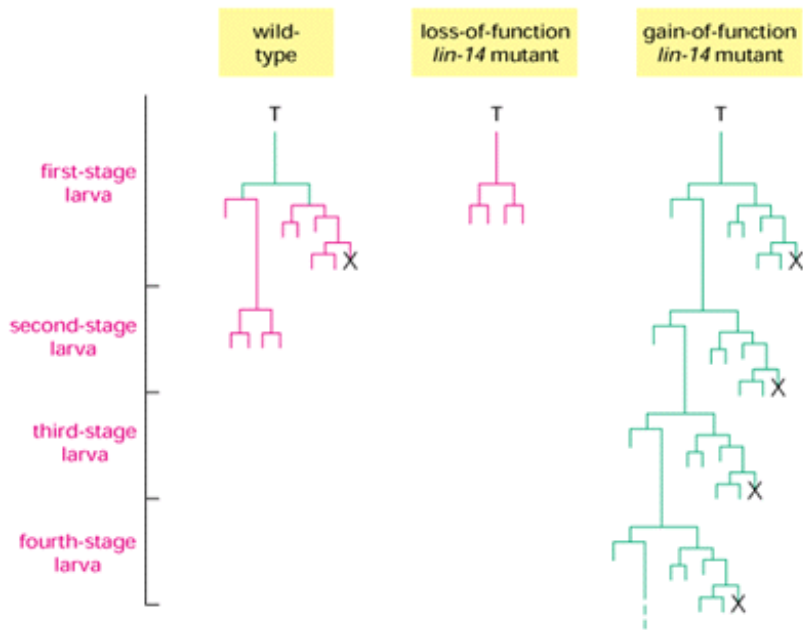
Figure 21-43. Expression of *lin-3* in the anchor cell. A *C. elegans* embryo has been transfected with an artificial reporter gene consisting of the control region of *lin-3* coupled to the gene for the enzyme b-galactosidase, whose presence is easily detected by a histochemical reaction that gives a blue reaction product. Only the anchor cell is stained blue, implying that it is only in the anchor cell that the *lin-3* gene is normally switched on. (Courtesy of Russell Hill.)
Figure 21-44. The pathway for vulval induction in *C elegans*. The diagram shows the functions of the gene products that have been identified. The names of the homologous vertebrate proteins are indicated in parentheses.


Figure 21-45. Heterochronic mutations in the *lin-14* gene of *C elegans*. The effects on only one of the many affected lineages are shown. The loss-of-function (recessive) mutation in *lin-14* causes premature occurrence of the pattern of cell division and differentiation characteristic of a late larva; the gain-of-function (dominant) mutation has the opposite effect. The cross denotes a programmed cell death. *Green* lines represent cells that contain Lin-14 protein, *red* lines those that do not. In normal development disappear-ance of Lin-14 is triggered by the beginning of larval feeding. (After V. Ambros and H.R. Horvitz, *Science* 226:409-416, 1984. © the AAAS; and P. Arasu, B. Wightman, and G. Ruvkun, *Growth Dev.Aging.*5:1825-1833, 1991.)
Figure 21-46. Apoptotic cell death in *C elegans*. Death depends on expression of the *ced-3* and *ced-4* genes in the dying cell

itself, whereas the subsequent engulfment and disposal of the remains depend on expression of other genes in the neighboring cells.

Drosophila and the Molecular Genetics of Pattern Formation. I. Genesis of the Body Plan <u>41</u>

Introduction

The structure of an organism is controlled by its genes: classical genetics is based on this proposition. Yet for almost a century, and even long after the role of DNA in inheritance had become clear, the mechanisms of the genetic control of body structure remained an intractable mystery. In recent years this chasm in our understanding has begun to be filled. In the previous section we used the nematode worm to illustrate some of the general principles of how developmental control genes orchestrate the events of development. But it is the fly *Drosophila melanogaster* (<u>Figure 21-47</u>), more than any other organism, that has really transformed our understanding of how genes govern the patterning of the body. Decades of genetic study, culminating in massive systematic searches, have yielded a large catalogue of developmental control genes in the fly whose specific function is to define the spatial pattern of cell types and body parts. It has become possible not only to identify the key genes, but also to watch them at work: by *in situ* hybridization using DNA or RNA probes, one can observe directly how the internal states of the cells in the embryo are defined by the sets of regulatory genes that they express. By analyzing mutants, transgenic animals, and animals that are a patchwork of mutant and nonmutant cells, one can go on to discover how each gene operates as part of a system to specify the organization of the body. Moreover, the fly has provided a crucial key to our own development; for the genes controlling the pattern of the body in *Drosophila* turn out to have close counterparts in higher animals, including ourselves.

Our account of *Drosophila* developmental genetics is divided into two sections. The first deals with events in the early embryo and describes how the basic body plan is created, with a head rudiment at one end, a posterior rudiment at the other, and in between them an ordered series of segments - the basic modular units from which all insects are constructed. The second section deals with later events and discusses the genetic apparatus that endows cells with positional values that make the cells of one segment different from those of the next; these processes ensure that, for example, the head will develop antennae and the thorax legs - and not, as happens in some mutants we shall encounter, the other way around.

The Insect Body Is Constructed by Modulation of a Fundamental Pattern of Repeating Units <u>41</u>, <u>42</u>

The timetable of *Drosophila* development, from egg to adult, is summarized in <u>Figure 21-48</u>. The period of *embryonic development* begins at fertilization and takes about a day, at the end of which the embryo hatches out of the egg shell to become a *larva*. The larva then passes through three stages, or *instars,* separated by molts in which it sheds its old coat of cuticle and lays down a larger one. At the end of the third instar it pupates. Inside the *pupa* a radical remodeling of the body takes place, and eventually, about nine days after fertilization, an adult fly, or *imago,* emerges.

The fly consists of a head, three thoracic segments (numbered T1 to T3), and eight or nine abdominal segments (numbered A1 to A9). Each segment, although different from the others, is built according to a similar plan. Segment T1, for example, carries a pair of legs, T2 carries a pair of legs plus a pair of wings, and T3 carries a pair of legs plus a pair of halteres - small knob-shaped balancers important in flight, evolved from the second pair of wings that more primitive insects possess. The quasi-repetitive segmentation develops in the early embryo during the first few hours after fertilization, but it is more obvious in the larva, where the segments look more similar than in the adult. In the embryo it can be seen that the rudiments of the head, or at least the future adult mouth parts, are likewise segmental (<u>Figure 21-49</u>). At the two ends of the animal, however, there are highly specialized terminal structures that are not segmentally derived.

It is partly a matter of convention where one draws the boundary between one segmental unit and the next. In discussing patterns of gene expression, we shall see that it is convenient to speak in terms of a total of 14 parasegments (numbered P1 to P14) that are half a segment out of register with traditionally defined segments (<u>Figure 21-50</u>).

Drosophila Begins Its Development as a Syncytium <u>41</u>, <u>43</u>

The egg of *Drosophila* is about 400 μm long and about 160 μm in diameter, with a clearly defined polarity. Like the eggs of other insects, it begins its development in an unusual way: a series of nuclear divisions without cell division creates a syncytium. The early nuclear divisions are synchronous and extremely rapid, occurring about every 8 minutes. The first nine divisions

generate a cloud of nuclei, most of which migrate from the middle of the egg toward the surface, where they form a monolayer called the syncytial blastoderm. After another four rounds of nuclear division, plasma membranes grow inward from the egg surface to enclose each nucleus, thereby converting the syncytial blastoderm into a *cellular blastoderm* consisting of about 6000 separate cells (Figure 21-51). A small subset of nuclei populating the extreme posterior end of the egg are segregated into cells a few cycles earlier; these *pole cells* are the primordial germ cells that will give rise to eggs or sperm.

As in a cleaving amphibian egg, the very rapid cycles of DNA replication seem to hinder transcription, so that up to the cellular blastoderm stage development depends largely - although not exclusively - on stocks of maternal mRNA and protein that accumulated in the egg before fertilization. After cellularization, cell division continues in a more conventional way, asynchronously and at a slower rate, and the rate of transcription increases dramatically.

The cellular blastoderm corresponds to the hollow blastula of an amphibian or a sea urchin, even though its interior is filled with yolk rather than being a fluid-filled cavity. Gastrulation follows as soon as cellularization is complete, and although the geometry of this process is very different in the insect, the general outcome is similar. Through coordinated cell movements, endodermal cells are invaginated into the interior to form the gut extending along the axis of the embryo. Mesoderm surrounds the gut rudiment and occupies the space between it and an enveloping layer of ectoderm on the exterior.

By marking and following the cells through their complex gastrulation movements, one can draw a fate map for the monolayer of cells on the surface of the blastoderm (Figure 21-52). The fate map is especially simple for a cross-section through the middle of the embryo, with prospective mesoderm ventrally and ectoderm on each side above it. As in a vertebrate, the cords of nerve cells that run the length of the body derive from part of the ectoderm: a subset of the cells in this *neurogenic ectoderm* will detach from their neighbors, escape from the epithelial sheet, and move into the interior of the embryo as neuronal precursors. For mesoderm, ectoderm, and nerve cord, the position of the cells along the anteroposterior axis is roughly preserved during gastrulation because their movements are in the transverse plane. The gut, however, is formed by invagination of two groups of cells from the opposite extremities of the embryo; these two invaginations meet in the middle to form eventually a continuous gut tube.

As gastrulation nears completion, a series of indentations and bulges appear in the surface of the embryo, marking the subdivision of the body into parasegments along its anteroposterior axis (see Figure 21-49). More subtle tests show that the main features of this segmental pattern are already established at the cellular blastoderm stage, before gastrulation begins.

Two Orthogonal Systems Define the Ground Plan of the Embryo 44

Two coordinates are needed to define each position in the blastoderm, and, correspondingly, one can distinguish two sets of egg-polarity genes that act independently at the outset of development to specify the two main axes of the embryo - the dorsoventral and the anteroposterior. These genes define the spatial coordinates of the embryo by setting up morphogen gradients in the egg.

The egg-polarity genes were found by exhaustive searches for mutants in which the polarity of the embryo is disrupted. In this way 12 *dorsoventral egg-polarity genes* were discovered. All but one of these have the same loss-of-function mutant phenotype, in which the embryo is *dorsalized* - that is, all its cells take on a dorsal character, so that the normal ventral structures fail to form. The remaining gene has the opposite loss-of-function phenotype - the embryo is ventralized. We shall see that all these genes are components of a single system that sets up a dorsoventral morphogen gradient in the early embryo.

The anteroposterior set of genes, by contrast, can be subdivided according to their mutant phenotypes into three subsystems, responsible for specifying different parts of the anteroposterior axis (Figure 21-53). The *anterior group* (4 genes) governs the anterior part of the axis. The *posterior group* (11 genes) governs the posterior part of the axis. Lastly, the *terminal group* (6 known genes) governs the two extreme ends of the embryo, comprising the specialized nonsegmental terminal structures and in particular the pair of regions - one anterior, one posterior - from which the gut is derived. Like the dorsoventral system, each of these three subsystems sets up a morphogen gradient - one in the anterior half of the embryo, one in the posterior half (although this is somewhat controversial), and one operating symmetrically at both of the extreme ends of the embryo. Loss-of-function mutations that inactivate a particular subsystem cause a loss of the corresponding anterior, posterior, or terminal structures.

The four primary spatial signals - anterior, posterior, terminal, and ventral - organize the subsequent patterning of the embryo by governing the expression of other sets of genes, which serve to interpret, refine, and record the positional information that the primary signals supply.

The Patterning of the Embryo Begins with Influences from the Cells Surrounding the Egg <u>44</u>, <u>45</u>

The egg-polarity genes are transcribed from the maternal genome during oogenesis, and their products act very soon after fertilization or in some cases even before. Thus the phenotype of the embryo is determined by the alleles present in the mother (and in her oocytes) rather than by the combination of maternal and paternal genes possessed by the embryo itself. Genes acting in this way are called maternal-effect genes. They are discovered by looking for the appropriate mutant phenotypes in the embryos produced from eggs laid by mothers who themselves appear normal but who carry a genetic mutation that makes their eggs abnormal (<u>Figure 21-54</u>). Most often, the maternal-effect mutation is recessive, and the mothers who make the defective eggs are homozygous for the mutant gene.

Once a gene has been identified, its site of action can be investigated by creating and analyzing *genetic mosaics* - flies containing marked clonal patches of cells in which the gene of interest is missing or mutated. (We explain later how this astonishing trick of genetic microsurgery is performed.) In the case of the egg-polarity genes it can be shown in this way that, while most are required in the oocyte lineage itself, a few crucial ones are required instead in the follicle cells that surround the oocyte in the ovary. The genes required in the follicle cells supply cues that act on the outside of the egg to localize the sources of the dorsoventral and terminal morphogen gradients that will develop inside it (<u>Figure 21-55</u>). In addition, localized products supplied to the growing oocyte by the giant nurse cells connected to it at one end serve to define the anteroposterior polarity of the egg.

To see how the patterns are set up inside the egg, we focus first on the dorsoventral system.

The Dorsoventral Axis Is Specified Inside the Embryo by a Gene Regulatory Protein with a Graded Intranuclear Concentration <u>44</u>, <u>45</u>, <u>46</u>

The role of the follicle cells in establishing the dorsoventral gradient in the *Drosophila* egg is to provide a localized signaling molecule that binds to a receptor on the outside of the egg and thereby controls the distribution of a gene regulatory protein inside the egg. The system can be analyzed genetically in much the same way as described earlier for the system mediating vulval induction in the nematode worm. Seven of the genes in the dorsoventral system are concerned with producing the localized extracellular signal; one, called *Toll,* encodes the transmembrane receptor for the signaling molecule, and the products of the remaining three act inside the embryo, downstream from *Toll.* The final maternal-effect gene in the signaling pathway codes for a gene regulatory protein and is called *dorsal.* The extracellular signaling molecule produced by the follicle cells is generated in active form only at the ventral surface of the egg and forms a gradient that is reflected in a graded activation of the Toll protein and ultimately in a graded concentration of the Dorsal protein in the nuclei of the embryo.

The Dorsal protein belongs to the same family as the NF-kB gene regulatory protein of vertebrates (see <u>Figure 15-32</u>) and is thought to act in a similar way. In the newly laid egg both the *dorsal* mRNA (detected by *in situ* hybridization) and the protein it encodes (detected with antibodies) are distributed uniformly in the cytoplasm. After the nuclei have migrated to the surface of the embryo to form the blastoderm, however, a remarkable redistribution of the Dorsal protein occurs: dorsally the protein remains in the cytoplasm, but ventrally it is concentrated in the nuclei, and between these two extremes there is a smooth gradient of nuclear localization (<u>Figure 21-56</u>). The partitioning of Dorsal protein between nucleus and cytoplasm appears to be governed, in part at least, by the product of a gene called *cactus.* The Cactus protein is homologous to the I-kB protein that inhibits NF-kB in vertebrate cells by preventing it from migrating into the nucleus (see <u>Figure 15-32</u>). By analogy, the Cactus protein is thought to bind to the Dorsal protein, trapping it in the cytoplasm; the signal transmitted by the Toll protein is thought to lead to the phosphorylation of the Dorsal protein, causing it to dissociate from the Cactus protein so that it can enter nuclei.

Once inside a nucleus the Dorsal protein turns on or off the expression of different sets of genes depending on its concentration. In this way the gradient of nuclear localization of the protein creates a dorsoventral series of territories - distinctive bands of cells that run the length of the embryo. Most ventrally, where the concentration of Dorsal protein is highest, it switches on, for example, expression of a gene called *twist,* specific for mesoderm. Most dorsally, where the concentration of Dorsal protein is lowest, a gene called *decapentaplegic (dpp)* is permitted to switch on, specifying dorsal structures. And in an intermediate region, where the concentration of Dorsal protein is high enough to repress *dpp* but too low to activate *twist,* the cells are specified to become neurogenic ectoderm (see <u>Figure 21-56</u>).

Products of the genes directly regulated by the Dorsal protein generate in turn more local signals that define finer subdivisions of the dorsoventral axis. In particular, *dpp* codes for a secreted protein of the TGF-β superfamily that is thought to form a local morphogen gradient in the dorsal part of the embryo. The action of this protein is reminiscent of the action of activin, also a

TGF-β family member, in early *Xenopus* development. From experiments with injected *dpp* mRNA, it seems that the highest concentrations of Dpp protein cause development of the most dorsal tissue of all - extraembryonic membrane - intermediate concentrations cause development of dorsal ectoderm, and very low concentrations allow development at neurogenic ectoderm.

Like the dorsoventral system, the terminal system depends on a transmembrane receptor that detects localized signals provided by follicle cells to generate gradients of gene regulatory proteins inside the embryo (Figure 21-57). These gradients serve to specify gut endoderm, as well as some specialized terminal structures, and so can be viewed, with the dorsoventral system, as part of the apparatus for defining the three basic germ layers of the insect. The dorsoventral and terminal systems in the fly, therefore, employing secreted molecules that act as inductive signals, are comparable with the inductive mechanisms for specifying germ layers in the early *Xenopus* embryo.

The anterior and posterior systems of egg-polarity genes, by contrast, set up gradients that depend instead on localized accumulations of specific mRNAs inside the egg (see Figure 21-57). These gradients govern the differences between head and rear and specify the series of body segments along the head-to-rear axis, as we shall see in detail for the anterior system. First, we pause briefly to discuss a special role of the posterior system: the specification of germ cells.

The Posterior System Specifies Germ Cells as well as Posterior Body Segments 47

In practically all animals that have been studied, the *primordial germ cells* - the precursors of the next generation of gametes - are singled out at a very early stage of development from the *somatic cells* - those that will form all the other tissues of the body (see Figure 21-51). In many species the egg contains localized cytoplasmic components - visible as *polar granules* in *C. elegans* and *Drosophila,* or as *germ plasm* in *Xenopus* - that are segregated into the primordial germ cells during egg cleavage and are suspected to include or to be associated with the determinants of germ-cell character. These components are generally concentrated at the posterior or vegetal end of the egg, and the cells that inherit them migrate from that site to colonize the gonads.

In *Drosophila* maternal-effect genes required for the formation of germ cells can be identified through the discovery of mutants that produce offspring in which germ cells are lacking. These abnormal offspring are found to lack posterior body segments also, indicating that the genes belong to the posterior system of egg-polarity genes. The products of many of these genes turn out to be localized at the posterior pole - among them, presumably, the determinants of germ-cell character. The morphogen gradient that organizes the posterior body segments depends on the machinery that creates and localizes the germ cell determinants. A key gene in this system is called *oskar.* Normally, *oskar* mRNA and protein are localized at the posterior pole of the egg. In their absence no germ cells develop there, and if *oskar* mRNA is artificially misdirected to the anterior end of the egg, germ cells will form there instead. The localized *oskar* mRNA, moreover, can be shown to control the localization of other components - products of other posterior-group genes involved in the development of posterior body segments as well as germ cells. By their localization at the posterior pole of the egg, these products can become specifically incorporated in the cells that form there, determining their fate as germ cells.

mRNA Localized at the Anterior Pole Codes for a Gene Regulatory Protein That Forms an Anterior Morphogen Gradient 44, 48

If a *Drosophila* egg is carefully punctured at its anterior end, allowing a small amount of the most anterior cytoplasm to leak out, the embryo fails to develop head segments. And if cytoplasm from the posterior end of another egg is injected into the site from which the anterior cytoplasm has leaked, a second set of abdominal segments will develop, with reversed polarity, in the anterior half of the recipient egg (Figure 21-58). This experiment shows that the segmental patterning of the anteroposterior axis is controlled by substances localized at the ends of the egg. These substances have been identified by the genetic approach, starting with a search for mutations that mimic the effects of losing anterior or posterior cytoplasm. Most notably, mothers that are homozygous for a mutation in the egg-polarity gene *bicoid* produce embryos that lack head and thoracic structures and have abdominal structures extended over an abnormally large fraction of the body length. Such a mutant embryo can be rescued from abnormal development, however, if cytoplasm from the anterior end of a normal egg is injected into its anterior end. Thus the normal *bicoid* gene is required to make some product at the anterior end of the egg that can act as the source of a long-range influence controlling the pattern of development of the anterior parts.

In situ hybridization studies show that *bicoid* mRNA is originally synthesized in the ovary by the nurse cells connected with the oocyte (see Figure 21-55). As the *bicoid* mRNA passes through the cytoplasmic bridges into the oocyte, it becomes anchored by part of its 3' untranslated tail to a component of the cytoplasm - presumably a part of the cytoskeleton - at the oocyte's anterior

end. Translation of this mRNA begins only when the egg is laid, giving rise to a concentration gradient of Bicoid protein with its high point at the anterior end of the embryo. The concentration gradient can be altered genetically by constructing mutants that contain multiple copies of the normal *bicoid* gene: as the gene dosage increases in the mother, so does the protein concentration increase in the egg. The segments of the resultant embryo are correspondingly shifted toward the posterior pole, as though their locations were determined by positional information derived from the local concentration of the Bicoid protein (Figure 21-59). This protein therefore fits exactly the definition of a morphogen. Like Dorsal, the Bicoid protein binds to DNA and functions by regulating the expression of other genes.

Three Classes of Segmentation Genes Subdivide the Embryo 49

Graded global cues are thus provided inside the egg by the products of the egg-polarity genes. For the anterior system the cues derive from the *bicoid* mRNA that is localized at the anterior end of the egg before fertilization, and they take the form of an anteroposterior gradient of the Bicoid gene regulatory protein. The gradient guides the creation of a series of discrete body segments. This process depends on a collection of segmentation genes, about 25 of which have been characterized. Mutations in any one of these genes will alter the number of segments or their basic internal organization without affecting the global polarity of the egg. The segmentation genes act at later stages than the egg-polarity genes, when the embryo is transcribing its own genome instead of relying on stored maternal mRNA. Because the embryonic gene transcripts, rather than maternal transcripts, determine the phenotype, these genes are classed as zygotic-effect genes rather than maternal-effect genes.

The segmentation genes fall into three groups according to their mutant phenotypes and the stages at which they act (Figure 21-60). First come a set of at least six gap genes, whose products mark out the coarsest subdivisions of the embryo. Mutations in a gap gene eliminate one or more groups of adjacent segments, and mutations in different gap genes cause different but partially overlapping defects. In the mutant *Krüppel*, for example, the larva lacks eight segments, from T1 to A5 inclusive.

The next segmentation genes to act are a set of eight pair-rule genes. Mutations in these cause a series of deletions affecting alternate segments, leaving the embryo with only half as many segments as usual. While all the pair-rule mutants display this two-segment periodicity, they differ in the precise positioning of the deletions relative to the segmental or parasegmental borders. The pair-rule mutant *even-skipped*, for example, which is discussed in Chapter 9, lacks the whole of each even-numbered parasegment, while the pair-rule mutant *fushi tarazu (ftz)* lacks the whole of each odd-numbered parasegment, and the pair-rule mutant *hairy* lacks a series of regions that are of similar width but out of register with the parasegmental units.

Finally, there are at least 10 segment-polarity genes. Mutations in these genes produce larvae with a normal number of segments but with a part of each segment deleted and replaced by a mirror-image duplicate of all or part of the rest of the segment. In *gooseberry* mutants, for example, the posterior half of each segment (that is, the anterior half of each parasegment) is replaced by an approximate mirror image of the adjacent anterior half-segment (see Figure 21-60).

We see later that, in parallel with the segmentation process, a further set of genes, the *homeotic selector genes*, serve to define and preserve the differences between one parasegment and the next.

The phenotypes of the various segmentation mutants suggest that the segmentation genes form a coordinated system that subdivides the embryo progressively into smaller and smaller domains along the anteroposterior axis distinguished by different patterns of gene expression. Again, molecular genetics provides the tools to investigate how this system works.

The Localized Expression of Segmentation Genes Is Regulated by a Hierarchy of Positional Signals 50, 51

Most of the segmentation genes have been cloned, and cDNA sequencing reveals that about three-quarters of them, including all of the gap genes, code for gene regulatory proteins. Their actions on one another and on other genes can therefore be observed by comparing gene expression in normal and mutant embryos. Using appropriate probes to detect the gene transcripts, one can, in effect, take snapshots as genes switch on or off in changing patterns. By analyzing in this way mutants that lack a particular segmentation gene, one can begin to deduce the logic of the gene control system.

We have already seen how *in situ* hybridization in normal embryos has helped to show that the *bicoid* gene transcripts are the source of a positional signal: the transcripts are localized at one end of the egg, even though the effects of a mutation in the gene are spread over a large part of the embryo. In a similar way it can be shown that the gap genes in their turn generate (directly or indirectly) positional signals that help to control the pattern of development in neighborhoods extending beyond their own

expression domain. Mutants that are defective in the gap gene *Krüppel* or *hunchback,* for example, show abnormalities within the region where the gene transcripts are detected in a normal embryo and also for several segments beyond (Figure 21-61). As with the Bicoid protein, it is thought that the gene regulatory proteins encoded by gap genes such as *Krüppel* and *hunchback* spread out as diffusible morphogens from the sites where the genes are transcribed.

The next finer level of spatial patterning is marked out by the pair-rule genes. Some of these, too, may code for proteins that spread by diffusion to exert effects on cells neighboring the site of gene transcription; others, by contrast, appear to affect the development only of those regions in which they are transcribed. Transcripts of the normal *ftz* gene, for example, occur in seven circumferential "zebra stripes" at the blastoderm stage (Figure 21-62), each of the stripes being roughly four cells wide, matching in width and location the rudiments of the even-numbered parasegments that would be missing in a *ftz* mutant.

Taken together, these observations imply that the products of the egg-polarity genes provide global positional signals that cause particular gap genes to be expressed in particular regions, and the products of the gap genes then provide a second tier of positional signals that act more locally to regulate finer details of patterning by influencing the expression of yet other genes, including the pair-rule genes. In this way the global gradients produced by the egg-polarity genes organize the creation of a fine-grained pattern through a process of sequential subdivision using a hierarchy of sequential positional controls. This is a reliable strategy: because the global positional signals do not have to specify fine details, the individual nuclei that respond to them do not have to react with extreme precision to small differences of signal concentration (Figure 21-63).

The Product of One Segmentation Gene Controls the Expression of Another to Create a Detailed Pattern [41], [50], [51], [52]

The hierarchy of control relationships between the successive tiers of segmentation genes can be demonstrated by observing the expression pattern of one such gene when another is inactivated by mutation. In a mutant embryo that lacks the normal *Krüppel* product, for example, the usual *ftz* stripes fail to develop in just that region of the blastoderm corresponding to the defect in the *Krüppel* mutant. Thus the *Krüppel* product, directly or indirectly, regulates *ftz* gene expression. In a *ftz* mutant, by contrast, the distribution of the normal *Krüppel* product is not disturbed, indicating that the *ftz* product does not regulate *Krüppel* gene expression.

There are also interactions between genes in the same tier of the regulatory hierarchy. The gap genes *Krüppel* and *hunchback,* for example, are expressed in adjacent regions of the blastoderm, with a sharp boundary between the *hunchback* territory anteriorly and the *Krüppel* territory posteriorly (see Figure 21-61). A repression of *Krüppel* gene expression by the Hunchback gene regulatory protein helps to establish this boundary, ensuring that the expression domains of the two genes are properly correlated. Interactions of this sort also guide the regular periodic pattern of expression of the pair-rule genes, setting up an exactly reproducible arrangement of mutual exclusions and overlaps that repeats itself reliably in every double-segment unit in the blastoderm of every normal embryo (Figures 21-64 and 21-65). In this way different bands of cells around the blastoderm are distinguished by different combinations of pair-rule gene expression, down to the finest possible level of detail - the width of a single cell, which corresponds to about a quarter of the width of a prospective segment or parasegment.

This whole elaborate patterning process depends on the long stretches of DNA sequence that control the expression of each of the segmentation genes. These regulatory regions bind multiple copies of the gene regulatory proteins produced by a subset of other segmentation genes, and the gene is turned on or off according to the combination of proteins bound. In Chapter 9 (see p. 426) we focus on one particular segmentation gene and discuss how the decision whether to transcribe the gene is made on the basis of all these inputs.

Egg-Polarity, Gap, and Pair-Rule Genes Create a Transient Pattern That Is Remembered by Other Genes [41], [50], [52]

Within the first few hours after fertilization, the gap genes and the pair-rule genes are activated one after another. Their mRNA products appear first in patterns that only approximate the final picture; then, within a short time - through a series of interactive adjustments - the fuzzy initial distribution of gene products resolves itself into a regular, crisply defined system of stripes (see Figure 21-65). But this system itself is unstable and transient. As the embryo proceeds through gastrulation and beyond, the regular segmental pattern of gap and pair-rule gene products disintegrates. Their actions, however, have stamped a permanent set of labels (positional values) on the cells of the blastoderm. These positional labels are recorded in the persistent activation of certain of the segment-polarity genes and of the homeotic selector genes, which serve to maintain the segmental organization of the larva and adult.

Segment-Polarity Genes Label the Basic Subdivisions of Every Parasegment [53]

Segment-polarity genes are expressed in a pattern that repeats itself from one parasegment to the next. The gene *engrailed* provides a good example (Figure 21-66). Its RNA transcripts are seen in the cellular blastoderm in a series of 14 bands, each approximately one cell wide, corresponding to the anteriormost portions of the future parasegments. These bands appear in a fixed relationship to the bands of expression of the pair-rule genes (see Figure 21-64). Again, the pattern is governed in a combinatorial fashion by the products of the previous set of genes in the hierarchy and is refined and elaborated by interactions among the segment-polarity genes themselves. Through expression of different segment-polarity genes in different bands of cells, each future parasegment is already subdivided at the cellular blastoderm stage into at least three distinct regions. The chemical distinctions will persist, maintained by continued transcription of at least some of the segment-polarity genes, after the pair-rule gene products have largely disappeared (see Figure 21-66). Some of the segment-polarity genes thus expressed - including, in particular, one called *wingless* - encode secreted proteins that act also during subsequent development as spatial signals within the parasegment to regulate the details of its internal patterning and growth.

Besides regulating the segment-polarity genes, the products of pair-rule genes collaborate with the products of gap genes (and perhaps egg-polarity genes) to cause the precisely localized activation of a further set of spatial labels - the homeotic selector genes, which permanently distinguish one parasegment from another. In the next section we examine these selector genes in detail and consider their role in cell memory.

Summary

Like other insects, Drosophila is constructed from a series of repeating modular units called segments, with specialized nonsegmental structures at each end of the body. Each major subdivision of each segment is distinguished by the expression of a particular selection of control genes that defines its "address." The pattern originates with asymmetry in the egg: positional information is supplied by four gradients set up by the products of four groups of maternal-effect genes called egg-polarity genes. The four groups of genes control four distinctions fundamental to the body plan of animals: dorsal versus ventral, endoderm versus mesoderm and ectoderm, germ cells versus somatic cells, and head versus rear. The egg-polarity genes operate by setting up graded distributions of gene regulatory proteins in the egg and early embryo, but the gradients are set up differently for the different egg axes.

The dorsoventral polarity is defined by a localized signal from the follicle cells that surround the egg. The signal molecule binds to transmembrane receptors in the ventral surface of the egg, leading ultimately to a graded intranuclear concentration of the gene regulatory protein Dorsal along the dorsoventral axis of the early embryo. The Dorsal protein regulates expression of other genes, including dpp, whose product acts in turn as a morphogen to specify finer subdivisions of the dorsoventral axis, like the early inductive signals that operate in Xenopus.

In the case of the anterior group of egg-polarity genes, the gradient arises from a localized deposit of mRNA, the product of the bicoid gene, at the anterior end of the egg. Because the insect egg develops initially as a syncytium, the Bicoid protein translated from this mRNA is able to diffuse in the cytosol along the length of the embryo, guiding the global organization of its anterior half. The Bicoid concentration gradient initiates the orderly expression of gap genes, pair-rule genes, segment-polarity genes, and homeotic selector genes. These, through a hierarchy of interactions, become expressed in some regions of the embryo and not others, progressively subdividing the body into a regular series of segmental and subsegmental units.

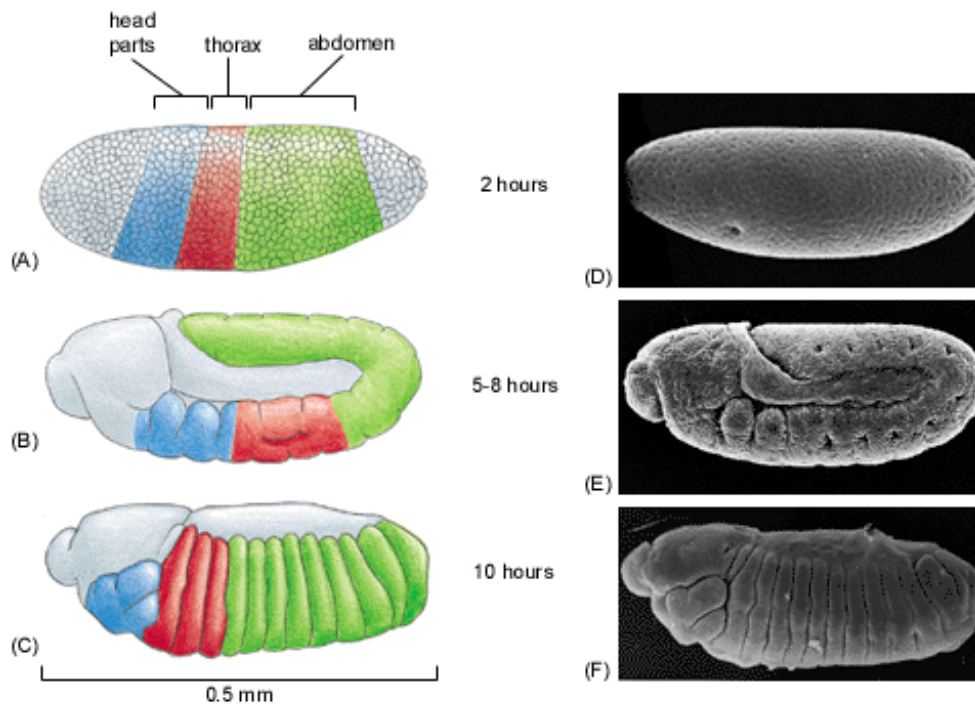
Synopsis of _Drosophila_ development from egg to adult fly.


Figure 21-49. The origins of the *Drosophila* body segments during embryonic development. The embryos are seen in side view in drawings (A-C) and corresponding scanning electron micrographs (D-F). (A and D) At 2 hours the embryo is at the *syncytial blastoderm* stage (see Figure 21-51) and no segmentation is visible, although a fate map can be drawn showing the future segmented regions (*color* in A). (B and E) At 5-8 hours the embryo is at the *extended germ band*stage: gastrulation has occurred, segmentation has begun to be visible, and the segmented axis of the body has lengthened, curving back on itself at the tail end so as to fit into the egg shell. (C and F) At 10 hours the body axis has contracted and become straight again, and all the segments are clearly defined. The head structures, visible externally at this stage, will subsequently become tucked into the interior of the larva, to emerge again only when the larva goes through pupation to become an adult. (D and E, courtesy of Rudi Turner and Anthony Mahowald; F, courtesy of Jane Petschek.)
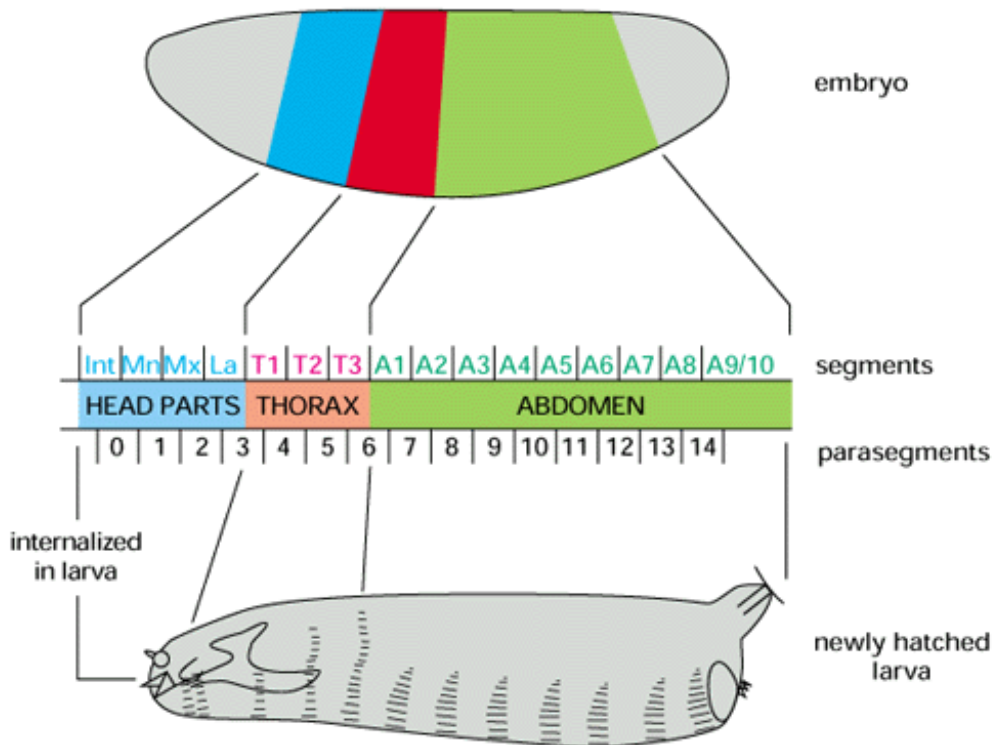

Figure 21-50. The segments of the *Drosophila* larva and their correspondence with regions of the blastoderm. Note that the ends of the blastoderm correspond to nonsegmental structures that form largely internal parts of the larva, as do the segmental rudiments of the adult head parts. Segmentation in *Drosophila* can be described in terms of either segments or parasegments: the relationship is shown in the middle part of the figure. Paraseg-ments often correspond more simply to patterns of gene expression. The exact number of abdominal segments is debatable: eight are clearly defined, and a ninth is probably present.
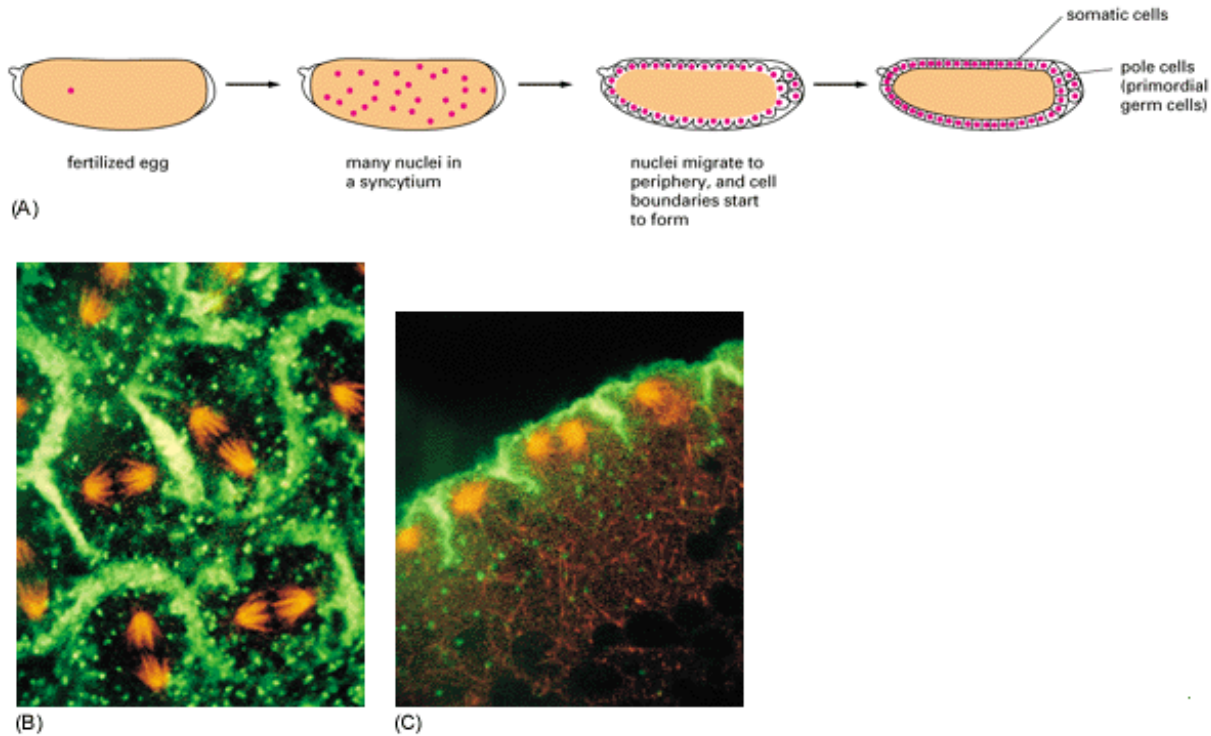

Figure 21-51. Development of the *Drosophila* egg from fertilization to the cellular blastoderm stage. (A) Schematic drawings. (B) Surface view and (C) optical section photographs of blastoderm nuclei undergoing mitosis at the transition from the syncytial to the cellular blastoderm stage. Actin is stained *green,* tubulin *orange.* (A, after H.A. Schneiderman, in Insect Development [P.A. Lawrence, ed.], pp. 3-34. Oxford, UK: Blackwell, 1976; B and C, courtesy of W. Theurkauf.)
Figure 21-52. Fate map of a *Drosophila* embryo at the cellular blastoderm stage. The embryo is shown in side view and in

cross-section, displaying the relationship between the dorsoventral subdivision into future major tissue types and the anteroposterior pattern of future segments. A heavy line encloses the region that will form segmental structures. During gastrulation the cells along the ventral midline invaginate to form mesoderm, while the cells fated to form the gut invaginate near each end of the embryo. Thus, with respect to their role in gut formation, the opposite ends of the embryo, although far apart in space, are close in function and in final fate. (After V. Hartenstein, G.M. Technau, and J.A. Campos-Ortega, *Wilhelm Roux' Arch. Dev. Biol.*194:213-216, 1985.)
Figure 21-53. The domains of the anterior, posterior, and terminal systems of egg-polarity genes. The upper diagrams show the fates of the different regions of the egg/early embryo and indicate in (*white*) the parts that fail to develop if the anterior, posterior, or terminal system is defective. The middle row shows schematically the appearance of a normal larva and of mutant larvae that are defective in a gene of the anterior system (for example, *bicoid*), of the posterior system (for example, *nanos*), or of the terminal system (for example, *torso*). The bottom row of drawings shows the appearances of larvae in which none or only one of the three gene systems is functional. The lettering beneath each larva specifies which systems are intact (A P T for a normal larva, -PT for a larva where the anterior system is defective but the posterior and terminal systems are intact, and so on). Inactivation of a particular gene system causes loss of the corresponding set of body structures; the body parts that form correspond to the gene systems that remain functional. Note that larvae with a defect in the anterior system can still form terminal structures at their anterior end, but these are of the type normally found at the rear end of the body rather than the front of the head. (Slightly modified from D. St. Johnston and C. Nüsslein-Volhard, *Cell* 68:201-219, 1992.© Cell Press.)
Figure 21-54. Inheritance of a recessive maternal-effect mutation. The pattern of inheritance is traced, starting with heterozygous (m/+) grandparents, for a mutation (m) that is recessive to the normal gene (+). The genotype of each animal or cell is shown to the left of it. *Red* color denotes presence of the normal (+) gene product. The gene product acts only at the beginning of development, and the appearance of the mature animal reflects the set of maternally specified components present in the egg. Note that the sperm makes no significant contribution of these gene products to the egg. The pattern of inheritance of a dominant maternal-effect mutation is different but can be worked out in a similar way.
Figure 21-55. A *Drosophila* oocyte in its follicle. The oocyte is derived from a germ cell that divides four times to give a family of 16 cells that remain in communication with one another via cytoplasmic bridges. One member of the family group becomes the oocyte, while the others become nurse cells, which make many of the components required by the oocyte and pass them into it via the cytoplasmic bridges. The follicle cells that partially surround the oocyte have a separate ancestry; they are the sources of terminal and ventral egg-polarizing signals.
Figure 21-56. The gradient of the Dorsal protein and its interpretation. (A) The concentration gradient of Dorsal protein in the nuclei of the blastoderm, as revealed by an antibody. (B) The interpretation of the Dorsal gradient by genes that demarcate the different dorsoventral territories; for simplicity, only two representative genes are shown. Subsequent processes will further subdivide these territories. The *decapentaplegic (dpp)* gene in particular codes for a secreted factor that will act as a local morphogen to control the detailed patterning of the ectoderm. (A, from S. Roth, D. Stein, and C. Nüsslein-Volhard, *Cell* 59:1189-1202, 1989. © Cell Press.)

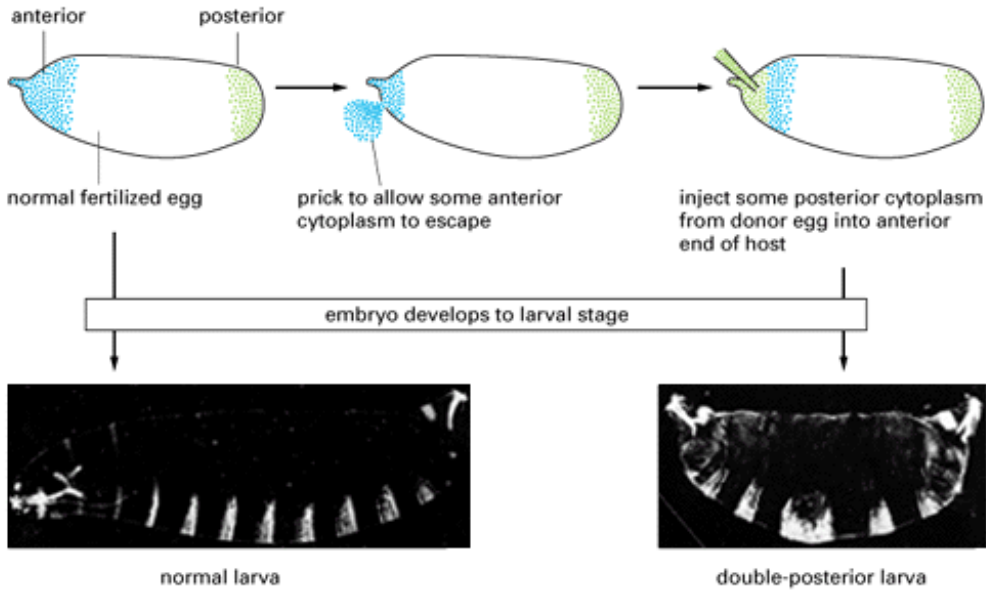

Figure 21-58. Localized determinants at the ends of the *Drosophila* egg control its anteroposterior polarity. A little anterior cytoplasm is allowed to leak out of the anterior end of the egg and is replaced by an injection of posterior cytoplasm. The resulting double-posterior larva (*photograph on right*) is compared with a normal control (*photograph on left*); the substitution of cytoplasm at one end of the egg has had a long-range effect, converting all the more anterior segments into a mirror-image duplicate of the last three abdominal segments. The larvae are shown in dark-field illumination. (From H.G. Frohnhöfer, R. Lehmann, and C. Nüsslein-Volhard, *J. Embryol. Exp. Morphol.* 97[Suppl]:169-179, 1986, by permission of the Company of Biologists Ltd.)
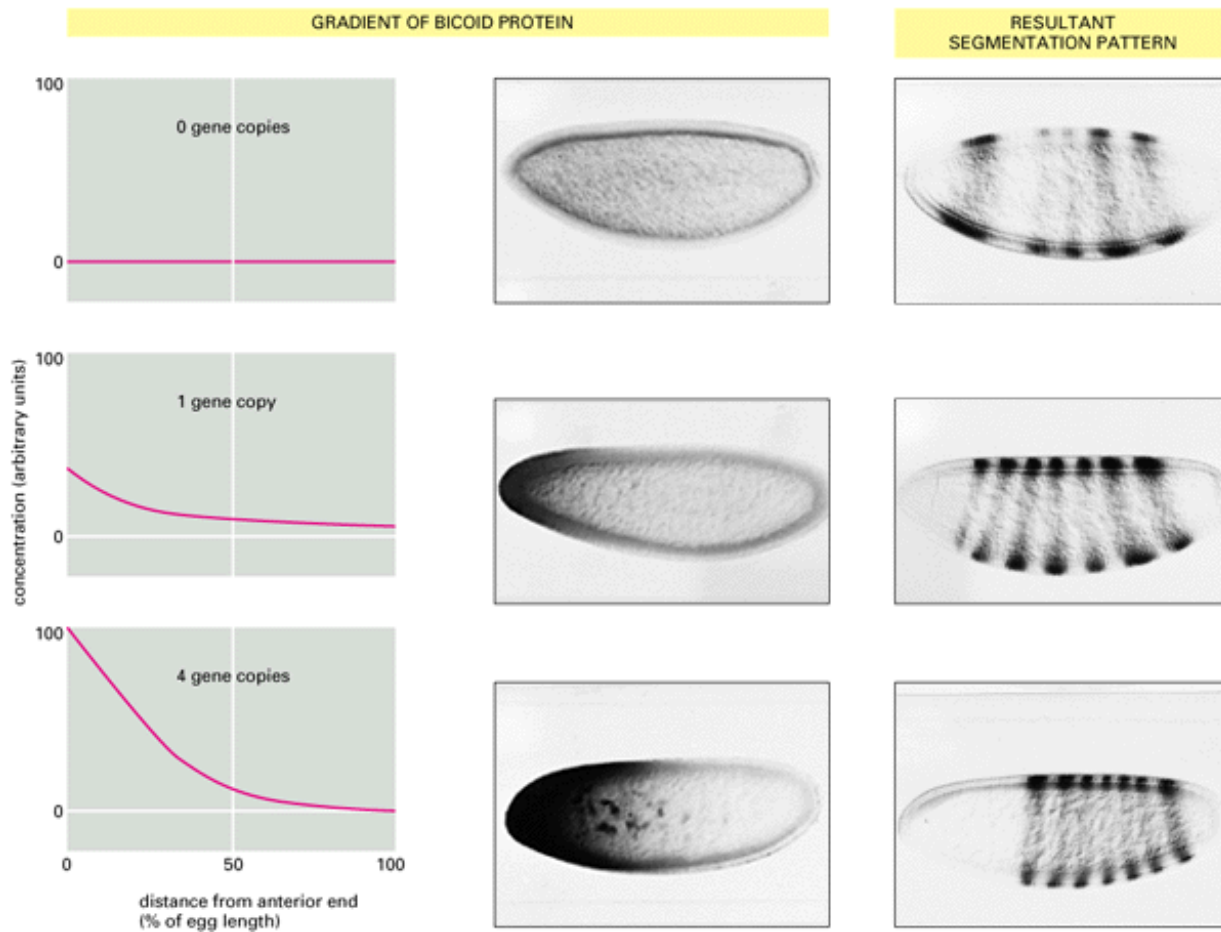

Figure 21-59. The gradient of Bicoid protein in the *Drosophila* egg and its effects on the pattern of segments. The gradient is revealed by staining with an antibody against the Bicoid protein; the segment pattern is revealed by an antibody against the product of a pair-rule gene, *even-skipped* (discussed later). Three embryos are compared, containing zero, one, and four copies, respectively, of the normal *bicoid* gene. With zero dosage of *bicoid*, segments with an anterior character do not form; with increasing gene dosage they form progressively farther from the anterior end of the egg, as expected if their position is determined by the local concentration of the Bicoid protein. Measurements of this concentration, as indicated by the intensity of staining, are shown in the graphs. Despite the considerable differences of position and spacing of the segment rudiments in the embryos with one and four doses of the gene, both embryos will develop into normally proportioned larvae and adults. A mechanism that may be responsible for this regulation is discussed on page 1064. (Slightly adapted from W. Driever and C. Nüsslein-Volhard, *Cell* 54:83-104, 1988. © Cell Press.)
Figure 21-60. Examples of the phenotypes of mutations affecting the three types of segmentation genes. In each case the areas shaded in *green* on the normal larva (*left*) are deleted in the mutant or are replaced by mirror-image duplicates of the unaffected regions. By convention, dominant mutations are written with an initial capital letter and recessive mutations are written with a lower-case letter. Several of the patterning mutations of *Drosophila* are classed as dominant because they have a perceptible effect on the phenotype of the heterozygote, even though the characteristic major, lethal effects are recessive - that is, visible only in the homozygote. Figure 21-62. The pattern of *ftz* gene expression in the *Drosophila* blastoderm. *In situ* hybridization reveals that the gene is transcribed in a pattern of seven stripes corresponding to the pattern of defects in *ftz* mutants. The bands of *ftz* expression appear as black patches of autoradiographic silver grains in this longitudinal section. (Courtesy of Philip Ingham.)
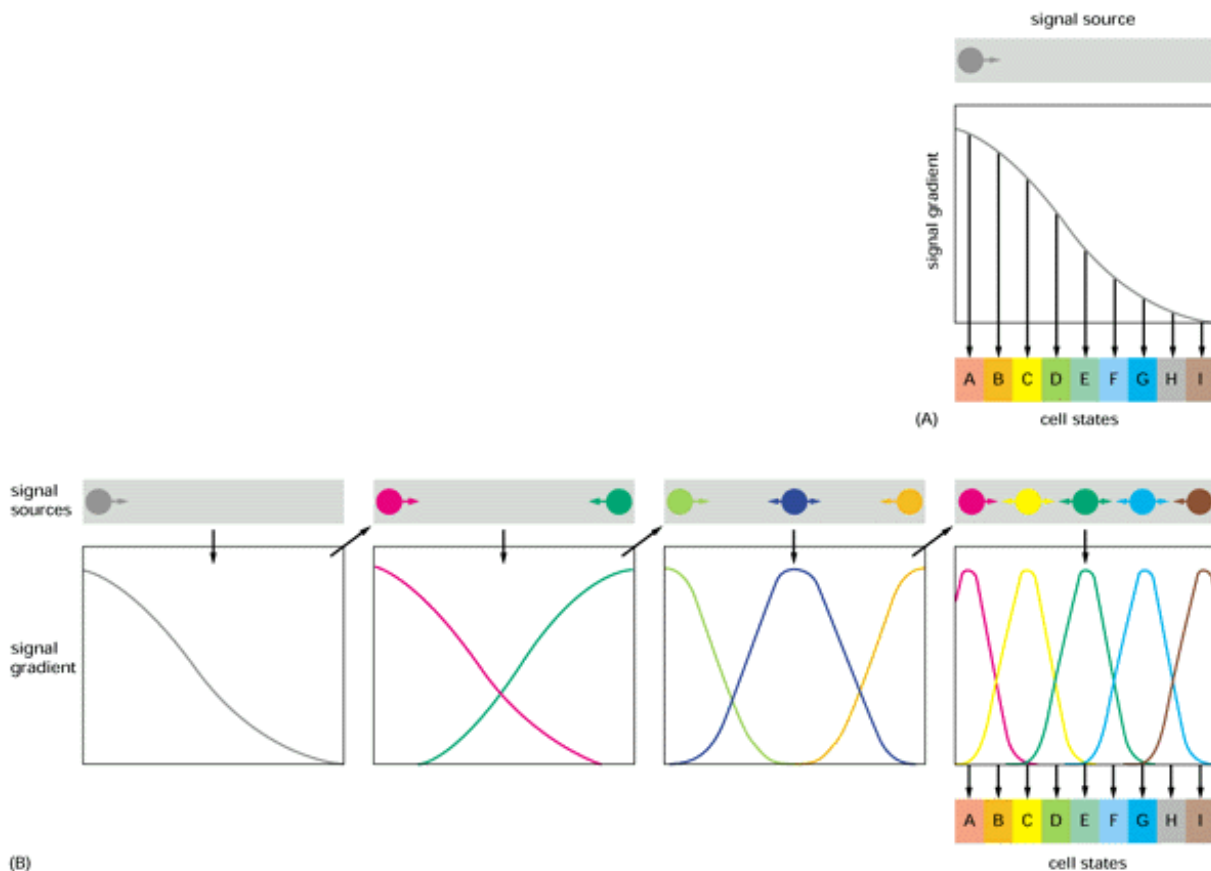

Figure 21-63. Two strategies for using signal concentration gradients to specify a fine-grained pattern of cells in different states. In (A) there is only one signal gradient, and cells select their states by responding accurately to small changes of signal concentration. In (B) the initial signal gradient controls establishment of a small number of more local signals, which control establishment of other still more narrowly local signals, and so on. Because there are multiple local signals, the cells do not have to respond very precisely to any single signal in order to create the correct spatial array of cell states. Case B corresponds more closely to the strategy of the real embryo.
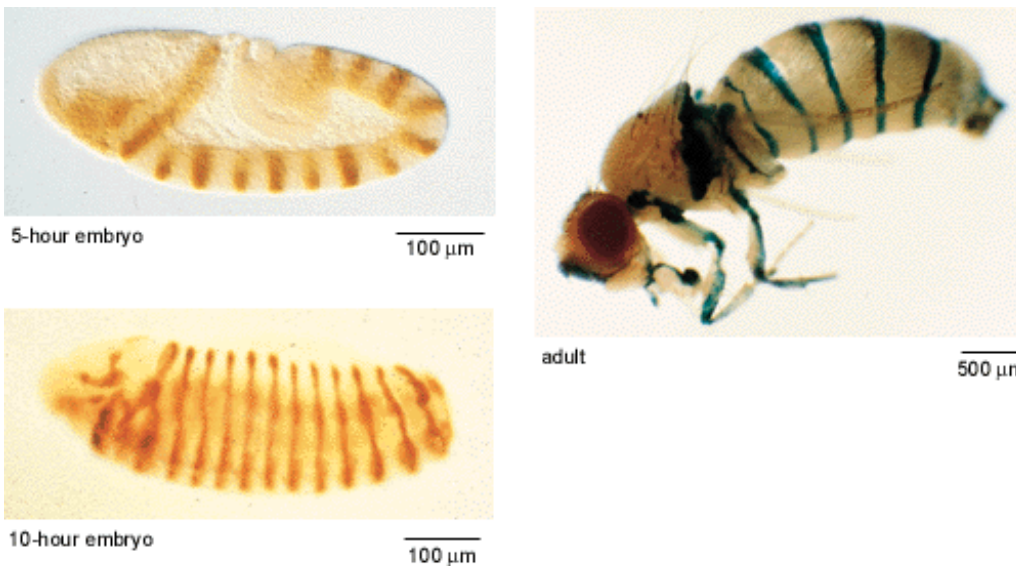
Figure 21-64. How pair-rule genes define segments in the *Drosophila* blastoderm. The diagram shows the pattern of transcription of four of the eight known pair-rule genes and of one of the segment-polarity genes, *engrailed*. Although each pair-rule gene by itself defines only a simple alternation with a repeat distance of two segments, the whole set of pair-rule genes in combination, by their pattern of adjacency and overlap, potentially defines a much finer subdivision of the blastoderm into stripes only one cell wide, such as those in which the *engrailed* gene is expressed. (After M. Akam, *Development* 101:1-22, 1987, by permission of the Company of Biologists Ltd.)
Figure 21-65. The formation of *ftz* and *eve* stripes in the *Drosophila* blastoderm. Genes *ftz* and *eve* are both pair-rule genes. Their expression patterns (shown in *brown* for *ftz* and in *gray* for *eve*) are at first blurred but rapidly resolve into sharply defined stripes. (From P.A. Lawrence, The Making of a Fly. Oxford, UK: Blackwell, 1992.)


Figure 21-66. The pattern of expression of *engrailed,* a segment-polarity gene. The *engrailed* pattern is shown in a 5-hour

embryo (at the extended germ-band stage), a 10-hour embryo, and an adult (whose wings have been removed in this preparation). The pattern is revealed by an antibody (*brown*) against the Engrailed protein (for the 5= and 10=hour embryos) or (for the adult) by constructing a strain of *Drosophila* containing the control sequences of the *engrailed* gene coupled to the coding sequence of the enzyme b-galactosidase, whose presence is easily detected histochemically through the *blue* product of a reaction that it catalyzes. Note that the *engrailed* pattern, once established, is preserved throughout the animal's life. (Courtesy of Tom Kornberg and Cory Hama.)

Drosophila and the Molecular Genetics of Pattern Formation. II. Homeotic Selector Genes and the Patterning of Body Parts 41, 50

Introduction

The first glimpses of the system of genes for pattern formation came over 70 years ago, with the discovery of the first of a set of mutations in *Drosophila* that cause bizarre disturbances of the organization of the adult fly. In the mutation *Antennapedia,* for example, legs sprout from the head in place of antennae (Figure 21-67), while in the mutation *bithorax,* portions of an extra pair of wings appear where normally there should be the much smaller appendages called halteres. These mutations transform parts of the body into structures appropriate to other positions and are called *homeotic.* A whole set of homeotic selector genes determines the anteroposterior character of the segments of the fly. In this section we follow *Drosophila* development through to the final steps in the formation of the adult fly to see how the homeotic selector genes do their job. At the end of the section we see that the same genes have a central role in patterning the body parts of other animals, including ourselves.

The Homeotic Selector Genes of the Bithorax Complex and the Antennapedia Complex Specify the Differences Among Parasegments 54, 55

The homeotic selector genes of interest to us here all lie in one or the other of two tight gene clusters known as the bithorax complex and the Antennapedia complex. Each complex contains several genes with analogous functions: those in the bithorax complex control the differences among the abdominal and thoracic segments of the body, while those in the Antennapedia complex control the differences among thoracic and head segments. In some other insects the corresponding groups of genes all lie in a single complex, called the *HOM complex;* the Antennapedia and bithorax complexes are thus thought to be the two halves of a single HOM complex that has become split in the course of the fly's evolution. Each homeotic selector gene has a characteristic domain of action, defined as the region of the body that is transformed as a result of mutation in that gene. Typically, this domain has sharp boundaries that are roughly half a segment out of register with the conventional segment boundaries, indicating that the domain is a parasegment or a block of parasegments (see Figure 21-50).

Many of the mutations of homeotic selector genes have a recessive lethal phenotype and allow the embryo to survive only to around the time of hatching. Observations of embryos or very early larvae therefore give the clearest and in some respects most complete picture of the role of the homeotic selector genes.

Larvae that are deficient in all the genes of the bithorax complex have a particularly simple structure: the head and anterior thorax are normal as far as the P4 parasegment, but all of the remaining 10 parasegments are converted to the character of P4. Partial deletions of the bithorax complex cause transformations that are less extensive (Figure 21-68). These observations, and analogous findings for the Antennapedia complex, illustrate the essential role of the homeotic selector genes in defining the differences among the parasegments: when the genes are missing, the distinctions between one parasegment and another are not made.

Homeotic Selector Genes Encode a System of Molecular Address Labels 50, 56

Like the segmentation genes, the homeotic selector genes are first activated in the blastoderm. Since all of the DNA in the Antennapedia and bithorax complexes has been cloned, nucleic acid probes are available to map the spatial pattern of transcription of each of the homeotic selector genes by *in situ* hybridization. The conclusions from these studies are striking: to a first approximation each homeotic selector gene is normally expressed in just those regions that develop abnormally, as though misplaced, when the gene is mutated or absent.

The products of the selector genes can thus be viewed as molecular address labels possessed by the cells of each parasegment. If the address labels are changed, the parasegment behaves as though it were located somewhere else. Because the segmentation

genes help to control the activation of the homeotic selector genes, the pattern of homeotic selector gene expression is in exact register with the parasegmental boundaries defined by the pair-rule and segment-polarity gene products. In this way the combination of a particular homeotic selector gene product (or set of such products) with a particular set of segmentation gene products reliably defines a unique address carried only by the cells in one subdivision of one segment.

Although the pattern of expression of the homeotic selector genes undergoes complex adjustments as development proceeds, these genes continue to play a crucial part throughout the subsequent development of the fly. They somehow equip cells with a memory of their positional value.

The Control Regions of the Homeotic Selector Genes Act as Memory Chips for Positional Information [54], [57], [58], [59]

The products of the homeotic selector genes, as discussed in Chapter 9, are gene regulatory proteins, all homologous to one another and all containing a highly conserved *homeobox sequence,* which codes for a DNA-binding *homeodomain* (60 amino acids long) in the corresponding proteins. Although many other genes also contain a homeobox, the particular type of homeobox sequence found in the homeotic selector genes is characteristic.

There are eight homeotic selector genes in the Antennapedia and bithorax complexes (which, for convenience, we shall refer to collectively as the HOM complex). Their coding sequences are interspersed amid a much larger quantity - a total of about 650,000 nucleotide pairs - of regulatory DNA. This DNA includes binding sites for the products of egg-polarity and segmentation genes - genes such as *bicoid, hunchback,* and *even-skipped.* The regulatory DNA in the HOM complex acts as an interpreter of the multiple items of positional information supplied to it by all these factors, and, in response to them, it makes a decision to transcribe or not to transcribe a particular set of homeotic selector genes. There are, however, some deep mysteries about how the HOM control system is organized and how it operates.

One remarkable feature is that the sequence in which the genes are ordered along the chromosome in both the Antennapedia and the bithorax complexes corresponds almost exactly to the order in which they are expressed along the axis of the body (Figure 21-69). It is as though the genes are activated serially by some process that spreads farther and farther along the chromosome in proportion to some intracellular indicator of distance along the body axis. It is not clear whether this ordering is merely an accident of evolution or truly reflects involvement of some activation mechanism that propagates along the chromosome, although we shall see later that it is a feature of the HOM complex that has been highly conserved in the course of evolution.

There is a further puzzle. The HOM complex serves to make each parasegment different from the next, but the number of homeotic selector genes is smaller than the number of parasegments. The bithorax complex, for example, contains just three genes, but it is responsible for the differences between 10 parasegments (see Figure 21-69). Moreover, there are many mutations, mapping to different sites in the complex, that alter the anteroposterior character of only a single parasegment or even of a part of a parasegment. Most of these mutations lie in noncoding *control regions* and are also ordered along the chromosome in a sequence that matches in detail the anatomical ordering of the regions they affect. This suggests that the differences between body regions are defined not simply by the presence of different homeotic selector gene products but, more subtly, by persistent differences of some sort in the states of the control regions associated with those genes. A control region, in this view, is to be pictured not as a simple on-off switch but as something more like a computer microchip: it receives inputs (in the form of gene regulatory factors and other molecules that bind to it), it produces an output (in the form of a directive to transcribe or not to transcribe the homeotic selector gene), and it can store a memory trace (a record of positional information) that affects the way the output is computed from the inputs. The positional value of a cell thus will not necessarily be reflected in a certain fixed level of expression of the homeotic selector gene but rather in a particular way of regulating that gene in response to changing conditions.

All this remains speculative as long as we have no answer to a third and most fundamental question about the HOM complex: what mechanism maintains the memory trace? As discussed earlier (see p. 1062), one possibility is that the mechanism involves positive feedback, where the product of a gene, once it is made, stimulates its own transcription. At least some of the homeotic selector genes seem to have this property. The gene *Deformed* (in the Antennapedia complex), for example, has multiple binding sites for the Deformed protein in its upstream control region, and in some cells these are sufficient for it to keep itself activated once activity has been triggered. Such self-stimulatory effects, however, are not sufficient by themselves to maintain the memory trace in most cells. A whole additional set of genes, called the *Polycomb group,* have been found to be required to keep silent those homeotic selector genes that should not be expressed: if any of the Polycomb-group genes are inactivated by mutations, the homeotic selector genes are initially switched on in a normal pattern but then become activated indiscriminately all over the embryo (Figure 21-70A). The Polycomb protein is bound to the chromatin of the genes it controls (Figure 21-70B).

Moreover, related genes appear to be involved elsewhere in the control of chromatin structure, suggesting that the memory of positional value may be carried by some persistent local modification of the chromatin in the HOM gene complex.

The Adult Fly Develops from a Set of Imaginal Discs That Carry Remembered Positional Information 60

The basic pattern of expression of the homeotic selector genes is established in the *Drosophila* embryo and determines the structure not only of the larva, but also, much later, that of the adult fly. To appreciate fully the role of these genes as carriers of a positional memory, it is necessary to have some idea of the curious way in which the adult, or *imago,* finally develops.

The adult fly is formed largely from groups of cells, called *imaginal cells,* that are set aside, apparently undifferentiated, in each segment of the larva. The imaginal cells for most of the adult body originate from the embryonic epidermis - the epithelium that covers the body. They remain connected with the epidermis of the larva, and they will form mainly the epidermal structures of the adult fly. The imaginal cells for the head, thorax, and genitalia are organized into imaginal discs; other clusters of imaginal cells will form the abdomen. There are also groups of imaginal cells in the viscera of the larva to give rise to the internal organs of the fly. Detailed studies have focused chiefly on the imaginal discs. There are 19 of these, arranged as 9 pairs on either side of the larva plus 1 disc in the midline (Figure 21-71). The discs are pouches of epithelium, shaped like crumpled and flattened balloons, that evaginate (turn inside out), extend, and differentiate at metamorphosis. The eyes and antennae develop from one pair of discs, the wings and part of the thorax from another, the first pair of legs from another, and so on.

The cells of one imaginal disc look like those of another, and when they differentiate, they will give rise to generally similar sets of specialized cell types. But grafting experiments show that they are in fact already regionally determined and nonequivalent. If one imaginal disc is transplanted into the position of another in the larva and the larva is then left to go through metamorphosis, the grafted disc is found to differentiate autonomously into the structure appropriate to its origin, regardless of its new site. This implies that the imaginal disc cells are governed by a memory of their original position. By an ingenious grafting procedure that lets the imaginal disc cells proliferate for an extended period before differentiating, it can be shown that this cell memory is stably heritable (with rare lapses) through an indefinitely large number of cell generations (Figure 21-72).

The homeotic selector genes are essential components of the memory mechanism. If they are eliminated from imaginal disc cells at any stage in the long period leading up to differentiation at metamorphosis, the cells will differentiate into incorrect structures, as though they belonged to a different segment of the body. This can be demonstrated by the very powerful technique of *x-ray-induced mitotic recombination* - in effect, a form of genetic surgery on individual cells by means of which mutant clones of cells of a specified genotype can be generated at a chosen time in development, as we now explain.

Homeotic Selector Genes Are Essential for the Memory of Positional Information in Imaginal Disc Cells 61

A short pulse of x-irradiation, as a side effect of the damage it does to DNA, can provoke crossing over between homologous chromosomes in a dividing cellan event that would normally occur only at meiosis. As explained in Figure 21-73, if the cell is heterozygous for a gene in the crossed-over chromosomal region, the process can result in a pair of daughter cells that are homozygous, the one receiving two copies of the maternal allele of the gene, the other receiving two copies of the paternal allele. The occurrence of the cross-over can be detected if the animal is chosen to be also heterozygous for a mutation in a marker gene - a pigmentation gene, for example - that lies near the gene of interest and so undergoes crossing over in company with it. In this way marked homozygous mutant clones of cells can be created to order (Figure 21-74).

The major effects of mutations in homeotic selector genes are generally recessive: only the homozygous mutant organism shows the homeotic transformation. By exploiting mitotic recombination, one can create a clonal patch of marked homozygous homeotic mutant cells in an imaginal disc and examine their behavior in a heterozygous, phenotypically normal background. The finding is that the marked cells, and only the marked cells, show the homeotic transformation (provided that they lie in the normal domain of action of the homeotic selector gene), and this applies whether the recombination event was provoked early in development or late. A 2-day larva heterozygous for a mutation that destroys the function of the *Ultrabithorax (Ubx)* gene (in the bithorax complex), for example, can be x-irradiated to produce isolated clones of homozygous cells in its imaginal discs that contain no functional *Ubx* gene. These clones, if they lie in the haltere disc, will give rise to patches of wing-type tissue in the haltere. These and other observations indicate that each cell's memory of positional information depends on the continued activity of the normal homeotic selector gene. This memory, furthermore, is expressed in a cell-autonomous fashion - each cell maintains its state independently, depending on its own history and genome, regardless of its neighbors.

The Homeotic Selector Genes and Segment-Polarity Genes Define Compartments of the Body 53, 62

The remembered distinctions specified by the homeotic selector genes are discrete: there is an abrupt difference of gene expression between cells in adjacent parasegments. The same is true for at least some of the segment-polarity genes, such as *engrailed* (see Figure 21-66), whose differential expression corresponds to an abrupt difference between cells in the posterior part of a parasegment and cells in its anterior part. Thus, through the differential expression of these two classes of genes, the body is subdivided into a series of discrete regions comprising cells in different states of determination. At the frontier between one such region and the next, the cells appear to be prevented from mixing, as though selective cohesion between cells with the same molecular address label keeps them segregated from cells with a different label (Figure 21-75). Thus, for example, when a clone of genetically marked but otherwise normal cells is created in the wing by mitotic recombination, the clone is observed to be confined strictly to one side or the other of a precisely specified boundary at the frontier between the two parasegments from which the wing is constructed. A subdivision of the body defined in this way - in the wing or any other organ - is called a compartment (Figure 21-75).

By definition, a compartment boundary is a frontier where two populations of cells in different states of determination are prohibited from mixing. Because the state of determination is not normally reversible, each compartment has to be a self-sufficient unit. It cannot recruit cells from the adjacent compartment or transfer surplus cells into it. It can and does, however, regulate its internal organization and its size in obedience to the rule of intercalation, discussed earlier, by adjustments that do not violate this constraint. Thus, in the regulation of pattern and growth, each compartment seems to behave as a more or less independent module during normal development (although during regeneration after a drastic disturbance cells sometimes do switch their character and their compartmental allegiance).

Some of the morphogenetic signals operating in the imaginal disc to control these processes have been identified. They appear to include products of the *dpp* and *wingless* genes, which, as we saw, are both active in patterning the early embryo also (see Figure 21-56). But we do not yet know in molecular genetic terms how these signaling systems are organized or how they collaborate with the homeotic selector genes to give each compartment its characteristic internal pattern and make it stop growing when it has reached its proper size.

Thus, in following the genetic pathways of pattern formation to later and later stages and finer and finer levels of detail, we come to a point where the chain of cause and effect becomes obscure. At the very last stage in the process, however, as cells prepare for terminal differentiation, the trail can be picked up again, and we can trace the genetic mechanisms that control some of the most minute details of patterning of the fly's body surface as displayed in its array of *sensory bristles.*

Localized Expression of Specific Gene Regulatory Proteins Foreshadows the Production of Sensory Bristles 63

Flies have many bristles on their body - some big, some small. The big ones are landmark structures on the surface of the fly: they are relatively few and far between and occupy exactly predictable positions. The small ones are more closely spaced and occur in fields covering precisely defined regions of the body surface. The bristles are miniature sense organs - components of the peripheral nervous system. Some respond to chemical stimuli, others to mechanical stimuli, but they are all constructed in a similar way. The structure is seen at its simplest and most stereotyped in the *mechanosensory bristles.* Each of these, whether big or small, consists of exactly four cells: a shaft cell, a socket cell, a glial sheath cell, and a neuron (Figure 21-76). Movement of the shaft of the bristle excites the neuron, which sends a signal to the central nervous system.

The cells of the bristle of the adult fly derive from the imaginal disc epithelium, and all four of them are granddaughters of a single *sensory mother cell* that becomes distinct from the neighboring prospective epidermal cells during the last larval instar (Figure 21-77). To account for the pattern of bristle differentiation, we have to explain first how the genesis of sensory mother cells is controlled and then how the four granddaughters of each such cell become different from one another.

Two genes, called *achaete* and *scute,* are crucial in initiating the formation of bristles in the imaginal disc epithelium. These genes have similar and overlapping functions and code for closely related gene regulatory proteins of the helix-loop-helix class (discussed in Chapter 9). They belong to a group of closely linked homologous genes, all located in the *achaete-scute complex. In situ* hybridization shows that *achaete* and *scute* are expressed in the imaginal disc in precisely the regions where bristles will form. Mutations that eliminate the expression of these genes at some of their usual sites block development of bristles at just those sites, and mutations that cause expression in additional, abnormal sites cause bristles to develop there. But expression of *achaete* and *scute* is transient, and only a minority of the cells initially expressing the genes go on to become sensory mother cells; the others become ordinary epidermis. The state that is specified by expression of *achaete* and *scute* is called *proneural.* The proneural cells are primed to take the neurosensory pathway of differentiation, but which of them will actually do so

depends on competitive interactions among them.

Lateral Inhibition Regulates the Fine-grained Pattern of Differentiated Cell Types 63, 64

Proneural cells, expressing *achaete* or *scute* or both genes together, occur in groups in the imaginal disc epithelium - a small, isolated cluster of fewer than 30 cells for a big bristle, a broad, continuous patch of hundreds or thousands of cells for a field of small bristles. In the former case just one member of the cluster becomes a sensory mother cell; in the latter case many cells scattered throughout the proneural region do so. The sensory mother cells are almost always separated from one another by a certain minimum number of epidermal cells. Experiments with genetic mosaics show that a cell that becomes committed to the sensory-mother-cell pathway of differentiation sends a signal to its neighbors not to do the same thing: it exerts a lateral inhibition (Figure 21-78). If a cell that would normally become a sensory mother is genetically disabled from doing so, a neighboring proneural cell, freed from lateral inhibition, will become a sensory mother instead.

The genes responsible for lateral inhibition were first identified as such through studies of mutant embryos. In the embryo, both the achaete-scute complex and the genes for lateral inhibition govern development of the central and peripheral nervous system in just the same way that they later govern development of the sense organs of the peripheral nervous system in imaginal discs. In both situations mutations abolishing lateral inhibition have a simple and striking effect: neural cells are produced in vast excess at the expense of epidermal cells (Figure 21-79). Genes are generally named according to their mutant phenotype; hence, the genes responsible for lateral inhibition are called, confusingly, neurogenic genes. They form a genetic system with at least seven members.

The best-known neurogenic gene is called *Notch.* It codes for a transmembrane protein that is thought to serve as the receptor for the lateral-inhibition signal. Experiments with genetic mosaics show that cells lacking *Notch* are blind to the signal and follow a neural pathway of differentiation. Another related transmembrane protein, encoded by the neurogenic gene *Delta,* appears to be a ligand that binds to *Notch* and activates it; lateral inhibition, it seems, is transmitted via direct cell-to-cell contact. Downstream from *Notch* the products of other neurogenic genes act intracellularly to interpret the signal and suppress neural differentiation.

The same lateral inhibition mechanism dependent on *Notch* can be shown to operate twice in the formation of bristles - first, to force the neighbors of sensory mother cells to follow a different pathway and become epidermal and, second, to make the four granddaughters of the sensory mother cell follow different pathways of differentiation so as to form the four components of the bristle. At both stages the default pathway is the neural pathway, and lateral inhibition mediates a competitive interaction that forces adjacent cells to differentiate in contrasting ways.

The same set of neurogenic genes in *Drosophila* not only mediates lateral inhibition repeatedly during development of the nervous system but also is required for the detailed patterning of many other tissues of the fly. Indeed, lateral inhibition is a key strategy in the control of multicellular patterns of differentiation throughout the animal world and almost certainly in plants also; the types of spacing patterns that it can generate are ubiquitous, from the stomata on a leaf to the photoreceptors in the eye. As homologues of the neurogenic genes are found in vertebrates, it may be that the same conserved molecular mechanisms operate in at least some of these cases. In the final part of this section we consider how far *Drosophila* does actually provide a universal model for the molecular genetics of pattern formation.

The Developmental Control Genes of *Drosophila* Have Homologues in Vertebrates 65

The theory of evolution tells us that all animals are our cousins. It is easy enough to see the family resemblances between a human being and a mouse, or even a fish, and to chart the homologies between the parts of their bodies and the parts of our own. But when we compare ourselves with flies or worms, from which we are separated by about 600 million years, the correspondences are far from clear. True, one can recognize some familiar cell types - neurons, striated muscle cells, and spermatozoa, for example. With a little less confidence, one can see similarities in the body plan, with its central gut tube and its head at one end. But how deep do these similarities go? The fossil record gives us no clear answer, but molecular genetics has begun to supply one.

Comparisons of gene sequences show that an astonishingly large proportion of the genes in an animal such as a fly have unmistakable homologues in vertebrates, and vice versa. Such homologies have been recognized for a majority of the developmental control genes we have mentioned in this chapter. But are these control genes used in the same combinations and for homologous purposes, so that the genetic *system* governing development is conserved? When we compare a human being

with a fly, there seem at first sight to be fundamental differences, in development as well as final structure. Vertebrate eggs do not, for example, develop through a syncytial stage as insects do, and their initial multicellular patterning therefore cannot be controlled by morphogen gradients such as that of Bicoid in *Drosophila,* set up by intracellular diffusion of a protein through a cytoplasm that is shared by many nuclei. And yet, when we turn to slightly later stages, we encounter a remarkable pattern of anatomical correspondences. These could never have been discerned without the help of molecular genetics, which reveals in very different animals similar positional markers expressed in body parts that we might not otherwise judge to have anything in common. The HOM gene complex has been central to this new appreciation of our relation to flies and worms.

Mammals Have Four Homologous HOM Complexes <u>59</u>, <u>66</u>

Because the homeodomain of the homeotic selector genes has been highly conserved in evolution, it has been relatively easy to discover homologues of the *Drosophila* genes in other classes of animals. They have been found in almost every sort of creature - in *Hydra,* in nematodes and earthworms, in beetles and mollusks and sea urchins, in fish, frogs, birds, and mammals. Remarkably, in those cases that have been investigated adequately, these genes seem to be grouped in complexes similar to the insect HOM complex. In the mouse there are four such complexes - called the HoxA, HoxB, HoxC, and HoxD complexes - each on a different chromosome. Individual genes in each complex can be recognized by their homeobox sequences, as counterparts of specific members of the *Drosophila* set. It appears that each of the four mammalian Hox complexes is, roughly speaking, the equivalent of a complete insect HOM complex (that is, an Antennapedia complex plus a bithorax complex) (<u>Figure 21-80</u>). The ordering of the genes within each Hox complex is essentially the same as in the insect HOM complex, suggesting that all four vertebrate complexes originated by duplications of a single primordial complex and have preserved its basic organization. Most tellingly, when the expression patterns of the Hox genes are examined in the vertebrate embryo by *in situ* hybridization, it turns out that the members of each complex are expressed in a head-to-tail series along the axis of the body, just as they are in *Drosophila* (<u>Figure 21-81</u>). The pattern is most clearly seen in the neural tube. With minor exceptions this anatomical ordering matches the chromosomal ordering of the genes in each complex, and corresponding genes in the four different Hox complexes have almost identical anteroposterior domains of expression.

The gene expression domains define a detailed system of correspondences between insect body regions and vertebrate body regions. As shown in <u>Figure 21-82</u>, the parasegments of the fly correspond to a similarly labeled series of segments in the anterior part of the vertebrate embryo. These are most clearly demarcated in the hindbrain, where they are called *rhombomeres.* In the tissues lateral to the hindbrain the segmentation is seen in the series of *branchial arches,* prominent in all vertebrate embryos - the precursors of the system of gills in fish and of the jaws and structures of the neck in mammals; each pair of rhombomeres in the hindbrain corresponds to one branchial arch (see <u>Figure 21-82</u>). In the hindbrain, as in *Drosophila,* the boundaries of the expression domains of the Hox genes are aligned with the boundaries of the anatomical segments. And as in *Drosophila* compartments, the cells of one rhombomere do not mix with those of the next rhombomere.

It is not yet clear, however, how similar in detail the mechanisms that set up the hindbrain and branchial arch segmentation of a vertebrate are to those that generate the parasegments of an insect. Although, for example, vertebrates have homologues of the *engrailed* and *wingless* genes, these are not expressed in a repetitive segmental fashion in the hindbrain.

Hox Genes Specify Positional Values in Vertebrates as in Insects <u>67</u>

Despite uncertainties over mechanisms of segmentation, there can be little doubt that our head-to-tail axis is homologous to that of an insect and that essentially the same sets of genes mark out the anteroposterior positional values of our cells. The Hox genes appear to have not only similar expression patterns to the insect HOM genes but also similar controlling functions. Because the vertebrate has four Hox gene complexes acting more or less in parallel along its body axis, in place of the insect's single HOM complex, it is not enough to eliminate or misexpress a single Hox gene to produce a full-blown homeotic transformation of one region into the character of another. Nevertheless, genetically engineered mice with alterations in single Hox genes do show localized abnormalities that can be interpreted as incomplete homeotic transformations.

This illustrates one of the fundamental difficulties in analyzing the genetics of developmental control systems in vertebrates. The vertebrate genome is very big, and it owes its size, in large measure, to gene duplications in the course of evolution. Thus it contains multiple variant copies of genes that are represented singly in a fly or a nematode: the four Hox complexes corresponding to the single HOM complex are typical in this respect. The multiple versions of a gene have overlapping and partially interchangeable functions, and this partial redundancy makes it very difficult to identify the basic role of any single gene, just as it is hard, by removing or inserting a single screw, to demonstrate the function of the multiple screws that hold a door on its hinges. Herein lies the cardinal importance of the insights that simpler model organisms such as *Drosophila* and

Caenorhabditis elegans have to offer.

This is not to say that an individual gene in a vertebrate set is superfluous; for as evolution proceeds, the duplicated genes diverge and begin to take on new and more specialized functions that distinguish them from one another. Old components can be adapted to organize the development of new types of structures in addition to the old. The limbs of higher vertebrates provide a beautiful example.

Subsets of Hox Genes Are Expressed in Order Along Two Orthogonal Axes in the Vertebrate Limb Bud <u>68</u>

Earlier in this chapter we used the developing limb buds of the chick embryo to show that cells in different regions are distinguished from one another by a property that we called their positional value. This remembered characteristic of the cells controls whether they will form the structures appropriate to leg or wing, upper arm or forearm, thumb or little finger. Molecular genetics has revealed what "positional value" means in molecular terms in the limb bud.

We have seen that along the main body axis, both in flies and in vertebrates, positional values are defined by the state of expression of HOM/Hox genes. *In situ* hybridization shows that the same is true in the limb buds of a mouse or chick embryo - but with a twist. Instead of finding the corresponding genes of all four Hox complexes expressed in similar, overlapping patterns, as in the hindbrain, one finds a subset of members of the HoxD complex expressed in a series of domains ordered along one limb axis (very roughly, the anteroposterior) and a subset of members of the HoxA complex expressed in series along a different axis (more or less proximodistal) (<u>Figure 21-83</u>). To test whether these genes actually control limb patterning, a retrovirus has been used as an expression vector in the chick embryo to introduce a particular Hox gene into the limb bud cells and force expression of the gene in an inappropriate site. When cells in the region from which the first toe will develop are thus caused to express the Hox gene characteristic of the second toe (*Hoxd-11*), their behavior is transformed, and at the site of the first toe a duplicate of the second toe develops. Evidently, when vertebrates evolved limbs, they co-opted the different sets of Hox genes in different ways to control limb patterning as well as the patterning of the main body axis.

A central problem now for vertebrate embryology is to find out how the Hox genes themselves are regulated. Several studies show that retinoic acid can control Hox gene expression both in the limb bud and along the main body axis, but how this control is exerted and what part it plays in normal development are as yet open questions.

The HOM/Hox genes provide at present the most spectacular example of conserved developmental control machinery. But the flood of genetic homologies discovered through gene sequencing in the past few years gives every reason to expect that many further developmental parallels between vertebrates and invertebrates, no less profound, will soon become apparent.

Classical and molecular genetic studies of small, tractable organisms such as flies and worms give us a key to unlock the mysteries of development in the animal world as a whole. But can we take the generalization a step further still, to the world of plants, or does plant development rest on an entirely different set of principles and mechanisms? This is the question that we tackle in the next section.

Summary

Homeotic selector genes specify the differences between body segments along the head-to-rear axis: they provide the cells with a record of their positional value. Mutations in homeotic selector genes can convert one body segment to the character of another, and deletion of the genes en masse results in a larva whose body segments are all alike. Similar transformations are seen in the external structures of the adult fly, which are derived from the imaginal discs of the larva. Transplantation experiments show that the cells in the discs retain a long-term memory of their positional value, and this memory depends on the continued presence of the homeotic selector genes.

The homeotic selector genes all code for DNA-binding proteins containing a characteristic highly conserved homeobox sequence. They are grouped in two clusters in the genome, thought to be the separated parts of a single ancestral gene cluster called the HOM complex. The chromosomal ordering of the genes in each part of the complex matches the spatial ordering of their expression domains in the body. The molecular mechanism of the memory phenomenon is unknown, but it is thought to depend on self-perpetuating changes in the state of the control regions in the HOM complex.

The expression patterns of the HOM genes and segment-polarity genes jointly subdivide the body into compartments whose

cells do not mix. Subsequent processes generate a fine-grained pattern of cell differentiation inside each compartment. Lateral inhibition, mediated by the so-called neurogenic genes, plays a key part in this final stage of cell diversification, causing cells that are in contact with one another to differentiate in different ways and so helping to organize the creation of minutely specialized sets of cells forming structures such as sensory bristles.

A large proportion of the developmental control genes identified in flies and worms have homologues in other types of animals, including vertebrates. In some cases the corresponding genes have been shown to have corresponding developmental functions, implying that fundamental mechanisms of animal development have been conserved even where the outward appearance of the body has evolved out of all recognition. Practically all animals appear to have HOM gene complexes organized in a similar way to those of insects: in mammals there are four such complexes, called Hox complexes, and their products are thought to specify positional values that control the anteroposterior pattern of parts in the region of the hindbrain and trunk. The Hox complexes have also acquired new functions as specifiers of positional information in the more recently evolved parts of the vertebrate body, in particular in the limbs.

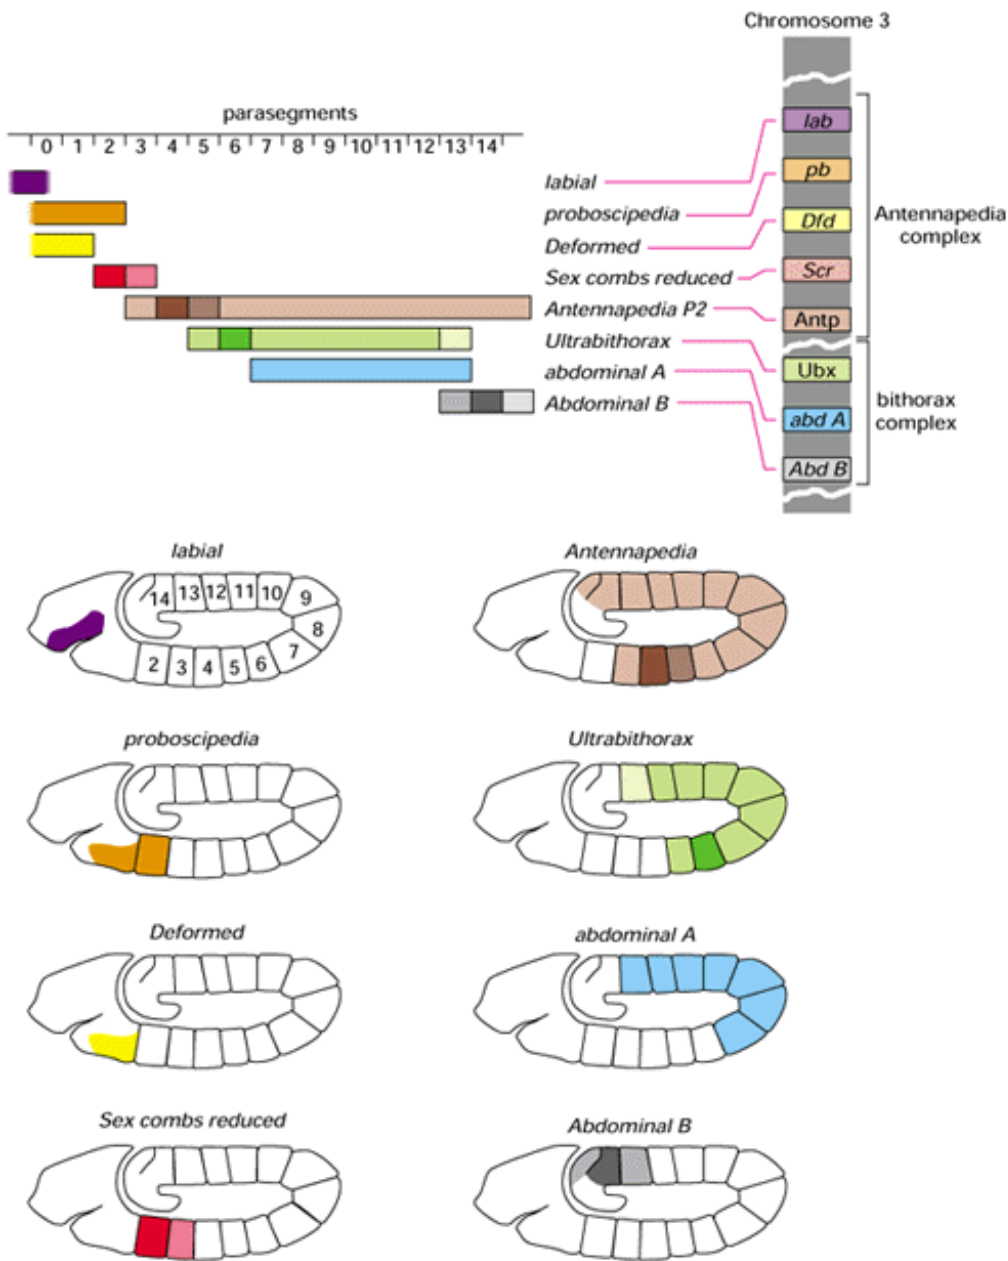
Figure 21-67. A homeotic mutation. The fly shown here is an *Antenna-pedia* mutant. Its antennae are converted into leg structures by a mutation in the *Antennapedia* gene that causes it to be expressed in the head. Compare with the normal fly shown in Figure 21-47. (Courtesy of Matthew Scott.)
Figure 21-68. The effect of deleting most of the genes of the bithorax complex. (A) A normal *Drosophila* larva shown in dark-field illumination; (B) the mutant larva with the bithorax complex largely deleted. In the mutant the parasegments posterior to P5 all have the appearance of P5. (Courtesy of Gary Struhl; A, from *Nature* 293:36-41. © 1981 Macmillan Journals Ltd.)


Figure 21-69. The patterns of expression compared to the chromosomal locations of the genes of the HOM complex. The sequence of genes in each of the two subdivisions of the chromosomal complex corresponds to the spatial sequence in which the genes are expressed. Note that most of the genes are expressed at a high level throughout one parasegment (*dark color*) and at a lower level in some adjacent parasegments (*medium color* where the presence of the transcripts is necessary for a normal phenotype, *light color* where it is not). In regions where the expression domains overlap, it is usually the most "posterior" of the locally active genes that determines the local phenotype. The drawings in the lower part of the figure represent the gene expression patterns in embryos at the extended germ band stage, about 5 hours after fertilization.
Figure 21-70. Action of genes of the Polycomb group. (A) Photograph of a mutant embryo defective for the gene *extra sex combs (esc)* and derived from a mother also lacking this gene. The gene belongs to the Polycomb group. Essentially all segments have been transformed to resemble the most posterior abdominal segment (compare with Figure 21-68). In the mutant the pattern of expression of the homeotic selector genes, which is roughly normal initially, is unstable in such a way that all these genes soon become switched on all along the body axis. (B) The normal pattern of binding of Polycomb protein to *Drosophila* giant chromosomes, visualized with an antibody against Polycomb. The protein is bound to the Antennapedia complex (ANT-C) and the bithorax complex (BX-C) as well as about 60 other sites. (A, from G. Struhl, *Nature* 293:36-41, 1981. ©1981 Macmillan Journals Ltd.; B, courtesy of B. Zink and R. Paro, from R. Paro, *Trends Genet.* 6:416-421, 1990.)

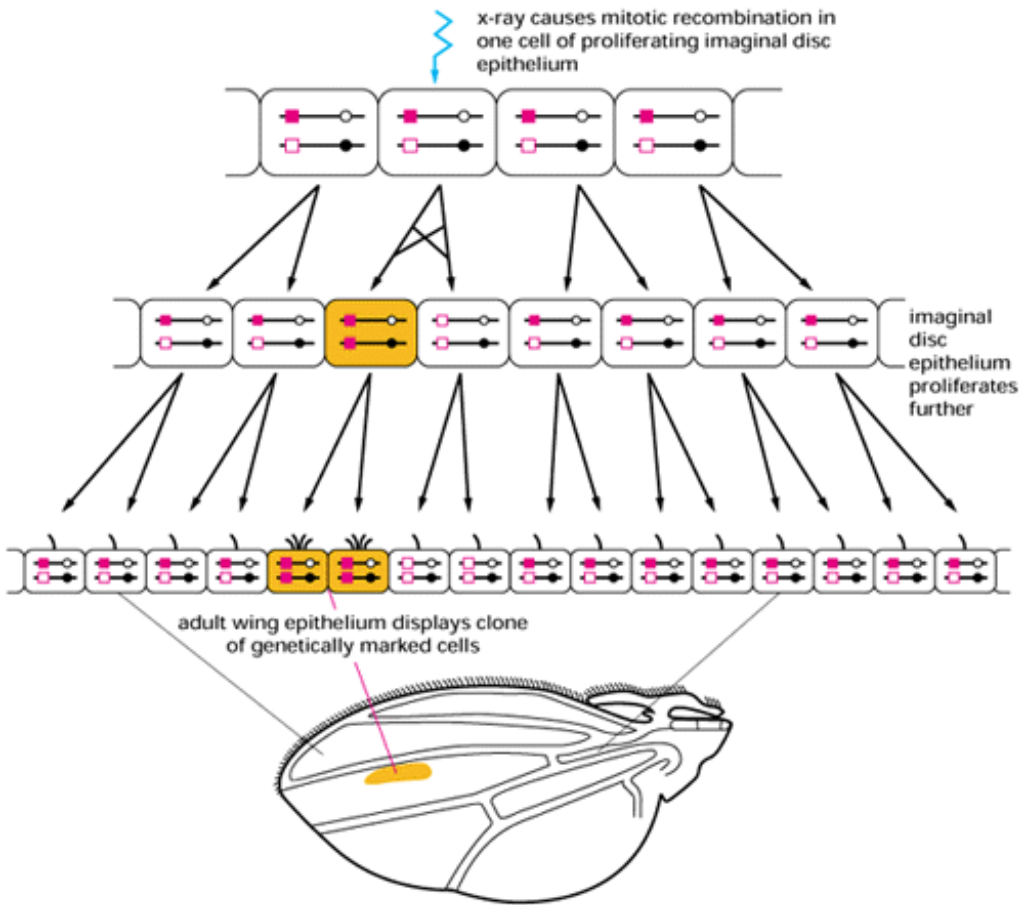
Figure 21-72. Experiments to test the state of determination of imaginal disc cells. The method of assay is to implant the cells in a larva that is about to undergo metamorphosis; the cells then differentiate to form recognizable adult structures, which lie, however, inside the body of the host fly after metamorphosis and are not integrated with it. The disc cells can either be assayed immediately or be implanted in the abdomen of adult flies, which serve as a natural culture chamber. Hormonal conditions in the adult allow the imaginal disc cells that have thus bypassed metamorphosis to continue to proliferate for an indefinite period, without differentiating, before the assay for cell determination is done. In both cases the cells generally differentiate to form the structures appropriate to the disc from which they derived originally.
Figure 21-73. Mitotic recombination (B) compared with normal mitosis (A). The diagrams follow the fate of a single pair of homologous chromosomes, one from the father (*shaded*), the other from the mother (*unshaded*). These chromosomes contain a locus for a pigmentation gene (or other marker gene) with a wild-type allele *A* (small *white square* on paternal chromosome) and a recessive mutant allele *a* (small *red square* on maternal chromosome) such that a homozygous *A/A* or heterozygous *A/a* cell has a normal appearance (shown as *white*) and a homozygous *a/a* cell has an altered appearance (shown as *orange*). Recombination by exchange of DNA between the maternal and paternal chromosomes can give rise to a pair of daughter cells, one homozygous *A/A* and therefore still normal in appearance, the other homozygous *a/a* and therefore visibly different. Mitotic recombination is a rare accidental event and occurs without the specialized apparatus that facilitates recombination during meiosis. A pulse of x-irradiation causes it to occur more frequently.


Figure 21-74. How mitotic recombination is used to produce a clone of genetically marked mutant cells in the *Drosophila* wing. The earlier the stage at which recombination occurs, the larger the eventual clone will be.
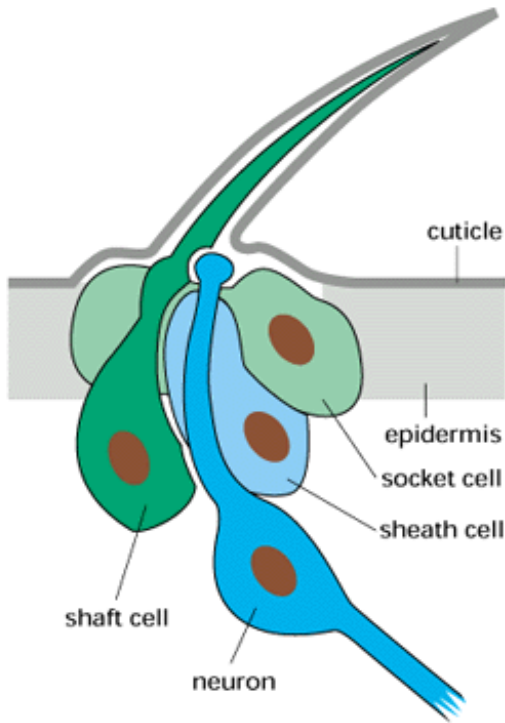
Figure 21-75. Compartments. (A) The shapes of marked clones in the *Drosophila* wing reveal the existence of a compartment boundary. The border of each marked clone is straight where it abuts the boundary. Even when a marked clone has been genetically altered so that it grows more rapidly than the rest of the wing and is therefore very large, it respects the boundary in the same way (*last drawing*). Note that the compartment boundary does not coincide with the central wing vein. (B) The pattern of expression of the *engrailed* gene in the wing, revealed by the same technique as in Figure 21-66. The compartment boundary coincides with the boundary of *engrailed* gene expression. (A, after F.H.C. Crick and P.A. Lawrence, *Science* 189:340-347, 1975. ©1975 the AAAS; B, courtesy of Cory Hama and Tom Kornberg.)


Figure 21-76. The basic structure of a mechanosensory bristle. The four cells of the bristle are shown diagrammatically.
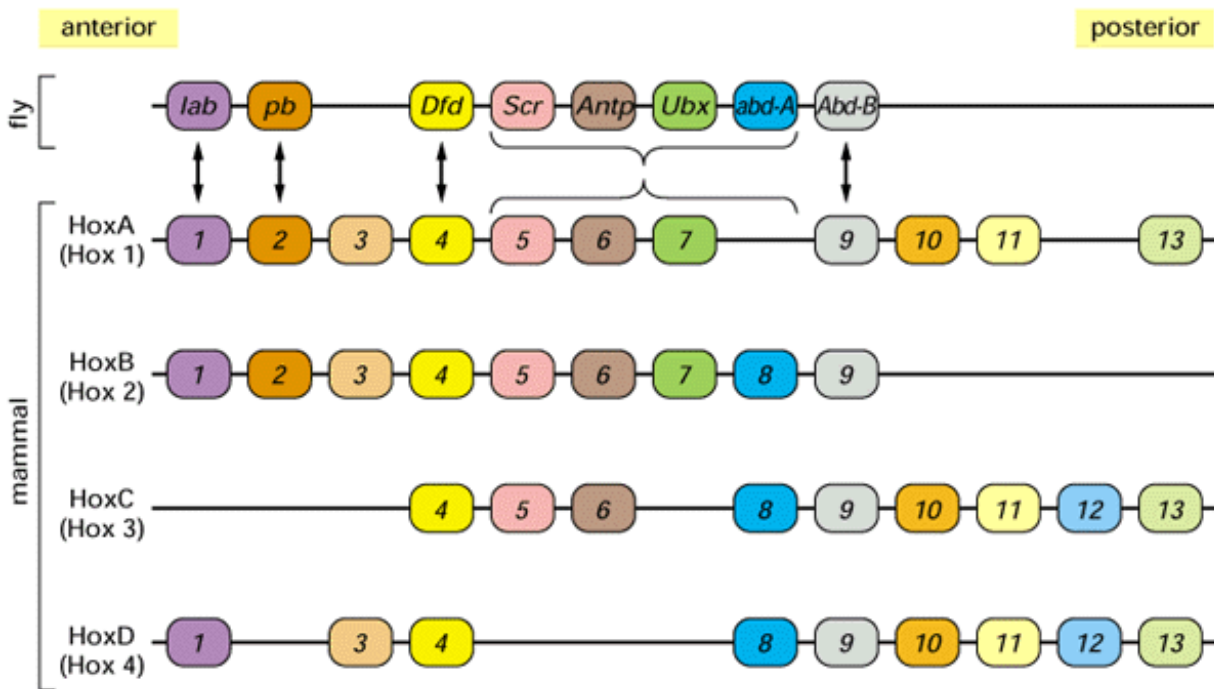
Figure 21-77. Sensory mother cells in the wing imaginal disc. The sensory mother cells (*bluish* here) are easily revealed in this special strain of *Drosophila,* which contains an artificial *lacZ* reporter gene that, by chance, has inserted itself in the genome next to a control region that causes it to be expressed selectively in sensory mother cells. Animals such as this provide a way to detect and track down specific control regions in the genome - the so-called *enhancer-trap*technique. The *purple* stain shows the expression pattern of the *scute* gene; this foreshadows the production of sensory mother cells and fades as the sensory mother cells successively develop. (From P. Cubas, J.-F. de Celis, S. Campuzano, and J. Modolell, *Genes Dev.* 5:996-1008, 1991.)
Figure 21-78. Lateral inhibition. At first, all cells in the patch are equivalent; each one has a tendency to differentiate as a sensory mother cell, and each sends an inhibitory signal to its neighbors to discourage them from differentiating in that way. This creates a competitive situation. As soon as an individual cell gains any advantage in the competition, that advantage becomes magnified. The winning cell, as it becomes more strongly committed to differentiating as a sensory mother, also inhibits its neighbors more strongly, and they, conversely, as they lose their capacity to differentiate as sensory mothers, also lose their capacity to inhibit other cells from doing so. Lateral inhibition thus makes adjacent cells follow different fates; it is the opposite of the community effect discussed on page 1063.
Figure 21-79. The result of switching off lateral inhibition. The photograph shows part of the thorax of a fly containing a mutant patch (created by x-ray-induced mitotic recombination) in which the neurogenic gene *Delta* has been partially inactivated. The reduction of lateral inhibition has caused almost all the cells in the mutant patch (*in the center of the picture*) to develop as sensory mother cells, producing a great excess of sensory bristles there. Mutant patches of cells carrying more extreme mutations, causing a total loss of lateral inhibition, form no visible bristles because all of the progeny of the sensory mother cells develop as neurons instead of diversifying to form both neurons and the external parts of the bristle structure. (Courtesy of Patricia Simpson.)


Figure 21-80. The HOM complex of an insect and the Hox complexes of a mammal compared. The genes of the Antennapedia and bithorax complexes of *Drosophila* are shown in their chromosomal order in the top line; the corresponding genes of the four mammalian (mouse or human) Hox complexes are shown below, also in chromosomal order. Genes with the most anterior expression domains are to the left, those with the most posterior expression domains to the right. The five complexes are aligned so that genes with the most closely corresponding sequences lie in the same column. The complexes are thought to have evolved as follows: first, in some common ancestor of worms, flies, and vertebrates, a single primordial homeotic selector gene underwent repeated duplication to form a series of such genes in tandema HOM complex. In the *Drosophila* sublineage this single complex became split into separate Antennapedia and bithorax complexes. Meanwhile, in the lineage leading to the mammals the whole complex was repeatedly duplicated to give the four Hox complexes. Thus *labial (lab)* in *Drosophila* is identifiable by its sequence as the counterpart of *Hoxa-1, Hoxb-1,* and *Hoxd-1; proboscipedia (pb)* is the counterpart of *Hoxa-2* and *Hoxb-2;* and so on. The parallelism is not perfect because apparently some individual genes have been duplicated and others lost since the complexes diverged. (Based on M.P. Scott, *Cell* 71:551-553, 1992. © Cell Press.)
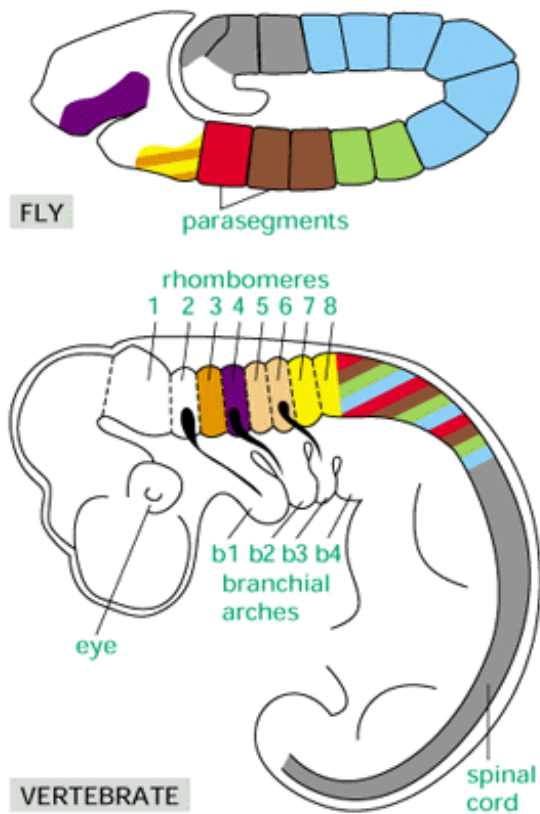
Figure 21-81. Expression domains of Hox genes in a mouse. The photographs show whole embryos displaying the expression domains of genes of the HoxB complex (*blue* stain). The expression domains can be revealed by *in situ* hybridization or, as in these examples, by constructing transgenic mice containing the control sequence of a Hox gene coupled to the coding sequence of b-galactosidase, whose presence is detected histochemically. Each gene is expressed in a long expanse of tissue with a sharply defined anterior limit. The earlier the position of the gene in its chromosomal complex, the more anterior the anatomical limit of its expression. Thus, with minor exceptions, the anatomical domains of the successive genes form a nested set, ordered according to the ordering of the genes in the chromosomal complex. (Courtesy of Robb Krumlauf.)


Figure 21-82. Correspondences between insect and vertebrate body regions as defined by HOM/Hox gene expression. A *Drosophila* embryo is shown at the extended germ band stage, with its parasegments colored according to the HOM genes that they express. The color code is as in Figure 21-80, and the same color code is used for the pattern of HoxB gene expression in the neural tube of a vertebrate embryo. For simplicity, the expression in other tissues of the vertebrate is not shown. Both in the fly and in the vertebrate, in regions where the expression domains of two or more HOM/Hox genes overlap, the coloring corresponds to the most "posterior" of the genes expressed. Where several genes have the same boundary to their expression domain, their common territory is shown striped. Note that just as the expression domains in the fly are related to parasegments, so the expression domains in the vertebrate are related to the rhombomeres (segments in the hindbrain). Each pair of rhombomeres is associated with a branchial arch (a modified gill rudiment), to which it sends innervation. The pattern of Hox gene expression in the branchial arches (not shown) matches that in the associated rhombomeres.
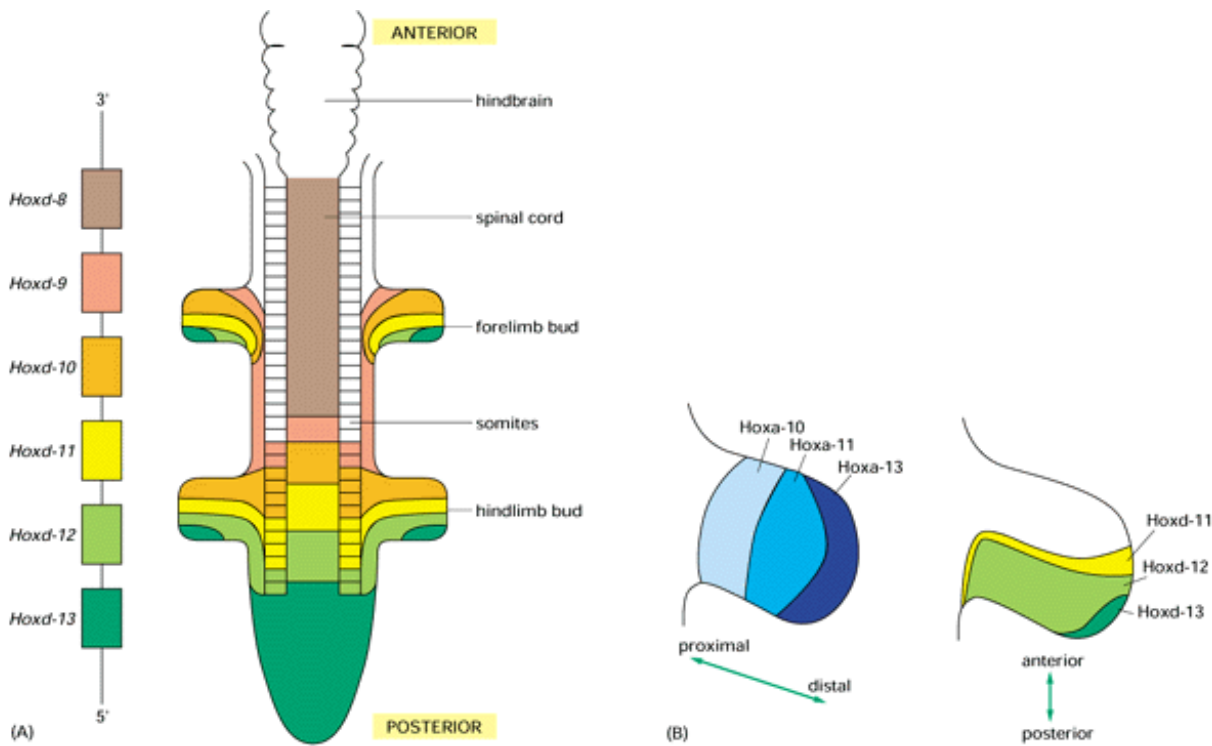

Figure 21-83. Hox gene expression patterns in vertebrate limb buds. In (A) the pattern of expression of the posteriorly expressed members of the HoxD complex in a 12 1/2-day mouse embryo is shown schematically. In (B) the expression patterns of chicken HoxD (ChoxD) and chicken HoxA (ChoxA) genes in the forelimb bud of a 4-day chick embryo are compared. The HoxD genes, in both chick and mouse, mark out an anteroposterior pattern of domains; the HoxA genes mark out a proximodistal pattern. (A, after D. Duboule, *BioEssays* 14:375-384, 1992. ©ICSU Press; B, after Y. Yokouchi, H. Sasaki, and A. Kuroiwa, *Nature* 353:443-445, 1991. © 1991 Macmillan Magazines Ltd.)

Plant Development 69

Introduction

Plants and animals are separated by about a billion years of evolutionary history. They have evolved their multicellular organization independently but using the same initial tool kit - the set of genes inherited from their common unicellular eucaryotic ancestor. Most of the contrasts in their developmental strategies spring from two basic peculiarities of plants. First, they get their energy from sunlight, not by ingesting other organisms. This dictates a different body plan. Second, their cells are encased in semirigid cell walls that are cemented together, preventing them from moving as animal cells do. This dictates a different set of mechanisms for shaping the body and different developmental mechanisms to cope with a changeable environment.

Animal development is largely buffered against environmental changes, and the embryo generates the same genetically determined body structure unaffected by external conditions. The development of most plants, by contrast, is dramatically influenced by the environment: because they cannot match themselves to their environment by moving to another place, plants adapt instead by altering the course of their development. Their strategy is opportunistic. A given type of organ - a leaf, a flower, or a root, say - can be produced from the fertilized egg by many different paths according to environmental cues. A begonia leaf pegged to the ground may sprout a root; the root may throw up a shoot; the shoot, given sunlight, may grow leaves and flowers.

The mature plant is typically made of many copies of a small set of standardized *modules,* as described in Figure 21-84. The positions and times at which those modules are generated are strongly influenced by the environment, causing the overall structure of the plant to vary. The choices between alternative modules and their organization into a whole plant depend on external cues and long-range hormonal signals that play a much smaller part in the control of animal development.

But although the global structure of a plant - its pattern of roots or branches, its numbers of leaves or flowers - can be highly variable, its detailed organization on a small scale is not. A leaf, a flower, or indeed an early plant embryo, is as precisely structured as any organ of an animal. The internal organization of a plant module raises essentially the same problems in the genetic control of pattern formation as does animal development, and they are solved in analogous ways. In this section we focus on the cellular mechanisms of development in flowering plants. We examine both the contrasts and the similarities with animals.

Embryonic Development Starts by Establishing a Root-Shoot Axis and Then Halts Inside the Seed 70

Flowering plants, despite their staggering variety, are of relatively recent origin. The earliest known fossil examples are 125 million years old, as against 350 million years for vertebrate animals. This helps to explain why certain features of their form and development are remarkably constant. Their basic strategy of sexual reproduction is briefly summarized in Panel 21-2, page 1109. The fertilized egg, or *zygote,* of a higher plant begins by dividing asymmetrically to establish the polarity of the future embryo. One product of this division is a small cell with dense cytoplasm, which will become the embryo proper. The other is a large vacuolated cell that divides further and forms a structure called the *suspensor,* which in some ways is comparable to the umbilical cord in mammals. The suspensor attaches the embryo to the adjacent nutritive tissue and provides a pathway for the transport of nutrients.

During the next step in development the diploid embryo cell proliferates to form a ball of cells that quickly acquires a polarized structure. This comprises two key groups of proliferating cells - one at the suspensor end of the embryo that will generate a *root*and one at the opposite pole that will generate a *shoot* (Figure 21-85). The main root-shoot axis established in this way is analogous to the head-to-tail axis of an animal. At the same time it begins to be possible to distinguish the future *epidermal cells,* forming the outermost layer of the embryo, the future *ground tissue cells,* occupying most of the interior, and the future *vascular tissue cells,* forming the central core. These three sets of cells can be compared to the three germ layers of an animal embryo. Slightly later in development, the rudiment of the shoot begins to produce the embryonic seed leaves, or *cotyledons* - one in the case of monocots and two in the case of dicots. Soon after this stage, development usually halts and the embryo becomes packaged in a *seed,* specialized for dispersal and for survival in harsh conditions. The embryo in a seed is stabilized by dehydration, and it can remain dormant for a very long time - even hundreds of years. When rehydrated, the seeds germinate and embryonic development resumes.

The Repetitive Modules of a Plant Are Generated Sequentially by Meristems 71

Roughly speaking, the embryo of an insect or a vertebrate animal is a rudimentary miniature scale model of the later organism, and the details of body structure are filled in progressively as it enlarges. The plant embryo grows into an adult in a quite different way: the parts of the adult plant are created sequentially by groups of cells that proliferate to lay down additional structures at the plant's periphery. These all-important groups of cells are called apical meristems (see Figure 21-84). Each meristem consists of a self-renewing population of stem cells. As these divide, they leave behind a trail of progeny that emerge from the meristem region, enlarge, and finally differentiate. Although the shoot and root apical meristems generate all the basic varieties of cells that are needed to build leaves, roots, and stems, many cells outside the apical meristems also retain a capacity for further proliferation. In this way trees and other perennial plants, for example, are able to increase the girth of their stems and roots as the years go by.

The rudiments of the apical meristems of root and shoot are already determined in the embryo. As soon as the seed coat ruptures during germination, a dramatic enlargement of nonmeristematic cells occurs, driving the emergence first of a root, to establish an immediate foothold in the soil, and then of a shoot (Figure 21-86). This is followed by rapid and continual cell divisions in the apical meristems: in the apical meristem of a maize root, for example, cells divide every 12 hours, producing 5×10^5 cells per day. The rapidly growing roots and shoots probe the environment - the roots increasing the plant's capacity for taking up water and minerals from the soil, the shoots increasing its capacity for photosynthesis (see Panel 21-2, p. 1109).

The Shaping of Each New Structure Depends on Oriented Cell Division and Expansion 72

Plant cells, imprisoned within their cell walls, cannot crawl about and cannot be shuffled as the plant grows, but they can divide, and they can swell, stretch, and bend. The morphogenesis of a developing plant therefore depends on orderly cell divisions followed by strictly oriented cell expansion. Most cells produced in the root-tip meristem, for example, go through three distinct phases of development - division, growth (elongation), and differentiation. These three steps, which overlap in both space and time, give rise to the characteristic architecture of a root tip. Although the process of cell differentiation often begins while a cell

is still enlarging, it is comparatively easy to distinguish in a root tip a zone of cell division, a zone of oriented cell elongation (which accounts for the growth in length of the root), and a zone of cell differentiation (Figure 21-87).

Because it affects the direction of cell elongation, the exact plane in which cells divide is crucial to plant morphogenesis, and changes in the plane of division are often associated with morphogenetic events such as the production of a leaf or petal primordium (Figure 21-88). The special intracellular mechanisms controlling the plane of cell division in plants are discussed in Chapter 18.

In the phase of controlled expansion that generally follows cell division, the daughter cells may often increase in volume by a factor of 50 or more. This expansion is driven by an osmotically based turgor pressure that presses outward on the plant cell wall, and its direction is determined by the orientation of the cellulose fibrils in the cell wall, which constrain expansion along one axis (see Figure 19-68). The orientation of the cellulose in turn is apparently controlled by the orientation of arrays of microtubules just inside the plasma membrane, which are thought to guide cellulose deposition (discussed in Chapter 19). These orientations can be rapidly changed by plant growth regulators, such as *ethylene* and *gibberellic acid* (Figure 21-89), but the molecular mechanisms underlying these dramatic cytoskeletal rearrangements are still unknown.

Each Plant Module Grows from a Microscopic Set of Primordia in a Meristem 73

The apical meristems are self-perpetuating: they carry on with their functions indefinitely, as long as the plant survives, and they are responsible for its continuous growth and development. But apical meristems also give rise to a second type of outgrowth, whose development is strictly limited and culminates in the formation of a structure such as a leaf or a flower, with a determinate size and shape and a short lifespan. Thus, as a vegetative shoot elongates, its apical meristem lays down behind itself an orderly sequence of *nodes,* where leaves have grown out, and *internodes* (segments of stem). In this way the continuous activity of the meristem produces an ever increasing number of similar modules, each consisting of a stem, a leaf, and a bud (see Figure 21-84). The modules are connected to one another by supportive and transport tissue, and successive modules are precisely located relative to each other, giving rise to a repetitively patterned structure. This iterative mode of development is characteristic of plants and is seen in many other structures besides the stem-leaf system (Figure 21-90).

Although the final module is large, its organization, like that of an animal embryo, is mapped out at first on a microscopic scale. At the apex of the shoot, within a space of a millimeter or less, one finds a small, low central dome surrounded by a set of distinctive swellings in various stages of enlargement (Figure 21-91). The central dome is the apical meristem itself; each of the surrounding swellings is the primordium of a leaf. This small region, therefore, contains the already distinct rudiments of several entire modules. Through a well-defined program of cell proliferation and cell enlargement, each leaf primordium and its adjacent cells will grow to form a leaf, a node, and an internode. Meanwhile, the apical meristem itself will give rise to new leaf primordia, so as to generate more and more modules in a potentially unending succession. The serial organization of the modules of the plant is thus controlled by events at the shoot apex. Local signals within this tiny region determine the pattern of primordia - the position of one leaf rudiment relative to the next, the spacing between them, and their location relative to the apical meristem itself.

Almost nothing is known of the mechanisms that mediate these central patterning processes in the plant kingdom. All the strategies that we discussed for animal pattern formation, such as those based on local morphogens, timing mechanisms, and lateral inhibition, are possibilities here too. Detailed studies of the fate and lineage of cells in the shoot apex and the root apex are beginning to provide some of the essential background information, however, and some of the key developmental control genes are beginning to be identified. The gene regulatory protein encoded by the gene *Knotted,*for example, is expressed in the central part of the meristem, and overexpression in tobacco causes leaf cells to behave as meristem, generating new organs from the leaf itself.

Long-range Hormonal Signals Coordinate Developmental Events in Separate Parts of the Plant 74

If a stem is to branch, new meristems must be created, and it is through control of this process that the environment exerts an important part of its influence over the form of a plant. At each node, in the acute angle, or *axil,* between the leaf branch and the stem, a bud is formed. This contains a nest of cells, derived from the apical meristem, that have kept a meristematic character (and express *Knotted*). They have the capacity to become the apical meristem of a new branch, but they also have the alternative option of remaining quiescent. The plant's pattern of branching is regulated through this choice, which the environment helps to dictate. Separate parts of the plant experience different environments and react to them individually by changes in their mode of development. The plant, however, must continue to function as a whole. This demands that developmental choices and events in

one part of the plant should affect developmental choices elsewhere. There must be long-range signals to bring about such coordination.

As gardeners know, for example, by pinching off the tip of a branch one can stimulate side growth: removal of the apical meristem relieves the quiescent axillary meristems of an inhibition and allows them to form new twigs. In this case the long-range signal from the apical meristem, or at least a key component of the system of signals, has been identified. It is an *auxin,* a member of one of five known classes of plant growth regulators (sometimes called *plant hormones*), all of which have powerful influences on plant development. The four other known classes are the gibberellins, the cytokinins, abscisic acid, and the gas ethylene. As shown in Figure 21-92, all are small molecules that readily penetrate cell walls. They are all synthesized by most plant cells and can either act locally or be transported to influence target cells at a distance. Auxin, for example, is transported from cell to cell at a rate of about 1 cm per hour from the tip of a shoot toward its base. Each growth regulator has multiple effects, and these are modulated by the other growth regulators as well as by environmental cues and nutritional status. Thus auxin alone can promote root formation, but in conjunction with gibberellin it can promote stem elongation, with cytokinin it can suppress lateral shoot outgrowth, and with ethylene it can stimulate lateral root growth. The receptors that recognize these growth regulators are only now being characterized, and their mechanisms of action remain unknown.

Arabidopsis Serves as a Model Organism for Plant Molecular Genetics 75

By screening systematically for mutations affecting the pattern of the plant embryo, it has been possible to begin to identify the genes that govern plant development and to start to work out how they function. This approach requires a plant that is, like *Drosophila* or *Caenorhabditis elegans,* small, quick to reproduce, and convenient for genetics. The role of "model plant" has fallen on a small weed, the common wall cress *Arabidopsis thaliana* (Figure 21-93), which can be grown indoors in test tubes in large numbers and produces thousands of offspring per plant after 8 to 10 weeks. *Arabidopsis* also has the advantage for molecular analysis of having one of the smallest plant genomes known (7×10^7 nucleotide pairs), comparable to yeast (2×10^7 nucleotide pairs), *C. elegans* (10^8 nucleotide pairs), and *Drosophila* (10^8 nucleotide pairs). Cell culture and genetic transformation methods have been established, large numbers of interesting mutants have been isolated, and an ordered collection of genomic DNA clones is now available. *Arabidopsis* has, in common with *C. elegans,* one significant advantage over *Drosophila* for genetics: like many flowering plants, it can reproduce as a hermaphrodite because a single flower produces both eggs and the pollen that can fertilize them. Therefore, when a flower that is heterozygous for a recessive lethal mutation is self-fertilized, one-fourth of its seeds will display the homozygous embryonic phenotype (Figure 21-94).

By using mutagens to create tens of thousands of mutant plants and inspecting their progeny in this way, a total of about 50 distinct genes governing embryonic pattern formation in *Arabidopsis* have thus far been identified. As in *Drosophila,* the patterning genes can be grouped according to their homozygous mutant phenotypes (Figure 21-95). Some are required for formation of the seedling root, some for the seedling stem, and some for the seedling apex with its cotyledons. Another class is required for formation of the three major tissue types - epidermis, ground tissue, and vascular tissue - and yet another class for the organized changes of cell shape that give the embryo and seedling their elongated form. Given this catalogue of key genes, it should soon be possible to take the next step and discover how they function. But from the range of mutant phenotypes, it already seems likely that the initial patterning of the plant embryo will be largely explicable within the same conceptual framework that we have presented for animals. As we now see, the same can be said for the later developmental processes by which a flower is made.

Homeotic Selector Genes Specify the Parts of a Flower 76

Meristems face other developmental choices besides that between quiescence and growth, and these also are frequently regulated by the environment. The most important is the decision to form a flower (Figure 21-96).

The switch from meristematic growth to flower formation is typically triggered by light. By poorly understood mechanisms based on light absorption by specific proteins known as *phytochromes,* the cells in the meristem are able to alter their pattern of gene expression in response to a change in day length and thereby undergo the change of state that initiates flower development. By this switch in its state the apical meristem abandons its chances of continuing vegetative growth and gambles its future on the production of gametes. Its cells embark on a strictly finite program of growth and differentiation: by a modification of the ordinary mechanisms for generating leaves, a series of whorls of specialized appendages are formed in a precise order - typically sepals first, then petals, then stamens carrying anthers containing pollen, and lastly carpels containing eggs (see Panel 21-2, p. 1109). By the end of this process the meristem has disappeared, but among its progeny it has created germ cells.

The series of modified leaves forming a flower can be compared to the series of body segments forming a fly. In plants, as in flies, one can find homeotic mutations that convert one part of the pattern to the character of another. The mutant phenotypes can be grouped into three classes (Figure 21-97) in which different but overlapping sets of organs are altered. The first class, exemplified by the *apetala2* mutant of *Arabidopsis,* has its two outermost whorls transformed: the sepals are converted into carpels and the petals into stamens. The second class, exemplified by *apetala3,* has its two middle whorls transformed: the petals are converted into sepals and the stamens into carpels. The third class, exemplified by *agamous,* has its two innermost whorls transformed, with a more drastic consequence: the stamens are converted into petals, the carpels are missing, and in their place the central cells of the flower behave as a floral meristem, which begins the developmental performance all over again, generating another abnormal set of sepals and petals nested inside the first and, potentially, another nested inside that, and so on, indefinitely. These phenotypes identify three classes of homeotic selector genes, which, like the homeotic selector genes of *Drosophila,* all code for gene regulatory proteins. These define the differences of cell state that give the different parts of a normal flower their different characters. *In situ* hybridization confirms that the genes are expressed in the patterns expected on this interpretation (Figure 21-98). In a triple mutant where all three genetic functions are absent, one obtains in place of a flower an indefinite succession of tightly nested leaves. Leaves therefore represent a "ground state" in which none of these homeotic selector genes are expressed, while the other types of organ result from expressing the genes in different combinations.

Similar studies have been carried out in the snapdragon *Antirrhinum majus,* and a similar set of phenotypes and genes have been identified. Gene sequencing reveals that, despite the large evolutionary distance between *Antirrhinum* and *Arabidopsis,* the corresponding homeotic phenotypes arise from mutations in homologous genes: plants, no less than animals, have conserved their homeotic selector gene systems. Again, the set of these genes appears to have arisen through gene duplication: several of them, required in different organs of the flower, have clearly homologous sequences. These are not of the homeobox class but are related to another family of gene regulatory proteins (the so-called MADS family) found in yeast and in vertebrates.

Investigation of the molecular genetics of plant development has only just begun. So far, almost nothing is known, for example, about the genetic systems responsible for local cell-cell communication and positional signaling in plant pattern formation. Yet it is clear already that plants and animals, despite their differences, have independently found very similar solutions to many of the fundamental problems of multicellular development.

Summary

The development of a flowering plant, like that of an animal, begins with division of a fertilized egg to form an embryo with a polarized organization: the apical part of the embryo will form the shoot, the basal part, the root, and the middle part, the stem. At first, cell division occurs throughout the body of the embryo. As the embryo grows, however, addition of new cells becomes restricted to small regions known as meristems. Apical meristems, at shoot tips and root tips, will persist throughout the life of the plant, enabling it to grow by sequentially adding new body parts at its periphery. Typically, the shoot generates a repetitive series of modules, each consisting of a segment of stem, a leaf, and an axillary bud. An axillary bud is a potential new meristem, capable of giving rise to a side branch, and the environment can control the development of the plant by regulating bud activation. Environmental cues can also cause the apical meristem to switch from a leaf-forming to a flower-forming mode. Long-range signaling mediated by plant hormones coordinates such developmental events occurring in separate parts of the plant.

The internal organization of each plant module, however, is controlled through strictly local pattern formation mechanisms analogous to those that govern animal development. These operate in the neighborhood of the apical meristem, where the relative positions of the rudiments of leaves and other organs are initially mapped out on a microscopic scale. The pattern of modified leaves - sepals, petals, stamens, and carpels - in a flower is set up similarly. The genetic basis of pattern formation in plants can be analyzed in the same way as in animals. The small weed Arabidopsis thaliana is widely used as a "model plant" for such studies. Genes governing the organization of the embryo, analogous to the egg-polarity and segmentation genes of Drosophila, can be identified. And the sequence of parts in a flower is controlled by homeotic selector genes closely analogous (although not homologous) to those of animals.
Figure 21-84. A simple example of the modular construction of plants. Each module (shown in different shades of *green*) consists of a stem, a leaf, and a bud containing a potential growth center, or *meristem.* The bud forms at the branch point, or *node,* where the leaf diverges from the stem. Modules arise sequentially from the continu-ous activity of the apical meristem.

Panel 21-2: Features of early development in flowering plants

THE FLOWER

Flowers, which contain the reproductive cells of higher plants, arise from vegetative shoot apical meristems (see Figures 21–84 and 21–88). They terminate further vegetative growth from that meristem. Environmental factors, often the rhythms of day length and temperature, trigger the switch from vegetative to floral development. The germ cells thus arise late in plant development from somatic cells rather than from a germ cell line, as in animals.

young flower bud

mature flower

Flower structure is both varied and species-specific but generally comprises four concentrically arranged sets of structures that may each be regarded as modified leaves.
Petal: distinctive leaflike structures, usually brightly colored, facilitate pollination via, for example, attracted insects.

Stamen: an organ containing cells that undergo meiosis and form haploid pollen grains, each of which contains two male sperm cells. Pollen transferred to a stigma germinates, and the pollen tube delivers the two nonmotile sperm to the ovary.

pollen grain
sperm cells
pollen tube nucleus

Carpel: an organ containing one or more ovaries, each of which contains ovules. Each ovule houses cells that undergo meiosis and form an embryo sac containing the female egg cell. At fertilization, one sperm cell fuses with the egg cell and will form the future diploid embryo, while the other fuses with two cells in the embryo sac to form the triploid endosperm tissue.

Sepals: leaflike structures that form a protective covering during early flower development.

THE SEED

A seed contains a dormant embryo, a food store, and a seed coat. At the end of its development a seed's water content can drop from 90% to 5%. The seed is usually protected in a *fruit* whose tissues are of maternal origin.

THE EMBRYO

shoot apical meristem
fertilized egg

The fertilized egg within the ovule will grow to form an embryo using nutrients transported from the endosperm by the suspensor. A complex series of cell divisions, illustrated here for the common weed called shepherd's purse, produces an embryo with a root apical meristem, a shoot apical meristem, and either one (monocots) or two (dicots) seed leaves, or cotyledons.

Development is arrested at this stage, and the ovule, containing the embryo, now becomes a seed, adapted for dispersal and survival.

root apical meristem
suspensor
two seed leaves (cotyledons)
GERMINATION

For the embryo to resume its growth the seed must germinate, a process dependent upon both internal factors (dormancy) and environmental factors including water, temperature, and oxygen. The food reserves for the early phase of germination may either be the endosperm (maize) or the cotyledons (pea and bean).

The primary root usually emerges first from the seed to ensure an early water supply for the seedling. The cotyledon(s) may appear above the ground, as in the garden bean shown here, or they may remain in the soil, as in peas. In both cases the cotyledons eventually wither away.

The apical meristem can now show its capacity for continuous growth, producing a typical pattern of nodes, internodes, and buds (see Figure 21–84).

New York: Worth, 1986.)
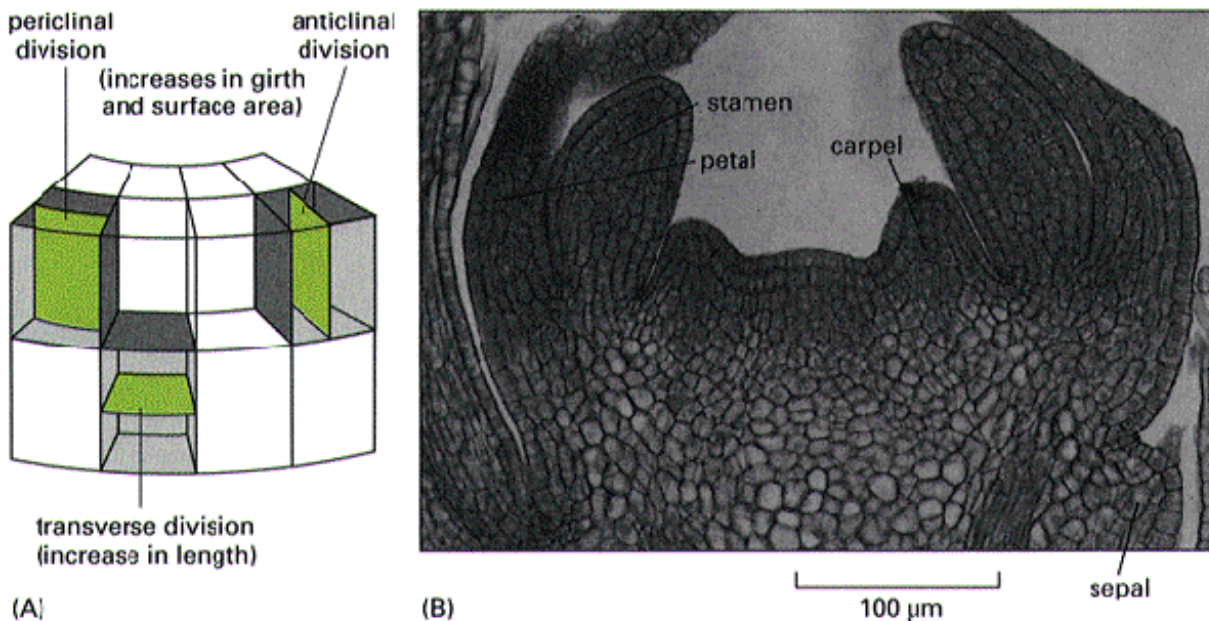

Figure 21-88. The relationship between division plane, cell expansion, and morphogenesis. (A) Three planes of cell division found in a typical plant organ. Variations in the relative proportion of each, combined with oriented cell expansion, can account for the morphogenetic patterns found in plants. (B) A longitudinal section of a young flower bud of a periwinkle. The small domes of cells destined to become the different floral parts have arisen by a combination of new planes of cell division and directional cell expansion determined by the reinforcing hoops of cellulose in the cell wall. (From N.H. Boke, *Am. J. Bot.* 36:535-547, 1949.)
Figure 21-89. The different effects of the plant growth regulators ethylene and gibberellic acid. These regulators exert rapid and opposing effects on the orientation of the cortical microtubule array in cells of young pea shoots. A typical cell in an ethylene-treated plant (B) shows a net longitudinal orientation of microtubules, while a typical cell in a gibberellic-acid-treated plant (C) shows a net transverse orientation. New cellulose microfibrils are deposited parallel to the microtubules. Since this influences the direction of cell expansion, gibberellic acid and ethylene encourage growth in opposing directions: ethylene-treated seedlings will develop short, fat shoots (A), while gibberellic-acid-treated seedlings will develop long, thin shoots (D).

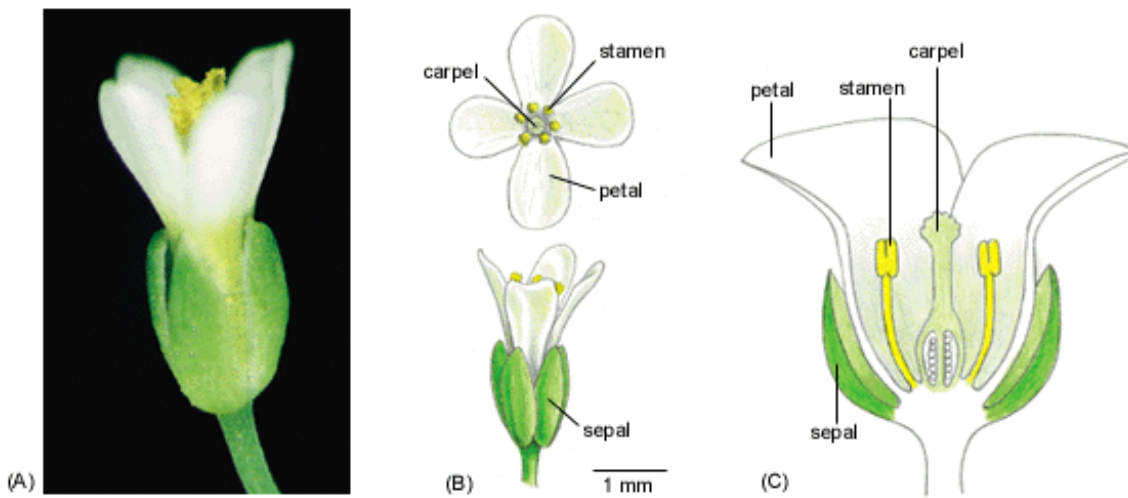
Figure 21-94. Production of mutants in *Arabidopsis*. A seed, containing a multicellular embryo, is treated with a chemical mutagen and left to grow into a plant. In general, this plant will be a mosaic of clones of cells carrying different induced mutations. An individual flower produced by this plant will usually be composed of cells belonging to the same clone, all carrying the same mutation, *m,* in heterozygous form (*m/+*). Self-fertilization of individual flowers by their own pollen results in seed pods, each of which contains a family of embryos of whose members half, on average, will be heterozygous (m/+), one quarter will be homozygous mutant (*m/ m*), and one quarter will be homozygous wild-type (+/+).
Figure 21-95. Mutant *Arabidopsis* seedlings. A normal seedling (A) compared with four types of mutant (B-E) defective in different parts of their apico-basal pattern: (B) has structures missing at its apex, (C) has an apex and a root but lacks a stem between them, (D) lacks a root, and (E) forms stem tissues but is defective at both ends. The seedlings have been "cleared" so as to show the vascular tissue inside them (pale strands). (From U. Mayer et al., *Nature* 353:402-407, 1991. © 1991 Macmillan Magazines Ltd.)


Figure 21-96. The structure of an *Arabidopsis* flower. (A) Photograph. (B) Drawings. (C) Schematic cross-sectional view. The basic plan, as shown in (C), is common to most flowering dicotyledonous plants. (A, courtesy of Leslie Sieburth.)

Figure 21-97. *Arabidopsis* flowers showing homeotic mutations. (A) In *agamous,* stamens are converted into petals and carpels into floral meristem; (B) In *apetala3,* petals are converted into sepals and stamens into carpels; (C) In *apetala2,* sepals are converted into carpels and petals into stamens. Another gene, *pistillata,* has a mutant phenotype similar to *apetala3;* thus three functional classes of homeotic selector genes can be identified. (D) In a triple mutant where these three functions are defective, all the organs of the flower are converted into leaves. (A-C, courtesy of Leslie Sieburth; D, courtesy of Mark Running.)
Figure 21-98. Homeotic selector gene expression in an *Arabidopsis* flower. (A) Diagram of the normal expression patterns of the three genes whose mutant phenotypes are illustrated in Figure 21-97. All three genes code for gene regulatory proteins. The colored shading on the flower indicates which organ develops from each whorl of the meristem, and does not imply that the homeotic selector genes are still expressed at this stage. (B) The patterns in a mutant where the *apetala3* gene is defective. Because the character of the organs in each whorl is defined by the set of homeotic selector genes that they express, the stamens and petals are converted into sepals and carpels. The consequence of a deficiency of a gene of class a, such as *apetala2,* is slightly more complex: the absence of this class a gene product allows the class c gene to be expressed in the outer two whorls as well as the inner two, causing these outer whorls to develop as carpels and stamens, respectively. Deficiency of a class c gene prevents the central region from undergoing terminal differentiation as a carpel and causes it instead to continue growth as a meristem, generating more and more sepals and petals.

Neural Development 77

Introduction

Nerve cells, or neurons, are among the most ancient of all specialized animal cell types, as important to jellyfish and sea anemones as they are to worms, flies, and people. Their structure is like that of no other class of cells, and the development of the nervous system poses problems that have no parallel in other tissues. A neuron is extraordinary above all for its enormously extended shape, with a long axon and dendrites connecting it through synapses to other cells (Figure 21-99). The central challenge of neural development is to explain how the axons and dendrites grow out, find their right partners, and synapse with them selectively to create a functional network (Figure 21-100).

Most of the components of a typical nervous system - the various classes of neurons, sensory cells, and muscles - originate in widely separate locations in the embryo and are initially unconnected. Thus, in the first phase of neural development (Figure 21-101), the different parts develop according to their own local programs, following principles of cell diversification common to other tissues of the body, as already discussed. The next phase involves a type of morphogenesis unique to the nervous system: a provisional but orderly set of connections is set up between the separate parts of the system through the outgrowth of axons and dendrites along specific routes, so that the parts can begin to interact. In the third and final phase, which continues into adult life, the connections are adjusted and refined through interactions among the far-flung components in a way that depends on the electrical signals that pass between them.

Stocks of Neurons Are Generated at the Outset of Neural Development and Are Not Subsequently Replenished 78

The nervous system develops from the ectoderm in all animals. In vertebrates, on which we concentrate here, it derives chiefly, as we saw earlier in this chapter, from two sets of cells - those of the *neural tube* (an invagination of the ectoderm) and those of the *neural crest* (a population of cells that break loose from the neural ectoderm and migrate to other regions of the embryo). The neural tube forms the central nervous system (the spinal cord and brain, including the retina of the eye), while the neural crest gives rise to most of the neurons and supporting cells of the peripheral nervous system (Figure 21-102).

The neural tube, with which we shall be mainly concerned, consists initially of a single-layered epithelium (Figure 21-103). This will generate both the neurons and the associated supporting, or glial, cells of the central nervous system. In the process it becomes transformed into a thicker and more complex structure with many layers of cells of various types.

Because differentiated neurons do not divide, each one can be assigned a "birthday," defined as the time of the final mitosis that generated it from a dividing neuronal precursor cell. In both higher vertebrates and invertebrates, the birthdays of the neurons of a given type generally all occur within a strictly limited period of development, after which no further neurons of that type are produced. Each region of the developing neural tube has its own program of cell divisions, and neurons with different birthdays are generally destined for different functions. Since neural stem cells usually do not persist once the production of nerve cells is complete, nerve cell numbers thereafter can only be regulated downward, through cell death, as we shall see.

The Time and Place of a Neuron's Birth Determine the Connections It Will Form 79

Before sending out its axon and dendrites, the immature neuron or its precursor commonly migrates from its birthplace and settles in some other location. In the central nervous system glial cells often provide a pathway for the migration. The neural

tube of a vertebrate embryo, for example, contains a scaffolding of *radial glial cells.* Each of these cells extends from the inner to the outer surface of the tube, a distance that may be as much as 2 cm in the cerebral cortex of the developing brain of a primate. Prospective neurons go through their final cell division close to the lumen of the neural tube and then travel outward by crawling along the radial glial cells (Figure 21-104).

Successive cohorts of migrant cells, born at different times, settle in different positions. In the cerebral cortex, for example, the neurons become arranged in layers according to their birthdays as a result of a migration in which the cells that are born later migrate outward past those born earlier. By transplanting cells between young and old embryos, it can be shown that these different choices of destination are already specified before the cells set off on their migration; they reflect differences in the intrinsic characters of the cells produced at different times - differences that will also dictate the synaptic connections that the cells later form. Thus, in the cerebral cortex the early-born cells (in inner layers) will send their axons to regions outside the cortex, while the late-born cells (in outer layers) will send their axons to regions within the cortex. This relationship between birthday and axonal connections is maintained even in a mutant mouse in which the migrations are abnormal and the final positions of the early- and late-born cells are inverted, confirming that the connections reflect the intrinsic character, rather than the final location, of the neurons (Figure 21-105).

No less important than the time of birth of a neuron is the place of its birth. Cells in different regions of the neural tube have different positional values that govern the connections they will form. These position-dependent differences are evident in the pattern of expression of the *Hox* genes, as we have already seen, and of a large number of other genes that code for gene regulatory proteins and other regulatory molecules. The mechanisms that create the molecular differences between prospective neurons are poorly understood, but they seem, where known, to be similar in principle to the mechanisms of pattern formation discussed earlier. The question we have to confront now, however, is a different one: how do the newborn nerve cells, equipped with their specific markers, proceed to set up an orderly pattern of connections?

Each Axon or Dendrite Extends by Means of a Growth Cone at Its Tip 77, 80

As a rule the axon and the dendrites begin to grow out from the nerve cell body soon after the cell body has reached its final location. The sequence of events was originally observed in intact embryonic tissue by the method of Golgi staining (Figure 21-106). This technique, and other methods developed subsequently, reveal an irregular, spiky enlargement at the tip of each developing nerve cell process. This structure, which is called the growth cone, appears to be crawling through the surrounding tissue. It comprises both the engine that produces the movement and the steering apparatus that directs the tip of each process along the proper path.

Much of what we know about the properties of growth cones has come from studies in tissue or cell culture. One can watch as a neuron begins to put out its processes, all at first alike, until one of the growth cones puts on a sudden turn of speed, identifying its process as the axon, with its own axon-specific set of proteins (Figure 21-107). The contrast between axon and dendrite established at this stage will cause the two types of process to grow out for different distances, to follow different paths, and to play different parts in synapse formation.

For an isolated neuron in culture the distinction between axon and dendrite is not always easy to see, and it is convenient to refer to both types of process as *neurites.* The growth cone at the end of a typical rapidly growing neurite moves forward at a speed of about 1 mm per day. It consists of a broad, flat expansion, like the palm of a hand, with many long *microspikes* or *filopodia* extending from it like fingers (Figure 21-108). These are continually active: some are retracting back into the growth cone while others are elongating, waving about, and touching down and adhering to the substratum. The "webs" or "veils" between the filopodia form *lamellipodia* with a typical ruffling membrane. All these features, as well as the configuration of the cytoskeleton internally, suggest that the growth cone is crawling forward in much the same way as the leading edge of a cell such as a neutrophil or fibroblast, as discussed in Chapter 16.

With its filopodia and lamellipodia the growth cone explores the regions that lie ahead and on either side. When such a protrusion contacts an unfavorable surface, it withdraws; when it contacts a more favorable surface, it persists longer, steering the growth cone as a whole to move in that direction. In this way the growth cone can be guided by subtle variations in the surface properties of the substrata over which it moves.

The Growth Cone Pilots the Developing Neurite Along a Precisely Defined Path *in Vivo* 81, 82, 83, 84

In living animals growth cones generally travel toward their targets along predictable routes, exploiting a multitude of different

cues to find their way. Most often, they take routes that have been pioneered by other neurites, which they follow by contact guidance. As a result, nerve fibers in a mature animal are usually found grouped together in tight parallel bundles (called *fascicles* or *fiber tracts*). Such crawling of growth cones along axons is thought to be mediated by homophilic cell-cell-adhesion molecules - membrane glycoproteins that help a cell displaying them to stick to any other cell that displays them also. As discussed in Chapter 19, two of the most important classes of such molecules are those that belong to the *immunoglobulin superfamily,* such as *N-CAM,* and those of the Ca^{2+}-dependent *cadherin* family, such as *N-cadherin.* Members of both families are generally present on the surfaces of growth cones, of axons, and of various other cell types that growth cones crawl over, including glial cells in the central nervous system and muscle cells in the periphery of the body. Growth cones also migrate over components of the extracellular matrix, especially laminin, which they bind to by means of cell-surface matrix receptors of the *integrin* family (discussed in Chapter 19).

In some cases one can demonstrate the importance of a given cell-cell or cell-matrix adhesion molecule by blocking its function with an antibody and observing a disturbance of axon outgrowth. But usually a growth cone employs several adhesion systems to migrate, and antibodies against any single one of them have little effect; only when multiple antibodies are applied, so as to block all of them together, is the growth cone severely hindered in its navigation. In principle, different combinations of adhesion molecules allow for great variety in the surface properties of growth cones and for subtle and complex pathway selection according to the combinations of molecules on the surfaces of cells along the way.

It is still uncertain how far different combinations of adhesion proteins such as N-CAM, N-cadherin, and integrins in the growth cone membrane are sufficient to explain why some growth cones take one route while others take another or how a set of axons, on reaching their target region, are able to form synapses there in an orderly array. Adhesion molecules are certainly not the only influences at work. The contacts a growth cone makes with cell surfaces and matrix can give rise to intracellular signals that can, for example, actively inhibit forward movement. Substances that diffuse through the extracellular medium can also give rise to gradients that provide guidance. In the developing spinal cord, for example, there is a group of neurons whose axons travel ventrally, toward the *floor plate* of the neural tube, to cross by that route to the other side of the tube. When these neurons are placed in culture a short distance from an explanted fragment of floor plate, their axons will again orient their outgrowth toward it, implying that the specialized cells in the floor plate secrete molecules that have a chemotactic guiding effect.

Target Tissues Release Neurotrophic Factors That Control Nerve Cell Growth and Survival 82, 85

Most types of neurons in the vertebrate central and peripheral nervous system are produced in excess; up to 50% or more of them then die soon after they reach their target, even though they appear perfectly normal and healthy up to the time of their death. About half of all the motor neurons that send axons to skeletal muscle, for example, die within a few days after making contact with their target muscle cells. This large-scale death of neurons is thought to reflect the outcome of a competition. Each type of target cell releases a limited amount of a specific neurotrophic factor that the neurons innervating that target require to survive: the neurons apparently compete to take up the factor, and those that do not get enough die by programmed cell death. This seemingly wasteful process provides a simple and elegant means of adjusting the number of neurons of each type to the number of target cells that they innervate.

The first neurotrophic factor to be identified, and still the best characterized, is known simply as nerve growth factor, or NGF. It was discovered by accident in the course of experiments in which foreign tissues and tumors were transplanted into chick embryos. Transplants of one particular tumor became exceptionally densely innervated and caused a striking enlargement of certain groups of peripheral neurons in the vicinity of the graft. Just two classes of neurons were affected: *sensory neurons* and *sympathetic neurons* (a subclass of peripheral neurons that control contractions of smooth muscle and secretion from exocrine glands). The cause of this phenomenon was traced to a specific protein, NGF, and it was shown that if anti-NGF antibodies are administered to mice while the nervous system is still developing, most sympathetic neurons and some sensory neurons die. Sympathetic neurons and some sensory neurons also die in culture in the absence of NGF; if NGF is present, they survive and send out neurites (Figure 21-109). Some classes of neurons in the central nervous system are dependent on NGF in a similar way.

NGF is produced by the tissues that are innervated by NGF-dependent neurons. Experimental manipulations confirm that the larger the quantity of target tissue, the larger the number of surviving neurons, and this effect can be shown to be mediated by NGF because it can be mimicked by direct manipulation of NGF concentrations. Later in life, after the phase of cell death is over, NGF has a continuing role in regulating the density of innervation by controlling the extent of local sprouting of axon branches. This mechanism is important in restoring innervation in tissues such as skin and smooth muscle after an injury. NGF acts in the intact animal just as it does in a culture dish (see Figure 21-109), both to sustain cell survival and as a local stimulus

for growth cone activity, thus adjusting the supply of innervation according to the requirements of the target.

NGF is only one of a family of homologous neurotrophic factors (called *neurotrophins*) that are responsible for this type of regulation in different parts of the vertebrate nervous system. They bind to a complementary family of transmembrane receptor proteins (named after a proto-oncogene called *trk* that codes for one of them), which belong to the tyrosine-kinase class of receptors discussed in Chapter 15. It is hoped that the neurotrophic factors will prove useful in the treatment of neurological diseases, such as Alzheimer's disease and motor neuron disease (Lou Gehrig's disease), in which neurons degenerate and die inappropriately.

We now return to the problem of the spatial patterning of nerve connections.

The Positional Values of Neurons Guide the Formation of Orderly Neural Maps: The Doctrine of Neuronal Specificity 86

The inputs from sense organs are generally *mapped* or *projected* in an orderly way onto the sensory regions in the central nervous system, and the outputs from the motor regions of the central nervous system are mapped in an orderly way onto the muscles. Thus, similar nerve cells in different regions of the vertebrate retina send their axons to synapse with neurons in correspondingly different regions of the *optic tectum* in the midbrain (Figure 21-110), and similar motor neurons at different locations in the spinal cord send their axons to different muscles.

In principle, the growth cones could be simply channeled to different destinations as a direct consequence of their different starting positions, like drivers on a multilane highway where it is forbidden to change lanes. This possibility was tested in the visual system by a famous experiment in the 1940s. If the optic nerve of a frog is cut, it will regenerate. The retinal axons grow back to the optic tectum, restoring normal vision. If, in addition, the eye is rotated in its socket at the time of cutting of the nerve, so as to put originally ventral retinal cells in the position of dorsal retinal cells, vision is still restored, but with an awkward flaw: the animal behaves as though it sees the world upside down. This is because the misplaced retinal cells make the connections appropriate to their *original,* not their actual, positions (Figure 21-111). The cells are evidently endowed with positional values, carrying a record of their original position, so that cells on opposite sides of the retina are intrinsically different. As in the cortex of the *reeler* mouse (see Figure 21-105), it is the intrinsic character, rather than the position, that decides the choice of target site. Such nonequivalence among neurons is referred to as neuronal specificity.

Axons from Opposite Sides of the Retina Respond Differently to a Gradient of Repulsive Molecules in the Tectum 87

On reaching the tectum, the retinal axons must choose, according to their individual character, which region of tectum to innervate. Axons from the nasal retina (the side closest to the nose), for example, project to the posterior tectum, and axons from the temporal retina (the side farthest from the nose) project to the anterior tectum. This choice is governed by differences in the intrinsic characters of the cells in different parts of the tectum. Thus the neuronal map depends on a correspondence between two systems of positional markers, one in the retina and the other in the tectum.

Experiments *in vitro* with tissues from the chick embryo give some insight into the nature of the tectal markers and the way in which the retinal axons respond to them. Fragments of retina are placed in culture and allowed to send out axons over a substratum that is carpeted with membrane vesicles prepared from tectal cells (Figure 21-112). The carpet is laid out in stripes, with bands of anterior tectal membrane alternating with bands of posterior tectal membrane. Axons from nasal retina, depending on details of the preparation, either show no preference and grow indiscriminately in all of the bands or show a preference, appropriately, for posterior tectal membrane. Axons from temporal retina consistently grow only along the bands of anterior tectal membrane, in accordance with their normal destiny. Surprisingly, this is not because the anterior tectal membrane is particularly adhesive or attractive to them but because the posterior tectal membrane is particularly repellent: filopodia that touch it withdraw and collapse. In fact, the growth cones of the temporal axons (but not those of nasal axons) will collapse and retract if a suspension of posterior tectal membranes is dripped onto them. No such collapse occurs in response to anterior tectal membrane.

The peculiar effects of the posterior tectal membrane on the temporal retinal cells have been traced to a specific inhibitory glycoprotein that is distributed in a gradient from posterior to anterior in the tectum. In other parts of the nervous system other surface molecules can be shown to have analogous functions as growth cone repellents. These crude systems of markers are adequate to define the anteroposterior *orientation* of the map in the frog optic tectum. Other mechanisms of an entirely different sort, however, are required to make the map precise.

Diffuse Patterns of Synaptic Connections Are Sharpened by Activity-dependent Synapse Elimination [88], [89]

In a normal animal the retinotectal map is initially fuzzy and imprecise. Studies in frogs and fish show that each retinal axon at first branches widely in the tectum and makes a profusion of synapses, distributed over a large area of tectum that overlaps with the territories innervated by other axons. These territories are subsequently trimmed back by elimination of synapses and retraction of axon branches. This refinement of the map through synapse elimination is governed by two competition rules that jointly create spatial order: (1) axons from separate regions of retina, which tend to be excited at different times, compete to dominate the available tectal territory, but (2) axons from neighboring sites in the retina, which tend to be excited at the same time, innervate neighboring territories in the tectum because they collaborate to retain synapses on shared tectal cells (Figure 21-113). The mechanism underlying both these rules depends on electrical activity and signaling at the synapses that are formed. If all action potentials are blocked by a toxin that binds to voltage-gated Na^+ channels, synapse elimination is inhibited and the map remains fuzzy.

This phenomenon of activity-dependent synapse elimination is encountered in almost every part of the developing vertebrate nervous system. Synapses are first formed in abundance and distributed over a broad target field; then the system of connections is pruned back by competitive processes that depend on electrical activity and synaptic signaling. The elimination of synapses in this way is distinct from the elimination of surplus neurons by cell death, and it occurs after the period of normal neuronal death is over.

The cellular mechanisms of synapse elimination are beginning to be clarified by experiments on the innervation of skeletal muscle in vertebrate embryos, where typically each muscle cell at first receives synapses from several neurons but in the end is left innervated by only one. Co-cultures of motor neurons with muscle cells can be used to analyze the mechanism *in vitro*. One can identify a muscle cell that is innervated by a single neuron and then directly excite the muscle cell repeatedly with puffs of acetylcholine delivered through a micropipette close to its surface. The synapse made on the muscle cell by the neuron is found to be permanently weakened by this treatment unless the neuron itself is stimulated electrically so that it fires in synchrony with the acetylcholine puffs delivered to the muscle cell, in which case the synapse remains strong (Figure 21-114). Weakening, or *repression,* of the synapse reflects a change on its presynaptic side, which causes the axon terminal to release less neurotransmitter when the neuron fires. It can be shown that this synaptic repression depends on the entry of Ca^{2+} into the muscle cell through the cation channels associated with the acetylcholine receptors. Somehow, a sudden rise in intracellular Ca^{2+} causes the postsynaptic cell to send a rebuff to any axon terminals synapsing on its surface in that neighborhood, but the axon terminals are immune to this rebuff if they themselves have just been active.

These and many other findings suggest a simple interpretation of the competition rules for synapse elimination in the retinotectal system. Axons from different parts of the retina fire at different times and so compete. Each time one of them fires, the synapse(s) made by the other on a shared tectal target cell are weakened, until one of the axons is left in sole command of that cell. Axons from neighboring retinal cells, on the other hand, tend to fire in synchrony with one another: they therefore do not compete but instead maintain synapses on shared tectal cells, creating a precisely ordered map in which neighboring cells of the retina project to neighboring sites in the tectum (see Figure 21-113).

Experience Molds the Pattern of Synaptic Connections in the Brain [89], [90]

The same "firing rule" relating synapse maintenance to neural activity helps to organize our developing brains in the light of experience. In the brain of a mammal axons relaying inputs from the two eyes are brought together in the visual region of the cerebral cortex, where they form two overlapping maps of the external visual field, one as perceived through the right eye, the other as perceived through the left. The organization and development of the cortical projections from the two eyes have been studied in great detail, both by anatomical tracing and by physiological tests in which single cortical cells are monitored to find out what kinds of visual stimulus will excite them. These studies reveal an extraordinary sensitivity to experience early in life: if, during a certain *critical period,* one eye is kept covered so as to deprive it of visual stimulation, while the other eye is allowed normal stimulation, the deprived eye loses its synaptic connections to the cortex and becomes almost entirely, and irreversibly, blind. In accordance with the firing rule, a competition has occurred in which synapses in the visual cortex made by inactive axons are eliminated while synapses made by active axons are consolidated. In this way cortical territory is allocated to axons that carry information and is not wasted on those that are silent.

But the firing rule also operates in more subtle ways to establish the nerve connections that enable us to see. For example, the

ability to see depth - stereo vision - depends on the presence in the visual cortex of cells that receive inputs from both eyes at once, conveying information about the same part of the visual field as seen from two slightly different angles. These binocularly driven cells allow us to compare the view through the right eye with that through the left so as to derive information about the relative distances of objects from us. If, however, the two eyes are prevented during the critical period from ever seeing the same scene at the same time - for example, by covering first one eye and then the other on alternate days or simply as a consequence of a childhood squint - almost no binocularly driven cells are retained in the cortex, and the capacity for stereo perception is irretrievably lost. Evidently, in accordance with the firing rule, the inputs from each eye to a binocularly driven neuron are maintained only if the two inputs are frequently triggered to fire in synchrony, as occurs when the two eyes look together at the same scene.

We saw in Chapter 15 that synaptic changes underlying memory in many parts of the brain hinge on the behavior of a particular type of receptor for the neurotransmitter glutamate - the NMDA receptor. Ca^{2+} flooding into the postsynaptic cell through the channels opened by this receptor triggers lasting changes in the strengths of the synapses on that cell, just as Ca^{2+} entering a muscle cell via acetylcholine-receptor channels during development affects the synapses made on it by motor neurons. The changes that are induced by the NMDA-dependent mechanism in the adult brain obey rules closely akin to the developmental firing rule. In fact, the refinement and remodeling of synaptic connections that we have just described in the developing visual systems of mammals and amphibians can be blocked by an inhibitor of the NMDA receptor. Both memory and the developmental adjustments, therefore, may depend on essentially the same machinery. The molecular basis of this device through which experience molds our brains is one of the central challenges that the nervous system presents to cell biology.

Summary

The development of the nervous system proceeds in three phases: first, nerve cells are generated through cell division; then, having ceased dividing, they send out axons and dendrites to form profuse synapses with other, remote cells so that communication can begin; last, the system of synaptic connections is refined and remodeled according to the pattern of electrical activity in the neural network.

Axons and dendrites grow out by means of growth cones at their tips, following specific pathways delineated by cells and extracellular matrix along the way. The guidance depends on many different classes of adhesion molecules and intercellular signals as well as on factors that inhibit and repel growth cones. Growth cones from different, nonequivalent neurons respond differently to these cues, and in this way neural maps are set up - orderly projections of one array of neurons onto another. After the growth cones have reached their targets, two major sorts of adjustment occur. First, many of the innervating neurons die as a result of a competition for survival factors such as NGF (nerve growth factor) secreted by the target tissue. This cell death adjusts the quantity of innervation according to the size of the target. Second, individual synapses are pruned away in some places, reinforced in others, so as to create a more precisely ordered pattern of connections. This process depends on electrical activity: synapses that are frequently active are reinforced, and different neurons contacting the same target cell tend to maintain their synapses on the shared target only if they are both frequently active at the same time. In this way the structure of the brain can be adjusted to reflect the connections between events in the external world. The underlying molecular mechanism may be similar to that responsible for the formation of memories in adult life.
Figure 21-99. A typical neuron of a vertebrate. The arrows indicate the direction in which signals are conveyed. The neuron shown is from the retina of a monkey. The longest and largest neurons in a human extend for about 1 million μm and have an axon diameter of 15 μm. (Drawing of neuron from B.B. Boycott in Essays on the Nervous System [R. Bellairs and E.G. Gray, eds.]. Oxford, UK: Clarendon Press, 1974.)

Figure 21-100. The complex organization of nerve cell connections. This semischematic drawing depicts a section through a small part of a mammalian brain - the olfactory bulb of a dog, stained by the Golgi technique. The black objects are neurons; the thin lines are axons and dendrites, through which the various sets of neurons are interconnected according to precise rules. (From C. Golgi, *Riv. sper. freniat. Reggio-Emilia* 1:405-425, 1875; reproduced in M. Jacobson, Developmental Neurobiology, 3rd ed. New York: Plenum, 1992.)

Figure 21-102. Diagram of an early (2 1/2-day) chick embryo, showing the origins of the nervous system. The neural tube (*light green*) has already closed, except at the tail end, and lies internally, beneath the ectoderm, of which it was originally a part

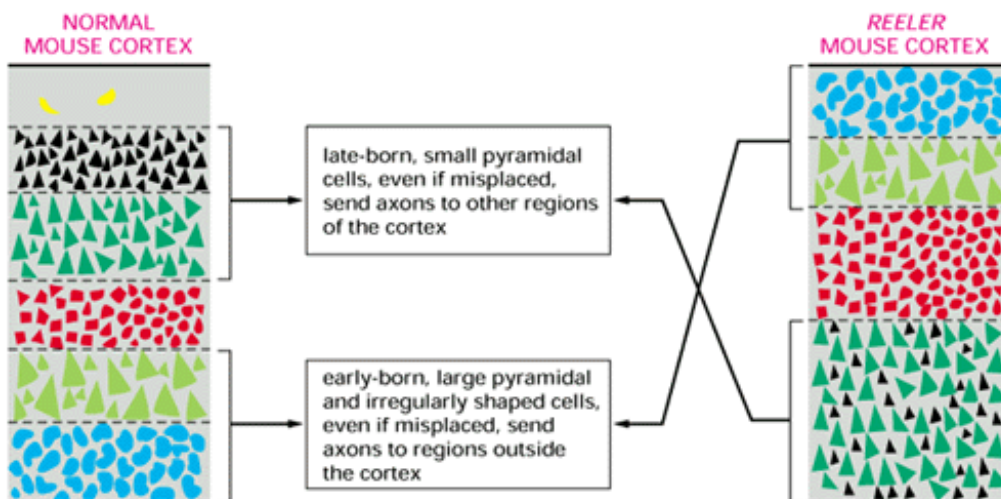
(see Figure 21-10). The neural crest (*red*) lies dorsally beneath the ectoderm, in or above the roof of the neural tube. In addition, thickenings, or *placodes* (*dark green*), in the ectoderm of the head give rise to some of the sensory transducer cells and neurons of that region, including those of the ear and the nose. The cells of the retina of the eye, by contrast, originate as part of the neural tube.
Figure 21-103. Formation of the neural tube. The scanning electron micrograph shows a cross-section through the trunk of a 2-day chick embryo. The neural tube is about to close and pinch off from the ectoderm; at this stage it consists (in the chick) of an epithelium that is only one cell thick. (Courtesy of Jean-Paul Revel.)
Figure 21-104. Migration of immature neurons along radial glial cells. The diagrams are based on reconstructions from sections of the cerebral cortex of a monkey (part of the neural tube). The neurons are born close to the inner, luminal surface of the neural tube and migrate outward. The radial glial cells can be considered as persisting cells of the original columnar epithelium of the neural tube that become extraordinarily stretched as the wall of the tube thickens. (After P. Raki#180c, *J. Comp. Neurol.* 145:61-84, 1972.)


Figure 21-105. Comparison of the layering of neurons in the cortex of normal and *reeler* mice. In the *reeler* mutant an abnormality of cell migration causes an approximate inversion of the normal relationship between neuronal birthday and position. The misplaced neurons nevertheless differentiate according to their birthdays and make the connections appropriate to their birthdays.
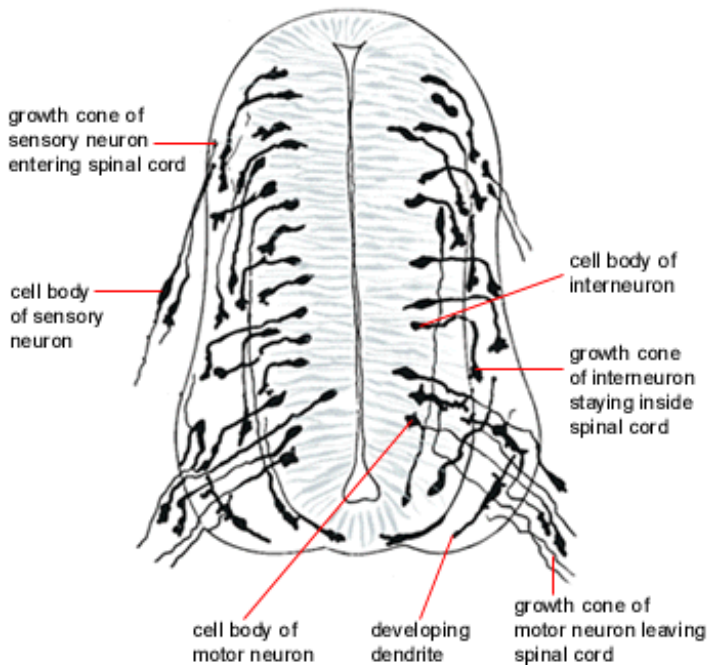

Figure 21-106. Growth cones in the developing spinal cord of a 3-day chick embryo. The drawing shows a cross-section stained by the Golgi technique. Most of the neurons, apparently, have as yet only one elongated process - the future axon. The growth cones of the interneurons remain inside the spinal cord, those of the motor neurons emerge from it (to make their way toward muscles), and those of the sensory neurons grow into it from outside (where their cell bodies lie). Many of the cells in the more central regions of the embryonic spinal cord are still proliferating and have not yet begun to differentiate as neurons or glial cells. (From S. Ramón y Cajal, Histologie du Système Nerveux de l'Homme et des Vertébrés. Paris: Maloine, 1909-1911; reprinted, Madrid: C.S.I.C., 1972.)
Figure 21-107. Formation of axon and dendrites in culture. A young neuron has been isolated from the brain of a mammal and put to develop in culture, where it sends out processes. One of these processes, the future axon, has begun to grow out faster than the rest (the future dendrites) and has bifurcated. (A) A phase-contrast picture; (B) the pattern of staining with fluorescent phalloidin, which binds to filamentous actin. Actin is concentrated in the growth cones at the tips of the processes that are actively extending and at some other sites of lamellipodial activity. (Courtesy of Kimberly Goslin, from Z.W. Hall, An Introduction to Molecular Neurobiology. Sunderland, MA: Sinauer, 1992.)
Figure 21-108. Neural growth cones. (A) Scanning electron micrograph of growth cones at the end of a neurite put out by a chick sympathetic neuron in culture. Here a previously single growth cone has recently divided in two. Note the many filopodia and the taut appearance of the neurite, due to tension generated by the forward movement of the growth cones, which are often the only firm points of attachment to the substratum. (B) Scanning electron micrograph of the growth cone of a sensory neuron *in vivo* crawling over the inner surface of the epidermis of a *Xenopus* tadpole. (A, from D. Bray, in Cell Behaviour [R. Bellairs, A. Curtis, and G. Dunn, eds.]. Cambridge, UK: Cambridge University Press, 1982; B, from A. Roberts, *Brain Res.* 118:526-530, 1976.)
Figure 21-109. NGF effects on neurite outgrowth. Dark-field photomicrographs of a sympathetic ganglion cultured for 48 hours with (*above*) or without (*below*) NGF. Neurites grow out from the sympathetic neurons only if NGF is present in the medium. Each culture also contains Schwann (glial) cells that have migrated out of the ganglion; these are not affected by NGF. Neuronal survival and maintenance of growth cones for neurite extension represent two distinct effects of NGF. The effect on growth cones is local, direct, rapid, and independent of communication with the cell body; when NGF is removed, the deprived growth cones halt their movements within a minute or two. The effect of NGF on cell survival is less immediate and is associated with uptake of NGF by endocytosis and its intracellular transport back to the cell body. (Courtesy of Naomi Kleitman.)
Figure 21-110. Connections between eye and brain in a *Xenopus* tadpole. In this specimen a tracer molecule has been injected into one eye (dark object at *left*), taken up by the neurons there, and carried along their axons, revealing the paths they take to the optic tectum in the brain. (Courtesy of Jeremy Taylor.)

the neurons in each retina send their axons to the opposite tectum, setting up an orderly map (A–a, V–v, etc.)

cut the right optic nerve and rotate the right eye; the severed ends of the axons from the retina degenerate

the neurons in each part of the retina, even though now misplaced, regenerate connections with the same part of the tectum that they were connected with before

Figure 21-111. The regeneration of connections between eye and brain in an amphibian after one eye has been rotated. The axons from each part of the rotated retina regenerate so as to reconnect with the part of the tectum appropriate to the *original* positions of the retinal bodies. Thus, for example, light falling on the ventral part of the rotated retina is perceived as though it were falling on the dorsal part, and the animal sees the world upside down; if food is dangled above it, it makes a lunge downward, and so on.
Figure 21-112. Selectivity of retinal axons growing over tectal membranes. The culture substratum has been coated with alternating stripes of membrane prepared either from posterior tectum (P) or from anterior tectum (A); the anterior tectal stripes

are made visible by staining them with a fluorescent marker in the vertical strips at the sides of the picture. Axons of neurons from the temporal half of the retina (growing in from the left) follow the stripes of anterior tectal membrane but avoid the posterior tectal membrane, while axons of neurons from the nasal half of the retina (growing in from the right) do the converse. Thus anterior tectum differs from posterior tectum and nasal retina from temporal retina, and the differences guide selective axon outgrowth. These experiments have been done with cells from the chick embryo. (From Y. von Boxberg, S. Diess, and U. Schwarz, *Neuron* 10:345-357, 1993.)
Figure 21-113. Sharpening of the retinotectal map by synapse elimination. At first the map is fuzzy because each retinal axon branches widely to innervate a broad region of tectum overlapping the regions innervated by other retinal axons. The map is then refined by synapse elimination. Where axons from separate parts of the retina synapse on the same tectal cell, competition occurs, eliminating the connections made by one of the axons. But axons from cells that are close neighbors in the retina cooperate, maintaining their synapses on shared tectal cells. Thus each retinal axon ends up innervating a small tectal territory, adjacent to and partly overlapping the territory innervated by axons from neighboring sites in the retina.
Figure 21-114. Synapse elimination and its dependence on the pattern of excitation. In the experiment illustrated schematically here, a neuron and a muscle cell from an embryo have been allowed to form a synapse *in vitro*. The muscle cell is then stimulated with puffs of acetylcholine (mimicking neural stimulation) either alone or in synchrony with electrical excitation of the neuron. The results illustrate a general principle: each excitation of a target cell tends to cause the rejection of any synapse where the presynaptic axon terminal has just been quiet but to maintain synapses where the presynaptic axon terminal has just been active.

22. Differentiated Cells and the Maintenance of Tissues

➜ ➜

Introduction

In the space of a few days or weeks, a single fertilized egg gives rise to a complex multicellular organism consisting of differentiated cells arranged in a precise pattern. As a rule, the pattern of the body of an animal is set up in this way on a small scale and then grows. During embryonic development the different cell types become determined, each in its proper place. In the subsequent period of growth the cells proliferate, but with certain exceptions, their specialized characters remain more or less fixed. The organism may continue to become bigger throughout life, as do most crustaceans and fish, or it may stop growing when it reaches a certain size, as do birds and mammals. But even when growth stops, cell proliferation in many species continues. Thus in our own adult tissues new cells are continually produced. The adult body of a vertebrate can be likened to a stable ecosystem in which one generation of individuals (cells in this case) succeeds another but the organization of the system as a whole remains unchanged. It is still not known how the precise balance between cell proliferation and cell death is achieved.

This chapter discusses how cells are born, live, and die in multicellular tissues and how the organization of these tissues is maintained. We concentrate on higher vertebrates, and in considering the problems of tissue maintenance and renewal, we shall try to convey something of the remarkable variety of structure, function, and life history to be found among their specialized cell types.

➜ ➜

Maintenance of the Differentiated State 1

Introduction

Although the tissues of the body differ in many ways, they all have certain basic requirements, usually provided for by a mixture of cell types, as illustrated for the skin in Figure 22-1. They all need mechanical strength, which is often provided by a supporting framework of *extracellular matrix,* mainly secreted by *fibroblasts.* In addition, almost all tissues need a blood supply to bring nutrients and remove waste products, and so they are pervaded by blood vessels lined with *endothelial cells.* Likewise, most tissues are innervated by *nerve cell* axons, which are ensheathed by *Schwann cells. Macrophages* are usually present to dispose of dying cells and to remove unwanted extracellular matrix, as are *lymphocytes* and other white blood cells to combat infection. *Melanocytes* may be present to provide a protective or decorative pigmentation. Most of these cell types, ancillary to the specialized function of the tissue, originate outside it and invade the tissue either early in the course of its development (endothelial cells, nerve cell axons, Schwann cells, and melanocytes) or continually during life (macrophages and other white blood cells). This complex supporting apparatus is required to maintain the principal specialized cells of the tissue: the contractile cells of the muscle, the secretory cells of the gland, or the blood-forming cells of the bone marrow, for example.

Almost every tissue is therefore an intricate mixture of many cell types that must remain different from one another while coexisting in the same environment. Moreover, the organization of the mixture must be preserved even though, in almost all adult tissues, cells are continually dying and being replaced. The retention of tissue form and function is made possible largely through two fundamental properties of cells. Because of *cell memory* (see Chapter 21), specialized cells autonomously maintain their distinctive character and pass it on to their progeny. At the same time each type of specialized cell continually senses its environment and adjusts its proliferation and properties to suit the circumstances; in fact, the very survival of most cells depends on signals from other cells. The intracellular mechanisms thought to be responsible for cell memory are discussed in Chapter 9, while the ways in which cells respond to environmental signals are considered in Chapter 15. In this preliminary section on the behavior of cells in tissues, we briefly review some of the evidence for the stability and heritability of the differentiated state and consider to what extent this state can be modified by environmental influences.

Most Differentiated Cells Remember Their Essential Character Even in a Novel Environment 2

Cell culture experiments demonstrate that even when cells are removed from their usual environment, they and their progeny generally remain true to their original instructions. Consider, for example, the epithelial cells that form the pigmented layer of the retina (Figure 22-2). Because they display their specialized character by manufacturing dark brown granules of melanin, it is easy to monitor their state of differentiation. When these cells are isolated from the retina of a chick embryo and grown in culture, they proliferate to form clones. Single cells taken from these clones breed true, giving subclones of similar pigment epithelial cells. The differentiated state can be maintained in this way through more than 50 cell generations.

The behavior of the cells is not, however, independent of their environment. In certain media or in conditions of extreme crowding, they may survive but synthesize little or no pigment. But even when they fail to express their differentiated character, they remain *determined* as pigment cells: when they are returned to more favorable culture conditions, they synthesize pigment once again. There are one or two known exceptions to this rule. In some vertebrate species, under certain conditions, retinal pigment cells will *transdifferentiate* into lens cells or into cells of the neural retina, but no manipulation of the conditions has been found to cause them to differentiate instead into blood cells, for example, or into liver cells or heart cells. Similarly, most types of specialized cells, including blood cells, liver cells, and heart cells, maintain their essential character in culture.

In the body, just as in culture, most specialized cells behave as though their basic character has been irreversibly determined by their developmental history. Epidermal cells, for example, remain epidermal cells even in the most alien surroundings: if a suspension of dissociated epidermal cells is prepared from the tail skin of a rat and injected beneath the capsule of the kidney, the cells grow there to form cysts lined with unmistakable epidermis, resembling that on the surface of the body.

The Differentiated State Can Be Modulated by a Cell's Environment 1, 3

Although radical transformations are largely forbidden, the character of many differentiated cells can be strongly influenced by the environment. The possible adjustments can be classified mostly as *modulations* of the differentiated state - that is, reversible changes between closely related cell phenotypes. Liver cells, for example, adjust their synthesis of specific enzymes (through

changes in specific mRNA levels) according to the ambient concentrations of the steroid hormone hydrocortisone, and the production of milk proteins by mammary gland cells can be switched on or off by changes in the extracellular matrix. Fibroblasts and their relatives - the family of *connective-tissue cells* - are a special case. These cells are exceptionally adaptable and can undergo various interconversions: fibroblasts, for example, can apparently change reversibly into cartilage cells. Such transformations are important in the healing of wounds and bone fractures and in other pathological processes; they are discussed later in this chapter. Even these conversions of one differentiated cell type into another, however, are narrowly restricted: the converted cell remains a member of the family of connective-tissue cells. Important but restricted changes of differentiated state occur also in many normal adult tissues where new differentiated cells are generated from *stem cells* - precursors that do not themselves display the mature differentiated character but are specialized to divide and to yield progeny that will. Distinct types of stem cells are committed to the production of distinct types of differentiated cells and are not interconvertible.

The majority of adult tissues, therefore, are composed of a number of distinct, irreversibly determined cell lineages. The numbers and spatial relationships of these components have to be maintained throughout life by mechanisms that do not require one type of differentiated cell to transform into another but depend on complex interactions between the different cell types.

Summary

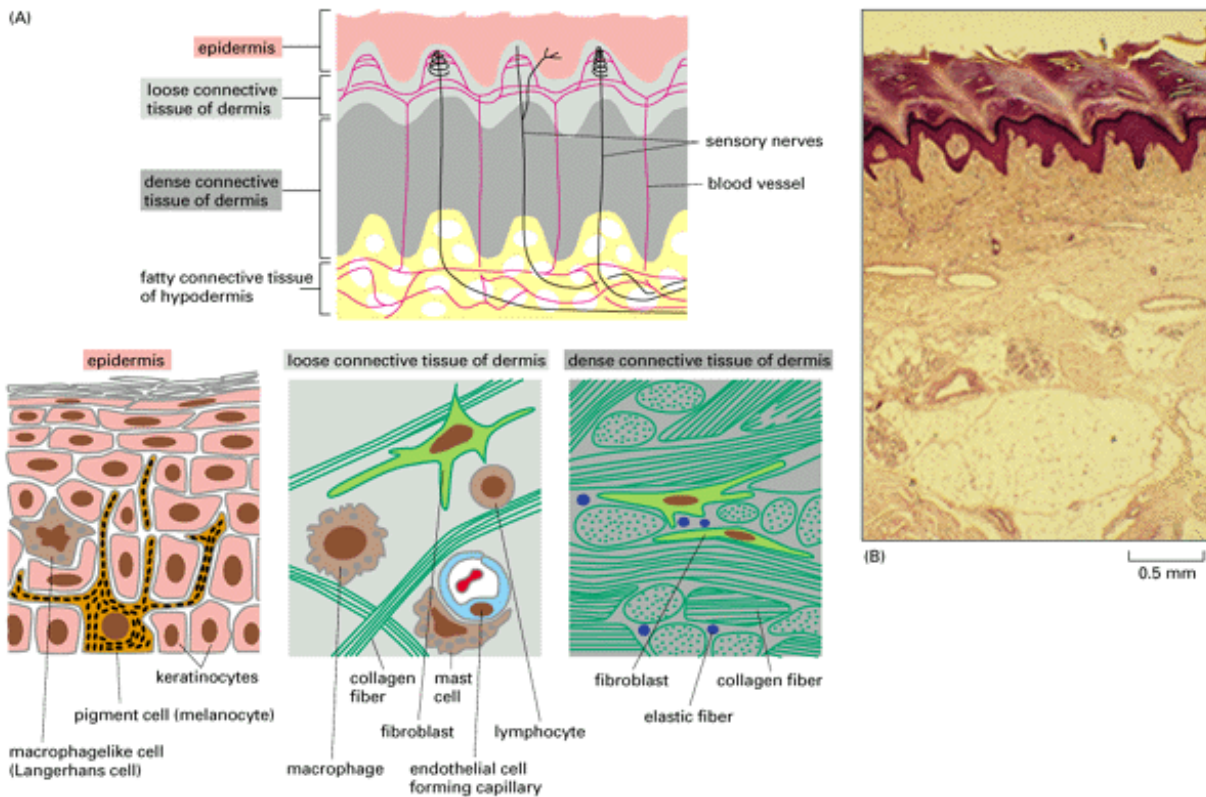
Most differentiated cells in adult tissues will maintain their specialized character even when placed in a novel environment. Although states of differentiation are generally stable and not interconvertible, even highly specialized cells can alter their properties to a limited extent in response to environmental cues. In many adult tissues, moreover, new differentiated cells are continually generated from stem cells that appear undifferentiated. Especially striking cell transformations occur within the family of connective-tissue cells that includes fibroblasts and cartilage cells.


Figure 22-1. Mammalian skin. (A) Schematic diagrams showing the cellular architecture of thick skin. (B) Photograph of a cross-section through the sole of a human foot, stained with hematoxylin and eosin. The skin can be viewed as a large organ composed of two main tissues: epithelial tissue (the *epidermis*), which lies outermost, and connective tissue, which consists of the tough dermis (from which leather is made) and the underlying fatty *hypodermis.* Each tissue is composed of a variety of cell types. The dermis and hypodermis are richly supplied with blood vessels and nerves. Some nerve fibers extend also into the epidermis.
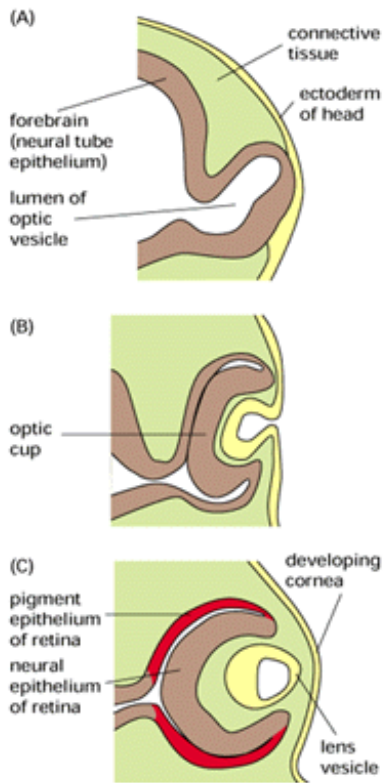

Figure 22-2. The development of the vertebrate eye. The retina develops from the *optic vesicle,* an epithelial outpocketing of the forebrain region of the neural tube. (A) The neural epithelium makes contact with the ectoderm covering the exterior of the head. (B) This contact induces the ectoderm to invaginate to form a lens. At the same time the outer part of the optic vesicle invaginates, reducing the vesicle lumen to an interface between two layers that together form a cuplike structure. (C) The layer of the optic cup closest to the lens differentiates into the *neural retina,* which contains the photoreceptor cells and the neurons that relay visual stimuli to the brain (see Figure 22-6). The other layer differentiates into the retinal *pigment epithelium.* Its cells are heavily loaded with melanin granules and thus form a dark enclosure for the photoreceptive system (serving to reduce the amount of scattered light, much as a coat of black paint does inside a camera).

➜ ➜

Tissues with Permanent Cells 4

Introduction

Not all the populations of differentiated cells in the body are subject to cell turnover. Some cell types, having been generated in appropriate numbers in the embryo, are retained throughout adult life; they seem never to divide, and they cannot be replaced if they are lost. Almost all nerve cells are permanent in this sense. So are a few other types of cells, including - in mammals - the muscle cells of the heart, the auditory hair cells of the ear (Figure 22-3), and the lens cells of the eye.

While all these cells have extremely long life-spans and necessarily live in protected environments, they are dissimilar in other respects, and it is difficult to give a general reason why they should be permanent and irreplaceable. For heart muscle cells and auditory hair cells it is difficult to give any reason at all. In the case of nerve cells it seems likely that cell turnover in the adult would be disadvantageous as a rule, since it would be difficult to reestablish in the adult the precise and complex patterns of nerve connections that are set up under very different circumstances during development. Moreover, any memories recorded in the form of slight modifications of the structure or interconnections of individual nerve cells would presumably be obliterated. In the lens of the eye, on the other hand, the permanence of the cells appears to be simply an inevitable consequence of the way the tissue grows.

The Cells at the Center of the Lens of the Adult Eye Are Remnants of the Embryo 5

Very little of the adult body consists of the same molecules that were laid down in the embryo. The lens of the eye is an

exception: it is one of the few structures containing cells that are not only preserved but are preserved without turnover of their contents.

The lens is formed from the ectoderm at the site where the developing optic vesicle makes contact with it: the ectoderm here thickens, invaginates, and finally pinches off as a *lens vesicle* (see Figure 22-2). The lens thus originates as a spherical shell of cells formed from an epithelium, one cell layer thick, surrounding a central cavity. The cells at the rear of the lens vesicle (those facing the retina) soon undergo a striking transformation. They synthesize and become filled with *crystallins,* the characteristic proteins of the lens. In the process they elongate enormously, differentiating into *lens fibers* (Figure 22-4). Eventually, their nuclei disintegrate and protein synthesis ceases. In this way the part of the lens vesicle epithelium facing the retina is expanded into a thick refractile body consisting of many long, lifeless cells packed side by side (Figure 22-5). The central cavity of the vesicle is obliterated, and the front part of the epithelium of the lens vesicle - the part facing the external world - remains as a thin sheet of low cuboidal cells. Growth of the lens depends on the proliferation of these cells at the front, pushing some of the cells from this region around the rim of the lens and toward the back (see Figures 22-4 and 22-5A). As cells move to the rear, they stop dividing, step up their rate of synthesis of crystallins, and differentiate into lens fibers. Additional lens fibers continue to be recruited in this way throughout life, although at an ever decreasing rate.

The types of crystallins filling the earliest generations of lens fibers are different from those of the later generations, just as the hemoglobins of fetal red blood cells are different from those of adult red blood cells. But whereas old red blood cells are discarded, old lens fibers are not. Thus at the core of the adult lens lie fibers that were laid down in the embryo and are still packed with the distinctive types of crystallins manufactured in that earlier period. Differences of refractive index between the early embryonic types of crystallins and those that are laid down later help to free the lens of the eye from the optical aberrations that bedevil simple lenses made out of homogeneous media such as glass.

Most Permanent Cells Renew Their Parts: The Photoreceptor Cells of the Retina 6

There are few cells as immutable as lens fibers. As a rule, even those cells that persist throughout life without dividing undergo renewal of their component parts. Thus, while they do not divide, heart muscle cells, auditory hair cells, and nerve cells are metabolically active and capable not only of synthesizing new RNA and protein, but also of altering their size and structure during adult life. Heart muscle cells, for example, replace the bulk of their protein molecules in the course of a week or two, and they will adjust the balance of protein synthesis and degradation so as to grow bigger if the load on the heart is increased - for example, by a sustained increase in blood pressure. Nerve cells also replace their protein molecules continuously; moreover, many nerve cells can regenerate axons and dendrites that have been cut off.

The turnover of cell components is dramatically illustrated in the highly specialized neural cells that form the photoreceptors of the retina. The neural retina (see Figure 22-2) consists of several cell layers organized in a way that seems perverse. The neurons that transmit signals from the eye to the brain (called *retinal ganglion cells*) lie closest to the external world, so that the light, focused by the lens, must pass through them to reach the photoreceptor cells. The photoreceptors, which are classified as rods or cones, according to their shape, lie with their photoreceptive ends, or *outer segments,* partly buried in the pigment epithelium (Figure 22-6). Rods and cones contain different photosensitive complexes of protein with visual pigment: rods are especially sensitive at low light levels, while cones (of which there are three types, each with different spectral responses) detect color and fine detail. The outer segment of a photoreceptor appears to be a modified cilium with a characteristic ciliumlike arrangement of microtubules in the region where the outer segment is connected to the rest of the cell (Figure 22-7). The remainder of the outer segment is almost entirely filled with a dense stack of membranes in which the photosensitive complexes are embedded; light absorbed here produces an electrical response, as discussed in Chapter 15. At their opposite ends the photoreceptors form synapses on interneurons, which relay the signal to the retinal ganglion cells (see Figure 22-6).

The photoreceptors are permanent cells that do not divide. But the photosensitive protein molecules are not permanent. There is a steady turnover, which can be demonstrated by showing that injected radioactive amino acids are incorporated into these molecules. In rods (although not, curiously, in cones) this turnover is organized in an orderly production line, which can be analyzed by following the passage of a cohort of radiolabeled protein molecules through the cell after a short pulse of radioactive amino acid (Figure 22-8). The radiolabeled proteins can be followed from the Golgi apparatus in the inner segment of the cell to the base of the stack of membranes in the outer segment. > From here they are gradually displaced toward the tip as new material is fed into the base of the stack. Finally (after about 10 days in the rat), on reaching the tip of the outer segment, the labeled proteins and the layers of membrane in which they are embedded are phagocytosed (chewed off and digested) by the cells of the pigment epithelium.

Summary

Some cells in mammals - including nerve cells, heart muscle cells, sensory receptor cells for light and sound, and lens fibers - persist throughout life without dividing and without being replaced. In mature lens fibers the cell nuclei have degenerated and protein synthesis has stopped, so that the core of the adult lens consists of lens proteins laid down early in embryonic life. In most other permanent cells biosynthetic activity continues, and there is a steady turnover of cell components. In the rod cells of the retina, for example, new layers of photoreceptive membrane are synthesized close to the nucleus and are steadily displaced outward until they are eventually engulfed and digested by cells of the pigment epithelium.

Figure 22-3. Auditory hair cells. (A) Diagrammatic cross-section of the auditory apparatus (the organ of Corti) in the inner ear of a mammal, showing the auditory hair cells held in an elaborate structure of supporting cells and overlaid by a mass of extracellular matrix (called the tectorial membrane). (B) Scanning electron micrograph showing the apical surface of some of the outer auditory hair cells, with their characteristic organ-pipe arrays of giant microvilli (called *stereocilia*). The auditory hair cells function as transducers, generating an electrical signal in response to sound vibrations that rock the organ of Corti and so cause the stereocilia to tilt. In mammals the auditory hair cells produced in the embryo have to last a lifetime: if they are destroyed by disease or by excessively loud noise, they are not regenerated and permanent deafness results. Figure 22-6. The structure of the retina. The stimulation of the photoreceptors by light is relayed via the interneurons to the
ganglion cells, which convey the signal to the brain. The spaces between neurons and between photoreceptors in the neural
retina are occupied by a population of specialized supporting cells, which are not shown here. (Modified from J.E. Dowling and
B.B. Boycott, *Proc. R. Soc. Lond. (Biol.)* 166:80-111, 1966.)

Figure 22-7. A rod photoreceptor. (A) Schematic drawing. The actual number of photoreceptive discs in the outer segment is about 1000. (B) Electron micrograph of part of a rod photoreceptor, showing the base of the outer segment and the modified cilium that connects it to the inner segment. (A, from T.L. Lentz, Cell Fine Structure. Philadelphia: Saunders, 1971; B, from M. J. Hogan, J.A. Alvarado, and J.E. Weddell, Histology of the Human Eye: An Atlas and Textbook. Philadelphia: Saunders, 1971.)
Figure 22-8. Turnover of membrane protein in a rod cell. Following a pulse of $3H$-leucine, the passage of radiolabeled proteins through the cell is followed by autoradiography. *Red dots* indicate sites of radioactivity. The method reveals only the $3H$-leucine that has been incorporated into proteins; the rest is washed out during the preparation of the tissue. The incorporated leucine is first seen concentrated in the neighborhood of the Golgi apparatus (1). From there it passes to the base of the outer segment into a newly synthesized disc of photoreceptive membrane (2). New discs are formed at a rate of three or four per hour (in a mammal), displacing the older discs toward the pigment epithelium (3-5).

Renewal by Simple Duplication 7

Introduction

Most of the differentiated cell populations in a vertebrate are not permanent: the cells are continually dying and being replaced. New differentiated cells can be produced during adult life in either of two ways: (1) they can form by the *simple duplication* of existing differentiated cells, which divide to give pairs of daughter cells of the same type; or (2) they can be generated from relatively undifferentiated *stem cells* by a process that involves a change of cell phenotype, as will be explained in detail later in this chapter.

Rates of renewal vary from one tissue to another. The turnover time may be as short as a week or less, as in the epithelial lining of the small intestine (which is renewed by means of stem cells), or as long as a year or more, as in the pancreas (which is renewed by simple duplication). Many tissues whose normal rates of renewal are very slow can be stimulated to produce new cells at higher rates when the need arises.

In this section we discuss two examples of cell populations that are renewed by simple duplication - liver cells and endothelial cells.

The Liver Functions as an Interface Between the Digestive Tract and the Blood 7, 8

Digestion is a complex process. The cells that line the digestive tract secrete into the lumen of the gut a variety of substances, such as hydrochloric acid and digestive enzymes, to break down food molecules into simpler nutrients. The cells absorb these nutrients from the gut lumen, process them, and then release them into the blood for utilization by other cells of the body. All of these activities are adjusted according to the composition of the food consumed and the levels of metabolites in the circulation. The complex set of tasks is performed by a division of labor: some of the cells are specialized for the secretion of hydrochloric acid, others for the secretion of enzymes, others for absorption of nutrients, others for the production of peptide hormones, such as gastrin, that regulate digestive and metabolic activities, and so on (Figure 22-9). Some of these cell types lie closely intermingled in the wall of the gut; others are segregated in large glands that communicate with the gut and originate in the embryo as outgrowths of the gut epithelium.

The liver is the largest of these glands. It develops at a site where a major vein runs close to the wall of the primitive gut tube, and the adult organ retains a singularly close relationship with the blood. The cells in the liver that derive from the primitive gut epithelium - the hepatocytes - are arranged in folded sheets, facing blood-filled spaces called *sinusoids* (Figure 22-10A). The blood is separated from the surface of the hepatocytes by a single layer of flattened endothelial cells that covers the sides of each hepatocyte sheet (Figure 22-10B). This structure facilitates the chief functions of the liver, which center on the exchange of metabolites between hepatocytes and the blood.

The liver is the main site at which nutrients that have been absorbed from the gut and then transferred to the blood are processed for use by other cells of the body. It receives a major part of its blood supply directly from the intestinal tract (via the portal vein). Hepatocytes are responsible for the synthesis, degradation, and storage of a vast number of substances; they play a central part in the carbohydrate and lipid metabolism of the body as a whole; and they secrete most of the protein found in blood plasma. At the same time the hepatocytes remain connected with the lumen of the gut via a system of minute channels (or *canaliculi*) and larger ducts (see Figure 22-10B) and secrete into the gut by this route both waste products of their metabolism and an emulsifying agent, *bile,* which helps in the absorption of fats. In contrast to the rest of the digestive tract, there seems to be remarkably little division of labor within the population of hepatocytes: each hepatocyte appears to be able to perform the same broad range of metabolic and secretory tasks.

Hepatocytes have a life-style different from the cells lining the lumen of the gut. The latter, exposed to the abrasive and corrosive contents of the gut, cannot live for long and must be rapidly replaced by a continual supply of new cells (see Figure 22-17). Hepatocytes, removed from direct contact with the contents of the gut, live much longer and are normally renewed at a slow rate.

Liver Cell Loss Stimulates Liver Cell Proliferation 9

Even in a slowly renewing tissue, a small but persistent imbalance between the rate of cell production and the rate of cell death will lead to disaster. If 2% of the hepatocytes in a human divided each week but only 1% died, the liver would grow to exceed the weight of the rest of the body within 8 years. Homeostatic mechanisms must operate to adjust the rate of cell proliferation and/or the rate of cell death in order to keep the organ at its standard size.

Direct evidence for homeostatic control of liver cell proliferation comes from experiments in which large numbers of hepatocytes are removed surgically or are intentionally killed by poisoning with carbon tetrachloride. Within a day or so after either sort of damage, a surge of cell division occurs among the surviving hepatocytes, and the lost tissue is quickly replaced. If two-thirds of a rat's liver is removed, for example, a liver of nearly normal size can regenerate from the remainder within about 2 weeks. In cases of this kind a signal for liver regeneration can be demonstrated in the circulation: if the circulations of two rats are connected surgically and two-thirds of the liver of one of them is excised, cell division is stimulated in the unmutilated liver of the other. One of the signals responsible for the increased cell proliferation has been identified as a protein called *hepatocyte growth factor.* It stimulates hepatocytes to divide in culture, and its concentration in the bloodstream rises steeply (by poorly understood mechanisms) in response to liver damage. The same factor affects several other cell types in a variety of ways and is also known as *scatter factor* because it causes some kinds of epithelial cells to become motile so that they dissociate and migrate away from one another. It is not clear why it is specifically the liver that is stimulated to grow after liver damage.

The balance between cell births and cell deaths in the adult liver (and other organs too) does not depend exclusively on the regulation of cell proliferation: cell survival controls seem also to play a part. If an adult rat is treated with the drug phenobarbital, for example, hepatocytes are stimulated to divide, causing the liver to enlarge. When the phenobarbital treatment is stopped, hepatocyte cell death greatly increases until the liver returns to its original size, usually within a week or so. The mechanism of this type of cell survival control is unknown, but it has been suggested that hepatocytes, like most vertebrate cells, depend on signals from other cells for their survival and that the normal level of these signals can support only a certain standard number of hepatocytes. If the number of hepatocytes rises above this (as a result of phenobarbital treatment, for example), hepatocyte death will automatically increase to bring their number back down. It is not known how the appropriate levels of survival factors are maintained.

Regeneration Requires Coordinated Growth of Tissue Components 10

Like all organs, the liver comprises a mixture of cell types. Besides the hepatocytes and the endothelial cells that line its sinusoids, it contains both specialized macrophages (*Kupffer cells*), which engulf particulate matter in the bloodstream and dispose of worn-out red blood cells, and a small number of fibroblasts, which provide a tenuous supporting framework of connective tissue (see Figure 22-10B). All of these cell types are capable of division. For optimal regeneration their proliferation must be properly coordinated.

The importance of balanced regeneration of cell types is demonstrated by what happens when an imbalance occurs. If hepatocytes, for example, are poisoned repeatedly with carbon tetrachloride or with alcohol at such frequent intervals that they cannot recover fully between attacks, the fibroblasts take advantage of the situation and the liver becomes irreversibly clogged with connective tissue, leaving little space for the hepatocytes to grow even after the toxic agents are withdrawn. This condition, called *cirrhosis,* is common in chronic alcoholics. In a similar way the regeneration of severely damaged skeletal muscle is often seriously hindered by the overgrowth of its connective tissue so that scar tissue replaces the contractile muscle fibers. These imbalances, however, require unusual tissue damage; in ordinary circumstances of tissue renewal, poorly understood mechanisms regulate cell proliferation and cell survival so as to ensure that the proper mixture of cell types is maintained.

Endothelial Cells Line All Blood Vessels 11

By contrast with the above examples of ill-coordinated behavior of fibroblasts, the endothelial cells that form the lining of blood vessels have a remarkable capacity to adjust their number and arrangement to suit local requirements. Almost all tissues depend on a blood supply, and the blood supply depends on endo-thelial cells. They create an adaptable life-support system spreading into almost every region of the body. If it were not for endothelial cells extending and remodeling the network of blood vessels, tissue growth and repair would be impossible.

The largest blood vessels are arteries and veins, which have a thick, tough wall of connective tissue and smooth muscle (Figure 22-11A). The wall is lined by an exceedingly thin single layer of endothelial cells, separated from the surrounding outer layers by a basal lamina. The amounts of connective tissue and smooth muscle in the vessel wall vary according to the vessel's diameter and function, but the endothelial lining is always present (Figure 22-11B). In the finest branches of the vascular tree - the capillaries and sinusoids - the walls consist of nothing but endothelial cells and a basal lamina (Figure 22-12). Thus endothelial cells line the entire vascular system, from the heart to the smallest capillary, and control the passage of materials - and the transit of white blood cells - into and out of the bloodstream. A study of the embryo reveals, moreover, that arteries and veins develop from small vessels constructed solely of endothelial cells and a basal lamina: connective tissue and smooth muscle are added later where required, under the influence of signals from the endothelial cells.

New Endothelial Cells Are Generated by Simple Duplication of Existing Endothelial Cells 12

Throughout the vascular system of the adult, endothelial cells retain a capacity for cell division and movement. If, for example, a part of the wall of the aorta is damaged and denuded of endothelial cells, neighboring endothelial cells proliferate and migrate in to cover the exposed surface. Newly formed endothelial cells will even cover the inner surface of plastic tubing used by surgeons to replace parts of damaged blood vessels.

The proliferation of endothelial cells can be demonstrated by using ³H-thymidine to label cells synthesizing DNA. In normal vessels the proportion of endothelial cells that become labeled is especially high at branch points in arteries, where turbulence and the resulting wear on the endothelial cells presumably stimulate cell turnover. On the whole, however, endothelial cells turn

over very slowly, with a cell lifetime of months or even years.

Endothelial cells not only repair the lining of established blood vessels, they also create new blood vessels. They must do this in embryonic tissues to keep pace with growth, in normal adult tissues to support recurrent cycles of remodeling and reconstruction, and in damaged adult tissues to support repair.

New Capillaries Form by Sprouting [13], [14]

New vessels always originate as capillaries, which sprout from existing small vessels. This process of angiogenesis occurs in response to specific signals. The process can be readily observed in rabbits by making a small hole in the ear and fixing glass coverslips on either side to create a thin transparent viewing chamber into which the cells that surround the wound can grow. Angiogenesis can also be conveniently observed in naturally transparent structures such as the cornea of the eye. Irritants applied to the cornea induce the growth of new blood vessels from the rim of the tissue surrounding the cornea, which has a rich blood supply, in toward the center of the cornea, which normally has none. Thus the cornea becomes vascularized through an invasion of endothelial cells into the tough collagen-packed corneal tissue.

Observations such as these reveal that endothelial cells that will form a new capillary grow out from the side of a capillary or small venule by extending long processes or pseudopodia (Figure 22-13). The cells at first form a solid sprout, which then hollows out to form a tube. This process continues until the sprout encounters another capillary, with which it connects, allowing blood to circulate. Experiments in culture show that endothelial cells in a medium containing suitable growth factors will spontaneously form capillary tubes even if they are isolated from all other types of cells. The first sign of tube formation in culture is the appearance in a cell of an elongated vacuole that is at first completely encompassed by cytoplasm (Figure 22-14A). Contiguous cells develop similar vacuoles, and eventually the cells arrange their vacuoles end to end so that the vacuoles become continuous from cell to cell, forming a capillary channel (Figure 22-14B). The process is strongly dependent on the nature of the extracellular matrix in the environment of the cells: formation of capillary tubes is promoted by basal lamina components, such as laminin, which the endothelial cells themselves can secrete. The capillary tubes that develop in a pure culture of endothelial cells do not contain blood, and nothing travels through them, indicating that blood flow and pressure are not required for the formation of a capillary network.

Angiogenesis Is Controlled by Growth Factors Released by the Surrounding Tissues [14]

In living animals endothelial cells form new capillaries wherever there is a need for them. It is thought that when cells in tissues are deprived of oxygen, they release angiogenic factors that induce new capillary growth. Probably for this reason, nearly all cells in a vertebrate are located within 50 mm of a capillary. Similarly, after wounding a burst of capillary growth is stimulated in the neighborhood of the damaged tissue (Figure 22-15). Local irritants or infections also cause a proliferation of new capillaries, most of which regress and disappear when the inflammation subsides.

Angiogenesis is also important in tumor growth. The growth of a solid tumor is limited by its blood supply: if it were not invaded by capillaries, a tumor would be dependent on the diffusion of nutrients from its surroundings and could not enlarge beyond a diameter of a few millimeters. To grow further, a tumor must induce the formation of a capillary network that invades the tumor mass. A small sample of such a tumor implanted in the cornea will cause blood vessels to grow quickly toward the implant from the vascular margin of the cornea, and the growth rate of the tumor increases abruptly as soon as the vessels reach it.

In all of these cases the invading endothelial cells must respond to a signal produced by the tissue that requires a blood supply. The response of the endo-thelial cells includes at least four components. First, the cells must breach the basal lamina that surrounds an existing blood vessel; endothelial cells during angiogenesis have been shown to produce *proteases,* which enable them to digest their way through the basal lamina of the parent capillary or venule. Second, the endothelial cells must move toward the source of the signal. Third, they must proliferate. Fourth, they must form tubes. In certain circumstances some of the components of this complex response can be elicited in the absence of the others. But there are also identified growth factors that can evoke all four components of the angiogenic response together. Foremost among these factors is a protein known as *vascular endothelial growth factor*(VEGF - a distant relative of platelet-derived growth factor [PDGF]). This acts selectively on endothelial cells to stimulate angiogenesis in many different circumstances, and it seems to be the agent by which some tumors acquire their rich blood supply. Other growth factors, including some members of the *fibroblast growth factor* family, also stimulate angiogenesis but at the same time influence other cell types besides endothelial cells. Angiogenic factors such as these are released during tissue repair, inflammation, and tissue growth; they are made by various cell types, including macrophages,

mast cells, and fat cells. A number of natural inhibitors have also been identified that can block the formation of new blood vessels. Thus angiogenesis, like the control of cell proliferation in general, seems to be regulated by complex combinations of signals rather than by one signal alone.

Summary

Most populations of differentiated cells in vertebrates are subject to turnover through cell death and cell division. In some cases, such as that of hepatocytes in the liver, the fully differentiated cells simply divide to produce daughter cells of the same type. Both the proliferation and the survival of hepatocytes are controlled to maintain appropriate total cell numbers. If a large part of the liver is destroyed, the remaining hepatocytes increase their division rate to restore the loss; and if hepatocyte proliferation is transiently increased by drug treatment, the increase in cell numbers is soon compensated for by an increase in cell death, returning cell numbers to normal. Such control mechanisms normally keep the numbers of cells of each type in a tissue in appropriate balance. In response to unusual damage, however, repair may be unbalanced, as when the fibroblasts in a repeatedly damaged liver grow too rapidly in relation to the hepatocytes and replace them with connective tissue.

Endothelial cells form a single cell layer that lines all blood vessels and regulates exchanges between the bloodstream and the surrounding tissues. New blood vessels develop from the walls of existing small vessels by the outgrowth of endothelial cells, which have the capacity to form hollow capillary tubes even when isolated in culture. In the living animal anoxic, damaged, or growing tissues stimulate angiogenesis by releasing angiogenic growth factors. These factors attract nearby endothelial cells and stimulate them to secrete proteases, to proliferate, and to form new capillaries.

Figure 22-13. Angiogenesis. A new blood capillary forms by the sprouting of an endothelial cell from the wall of an existing small vessel. This schematic diagram is based on observations of cells in the transparent tail of a living tadpole. (After C.C. Speidel, *Am. J. Anat.* 52:1-79, 1933.)
Figure 22-14. Capillary formation *in vitro*. Endothelial cells in culture spontaneously develop internal vacuoles that join up, giving rise to a network of capillary tubes. Photographs (A) and (B) show successive stages in the process; the arrow in (A) indicates a vacuole forming initially in a single endothelial cell. The cultures are set up from small patches of two to four endothelial cells taken from short segments of capillary. These cells will settle on the surface of a collagen-coated culture dish and form a small flattened colony that enlarges gradually as the cells proliferate. The colony spreads across the dish, and eventually, after about 20 days, capillary tubes begin to form in the central regions. Once tube formation has started, branches soon appear, and after 5 to 10 more days an extensive network of tubes is visible, as seen in (B). (From J. Folkman and C. Haudenschild, *Nature* 288:551-556, 1980. © Macmillan Journals Ltd.)
Figure 22-15. New capillary formation in response to wounding. Scanning electron micrographs of casts of the system of blood vessels surrounding the margin of the cornea show the reaction to wounding. The casts are made by injecting a resin into the vessels and letting the resin set; this reveals the shape of the lumen, as opposed to the shape of the cells. Sixty hours after

wounding many new capillaries have begun to sprout toward the site of injury, which is just above the top of the picture. Their oriented outgrowth reflects a chemotactic response of the endothelial cells to an angiogenic factor released at the wound. (Courtesy of Peter C. Burger.)

Renewal by Stem Cells: Epidermis 7, 15

Introduction

We turn now from cell populations that are renewed by simple duplication to those that are renewed by means of stem cells. These populations vary widely - not only in cell character and rate of turnover, but also in the geometry of cell replacement. In the lining of the small intestine, for example, cells are arranged as a single-layered epithelium. This epithelium covers the surfaces of the *villi* that project into the lumen of the gut, and it lines the *crypts* that descend into the underlying connective tissue (Figure 22-16). The stem cells lie in a protected position in the depths of the crypts. The differentiated cells generated from them are carried upward by a sliding movement in the plane of the epithelial sheet until they reach the exposed surfaces of the villi; at the tips of the villi the cells die and are shed into the lumen of the gut. A contrasting example is found in the epithelium that forms the outer covering of the skin, called the *epidermis.* The epidermis is a many-layered epithelium, and the differentiating cells travel outward from their site of origin in a direction perpendicular to the plane of the cell sheet. In the case of blood cells the spatial pattern of production is complex and appears chaotic. Before going into such details, however, we must pause to consider what a stem cell is.

Stem Cells Can Divide Without Limit and Give Rise to Differentiated Progeny 16

The defining properties of a stem cell are as follows:

1. It is not itself terminally differentiated (that is, it is not at the end of a pathway of differentiation).

2. It can divide without limit (or at least for the lifetime of the animal).

3. When it divides, each daughter has a choice: it can either remain a stem cell, or it can embark on a course leading irreversibly to terminal differentiation (Figure 22-17).

Stem cells are required wherever there is a recurring need to replace differentiated cells that cannot themselves divide. In several tissues the terminal state of cell differentiation is obviously incompatible with cell division. The cell nucleus may be digested, for example, as in the outermost layers of the skin, or it may be extruded, as in the mammalian red blood cell. Alternatively, the cytoplasm may be heavily encumbered with structures, such as the myofibrils of striated muscle cells, that would hinder mitosis and cytokinesis. In other terminally differentiated cells the chemistry of differentiation may be incompatible with cell division in some more subtle way. In any such case, renewal must depend on stem cells.

The job of the stem cell is not to carry out the differentiated function but rather to produce cells that will. Consequently, stem cells often have a non-descript appearance, making them hard to identify. But that is not to say that stem cells are all alike. Although not terminally differentiated, they are nevertheless *determined* (see p. 1060): the muscle satellite cell, as a source of skeletal muscle; the epidermal stem cell, as a source of keratinized epidermal cells; the spermatogonium, as a source of spermatozoa; the basal cell of olfactory epi-thelium, as a source of olfactory neurons (Figure 22-18); and so on. Those stem cells that give rise to only one type of differentiated cell are called *unipotent,* and those that give rise to several cell types are called *pluripotent.*

Tissues that form from stem cells raise many important questions. We need to consider what factors determine whether a stem cell divides or stays quiescent, what decides whether a given daughter cell remains a stem cell or differentiates, and in what ways the differentiation of a daughter cell is regulated after it has become committed to differentiate. On the opposite side of the balance sheet, we have to consider how cells die and are disposed of and how their survival is controlled. We begin our discussion with the epidermis, for its simple spatial organization makes it relatively easy to study the natural history of its stem cells and the fate of their progeny.

Epidermal Stem Cells Lie in the Basal Layer 17, 18

The epidermal layer of the skin and the epithelial lining of the digestive tract are the two tissues that suffer the most direct and damaging encounters with the external world. In both, mature differentiated cells are rapidly lost from the most exposed positions and are replaced by the proliferation of less differentiated cells in more sheltered niches.

The epidermis is a multilayered epithelium composed largely of *keratinocytes* (so called because their characteristic differentiated activity is the synthesis of intermediate filament proteins called *keratins*) (Figure 22-19). These cells change their appearance from one layer to the next. Those in the innermost layer, attached to an underlying basal lamina, are termed *basal cells,* and it is normally only these that undergo mitosis. Above the basal cells are several layers of larger *prickle cells* (Figure 22-20), whose numerous desmosomes - each a site of anchorage for thick tufts of keratin filaments - are just visible in the light microscope as tiny prickles around the cell surface (hence the name). Beyond the prickle cells lies the thin granular cell layer (see Figure 22-19). This marks the boundary between the inner, metabolically active strata and the outermost layer, consisting of dead cells whose intracellular organelles have disappeared. These outermost cells are reduced to flattened scales, or *squames,* filled with densely packed keratin. The plasma membranes of both the squames and the outer granular cells are reinforced on their cytoplasmic surface by a thin (12-nm), tough, cross-linked layer containing an intracellular protein called *involucrin.* The squames themselves are normally so compressed and thin that their boundaries are hard to make out in the light microscope, but soaking in sodium hydroxide makes them swell slightly, and with suitable staining a remarkably ordered geometric arrangement can often be seen in regions where the skin is thin. The squames are found to be stacked in hexagonal columns that interlock neatly at their edges (Figure 22-21), a typical column being 10-20 cells high and resting on about 10 basal cells.

Differentiating Epidermal Cells Synthesize a Sequence of Different Keratins as They Mature 18

Having described the static picture, let us now set it in motion. While some basal cells are dividing, adding to the population in the basal layer, others (their sisters or cousins) are slipping out of the basal cell layer into the prickle cell layer, taking the first step on their outward journey. When they reach the granular layer, the cells start to lose their nuclei and cytoplasmic organelles and are transformed into the keratinized squames of the keratinized layer. These finally flake off from the surface of the skin (and become a main constituent of household dust). The period from the time a cell is born in the basal layer of the human skin to the time it is shed from the surface varies from 2 to 4 weeks, depending on the region of the body.

The accompanying molecular transformations can be studied by analyzing either thin slices of epidermis cut parallel to the surface or successive layers of cells stripped off by repeatedly applying and removing strips of adhesive tape. The keratin molecules, for example, which are plentiful in all layers of the epidermis, can be extracted and characterized. They are of many types (discussed in Chapter 16), encoded by a large family of homologous genes, with the variety further increased through alternative splicing of the gene transcripts. As the new keratinocyte at the base of the column is transformed into the squame at the top (see Figure 22-21), it expresses a succession of different selections from its keratin gene repertoire. During this process other characteristic proteins, such as involucrin, also begin to be synthesized as part of a coordinated program of terminal cell differentiation.

Epidermal Stem Cells Are a Subset of Basal Cells 19

If each patch of epidermis is maintained indefinitely by proliferation of its basal cells, there must be among these basal cells at least one whose line of descendants will not die out in the lifetime of the animal. We shall call such a cell an *immortal stem cell* (Figure 22-22). In principle, the division of an immortal stem cell could generate two initially similar daughters whose different fates would be governed by subsequent circumstances. At the opposite extreme, the stem cell division could be always asymmetric: one and only one of the daughters would inherit a special character required for immortality, while the other would be somewhat altered already at the time of its birth in a way that forced it to differentiate and ultimately to die. In the latter case there could never be any increase in the existing number of immortal stem cells, and this is contradicted by the facts. If a patch of epidermis is destroyed, the damage is repaired by surrounding healthy epidermal cells that migrate and proliferate to cover the denuded area. In this process a new self-renewing patch of epidermis is established, implying that additional immortal stem cells have been generated to make up for the loss.

Thus the fate of the daughters of a stem cell must be governed at least partly by the circumstances. One possible determining factor might be contact with the basal lamina or with the exposed connective tissue at a wound, with a loss of contact triggering the start of terminal differentiation, and maintenance of contact tending to preserve stem cell potential. Studies *in vitro* indicate that this is not the only determinant of basal cell fate, however.

Basal keratinocytes can be dissociated from intact epidermis and will proliferate in a culture dish, giving rise to new basal cells

and to terminally differentiated cells. Even within a population of cultured basal keratinocytes that all appear undifferentiated, there is great variation in the ability to proliferate. When cells are taken singly and tested for their ability to found new colonies, some appear unable to divide at all, others go through only a few division cycles and then halt, and still others can divide enough times to form large colonies. The basal cells differ also in their expression of extracellular matrix receptors of the integrin family (discussed in Chapter 19): the cells that have more of these receptors, and so are better able to bind to basal laminal components, are the ones with the greater proliferative potential. This suggests that not all basal cells are alike *in vivo* and that mere contact with the basal lamina is not enough to keep them as stem cells. Rather, it appears that stem cells are a small subset - about 10% of the basal cell population and are programmed to generate a certain proportion of progeny that become committed to terminal differentiation even before they have left the basal layer. In fact, if the keratinocytes are cultured in a Ca^{2+}-deficient medium, which keeps them as a monolayer and therefore all in a basal position, some of them will actually embark on terminal differentiation despite their location, as indicated by the synthesis of involucrin; these differentiating cells emerge from the basal layer as soon as the Ca^{2+} concentration is raised.

Nevertheless, contact with extracellular matrix has a critical influence on the choice of cell fate, which is evidently not programmed rigidly. If the cells are held in suspension, instead of being allowed to settle and attach to the bottom of the culture dish, they all stop dividing and differentiate. Some of the cells will refrain from differentiating even in suspension, however, if the medium includes fibronectin (a minor component of basal lamina and a major component of the extracellular matrix that keratinocytes migrate onto during wound healing). The cells that show this response to fibronectin are those that possess appropriate integrins. In normal conditions possession of such receptors presumably holds the cells bound to the basal lamina, keeping open their option to remain as stem cells; loss or inactivation of the receptors leads to ejection from the basal layer, confirming the decision to differentiate; and ejection from the basal layer through other causes leads to loss of the receptors, forcing the cell to differentiate prematurely.

Basal Cell Proliferation Is Regulated According to the Thickness of the Epidermis [20]

Whatever the influence of the basal lamina may be, additional controls must operate to regulate the rate of production and the rate of sloughing of epidermal cells. If the outer layers of the epidermis are stripped away, for example, the division rate of the basal cells increases. After a transient overshoot, normal thickness is restored, and the division rate in the basal layer declines to normal. It is as though the removal of the outer differentiated layers releases the cells in the proliferative basal layer from an inhibitory influence, which is restored as soon as the outer layers regain their full thickness.

Although keratinocytes in culture are known to respond to a variety of hormones and growth factors, including epidermal growth factor (EGF), the molecular mechanisms that regulate their proliferation in the body remain an unsolved problem of great clinical importance. The consequences of faulty control of basal cell proliferation are seen in *psoriasis.* In this common skin disorder the rate of basal cell proliferation is greatly increased - the epidermis thickens, and cells are shed from the surface of the skin within as little as a week after emerging from the basal layer, before they have had time to keratinize fully.

Secretory Cells in the Epidermis Are Secluded in Glands That Have Their Own Population Kinetics [21]

In certain specialized regions of the body surface other types of cells besides the keratinized cells described above develop from the embryonic epidermis. In particular, secretions such as sweat, tears, saliva, and milk are produced by cells segregated in deep-lying glands that originate as ingrowths of the epidermis but have patterns of renewal quite different from those of keratinizing regions.

The mammary gland is of special interest because of the hormonal control of its cell division and differentiation. Milk production must be switched on when a baby is born and switched off when the baby is weaned. A "resting" mammary gland consists of branching systems of ducts embedded in connective tissue; these ducts are lined, in their secretory portions, by a single layer of relatively inactive epithelial cells that serve as stem cells. As a first step toward large-scale milk production, the hormones that circulate during pregnancy cause the duct cells to proliferate and the terminal portions of the ducts to grow and branch, forming little dilated outpocketings, or *alveoli,* containing secretory cells (Figure 22-23). Milk secretion begins only when these cells are stimulated by the different combination of hormones circulating in the mother after the birth of the baby. Later, when suckling stops, the secretory cells die and most of the alveoli disappear; macrophages rapidly clear away the dead cells, and the gland reverts to its resting state. Degradation of the basal lamina seems to play a critical part in this process of *involution.*

Cell division in the mammary gland is regulated not only by hormones but also by local signals passing between cells within the

epithelium and between the epithelial cells and the connective tissue, or *stroma,* in which the epithelial cells are embedded. Mutations in genes involved in these local controls promote the development of cancer, as we discuss in Chapter 24, and it is through studies of breast cancer that several of these control mechanisms have come to light.

Summary

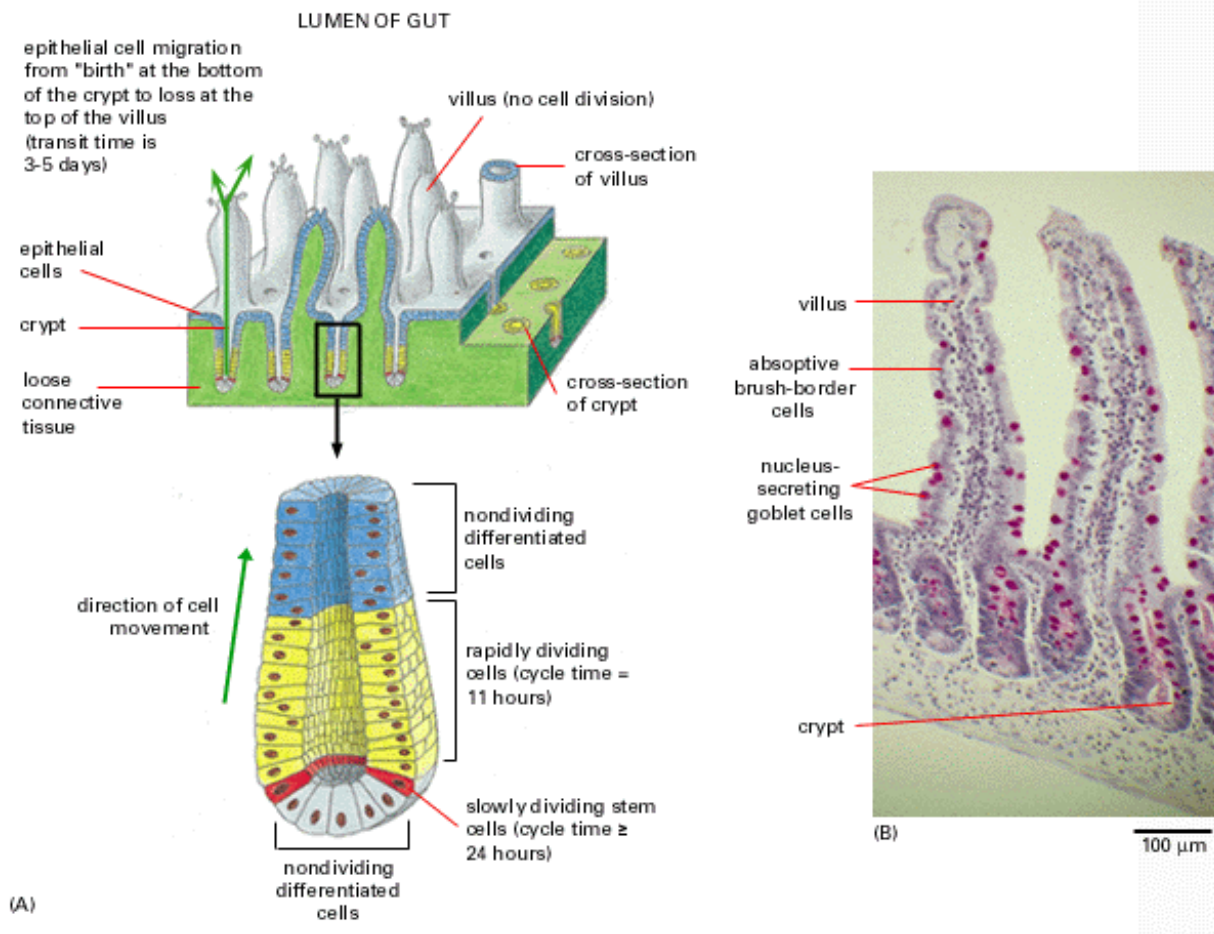
Many tissues, especially those with a rapid turnover - such as the lining of the gut, the epidermal layer of the skin, and the blood-forming tissues - are renewed by means of stem cells. Stem cells, by definition, are not terminally differentiated and have the ability to divide throughout the lifetime of the organism, yielding some progeny that differentiate and others that remain stem cells. In the skin the stem cells of the epidermis lie in the basal layer, attached to the basal lamina. The progeny of the stem cells differentiate on leaving this layer and, as they move outward, synthesize a succession of different types of keratin until, eventually, their nuclei degenerate, producing an outer layer of dead keratinized cells that are continually shed from the surface. Only a minority of basal cells are stem cells. The fate of the daughters of a stem cell is controlled in part by interactions with the basal lamina and in part by other poorly understood factors. These factors allow two stem cells to be generated from one during repair processes, and they regulate the rate of basal cell proliferation according to the thickness of the epidermis. Glands connected to the epidermis, such as the mammary glands, have their own stem cells and their own distinct patterns of cell renewal.


Figure 22-16. Renewal of the gut lining. (A) The pattern of cell turnover and the proliferation of stem cells in the epithelium that forms the lining of the small intestine. The nondividing differentiated cells at the base of the crypts also have a finite lifetime, terminated by programmed cell death, and are continually replaced by progeny of the stem cells. (B) Photograph of a section of part of the lining of the small intestine, showing the villi and crypts. Note how mucus-secreting goblet cells (stained *red*) are interspersed among the absorptive brush-border cells in the epithelium of the villi. See Figure 22-9 for the structure of these cells.
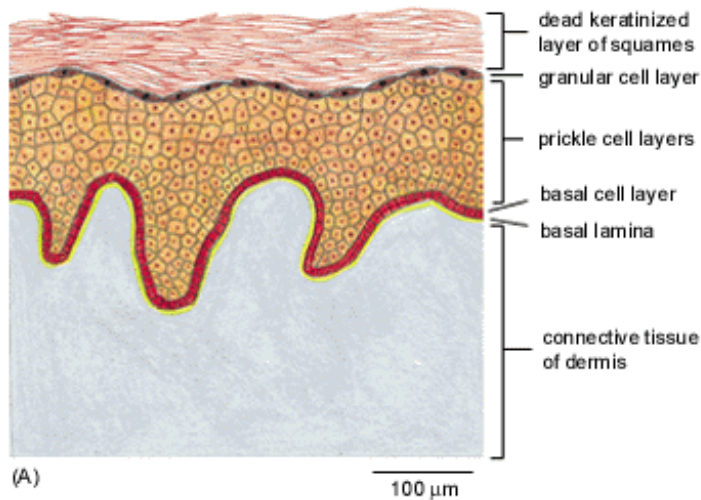
Figure 22-18. A schematic cross-section of olfactory epithelium. In this epithelium, which is specialized for sensing smells, three cell types can be distinguishedsupporting cells, basal cells, and olfactory neurons. Autoradiographic experiments show that the basal cells are the stem cells for production of the olfactory neurons, which constitute one of the very few exceptions to the rule that neurons are permanent cells. Each olfactory neuron survives for about a month (in a mammal) before it is replaced. Six to eight modified cilia project from the globular head of the olfactory neuron and are believed to contain the smell receptors. The axon extending from the other end of the neuron conveys the message to the brain. A new axon must grow out and make appropriate connections in the brain whenever a basal cell differentiates into an olfactory neuron.


Figure 22-19. Cross-section of mammalian epidermis. (A) Schematic diagram. (B) Photomicrograph of a section through the sole of the foot (hematoxylin and Van Gieson stain). The *granular cells* between the prickle cells and the flattened squames are in the penultimate stages of keratinization; they appear granular because they contain darkly staining aggregates of a material called *keratohyalin,* which is thought to be involved in the intracellular compaction and cross-linking of the keratin. Keratohyalin consists mainly of a protein known as *filaggrin.* In addition to the cells destined for keratinization, the deep layers of the epidermis include small numbers of cells of different character (not shown here) - including macrophagelike *Langerhans* cells, derived from bone marrow; *melanocytes,* derived from the neural crest; and *Merkel cells,* which are associated with nerve endings in the epidermis. See also Figure 22-1.
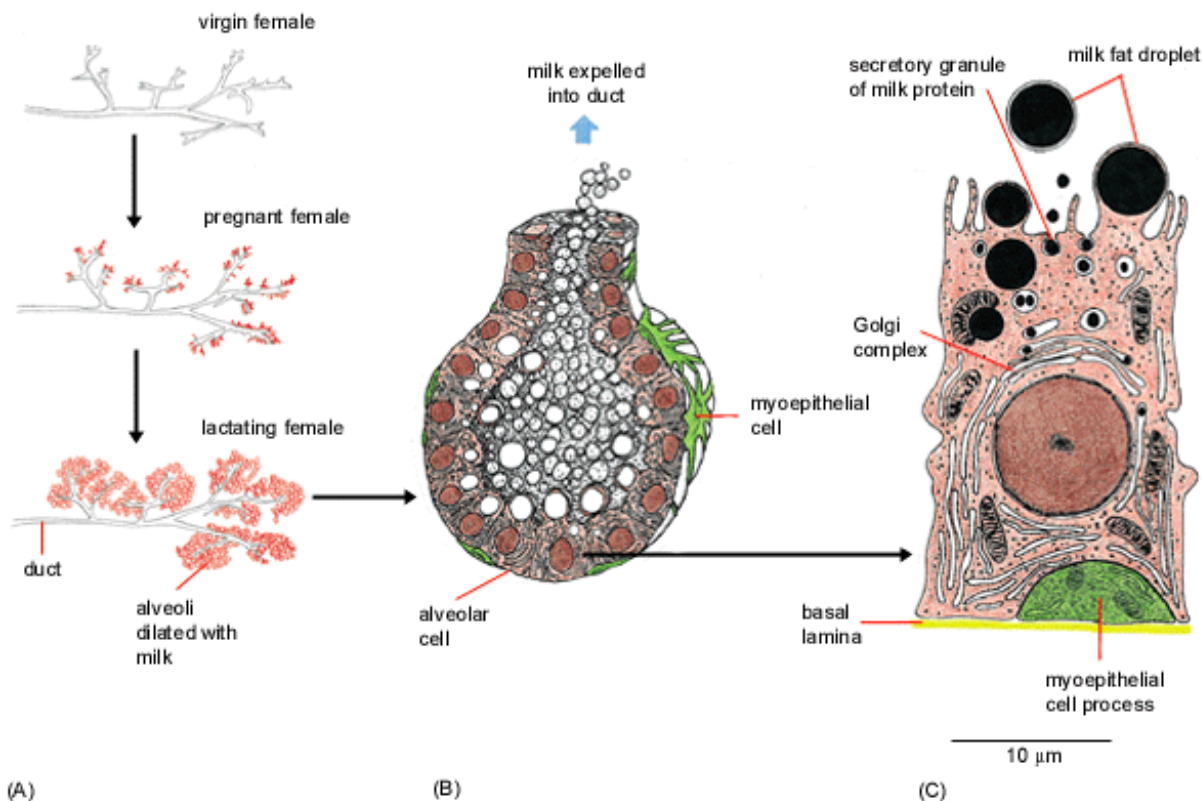
Figure 22-20. A prickle cell. Drawing from an electron micrograph of a section of the epidermis, showing the bundles of keratin filaments that traverse the cytoplasm and are inserted at the desmosome junctions that bind the prickle cell (*red*) to its neighbors. Note that between adjacent cells there are open channels that allow nutrients to diffuse freely through the metabolically active layers of the epidermis. Further out, at the level of the granular cells, there is a waterproof barrier that is thought to be created by a sealant material that the granular cells secrete from vesicles called *membrane-coating granules.* (From R.V. Krstić, Ultrastructure of the Mammalian Cell: An Atlas. Berlin: Springer, 1979.)
Figure 22-21. The columnar organization of squames in the epidermal layer of thin skin. The structure is revealed by swelling the keratinized squames in a solution containing sodium hydroxide. This type of organization occurs only where the epidermis is thin. Some studies suggest that each such column is a "proliferative unit," corresponding to a single stem cell among the 10-12 basal cells on which the column rests.
Figure 22-22. An immortal stem cell. Each self-renewing patch of epidermis must contain in each cell generation at least one "immortal" stem cell, whose descendants will still be present in the patch in the distant future. The arrows indicate lines of descent. An immortal stem cell is shown here occupying the same position in each cell generation. Other basal cells might be born chemically different in a way that commits them to leave the basal layer and differentiate; or they too might be stem cells, equivalent to the immortal stem cell in character and mortal only in the sense that their progeny happen subsequently to be jostled out of the basal layer and shed from the skin.


Figure 22-23. The mammary gland. (A) Schematic diagram of the growth of alveoli from the ducts of the mammary gland during pregnancy and lactation. Only a small part of the gland is shown. The "resting" gland contains a small amount of inactive glandular tissue embedded in a large amount of fatty connective tissue . During pregnancy an enormous proliferation of the glandular tissue takes place at the expense of the fatty connective tissue, with the secretory portions of the gland developing preferentially to create alveoli. (B) One of the milk-secreting alveoli with a basket of *myoepithelial cells* (*green*) embracing it. The myoepithelial cells contract and expel milk from the alveolus in response to the hormone oxytocin, which is released as a reflex response to the stimulus of suckling. (C) A single type of secretory alveolar cell produces both the milk proteins and the milk fat. The proteins are secreted in the normal way by exocytosis, while the fat is released as droplets surrounded by plasma membrane detached from the cell. (B, after R. Krsti'c, from D.W. Fawcett, A Textbook of Histology, 11th ed. Philadelphia: Saunders, 1986.)

Renewal by Pluripotent Stem Cells: Blood Cell Formation <u>22</u>, <u>23</u>

Introduction

The blood contains many types of cells with very different functions, ranging from the transport of oxygen to the production of antibodies. Some of these cells function entirely within the vascular system, while others use the vascular system only as a means of transport and perform their function elsewhere. All blood cells, however, have certain similarities in their life history. They all have limited life-spans and are produced throughout the life of the animal. Most remarkably, they are all generated ultimately from a common stem cell in the bone marrow. This *hemopoietic* (or blood-forming) *stem cell* is thus pluripotent, giving rise to all of the types of terminally differentiated blood cells as well as some other types of cells, such as bone osteoclasts, which we discuss later.

Blood cells can be classified as red or white (<u>Figure 22-24</u>). The red blood cells, or erythrocytes, remain within the blood vessels and transport O_2 and CO_2 bound to hemoglobin. The white blood cells, or leucocytes, combat infection and in some cases phagocytose and digest debris. Leucocytes, unlike erythrocytes, must make their way across the walls of small blood vessels and migrate into tissues to perform their tasks. In addition, the blood contains large numbers of *platelets,* which are not entire cells but small detached cell fragments or "minicells" derived from the cortical cytoplasm of large cells called *megakaryocytes.* Platelets adhere specifically to the endothelial cell lining of damaged blood vessels, where they help repair breaches and aid in the process of blood clotting.

There Are Three Main Categories of White Blood Cells: Granulocytes, Monocytes, and Lymphocytes [22], [23]

All red blood cells are similar to one another, as are all platelets, but there are many distinct types of white blood cells. They are traditionally grouped into three major categories, called granulocytes, monocytes, and lymphocytes, on the basis of their appearance in the light microscope.

The granulocytes all contain numerous lysosomes and secretory vesicles (or granules) and are subdivided into three classes on the basis of the morphology and staining properties of these organelles (Figure 22-25). The differences in staining reflect major differences of chemistry and function. *Neutrophils*(also called *polymorphonuclear leucocytes* because of their multilobed nucleus) are the most common type of granulocyte; they phagocytose and destroy small organisms - especially bacteria. *Basophils*secrete histamine (and, in some species, serotonin) to help mediate inflammatory reactions; they are closely related in function to *mast cells,* which reside in connective tissues but are also generated from the hemopoietic stem cells. *Eosinophils*help destroy parasites and modulate allergic inflammatory responses.

Once they leave the bloodstream, monocytes (see Figure 22-25D) mature into *macrophages,*which together with neutrophils are the main "professional phagocytes" in the body. As discussed in Chapter 13, both types of phagocytic cells contain specialized lysosomes that fuse with newly formed phagocytic vesicles (phagosomes), exposing phagocytosed microorganisms to a barrage of enzymatically produced, highly reactive molecules of superoxide (O_2^-) and hypochlorite (HOCl, the active ingredient in bleach), as well as to a concentrated mixture of lysosomal hydrolases. Macrophages, however, are much larger and longer lived than neutrophils. They are responsible for removing senescent, dead, and damaged cells in many tissues, and they are unique in being able to ingest large microorganisms such as protozoa.

There are two main classes of lymphocytes, both involved in immune responses: *B lymphocytes* make antibodies, while *T lymphocytes* kill virus-infected cells and regulate the activities of other white blood cells. In addition, there are lymphocytelike cells called *natural killer (NK)*cells, which kill some types of tumor cells and some virus-infected cells. The production of lymphocytes is a specialized topic that is discussed in detail in Chapter 23. Here we shall concentrate mainly on the development of the other blood cells, often referred to collectively as myeloid cells.

The various types of blood cells and their functions are summarized in Table 22-1.

The Production of Each Type of Blood Cell in the Bone Marrow Is Individually Controlled [22], [24]

Most white blood cells function in tissues other than the blood. The blood simply transports them to where they are needed. A local infection or injury in any tissue rapidly attracts white blood cells into the affected region as part of the inflammatory response, which helps fight the infection or heal the wound. The inflammatory response is complex and is mediated by a variety of signaling molecules produced locally by mast cells, nerve endings, platelets, and white blood cells, as well as by the activation of complement (discussed in Chapter 23). Some of these signaling molecules act on nearby capillaries, causing the endothelial cells to adhere less tightly to one another but making their surfaces adhesive to passing white blood cells. The white blood cells are thus caught like flies on flypaper and then can escape from the vessel by squeezing between the endothelial cells and crawling across the basal lamina with the aid of digestive enzymes; the initial binding to endothelial cells is mediated by *selectins* (discussed in Chapter 10), and the stronger binding required for the white blood cells to crawl out of the blood vessel is mediated by *integrins* (discussed in Chapter 19). Other molecules act as chemoattractants for specific types of white blood cells, causing these cells to become polarized and crawl toward the source of the attractant. As a result, large numbers of white blood cells enter the affected tissue (Figure 22-26).

Other signaling molecules produced in the course of an inflammatory response escape into the blood and stimulate the bone marrow to produce more leucocytes and release them into the bloodstream. The bone marrow is the key target for such regulation because, with the exception of lymphocytes and some macrophages, most types of blood cells in adult mammals are generated only in the bone marrow. The regulation tends to be cell-type-specific: some bacterial infections, for example, cause a selective increase in neutrophils, while infections with some protozoa and other parasites cause a selective increase in eosinophils. (For this reason, physicians routinely use differential white blood cell counts to aid in the diagnosis of infectious and other inflammatory diseases.)

In other circumstances erythrocyte production is selectively increased - for example, if one goes to live at high altitude, where oxygen is scarce. Thus blood cell formation (hemopoiesis) necessarily involves complex controls in which the production of

each type of blood cell is regulated individually to meet changing needs. It is a problem of great medical importance to understand how these controls operate, and much progress has been made in this area in recent years.

In intact animals hemopoiesis is more difficult to analyze than is cell turnover in a tissue such as the epidermal layer of the skin. In epidermis there is a simple, regular spatial organization that makes it easy to follow the process of renewal and to locate the stem cells. This is not true of the hemopoietic tissues. On the other hand, the hemopoietic cells have a nomadic life-style that makes them more accessible to experimental study in other ways. Dispersed hemopoietic cells can be easily transferred, without damage, from one animal to another, and the proliferation and differentiation of individual cells and their progeny can be observed and analyzed in culture. Because of this, more is known about the molecules that control blood cell production than about those that control cell production in other mammalian tissues.

Bone Marrow Contains Hemopoietic Stem Cells <u>22</u>, <u>25</u>

The different types of blood cells and their immediate precursors can be recognized in the bone marrow by their distinctive appearances (<u>Figure 22-27</u>). They are intermingled with one another, as well as with fat cells and other *stromal cells* (connective-tissue cells) that produce a delicate supporting meshwork of collagen fibers and other extracellular-matrix components. In addition, the whole tissue is richly supplied with thin-walled blood vessels (called *blood sinuses*) into which the new blood cells are discharged. Megakaryocytes are also present; these, unlike other blood cells, remain in the bone marrow when mature and are one of its most striking features, being extraordinarily large (diameter up to 60 mm), with a highly polyploid nucleus. They normally lie close beside blood sinuses, and they extend processes through holes in the endothelial lining of these vessels; platelets pinch off from the processes and are swept away into the blood (<u>Figure 22-28</u>).

Because of the complex arrangement of the cells in bone marrow, it is difficult to identify any but the immediate precursors of the mature blood cells. The corresponding cells at still earlier stages of development, before any overt differentiation has begun, are confusingly similar in appearance, and there is no visible feature by which the ultimate stem cells can be recognized. To identify and characterize the stem cells, one needs a functional test, which involves tracing the progeny of single cells. As we shall see, this can be done *in vitro* simply by examining the colonies that isolated cells produce in culture. The hemopoietic system, however, can also be manipulated so that such clones of cells can be recognized *in vivo* in the intact animal.

If an animal is exposed to a large dose of x-irradiation, most of the hemopoietic cells are destroyed and the animal dies within a few days as a result of its inability to manufacture new blood cells. The animal can be saved, however, by a transfusion of cells taken from the bone marrow of a healthy, immunologically compatible donor. Among these cells there are small numbers (about 1 cell in 10,000) that can colonize the irradiated host and permanently reequip it with hemopoietic tissue. One of the tissues where colonies develop is the spleen, which in a normal mouse is an important additional site of hemopoiesis. When the spleen of an irradiated mouse is examined a week or two after the transfusion of cells from a healthy donor, a number of distinct nodules are seen in it, each of which is found to contain a colony of myeloid cells (<u>Figure 22-29</u>); after 2 weeks some colonies may contain more than a million cells. The discreteness of the nodules suggests that each might be a clone of cells descended from a single founder cell, like a bacterial colony on a culture plate; and with the help of genetic markers, it can be established that this is indeed the case.

The founder of such a colony is called a colony-forming cell, or CFC (also known as a colony-forming unit, CFU). The colony-forming cells are heterogeneous. Some give rise to only one type of myeloid cell, while others give rise to mixtures. Some go through many division cycles and form large colonies, while others divide less and form small colonies. Most of the colonies die out after generating a restricted number of terminally differentiated blood cells. A few of the colonies, however, are capable of extensive self-renewal and produce new colony-forming cells in addition to terminally differentiated blood cells. The founders of such self-renewing colonies are assumed to be the hemopoietic stem cells in the transfused bone marrow.

A Pluripotent Stem Cell Gives Rise to All Classes of Blood Cells <u>26</u>

All the types of myeloid cells can often be found together in one spleen colony, derived from a single stem cell. The hemopoietic stem cell, therefore, is *pluri-potent:* it can give rise to many cell types. Although the spleen colonies do not seem to contain lymphocytes, another approach shows that these cells also derive from the same stem cell that gives rise to all of the myeloid cells. The demonstration employs genetic markers that make it possible to identify the members of a clone even after they have been released into the bloodstream. Although several types of clonal markers have been used for this, a specially engineered retrovirus (a *retroviral vector* carrying a marker gene) serves the purpose particularly well. The marker virus, like other retroviruses, can insert its own genome into the chromosomes of the cell it infects, but the genes that would enable it to

generate new infectious virus particles have been removed. The marker, therefore, is confined to the progeny of the cells that were originally infected, and the progeny of one such cell can be distinguished from the progeny of another because the chromosomal sites of insertion of the virus are different. To analyze hemopoietic cell lineages, bone marrow cells are first infected with the retroviral vector *in vitro* and then are transferred into a lethally irradiated recipient; DNA probes can then be used to trace the progeny of individual infected cells in the various hemopoietic and lymphoid tissues of the host.

These experiments not only confirm that all classes of blood cells - both myeloid and lymphoid - derive from a common stem cell (Figure 22-30), but they also make it possible to follow the pedigrees of the blood cells over long periods of time. After many months, when the hemopoietic system has had time to stabilize fully following the transfusion, practically all of the blood cells in the irradiated host mouse are found to be descendants of a remarkably small number - sometimes as few as a single one - of the original transfected cells. A single pluripotent stem cell evidently has the capacity to generate an indefinitely large clone of progeny, among them, presumably, many daughter stem cells with a similar capacity, as well as cells that are terminally differentiated.

The Number of Specialized Blood Cells Is Amplified by Divisions of Committed Progenitor Cells 22, 27

Once a cell has differentiated as an erythrocyte or a granulocyte or some other type of blood cell, there seems to be no going back: the state of differentiation is not reversible. Therefore, at some stage in their development, some of the progeny of the pluripotent stem cell must become irreversibly committed or determined for a particular line of differentiation. It is clear from simple microscopic examination of the bone marrow that this commitment occurs well before the final division in which the mature differentiated cell is formed: one can recognize specialized precursor cells that are still proliferating but already show signs of having begun differentiation. It thus appears that commitment to a particular line of differentiation is followed by a series of cell divisions that amplify the number of cells of a given specialized type.

The hemopoietic system, therefore, can be viewed as a hierarchy of cells. Pluripotent stem cells give rise to committed progenitor cells, which are irreversibly determined as ancestors of only one or a few blood cell types. The committed progenitors divide rapidly but only a limited number of times. At the end of this series of *amplification divisions,* they develop into terminally differentiated cells, which usually divide no further and die after several days or weeks. Cells may also die at any of the earlier steps in the pathway. Studies in culture provide a way to find out how these cellular events - proliferation, differentiation, and death - are regulated.

The Factors That Regulate Hemopoiesis Can Be Analyzed in Culture 28

Hemopoietic cells will survive, proliferate, and differentiate in culture if, and only if, they are provided with specific growth factors or accompanied by cells that produce these factors; if deprived of such factors, the cells die. Long-term proliferation of pluripotent stem cells can be achieved, for example, by culturing dispersed bone-marrow hemopoietic cells on top of a layer of bone-marrow stromal cells, presumably mimicking the environment in intact bone marrow; such cultures can generate all the types of myeloid cells. Alternatively, dispersed bone-marrow hemopoietic cells can be cultured in a semisolid matrix of dilute agar or methylcellulose, and factors derived from other cells can be added artificially to the medium. Because cells in the semisolid matrix cannot migrate, the progeny of each isolated precursor cell remain together as an easily distinguishable colony. A single committed neutrophil progenitor, for example, may be seen to give rise to a clone of thousands of neutrophils. Such culture systems, developed in the mid-1960s, provide a way to assay for the factors that support hemopoiesis and hence to purify them and explore their actions. These substances are found to be glycoproteins and are usually called colony-stimulating factors, or CSFs. Of the growing number of CSFs that have been defined and purified, some circulate in the blood and act as hormones, while others act in the bone marrow either as secreted local mediators or as membrane-bound signals that act through cell-cell contact. The best understood of the CSFs that act as hormones is the glycoprotein *erythropoietin,* which is produced in the kidney and regulates *erythropoiesis* (the formation of red blood cells).

Erythropoiesis Depends on the Hormone Erythropoietin 29

The erythrocyte is by far the most common type of cell in the blood (see Table 22-1). When mature, it is packed full of hemoglobin and contains practically none of the usual cell organelles. In an erythrocyte of an adult mammal, even the nucleus, endoplasmic reticulum, mitochondria, and ribosomes are absent, having been extruded from the cell in the course of its development (Figure 22-31). The erythrocyte therefore cannot grow or divide; the only possible way of making more erythrocytes is by means of stem cells. Furthermore, erythrocytes have a limited life-span - about 120 days in humans or 55 days in mice. Worn-out erythrocytes are phagocytosed and digested by macrophages in the liver and spleen, which remove more than

10^{11} senescent erythrocytes in each of us each day.

A lack of oxygen or a shortage of erythrocytes stimulates cells in the kidney to synthesize and secrete increased amounts of erythropoietin into the bloodstream. The erythropoietin in turn stimulates the production of more erythrocytes. Since a change in the rate of release of new erythrocytes into the bloodstream is observed as early as 1 or 2 days after an increase in erythropoietin levels in the bloodstream, the hormone must act on cells that are very close precursors of the mature erythrocytes.

The cells that respond to erythropoietin can be identified by culturing bone marrow cells in a semisolid matrix in the presence of erythropoietin. In a few days colonies of about 60 erythrocytes appear, each founded by a single committed erythroid progenitor cell. This cell is known as an erythrocyte colony-forming cell, or CFC-E, and it gives rise to mature erythrocytes after about six division cycles or less. The CFC-Es do not yet contain hemoglobin, and they are derived from an earlier type of progenitor cell whose proliferation does not depend on erythropoietin. CFC-Es themselves depend on erythropoietin for their survival as well as for proliferation: if erythropoietin is removed from the cultures, the cells rapidly undergo programmed cell death.

A second CSF, called interleukin 3 (IL-3), promotes the survival and proliferation of the earlier erythroid progenitor cells. In its presence much larger erythroid colonies, each comprising up to 5000 erythrocytes, develop from cultured bone marrow cells in a process requiring a week or 10 days. These colonies derive from erythroid progenitor cells called erythrocyte burst-forming cells, or BFC-Es. The BFC-E is distinct from the pluripotent stem cell in that it has a limited capacity to proliferate and gives rise to colonies that contain erythrocytes only, even under culture conditions that enable other progenitor cells to give rise to other classes of differentiated blood cells. It is distinct from the CFC-E in that it is insensitive to erythropoietin, and its progeny must go through as many as 12 divisions before they become mature erythrocytes (for which erythropoietin must be present). The cell also differs in size from the CFC-E and can be separated from it by sedimentation. Thus the BFC-E is thought to be a progenitor cell committed to erythrocyte differentiation and an early ancestor of the CFC-E (Figure 22-32).

Multiple CSFs Influence the Production of Neutrophils and Macrophages [28], [30]

The two professional phagocytic cells, neutrophils and macrophages, develop from a common progenitor cell called the granulocyte/macrophage (or GM) progenitor cell. Like the other granulocytes (eosinophils and basophils), neutrophils circulate in the blood for only a few hours before migrating out of capillaries into the connective tissues or other specific sites, where they survive for only a few days and then die and are phagocytosed by macrophages. Macrophages, by contrast, can persist for months or perhaps even years outside the bloodstream, where they can be activated by local signals to resume proliferation.

At least seven distinct CSFs that stimulate neutrophil and macrophage colony formation in culture have been defined, and some or all of these are thought to act in different combinations to regulate the selective production of these cells *in vivo*. These CSFs are synthesized by various cell types - including endothelial cells, fibroblasts, macrophages, and lymphocytes - and their concentration in the blood typically increases rapidly in response to bacterial infection in a tissue, thereby increasing the number of phagocytic cells released from the bone marrow into the bloodstream. IL-3 is one of the least specific of the factors, acting on pluripotent stem cells as well as on most classes of committed progenitor cells, including GM-progenitor cells. Various other factors act more selectively on committed GM-progenitor cells and their differentiated progeny (Table 22-2), although in many cases they act on certain other branches of the hemopoietic family tree as well.

All of these CSFs, like erythropoietin, are glycoproteins that act at low concentrations ($\sim 10^{-12}$ M) by binding to specific cell-surface receptors, as discussed in Chapter 15. A few of these receptors are transmembrane tyrosine kinases. The others belong to another large receptor family (sometimes called the *cytokine receptor* family), whose members are usually composed of two or more subunits, one of which is frequently shared among several receptor types (Figure 22-33). The CSFs not only operate on the precursor cells to promote the production of differentiated progeny, they also activate the specialized functions (such as phagocytosis and target-cell killing) of the terminally differentiated cells. Proteins produced artificially from the cloned genes for these factors (sometimes referred to as *recombinant* factors because they are made using recombinant DNA technology) are strong stimulators of hemopoiesis in experimental animals. They are now being used in human patients to stimulate the regeneration of hemopoietic tissue and to boost resistance to infection - an impressive demonstration of how basic cell biological research and animal experiments can lead to better medical treatment.

Factors that promote the development of the other classes of myeloid cells, such as megakaryocytes and eosinophils, have also been identified. Again, there are many of these factors, and they have overlapping actions when tested in laboratory assay systems. It is not easy to discover precisely what their individual roles are in natural circumstances. Perhaps the most direct test of the normal function of a CSF is to inactivate the CSF or its receptor in a living animal and study the consequences. This has

now been done for several CSFs. Anti-G-CSF antibodies, which neutralize the activity of G-CSF - a CSF that promotes neutrophil production *in vitro* - have been shown to cause a marked decrease in neutrophils when injected into healthy dogs, establishing that G-CSF is required for the normal production of neutrophils. Genetic approaches can be even more powerful. Mice with a mutation in the gene that encodes M-CSF, for example, are deficient in macrophages, as well as in osteoclasts, which also develop from monocytes. Because osteoclasts are required for bone resorption (as we discuss later), these mice produce an excessive amount of bone, which encroaches on the bone marrow and produces abnormally thickened bones and decreased blood cell formation - a condition called *osteopetrosis.*

Hemopoietic Stem Cells Depend on Contact with Cells Expressing the Steel Factor [31]

CSFs that act on the pluripotent stem cells are the most intriguing of all. IL-3, as we have seen, seems to be in this class. Another such factor of fundamental importance came to light through the analysis of mouse mutants that show a curious combination of defects: a shortage of red blood cells (anemia), of germ cells (sterility), and of pigment cells (white spotting of the skin). As discussed in Chapter 21, this syndrome results from mutations in either of two genes: one, called *c-kit,* codes for a receptor tyrosine kinase; the other, called *Steel,* codes for its ligand. The cell types affected by the mutations all derive from migratory precursors, and it seems that these precursors in each case must express the receptor (Kit) and be provided with the ligand (Steel) by their environment if progeny cells are to be produced in normal numbers.

Like IL-3, the Steel factor acts on several of the committed blood-cell lineages, including the erythroid lineage, as well as on the pluripotent stem cells. But it has little effect on its own. It mainly potentiates the effects of other CSFs, greatly increasing the number and size of clonal blood-cell colonies of all kinds in culture. It is an unusual CSF in another way too. It is made in both a membrane-bound and a secreted form, generated by alternative splicing of the mRNA, and it seems to be the membrane-bound form that is most important: mutant mice that make the secreted form of the Steel factor but not the membrane-bound form show severe defects. This implies that normal hemopoiesis requires direct cell-cell contact between the hemopoietic stem cell and a stromal cell that expresses *Steel* and that only this contact enables the Steel factor to activate the Kit receptor protein efficiently. Kit may thus behave as a coreceptor (discussed in Chapter 23), which has to be activated at the same time as receptors for factors such as IL-3 in order to stimulate hemopoiesis. This could help explain why hemopoiesis occurs only in a few special environments, such as that provided by the stromal cells of the bone marrow, while other tissues escape invasion and colonization even though there are always some hemopoietic stem cells circulating in the bloodstream.

The Behavior of a Hemopoietic Cell Depends Partly on Chance [28], [32]

Up to this point we have glossed over a central question. The CSFs are defined as factors that promote the production of colonies of differentiated blood cells. But what effect precisely does a CSF have on an individual hemopoietic cell? The factor might control the rate of cell division or the number of division cycles that the progenitor cell goes through before differentiating; it might act late in the hemopoietic lineage to facilitate differentiation; it might act early to influence commitment; or it might simply increase the probability of cell survival (Figure 22-34). By monitoring the fate of isolated individual hemopoietic cells in culture, it has been possible to show that a single CSF, such as GM-CSF, can exert all these different effects. Nevertheless, it is still not clear which actions are most important *in vivo.* The behavior of the pluripotent stem cells remains especially elusive: these crucial cells are few and far between - less than 1 in 1000 of the cells in the bone marrow - and are difficult to identify unambiguously.

Studies *in vitro* indicate, moreover, that there is a large element of chance in the way a hemopoietic cell behaves. The CSFs seem to act by regulating probabilities, not by dictating directly what the cell shall do. In hemopoietic cell cultures, even if the cells have been selected to be as homogeneous a population as possible, there is a remarkable variability in the sizes and often in the characters of the colonies that develop. And if two sister cells are taken immediately after a cell division and cultured apart under identical conditions, they will frequently give rise to colonies that contain different types of blood cells or the same types of blood cells in different numbers. Thus both the programming of cell division and the process of commitment to a particular path of differentiation seem to involve random events at the level of the individual cell, even though the behavior of the multicellular system as a whole is regulated in a reliable way.

Regulation of Cell Survival Is as Important as Regulation of Cell Proliferation [33]

While such observations show that CSFs are not strictly required to instruct the hemopoietic cells how to differentiate or how many times to divide, CSFs *are* required to keep the cells alive: the default behavior of the cells in the absence of CSFs is suicide. In principle, the CSFs could regulate the numbers of the various types of blood cells entirely through selective control

of cell survival in this way, and there is increasing evidence that the control of cell survival plays a central part in the normal regulation of the numbers of blood cells and, as discussed earlier for hepatocytes, of many other cell types too. In many tissues, it seems, cells are programmed to kill themselves if they do not receive specific signals for survival. We have already discussed the importance and the mechanism of *programmed cell death* during development (see p. 1076); it is no less important in the turnover and renewal of cell populations in the adult body (Figure 22-35). The genes that regulate it have been highly conserved in evolution, to the extent that at least one of them, called *bcl-2,* coding for an intracellular inhibitor of the cell death program in mammalian cells, can perform the same function in cells of a nematode worm. Too little cell death can be as dangerous to the health of the multicellular organism as too much proliferation, and mutations that inhibit cell death by causing overexpression of *bcl-2* have been implicated in the development of cancer, as discussed in Chapter 24.

The amount of programmed cell death in the vertebrate hemopoietic system is enormous: billions of neutrophils die in this way each day in an adult human, for example. Although the mechanism of programmed cell death remains a mystery, the dying cells usually undergo a characteristic morphological change called apoptosis, in which the cell and its nucleus shrink and condense and frequently fragment. By contrast, cells that die accidentally, as a result of acute injury, usually swell and burst - a process called *cell necrosis.* Whereas cells that die by necrosis spill their cytosolic contents into the extracellular space and elicit an inflammatory response, cells that die by apoptosis disappear in a way that is more efficient for the organism: they are so rapidly phagocytosed by macrophages (or other neighboring cells) that there is no leakage of cytosolic components and no inflammatory response. Once inside the macrophage, the apoptotic cell is quickly disassembled and its chemical building blocks reused.

To activate this disposal mechanism, apoptotic cells change their surface chemistry so that macrophages can recognize them. The recognition mechanism varies depending on the tissue and the type of blood cell. In some cases a lectin on the macrophage surface seems to recognize altered sugar groups on the apoptotic cell surface. In others an integrin (discussed in Chapter 19) on the macrophage surface recognizes an extracellular matrix protein called *thrombospondin,* which is secreted by the macrophage and seems to act as a bridge between it and the apoptotic cell; the mechanism by which thrombospondin binds to apoptotic cells is unknown. In still other cases the macrophage is thought to recognize phosphatidylserine, a negatively charged phospholipid that is normally confined to the cytosolic leaflet of the plasma membrane lipid bilayer (see Figure 10-11) but apparently relocates to the extracellular leaflet in some apoptotic blood cells. No matter which of these recognition systems is used, macrophages react to the apoptotic cells in a specific way: they engulf and digest them, but they do not secrete inflammation-inducing signals as they do when they phagocytose and digest necrotic cells. This is a second reason why cell necrosis is associated with inflammation, whereas apoptosis is not.

Although biologists have paid much more attention to the control of cell proliferation than to the control of cell survival, it is becoming increasingly clear that both kinds of controls can serve to regulate cell numbers. Both depend on specific signals produced by other cells, ensuring that a cell divides only when more cells are required and that a cell survives only when and where it is needed. The challenge is to define all of the signals that regulate the survival and proliferation of each cell type, to determine how their levels are controlled to balance cell proliferation and cell death according to the varying needs of the organism, and to understand how an individual cell integrates these diverse extracellular signals and decides whether to live or die and whether to divide or remain quiescent.

Summary

The many types of blood cells all derive from a common pluripotent stem cell. In the adult the stem cells are found mainly in bone marrow, where they normally divide infrequently to produce more stem cells (self-renewal) and various committed progenitor cells, each able to give rise to only one or a few types of blood cells. The committed progenitor cells divide profusely under the influence of various protein signaling molecules (called colony-stimulating factors, or CSFs) and then differentiate into mature blood cells, which usually die after several days or weeks. Studies of hemopoiesis have been greatly aided by in vitro assays in which stem cells or committed progenitor cells form clonal colonies when cultured in a semisolid matrix. The progeny of stem cells appear to make their choices among alternative developmental pathways in a partly random manner. Cell death, controlled by the availability of CSFs, also plays a central part in regulating the numbers of mature differentiated blood cells; it depends on activation of an intracellular suicide program and is thought to help regulate cell numbers in many other tissues and in other kinds of animals.

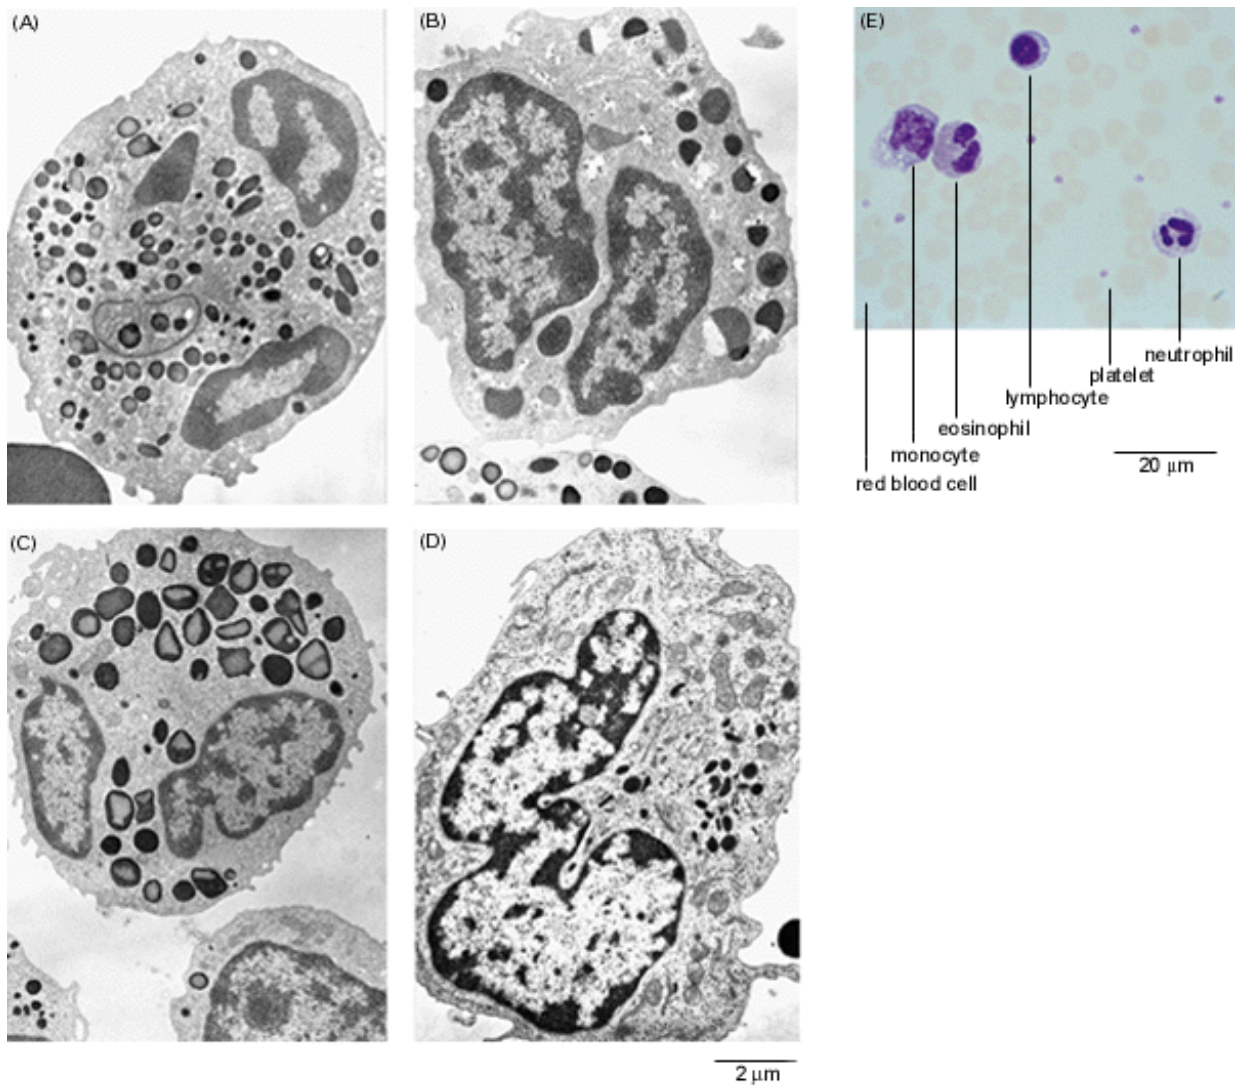
Figure 22-24. Scanning electron micrograph of mammalian blood cells in a small blood vessel. The larger, more spherical cells with a rough surface are white blood cells; the smaller, smoother, flattened cells are red blood cells. (From R.G. Kessel and R.H. Kardon, Tissues and Organs: A Text-Atlas of Scanning Electron Microscopy. San Francisco: Freeman, 1979. Copyright © 1979 W.H. Freeman and Company.)


Figure 22-25. White blood cells. (A-D) Electron micrographs showing, respectively, a neutrophil, a basophil, an eosinophil, and a monocyte. Electron micrographs of lymphocytes are shown in Figure 23-4. Each of the cell types shown here has a different function, which is reflected in the distinctive types of secretory granules and lysosomes it contains. There is only one nucleus per cell, but it has an irregular lobed shape, and in (B), (C), and (D) the connections between the lobes are out of the plane of section. (E) Light micrograph of a blood smear stained with the Romanowsky stain, which colors the white blood cells strongly. (A-D, courtesy of Dorothy Bainton; E, courtesy of David Mason.)

Table 22-1. Blood Cells

Type of Cell	Main Functions	Typical Concentration in Human Blood (cells/liter)
Red blood cells (erythrocytes)	transport O_2 and CO_2	5×10^{12}
White blood cells (leucocytes)		
Granulocytes		
Neutrophils (polymorphonuclear leucocytes)	phagocytose and destroy invading bacteria	5×10^9
Eosinophils	destroy larger parasites and modulate allergic inflammatory responses	2×10^8
Basophils	release histamine (and in some species serotonin) in certain immune reactions	4×10^7
Monocytes	become tissue macrophages, which phagocytose and digest invading microorganisms and foreign bodies as well as damaged and senescent cells	4×10^8
Lymphocytes		
B cells	make antibodies	2×10^9
T cells	kill virus-infected cells and regulate activities of other leucocytes	1×10^9
Natural killer (NK) cells	kill virus-infected cells and some tumor cells	1×10^8
Platelets (cell fragments, arising from *megakaryocytes* in bone marrow)	initiate blood clotting	3×10^{11}

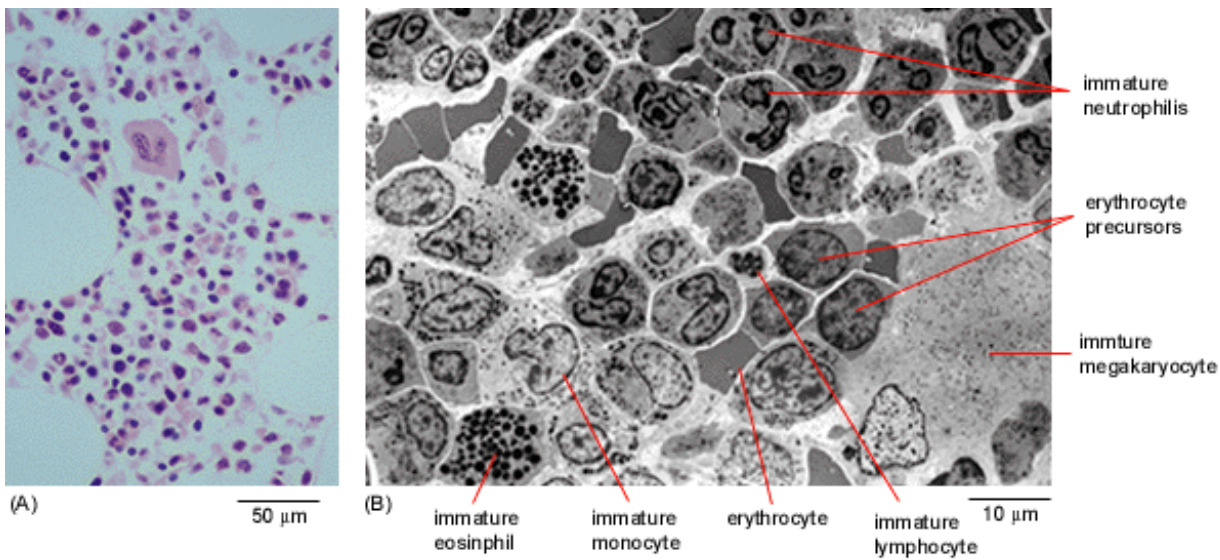
Humans contain about 5 liters of blood, accounting for 7% of body weight. Red blood cells constitute about 45% of this volume and white cells about 1%, the rest being the liquid *blood plasma.*
Figure 22-26. Migration of white blood cells out of the bloodstream in an inflammatory response. The response is initiated by a variety of signaling molecules produced locally by cells (mainly in the connective tissue) or by complement activation. Some of these mediators act on capillary endothelial cells, causing them to loosen their attachments to their neighbors so that the capillaries become more permeable; the endothelial cells are also stimulated to express *selectins* - cell-surface molecules that recognize specific carbohydrates that are present on the surface of leucocytes in the blood and cause them to stick to the endothelium. Other mediators act as chemoattractants, causing the bound leucocytes to crawl between the capillary endothelial cells into the tissue.


Figure 22-27. Bone marrow. (A) Light micrograph of a stained section. The large empty spaces correspond to fat cells, whose fatty contents have been dissolved away during specimen preparation. The giant cell with a lobed nucleus is a megakaryocyte. (B) Low-magnification electron micrograph. This tissue is the main source of new blood cells (except for T lymphocytes, which are produced in the thymus). Note that the immature blood cells of a particular type tend to cluster in "family groups." (A, courtesy of David Mason; B, from J.A.G. Rhodin, Histology: A Text and Atlas. New York: Oxford University Press, 1974.)

LARGE NODULES ON ITS SURFACE

each spleen nodule contains a
clone of hemopoietic cells,
descended from one of the
injected bone marrow cells

Figure 22-29. The spleen colony assay. The spleen of a heavily irradiated animal becomes seeded with bone marrow cells transfused from a healthy donor. This assay, developed in 1961, revolutionized the study of hemopoiesis by allowing individual myeloid precursor cells to be analyzed for the first time.
Figure 22-30. A tentative scheme of hemopoiesis. The pluripotent stem cell normally divides infrequently to generate either more pluripotent stem cells (self-renewal) or *committed progenitor cells* (labeled CFC = colony-forming cells), which are irreversibly determined to produce only one or a few types of blood cells. The progenitor cells are stimulated to proliferate by specific growth factors but progressively lose their capacity for division and develop into terminally differentiated blood cells, which usually live for only a few days or weeks.In adult mammals all of the cells shown develop mainly in the bone marrow - except for T lymphocytes, which develop in the thymus, and macrophages and osteoclasts, which develop from blood monocytes. The most controversial part of the scheme is where the precursors for T and B lymphocytes fit into the scheme. The dashed lines reflect this uncertainty. The pluripotent stem cells also give rise to various types of tissue cells not shown in this scheme, such as NK cells, mast cells, and a variety of classes of antigen-presenting cells (discussed in Chapter 23), but the pathways by which these cells develop are uncertain.
Figure 22-31. Schematic diagram of a developing red blood cell (erythroblast). The cell is shown extruding its nucleus to become an immature erythrocyte (*reticulocyte*), which then leaves the bone marrow and passes into the bloodstream. The reticulocyte will lose its mitochondria and ribosomes within a day or two to become a mature erythrocyte. Erythrocyte clones develop in the bone marrow on the surface of a macrophage, which phagocytoses and digests the nuclei discarded by the erythroblasts.
Figure 22-32. The development of red blood cells. The drawing shows the relationship between the BFC-E, the CFC-E, and the mature erythrocyte. BFC-Es and CFC-Es are both committed erythroid progenitor cells. BFC-Es respond to the factor IL-3 but not to erythropoietin, whereas CFC-Es respond to erythropoietin. The series of cell divisions that occur in this lineage under the influence of erythropoietin provides a powerful means of controlling the production of erythrocytes without upsetting the production of other types of blood cells.

Table 22-2. Some Colony-stimulating Factors (CSFs) That Influence Blood Cell Formation

Factor	Size (in mouse)	Target Cells	Producing Cells	Receptors
Erythropoietin	51,000 daltons	CFC-E	kidney cells	cytokine family
Interleukin 3 (IL3)	25,000 daltons	pluripotent stem cell, most progenitor cells, many terminally differentiated cells	T lymphocytes, epidermal cells	cytokine family
Granulocyte/ macrophage CSF (GMCSF)	23,000 daltons	GM progenitor cells	T lymphocytes, endothelial cells, fibroblasts	cytokine family
Granulocyte CSF (GCSF)	25,000 daltons	GM progenitor cells and neutrophils	macrophages, fibroblasts	cytokine family
Macrophage CSF (MCSF)	70,000 daltons (dimer)	GM progenitor cells and macrophages	fibroblasts, macrophages, endothelial cells	receptor tyrosine kinase family
Steel factor (stem cell factor)	40-50,000 daltons (dimer)	hemopoietic stem cell	stromal cells in bone marrow and many other cells	receptor tyrosine kinase family
Figure 22-33. Sharing of subunits among CSF receptors. Human IL-3 receptors and GM-CSF receptors have different a subunits and a common b subunit. Their ligands bind to the free a subunit with low affinity, and this triggers the assembly of the heterodimer that binds the ligand with high affinity.

CONTROLLABLE PARAMETER

1. Frequency of stem cell division
2. Probability of stem cell death
3. Probability that stem cell daughter will become a committed progenitor cell of the given type

4. Division cycle time of committed progenitor cell

5. Probability of progenitor cell death

6. Number of committed progenitor cell divisions before terminal differentiation

7. Lifetime of differentiated cells

Figure 22-34. Some of the parameters through which the production of blood cells of a specific type might be regulated. Studies *in vitro* suggest that colony-stimulating factors (CSFs) can affect all of these aspects of hemopoiesis.

2 µm
Figure 22-35. Cells dying by apoptosis. The electron micrograph shows an apoptotic cell in the mammary gland. Apoptotic cell death is a normal occurrence here, balancing the proliferation of mammary epithelial cells that occurs in each menstrual cycle. Note the disintegrating nuclear envelope and the dark clumps of condensed chromatin. For comparison, part of a normal cell is visible to one side of the picture. (Courtesy of David Ferguson.)

Genesis, Modulation, and Regeneration of Skeletal Muscle <u>34</u>

Introduction

The term "muscle" covers a multitude of cell types, all specialized for contraction but in other respects dissimilar. As noted in <u>Chapter 16</u>, a contractile system involving actin and myosin is a basic feature of animal cells in general, but muscle cells have developed this apparatus to a high degree. Mammals possess four main categories of cells specialized for contraction: *skeletal muscle cells, heart* (or *cardiac*) *muscle cells, smooth muscle cells,* and *myoepithelial cells* (<u>Figure 22-36</u>). These differ in function, structure, and development. Although all of them appear to generate contractile forces by means of organized filament systems based on actin and myosin, the actin and myosin molecules employed are somewhat different in amino acid sequence, are differently arranged in the cell, and are associated with different sets of proteins to control contraction.

Skeletal muscle cells, whose contractile apparatus is discussed in detail in <u>Chapter 16</u>, are responsible for practically all movements that are under voluntary control. These cells can be very large (2 or 3 cm long and 100 mm in diameter in an adult human) and are often referred to as *muscle fibers* because of their highly elongated shape. Each one is a syncytium, containing many nuclei within a common cytoplasm. The other types of muscle cells are more conventional, having only a single nucleus. Heart muscle cells resemble skeletal muscle cells in that their actin and myosin filaments are aligned in very orderly arrays to form a series of contractile units called *sarcomeres,* so that the cells have a striated appearance. Smooth muscle cells are so called because they, in contrast, do not appear striated. The functions of smooth muscle vary greatly, from propelling food along the digestive tract to erecting hairs in response to cold or fear. Myoepithelial cells also have no striations, but unlike all other muscle cells they lie in epithelia and are derived from the ectoderm. They form the dilator muscle of the iris and serve to expel saliva, sweat, and milk from the corresponding glands (see <u>Figure 22-36E</u>). The four main categories of muscle cells can be further divided into distinctive subtypes, each with its own characteristic features.

The mechanisms of muscle contraction are discussed in <u>Chapter 16</u>; here, we consider how muscle tissue is generated and maintained. We focus on the skeletal muscle cell, which has a curious mode of development, a striking ability to modulate its differentiated character, and an unusual strategy for repair.

New Skeletal Muscle Cells Form by the Fusion of Myoblasts <u>2</u>, <u>35</u>

The previous chapter described how certain cells, originating from the somites of a vertebrate embryo at a very early stage, become determined as *myoblasts* (that is, as precursors of skeletal muscle cells) and migrate into the adjacent embryonic connective tissue, or mesenchyme. As discussed in <u>Chapter 9</u>, the commitment to be a myoblast (rather than, say, a fibroblast) depends on the activation of one or more *myogenic genes,* which encode gene regulatory proteins of the helix-loop-helix family. After a period of proliferation the myoblasts fuse with one another to form multinucleate skeletal muscle cells (<u>Figure 22-37</u>). As they fuse, they undergo a dramatic switch of phenotype that depends on the coordinated activation of a whole battery of muscle-specific genes. Once fusion has occurred, the nuclei never again replicate their DNA. Fusion involves specific cell-cell adhesion molecules that mediate recognition between myoblasts.

Myoblasts that have been kept proliferating in culture for as long as 2 years still retain the ability to differentiate and will fuse to form muscle cells in response to a suitable change in culture conditions. *Fibroblast growth factor (FGF)* in the medium seems to be crucial for keeping the myoblasts proliferating and preventing their differentiation: if FGF is removed, the cells rapidly stop dividing, fuse, and differentiate. The system of controls is complex, however, and in order to differentiate, myoblasts must attach to the extracellular matrix. Moreover, the process of fusion is cooperative: fusing myoblasts secrete factors that encourage other myoblasts to fuse. In the intact animal the myoblasts and muscle fibers are held in the meshes of a connective-tissue framework formed by fibroblasts. This framework guides muscle development and controls the arrangement and orientation of the muscle cells.

Muscle Cells Can Vary Their Properties by Changing the Protein Isoforms That They Contain <u>36</u>

Once formed, a skeletal muscle cell is generally retained for the entire lifetime of the animal. Over this period it grows, matures, and modulates its character according to functional requirements. The genome contains multiple variant copies of the genes encoding many of the characteristic proteins of the skeletal muscle cell, and the RNA transcripts of many of these genes can be spliced in several ways. As a result, a wealth of protein variants (*isoforms*) can be produced for the components of the

contractile apparatus. As the muscle cell matures, different selections of isoforms are produced, adapted to the changing demands for speed, strength, and endurance in the fetus, the newborn, and the adult. Within a single adult muscle, several distinct types of skeletal muscle cells, each with different sets of protein isoforms and different functional properties, can be found side by side (Figure 22-38).

Some Myoblasts Persist as Quiescent Stem Cells in the Adult [37]

A muscle can grow in three ways: its differentiated muscle cells can increase in number, in length, or in girth. Because skeletal muscle cells are unable to divide, more of them can be made only by the fusion of myoblasts. The adult number of multinucleated skeletal muscle cells is in fact attained early - before birth in humans. The subsequent enormous increase in muscle bulk is achieved by cell enlargement. Growth in length depends on recruitment of more myoblasts into the existing multinucleate cells, mainly by fusion at their ends, which increases the number of nuclei in each cell. In contrast, growth in girth, such as occurs in the muscles of weightlifters, depends on an increase in the size and numbers of the contractile myofibrils that each muscle cell contains rather than on changes in the numbers of muscle cells or of their nuclei.

In the adult, nevertheless, a few myoblasts persist as small, flattened, and inactive cells lying in close contact with the mature muscle cell and contained within its sheath of basal lamina. If the muscle is damaged or if it is treated artificially with FGF, these so-called *satellite cells* are activated to proliferate (Figure 22-39), and their progeny can fuse to form new muscle cells. Satellite cells are thus the stem cells of adult skeletal muscle, normally held in reserve in a quiescent state but available when needed as a self-renewing source of terminally differentiated cells.

Although this muscle repair mechanism operates well in small animals such as mice, it is less efficient in humans. In muscular dystrophy, for example, differentiated skeletal muscle cells die because of a genetic defect in the cytoskeletal dystrophin protein (see p. 855). As a result, satellite cells proliferate to form new muscle cells; but this regenerative response is unable to keep pace with the damage, and the muscle cells are eventually replaced by connective tissue, blocking any further possibility of regeneration.

Summary

Skeletal muscle cells are one of the four main categories of vertebrate cells specialized for contraction, and they are responsible for voluntary movement. Each skeletal muscle cell is a syncytium and develops by the fusion of many myoblasts. Myoblasts are stimulated to proliferate by growth factors such as FGF, but once they fuse, they can no longer divide. Myoblast fusion is generally coupled with the onset of muscle cell differentiation, in which many genes encoding muscle-specific proteins are switched on coordinately. Some myoblasts persist (in a quiescent state) as satellite cells in adult muscle; when a muscle is damaged, these cells are reactivated to proliferate and to fuse to replace the muscle cells that have been lost.

Figure 22-36. The four classes of muscle cells of a mammal. (A) Schematic drawings (to scale). (B-E) Scanning electron micrographs, showing (B) skeletal muscle from the neck of a hamster, (C) heart muscle from a rat, (D) smooth muscle from the urinary bladder of a guinea pig, and (E) myoepithelial cells in a secretory alveolus from a lactating rat mammary gland. The arrows in (C) point to intercalated discs - end-to-end junctions between the heart muscle cells; skeletal muscle cells in long muscles are joined end to end in a similar way. Note that the smooth muscle is shown at a lower magnification than the others. (B, courtesy of Junzo Desaki; C, from T. Fujiwara, in Cardiac Muscle in Handbook of Microscopic Anatomy [E.D. Canal, ed.]. Berlin: Springer Verlag, 1986; D, courtesy of Satoshi Nakasiro; E, from T. Nagato, Y. Yoshida, A. Yoshida, and Y. Uehara, *Cell and Tissue Res.* 209:1-10, 1980.)
Figure 22-37. Myoblast fusion in culture. The phase-contrast micrographs show how the cells will proliferate, line up, and fuse to form multinucleate muscle cells. (C) is at higher magnification, showing the cross-striations that are just beginning to be visible as the contractile apparatus develops (*red arrow*) and the accumulations of many nuclei within a single cell (*green arrows*). (Courtesy of Rosalind Zalin.)
Figure 22-38. Fast and slow muscle fibers. Two consecutive cross-sections of the same piece of adult chicken muscle have been stained with two fluorescent antibodies, each specific for a different isoform of myosin-II. In (A) cells specialized to produce fast-twitch contractions are stained with antibodies against "fast" myosin; in (B) cells specialized to produce slow, sustained contractions are stained with antibodies against "slow" myosin. The fast-twitch cells are known as *white muscle cells* because they contain relatively little of the colored oxygen-binding protein myoglobin; the slow muscle cells are called *red muscle cells* because they contain much more of it. The cells can adjust their fast or slow character through changes of gene expression according to the pattern of nerve stimulation they receive. (From G. Gauthier et al., *J. Cell Biol.* 92:471-484, 1982, by copyright permission of the Rockefeller University Press.)
Figure 22-39. Autoradiograph of a single multinucleate muscle cell with associated satellite cells. The fiber has been isolated from an adult rat and transferred into culture medium containing 3H-thymidine plus an extract from damaged muscle that stimulates the satellite cells to divide. The dividing satellite cells (*arrows*) have become radioactively labeled (silver grains visible as *black dots*); the muscle cell nuclei are unable to proliferate and remain unlabeled. (From R. Bischoff, *Dev. Biol.* 115:140-147, 1986.)

Fibroblasts and Their Transformations: The Connective-Tissue Cell Family [38]

Introduction

Many of the differentiated cells in the adult body can be grouped into families whose members are closely related by origin and by character. An important example is the family of connective-tissue cells, whose members are not only related but are also to an unusual extent interconvertible. The family includes *fibroblasts, cartilage cells,* and *bone cells,* all of which are specialized for secretion of collagenous extracellular matrix and are jointly responsible for the architectural framework of the body, as well as *fat cells* and *smooth muscle cells,* which appear to have a common origin with them. These cell types and the interconversions that are thought to occur between them are illustrated in Figure 22-40. Connective-tissue cells play a central part in the support and repair of almost every tissue and organ, and the adaptability of their differentiated character is an important feature of the responses to many types of damage.

Fibroblasts Change Their Character in Response to Signals in the Extracellular Matrix [38], [39]

Fibroblasts appear to be the least specialized cells in the connective-tissue family. They are dispersed in connective tissue throughout the body, where they secrete a nonrigid extracellular matrix that is rich in type I and/or type III collagen, as discussed in Chapter 19. When a tissue is injured, the fibroblasts nearby migrate into the wound, proliferate, and produce large amounts of collagenous matrix, which helps to isolate and repair the damaged tissue. Their ability to thrive in the face of injury, together with their solitary life-style, may explain why fibroblasts are the easiest of cells to grow in culture - a feature that has made them a favorite subject for cell biological studies (Figure 22-41).

As indicated in Figure 22-40, fibroblasts also seem to be the most versatile of connective-tissue cells, displaying a remarkable capacity to differentiate into other members of the family. There are some important uncertainties about their interconversions, however. There is good evidence that fibroblasts in different parts of the body are intrinsically different, and it is far from proven that all fibroblasts in a given region are equivalent. In the absence of firm evidence to the contrary, it is simplest to suppose that they are indeed equivalent, but it is conceivable that connective tissue may contain a mixture of distinct fibroblast lineages, some capable of transformation into chondrocytes, others capable of transformation into fat cells, and so on, rather than just one type of fibroblast with multiple developmental capabilities. It is possible also that "mature" fibroblasts incapable of transformation may exist side by side with "immature" fibroblasts (often called *mesenchymal cells*) that can develop into a variety of mature cell types.

Despite these uncertainties, there is clear evidence, from studies both *in vivo* and *in vitro,* that connective-tissue cells can undergo radical changes of character. Thus, if a preparation of bone matrix, made by grinding bone into a fine powder and dissolving away the hard mineral component, is implanted in the dermal layer of the skin, some of the cells there (probably dermal fibroblasts) become transformed into cartilage cells and, a little later, others into bone cells, thereby creating a small lump of bone, complete with a marrow cavity. These experiments suggest that components in the extracellular matrix can dramatically influence connective-tissue cell differentiation. We shall see that similar cell transformations are important in the natural repair of broken bones. In fact, bone matrix has been found to contain trapped within it high concentrations of several growth factors that can affect the behavior of connective-tissue cells, including, in particular, transforming growth factor β (TGF-β) and a set of distinct *bone morphogenetic proteins (BMPs)* that belong to the TGF-β superfamily. These factors are powerful regulators of growth, differentiation, and matrix synthesis by connective-tissue cells, exerting a variety of actions depending on the target cell type and the combination of other factors and matrix components that are present. When injected into a living animal, they can induce formation of cartilage, of bone, or of fibrous matrix, according to the site and circumstances of injection.

The Extracellular Matrix May Influence Connective-Tissue Cell Differentiation by Affecting Cell Shape and Attachment 40

The extracellular matrix may influence the differentiated state of connective-tissue cells through physical as well as chemical effects. This has been shown in studies on cultured cartilage cells, or *chondrocytes.* Under appropriate culture conditions these cells will proliferate and maintain their differentiated character, continuing for many cell generations to synthesize large quantities of highly distinctive cartilage matrix, with which they surround themselves. However, under conditions where the cells are kept at relatively low density and remain as a monolayer on the culture dish, a transformation occurs. The cells lose the rounded shape that is typical of chondrocytes, flatten down on the substratum, and stop making cartilage matrix. In particular, they stop producing type II collagen - the type characteristic of cartilage - and instead start producing type I collagen - the type characteristic of fibroblasts. By the end of a month in culture, almost all the cartilage cells have switched their collagen gene expression and taken on the appearance of fibroblasts. The biochemical change must occur abruptly, since very few cells are observed to make both types of collagen simultaneously.

Several lines of evidence suggest that the biochemical change is induced at least in part by the change of cell shape and attachments. Cartilage cells that have made the transition to a fibroblastlike character, for example, can be gently detached from the culture dish and transferred to a dish of agarose. By forming a gel around them, the agarose holds the cells suspended without any attachment to a substratum, forcing them to adopt a rounded shape. In these circumstances the cells promptly revert to the character of chondrocytes and start making type II collagen again. Cell shape and anchorage may control gene expression through intracellular signals generated at focal contacts, as we saw in Chapter 16.

For most types of cells, and especially for a connective-tissue cell, the opportunities for anchorage and attachment depend on the surrounding matrix, which is usually made by the cell itself. Thus a cell can create an environment that then acts back on the cell to reinforce its differentiated state. Furthermore, the extracellular matrix that a cell secretes forms part of the environment for its neighbors as well as for the cell itself and thus tends to make neighboring cells differentiate in the same way. A group of chondrocytes forming a nodule of cartilage, for example, either in the developing body or in a culture dish, can be seen to enlarge by the conversion of neighboring fibroblasts into chondrocytes.

Different Signaling Molecules Act Sequentially to Regulate Production of Fat Cells 41

Fat cells, or adipocytes, are also thought to develop from fibroblastlike cells, both during normal mammalian development and in various pathological circumstances - for example, in muscular dystrophy, where the muscle cells die and are gradually replaced by fatty connective tissue. Fat cell differentiation begins with the production of specific enzymes, followed by the accumulation of fat droplets, which then coalesce and enlarge until the cell is hugely distended, with only a thin rim of cytoplasm around the mass of lipid (Figure 22-42).

The process can be studied in culture (using fibroblast cell lines such as mouse 3T3 cells) so that the factors that influence it can be analyzed. It was initially found that the development of fat cells in culture required the presence of fetal calf serum, a common additive to culture media. The crucial factor in the serum that triggers fat cell differentiation was later identified as *growth hormone* a protein normally secreted into the bloodstream by the pituitary gland. There is evidence that growth hormone stimulates chondrocyte as well as fat cell differentiation and that it acts in this way *in vivo* as well as *in vitro.* But growth

hormone is not the only secreted signaling molecule that regulates fat cell development. Fat cell precursors that have been stimulated by growth hormone become sensitive to *IGF-1 (insulinlike growth factor-1),* which stimulates the proliferation of the differentiating fat cells.

The differentiation of fat cells, like that of chondrocytes, is also influenced by factors that affect cell shape and anchorage. The differentiation of 3T3 cells into fat cells is inhibited if the cells are allowed to flatten onto a culture dish coated with fibronectin, to which they adhere strongly. This inhibition is reversed, however, by treatment with the drug cytochalasin, which disrupts actin filaments and causes the cells to round up.

All of these experiments on connective-tissue cells illustrate a recurrent theme: differentiation is regulated by a combination of soluble signals and contacts with the extracellular matrix. The effects of each of these factors depend on the character of the responding cell, and this in turn depends on the cell's developmental history.

Bone Is Continually Remodeled by the Cells Within It 42

Bone is a very dense, specialized form of connective tissue. Like reinforced concrete, bone matrix is predominantly a mixture of tough fibers (type I collagen fibrils), which resist pulling forces, and solid particles (calcium phosphate as hydroxyapatite crystals), which resist compression. The volume occupied by the collagen is nearly equal to that occupied by the calcium phosphate. The collagen fibrils in adult bone are arranged in regular plywoodlike layers, with the fibrils in each layer lying parallel to one another but at right angles to the fibrils in the layers on either side.

For all its rigidity, bone is by no means a permanent and immutable tissue. Throughout its hard extracellular matrix are channels and cavities occupied by living cells, which account for about 15% of the weight of compact bone. These cells are engaged in an unceasing process of remodeling: one class of cells demolishes old bone matrix while another deposits new bone matrix. This mechanism provides for continuous turnover and replacement of the matrix in the interior of the bone.

Bone can grow only by *apposition* - that is, by the laying down of additional matrix and cells on the free surfaces of the hard tissue. This process must occur in the embryo in coordination with the growth of other tissues in such a way that the pattern of the body can be scaled up without its proportions being radically disturbed. For most of the skeleton, and in particular for the long bones of the limbs and trunk, the coordinated growth is achieved by a complex strategy. A set of minute "scale models" of the bones are first formed out of cartilage. Each scale model grows, and as new cartilage is formed, the older cartilage is replaced by bone. Cartilage growth and erosion and bone deposition are so ingeniously coordinated during development that the adult bone, though it may be half a meter long, is almost the same shape as the initial cartilaginous model, which was no more than a few millimeters long.

Osteoblasts Secrete Bone Matrix, While Osteoclasts Erode It 40, 42, 43

Cartilage is a simple tissue, consisting of cells of a single type - chondrocytes - embedded in a more or less uniform matrix. The cartilage matrix is deformable, and the tissue grows by expanding as the chondrocytes divide and secrete more matrix (Figure 22-43). Bone is more complex. The bone matrix is secreted by osteoblasts that lie at the surface of the existing matrix and deposit fresh layers of bone onto it. Some of the osteoblasts remain free at the surface, while others gradually become embedded in their own secretion. This freshly formed material (consisting chiefly of type I collagen) is called *osteoid.* It is rapidly converted into hard bone matrix by the deposition of calcium phosphate crystals in it. Once imprisoned in hard matrix, the original bone-forming cell, now called an osteocyte, has no opportunity to divide, although it continues to secrete further matrix in small quantities around itself. The osteocyte, like the chondrocyte, occupies a small cavity, or *lacuna,* in the matrix, but unlike the chondrocyte it is not isolated from its fellows. Tiny channels, or *canaliculi,* radiate from each lacuna and contain cell processes from the resident osteocyte, enabling it to form gap junctions with adjacent osteocytes (Figure 22-44). Although the networks of osteocytes do not themselves secrete or erode substantial quantities of matrix, they probably play a part in controlling the activities of the cells that do.

While bone matrix is deposited by osteoblasts, it is eroded by osteoclasts (Figure 22-45). These large multinucleated cells originate, like macrophages, from hemopoietic stem cells in the bone marrow. The precursor cells are released as monocytes into the bloodstream and collect at sites of bone resorption, where they fuse to form the multinucleated osteoclasts, which cling to surfaces of the bone matrix and eat it away. Osteoclasts are capable of tunneling deep into the substance of compact bone, forming cavities that are then invaded by other cells. A blood capillary grows down the center of such a tunnel, and the walls of the tunnel become lined with a layer of osteoblasts (Figure 22-46). To produce the plywoodlike structure of compact bone, these

osteoblasts lay down concentric layers of new bone, which gradually fill the cavity, leaving only a narrow canal surrounding the new blood vessel. Many of the osteoblasts become trapped in the bone matrix and survive as concentric rings of osteocytes. At the same time as some tunnels are filling up with bone, others are being bored by osteoclasts, cutting through older concentric systems. The consequences of this perpetual remodeling are beautifully displayed in the layered patterns of matrix observed in compact bone (Figure 22-47).

There are many unsolved problems about these processes. Bones, for example, have a remarkable ability to adapt to the load imposed on them by remodeling their structure, and this implies that the deposition and erosion of the matrix are somehow controlled by local mechanical stresses. We do not understand the mechanisms that determine whether matrix will be deposited by osteoblasts or eroded by osteoclasts at a given bone surface, but it seems likely that an important part is played by growth factors that are made by the bone cells, trapped in the matrix, and released, perhaps, when the matrix is degraded or suitably stressed.

During Development, Cartilage Is Eroded by Osteoclasts to Make Way for Bone 44

The replacement of cartilage by bone in the course of development is also thought to depend on the activities of osteoclasts. As the cartilage matures, its cells in certain regions become greatly enlarged at the expense of the surrounding matrix, and the matrix itself becomes mineralized, like bone, by deposition of calcium phosphate crystals. The swollen chondrocytes die, leaving large empty cavities. Osteoclasts and blood vessels invade the cavities and erode the residual cartilage matrix, while osteoblasts following in their wake begin to deposit bone matrix. The only surviving remnant of cartilage in the adult long bone is a thin layer that forms a smooth covering on the bone surfaces at joints, where one bone articulates with another (Figure 22-48).

Some cells capable of forming new cartilage persist, however, in the connective tissue that surrounds a bone. If the bone is broken, the cells in the neighborhood of the fracture will carry out a repair by a rough-and-ready recapitulation of the original embryonic process, in which cartilage is first laid down to bridge the gap and is then replaced by bone.

The Structure of the Body Is Stabilized by Its Connective-Tissue Framework and by the Selective Cohesion of Cells 45

A bone, like the body as a whole, is a dynamic system, maintaining its structure through a balance between the opposed activities of a variety of specialized cells. Any dynamic system poses a problem of stability, and this leads us to a general question about the maintenance of body structure. We have seen how cells in various types of tissues maintain their differentiated state, how new cells are produced in a controlled fashion to replace those that are lost, and how the extracellular matrix is remodeled and renewed. But why do the different types of cells not become progressively jumbled and misplaced? Why does the whole structure not sag, warp, or otherwise change its proportions as new parts are substituted for old?

To some extent, of course, the body does sag and warp with the passage of time - that is a part of aging. But it does so remarkably little. The skeleton, despite constant remodeling, provides a rigid framework whose dimensions scarcely change. This is partly because the parts of a bone are renewed not all at once but little by little, rather like a building whose bricks are replaced one at a time. Besides such conservatism in the mode of renewal, active homeostatic mechanisms are at work. Thus small departures of a bone from its normal shape set up altered patterns of stresses, which regulate bone remodeling in such a way as to restore the bone to its normal shape (Figure 22-49).

The growth and renewal of many of the soft parts of the body are also homeostatically controlled so that each component is adjusted to fit its niche. The epidermis spreads to keep the surface of the body covered; if it is damaged, the cells grow back to cover the lesion, halting their migration when that end is achieved; connective tissue grows to just the extent necessary to fill the gap created by a wound; and so on. In all this, something more than mere control of cell numbers is required. The various types of differentiated cells must be maintained not only in the correct relative quantities but also in the correct relative positions. Tissue turnover necessarily involves cell movements. Somehow those movements must be limited; the cells must be subject to territorial restraints.

These restraints are of various kinds. Glands and other masses of specialized cells are often contained within tough capsules of connective tissue. Many types of cells die if they find themselves outside their normal environment, deprived of specific growth factors on which their survival depends. Perhaps the most important strategy for keeping the different cells in their places is the strategy of selective cell-cell adhesion: cells of the same type tend to stick together, either in solid masses, such as smooth muscle, or in epithelial sheets, such as the lining of the gut. As described in Chapter 19, this mechanism, for example, enables

dissociated epidermal cells to reassociate spontaneously to form a correctly structured epithelium. And on a larger scale, stable epithelial sheets of cells serve to divide the body into compartments, thereby keeping other cells properly segregated and confined to their correct territories.

Clearly, the checks and balances that preserve the structure of the body and the organization of its cells in the face of continual turnover and renewal are intricate and subtle. The importance of these controls is all too clearly evident when they fail, as we see when we come to the topic of cancer in the final chapter of this book.

Summary

The family of connective-tissue cells includes fibroblasts, cartilage cells, bone cells, fat cells, and smooth muscle cells. Fibroblasts seem to be able to transform into any of the other members of the family - in some cases reversibly - although it is not clear whether this is a property of a single type of fibroblast that is pluripotent or of a mixture of distinct types of fibroblasts with more restricted potentials. These transformations of connective-tissue cell type are regulated by the composition of the surrounding extracellular matrix, by cell shape, and by hormones and growth factors.

Cartilage and bone both consist of cells embedded in a solid matrix. Cartilage has a deformable matrix and can grow by swelling, whereas bone is rigid and can grow only by accretion at its surfaces. Bone is, nonetheless, subject to perpetual remodeling through the combined action of osteoclasts, which erode matrix, and osteoblasts, which secrete it. Some osteoblasts become trapped in the matrix as osteocytes and play a part in regulating the turnover of bone matrix. Most long bones develop from miniature cartilage "models," which, as they grow, serve as templates for the deposition of bone by the combined action of osteoblasts and osteoclasts. Similarly, in the repair of a bone fracture in the adult, the gap is first bridged by cartilage, which is later replaced by bone. Although bone, like most other tissues, is subject to continual turnover, this dynamic process is regulated so that the global structure is preserved. In this way, and through other mechanisms such as selective cell-cell adhesion, the organization of the body is stably maintained even though most of its components are continually being replaced.
Figure 22-40. The family of connective-tissue cells. Arrows show the interconversions that appear to occur within the family. For simplicity, the fibroblast is shown as a single cell type, but in fact it is uncertain how many types of fibroblasts exist and whether the differentiation potential of different types may be restricted in different ways.

fibroblastlike
precursor cell
fat cell

Figure 22-42. Development of a fat cell. A fibroblastlike precursor cell is converted into a mature fat cell by the accumulation and coalescence of lipid droplets. The process is at least partially reversible, as indicated by the arrows. The cells in the early and intermediate stages can divide, but the mature fat cell cannot.
Figure 22-43. The growth of cartilage. The tissue expands as the chondrocytes divide and make more matrix. The freshly synthesized matrix with which each cell surrounds itself is shaded *dark green.*Cartilage may also grow by recruiting fibroblasts from the surrounding tissue and converting them into chondrocytes.
Figure 22-44. Deposition of bone matrix by osteoblasts. Osteoblasts lining the surface of bone secrete the organic matrix of bone (osteoid) and are converted into osteocytes as they become embedded in this matrix. The matrix calcifies soon after it has been deposited. The osteoblasts themselves are thought to derive from osteogenic stem cells that are closely related to fibroblasts.
Figure 22-45. An osteoclast shown in cross-section. This giant, multinucleated cell erodes bone matrix. The "ruffled border" is a site of secretion of acids (to dissolve the bone minerals) and hydrolases (to digest the organic components of the matrix). Osteoclasts vary in shape, are motile, and often send out processes to resorb bone at multiple sites. They develop from monocytes and can be viewed as specialized macrophages. (From R.V. Krstić, Ultrastructure of the Mammalian Cell: An Atlas. Berlin: Springer, 1979.)
Figure 22-46. The remodeling of compact bone. Osteoclasts acting together in a small group excavate a tunnel through the old bone, advancing at a rate of about 50 mm per day. Osteoblasts enter the tunnel behind them, line its walls, and begin to form new bone, depositing layers of matrix at a rate of 1 or 2 mm per day. At the same time a capillary sprouts down the center of the tunnel. The tunnel will eventually become filled with concentric layers of new bone, with only a narrow central canal remaining.

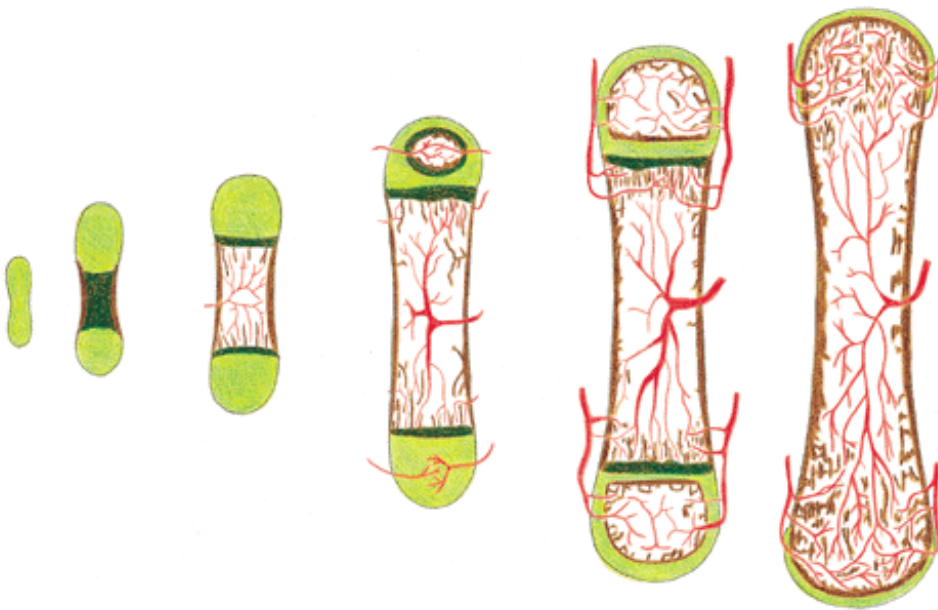
Each such canal, besides providing a route of access for osteoclasts and osteoblasts, contains one or more blood vessels bringing the nutrients the bone cells must have to survive. Typically, about 5-10% of the bone in a healthy adult mammal is replaced in this way each year. (After Z.F.G. Jaworski, B. Duck, and G. Sekaly, *J. Anat.* 133:397-405, 1981.)
Figure 22-47. Transverse section through a compact outer portion of a long bone. The micrograph shows the outlines of tunnels formed by osteoclasts and then filled in by osteoblasts during successive rounds of bone remodeling. The section has been prepared by grinding; the hard matrix has been preserved but not the cells. Lacunae and canaliculi that were occupied by osteocytes are clearly visible, however. The alternating bright and dark concentric rings correspond to an alternating orientation of the collagen fibers in the successive layers of bone matrix laid down by the osteoblasts that lined the wall of the canal during life. (This pattern is revealed here by viewing the specimen between partly crossed Polaroid filters.) Note how older systems of concentric layers of bone have been partly cut through and replaced by newer systems.


Figure 22-48. The development of a long bone. Long bones, such as the femur or the humerus, develop from a miniature cartilage model. Uncalcified cartilage is shown in *green*, calcified cartilage in *black*, bone in *brown*, and blood vessels in *red*. The cartilage is not converted to bone but is gradually replaced by it through the action of osteoclasts and osteoblasts, which invade the cartilage in association with blood vessels. Osteoclasts erode cartilage and bone matrix, while osteoblasts secrete bone matrix. The process of ossification begins in the embryo and is not completed until the end of puberty. The resulting bone consists of a thick-walled hollow cylinder of compact bone enclosing a large central cavity occupied by the bone marrow. Note

that not all bones develop in this way. The *membrane bones* of the skull, for example, are formed directly as bony plates, not from a prior cartilage model. (Adapted from D.W. Fawcett, A Textbook of Histology, 11th ed. Philadelphia: Saunders, 1986.)
Figure 22-49. Remodeling of a long bone in the leg after a fracture that has healed out of true. The deformity in the recently healed bone exposes it to abnormal stresses. Where the compressive forces are increased, the rate of bone deposition is increased relative to the rate of erosion; where the forces are decreased, the rate of deposition is decreased relative to the rate of erosion. In this way the bone is gradually remodeled back to its normal form.

Cells of the Adult Human Body: A Catalogue

How many distinct cell types are there in an adult human being? In other words, how many normal adult ways are there of expressing the human genome? A large textbook of histology will mention about 200 cell types that qualify for individual names. These traditional names are not, like the names of colors, labels for parts of a continuum that has been subdivided arbitrarily: they represent, for the most part, discrete and distinctly different categories. Within a given category there is often some variation - the skeletal muscle fibers that move the eyeball are small, while those that move the leg are big; auditory hair cells in different parts of the ear may be tuned to different frequencies of sound; and so on. But there is no continuum of adult cell types intermediate in character between, say, the muscle cell and the auditory hair cell.

The traditional histological classification is based on the shape and structure of the cell as seen in the microscope and on its chemical nature as assessed very crudely from its affinities for various stains. Subtler methods reveal new subdivisions within the traditional classification. Thus modern immunology has shown that the old category of "lymphocyte" includes more than 10 quite distinct cell types. Similarly, pharmacological and physiological tests reveal that there are many varieties of smooth muscle cell - those in the wall of the uterus, for example, are highly sensitive to estrogen, and in the later stages of pregnancy to oxytocin, while those in the wall of the gut are not. Another major type of diversity is revealed by embryological experiments of the sort discussed in Chapter 21. These show that, in many cases, apparently similar cells from different regions of the body are nonequivalent, that is, they are inherently different in their developmental capacities and in their effects on other cells. Thus, within categories such as "fibroblast" there are probably many distinct cell types, different chemically in ways that are not easy to perceive directly.

For these reasons any classification of the cell types in the body must be somewhat arbitrary with respect to the fineness of its subdivisions. Here, we list only the adult human cell types that a histology text would recognize to be different, grouped into families roughly according to function. We have not attempted to subdivide the class of neurons of the central nervous system. Also, where a single cell type such as the keratinocyte is conventionally given a succession of different names as it matures, we give only two entries - one for the differentiating cell and one for the stem cell. With these serious provisos, the 210 varieties of cells in the catalogue represent a more or less exhaustive list of the distinctive ways in which a given mammalian genome can be expressed in the phenotype of a normal cell of the adult body.

keratinocyte of epidermis (= differentiating epidermal cell)
basal cell of epidermis (stem cell)
keratinocyte of fingernails and toenails

basal cell of nail bed (stem cell)
hair shaft cells
-- medullary
-- cortical
-- cuticular
hair-root sheath cells
-- cuticular
-- of Huxley's layer
-- of Henle's layer
-- external
hair matrix cell (stem cell)

surface epithelial cell of stratified squamous epithelium of cornea, tongue, oral cavity, esophagus, anal canal, distal urethra, vagina
basal cell of these epithelia (stem cell)
cell of urinary epithelium (lining bladder and urinary ducts)

cells of salivary gland
-- mucous cell (secretion rich in polysaccharide)
-- serous cell (secretion rich in glycoprotein enzymes)
cell of von Ebner's gland in tongue (secretion to wash over taste buds)
cell of mammary gland, secreting milk
cell of lacrimal gland, secreting tears
cell of ceruminous gland of ear, secreting wax
cell of eccrine sweat gland, secreting glycoproteins (dark cell)
cell of eccrine sweat gland, secreting small molecules (clear cell)
cell of apocrine sweat gland (odoriferous secretion, sex-hormone sensitive)
cell of gland of Moll in eyelid (specialized sweat gland)
cell of sebaceous gland, secreting lipid-rich sebum
cell of Bowman's gland in nose (secretion to wash over olfactory epithelium)
cell of Brunner's gland in duodenum, secreting alkaline solution of mucus and enzymes
cell of seminal vesicle, secreting components of seminal fluid, including fructose (as fuel for swimming sperm)
cell of prostate gland, secreting other components of seminal fluid
cell of bulbourethral gland, secreting mucus
cell of Bartholin's gland, secreting vaginal lubricant
cell of gland of Littré, secreting mucus
cell of endometrium of uterus, secreting mainly carbohydrates
isolated goblet cell of respiratory and digestive tracts, secreting mucus
mucous cell of lining of stomach
zymogenic cell of gastric gland, secreting pepsinogen
oxyntic cell of gastric gland, secreting HCl
acinar cell of pancreas, secreting digestive enzymes and bicarbonate
Paneth cell of small intestine, secreting lysozyme
type II pneumocyte of lung, secreting surfactant
Clara cell of lung (function unknown)

cells of anterior pituitary, secreting
-- growth hormone
-- follicle-stimulating hormone
-- luteinizing hormone
-- prolactin
-- adrenocorticotropic hormone
-- thyroid-stimulating hormone
cell of intermediate pituitary, secreting
-- melanocyte-stimulating hormone

cells of posterior pitutiary, secreting
-- oxytocin
-- vasopressin
cells of gut and respiratory tract, secreting
-- serotonin
-- endorphin
-- somatostatin
-- gastrin
-- secretin
-- cholecystokinin
-- insulin
-- glucagon
-- bombesin
cells of thyroid gland, secreting
-- thyroid hormone
-- calcitonin
cells of parathyroid gland, secreting
-- parathyroid hormone
-- oxyphil cell (function unknown)
cells of adrenal gland, secreting
-- epinephrine
-- norepinephrine
-- steroid hormones
-- mineralocorticoids
-- glucocorticoids
cells of gonads, secreting
-- testosterone (Leydig cell of testis)
-- estrogen (theca interna cell of ovarian follicle)
-- progesterone (corpus luteum cell of ruptured ovarian follicle)
cells of juxtaglomerular apparatus of kidney
-- juxtaglomerular cell (secreting renin)
-- macula densa cell
-- (uncertain but probably related in function; possibly involved secretion of erythropoietin)
-- Peripolar cell
-- (uncertain but probably related in function; possibly involved secretion of erythropoietin)
-- mesangial cel
-- (uncertain but probably related in function; possibly involved secretion of erythropoietin)

brush border cell of intestine (with microvilli)
striated duct cell of exocrine glands
gall bladder epithelial cell
brush border cell of proximal tubule of kidney
distal tubule cell of kidney
nonciliated cell of ductulus efferens
epididymal principal cell
epididymal basal cell

hepatocyte (liver cell)
fat cells
-- white fat
-- brown fat
-- lipocyte of liver

type I pneumocyte (lining air space of lung)
pancreatic duct cell (centroacinar cell)

nonstriated duct cell of sweat gland, salivary gland, mammary gland, etc. (various)
parietal cell of kidney glomerulus
podocyte of kidney glomerulus
cell of thin segment of loop of Henle (in kidney)
collecting duct cell (in kidney)
duct cell of seminal vesicle, prostate gland, etc. (various)

vascular endothelial cells of blood vessels and lymphatics
-- fenestrated
-- continuous
-- splenic
synovial cell (lining joint cavities, secreting largely hyaluronic acid)
serosal cell (lining peritoneal, pleural, and pericardial cavities)
squamous cell lining perilymphatic space of ear
cells lining endolymphatic space of ear
-- squamous cell
-- columnar cells of endolymphatic sac
-- with microvilli
-- without microvilli
-- "dark" cell
-- vestibular membrane cell
-- stria vascularis basal cell
-- stria vascularis marginal cell
-- cell of Claudius
-- cell of Boettcher
choroid plexus cell (secreting cerebrospinal fluid)
squamous cell of pia-arachnoid
cells of ciliary epithelium of eye
-- pigmented
-- nonpigmented
corneal "endothelial" cell

of respiratory tract
of oviduct and of endometrium of uterus (in female)
of rete testis and ductulus efferens (in male)
of central nervous system (ependymal cell lining brain cavities)

epithelial
-- ameloblast (secreting enamel of tooth)
-- planum semilunatum cell of vestibular apparatus of ear (secreting proteoglycan)
-- interdental cell of organ of Corti (secreting tectorial "membrane" covering hair cells of organ of Corti)
nonepithelial (connective tissue)
-- fibroblasts (various - of loose connective tissue, of cornea, of tendon, of reticular tissue of bone marrow, etc.)
-- pericyte of blood capillary
-- nucleus pulposus cell of intervertebral disc
-- cementoblast/cementocyte (secreting bonelike cementum of root of tooth)
-- odontoblast/odontocyte (secreting dentin of tooth)
-- chondrocytes
-- of hyaline cartilage
-- of fibrocartilage
-- of elastic cartilage
-- osteoblast/osteocyte
-- osteoprogenitor cell (stem cell of osteoblasts)
-- hyalocyte of vitreous body of eye
-- stellate cell of perilymphatic space of ear

skeletal muscle cells
-- red (slow)
-- white (fast)
-- intermediate
-- muscle spindlenuclear bag
-- muscle spindlenuclear chain
-- satellite cell (stem cell)
heart muscle cells
-- ordinary
-- nodal
-- Purkinje fiber
smooth muscle cells (various)
myoepithelial cells
-- of iris
-- of exocrine glands

red blood cell
megakaryocyte
macrophages and related cells
-- monocyte
-- connective-tissue macrophage (various)
-- Langerhans cell (in epidermis)
-- osteoclast (in bone)
-- dendritic cell (in lymphoid tissues)
-- microglial cell (in central nervous system)
neutrophil
eosinophil
basophil
mast cell
T lymphocyte
-- helper T cell
-- suppressor T cell
-- killer T cell
B lymphocyte
-- IgM
-- IgG
-- IgA
-- IgE
killer cell
stem cells and committed progenitors for the blood and immune system (various)

photoreceptors
-- rod
-- cones
-- blue sensitive
-- green sensitive
-- red sensitive
hearing
-- inner hair cell of organ of Corti
-- outer hair cell of organ of Corti
acceleration and gravity
-- type I hair cell of vestibular apparatus of ear
-- type II hair cell of vestibular apparatus of ear
taste

-- type II taste bud cell
smell
-- olfactory neuron
-- basal cell of olfactory epithelium (stem cell for olfactory neurons)
blood pH
-- carotid body cell
-- type I
-- type II
touch
-- Merkel cell of epidermis
-- primary sensory neurons specialized for touch (various)
temperature
-- primary sensory neurons specialized for temperature
-- cold sensitive
-- heat sensitive
pain
-- primary sensory neurons specialized for pain (various)
configurations and forces in musculoskeletal system
-- proprioceptive primary sensory neurons (various)

cholinergic (various)
adrenergic (various)
peptidergic (various)

supporting cells of organ of Corti
-- inner pillar cell
-- outer pillar cell
-- inner phalangeal cell
-- outer phalangeal cell
-- border cell
-- Hensen cell
supporting cell of vestibular apparatus
supporting cell of taste bud (type I taste bud cell)
supporting cell of olfactory epithelium
Schwann cell
satellite cell (encapsulating peripheral nerve cell bodies)
enteric glial cell

neurons (huge variety of types - still poorly classified)
glial cells
-- astrocyte (various)
-- oligodendrocyte

anterior lens epithelial cell
lens fiber (crystallin-containing cell)

melanocyte
retinal pigmented epithelial cell

oogonium/oocyte
spermatocyte
spermatogonium (stem cell for spermatocyte)

ovarian follicle cell
Sertoli cell (in testis)
thymus epithelial cell

23 . The Immune System

➡ ➡

Introduction

Our immune system saves us from certain death by infection. Any vertebrate born with a severely defective immune system will soon die unless extraordinary measures are taken to isolate it from a host of infectious agentsbacterial, viral, fungal, and parasitic. Whereas all vertebrates have an immune system, invertebrates have more primitive defense systems, which often rely chiefly on phagocytic cells. Such cells (mainly macrophages and neutrophils) also play an important role in defending vertebrates against infection, but they are only one part of a much more complex and sophisticated defense strategy.

Immunology, the study of the immune system, grew out of the common observation that people who recover from certain infections are thereafter "immune" to the disease; that is, they rarely develop the same disease again. Immunity is highly specific: an individual who recovers from measles is protected against the measles virus but not against other common viruses, such as mumps or chicken pox. Such specificity is a fundamental characteristic of immune responses.

Many of the responses of the immune system initiate the destruction and elimination of invading organisms and any toxic molecules produced by them. Because these immune reactions are destructive, it is essential that they be made only in response to molecules that are foreign to the host and not to those of the host itself. This ability to distinguish *foreign* molecules from *self* molecules is another fundamental feature of the immune system. Occasionally, it fails to make this distinction and reacts destructively against the host's own molecules; such *autoimmune diseases* can be fatal.

Although the immune system evolved to protect vertebrates from infection by microorganisms and larger parasites, most of what we know about immunity has come from studies of the responses of laboratory animals to injections of noninfectious substances, such as foreign proteins and polysaccharides. Almost any macromolecule, as long as it is foreign to the recipient, can induce an immune response; any substance capable of eliciting an immune response is referred to as an antigen (*anti* body *gen* erator). Remarkably, the immune system can distinguish between antigens that are very similarsuch as between two proteins that differ in only a single amino acid or between two optical isomers of the same molecule.

There are two broad classes of immune responses: (1) antibody responses and (2) cell-mediated immune responses. Antibody responses involve the production of antibodies, which are proteins called *immunoglobulins* . The antibodies circulate in the bloodstream and permeate the other body fluids, where they bind specifically to the foreign antigen that induced them. Binding by antibody inactivates viruses and bacterial toxins (such as tetanus or botulinum toxin) by blocking their ability to bind to receptors on host cells. Antibody binding also marks invading microorganisms for destruction, either by making it easier for a phagocytic cell to ingest them or by activating a system of blood proteins, collectively called *complement,* that kills the invaders.

Cell-mediated immune responses, the second class of immune responses, involve the production of specialized cells that react with foreign antigens on the surface of other host cells. The reacting cell, for example, can kill a virus-infected host cell that has viral antigens on its surface, thereby eliminating the infected cell before the virus has replicated. In other cases the reacting cell secretes chemical signals that activate macrophages to destroy the invading microorganisms.

The main challenge in immunology has been to understand how the immune system specifically recognizes and reacts aggressively to a virtually unlimited number of different foreign macromolecules but avoids reacting against the tens of thousands of different self macromolecules made by host cells. We begin our discussion of the immune system by considering the cells that are principally responsible for the two types of immunity. We then consider the functional and structural features of antibodies that enable them to recognize and destroy extracellular antigens. After discussing how antibody diversity is generated, we consider the special features of cell-mediated immune responses, which are crucial in the defense against intracellular microorganisms.

➡ ➡

The Cellular Basis of Immunity

Introduction

The Human Immune System Is Composed of Trillions of Lymphocytes [1]

The cells responsible for immune specificity belong to a class of white blood cells known as lymphocytes. They are found in large numbers in the blood and the lymph (the colorless fluid in the lymphatic vessels that connect the lymph nodes in the body) and in specialized lymphoid organs, such as the thymus, lymph nodes, spleen, and appendix (Figure 23-1).

There are ~2 x 10^{12} lymphocytes in the human body, which makes the immune system comparable in cell mass to the liver or brain. Although lymphocytes have long been recognized as a major cellular component of the blood, their central role in immunity was demonstrated only in the late 1950s. The proof came from experiments in which mice or rats were heavily irradiated in order to kill most of their white blood cells, including lymphocytes. Since such animals are unable to make immune responses, it is possible to transfer various types of cells into them and determine which ones reverse the deficiency. Only lymphocytes restored the immune responses of irradiated animals (Figure 23-2). Since both antibody and cell-mediated responses were restored, these experiments established that lymphocytes are responsible for both types of immune response. At the time these experiments were done, lymphocytes were among the least understood of vertebrate cells; now they are among the cells we understand best.

B Lymphocytes Make Humoral Antibody Responses; T Lymphocytes Make Cell-mediated Immune Responses [2]

During the 1960s it was discovered that the two major classes of immune responses are mediated by different classes of lymphocytes: T cells, which develop in the *thymus* , are responsible for cell-mediated immunity; B cells, which in mammals develop in the adult *bone marrow* or the fetal liver, produce antibodies. This dichotomy of the lymphoid system was initially demonstrated in animals with experimentally induced immunodeficiencies. It was found that removing the thymus from a newborn animal markedly impairs cell-mediated immune responses but has much less effect on antibody responses. In birds it

was also possible to demonstrate the converse effect because B cells develop in a discrete gut-associated lymphoid organ, the *bursa of Fabricius,* that is unique to birds. Removing the bursa of Fabricius at the time of hatching impaired the bird's ability to make antibodies but had little effect on cell-mediated immunity. In addition, studies of children born with impaired immunity showed that some of these children could not make antibodies but had normal cell-mediated immunity, while others had the reverse deficiency; and those with selectively impaired cell-mediated responses almost always had thymus abnormalities.

One of the puzzling features of these studies on immunodeficient animals was that individuals deficient in T cells (because their thymus was removed at birth or was abnormal) not only were unable to make cell-mediated immune responses, but also had somewhat impaired antibody responses. We now know the explanation. There are two main classes of T cells - *helper T cells* and *cytotoxic T cells* . Helper T cells enhance the responses of other white blood cells, and some of these T cells help B cells make antibody responses. Cytotoxic T cells, by contrast, kill infected cells; because they are involved *directly* in defense against infection, unlike helper T cells, they (together with B cells) are sometimes referred to as *effector cells* .

Lymphocytes Develop in Primary Lymphoid Organs and React with Foreign Antigens in Secondary Lymphoid Organs 3

Lymphocytes develop from *pluripotent hemopoietic stem cells,* which give rise to all of the blood cells, including red blood cells, white blood cells, and platelets. These stem cells, which are discussed in Chapter 22 , are located primarily in *hemopoietic* tissues - the liver in fetuses and the bone marrow in adults. T cells develop in the thymus from precursor cells that migrate in from the hemopoietic tissues via the blood. In mammals B cells develop from stem cells in the hemopoietic tissues themselves; in birds, however, B cells develop in the bursa of Fabricius from precursor cells that migrate in from the hemopoietic tissues via the blood. Because they are sites where lymphocytes develop from precursor cells, the thymus, the hemopoietic tissues, and the bursa of Fabricius are referred to as primary (central) lymphoid organs (see Figure 23-1).

As we discuss later, most lymphocytes die soon after they develop in a primary lymphoid organ. Others, however, mature and migrate via the blood to the secondary (peripheral) lymphoid organs - mainly, the lymph nodes, spleen, and epithelium-associated lymphoid tissues found in the gastrointestinal tract, respiratory tract, and skin (see Figure 23-1). It is chiefly in the secondary lymphoid organs that T cells and B cells react with foreign antigens (Figure 23-3).

Because most of the migration of lymphocytes out of the thymus and bursa occurs early in development, removing these organs from *adult* animals has relatively little effect on immune responses, which is why their role in immunity remained undiscovered for so long. In contrast, the bone marrow in mammals continues to generate large numbers of new B cells (~5 x 10^7 /day in a mouse) throughout life.

Cell-Surface Markers Make It Possible to Distinguish and Separate T and B Cells 2 , 4

T and B cells become morphologically distinguishable only after they have been stimulated by antigen. Unstimulated ("resting") T and B cells look very similar, even in an electron microscope: both are small, only marginally bigger than red blood cells, and are largely filled by the nucleus (Figure 23-4A). Both are activated by antigen to proliferate and mature further. Activated B cells develop into antibody-secreting cells, the most mature of which are *plasma cells,* which are filled with an extensive rough endoplasmic reticulum (Figure 23-4B). In contrast, activated T cells contain very little endoplasmic reticulum and do not secrete antibodies, although they do secrete a variety of mediators called *lymphokines, interleukins,* or *cytokines* (Figure 23-4C).

Since both T and B cells occur in all secondary lymphoid organs, it has been necessary to find ways to distinguish and separate the two cell types and their various subtypes in order to study their individual properties. Fortunately, there are many differences in the plasma membrane proteins of the different types of lymphocytes that can serve as distinguishing markers. Antibodies that react with the *Thy-1 protein,* for example, which is found on T but not B cells in mice, are widely used to remove or purify T cells from a mixed population of mouse lymphocytes. Similarly, antibodies against the *CD4* and *CD8 proteins,* which we discuss later, are widely used to distinguish and separate helper T cells and cytotoxic T cells, respectively, in both mice and humans.

The Immune System Works by Clonal Selection 5

The most remarkable feature of the immune system is that it can respond to millions of different foreign antigens in a highly specific way - for example, by making antibodies that react specifically with the antigen that induced their production. How can

the immune system produce such a diversity of specific antibodies? The answer began to emerge in the 1950s with the formulation of the clonal selection theory. According to this theory, each animal first randomly generates a vast diversity of lymphocytes, and then those cells that react against the foreign antigens that the animal actually encounters are specifically selected for action. The theory is based on the proposition that during development each lymphocyte becomes committed to react with a particular antigen before ever being exposed to it. Each cell expresses this commitment in the form of cell-surface receptor proteins that specifically fit the antigen. The binding of antigen to the receptors activates the cell, causing it to both proliferate and mature. A foreign antigen, therefore, selectively stimulates those cells that express complementary antigen-specific receptors and are thus already committed to respond to it. This is what makes immune responses antigen-specific.

The term "clonal" in clonal selection derives from the postulate that the immune system is composed of millions of different families, or *clones,* of cells, each consisting of T or B cells descended from a common ancestor. Each ancestral cell is already committed to make one particular antigen-specific receptor protein, and all cells in a clone have the same antigen specificity (Figure 23-5). Thus, according to the clonal selection theory, the immune system functions on the "ready-made" rather than the "made-to-measure" principle.

There is compelling evidence to support the main tenets of the clonal selection theory. When lymphocytes from an animal that has not been immunized, for example, are incubated in a test tube with any of a number of radioactively labeled antigens - say, A, B, C, and D - only a very small proportion (<0.01%) bind each antigen, suggesting that only a few cells can respond to A, B, C, or D. This interpretation is confirmed by making antigen A so highly radioactive that any cell that binds it is lethally irradiated; the remaining population of lymphocytes is then no longer able to produce an immune response to A but can still respond normally to antigen B, C, or D. The same effect can be achieved by constructing an affinity column of glass beads coated with antigen A and then passing the lymphocytes through the column. The cells with receptors for A stick to the beads, while other cells pass through; as a result, the cells that emerge from the column no longer respond to A but do respond normally to other antigens (Figure 23-6).

These two experiments indicate, first, that lymphocytes are committed to respond to a particular antigen before they have been exposed to it and, second, that the committed lymphocytes have receptors on their surface that specifically bind the antigen. Two major predictions of the clonal selection theory are therefore confirmed. Although almost all of the experiments of this kind have involved B cells and antibody responses, other experiments indicate that T-cell-mediated responses also operate by clonal selection.

It is now known that the antigen-specific receptors on both T and B cells are encoded by genes that are assembled from series of gene segments by a unique form of genetic recombination that occurs early in the cell's development, before it has encountered antigen. We shall see later how the assembly process generates the enormous diversity of receptors that enables the immune system to respond to an almost unlimited diversity of antigens.

Most Antigens Stimulate Many Different Lymphocyte Clones 6

Most macromolecules, including virtually all proteins and many polysaccharides, can serve as antigens. Those parts of an antigen that combine with the antigen-binding site on an antibody molecule or on a lymphocyte receptor are called antigenic determinants (or *epitopes*). Most antigens have a variety of antigenic determinants that stimulate the production of antibodies or T cell responses. Some determinants are more antigenic than others, so that the reaction to them may dominate the overall response. Such determinants are said to be *immuno-dominant* .

As one might expect of a system that works by clonal selection, even a single antigenic determinant, in general, will activate many clones, each of which produces an antigen-binding site with its own characteristic affinity for the determinant. Even a relatively simple structure like the *dinitrophenyl (DNP)* group shown in Figure 23-7 , for example, can be "looked at" in many ways. When it is coupled to a protein, it usually stimulates the production of hundreds of species of anti-DNP antibodies, each made by a different B cell clone. Such responses are said to be *polyclonal* . When only a few clones respond, the response is said to be *oligoclonal;* and when the total response is made by a single B or T cell clone, it is said to be *monoclonal* . The responses to most antigens are polyclonal.

Even an antigen that activates many clones will stimulate only a tiny fraction of the total lymphocyte population. To ensure that these few lymphocytes are exposed to the antigen, antigens are generally collected by specialized *antigen-presenting cells* in secondary lymphoid organs, through which T and B cells continuously recirculate. Antigens that enter through the gut are trapped by gut-associated lymphoid tissues; those that enter through the skin or respiratory tract are retained locally and/or are

transported via the lymph to local lymph nodes; and those that enter the blood are filtered out in the spleen.

Most Lymphocytes Continuously Recirculate 7

The majority of T and B cells continuously recirculate between the blood and the secondary lymphoid tissues. In a lymph node, for example, lymphocytes leave the bloodstream, squeezing out between specialized endothelial cells; after percolating through the node, they accumulate in small lymphatic vessels that leave the node and connect with other lymphatic vessels, which then pass through other lymph nodes downstream. Passing into larger and larger vessels, the lymphocytes eventually enter the main lymphatic vessel (the *thoracic duct*), which carries them back into the blood. This continuous recirculation not only ensures that the appropriate lymphocytes will come into contact with antigen, it also ensures that appropriate lymphocytes encounter one another: we shall see that interactions between specific lymphocytes are a crucial part of most immune responses.

Lymphocyte recirculation depends on specific interactions between the lymphocyte cell surface and the surface of specialized endothelial cells lining small veins in the secondary lymphoid organs; because their endothelial cells are unusually tall, they are called *postcapillary high endothelial venules* (Figure 23-8) . Many cell types in the blood come into contact with these high endothelial cells, but only lymphocytes adhere and then migrate out of the bloodstream. Different subpopulations of lymphocytes migrate through different lymphoid tissues: whereas most lymphocytes migrate into lymph nodes, for example, some migrate preferentially into Peyer's patches in the small intestine and constitute, in effect, a gut-specific subsystem of lymphocytes specialized for responding to antigens that enter the body from the intestine.

These migrations are guided by various homing receptors on lymphocytes and by the ligands for these receptors (often called *counterreceptors*) on endo-thelial cells. Both receptors and counterreceptors have been identified by monoclonal antibodies that bind to the surface of either lymphocytes or the specialized high endothelial cells and inhibit the ability of the lymphocytes both to bind to the endothelial cells in tissue sections of secondary lymphoid organs and to recirculate *in vivo.* Lymphocyte migration into lymph nodes, for example, depends on a cell adhesion protein called *E-selectin,* which belongs to the selectin family of cell-surface lectins discussed in Chapter 10 . This homing receptor, which is present on most lymphocytes, binds to specific sugar groups on a highly glycosylated, mucinlike counterreceptor that is expressed exclusively on the surface of high endothelial cells lining postcapillary venules in lymph nodes (see Figure 23-8). E-selectin binding causes the lymphocytes to adhere weakly to the endothelial cells and to roll slowly along their surface. The rolling continues until another, much stronger adhesion system is activated. This strong adhesion, which is mediated by a member of the *integrin* family of cell adhesion molecules on the lymphocyte surface (discussed in Chapter 19), allows the lymphocytes to stop rolling and crawl out of the blood vessel into the lymph node (Figure 23-9).

Other homing receptors on lymphocytes are thought to be responsible for the subsequent segregation of T and B cells into distinct areas in the lymph node (see Figure 23-8). Once they are activated by antigen, most lymphocytes lose many of their original homing receptors and acquire new ones: instead of migrating through lymphoid organs they migrate through nonlymphoid tissues to sites of inflammation. The migration of activated lymphocytes and other white blood cells into sites of inflammation is largely mediated by other combinations of selectins and integrins (discussed in Chapter 10).

Immunological Memory Is Due to Clonal Expansion and Lymphocyte Maturation 8

The immune system, like the nervous system, can remember. This is why we develop lifelong immunity to many common viral diseases after our initial exposure to the virus, and it is why immunization works. The same phenomenon can be demonstrated in experimental animals. If an animal is injected once with antigen A, its immune response (either antibody or cell-mediated) will appear after a lag period of several days, rise rapidly and exponentially, and then, more gradually, fall again. This is the characteristic course of a primary immune response, occurring on an animal's first exposure to an antigen. If some weeks or months or even years are allowed to pass and the animal is reinjected with antigen A, it will usually produce a secondary immune response that is very different from the primary response: the lag period is shorter and the response is greater. These differences indicate that the animal has "remembered" its first exposure to antigen A. If the animal is given a different antigen (for example, antigen B) instead of a second injection of antigen A, the response is typical of a primary, and not a secondary, immune response. Therefore, the secondary response reflects antigen-specific immunological memory for antigen A (Figure 23-10).

The clonal selection theory provides a useful conceptual framework for understanding the cellular basis of immunological memory. In an adult animal the T and B cells in the secondary lymphoid organs are a mixture of cells in at least three stages of maturation, which can be designated *virgin* (or *naïve*) *cells, memory cells,* and *activated cells* . When virgin cells encounter

antigen for the first time, some of them are stimulated to multiply and become activated cells, which we define as cells that are actively engaged in making a response (activated T cells carry out cell-mediated responses, while activated B cells secrete antibody). Other virgin cells are stimulated to multiply and mature instead into memory cells - cells that are not themselves making a response but are readily induced to become activated cells by a later encounter with the same antigen (Figure 23-11). Whereas virgin cells and memory cells can live for months or even years, activated cells die by programmed cell death within days.

Memory cells respond much more readily to antigen than do virgin cells. We shall see later that one reason for the increased responsiveness of memory B cells is that their receptors have a higher affinity for antigen. In contrast, memory T cells seem to respond to antigen more readily than virgin T cells - not because they have higher-affinity receptors for antigen, but because they adhere more strongly to other cells and transduce extracellular signals more efficiently. Thus immunological memory is generated during the primary response in part because the proliferation of antigen-triggered virgin cells creates many memory cellsa process known as *clonal expansion* and in part because virgin cells differentiate into memory cells that are able to respond more readily to antigen than do virgin cells. Antigens can persist in lymphoid tissues for a very long time following a primary response, and it is thought that continual stimulation by antigen contributes to the long-term maintenance of memory.

The Failure to Respond to Self Antigens Is Due to Acquired Immunological Tolerance <u>9</u>

How is the immune system able to distinguish foreign molecules from self molecules? One possibility might be that an animal inherits genes that encode receptors for foreign antigens but not self antigens, so that its immune system is genetically constituted to respond only to foreign antigens. Alternatively, the immune system could be inherently capable of responding to both foreign and self antigens but could "learn" during development not to respond to self antigens. The latter explanation has been shown to be correct. The first evidence for this was an observation made in 1945. Normally, when tissues are transplanted from one individual to another, they are recognized as foreign by the immune system of the recipient and are destroyed. Dizygotic cattle twins, however, which develop from two fertilized ova and are therefore nonidentical, sometimes exchange blood cells *in utero* as a result of the spontaneous fusion of their placentas; such twins were shown to accept skin grafts from each other. These findings were later reproduced experimentally - in chicks, by allowing the blood vessels of two embryos to fuse, and in mice, by introducing cells from one strain of mouse into a neonatal mouse of another strain, where they survived for most of the recipient animal's life. In both cases, when the animals matured, grafts from the joined or donor animal were accepted (Figure 23-12), while "third-party" grafts from a different animal were rejected. Thus the continuous presence of nonself antigens from before the time the immune system matures leads to a long-lasting unresponsiveness to the specific nonself antigens. The resulting state of antigen-specific immunological unresponsiveness is known as acquired immunological tolerance.

There is strong evidence that the unresponsiveness of an animal's immune system to its own macromolecules (*natural immunological tolerance*) is acquired in the same way and is not inborn. Normal mice, for example, cannot make an immune response against their own blood complement protein C5, but mutant mice that lack the gene encoding C5 (but are otherwise genetically identical to the normal mice) can make an immune response to this protein. Maintaining self-tolerance requires the constant presence of the self antigens. If an antigen such as C5 is removed, an animal regains the ability to respond to it within weeks or months. Thus it is clear that the immune system is genetically capable of responding to self but learns not to do so.

The learning process that leads to self-tolerance can involve either killing the self-reactive lymphocytes (*clonal deletion*) or functionally inactivating the cells but leaving them alive (*clonal anergy*). As we discuss later, many self-reactive lymphocytes are eliminated or inactivated when they first encounter antigen in the primary lymphoid organs. It seems that newly formed lymphocytes in these organs are not activated by binding antigen but instead are either killed or inactivated by it.

Tolerance to self antigens sometimes breaks down, causing T or B cells (or both) to react against their own tissue antigens. *Myasthenia gravis* is an example of such an autoimmune disease. Affected individuals make antibodies against the acetylcholine receptors on their own skeletal muscle cells; the antibodies interfere with the normal functioning of the receptors so that such patients become weak and can die because they cannot breathe.

Summary

The immune system evolved to defend vertebrates against infection. It is composed of millions of lymphocyte clones. The lymphocytes in each clone share a unique cell-surface receptor that enables them to bind a particular antigenic determinant consisting of a specific arrangement of atoms on a part of a molecule. There are two classes of lymphocytes: B cells, which are

produced in the bone marrow and make antibodies, and T cells, which are produced in the thymus and make cell-mediated immune responses.

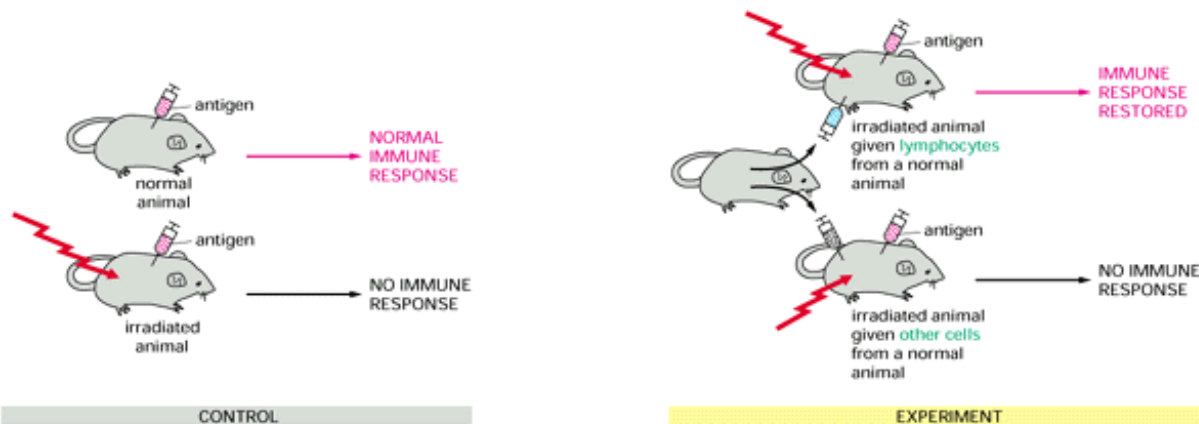
Beginning early in lymphocyte development, many lymphocytes that would react against antigenic determinants on self macromolecules are eliminated or inactivated; as a result, the immune system normally reacts only to foreign antigens. The binding of a foreign antigen to a lymphocyte initiates a response by the cell that helps to eliminate the antigen. As part of the response, some lymphocytes proliferate and mature into memory cells that are able to respond more readily to antigen than do virgin cells. Thus the next time the same antigen is encountered, the immune response to it is much faster and stronger.
Figure 23-1 . Human lymphoid organs . Lymphocytes develop in the thymus and bone marrow (*yellow*), which are therefore referred to as *primary (or central) lymphoid organs* . The newly formed lymphocytes migrate from these primary organs to *secondary (or peripheral) lymphoid organs* (*blue*), where they can react with antigen. Only some of the secondary lymphoid organs are shown; many lymphocytes, for example, are found in the skin and lungs.


Figure 23-2 . The classic experiment showing that lymphocytes are responsible for recognizing and responding to foreign antigens . An important feature of all such cell-transfer experiments is that cells are transferred between animals of the same *inbred strain* . Members of an inbred strain are genetically identical. If lymphocytes are transferred to a genetically different animal that has been irradiated, they react against the "foreign" antigens of the host and can kill the animal.
Figure 23-3 . The development of T and B cells . The primary lymphoid organs, where lymphocytes develop from precursor cells, are labeled in *yellow boxes* .

(A) resting T or B cell   1 μm

(C) active T cell   1 μm

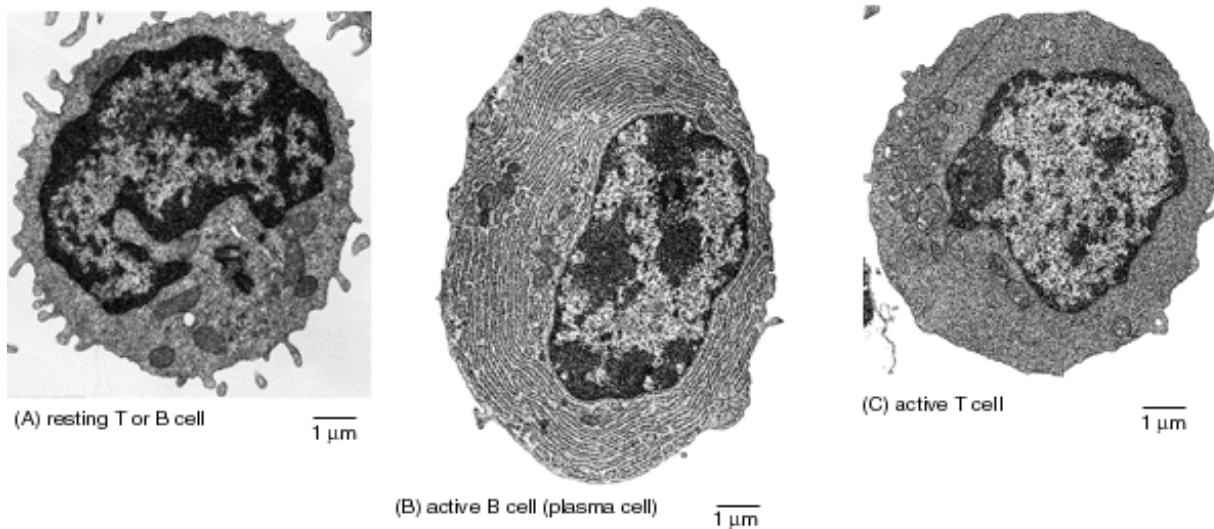
(B) active B cell (plasma cell)   1 μm


Figure 23-4 . Electron micrographs of resting and activated lymphocytes . The resting lymphocyte in (A) could be a T cell or a B cell, for these cells are difficult to distinguish morphologically until they have been activated. The activated B cell (a plasma cell) in (B) is filled with an extensive rough endoplasmic reticulum (ER), which is distended with antibody molecules. The activated T cell in (C) has relatively little rough ER but is filled with free ribosomes. Note that the three cells are shown at the same magnification. (A, courtesy of Dorothy Zucker-Franklin; B, courtesy of Carlo Grossi; A and B, from D. Zucker-Franklin et al., Atlas of Blood Cells: Function and Pathology, 2nd ed. Milan, Italy: Edi. Ermes, 1988; C, courtesy of Stefanello de Petris.)
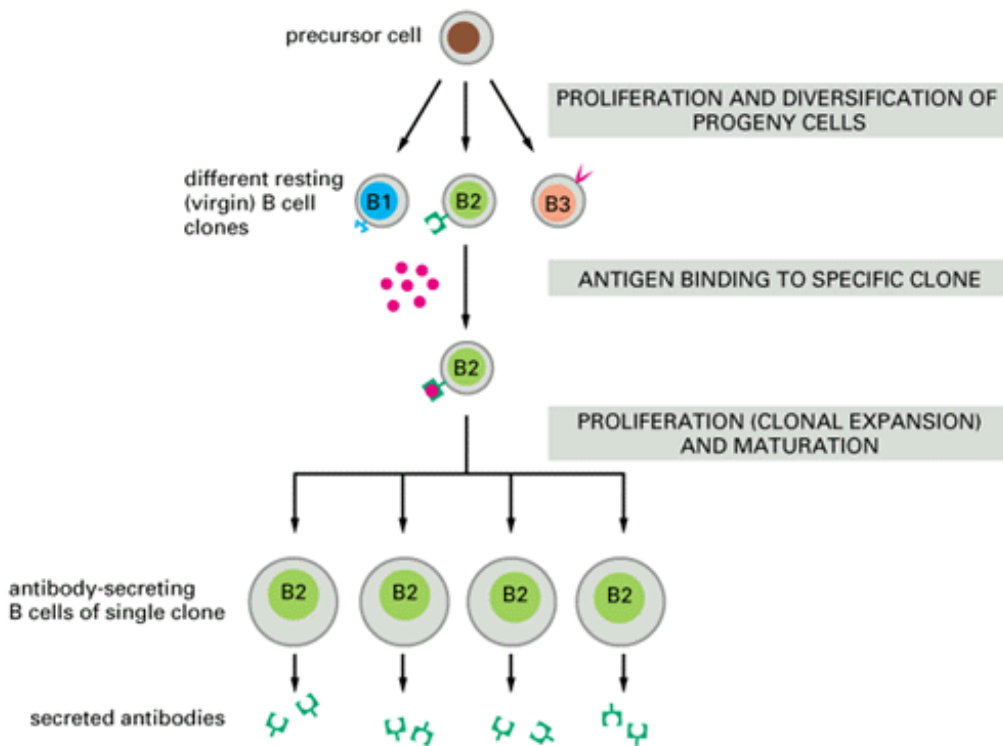

Figure 23-5 . The clonal selection theory . An antigen activates only those lymphocyte clones that are already committed to respond to it. A cell committed to respond to a particular antigen displays cell-surface receptors that specifically recognize the antigen, and all cells within a clone display the same receptor. The immune system is thought to consist of millions of different lymphocyte clones, hundreds of which may be activated by a particular antigen (see below). Although only B cells are shown, T cells operate in a similar way.
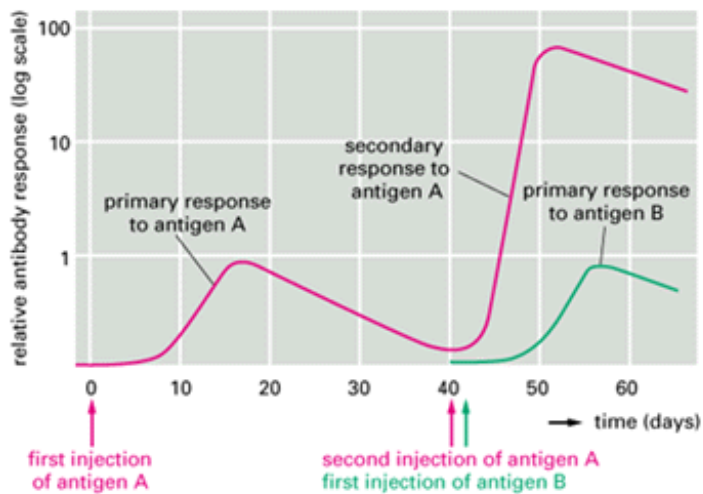
Figure 23-6 . Two types of experiments that support the clonal selection theory . For simplicity, cell-surface receptors are shown only on those lymphocytes committed to respond to antigen A; in fact, however, all T and B cells have antigen-specific receptors on their surface. The experiments shown have been carried out mainly with B cells since T cells recognize an antigen only when it is bound to the surface of a host cell, as we discuss later.
Figure 23-7 . The dinitrophenyl (DNP) group . Although it is too small to induce an immune response on its own, when it is coupled covalently to a lysine side chain on a protein, as illustrated, DNP stimulates the production of many different species of antibodies that all bind specifically to it.
Figure 23-8 . A simplified drawing of a human lymph node . B cells are located primarily in the *cortex,* where they are clustered in structures called *lymphoid follicles* . T cells are found mainly in the *paracortex.* Both types of lymphocytes enter the lymph node from the blood via specialized small veins called *postcapillary high endothelial venules* and then migrate to their respective areas. Eventually, both T cells and B cells migrate to the medullary sinuses and leave the node via the efferent lymphatic vessel. This vessel ultimately empties into the bloodstream, allowing the lympho-cytes to begin another cycle of circulation through a secondary lymphoid organ. Foreign antigens that enter the lymph node are displayed on the surface of specialized *antigen-presenting cells:* one type (*interdigitating dendritic cells*) presents antigen to T cells in the paracortical area; another type (*follicular dendritic cells*) is thought to be involved in activating memory B cells (discussed below) in the activated center (called a *germinal center*) of lymphoid follicles.
Figure 23-9 . Migration of a lymphocyte out of the bloodstream into a lymph node . A circulating lymphocyte adheres weakly to the surface of the specialized high endothelial cells in a postcapillary venule in a lymph node. This initial adhesion, mediated by E-selectin on the lymphocyte surface, is sufficiently weak that it enables the lymphocyte to roll along the surface of the endothelial cells. The lymphocyte rapidly activates a stronger adhesion system, mediated by an integrin, that enables the cell to stop rolling and migrate out of the venule between the endothelial cells.


Figure 23-10 . Primary and secondary antibody responses . The secondary response induced by a second exposure to antigen A is faster and greater than the primary response and is specific for A, indicating that the immune system has specifically remembered encountering antigen A before. Evidence for the same type of immunological memory is obtained if T-cell-mediated responses rather than B cell antibody responses are measured.
Figure 23-11 . A model for the cellular basis of immunological memory . When virgin T or B cells are stimulated by their specific antigen, they proliferate and mature; some become activated to make a response, while others become memory cells. During a subsequent exposure to the same antigen, the memory cells respond more readily than did the virgin cells: they proliferate and give rise to activated cells and to more memory cells. In the model shown an individual virgin cell can give rise to either a memory cell or an activated cell, depending on the conditions. In an alternative model (not shown) the virgin cells

that mature into memory cells are different from those that mature into activated cells. It is not known which of these models is correct.
Figure 23-12 . Immunological tolerance . The skin graft seen here, transplanted from an adult brown mouse to an adult white mouse, has survived for many weeks only because the latter was made immunologically tolerant by injecting cells from the brown mouse into it at the time of birth. The Functional Properties of Antibodies 10

Introduction

Vertebrates rapidly die of infection if they are unable to make antibodies. Antibodies defend us against infection by inactivating viruses and bacterial toxins and by recruiting the complement system and various types of white blood cells to kill extracellular microorganisms and larger parasites. Synthesized exclusively by B cells, antibodies are produced in millions of forms, each with a different amino acid sequence and a different binding site for antigen. Collectively called immunoglobulins (abbreviated as Ig), they are among the most abundant protein components in the blood, constituting about 20% of the total plasma protein by weight. In this section we describe the five classes of antibodies found in higher vertebrates, each of which mediates a characteristic biological response following antigen binding.

The Antigen-specific Receptors on B Cells Are Antibody Molecules 11

As predicted by the clonal selection theory, all antibody molecules made by an individual B cell have the same antigen-binding site. The first antibodies made by a newly formed B cell are not secreted. Instead, they are inserted into the plasma membrane, where they serve as receptors for antigen. Each B cell has approximately 10^5 such antibody molecules in its plasma membrane. Each of these antibody molecules is noncovalently associated with an invariant set of transmembrane polypeptide chains that are involved in passing signals to the cell interior when the extracellular binding site of the antigen is occupied by antigen. These invariant polypeptides are thought to couple the antigen receptors on B cells to one or more members of the Src family of tyrosine protein kinases (including the Lyn kinase), thereby activating a phosphorylation cascade when antigen is bound (see Figure 23-54B).

Each B cell produces a single species of antibody, with a unique antigen-binding site. When a virgin or a memory B cell is activated by antigen (with the aid of helper T cells), it proliferates and matures to become an antibody-secreting cell. The activated cells make and secrete large amounts of soluble (rather than membrane-bound) antibody, which has the same unique antigen-binding site as the cell-surface antibody that served earlier as the antigen receptor (Figure 23-13). Activated B cells can begin secreting antibody while they are still small lymphocytes, but the end stage of their maturation pathway is a large plasma cell (see Figure 23-4B), which secretes antibodies at the rapid rate of about 2000 molecules per second. Plasma cells seem to have committed so much of their protein-synthesizing machinery to making antibody that they are incapable of further growth and division, and most die after several days.

B Cells Can Be Stimulated to Secrete Antibodies in a Culture Dish 12

Two advances in the 1960s revolutionized research on B cells. The first was the development of the hemolytic plaque assay, which made it possible to identify and count individual activated B cells secreting antibody against a specific antigen. In the simplest form of this assay, lymphocytes (commonly from the spleen) are taken from animals that have been immunized with

sheep red blood cells (SRBCs). They are then embedded in agar together with an excess of SRBCs so that the dish contains a "lawn" of immobilized SRBCs with occasional lymphocytes in it. Under these conditions the cells are unable to move, but any anti-SRBC antibody secreted by a B cell will diffuse outward and coat all SRBCs in the vicinity of the secreting cell. Once the SRBCs are coated with antibody, they can be killed by adding complement. In this way the presence of each antibody-secreting cell is indicated by the presence of a clear spot, or *plaque,* in the opaque layer of SRBCs. The same assay can be used to count cells making antibody to other antigens, such as proteins or polysaccharides, if these antigens are chemically coupled to the surface of the SRBC.

The second important advance was the demonstration that B cells can be induced to secrete antibodies by exposing them to antigen in a test tube or cell culture dish, where cell-cell interactions can be manipulated and the environment controlled. This led to the discovery that both helper T cells and specialized *antigen-presenting cells* are required for most antigens to stimulate virgin B cells to secrete antibodies, as we discuss later.

Antibodies Have Two Identical Antigen-binding Sites 13

The simplest antibodies are Y-shaped molecules with two identical antigen-binding sites, one at the tip of each arm of the Y (Figure 23-14). Because of their two antigen-binding sites, they are said to be *bivalent* . As long as an antigen has three or more antigenic determinants, bivalent antibody molecules can cross-link it into a large lattice (Figure 23-15), which can be rapidly phagocytosed and degraded by macrophages. The efficiency of antigen binding and cross-linking is greatly increased by a flexible *hinge region* in antibodies, which allows the distance between the two antigen-binding sites to vary (Figure 23-16).

The protective effect of antibodies is not due simply to their ability to bind antigen. They engage in a variety of activities that are mediated by the tail of the Y-shaped molecule. This part of the molecule determines what will happen to the antigen once it is bound to the antibody. We shall see that antibodies with the same antigen-binding sites can have any one of several different tail regions, each of which confers on the antibody different functional properties, such as the ability to activate complement or to bind to phagocytic cells.

An Antibody Molecule Is Composed of Two Identical Light Chains and Two Identical Heavy Chains 13

The basic structural unit of an antibody molecule consists of four polypeptide chains, two identical light (L) chains (each containing about 220 amino acids) and two identical heavy (H) chains (each usually containing about 440 amino acids). The four chains are held together by a combination of noncovalent and covalent (disulfide) bonds. The molecule is composed of two identical halves, each with the same antigen-binding site, and both light and heavy chains usually cooperate to form the antigen-binding surface (Figure 23-17).

The proteolytic enzymes papain and pepsin split antibody molecules into different characteristic fragments. *Papain* produces two separate and identical Fab (*f* ragment *a* ntigen *b* inding) fragments, each with one antigen-binding site, and one Fc fragment (so called because it readily crystallizes). Pepsin, on the other hand, produces one F(ab')$_2$ fragment, so called because it consists of two covalently linked F(ab') fragments (each slightly larger than a Fab fragment); the rest of the molecule is broken down into smaller fragments (Figure 23-18). Because F(ab')$_2$ fragments are bivalent, they can still cross-link antigens and form precipitates, unlike the univalent Fab fragments. Neither of these fragments has the other biological properties of intact antibody molecules because they lack the tail (Fc) region that is responsible for these properties.

There Are Five Classes of Heavy Chains, Each with Different Biological Properties 10 , 14

In higher vertebrates there are five *classes* of antibodies, IgA, IgD, IgE, IgG, and IgM, each with its own class of heavy chain - α, δ, ε, γ, and μ , respectively. IgA molecules have α chains, IgG molecules have γ chains, and so on. In addition, there are a number of subclasses of IgG and IgA immunoglobulins; for example, there are four human IgG subclasses (IgG1, IgG2, IgG3, and IgG4) having γ_1 , γ_2 , γ_3 , and γ_4 heavy chains, respectively. The various heavy chains impart a distinctive conformation to the hinge and tail regions of antibodies and give each class (and subclass) characteristic properties of its own.

IgM, which has a μ heavy chain, is always the first class of antibody produced by a developing B cell, although many B cells eventually switch to making other classes of antibody (discussed below). The immediate precursor of a B cell, called a pre-B cell, initially makes μ chains, which associate with non-light-chain polypeptides (often referred to as surrogate light chains) and insert into the plasma membrane. As the synthesis of bona fide light chains increases, these combine with the mu chains,

displacing the surrogate light chains, to form a four-chain IgM molecule (with two μ chains and two light chains), which inserts into the plasma membrane. The cell now has cell-surface receptors with which it can bind antigen, and at this point it is called a *virgin B cell* . Many virgin B cells soon start to produce cell-surface IgD molecules as well, with the same antigen-binding site as the IgM molecules.

IgM is not only the first class of antibody to appear on the surface of a developing B cell, it is also the major class secreted into the blood in the early stages of a *primary* antibody response. In its secreted form IgM is a pentamer composed of five four-chain units and thus has a total of 10 antigen-binding sites. Each pentamer contains one copy of another polypeptide chain, called a *J (joining) chain.* The J chain is produced by IgM-secreting cells and is covalently inserted between two adjacent tail (Fc) regions (Figure 23-19).

The binding of antigen to the Fab regions of the secreted pentameric IgM molecule induces the Fc regions to bind to and thereby activate the first component of the *complement system* . As we discuss later, when the antigen is on the surface of an invading microorganism, the resulting activation of complement unleashes a biochemical attack that kills the microorganism. Unlike IgM, IgD molecules are rarely secreted by an activated B cell, and their functions (other than as receptors for antigen) are unknown.

The major class of immunoglobulin in the blood is IgG, which is produced in large quantities during *secondary* immune responses. Besides activating the complement system, the Fc region of an IgG molecule binds to specific receptors on macrophages and neutrophils. Largely by means of such Fc receptors, these phagocytic cells bind, ingest, and destroy infecting microorganisms that have become coated with the IgG antibodies produced in response to the infection (Figure 23-20). Some white blood cells that express Fc receptors can also kill IgG-coated foreign eucaryotic cells without phagocytosing them.

IgG molecules are the only antibodies that can pass from mother to fetus via the placenta. Cells of the placenta that are in contact with maternal blood have Fc receptors that bind IgG molecules and mediate their passage to the fetus. The antibodies are first taken up from the maternal blood by receptor-mediated endocytosis and then transported across the cell in vesicles and released by exocytosis into the fetal blood (a process called *transcytosis,* discussed in Chapter 13). Because other classes of antibodies do not bind to these receptors, they cannot pass across the placenta. IgG is also secreted into the mother's milk and is taken up from the gut of the neonate into the blood.

IgA is the principal class of antibody in secretions (saliva, tears, milk, and respiratory and intestinal secretions) (Figure 23-21). It is transported through secretory epithelial cells from the extracellular fluid into the secreted fluid by another type of Fc receptor that is unique to secretory epithelia (Figure 23-22).

The Fc region of IgE molecules binds with unusually high affinity ($K_a = 10^{10}$ liters/mole) to yet another class of Fc receptors. These receptors are located on the surface of *mast cells* in tissues and on *basophils* in the blood, and the IgE molecules bound to them in turn serve as receptors for antigen. Antigen binding triggers the cells to secrete a variety of biologically active amines, especially *histamine* (Figure 23-23). These amines cause dilation and increased permeability of blood vessels and are largely responsible for the clinical manifestations of such *allergic* reactions as hay fever, asthma, and hives. In normal circumstances the blood vessel changes are thought to help white blood cells, antibodies, and complement components to enter sites of inflammation. Mast cells also secrete factors that attract and activate a special class of white blood cells called *eosinophils,* which can kill various types of parasites, especially if the parasites are coated with IgE or IgA antibodies.

The properties of the various classes of antibodies in humans are summarized in Table 23-1 .

Antibodies Can Have Either k or l Light Chains, but Not Both

In addition to the five classes of heavy chains, higher vertebrates have two types of light chains, κ and λ, either of which may be associated with any of the heavy chains. An individual antibody molecule always consists of identical light chains and identical heavy chains; therefore, its two antigen-binding sites are always identical. This symmetry is crucial for the cross-linking function of secreted antibodies. An Ig molecule, consequently, may have either κ or λ light chains, but not both. No difference in the biological function of these two types of light chain has yet been identified.

The Strength of an Antibody-Antigen Interaction Depends on Both the Number of Antigen-binding Sites Occupied and the Affinity of Each Binding Site 10 , 15

The binding of an antigen to antibody, like the binding of a substrate to an enzyme, is reversible. It is mediated by the sum of many relatively weak noncovalent forces, including hydrophobic and hydrogen bonds, van der Waals forces, and ionic interactions. These weak forces are effective only when the antigen molecule is close enough to allow some of its atoms to fit into complementary recesses on the surface of the antibody. The complementary regions of a four-chain antibody unit are its two identical antigen-binding sites; the corresponding region on the antigen is an *antigenic determinant* (Figure 23-24). Most antigenic macromolecules have many different antigenic determinants; if two or more of them are identical (as in a polymer with a repeating structure), the antigen is said to be *multivalent* (Figure 23-25).

The reversible binding reaction between an antigen with a single antigenic determinant (denoted Ag) and a single antigen-binding site (denoted Ab) can be expressed as

$$Ag + Ab \rightleftharpoons AgAb$$
The equilibrium point depends both on the concentrations of Ab and Ag and on the strength of their interaction. Clearly, a larger fraction of Ab will become associated with Ag as the concentration of Ag is increased. The strength of the interaction is generally expressed as the affinity constant (K_a) (see Figure 3-9), where

$$K_a = \frac{[AgAb]}{[Ag][Ab]}$$

(the square brackets indicate the concentration of each component at equilibrium).

The affinity constant, sometimes called the association constant, can be determined by measuring the concentration of free Ag required to fill half of the antigen-binding sites on the antibody. When half the sites are filled, [AgAb] = [Ab] and $K_a = 1/[Ag]$. Thus the reciprocal of the antigen concentration that produces half-maximal binding is equal to the affinity constant of the antibody for the antigen. Common values range from as low as 5×10^4 to as high as 10^{11} liters/mole. The affinity constant at which an immunoglobulin molecule ceases to be considered an antibody for a particular antigen is somewhat arbitrary, but it is unlikely that an antibody with a K_a below 10^4 would be biologically effective; moreover, B cells with receptors that have such a low affinity for an antigen are unlikely to be activated by the antigen.

The affinity of an antibody for an antigenic determinant describes the strength of binding of a single copy of the antigenic determinant to a single antigen-binding site, and it is independent of the number of sites. When, however, an antigen carrying multiple copies of the same antigenic determinant combines with a multivalent antibody, the binding strength is greatly increased because all of the antigen-antibody bonds must be broken simultaneously before the antigen and antibody can dissociate. Thus a typical IgG molecule can bind at least 50-100 times more strongly to a multivalent antigen if both antigen-binding sites are engaged than if only one site is engaged. The total binding strength of a multivalent antibody with a multivalent antigen is referred to as the avidity of the interaction.

If the affinity of the antigen-binding sites in an IgG and an IgM molecule is the same, the IgM molecule (with 10 binding sites) will have a very much greater avidity for a multivalent antigen than an IgG molecule (which has two sites). This difference in avidity, often 10^4 -fold or more, is important because antibodies produced early in an immune response usually have much lower affinities than those produced later. (The increase in the average affinity of antibodies produced with time after immunization, called *affinity maturation,* is discussed later.) Because of its high total avidity, IgM - the major Ig class produced early in immune responses - can function effectively even when each of its binding sites has only a low affinity.

Antibodies Recruit Complement to Help Fight Bacterial Infections [16]

Complement, so called because it *complements* and amplifies the action of antibody, is one of the principal means by which antibodies defend vertebrates against most bacterial infections. Individuals with a deficiency in one of the central complement components (called C3) are subject to repeated bacterial infections, just as are individuals deficient in antibodies themselves.

The complement system consists of about 20 interacting soluble proteins that are made mainly by the liver and circulate in the blood and extracellular fluid. Most are inactive until they are triggered by an immune response or, more directly, by an invading microorganism itself. The ultimate consequence of complement activation is the assembly of the so-called *late complement components* into large protein complexes, called *membrane attack complexes,* that form holes in the membrane of a

microorganism and thereby destroy the microorganism.

Because one of its main functions is to attack the membrane of microbial cells, the activation of complement is focused on the microbial cell membrane, where it is triggered either by antibody bound to the microorganism or by microbial envelope polysaccharides, both of which activate the *early complement components* . There are two sets of early components belonging to two distinct pathways of complement activation, the classical pathway and the alternative pathway. The early components of both pathways act locally to activate C3, which is the pivotal component of complement, whose cleavage leads not only to the assembly of membrane attack complexes but also to the recruitment of various white blood cells (Figure 23-26).

The early components and C3 are proenzymes that are activated sequentially by limited proteolytic cleavage: the cleavage of each proenzyme in the sequence activates the component to generate a serine protease, which cleaves the next proenzyme in the sequence, and so on. Since each activated enzyme cleaves many molecules of the next proenzyme in the chain, the activation of the early components consists of an amplifying *proteolytic cascade* . Thus each molecule activated at the beginning of the sequence leads to the production of many active components, including many membrane attack complexes.

Many of these cleavages liberate a small peptide fragment and thereby expose a membrane-binding site on the larger fragment, which binds tightly to the target cell membrane and helps to carry out the next reaction in the sequence, eventually leading to the formation of membrane attack complexes. In this way complement activation is confined largely to the particular cell surface where it began. The larger fragment of C3 is called C3b. It binds covalently to the surface of a target cell. There it not only acts as a protease to catalyze the subsequent steps in the complement cascade, but also is recognized by specific receptor proteins on macrophages and neutrophils that enhance the ability of these cells to phagocytose the target cell. The smaller fragment of C3 (called C3a) acts independently as a diffusible signal that promotes an inflammatory response by encouraging white blood cells to migrate into the site of infection.

The classical pathway is usually activated by clusters of IgG or IgM antibodies bound to antigens on the surface of a microorganism. The first step in this pathway is illustrated in Figure 23-27 . The alternative pathway, by contrast, is activated by polysaccharides in the cell envelopes of microorganisms even in the absence of antibody, although activation of the classical pathway also activates the alternative pathway through a positive feedback loop. The alternative pathway therefore provides a first line of defense against infection before an immune response can be mounted, and it also amplifies the effects of the classical pathway once an immune response has begun.

Membrane-immobilized C3b, produced by either the classical or alternative pathway, triggers a further cascade of reactions that leads to the assembly of membrane attack complexes from the late components (Figure 23-28). These complexes form in the membrane near the site of C3 activation and have a characteristic appearance in negatively stained electron micrographs, where they are seen to form aqueous pores through the membrane (Figure 23-29). For this reason, and because they perturb the structure of the lipid bilayer in their vicinity, they make the membrane leaky. Small molecules leak into and out of the cell around and through the complexes while macromolecules remain inside, so that the cell's normal mechanism for controlling water balance is disrupted. Water is therefore drawn into the cell by osmosis, causing it to swell and burst. The process is so efficient that a very small number of membrane attack complexes (perhaps even one) can lyse a red blood cell. Even an enveloped virus, which does not have a large osmotic pressure gradient across its membrane and is therefore not susceptible to such osmotic lysis, can be destroyed by these complexes, presumably because they disorganize the viral membrane.

The self-amplifying destructive properties of the complement cascade make it essential that key activated components be rapidly inactivated after they are generated to ensure that the attack does not spread to nearby host cells. Deactivation is achieved in at least two ways. First, specific inhibitor proteins in the blood terminate the cascade by either binding or cleaving certain components once they have been activated by proteolytic cleavage. Second, many of the activated components in the cascade are unstable; unless they bind immediately to either an appropriate component in the chain or a nearby membrane, they rapidly become inactive.

Summary

A typical antibody molecule is a Y-shaped protein with two identical antigen-binding sites at the tips of the Y (the Fab regions) and binding sites for complement components and/or various cell-surface receptors on the tail of the Y (the Fc region). Antibodies defend vertebrates against infection by inactivating viruses and bacterial toxins and by recruiting the complement system and various cells to kill and ingest invading microorganisms.

Each B cell clone makes antibody molecules with a unique antigen-binding site. Initially, the molecules are inserted into the plasma membrane, where they serve as receptors for antigen. Antigen binding to these receptors activates the B cells (usually with the aid of helper T cells) to multiply and mature either into memory cells or into antibody-secreting cells, which secrete antibodies with the same unique antigen-binding site as the membrane-bound antibodies.

Each antibody molecule is composed of two identical heavy chains and two identical light chains. Typically, parts of both the heavy and light chains form the antigen-binding sites. There are five classes of antibodies (IgA, IgD, IgE, IgG, and IgM), each with a distinctive heavy chain (α, δ, λ, γ, and μ , respectively). The heavy chains also form the Fc region of the antibody, which determines what other proteins will bind to the antibody and therefore what biological properties the antibody class has. Either type of light chain (κ or λ) can be associated with any class of heavy chain, but the type of light chain does not seem to influence the properties of the antibody.

The complement system cooperates with antibodies to defend vertebrates against infection. The early components are proenzymes that circulate in the blood and are sequentially activated in an amplifying series of limited proteolytic reactions. The most important complement component is the C3 protein, which is activated by proteolytic cleavage and binds to the membrane of a microbial cell, where it helps to initiate the local assembly of the late complement components and to induce the phagocytosis of the microbial cell. The late components form large membrane attack complexes in the microbial cell membrane and thereby kill the invading microorganism.
Figure 23-54 . Comparison of the antigen receptors on T and B cells . In both cases the receptors (*black*) are associated with invariant trans-membrane polypeptide chains (*green*) that act as signal transducers. The invariant chains associated with the T cell receptor form the CD3 complex, while those associated with the B cell receptor are called Ig-alpha, Ig-b, and Ig-g. At

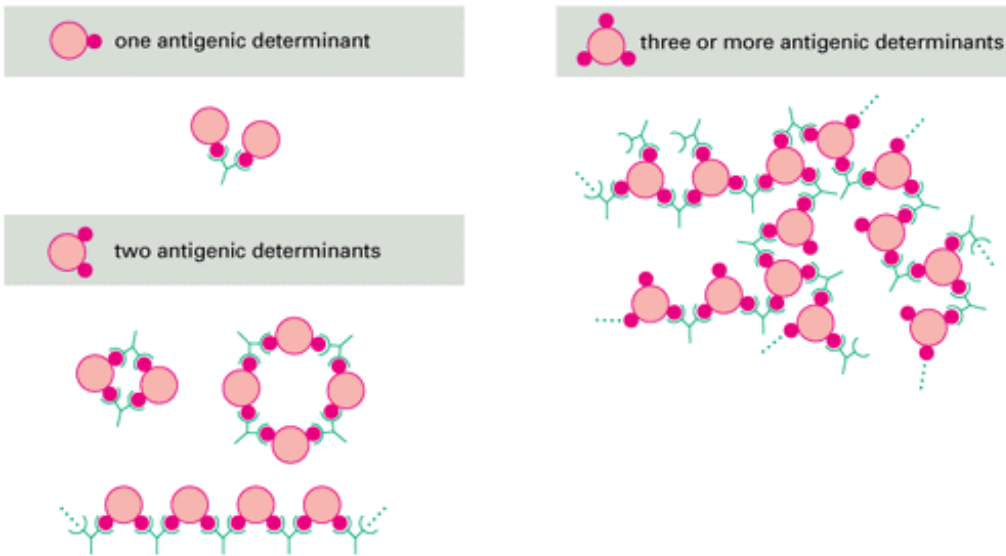
least one of the invariant chains in both cases binds a Src-like tyrosine kinase (*red*). All of the chains shown, except for the CD3-z chains and the Src-like kinases, have extracellular Ig-like domains and are therefore members of the Ig superfamily.
Figure 23-13 . B cell activation . When resting B cells are activated by antigen to proliferate and mature into antibody-secreting cells, they produce and secrete antibodies with a unique antigen-binding site, which is the same as that of their original membrane-bound antibodies that served as antigen receptors.
Figure 23-14 . A simple representation of an antibody molecule . Note that its two antigen-binding sites are identical.


Figure 23-15 . Antibody-antigen interactions . Because antibodies have two identical antigen-binding sites, they can cross-link antigens. The types of antibody-antigen complexes that form depend on the number of antigenic determinants on the antigen. Here a single species of antibody (a monoclonal antibody) is shown binding to antigens containing one, two, or three copies of a single type of antigenic determinant. Antigens with two antigenic determinants can form small cyclic complexes or linear chains with antibody, while antigens with three or more antigenic determinants can form large three-dimensional lattices that readily precipitate out of solution. Most antigens have many different antigenic determinants (see Figure 23-25A) and the different antibodies that recognize these different determinants can cooperate in cross-linking the antigen (not shown).
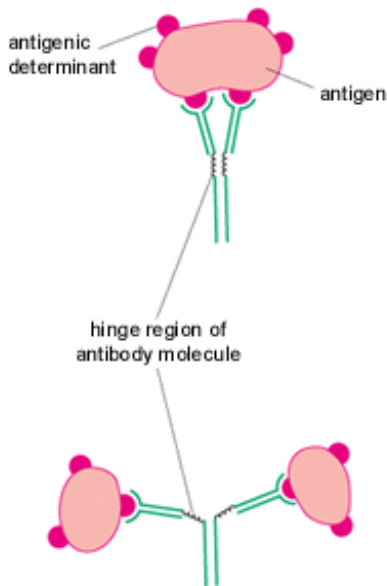

Figure 23-16 . The hinge region of an antibody molecule . Because of its flexibility, the hinge region improves the efficiency of antigen binding and cross-linking.
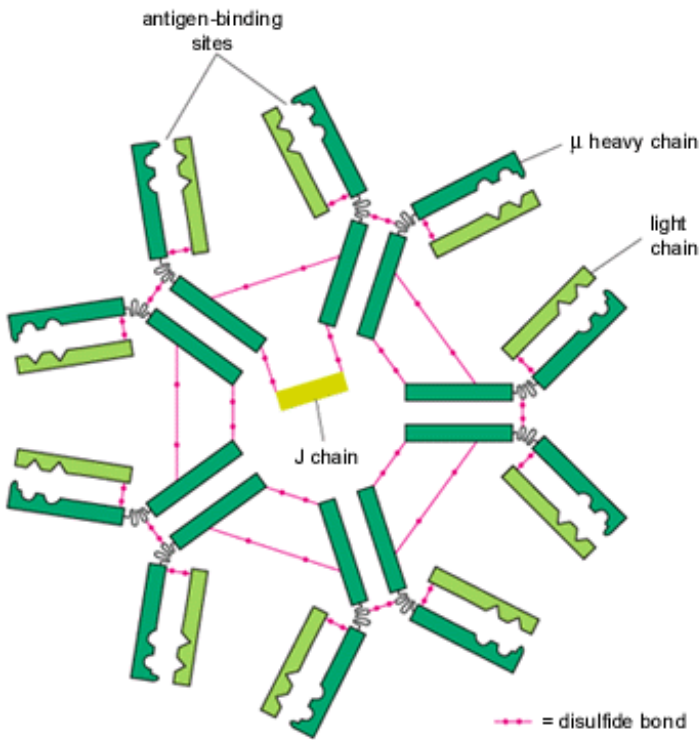
Figure 23-17 . A schematic drawing of a typical antibody molecule . It is composed of two identical heavy chains and two identical light chains. Note that the antigen-binding sites are formed by a complex of the amino-terminal regions of both light and heavy chains, but the tail and hinge regions are formed by the heavy chains alone.
Figure 23-18 . Fab and F(ab')₂ antibody fragments . These fragments are produced when antibody molecules are cleaved with the proteolytic enzymes papain and pepsin, respectively.


Figure 23-19 . **A pentameric IgM molecule** . The five subunits are held together by disulfide bonds. A single J chain, which has a structure similar to that of a single Ig domain (discussed later), is disulfide-bonded between two m heavy chains. The J chain is required for the polymerization process. The addition of each successive four-chain IgM subunit requires a J chain, which is then discarded, except for the last one, which is retained.
Figure 23-20 . Antibody-activated phagocytosis . An IgG-antibody-coated bacterium is efficiently phagocytosed by a macrophage or neutrophil, which has cell-surface receptors able to bind the Fc region of IgG molecules. The binding of the antibody-covered bacterium to these Fc receptors activates the phagocytic process.
Figure 23-21 . A highly schematized diagram of a dimeric IgA molecule found in secretions . In addition to the two IgA monomers, there is a single J chain and an additional polypeptide chain called the *secretory component,* which is thought to protect the IgA molecules from being digested by proteolytic enzymes in the secretions.
Figure 23-22 . The mechanism of transport of a dimeric IgA molecule across an epithelial cell . The IgA molecule, as a J-chain-containing dimer, binds to a specialized transmembrane Fc receptor protein on the nonluminal surface of the secretory epithelial cell. The receptor-IgA complexes are ingested by receptor-mediated endocytosis, transferred across the epithelial cell cytoplasm in vesicles, and secreted into the lumen on the opposite side of the cell by exocytosis. When exposed to the lumen, the part of the Fc receptor protein that is bound to the IgA dimer (the *secretory component*) is cleaved from its transmembrane tail, thereby releasing the antibody in the form shown in Figure 23-21 .
Figure 23-23 . The role of IgE in histamine secretion by mast cells . A mast cell (or a basophil) binds IgE molecules after they are secreted by activated B cells; the soluble IgE antibodies bind to Fc receptor proteins on the mast cell surface that specifically recognize the Fc region of these antibodies. The passively acquired IgE molecules on the mast cell serve as cell-surface receptors for antigen. Thus, unlike B cells, each mast cell (and basophil) has a set of cell-surface antibodies with a wide variety of antigen-binding sites. When an antigen molecule binds to these membrane-bound IgE antibodies so as to cross-link them to their neighbors, it activates the mast cell to release its histamine by exocytosis.

Table 23-1 . Properties of the Major Classes of Antibody in Humans

Properties	Class of Antibody				
	IgM	IgD	IgG	IgA	IgE
Heavy chains	m	d	g	a	e
Light chains	k or l	k or l	k or l	k or l	k or l

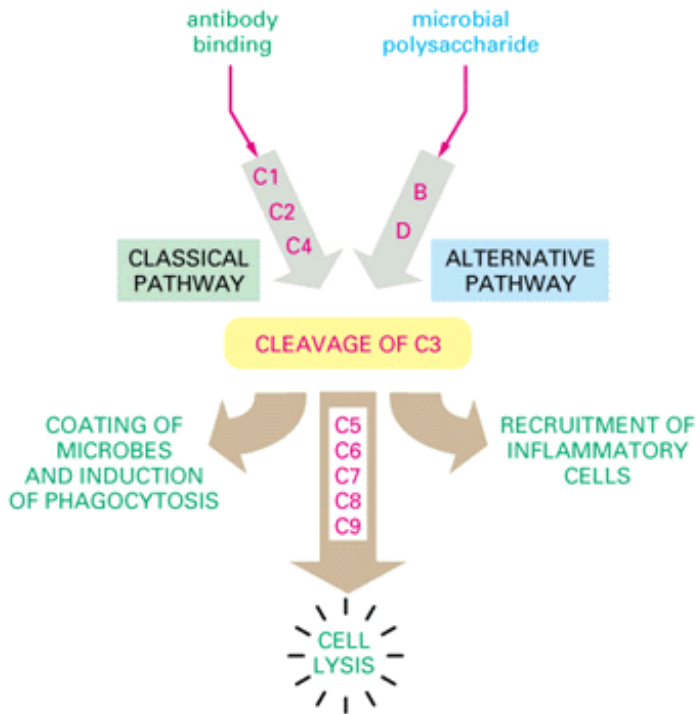
Number of four-chain units	5	1	1	1 or 2	1
Percent of total Ig in blood	10	<1	75	15	<1
Activates complement	++++	-	++	-	-
Crosses placenta	-	-	+	-	-
Binds to macrophages and neutrophils	-	-	+	-	-
Binds to mast cells and basophils	-	-	-	-	+
Figure 23-24 . Antigen binding to antibody . In this highly schematized diagram, an antigenic determinant on a macromolecule is shown interacting with the antigen-binding site of two different antibody molecules, one of high and one of low affinity. The antigenic determinant is held in the binding site by various weak noncovalent forces, and the site with the better fit to the antigen has a greater affinity. Note that both the light and heavy chains of the antibody molecule usually contribute to the antigen-binding site.
Figure 23-25 . Molecules with multiple antigenic determinants . (A) A globular protein with a number of different antigenic determinants. Different regions of a polypeptide chain usually come together in the folded structure to form each antigenic determinant on the surface of the protein. (B) A polymeric structure with many *identical* antigenic determinants; such a molecule is called a *multivalent antigen.*


Figure 23-26 . The principal stages in complement activation by the classical and alternative pathways . In both pathways the reactions of complement activation usually take place on the surface of an invading microbe, such as a bacterium. C1-C9 and factors B and D are the reacting components of the complement system; various other components (not shown) regulate the system. The *early components* are shown within *gray arrows,* while the *late components* are shown within a *brown arrow* .
Figure 23-27 . The complex structure of C1 . The binding of two or more IgG molecules (or one pentameric IgM moleculenot shown) to the surface of a microorganism enables their Fc regions to bind the first component of the classical pathway, C1, which is a large complex composed of three subcomponentsC1q, C1r, and C1s. When C1q binds to antibody-antigen complexes, it activates C1r, which becomes proteolytic, cleaving C1s to begin the proteolytic cascade. Note that C1q is composed of six identical subunits, each with a globular head (which binds to antibody) and a collagenlike tail.
Figure 23-28 . Assembly of the late complement components to form a membrane attack complex . When C3b is produced by either the classical or alternative pathway, it is immobilized on a membrane, where it causes the cleavage of a complement protein called C5 to produce C5a (not shown) and C5b. C5b remains loosely bound to C3b (not shown) and rapidly assembles with C6 and C7 to form C567, which then binds firmly via C7 to the membrane, as illustrated. This complex adds one molecule of C8 to form C5678. The binding of a molecule of C9 to C5678 induces a conformational change in the C9 that exposes a hydrophobic region and causes the C9 to insert into the lipid bilayer of the target cell next to C8. This starts a chain reaction in which the altered C9 binds a second molecule of C9, which undergoes a conformational change and inserts into the bilayer, where it can bind another molecule of C9, and so on. In this way a large transmembrane channel is formed by a chain of C9 molecules.
Figure 23-29 . Electron micrographs of negatively stained complement lesions in the plasma membrane of a red blood cell . The lesion in (A) is seen *en face,* while that in (B) is seen from the side as an apparent transmembrane channel. The negative stain fills the individual channels, which therefore look black. The Fine Structure of Antibodies

Introduction

Because antibodies exist in so many forms, in an unimmunized individual any one form will constitute a minute fraction of the Ig molecules in the blood. This fact presented immunochemists with a uniquely difficult problem in protein chemistry: how to obtain enough of any one antibody molecule to determine its amino acid sequence and three-dimensional structure.

The problem was solved by the discovery that the cells of a type of cancer known as multiple myeloma (because multiple tumors develop in the bone marrow, or myeloid tissues) secrete large amounts of a single species of antibody into the patient's blood. The antibody is homogeneous, or monoclonal, because cancer usually begins with the uncontrolled growth of a single cell, and in multiple myeloma the single cell is an antibody-secreting plasma cell. The antibody, which accumulates in the blood, is known as a myeloma protein.

The detailed structure of antibodies was initially determined by studying myeloma proteins from patients or from mice in which similar tumors had been purposely induced. Later it became possible to immortalize single antibody-secreting B cells by fusing them with non-antibody-secreting myeloma cells. The resultant *hybridomas* provide a ready source of monoclonal antibodies, which can be produced in unlimited amounts against any desired antigen, as discussed in <u>Chapter 4</u> . Today, homogeneous

antibodies can also be produced in unlimited quantities by recombinant DNA technology.

Light and Heavy Chains Consist of Constant and Variable Regions [10], [13]

Comparison of the amino acid sequences of different myeloma proteins reveals a striking feature with important genetic implications. Both light and heavy chains have a variable sequence at their amino-terminal ends but a constant sequence at their carboxyl-terminal ends. When the amino acid sequences of many different myeloma κ chains are compared, for example, the carboxyl-terminal halves are the same or show only minor differences, whereas the amino-terminal halves are all different. Thus light chains have a constant region about 110 amino acids long and a variable region of the same size. The variable region of the heavy chains (at their amino terminus) is also about 110 amino acids long, but the heavy-chain constant region is about 330 or 440 amino acids long, depending on the class (Figure 23-30).

It is the amino-terminal ends of the light and heavy chains that come together to form the antigen-binding site (see Figure 23-17), and the variability of their amino acid sequences provides the structural basis for the diversity of antigen-binding sites. The existence of variable and constant regions raises important questions about the genetic mechanisms that produce antibody molecules, and we consider these later. Before it became possible to investigate these genetic questions directly, other important features of antibody molecules emerged from structural studies on myeloma proteins.

The Light and Heavy Chains Each Contain Three Hypervariable Regions That Together Form the Antigen-binding Site [17]

Scrutiny of the amino acid sequences of a variety of Ig chains shows that the variability in the variable regions of both light and heavy chains is for the most part restricted to three small hypervariable regions in each chain. The remaining parts of the variable region, known as *framework regions,* are relatively constant. These findings led to the prediction that only the 5 to 10 amino acids in each hypervariable region form the antigen-binding site (Figure 23-31). This prediction has since been confirmed by x-ray diffraction studies of antibody molecules (see below). In agreement with the size of the antigen-binding site of an antibody molecule, the antigenic determinant that is specifically recognized by an antibody is generally comparably small: it can consist of fewer than 25 amino acid residues on the surface of a globular protein (see Figure 23-35), for example, and can be as small as a dinitrophenyl group (see Figure 23-7).

The Light and Heavy Chains Are Folded into Repeating Similar Domains [10], [18]

Both light and heavy chains are made up of repeating segments - each about 110 amino acids long and each containing one intrachain disulfide bond - that fold independently to form compact functional units, or domains. As shown in Figure 23-32 , a light chain consists of one variable (V_L) and one constant (C_L) domain, while most heavy chains consist of a variable domain (V_H) and three constant domains ($C_H 1$, $C_H 2$, and $C_H 3$). (The μ and ε chains each have one variable and four constant domains.) The variable domains are responsible for antigen binding, while the constant domains of the heavy chains (excluding $C_H 1$) form the Fc region that determines the other biological properties of the antibody.

The similarity between their domains suggests that Ig chains arose during evolution by a series of gene duplications, beginning with a primordial gene coding for a single 110 amino acid domain of unknown function. This hypothesis is supported by the finding that each domain of the constant region of a heavy chain is encoded by a separate coding sequence (exon) (Figure 23-33).

X-ray Diffraction Studies Have Revealed the Structure of Ig Domains and Antigen-binding Sites in Three Dimensions [19]

Even when the complete amino acid sequence of a large protein is known, it is not yet possible to deduce its three-dimensional structure; x-ray diffraction studies of protein crystals are generally needed. A number of fragments of both myeloma proteins and antibodies, as well as an intact IgG molecule, have been crystallized, and x-ray studies of their structures have confirmed the predictions of the immunochemists. More important, these studies have revealed the way in which millions of different antigen-binding sites are constructed on a common structural theme.

As illustrated in Figure 23-34 , each Ig domain has a very similar three-dimensional structure based on what is called the immunoglobulin fold. Each domain is roughly a cylinder (4 x 2.5 x 2.5 nm) composed of a "sandwich" of two extended protein layers: one layer contains three strands of polypeptide chain and the other contains four. In each layer the adjacent strands are

antiparallel and form a β sheet. The two layers are roughly parallel and are connected by a single intrachain disulfide bond. We shall see later that many other proteins on the surface of lymphocytes and other cells, many of which function as cell-cell adhesion molecules (discussed in Chapter 19), contain similar domains and hence are members of a very large *immunoglobulin (Ig) superfamily* of proteins.

The variable domains of Ig molecules are unique in that each has its particular set of three hypervariable regions, which are arranged in three *hypervariable loops* (see Figure 23-34B). The hypervariable loops of both the light and heavy variable domains are clustered together to form the antigen-binding site, as had been predicted. An important principle to emerge from these studies is that the variable region of an antibody molecule consists of a highly conserved rigid framework, with hypervariable loops attached at one end. Therefore, an enormous diversity of antigen-binding sites can be generated by changing only the length and amino acid sequence of the hypervariable loops without disturbing the overall three-dimensional structure necessary for antibody function.

X-ray analysis of crystals of antibody fragments bound to an antigenic determinant has revealed exactly how the hypervariable loops of the light and heavy variable domains cooperate to form an antigen-binding surface in particular cases (Figure 23-35). The dimensions and shape of each different site vary depending on the conformation of the polypeptide chain in the hypervariable loops, which in turn is determined by the sequence of the amino acid side chains in the loops. The shapes of binding sites vary greatly - from clefts, to grooves, to flatter undulating surfaces, and even to protrusions - depending on the antibody. Smaller ligands tend to bind to deeper pockets, whereas larger ones tend to bind to flatter surfaces. In addition, the binding site can alter its shape following antigen binding to better fit the ligand. Thus the general principles of antibody structure are now clear.

Summary

Each immunoglobulin light and heavy chain consists of a variable region of about 110 amino acids at its amino-terminal end, followed by a constant region, which is the same size as the variable region in the light chain and three or four times larger in the heavy chain. Each chain is composed of repeating, similarly folded domains: a light chain has one variable-region (V_L) and one constant-region (C_L) domain, while a heavy chain has one variable-region (V_H) and three or four constant-region (C_H) domains. The amino acid sequence variation in the variable regions of both light and heavy chains is for the most part confined to several small hypervariable regions; they form protruding surface loops that come together to form the antigen-binding site.

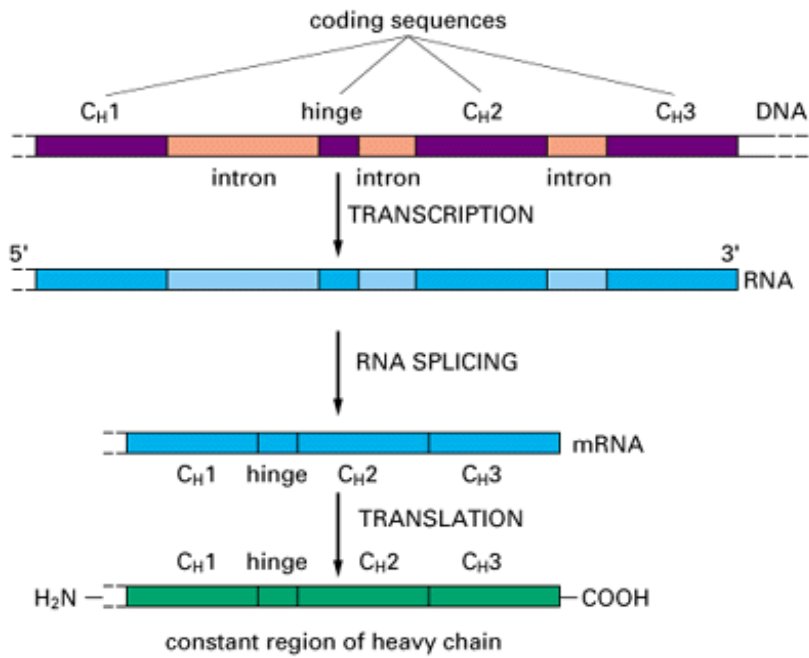
Figure 23-35 . **The three-dimensional structure of an antigen-antibody complex as determined by x-ray diffraction analysis .** The protein antigen, which is the enzyme lysozyme, is shown in *green* . The antigen-binding site of the Fab fragment of the antibody is formed by both the light chain (*yellow*) and the heavy chain (*blue*). About 20 amino acid residues in the binding site contact a similar number of residues on the lysozyme surface. In (B) the antigen and antibody have been pulled apart to reveal their complementary contacting surfaces. The bit of the antigen that protrudes from the complementary surface (shown in *red*) is a glutamine residue. In (C) the separated molecules have been rotated about 90 degrees around the vertical axis from (A) to show the interacting surfaces; the amino acid side chains that interact are shown in *red,* with the protruding glutamine now in *pink* . In several other antibody molecules that have been studied in this way, the antigen-binding site (for a small antigenic determinant) is formed by a much deeper cleft. (From A. Amit, R. Mariuzza, S. Phillips, and R. Poljak, S *cience* 233:747-753, 1986. Copyright 1986 by the AAAS.)
Figure 23-32 . **Immunoglobulin domains .** The light and heavy chains in an Ig molecule are each folded into repeating domains that are similar to one another. The variable domains (shaded in *blue*) of the light and heavy chains (V_L and V_H) make up the antigen-binding sites, while the constant domains of the heavy chains (mainly $C_H 2$ and $C_H 3$) determine the other biological properties of the molecule. The heavy chains of IgM and IgE antibodies have an extra constant domain ($C_H 4$). Hydrophobic interactions between domains on adjacent Ig chains play an important part in holding the chains together in the Ig molecule: C_L binds to $C_H 1$, for example, and the $C_H 3$ domains bind to each other.


Figure 23-33 . The organization of the DNA sequences that encode the constant region of an Ig heavy chain . The coding sequences (exons) for each domain and for the hinge region are separated by noncoding sequences (introns). The intron sequences are removed by splicing the primary RNA transcripts to form mRNA. The presence of introns in the DNA is thought to have facilitated accidental duplications of DNA segments that gave rise to the antibody genes during evolution (discussed in Chapter 8). The DNA and RNA sequences that encode the variable region of the heavy chain are not shown.

The Generation of Antibody Diversity

Introduction

It is estimated that even in the absence of antigen stimulation a human makes at least 10^{15} different antibody molecules - its *preimmune antibody repertoire* . The antigen-binding sites of many antibodies can cross-react with a variety of related but different antigenic determinants, and the preimmune repertoire is apparently large enough to ensure that there will be an antigen-binding site to fit almost any potential antigenic determinant, albeit with low affinity.

Antibodies are proteins, and proteins are encoded by genes. Antibody diversity therefore poses a special genetic problem: how can an animal make more antibodies than there are genes in its genome? (The human genome, for example, is thought to contain fewer than 10^5 genes.) This problem is not quite as formidable as it might first appear. Because the variable regions of both the light and heavy chains contribute to an antigen-binding site, an animal with 1000 genes encoding light chains and 1000 genes encoding heavy chains could combine their products in 1000 x 1000 different ways to make 10^6 different antigen-binding sites (assuming that any light chain can combine with any heavy chain to make an antigen-binding site). Nonetheless, the mammalian immune system has evolved unique genetic mechanisms that enable it to generate an almost unlimited number of different light and heavy chains in a remarkably economical way by joining separate *gene segments* together before they are transcribed. Birds and fish use very different strategies for diversifying antibodies, but we shall confine our discussion to the mechanisms used by mammals.

Antibody Genes Are Assembled from Separate Gene Segments During B Cell Development [20]

The first direct evidence that DNA is rearranged during B cell development came from experiments done in 1976 in which DNA from early mouse embryos, which do not make antibodies, was compared with the DNA of a mouse myeloma cell line, which does. The experiments showed that the specific variable (V)-region and constant (C)-region coding sequences used by the myeloma cells were present on the same DNA restriction fragment in the myeloma cells but on two different restriction fragments in the embryos, demonstrating that the DNA sequences encoding an antibody molecule are rearranged at some stage in the differentiation of B cells (Figure 23-36).

It is now known that for each type of Ig chain - κ light chains, λ light chains, and heavy chains - there is a separate pool of gene segments from which a single polypeptide chain is eventually synthesized. Each pool is on a different chromosome and usually contains a large number of gene segments encoding the V region of an Ig chain and a smaller number of gene segments encoding the C region. During B cell development a complete coding sequence for each of the two Ig chains to be synthesized is assembled by site-specific genetic recombination (discussed in Chapter 6), bringing together the entire coding sequence for a V region and the coding sequence for a C region. In addition to bringing together the separate gene segments of the antibody gene, these rearrangements also activate transcription from the gene promoter through changes in the relative positions of the enhancers and silencers acting on the promoter. Thus a complete Ig chain can be synthesized only after a DNA rearrangement

has occurred. As we shall see, the process of joining gene segments contributes to the diversity of antigen-binding sites in several ways.

Each V Region Is Encoded by More Than One Gene Segment <u>21</u>

When genomic DNA sequences encoding V and C regions were analyzed, it was found that a single *C* gene segment encodes the C region of an Ig chain, but two or more gene segments are combined to encode each V region. Each light-chain V region is encoded by a DNA sequence assembled from two gene segments - a long *V* gene segment and a short *joining,* or *J* gene segment (not to be confused with the protein *J chain* (see <u>Figure 23-19</u>), which is encoded elsewhere in the genome. <u>Figure 23-37</u> illustrates the genetic mechanisms involved in producing an intact light-chain polypeptide from separate *V, J,* and *C* gene segments.

Each heavy-chain V region is encoded by a DNA sequence assembled from three gene segmentsa *V* segment, a *J* segment, and a *diversity segment* , or *D* gene segment. <u>Figure 23-38</u> shows the organization of the gene segments used in making heavy chains.

The large number of inherited *V, J,* and *D* gene segments available for encoding Ig chains makes a substantial contribution on its own to antibody diversity, but the combinatorial joining of these segments (called combinatorial diversification) greatly increases this contribution. Any of the 300 or so *V* segments in the mouse κ light-chain gene-segment pool, for example, can be joined to any of the 4 *J* segments (see <u>Figure 23-37</u>), so that at least 1200 (300 x 4) different κ-chain V regions can be encoded by this pool. Similarly, any of the 500 or so *V* segments in the mouse heavy-chain pool can be joined to any of the 4 *J* segments and any of at least 12 *D* segments to encode at least 24,000 (500 x 4 x 12) different heavy-chain V regions. These are only rough estimates, since the exact numbers of *V* gene segments in these pools are not known.

The combinatorial diversification resulting from the assembly of different combinations of inherited *V, J,* and *D* gene segments, just discussed, is an important mechanism for diversifying the antigen-binding sites of antibodies. By this mechanism alone, it is estimated that a mouse could produce at least 1000 different V_L regions and on the order of 25,000 different V_H regions. These could then be combined to make 25×10^6 different antigen-binding sites. In addition, the joining mechanism itself, as we discuss next, greatly increases this number of possibilities (probably more than 10^8 -fold), making it much greater than the total number of B cells in a mouse (about 5×10^8).

Imprecise Joining of Gene Segments Greatly Increases the Diversity of V Regions <u>21</u> , <u>22</u>

The mechanism by which gene segments that may be hundreds of thousands of nucleotide pairs apart are joined to form a functional V_L - or V_H -region coding sequence is not known in detail. Conserved DNA sequences flank each gene segment and serve as recognition sites for a site-specific recombination system, ensuring that only appropriate gene segments recombine. Thus, for example, a *V* segment will always join to a *J* or *D* segment and not to another *V* segment. Two closely linked genes called *rag-1* and *rag-2* (*rag* = recombination activating genes) appear to encode the lymphocyte-specific proteins of the *V(D)J recombination system* . Thus, if a fibroblast is transfected with both of these genes, it is now able to rearrange experimentally introduced Ig gene segments just as a developing B cell normally does. Moreover, transgenic mice that are deficient in either gene are unable to initiate *V(D)J* rearrangements and consequently do not have functional B or T cells. (T cells use the same recombination system to assemble the genes that encode their antigen-specific receptors.)

In most cases of site-specific recombination, DNA joining is precise. But during the joining of antibody (and T cell receptor) gene segments, a variable number of nucleotides are often lost from the ends of the recombining gene segments, and, in the case of the heavy chain, one or more randomly chosen nucleotides may also be inserted. This random loss and gain of nucleotides at joining sites (called junctional diversification) enormously increases the diversity of V-region coding sequences created by recombination, specifically in the third hypervariable region. The increased diversification in this case comes at a price, since in many cases it will result in a shift in the reading frame so that a nonfunctional gene will be produced. Such "nonproductive" joining is thought to occur commonly in developing B cells.

Antigen-driven Somatic Hypermutation Fine-tunes Antibody Responses <u>23</u>

As mentioned earlier, with the passage of time after immunization there is usually a progressive increase in the affinity of the antibodies produced against the immunizing antigen. This phenomenon, known as affinity maturation, is unique to antibodies (it does not occur in T cell receptors) and is due to the accumulation of point mutations specifically in both heavy- and light-chain

V-region coding sequences. These mutations occur long after the coding regions have been assembled, when B cells are stimulated by antigen and helper T cells to generate memory cells in the activated center (so-called *germinal center*) of a lymphoid follicle in secondary lymphoid organs (see Figure 23-8). The point mutations occur at the rate of about one mutation per V-region coding sequence per cell generation, which is about a million times greater than the spontaneous mutation rate in other genes; hence, the process is called somatic hypermutation. The mechanism that allows the nucleotide changes to be targeted to the DNA of a precisely specified part of the genome in this way is not known.

Only a small minority of these point mutations will result in antigen receptors that have an increased affinity for the antigen. The few B cells expressing these high-affinity receptors, however, will be preferentially stimulated by antigen to survive and proliferate, while the other B cells will undergo programmed cell death. Thus, as a result of repeated cycles of somatic hypermutation followed by antigen-driven selection, antibodies of increasingly higher affinity are produced during the course of an immune response, providing progressively better protection against harmful antigens.

Antibody Gene-Segment Joining Is Regulated to Ensure That B Cells Are Monospecific 24

As the clonal selection theory predicts, B cells are *monospecific* . That is, all antibodies produced by one B cell have the same antigen-binding sites. This ensures that the antigen-binding sites on any one antibody molecule are identical and, therefore, that secreted antibodies can form large lattices of cross-linked antigens, thereby promoting antigen elimination (see Figure 23-15). It also ensures that an activated B cell secretes antibodies with the same specificity as that of the membrane-bound antibody on the B cell that was originally stimulated.

The requirement of monospecificity means that there must be some mechanism for ensuring that when Ig genes are activated during B cell development, only one type of V_L region and one type of V_H region are made by each B cell. Since B cells, like other somatic cells, are diploid, each cell has six gene-segment pools encoding antibodies: two heavy-chain pools (one from each parent) and four light-chain pools (one κ and one λ from each parent). If DNA rearrangements occurred independently in each heavy-chain pool and each light-chain pool, a single cell could make up to eight different antibodies, each with a different antigen-binding site. In fact, however, each B cell uses only two of the six gene-segment pools: one of the four light-chain pools and one of the two heavy-chain pools. Thus each B cell must choose not only between its κ and λ light-chain pools, but also between its maternal and paternal light-chain and heavy-chain pools (Figure 23-39). The latter choice is called allelic exclusion and seems to occur only in genes that encode antibodies (and T cell receptors). For other proteins that are encoded by autosomal genes (except for those encoded by genes that are subject to genomic imprinting - discussed in Chapter 9), both maternal and paternal genes in a cell appear to be expressed about equally.

The mechanism of allelic exclusion and κ versus λ light-chain choice during B cell development is uncertain. One possibility is that B cells are monospecific simply because the chance of a successful rearrangement occurring in more than one gene pool for each Ig chain is very low. This is unlikely to be the only mechanism, however, as there is evidence for some kind of *negative feedback regulation* on the V(D)J recombination system, whereby a functional rearrangement in one gene-segment pool suppresses rearrangements in the remaining pools that encode the same type of polypeptide chain. In B cell clones isolated from transgenic mice expressing a rearranged μ -chain gene, for example, the rearrangement of endogenous heavy-chain genes is usually suppressed, but only if the μ chain encoded by the transgene is inserted into the plasma membrane. Similar results have been obtained for light chains. It therefore seems that the product of an assembled heavy- or light-chain gene must be expressed on the cell surface for the feedback suppression to operate, suggesting that extracellular signals participate in the regulation process.

The assembly of V-region coding sequences in a developing B cell proceeds in an orderly sequence, one segment at a time, usually beginning with the heavy-chain pool. In this pool, *D* segments first join to J_H segments on both parental chromosomes. Then V_H to DJ_H joining occurs on one of these chromosomes. If this rearrangement produces a functional gene, the resulting production of complete μ chains (always the first heavy chains made) leads to their expression on the cell surface in association with a surrogate light chain. These cell-surface receptors enable the B cell to receive signals from their neighbors (called *stromal cells*), and these signals shut down all further rearrangements of V_H -region-encoding gene segments and may speed up the rate of V_L rearrangements. In mice, at least, V_L rearrangement usually occurs first in a κ gene-segment pool, and only if that fails does it occur in the other κ pool or in the λ pools. If, at any point, "in-phase" V_L -to- J_L joining leads to the production of light chains, these combine with preexisting μ chains to form IgM antibody molecules, which insert into the plasma membrane. The IgM cell-surface receptors are thought to enable the newly formed B cell to receive extracellular signals that shut down further *V*

(D)J recombination by turning off the expression of the *rag-1* and *rag-2* genes. If a developing B cell fails to assemble both a functional V_H-region and a functional V_L-region coding sequence, it is unable to make antibody molecules and dies.

Although no biological differences between κ and λ light chains have been discovered, there is an obvious advantage in having two separate pools of gene segments that encode light chains: it increases the chance that a pre-B cell that has successfully assembled a V_H-region coding sequence will go on to assemble successfully a V_L-region coding sequence to become a B cell.

When Stimulated by Antigen, B Cells Switch from Making a Membrane-bound Antibody to Making a Secreted Form of the Same Antibody 25

We now turn from the genetic mechanisms that determine the antigen-binding site of an antibody to those that determine its biological properties - the mechanisms that determine what form of heavy-chain constant region is synthesized. The choice of the particular gene segments that encode the antigen-binding site is usually a commitment for the life of a B cell and its progeny, but the type of C_H region that is made changes during B cell development. The changes are of two types: changes from a membrane-bound form to a secreted form of the same C_H region and changes in the class of the C_H region made.

All classes of antibody can be made in a membrane-bound form as well as in a soluble, secreted form. The membrane-bound form serves as an antigen receptor on the B cell surface, while the soluble form is made only after the cell is stimulated by antigen to become an antibody-secreting cell. The sole difference between the two forms resides in the carboxyl terminus of the heavy chain: the heavy chains of membrane-bound Ig molecules have a hydrophobic carboxyl terminus, which anchors them in the lipid bilayer of the B cell plasma membrane; those of secreted Ig molecules have instead a hydrophilic carboxyl terminus, which allows them to escape from the cell. The switch in the character of the Ig molecules made occurs because the activation of B cells by antigen (and helper T cells) induces a change in the way that the Ig RNA transcripts are processed in the nucleus (see Figure 9-78).

B Cells Can Switch the Class of Antibody They Make 26

During B cell development many B cells switch from making one class of antibody to making another - a process called class switching. All B cells begin their antibody-synthesizing lives by making IgM molecules and inserting them into the plasma membrane as receptors for antigen. Before they have interacted with antigen, many B cells then switch and make both IgM and IgD molecules as membrane-bound antigen receptors. Upon stimulation by antigen, some of these cells are activated to secrete IgM antibodies, which dominate the primary antibody response. Other antigen-stimulated cells switch to making IgG, IgE, or IgA antibodies; memory cells express one of these three classes of molecules on their surface, while activated B cells secrete them. The IgG, IgE, and IgA molecules are collectively referred to as *secondary* classes of antibodies because they are thought to be produced only after antigen stimulation and because they dominate secondary antibody responses. As we saw earlier, these different classes of antibodies are each specialized to attack microorganisms in different ways and in different sites.

Since the class of an antibody is determined by the constant region of its heavy chain, the fact that B cells can switch the class of antibody they make without changing the antigen-binding site implies that the same assembled V_H-region coding sequence (which specifies the antigen-binding part of the heavy chain) can sequentially associate with different C_H gene segments. This has important functional implications. It means that in an individual animal a particular antigen-binding site that has been selected by environmental antigens can be distributed among the various classes of immunoglobulin and thereby acquire the different biological properties characteristic of each class.

Class switching occurs by at least two distinct molecular mechanisms. When virgin B cells change from making membrane-bound IgM alone to the simultaneous production of membrane-bound IgM and IgD, the switch is thought to be due to a change in RNA processing. The cells produce large primary RNA transcripts that contain the assembled V_H-region coding sequence along with both the C_μ and C_δ sequences; IgM and IgD molecules are then produced by differential splicing of these RNA transcripts (Figure 23-40).

By contrast, terminal maturation to an activated B cell that secretes one of the secondary classes of antibody is accompanied by an irreversible change at the DNA level - a process called *class switch recombination* . It entails deletion of all the C_H gene segments upstream (that is, on the 5' side as measured on the coding strand) of the particular C_H segment the cell is destined to express (Figure 23-41). Evidence that this step in class switching involves DNA deletion comes from experiments on myeloma

cells: myeloma cells that secrete IgG lack the DNA coding for C_μ and C_δ regions, and those that secrete IgA lack the DNA coding for all of the other classes of heavy-chain C regions.

Summary

Antibodies are produced from three pools of gene segments, encoding κ light chains, λ light chains, and heavy chains, respectively. In each pool, separate gene segments that code for different parts of the variable regions of light and heavy chains are brought together by site-specific recombination during B cell differentiation. The light-chain pools contain one or more constant (C) gene segments and sets of variable (V) and joining (J) gene segments. The heavy-chain pool contains a set of C gene segments and sets of V, diversity (D), and J gene segments. To make an antibody molecule, a V_L gene segment is recombined with a J_L gene segment to produce a DNA sequence coding for the V region of the light chain, and a V_H gene segment is recombined with a D and a J_H gene segment to produce a DNA sequence coding for the V region of the heavy chain. Each of the assembled gene segments is then co-transcribed with the appropriate C-region sequence to produce an mRNA molecule that codes for the complete polypeptide chain. By variously combining inherited gene segments that code for V_L and V_H regions, mammals can make thousands of different light chains and thousands of different heavy chains. Since the antigen-binding site is formed where V_L and V_H come together in the final antibody, the heavy and light chains can pair to form antibodies with millions of different antigen-binding sites. This number is enormously increased by the loss and gain of nucleotides at the site of gene-segment joining, as well as by somatic mutations that occur with very high frequency in the assembled V-region coding sequences following antigen stimulation.

All B cells initially make IgM antibodies. Later some make antibodies of other classes but with the same antigen-binding site as the original IgM antibodies. Such class switching allows the same antigen-binding sites to be distributed among antibodies with varied biological properties.

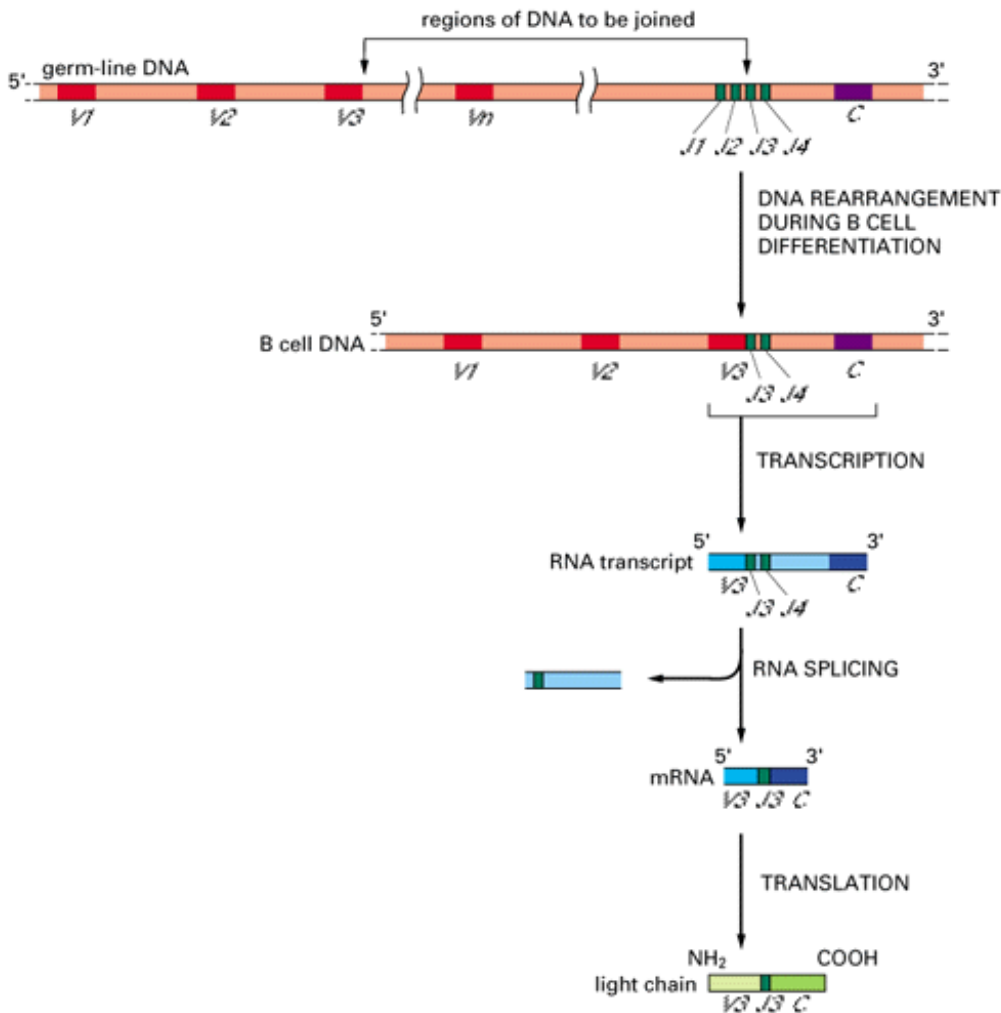
Figure 23-36 . The experiment that first directly demonstrated that DNA is rearranged during B cell development . The two radioactive DNA probes used were specific for the DNA sequences encoding the C region and the V region of the myeloma light chain.


Figure 23-37 . The *V-J* joining process involved in making a k light chain in the mouse . In the "germ-line" DNA (where the immunoglobulin genes are not being expressed and are therefore not rearranged), the cluster of four *J* gene segments is separated from the *C* gene segment by a short intron and from the 300 or so *V* gene segments by thousands of nucleotide pairs. During B cell development the chosen *V* gene segment (*V3* in this case) is moved to lie precisely next to one of the *J* gene segments (*J3* in this case). The "extra" *J* gene segment (*J4*) and the intron sequence are transcribed (along with the joined V3, J3, and C gene segments) and then removed by RNA splicing to generate mRNA molecules in which the V3, J3, and C sequences are contiguous. These mRNAs are then translated into k light chains. A *J* gene segment encodes the carboxyl-terminal 15 or so amino acids of the V region, and the *V-J* segment junction coincides with the third hypervariable region of the light chain.
Figure 23-38 . **The heavy-chain gene-segment pool in the mouse .** There are thought to be between 100 and 1000 *V* segments, at least 12 *D* segments, 4 *J* segments, and an ordered cluster of *C* segments, each encoding a different class of heavy chain. The *D* segment encodes amino acids in the third hypervariable region of the V region, as does part of the *J* segment. The figure is not drawn to scale: about 200,000 nucleotide pairs separate the *J1* and C_a gene segments, for example. Moreover, many details are omitted: for instance, there are 4 *Cg* gene segments (C_{g1} , C_{g2a} , C_{g2b} , and C_{g3}); each *C* gene segment is composed of multiple exons (see Figure 23-33); and the V_H gene segments are clustered on the chromosome in groups of homologous families. The genetic mechanisms involved in producing a heavy chain are the same as those shown in Figure 23-37 for light chains except that two DNA rearrangement steps are required instead of one: first a *D* segment joins to a *J* segment, and then a *V* segment joins to the rearranged *DJ* segments.
Figure 23-39 . **B cell development .** This drawing shows the choices in Ig gene activation that a developing B cell must make in order to produce antibodies with only one type of antigen-binding site. The choice between maternal and paternal gene-segment pools is thought to be random.
Figure 23-40 . Simultaneous synthesis of IgM and IgD . B cells that simultaneously make plasma-membrane-bound IgM and IgD molecules that have the same antigen-binding sites produce long RNA transcripts that contain both C_μ and C_d sequences. These transcripts are spliced in two ways to produce mRNA molecules that have the same V_H -region coding sequence (*V3D4J4*) joined to either a C_μ or a C_d sequence.
Figure 23-41 . An example of the DNA rearrangement that occurs in class switch recombination . When a B cell making IgM antibodies from an assembled *VDJ* DNA sequence is stimulated by antigen to mature into an IgA-antibody-secreting cell, it deletes the DNA between the *VDJ* sequence and the C_a gene segment. Specific DNA sequences (*switch sequences* , shown as *black spheres*) located upstream of each C_H gene segment (except C_d) recombine with one another to delete the intervening DNA. Class switch recombination is thought to be mediated by a *switch recombinase,* which is directed to the appropriate switch sequences when these become accessible under the influence of extracellular signals (lymphokines) secreted by helper T cells, as we discuss later.

T Cell Receptors and Subclasses

Introduction

The diverse responses of T cells are collectively called *cell-mediated immune reactions* . Like antibody responses, they are exquisitely antigen-specific and are at least as important in defending vertebrates against infection.

T cells differ from B cells, however, in several important ways. First, they act only at short range, interacting directly with another cell in the body, which they either kill or signal in some way (we shall refer to such cells as *target cells*); B cells, by contrast, secrete antibodies that can act far away. Second, T cells are specialized to recognize foreign antigen only when it is displayed on the surface of a target cell. For this reason the form of antigen recognized by T cells is different from that recognized by B cells: whereas B cells recognize intact antigen, T cells recognize peptide fragments of protein antigens that have been partially degraded inside the target cell and then carried to the cell surface and displayed there. In this way T cells are able to detect the presence of microorganisms that proliferate inside cells, as well as foreign extracellular antigens that cells have ingested.

There are two main classes of T cells - cytotoxic T cells and helper T cells. *Cytotoxic T cells* directly kill cells that are infected with a virus or some other intracellular microorganism. *Helper T cells,* by contrast, help stimulate the responses of other cells: they help activate macrophages and B cells, for example.

T Cell Receptors Are Antibodylike Heterodimers <u>27</u>

Because T cell responses depend on direct contact with a target cell, the antigen receptors made by T cells, unlike antibodies made by B cells, exist only in membrane-bound form and are not secreted. For this reason T cell receptors were difficult to isolate, and it was not until 1983 that they were first identified biochemically. On both cytotoxic and helper T cells, the receptors are composed of two disulfide-linked polypeptide chains (called α and β), each of which contains two Ig-like domains and shares with antibodies the distinctive property of a variable amino-terminal region and a constant carboxyl-terminal region (<u>Figure 23-42</u>).

The gene pools that encode the α and β chains are located on different chromosomes and contain, like antibody gene pools, separate *V, D, J,* and *C* gene segments, which are brought together by site-specific recombination during T cell development in the thymus. With one exception, all the mechanisms used by B cells to generate antibody diversity are also used by T cells to generate T cell receptor diversity; in particular, the same *V(D)J* recombination system is used, requiring the proteins encoded by the *rag-1* and *rag-2* genes discussed earlier. The mechanism that does not operate in T cell receptor diversification is antigen-driven somatic hypermutation, and so the affinity of the receptors remains low ($K_a = 10^4$ liters/mole), even late in an immune response. We discuss later how antigen-nonspecific cell-cell adhesion mechanisms greatly strengthen the binding of a T cell to its target cell, helping to compensate for the low affinity of the T cell receptors.

A small minority of T cells, instead of making α and β chains, make a different type of receptor heterodimer, composed of γ and δ chains. These cells arise early in development and are found mainly in epithelia (in the skin and gut, for example), where they may provide a first line of defense against microorganisms that attempt to penetrate these cell sheets.

As is the case for antigen receptors on B cells, the T cell receptors are tightly associated in the plasma membrane with a number of invariant proteins that are involved in passing the signal from an antigen-activated receptor to the cell interior. We discuss these proteins in more detail later.

Different T Cell Responses Are Mediated by Distinct Classes of T Cells <u>28</u>

The two major classes of T cells have very different functions. Cytotoxic T cells kill cells harboring harmful microbes, while helper T cells help activate the responses of other white blood cells, mainly by secreting a variety of local mediators, collectively called *lymphokines, interleukins,* or *cytokines* . Thus cytotoxic T cells provide protection against pathogenic microorganisms, such as viruses and some intracellular bacteria, that multiply in the host cytoplasm, where they are sheltered from attack by antibodies. The most efficient way of preventing such microorganisms from spreading to other cells is to kill the

infected cell before the microorganisms can proliferate. Helper T cells, by contrast, are crucial for stimulating responses to extracellular microorganisms and their toxic products. There are two types of helper T cells: T_H1 *cells,* which activate macrophages to destroy microorganisms that they have ingested, and T_H2 *cells,* which stimulate B cells to proliferate and secrete antibodies.

Both cytotoxic T cells and helper T cells recognize antigen in the form of peptide fragments that are generated by the degradation of foreign protein antigens inside the target cell, and both, therefore, depend on the presence in the target cell of special proteins that bind these fragments, carry them to the cell surface, and present them there to the T cells. These special proteins are called *MHC molecules* because they are encoded by a complex of genes called the *major histocompatibility complex (MHC)* . There are two structurally and functionally distinct classes of MHC molecules: *class I MHC molecules,* which present foreign peptides to cytotoxic cells, and *class II MHC molecules,* which present foreign peptides to helper cells. Before we examine the different mechanisms by which protein antigens are processed for display to the two types of T cells, we must look more closely at the MHC molecules themselves, which play such an important part in T cell immunity.

Summary

There are at least two functionally distinct subclasses of T cells: cytotoxic T cells directly kill infected cells, especially those infected with a virus, while helper T cells help activate both B cells to make antibody responses and macrophages to ingest and destroy invading microorganisms. Both types of T cells express cell-surface, anti-bodylike receptors, which are encoded by genes that are assembled from multiple gene segments during T cell development in the thymus. These receptors recognize fragments of foreign proteins that are displayed on the surface of host cells in association with MHC molecules.
Figure 23-42 . A T cell receptor heterodimer . The receptor is composed of an a and a b polypeptide chain. Each chain is about 280 amino acids long and has a large extracellular part that is folded into two Ig-like domainsone variable (V) and one constant (C). It is thought that an antigen-binding site formed by a V_a and V_b domain (shaded in *blue*) is similar in its overall dimensions and geometry to the antigen-binding site of an antibody molecule. Unlike antibodies, however, which have two binding sites for antigen, T cell receptors have only one. The a/b heterodimer shown is noncovalently associated with a large set of invariant proteins (not shown), which help activate the T cell when the T cell receptors bind to antigen. A typical T cell has about 20,000 such receptor complexes on its surface.

MHC Molecules and Antigen Presentation to T Cells <u>29</u>

Introduction

MHC molecules were recognized long before their normal function was understood. They were initially defined as the main target antigens in transplantation reactions. When organ grafts are exchanged between adult individuals, either of the same species (*allografts*) or of different species (*xenografts*), they are usually rejected. In the 1950s experiments involving skin grafting between different strains of mice demonstrated that *graft rejection* is an immune response to the foreign antigens on the surface of the grafted cells. It was later shown that these reactions are mediated mainly by T cells and that they are directed against genetically "foreign" versions of cell-surface proteins called *histocompatibility molecules* (histo = tissue). The MHC family of proteins encoded by the clustered genes of the major histocompatibility complex (MHC) are by far the most important of these. MHC molecules are expressed on the cells of all higher vertebrates. They were first demonstrated in mice and called *H-2 antigens* (histocompatibility-2 antigens). In humans they are called *HLA antigens* (human-leucocyte-associated antigens) because they were first demonstrated on leucocytes (white blood cells).

Three remarkable properties of MHC molecules baffled immunologists for a long time. First, MHC molecules are overwhelmingly the preferred target antigens for T-cell-mediated transplantation reactions. Second, an unusually large fraction of T cells are able to recognize foreign MHC molecules: whereas fewer than 0.001% of an individual's T cells respond to a typical viral antigen, for example, more than 0.1% of them respond to a single foreign MHC antigen. Third, many of the loci that code for MHC molecules are the most *polymorphic* known in higher vertebrates; that is, within a species there is an extraordinarily large number of *alleles* (alternative forms of the same gene) at each locus (in some cases as many as 100), each allele being present at a relatively high frequency in the population. For this reason, and because each individual has five or more loci encoding MHC molecules (see below), it is very rare for two individuals to have an identical set of MHC proteins, making it very difficult to match donor and recipient for organ transplantation in humans (except in the case of genetically identical twins).

A vertebrate does not need to be protected against invasion by foreign vertebrate cells. So the apparent obsession of its T cells with foreign MHC molecules and the extreme polymorphism of these molecules were a great puzzle to immunologists. The puzzle was solved only after it was discovered that MHC molecules serve to focus T cells on those host cells that have foreign antigen on their surface and that the T cells respond to foreign MHC molecules in the same way as to self MHC molecules that have foreign antigen bound to them.

There Are Two Principal Classes of MHC Molecules <u>29</u>

Class I and class II MHC proteins have very similar overall structures. They are both transmembrane heterodimers whose extracellular amino-terminal domains bind antigen for presentation to T cells.

Each class I MHC gene encodes a single transmembrane polypeptide chain (called α), most of which is folded into three extracellular globular domains (α_1 , α_2 , α_3). Each α *chain* is noncovalently associated with a small extracellular protein called β_2 *-microglobulin,* which does not span the membrane and is encoded by a gene that does not lie in the MHC gene cluster (<u>Figure 23-43A</u>). β_2 -microglobulin and the α_3 domain, which are closest to the membrane, are both homologous to an Ig domain. The two amino-terminal domains of the α chain, which are farthest from the membrane, bind antigen and contain the polymorphic (variable) amino acids that are recognized by T cells in transplantation reactions.

Like class I MHC molecules, class II MHC molecules are heterodimers with two conserved Ig-like domains close to the membrane and two antigen-binding polymorphic (variable) amino-terminal domains farthest from the membrane. In these molecules, however, both chains (α and β) are encoded within the MHC, and both span the membrane (<u>Figure 23-43B</u>). The presence of Ig-like domains in class I and class II proteins suggests that MHC molecules and antibodies have a common evolutionary history. The locations of the genes that encode class I and class II MHC proteins in mice and humans are shown in <u>Figure 23-44</u> .

X-ray Diffraction Studies Reveal the Antigen-binding Site of MHC Proteins as well as the Bound Peptide <u>30</u>

Any individual has only a small number of types of MHC molecules, which together must be able to present peptide fragments from almost any foreign protein to T cells. Thus each MHC molecule has to be able to bind a very large number of different peptides. The structural basis for this versatility has emerged from the x-ray crystallographic analysis of MHC molecules.

As shown in Figure 23-45A, a class I MHC protein has a single peptide-binding site located at one end of the molecule. This site consists of a deep groove between two long α helices derived from the nearly identical α_1 and α_2 domains; the base of the groove is formed by eight β strands derived from the same two domains. The groove is large enough to accommodate an extended peptide of about 10 amino acid residues. In fact, when a class I MHC protein was first analyzed by x-ray crystallography, this groove was found to contain a small density, suspected to be bound peptide that had co-crystallized with the MHC protein (Figure 23-45B). This finding implicated the groove as the antigen-binding site and suggested that once a peptide binds to this site, it dissociates very slowly. This conclusion is supported by the observation that cells exposed for a short period to fragments of a viral protein can remain targets for specific cytotoxic T cells for days. In acidified solutions, however, the bound peptides can be eluted from isolated class I MHC molecules, and they are indeed found to be 8 to 10 amino acid residues long. Almost all of the polymorphic amino acids in the MHC protein (those that vary between allelic forms of this type of molecule) are located inside the groove, where they would be expected to bind antigen, or on its edges, where they would be accessible for recognition by the T cell receptor.

Different peptides have been found to bind in the groove of a class I MHC protein through a combination of invariant and variable contacts. In each case the peptide is seen as an extended chain of 8 to 10 amino acids, with the invariant peptide backbone of the terminal amino acids at each end of the peptide anchored in highly conserved pockets located at each end of the groove (Figure 23-46). Other parts of the peptide bind to "specificity pockets" formed by polymorphic portions of the MHC protein, while the side chains of some residues point outward, in a position to be recognized by receptors on cytotoxic T cells. Because the conserved pockets at the ends of the binding groove recognize features of the peptide backbone that are common to many peptides, and not the amino acid side chains, which vary, a single class I MHC protein can bind a large variety of peptides of diverse sequence. At the same time the differing specificity pockets along the groove ensure that each allelic form of MHC molecule binds and presents its own characteristic set of peptides. Thus the several types of class I MHC molecules in an individual can present a broad range of foreign peptides to the cytotoxic T cells, but in each individual they do so in slightly different ways.

Class II MHC molecules have a three-dimensional structure that is very similar to that of class I molecules, but their antigen-binding grooves accommodate longer and much more heterogeneous peptides, ranging in size from 15 to 24 amino acid residues. Thus, although an individual probably makes fewer than 20 types of class II molecules, each with its own unique antigen-binding site, together these molecules seem to be able to bind and present an apparently unlimited variety of foreign peptides to helper T cells, which play a crucial part in almost all immune responses.

Class I and Class II MHC Molecules Have Different Functions 29

Class I MHC molecules are expressed on virtually all nucleated cells, presumably because cytotoxic T cells must be able to focus on any cell in the body that happens to become infected with an intracellular microbe such as a virus. Class II molecules, by contrast, are normally confined to specialized cells, such as B cells, macrophages, and other antigen-presenting cells, that take up foreign antigens from the extracellular fluid and interact with helper T cells (Figure 23-47). The principal features of the two classes of MHC proteins are summarized in Table 23-2 .

It is important that cytotoxic T cells focus their attack on cells that *make* foreign antigens, while helper T cells focus their help on cells that take up foreign antigens from the extracellular fluid. The former type of target cell is a menace, but the latter type is essential for the body's immune defenses. The immune system must be able to dispose of extracellular foreign antigens, as many bacteria multiply outside cells, and some secrete protein toxins, such as tetanus toxin and botulinum toxin, that can be lethal. Helper T cells help eliminate such pathogens both by helping B cells make antibodies against microbes and against their toxins and by activating macrophages to destroy ingested microbes.

To ensure that there is no misdirection of cytotoxic and helper functions, each of the two major classes of T cells, in addition to the antigen receptor that recognizes a peptide-MHC complex, also expresses a *co-receptor* that recognizes a nonpolymorphic part of the appropriate class of MHC molecule, as we now discuss.

CD4 and CD8 Proteins Act as MHC-binding Co-Receptors on Helper and Cytotoxic T Cells, Respectively 31

The affinity of T cell receptors for peptide-MHC complexes on a target cell is usually too low to mediate a functional interaction between the two cells. *Accessory receptors* are normally required to help stabilize the interaction by increasing the overall strength of the cell-cell adhesion; when they also have a direct role in activating the T cell by generating their own intracellular signals, they are called *co-receptors.* Unlike T cell receptors or MHC molecules, the accessory receptors do not bind antigen and are invariant and nonpolymorphic.

The most important and best understood of the co-receptors on T cells are the CD4 and CD8 proteins, both of which are single-pass transmembrane proteins with extracellular Ig-like domains. Like T cell receptors, they recognize MHC proteins, but, unlike T cell receptors, they bind to nonvariable parts of the protein, far away from the peptide-binding groove. CD4 is expressed on helper T cells and binds to class II MHC molecules, whereas CD8 is expressed on cytotoxic T cells and binds to class I MHC molecules (Figure 23-48). Thus CD4 and CD8 contribute to T cell recognition by helping to focus the cell on particular MHC molecules, and thus on particular types of target cells. The cytoplasmic tail of these transmembrane proteins is associated with a member of the Src family of tyrosine-specific protein kinases called the *Lck* protein, which phosphorylates various cellular proteins on tyrosine residues and thereby participates in the activation of the T cell.

The CD4 and CD8 proteins not only are required to increase the strength of cell-cell adhesion and to help activate the T cell, they are also needed for T cell development: if the genes that encode CD4 or CD8 are inactivated in a mouse by targeted genetic recombination, then either helper T cells or cytotoxic T cells, respectively, do not develop. Ironically, CD4 also functions as a receptor for the AIDS virus (HIV), allowing the virus to infect helper T cells.

Summary

Class I and class II MHC molecules are the most polymorphic proteins known - that is, they show the greatest genetic variability from one individual to another - and they play a crucial role in presenting foreign protein antigens to cytotoxic and helper T cells, respectively. Whereas class I molecules are expressed on almost all vertebrate cells, class II molecules are restricted to a few cell types that interact with helper T cells, such as B lymphocytes and macrophages. Both classes of MHC molecules have Ig-like domains and a single peptide-binding groove, which binds small peptide fragments derived from foreign proteins. Each MHC molecule can bind a large and characteristic set of peptides, which are produced intracellularly by protein degradation. After they form inside the target cell, the peptide-MHC complexes are transported to the cell surface, where they are recognized by T cell receptors. In addition to their antigen-specific receptors that recognize peptide-MHC complexes on the surface of target cells, T cells express CD4 or CD8 co-receptors, which recognize nonpolymorphic regions of MHC molecules on the target cell: helper cells express CD4, which recognizes class II MHC molecules, while cytotoxic T cells express CD8, which recognizes class I MHC molecules.
Figure 23-43 . Class I and class II MHC proteins . (A) The a chain of the class I molecule has three extracellular domains, a_1, a_2, and a_3, encoded by separate exons. It is noncovalently associated with a smaller polypeptide chain, b_2 -micro-globulin, which is not encoded within the MHC. The a_3 domain and b_2 -microglobulin are Ig-like. While b_2 -microglobulin is invariant, the a chain is extremely polymorphic, mainly in the a_1 and a_2 domains. (B) In class II MHC molecules both chains are polymorphic (b more than a), mainly in the a_1 and b_1 domains; the a_2 and b_2 domains are Ig-like. Thus there are striking similarities between class I and class II MHC proteins. In both, the two outermost domains (shaded in *blue*) interact to form a groove that binds foreign antigen and presents it to T cells. All of the chains are glycosylated except for b_2 -microglobulin (not shown).
Figure 23-44 . The *H-2* and *HLA* gene complexes . This simplified schematic drawing shows the location of the genetic loci that encode the transmembrane subunits of class I (*light green*) and class II (*dark green*) MHC proteins. There are three types of class I proteins (H-2K, H-2D, and H-2L in mouse, and HLA-A, HLA-B, and HLA-C in human). There are two class II MHC loci in the mouse *H-2A* and *H-2E* and more than three in humans, of which only three are shown *HLA-DP, HLA-DQ,* and *HLA-DR* . Each class II locus encodes at least one a chain and at least one b chain, but some encode more than one a or b chain (not

shown).
Figure 23-45 . (A) The structure of a human class I MHC protein as determined by x-ray diffraction analysis of crystals of the extracellular part of the molecule . The extracellular part of the protein was cleaved from the transmembrane segment by the proteolytic enzyme papain prior to crystallization. Each of the two domains closest to the plasma membrane (a_3 and b_2 - microglobulin) resembles a typical immunoglobulin domain (see Figure 23-34B), while the two domains farthest from the membrane (a_1 and a_2) are very similar to each other and together form a peptide-binding groove at the top of the molecule.

Class II MHC molecules are thought to have a very similar structure. (B) The peptide-binding groove viewed from above, containing the small peptides that co-purified with the MHC protein. This is the part of the MHC molecule that interacts with the T cell receptor. (After P.J. Bjorkman, M.A. Saper, B. Samraoui, W.S. Bennett, J.L. Strominger, and D.C. Wiley, *Nature* 329:506-512, 1987.)
Figure 23-46 . Highly schematized drawing of a peptide in the binding groove of a class I MHC molecule . In this top view the peptide backbone is shown as a string of *red* balls, each of which represents one of the nine amino acid residues. The backbones of the "anchor residues" at the ends of the peptide bind to conserved pockets at the ends of the groove.

Table 23-2 . Properties of Class I and Class II MHC Molecules

	Class I	Class II
Genetic loci	*H-2K, H-2D, H-2L* in mice; *HLA-A, HLA-B, HLA-C* in humans	*H-2A* and *H-2E* clusters in mice; *DP, DQ, DR,* and several others in humans
Chain structure	a chain + b_2 -microglobulin	a chain + b chain
Cell distribution	most nucleated cells	antigen-presenting cells (including B cells), thymus epithelial cells, some others
Involved in presenting antigen to	cytotoxic T cells	helper T cells
Source of peptide fragments	proteins made in cytosol	endocytosed plasma membrane and extracellular proteins
Polymorphic domains	$a_1 + a_2$	$a_1 + b_1$
Figure 23-47 . Cytotoxic and helper T cells recognize different MHC molecules . Cytotoxic T cells recognize foreign antigens in association with class I MHC proteins on the surface of any infected host cell, whereas helper T cells recognize foreign antigens in association with class II MHC proteins on the surface of an antigen-presenting cell, such as a macrophage or a B cell. The foreign antigen bound to a class I MHC molecule is synthesized within the target cell, while the foreign antigen bound to a class II MHC molecule has been taken up by the cell by endocytosis and processed before it is presented on the cell surface (not shown). In transplantation reactions as well, helper T cells react against foreign class II MHC proteins, whereas cytotoxic T cells react against foreign class I MHC proteins.
Figure 23-48 . CD4 and CD8 co-receptors on the surface of T cells . Note that these proteins bind to the nonvariable part of the same MHC molecule that the T cell receptor has engaged, so that they are brought together with T cell receptors during the cell activation process. Antibodies against CD4 and CD8 are widely used to distinguish helper and cytotoxic T cells, respectively.

Cytotoxic T Cells

Introduction

As previously discussed, cytotoxic T cells defend us against microorganisms such as viruses that grow inside cells, away from the reach of antibodies. Cytotoxic T cells, unlike antibodies, can recognize such infected cells because class I MHC molecules continually ferry fragments of the microbe's proteins to the cell surface, where they can be detected by the T cells. In this section we discuss how these fragments are generated and delivered to the class I MHC molecules, and we consider how cytotoxic T cells kill infected target cells.

Cytotoxic T Cells Recognize Fragments of Viral Proteins on the Surface of Virus-infected Cells 32

The first clear evidence that MHC molecules present foreign antigens to T cells came from an experiment performed in 1974 that showed that cytotoxic T cells from a virus-infected mouse could kill cultured cells infected with the same virus only if these cells expressed some of the same class I MHC molecules as the infected mouse (Figure 23-49). This experiment demonstrated that the T cells of any individual that recognize a specific antigen will do so only when that antigen is associated with the allelic forms of MHC molecules expressed by that individual, a phenomenon known as *MHC restriction* . It was not until 10 years later, however, that the chemical nature of the viral antigens recognized by cytotoxic T cells was discovered. In experiments on cells infected with influenza virus, it was unexpectedly found that some of the cytotoxic T cells activated by the virus specifically recognize internal proteins of the virus that would not be accessible in the intact virus particle. Subsequent evidence suggested that the T cells were recognizing degraded fragments of the internal viral proteins. Because a T cell can recognize tiny amounts of antigen (only a few hundred molecules), only a small fraction of the fragments generated from viral proteins have to get to the cell surface to attract an attack by a cytotoxic T cell. A mystery remained, however.

Since almost all proteins in a cell are known to be continually degraded (as discussed in Chapter 5), it is not difficult to understand how peptide fragments of internal viral proteins are produced in an infected cell. But it is less obvious how these fragments get exposed on the cell surface. Like other cellular proteins, the viral proteins are synthesized on cytosolic ribosomes, and, as explained in Chapter 12 , special mechanisms are required if they are to leave the cytosol by crossing a membrane into some other compartment. Proteins destined for the cell surface usually begin their journey by crossing from the cytosol into the lumen of the endoplasmic reticulum (ER) (Figure 23-50). The puzzle of how viral protein fragments reach the cell surface was solved by the discovery of a remarkable transport system that vertebrate cells have for transporting such peptides from the cytosol into the ER lumen. Once inside the ER, the peptides can bind to MHC molecules that they encounter there and so can be carried to the cell surface with them.

MHC-encoded ABC Transporters Transfer Peptide Fragments from the Cytosol to the ER Lumen 33

As noted in Chapter 5 , proteolytic degradation in the cytosol is mainly mediated by an ATP- and ubiquitin-dependent mechanism that operates in *proteasomes* , which are large proteolytic enzyme complexes constructed from many different protein subunits. Although all proteasomes are probably able to generate peptide fragments that will bind to class I MHC molecules, some are thought to be specialized for this purpose because they contain two subunits that are encoded by genes located within the MHC chromosomal region.

The mechanism whereby peptides are delivered to the ER lumen from the cytosol was discovered through observations on mutant cells in which class I MHC molecules are not expressed at the cell surface but are instead degraded within the ER. The mutant genes in these cells proved to encode subunits of a protein belonging to the family of *ABC transporters,* which we encountered in Chapter 11 . This transporter protein is located in the ER membrane and uses the energy of ATP hydrolysis to pump peptides from the cytosol into the ER lumen. The genes encoding its two subunits are in the MHC chromosomal region, and if either gene is inactivated by mutation, cells are unable to supply peptides to class I MHC molecules. The fact that the class I MHC molecules in such mutant cells are degraded in the ER suggests that peptide binding is normally required for the proper folding and/or stable assembly of MHC molecules. In cells that are not infected by viruses, peptide fragments come from normal cytosolic and nuclear proteins that are degraded in the process of normal protein turnover; these peptides are carried to the cell surface by MHC molecules but are not antigenic because the cytotoxic T cells that could recognize them have been eliminated or inactivated during T cell development, as we discuss later. A current view of how viral proteins are processed for presentation to cytotoxic T cells is shown in Figure 23-51 .

When T cells are activated by antigen, they secrete various signaling molecules, including γ-interferon, which greatly enhances anti-viral responses. The γ-interferon induces the expression of many genes within the MHC chromosomal region, including those that encode class I (and class II) MHC proteins, the two specialized proteasome subunits, and the two subunits of the peptide pump located in the ER. Thus all of the machinery required for presenting viral antigens to cytotoxic T cells is coordinately called into action by γ-interferon, creating a positive feedback that amplifies the immune response and culminates in the death of the infected cell.

Cytotoxic T Cells Induce Infected Target Cells to Kill Themselves 34

Once a cytotoxic T cell has recognized a viral peptide bound to a class I MHC molecule on the surface of a target cell, its job is to destroy the cell before the virus that gave rise to the peptide can produce new viral particles that can escape from the infected cell. When a cytotoxic T cell, caught in the act of killing its target, is labeled with anti-tubulin antibodies, its centrosome is seen to be oriented toward the point of contact with the target cell (Figure 23-52). Moreover, antibody labeling shows that talin, a protein that helps link cell-surface receptors to cortical actin filaments, is concentrated in the cortex of the T cell at the contact site. It is thought that the aggregation of T cell receptors at the contact site leads to a local, talin-dependent alteration in the actin filaments in the cell cortex; a microtubule-dependent mechanism then moves the centrosome and its associated Golgi apparatus toward the contact site, focusing the killing machinery on the target cell. A similar cytoskeletal polarization is seen when a helper T cell functionally interacts with a target cell.

The mechanism by which cytotoxic T cells kill their targets is not known for certain. They seem to employ at least two strategies, both of which are thought to operate by inducing the target cell to undergo *programmed cell death* (also called *apoptosis,* see p. 1169). In one strategy, binding to a target cell stimulates these cytotoxic T cells to release pore-forming protein called perforin, which is homologous to the complement component C9 and polymerizes in the target cell plasma membrane to form transmembrane channels. Perforin is stored in secretory vesicles and is released by local exocytosis at the point of contact with the target cell. The secretory vesicles also contain serine proteases and other proteins, which are also thought to play a part in killing the target cell, perhaps, by entering the target cell through the perforin channels and inducing programmed cell death. The second strategy, by contrast, involves the cytotoxic T cell activating a receptor on the surface of the target cell, thereby signaling the target cell to undergo programmed cell death.

Summary

Cytotoxic T cells directly kill infected target cells that display fragments of microbial protein on their surface. Some of the microbial proteins that are synthesized in the cytosol of the target cell are degraded by proteasomes, and some of the resulting peptide fragments are pumped by an ABC transporter into the lumen of the ER, where they bind to class I MHC molecules. The peptide-MHC complexes are then transported to the target cell surface, where they are recognized by cytotoxic T cells. These T cells are thought to kill infected target cells by inducing the target cell to undergo programmed cell death.
Figure 23-49 . The classic experiment showing that a cytotoxic T cell recognizes some aspect of the surface of the host target cell in addition to a viral antigen . Mice of strain X are infected with virus A. Seven days later, the spleens of these mice contain active cytotoxic T cells able to kill virus-infected, strain-X fibroblasts in cell culture. As expected, they kill only

fibroblasts infected with virus A and not those infected with virus B; thus the cytotoxic T cells are virus-specific. The same T cells, however, are also unable to kill fibroblasts from strain-Y mice infected with the same virus A, indicating that the cytotoxic T cells recognize a genetic difference between the two kinds of fibroblasts and not just the virus. Pinning down the difference required the use of special strains of mice (known as *congenic strains*) that either were genetically identical except for the alleles at their class I MHC loci or were genetically different except for these alleles. In this way it was found that the killing of infected target cells required that they express at least one of the same class I MHC alleles expressed by the original infected mouse. This indicated that class I MHC proteins are necessary to present cell-surface-bound viral antigens to cytotoxic T cells.
Figure 23-50 . The peptide-transport problem . How do peptide fragments get from the cytosol, where they are produced, into the ER lumen, where class I MHC molecules are made? A special transport process is required.
Figure 23-51 . The processing of viral protein for presentation to cytotoxic T cells . A cytotoxic T cell will kill a virus-infected cell when it recognizes fragments of foreign protein bound to class I MHC molecules on the surface of the infected cell. Although not all viruses enter the cell in the way that this enveloped RNA virus does, fragments of internal viral proteins always follow the pathway shown. Only a very small proportion of the viral proteins synthesized in the cytosol are degraded, but it is a sufficient amount to attract an attack by a cytotoxic T cell.
Figure 23-52 . Cytotoxic T cells in the process of killing target cells in culture . The cells are visualized by electron microscopy in (A) and (B) and by immunofluorescence microscopy after staining with anti-tubulin antibodies in (C). The cytotoxic T cells were obtained from mice immunized with the target cells, which are foreign tumor cells. The T cells (the small cells) are shown binding to the target cell in (A) and (C) and having killed the target cell in (B). In an animal, as opposed to in a tissue culture dish, the killed target cell would be phagocytosed by neighboring cells before it disintegrated in the way that it has here. Note that the centrosome in the T cell and the microtubules radiating from it are oriented toward the point of cell-cell contact with the target cell (C). (A and B, from D. Zagury, J. Bernard, N. Thierness, M. Feldman, and G. Berke, *Eur. J. Immunol.* 5:818-822, 1975; C, reproduced from B. Geiger, D. Rosen, and G. Berke, *J. Cell Biol* . 95:137-143, 1982, by copyright permission of the Rockefeller University Press.)

Helper T Cells and T Cell Activation 35

Introduction

Unlike cytotoxic T cells, helper T cells do not act directly to kill infected cells or to eliminate microorganisms. Instead, they stimulate macrophages to be more effective in destroying pathogens, and they help other types of lymphocytes to respond to antigen. The crucial importance of helper T cells in immunity is dramatically demonstrated by the devastating epidemic of *acquired immunodeficiency syndrome (AIDS)* . The disease is caused by a retrovirus (human immunodeficiency virus, HIV) that depletes the number of helper T cells by an unknown mechanism, thereby crippling the immune system and rendering the patient susceptible to infection by microorganisms that are normally not dangerous. As a result, most AIDS patients die of infection within several years of the onset of symptoms.

In this section we consider how class II MHC molecules on antigen-presenting cells acquire peptide fragments from endocytosed proteins and present them to helper T cells. We then discuss the multiple signals required to activate helper T cells and how these cells, once activated, help activate B cells and macrophages.

Helper T Cells Recognize Fragments of Endocytosed Foreign Protein Antigens in Association with Class II MHC Proteins 36

Before they can help other lymphocytes respond to antigen, helper T cells must first be activated themselves. This activation occurs when helper T cells recognize foreign antigen bound to class II MHC proteins on the surface of specialized *antigen-presenting cells,* which are found in most tissues. We discuss these cells in more detail later.

Like the viral antigens presented to cytotoxic T cells, the antigens presented to helper T cells on antigen-presenting cells are degraded fragments of foreign protein that are bound to class II MHC molecules in much the same way that virus-derived peptides are bound to class I MHC molecules. But both the source of the peptide fragments presented and the route they take to

find the MHC molecules are different from those of peptide fragments presented by class I MHC molecules to cytotoxic T cells. Rather than being derived from foreign protein synthesized inside the target cell, the peptides presented to helper T cells are derived from extracellular microbes or their products, which have been ingested by antigen-presenting cells and degraded in the acidic environment of endosomes. These peptides do not have to be pumped across a membrane because they do not originate in the cytosol; they are generated in a compartment that is topologically equivalent to the extracellular space. They never enter the lumen of the ER, where the class II MHC molecules are synthesized and assembled, but instead bind to preassembled class II heterodimers in a late endosomal compartment. Once the peptide binds, the class II MHC molecule alters its conformation, trapping the peptide in the binding groove for presentation at the cell surface to helper T cells.

If it is to function in the presentation of peptides derived from extracellular foreign proteins, a newly synthesized class II MHC molecule must avoid clogging its binding site prematurely with peptides derived from endogenously synthesized proteins in the ER lumen. A nonpolymorphic polypeptide, called the invariant chain, acts in at least two ways to help ensure this. First, it associates with newly synthesized class II MHC heterodimers in the ER in such a way as to prevent them from binding peptides in the lumen of the ER. Second, it directs class II MHC molecules from the *trans* Golgi network to the endosome compartment, where the invariant chain is released by proteolysis, freeing the class II molecules to bind peptide fragments derived from endocytosed proteins (Figure 23-53). In this way the functional differences between class I and class II MHC molecules are maintained - the former presenting molecules that come from the cytosol, the latter presenting molecules that come from the extracellular space.

Most of the class I and class II MHC molecules on the surface of a target cell have peptides derived from self proteins in their binding groove - for class I molecules, fragments of degraded cytosolic and nuclear proteins; for class II molecules, fragments of degraded membrane and serum proteins that pass through the endosome-lysosome system. Only a small fraction of the class II MHC molecules on the surface of an antigen-presenting cell will have foreign peptides bound to them. This, however, suffices to initiate an immune response, because only a few hundred such molecules are required to activate a helper T cell, just as only a few hundred peptide-class-I-MHC complexes on a target cell are required to activate a cytotoxic T cell.

Helper T Cells Are Activated by Antigen-presenting Cells 37

Just as a B cell must be activated to proliferate and differentiate into an antibody-secreting cell before it can function, so a T cell must be activated to proliferate and differentiate before it can kill an infected target cell or help a macrophage or B cell. The initial activation of a T cell usually occurs when it recognizes a foreign peptide bound to an MHC molecule on the surface of an appropriate target cell. For a helper T cell the appropriate target is an antigen-presenting cell.

Antigen-presenting cells are derived from the bone marrow and comprise a heterogeneous set of cells, including *interdigitating dendritic cells* in lymphoid organs and *Langerhans cells* in skin, as well as the B cells and macrophages that will subsequently be the target of T cell help. Together with thymus epithelial cells, which have a special role in T cell development (discussed later), and activated T cells in some mammals, these specialized antigen-presenting cells are the only cell types that normally express class II MHC molecules (see Table 23-2). In addition to class II MHC molecules, antigen-presenting cells also express a second cell-surface molecule, called B7, that plays a crucial part in activating T cells, as we discuss below.

The T Cell Receptor Forms Part of a Large Signaling Complex in the Plasma Membrane 38

The activation of a cytotoxic or helper T cell is a complicated process that is still incompletely understood. The T cell receptor heterodimer recognizes foreign peptides bound to MHC molecules on the surface of the target cell. As in the case of B cells, the receptor is associated with a set of invariant transmembrane polypeptide chains (called the CD3 complex) that transduce the extracellular binding event into intracellular activating signals. The CD3 complex is thought to activate one or more members of the Src family of tyrosine kinases, including the *Fyn* protein, to phosphorylate various cellular proteins, including components of the CD3 complex itself and the enzyme phospholipase C-g, which in turn activates the inositol phospholipid signaling pathway described in Chapter 15 . The T cell and B cell receptors and their associated polypeptide chains are compared in Figure 23-54 .

The T cell receptor and CD3 complex do not act on their own to activate a T cell. A variety of co-receptors also play important roles. We have already discussed the CD4 and CD8 co-receptors and their associated Lck kinase, and a number of others have also been defined. In the process of T cell activation, these receptors and co-receptors, as well as their associated Src-like tyrosine kinases, are thought to assemble into a large signaling complex in the plasma membrane of the T cell. Even this large signaling complex, however, is not enough on its own to activate a helper T cell: another, independent signaling pathway is also

required.

Two Simultaneous Signals Are Required for Helper T Cell Activation 39

To activate a helper T cell, an antigen-presenting cell must provide at least two signals. S *ignal 1* we have already discussed: it is provided by a foreign peptide bound to a class II MHC molecule on the surface of the presenting cell, which activates the T cell receptor complex illustrated in Figure 23-54A. Depending on the type of helper T cell (discussed below), *signal 2* is provided either by a secreted chemical signal, such as *interleukin-1 (IL-1),* or by the plasma-membrane-bound signaling molecule B7 on the surface of the antigen-presenting cell. B7 is recognized by a co-receptor protein called CD28, which is present on the surface of the helper T cell and is a member of the Ig superfamily. If helper T cells receive both signals, they are activated to proliferate and to secrete a variety of *interleukins* . In contrast, if they receive signal 1 without signal 2, they are altered so that they can no longer be activated even if they receive both signals (Figure 23-55). This has been suggested to be one mechanism whereby T cells become *tolerant,* as we discuss later.

Once a helper or cytotoxic T cell has been stimulated by antigen, other accessory proteins on its surface are called into play to increase the strength of T cell binding to the target cell. In Chapter 19 , for example, we discussed how stimulation of a T cell activates the *lymphocyte-function-associated* protein *LFA-1* , a member of the integrin family of cell-adhesion proteins, so that LFA-1 can bind to its ligand on the target cell; the ligand is called *intercellular adhesion molecule 1 (ICAM-1)* , and it is a member of the Ig superfamily.

Some of the co-receptors and other accessory proteins on the surface of T cells are summarized in Table 23-3 .

Helper T Cells, Once Activated, Stimulate Themselves and Other T Cells to Proliferate by Secreting Interleukin-2 40

The combined action of signal 1 and signal 2 provokes helper T cell proliferation by a curiously indirect mechanism. It causes the T cells to stimulate their own proliferation by simultaneously secreting a growth factor called interleukin-2 (IL-2) and synthesizing cell-surface receptors that bind it. The binding of IL-2 to these IL-2 receptors then directly stimulates the T cells to proliferate. By this *autocrine mechanism,* helper T cells can continue to proliferate after they have left the surface of the antigen-presenting cell (Figure 23-56). The helper T cells can also stimulate the proliferation of any other nearby T cells, including cytotoxic T cells, that have first been induced by antigen to express IL-2 receptors. Because the expression of IL-2 receptors is strictly dependent on antigen stimulation, however, IL-2 causes the proliferation of only T cells that have encountered their specific antigen.

Once the requirements for T cell proliferation were discovered, it was possible to produce indefinitely proliferating, antigen-specific *T cell lines* in culture by administering IL-2 and periodically stimulating the cells with antigen to maintain the expression of IL-2 receptors. Single cells from such lines can be isolated to generate T cell clones. Such clones have been crucially important in T cell research. Together with *T cell hybridomas* (which are analogous to the monoclonal-antibody-secreting B cell hybridomas mentioned earlier and are produced by fusing antigen-specific T cells with a T cell tumor line), T cell clones made it possible to isolate T cell receptors and their genes. They have also been widely used to study the mechanisms of T cell activation and the role of helper T cells in stimulating the responses of other cells, such as B cells and macrophages.

Helper T Cells Are Required for Most B Cells to Respond to Antigen 41

The role of helper T cells in B cell antibody responses was first discovered in the mid-1960s through experiments in which either thymus cells or bone marrow cells were injected together with antigen into irradiated mice. Mice that had received only bone marrow or only thymus cells were unable to make antibody, but if a mixture of thymus and bone marrow cells was injected, large amounts of antibody were produced. It was later shown that the thymus provides T cells while the bone marrow provides B cells. The use of specific markers to distinguish between the injected T and B cells showed that the antibody-secreting cells are B cells, leading to the conclusion that T cells must help B cells respond to antigen.

There are some antigens, however, including many microbial polysaccharides, that can stimulate B cells to proliferate and differentiate into antibody-secreting cells without T cell help. Such *T-cell-independent antigens* are often large polymers with repeating, identical antigenic determinants (see Figure 23-25B); their multipoint binding to the membrane-bound antibody molecules that serve as antigen receptors on B cells may generate a signal strong enough to activate the B cells directly, but only some B cells can be activated in this way. Because these antigens do not activate helper T cells, they fail to induce memory B

cells or antibody class switching (both of which require T cell help) and, therefore, mainly cause the production of low-affinity IgM antibodies.

The Activation of B Cells by Helper T Cells Is Mediated by Both Membrane-bound and Secreted Signals 42

Whereas antigen-presenting cells such as dendritic cells and macrophages are omnivorous and ingest and present antigens nonspecifically, a B cell generally presents only an antigen that it specifically recognizes. In a primary antibody response helper T cells are normally activated by binding to a foreign antigen bound to a class II MHC protein on the surface of an antigen-presenting cell of the omnivorous type - such as an interdigitating dendritic cell in a secondary lymphoid organ. Once activated, the helper T cell can then help activate a B cell that specifically displays the same complex of foreign antigen and class II MHC protein on its surface. The display of antigen on the B cell surface reflects the selectivity with which it takes up foreign molecules from the extracellular fluid. These are selected by their binding to the specific membrane-bound antibodies (antigen receptors) on the surface of the B cell and are ingested by receptor-mediated endocytosis; they are then degraded and recycled to the cell surface in the form of peptides bound to class II MHC proteins. Thus the helper T cell activates those B cells that make membrane-bound antibodies that specifically recognize the antigen that initially activated the T cell. In secondary antibody responses memory B cells themselves may act as antigen-presenting cells and activate helper T cells, as well as being the subsequent targets of the helper T cells. The mutually reinforcing actions of T cells and B cells lead to an immune response that is both intense and highly selective.

Once a helper T cell has been activated and contacts a B cell, the contact initiates an internal rearrangement of the helper cell cytoplasm that orients the centrosome and Golgi apparatus toward the B cell, as described previously for a cytotoxic T cell contacting its target cell (see Figure 23-52). In this case, however, the orientation is thought to enable the helper T cell to direct membrane-bound and secreted signaling molecules onto the B cell surface. The membrane-bound signaling molecule is a transmembrane protein called CD40 ligand, which is expressed on the surface of activated, but not resting, helper T cells. It is recognized by the CD40 transmembrane protein on the B cell surface. The interaction between CD40 ligand and CD40 is required for helper T cells to activate B cells to proliferate and mature into memory and antibody-secreting cells. This interaction is critical for T cell help: individuals whose T cells lack the CD40 ligand because of a mutation in the gene encoding the protein can make only IgM antibodies and are severely immunodeficient, being susceptible to the same infections that affect AIDS patients, whose helper T cells have been destroyed.

Secreted signals from the T cells provide additional help by activating B cells to proliferate and mature and, in some cases, to switch the class of antibody they produce. Interleukin-4 (IL-4) is one such signal. It stimulates B cell proliferation and maturation and promotes switching to IgE and IgG1 antibody production: if the *IL-4* gene is inactivated in a mouse by targeted genetic recombination, the mouse is unable to make IgE and makes very little IgG1.

Thus most B cells, like T cells, require multiple signals for activation, one provided by antigen binding to membrane-bound Ig molecules and the others provided by helper T cells; as in the case of T cells, if a B cell receives the first signal only, it may be functionally inactivated. The signals required for helper T and B cell activation are compared in Figure 23-57 .

Some Helper T Cells Help Activate Cytotoxic T Cells and Macrophages by Secreting Interleukins 43

There are at least two functionally distinct subclasses of helper T cells that can be distinguished by the interleukins that they secrete. $T_H 1$ cells secrete IL-2 and γ-interferon and are concerned mainly with helping cytotoxic T cells and macrophages. $T_H 2$ cells secrete IL-4 and IL-5 and are concerned mainly with helping B cells and eosinophils. We saw earlier that IL-2 secreted by activated helper T cells can stimulate activated cytotoxic T cells (as well as other activated helper T cells) to proliferate. Stimulated T cells also secrete other interleukins, such as γ-*interferon,* that help activate cytotoxic T cells to kill infected target cells and that enhance the ability of macrophages to phagocytose and destroy invading microorganisms. The activation of macrophages by T cells is especially important in defense against infections by microorganisms that can survive phagocytosis by nonactivated macrophages. Tuberculosis is one such infection.

The antigen-triggered secretion of interleukins underlies the familiar tuberculin skin test. If tuberculin (an extract of the bacterium responsible for tuberculosis) is injected into the skin of individuals who have had or have been immunized against tuberculosis (and therefore contain appropriate memory T cells), a characteristic immune response occurs in the skin. It is initiated at the site of injection by the secretion of interleukins by memory helper T cells that react to tuberculin. The interleukins attract macrophages (and lymphocytes) into the site, thereby causing the characteristic swelling of a positive

reaction to tuberculin.

Another important effect of γ-interferon is to induce the expression of class II MHC proteins on the surface of some cells (such as endothelial cells) that do not normally express them, thereby enabling these cells to present antigen to helper T cells. As discussed earlier, γ-interferon also increases the efficiency with which target cells present viral peptide in association with class I MHC molecules for recognition by cytotoxic T cells.

Some of the interleukins secreted by helper T cells, along with some secreted by antigen-presenting cells, are listed in Table 23-4 .

Summary

Helper T cells help activate B cells and macrophages. They are themselves initially activated when they recognize peptide fragments derived from foreign extracellular proteins that are endocytosed by specialized antigen-presenting cells. The ingested proteins are degraded in endosomes, and some of the resulting peptide fragments bind to class II MHC molecules, forming complexes that are carried to the cell surface, where the helper T cells recognize them. The activation of a helper T cell requires at least two signals: signal 1 is provided by the MHC-peptide complex, while signal 2 is provided by either the B7 protein on the surface of an antigen-presenting cell or a signal secreted by this cell. Once activated, helper T cells stimulate their own proliferation by secreting interleukin-2 and activate their target cells by a combination of membrane-bound and secreted signaling molecules.
Figure 23-53 . The processing of an extracellular protein antigen for presentation to a helper T cell . A current view of how peptide-class-II-MHC complexes are formed in endosomes and delivered to the surface of an antigen-presenting cell.
Figure 23-55 . Two signals are required for helper T cell activation . Signal 2 can be provided by either a secreted signal such as interleukin-1 (IL-1) or the membrane-bound B7 protein on the antigen-presenting cell surface. Signal 1 without signal 2 can inactivate the T cell. The accessory proteins associated with the T cell receptor (illustrated in Figure 23-54A) that are required for generating signal 1 are not shown.

Table 23-3 . Some Accessory Proteins on the Surface of T Cells

Protein*	Approximate Molecular Weight	Super-family	Expressed on	Ligand on Target Cell	Functions
CD3	γ chain = 25,000 δ chain = 20,000 ε chain = 20,000 ζ chain = 16,000	Ig Ig Ig —	all T cells	—	helps transduce signal when antigen-MHC complex binds to T cell receptors
CD4	55,000	Ig	helper T cells	class II MHC	promotes adhesion to antigen-presenting cells and to B cells; signals T cell
CD8	70,000 (homodimer or heterodimer)	Ig	cytotoxic T cells	class I MHC	promotes adhesion to infected target cells; signals T cell
CD28	80,000 (homodimer)	Ig	many helper and cytotoxic T cells	B7	provides signal 2 to some T cells
LFA-1	a_1 chain = 190,000 b_2 chain = 95,000	integrin	most white blood cells, including T cells	ICAM-1	promotes cell-cell adhesion

*CD stands for *cluster of differentiation*, as each of the CD proteins was originally defined as a T cell "differentiation antigen" recognized by multiple monoclonal antibodies. Their identification depended on large-scale collaborative studies in which hundreds of such antibodies, generated in many laboratories, were compared and found to consist of relatively few groups (or "clusters"), each recognizing a single cell-surface protein. Since these initial studies, however, about 100 CD proteins have been identified.
Figure 23-56 . The stimulation of T cell proliferation by IL-2 . Signals 1 and 2 activate the helper T cell to make IL-2 receptors and to secrete IL-2. The binding of IL-2 to its receptors stimulates the cell to grow and divide. When the antigen is eliminated, the T cells eventually stop producing IL-2 and IL-2 receptors, so cell proliferation stops. We shall see later that some helper T cells do not make IL-2; their proliferation, like that of cytotoxic T cells, is stimulated by IL-2 made by neighboring helper T cells.
Figure 23-57 . Comparison of the signals required to activate a helper T cell and a B cell . Note that signal 2 can be provided either by a secreted signaling molecule (an interleukin) or by a cell-cell contact interaction.

Table 23-4 . Properties of Some Interleukins*

Interleukin (IL)	Approximate Molecuar Weight	Source	Target	Action
IL-1	15,000	antigen-presenting cells	helper T cells	helps activate
IL-2	15,000	some helper T cells	all activated T cells and B cells	stimulates proliferation
IL-3	25,000	some helper T cells	various hemopoietic cells	stimulates proliferation

IL-4	20,000	some helper T cells	B cells	stimulates proliferation, maturation, and class switching to IgE and IgG1
IL-5	20,000	same helper T cells that make IL-4	B cells, eosinophils	promotes proliferation and maturation
IL-6	25,000	some helper T cells and macrophages	activated B cells, T cells	promotes B cell maturation to Ig-secreting cells; helps activate T cells
g -Interferon	25,000 (dimer)	same helper T cells that make IL-2	B cells, macrophages, endothelial cells	activates various MHC genes and macrophages

*. *Interleukins* are secreted peptides and proteins that mainly mediate local interactions between white blood cells (leucocytes) but do not bind antigen; those secreted by lymphocytes are also called *lymphokines* . The amino acid sequence is known for all the proteins listed. The sources, target cells, and actions listed are those most relevant to the immune system, but most of the interleukins have many more sources, targets, and actions than are shown. This is especially the case for IL1 and IL6, which are also made by non-blood cells and act on many types of target cells other than blood cells; they are therefore more accurately called *cytokines* .

➜ ➜

Selection of the T Cell Repertoire

Introduction

T cells develop in the thymus. Remarkably, more than 95% of the cells produced there die before they are able to mature and migrate to peripheral lymphoid organs. This waste is largely due to the stringent selection processes that operate on developing T cells to ensure that only cells with potentially useful receptors survive. In this section we examine both the positive and negative selection processes that help shape the T cell repertoire. This will lead us to consider why individuals differ genetically in their immune responsiveness and why the MHC molecules that present antigen to T cells show such extreme genetic variability.

Developing T Cells That Recognize Peptides in Association with Self MHC Molecules Are Positively Selected in the Thymus [44]

We have seen that T cells recognize antigen in association with self MHC molecules but not in association with foreign MHC molecules: that is, T cells show *MHC restriction* . This restriction reflects a process of positive selection during T cell development in the thymus, whereby those immature T cells that will be capable of recognizing foreign peptides presented by self MHC molecules are selected to survive, while the remainder, which would be of no use to the animal, die. Thus MHC restriction is an acquired property of the immune system that emerges as T cells develop in the thymus.

If, for example, a Y-strain thymus is transplanted into an X-strain mouse that has been irradiated to eliminate all of its mature T cells and then supplied with fresh bone marrow that can generate precursors of new ones, new X-strain T cells will develop in the Y-strain thymus. In most experiments of this type the mature X-strain T cells produced recognize foreign antigen in association with Y-strain but not X-strain MHC proteins, suggesting that the thymus dictates the specificity of MHC restriction. As T cells develop in the thymus, those with receptors that can recognize antigen in association with the types of MHC molecules expressed in the thymus are somehow selected to survive and proliferate. Similar experiments show that it is the epithelial cells of the thymus that are responsible for this positive selection process.

The most direct way to study the selection process is to follow the fate of a set of developing T cells of known specificity. This can be done using transgenic mice that express a specific pair of a and b T cell receptor genes derived from a T cell clone of known antigen and MHC specificity. As is the case for immunoglobulin genes in B cells, the expression of the rearranged T cell receptor transgenes inhibits the rearrangement of endogenous T cell receptor genes to ensure allelic exclusion, so that a large proportion of the T cells in these transgenic mice express only the transgenic receptor. Thus the fate of T cells with a known

specificity can be readily followed. Such experiments show that the transgenic T cells mature and populate the peripheral lymphoid tissues only if the transgenic mouse also expresses the same allelic form of MHC molecule as is recognized by the transgenic T cell receptor; if the mouse does not express the appropriate MHC molecule, the transgenic T cells die in the thymus. Thus, as suggested by the thymus transplantation experiments, the survival and maturation of a T cell depend on a match between its receptor and the MHC molecules expressed in the thymus. As part of this positive selection process, cytotoxic T cells are selected for recognition of class I MHC molecules while helper T cells are selected for recognition of class II MHC molecules. Thus genetically engineered mice that lack cell-surface class I MHC molecules specifically lack cytotoxic T cells, whereas mice that lack class II MHC molecules specifically lack helper T cells.

Positive selection still leaves a large problem to be solved. If developing T cells with receptors that recognize self peptides associated with self MHC molecules were to mature in the thymus and migrate to peripheral lymphoid tissues, they would wreak havoc. A second, *negative selection* process in the thymus is required to avoid this disaster.

Developing T Cells That React Strongly with Self Peptides Bound to Self MHC Molecules Are Eliminated in the Thymus [44] , [45]

As discussed previously, a fundamental feature of the immune system is that it can distinguish self from nonself and normally does not react against self molecules. This state of *immunological self tolerance* is acquired mainly during T cell development. Although some self-reactive B cells are eliminated or inactivated during B cell development, the main mechanism for self tolerance is thought to be the deletion in the thymus of developing self-reactive T cells - that is, T cells whose receptors bind strongly to the complex of a self peptide bound to a self MHC molecule. Because most B cells require helper T cells to respond to antigen, the elimination of self-reactive helper T cells also ensures that self-reactive B cells are harmless.

It is not enough, therefore, for the thymus to select *for* T cells that recognize self MHC molecules; it must also select *against* T cells that recognize self MHC molecules complexed with self peptides - in other words, it must pick out for survival just those T cells that will be capable of recognizing self MHC molecules complexed with foreign peptides, even though these peptides are not present in the developing thymus. It is thought that such T cells bind weakly in the thymus to self MHC molecules that are carrying self peptides mismatched to the T cell receptors. Thus the required goal can be achieved by (1) ensuring the death of T cells that bind *strongly* to the peptide-MHC complexes in the thymus while (2) promoting the survival of those that bind weakly and (3) permitting the death of those that do not bind at all. Process 2 is the positive selection we have just discussed. Process 1 is called negative selection (Figure 23-58).

The most convincing evidence for negative selection derives once again from experiments with transgenic mice. After the introduction of T cell receptor transgenes encoding a receptor that recognizes a male-specific peptide antigen, for example, large numbers of mature T cells expressing the transgenic receptor are found in the thymus and peripheral lymphoid organs of female mice, but very few are found in males, where the cells die in the thymus before they have a chance to mature. Like positive selection, negative selection requires the interaction of a T cell receptor and a CD4 or CD8 co-receptor with an appropriate MHC molecule. Unlike positive selection, however, which occurs mainly on the surface of the thymus epithelial cells, negative selection occurs mainly on the surface of other cells, such as dendritic cells or macrophages, that originate in the bone marrow and migrate into the thymus. Like the epithelial cells, they have both class I and class II MHC molecules on their surface.

The mechanisms responsible for positive and negative T cell selection in the thymus are unknown, but in both cases programmed cell death (discussed in Chapters 21 and 22) is thought to be involved. During positive selection thymus epithelial cells seem to provide survival signals to weakly bound T cells, preventing the T cells from killing themselves. In negative selection, by contrast, the bone-marrow-derived cells signal the tightly bound T cells to kill themselves (Figure 23-58).

The deletion of self-reactive T cells in the thymus cannot eliminate all potentially self-reactive T cells, as some self molecules are not present in the thymus. Whereas at least some of the T cells with receptors that recognize such self molecules are presumably eliminated after they leave the thymus, others may be functionally inactivated by a process called *clonal anergy* (to distinguish it from *clonal deletion* , in which the self-reactive cells die). Although the molecular mechanism of clonal anergy is uncertain, it is postulated that the T cells recognize self peptides bound to MHC molecules on the surface of tissue cells that are unable to provide a signal 2; as discussed earlier, signal 1 without signal 2 can inactivate a T cell without killing it.

Some Allelic Forms of MHC Molecules Are Ineffective at Presenting Specific Antigens to T Cells: Immune Response (*Ir*) Genes [46]

Unlike class I MHC genes, which were first recognized by their effects on graft rejection, class II MHC genes were first recognized by their effects on T-cell-dependent immune responses to specific soluble antigens. When animals were immunized with a simple antigen, some made vigorous T-cell-dependent responses while others did not respond at all. Genetic studies indicated that the ability to respond to the antigen was controlled by a single gene, called an immune response (*Ir*)gene, and responses to different antigens were often controlled by different *Ir* genes. These, it transpired, are the MHC genes under a different name: *Ir* genes that control the response of helper T cells to an antigen map to one or other of the class II MHC loci; those that control the response of cytotoxic T cells to an antigen map to one or other of the class I MHC loci.

These observations initially were extremely puzzling, but once it was recognized that the MHC proteins play a crucial role in binding and presenting antigen to T cells, they could be readily explained: a genetic nonresponder to a simple antigen (usually one with only a single antigenic determinant) presumably lacks an MHC molecule that can bind and effectively present the antigenic determinant to an appropriate T cell. This explanation is supported by *in vitro* studies showing that purified class II MHC molecules from a *responder* animal can bind the relevant antigenic peptide, while those from a genetic *nonresponder* cannot.

Another mechanism, however, seems to be responsible for some cases of genetic nonresponsiveness to specific antigens. Certain combinations of self MHC molecules and foreign peptides are likely to resemble some combinations of self MHC molecules and self peptides. Because the helper T cells that react to such combinations are eliminated by negative selection during T cell development in the thymus, an animal may be genetically unable to respond to these foreign peptides.

The Role of MHC Proteins in Antigen Presentation to T Cells Provides an Explanation for Transplantation Reactions and MHC Polymorphism 47

The role of MHC proteins in binding foreign antigens and presenting them to T cells provides an explanation for why so many T cells respond to foreign MHC molecules and thereby reject foreign organ grafts. Presumably, foreign MHC proteins with an endogenous peptide in their peptide-binding groove create complexes that can resemble self MHC molecules complexed with foreign peptides. Some cytotoxic T cell clones that react to a viral antigen in association with a self class I MHC molecule, for example, have been shown to react to a foreign class I MHC molecule in the absence of the viral antigen (Figure 23-59).

The antigen-presenting function of MHC proteins can also explain the extensive polymorphism of these molecules. In the evolutionary war between pathogenic microorganisms and the vertebrate immune system, microorganisms will tend to change their antigens to avoid associating with MHC molecules. When one succeeds, it will be able to sweep through a population as an epidemic. In such circumstances the few individuals that produce a new MHC molecule that can associate with an antigen of the altered microorganism will have a large selective advantage. In addition, individuals with two different alleles for each MHC molecule (heterozygotes) will have a better chance of resisting infection than those with identical alleles at any given MHC locus, as they will have a greater capacity to present antigens from a wide range of pathogens. Thus selection will tend to promote and maintain a large diversity of MHC molecules in the population. This hypothesis that infectious diseases have provided the driving force for MHC polymorphism recently has received strong support from the finding that individuals in West Africa with a specific MHC allele have a reduced susceptibility to a severe form of malaria; while the allele is rare elsewhere, it is found in 25% of the West African population where this form of malaria is common.

If greater MHC diversity means greater resistance to infection, why do we each have so few MHC loci encoding these molecules, and why have we not evolved strategies for increasing their diversity - by alternative RNA splicing, for example, or by the genetic recombination mechanisms used to diversify antibodies? Presumably, this is because each time a new MHC molecule is added to the repertoire, the T cells that recognize self peptides in association with the new MHC molecule must be eliminated to maintain self tolerance. The elimination of these T cells would counteract the advantage of adding the new MHC molecule. Thus the number of MHC molecules we express may represent a balance between the advantages of presenting a wide diversity of foreign peptides to T cells against the disadvantages of restricting the T cell repertoire.

Immune Recognition Molecules Belong to an Ancient Superfamily 48

Most of the proteins that mediate cell-cell recognition or antigen recognition in the immune system contain related structural elements, suggesting that the genes that encode them have a common evolutionary history. Included in this Ig superfamily are *antibodies, T cell receptors, MHC proteins,* the *CD4, CD8,* and *CD28* co-receptors, most of the invariant polypeptide chains associated with B and T cell receptors, and the various *Fc receptors* on lymphocytes and other white blood cells - all of which contain one or more Ig or Ig-like domains (*Ig homology units*). In fact, 40% of the 150 or so polypeptides that have been

characterized on the surface of white blood cells belong to this superfamily. Each of the Ig-like domains is 70-110 amino acids long and is thought to be folded into the characteristic sandwichlike structure made of two antiparallel β sheets, usually stabilized by a conserved disulfide bond. Many of these molecules are dimers or higher oligomers in which Ig-like domains of one chain interact with those in another (Figure 23-60).

Most of the amino acids in each Ig-like domain are usually encoded by a separate exon, and it seems likely that the entire supergene family evolved from a gene coding for a single Ig-like domain - similar to that encoding b_2 -micro-globulin (see Figure 23-45A) or the Thy-1 protein (see Figure 23-60)that may have been involved in mediating cell-cell interactions. There is evidence that such a primordial gene arose before vertebrates diverged from their invertebrate ancestors some 400 million years ago. New family members presumably arose by exon and gene duplications, and similar duplication events probably gave rise to the multiple gene segments that encode antibodies and T cell receptors.

Summary

The T cell repertoire is shaped mainly by a combination of positive and negative selection processes that operate during T cell development in the thymus. These processes ensure that only T cells with potentially useful receptors survive and mature while the others undergo programmed cell death: T cells that will be able to recognize foreign peptides complexed with self MHC molecules are positively selected, while T cells that react strongly with self peptides complexed with self MHC molecules are eliminated.

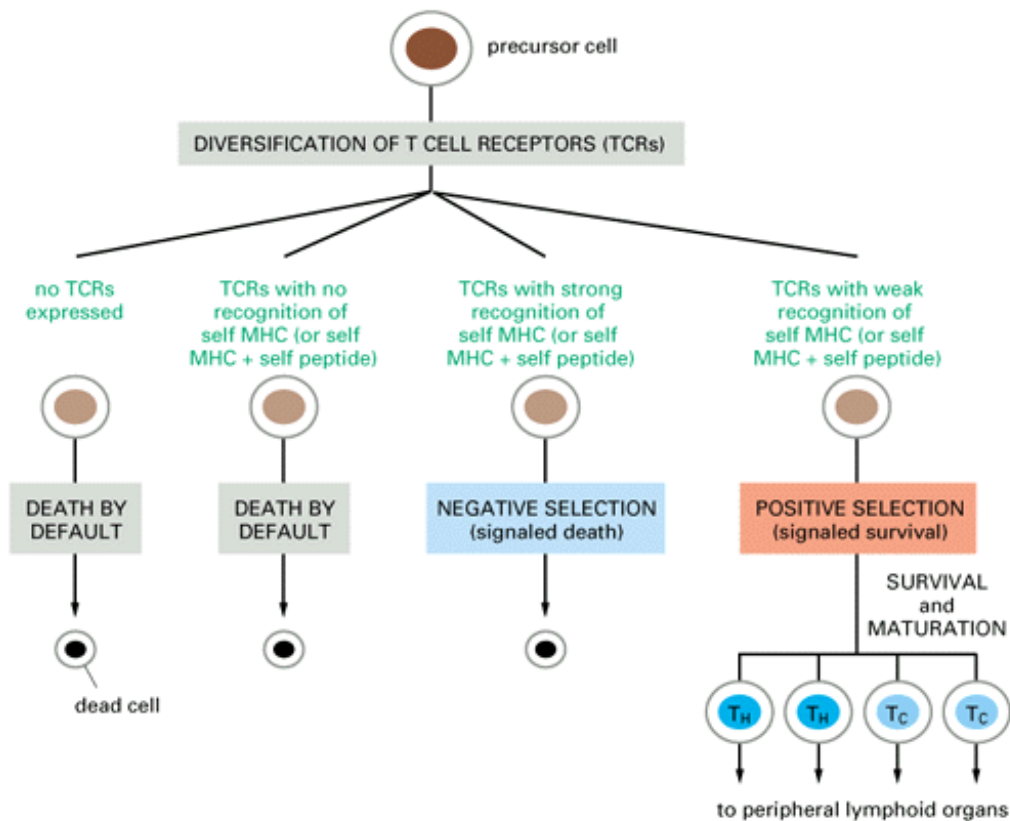
Most of the proteins involved in cell-cell recognition and antigen recognition in the immune system, including antibodies, T cell receptors, and MHC molecules, as well as the various co-receptors discussed in this chapter, belong to the ancient Ig superfamily, which is thought to have evolved from a primordial gene encoding a single Ig-like domain.


Figure 23-58 . Positive and negative selection in the thymus . Only cells with receptors that recognize foreign peptides in association with self MHC molecules are selected to survive, mature, and migrate to peripheral lymphoid organs; all of the other cells undergo programmed cell death. During the process of positive selection, helper T cells (T_H) and cytotoxic T cells (T_C) diverge by an unknown mechanism such that helper cells express the CD4 co-receptor but not CD8 and recognize foreign peptides in association with class II MHC molecules, while cytotoxic cells express CD8 but not CD4 and recognize foreign

peptides in association with class I MHC molecules (not shown).
Figure 23-59 . Foreign MHC mimicry . A foreign MHC molecule with an endogenous peptide bound in its binding groove can resemble a self MHC molecule with a foreign peptide (such as a viral peptide) bound to it. This is thought to explain why so many of our T cells can be activated by foreign MHC molecules in transplantation reactions.
Figure 23-60 . Some of the membrane proteins belonging to the Ig superfamily . The Ig domains are shaded in *gray,* and the antigen-binding domains, in *blue* . The immunoglobulin superfamily also includes many cell-surface proteins involved in cell-cell interactions outside the immune system, such as the neural cell-adhesion molecule (N-CAM) discussed in Chapter 19 and the receptors for various protein growth factors discussed in Chapters 15 and 17 (not shown).

24. Cancer

➔ ➔

Introduction

Roughly one person in five, in the prosperous countries of the world, will die of cancer; but that is not the reason for devoting a chapter of this book to the subject. Heart disease causes more deaths, and in the world as a whole, other health problems, such as malnutrition and parasitic infections, are more serious. In the context of cell biology, however, cancer has a unique importance, for the family of diseases grouped under this heading reflect disturbances of the most fundamental rules of behavior of the cells in a multicellular organism. To understand cancer and to devise rational ways to treat it, we have to understand both the inner workings of cells and their social interactions in the tissues of the body. Thus the cancer research effort has profoundly benefited a much wider area of medical knowledge than that of cancer alone.

We have already discussed many offshoots of cancer research in the preceding chapters. In this concluding chapter we examine the disease itself. In the first section we consider the nature of cancer and the natural history of the disease from a cellular standpoint; in the second section we focus on its molecular basis.

➔ ➔

Cancer as a Microevolutionary Process [1]

Introduction

The body of an animal can be viewed as a society or ecosystem whose individual members are cells, reproducing by cell division and organized into collaborative assemblies or tissues. In our earlier discussion of the maintenance of tissues (in Chapter 22), our concerns were similar to those of the ecologist: cell births, deaths, habitats, territorial limitations, the maintenance of population sizes, and the like. The one ecological topic conspicuously absent was that of natural selection: we said nothing of competition or mutation among somatic cells. The reason is that a healthy body is in this respect a very peculiar society, where self-sacrifice, rather than competition, is the rule: all somatic cell lineages are committed to die, leaving no progeny but dedicating their existence to support of the germ cells, which alone have a chance of survival. There is no mystery in this, for the body is a clone, and the genome of the somatic cells is the same as the genome of the germ cells; by their self-sacrifice for the sake of the germ cells, the somatic cells help to propagate copies of their own genes.

Thus, unlike free-living cells such as bacteria, which compete to survive, the cells of a multicellular organism are committed to collaboration. Any mutation that gives rise to selfish behavior by individual members of the cooperative will jeopardize the future of the whole enterprise. Mutation, competition, and natural selection operating within the population of somatic cells are the basic ingredients of cancer: it is a disease in which individual mutant cells begin by prospering at the expense of their neighbors but in the end destroy the whole cellular society and die.

In this section we discuss the development of cancer as a microevolutionary process. This process occurs on a time scale of months or years in a population of cells in the body, and it is dependent on the same principles of mutation and natural selection that govern the long-term evolution of all living organisms.

Cancers Differ According to the Cell Type from Which They Derive [2]

Cancer cells are defined by two heritable properties: they and their progeny (1) reproduce in defiance of the normal restraints and (2) invade and colonize territories normally reserved for other cells. It is the combination of these features that makes cancers peculiarly dangerous. An isolated abnormal cell that does not proliferate more than its normal neighbors does no significant damage, no matter what other disagreeable properties it may have; but if its proliferation is out of control, it will give rise to a tumor, or *neoplasm-* a relentlessly growing mass of abnormal cells. As long as the neoplastic cells remain clustered together in a single mass, however, the tumor is said to be benign, and a complete cure can usually be achieved by removing the mass surgically. A tumor is counted as a cancer only if it is malignant, that is, only if its cells have the ability to invade surrounding tissue. Invasiveness usually implies an ability to break loose, enter the bloodstream or lymphatic vessels, and form secondary tumors, or metastases, at other sites in the body (Figure 24-1). The more widely a cancer metastasizes, the harder it becomes to eradicate.

Cancers are classified according to the tissue and cell type from which they arise. Cancers arising from epithelial cells are

termed carcinomas; those arising from connective tissue or muscle cells are termed sarcomas. Cancers that do not fit in either of these two broad categories include the various leukemias, derived from hemopoietic cells, and cancers derived from cells of the nervous system. Table 24-1 lists the types of cancers that are common in the United States, together with their incidence and the death rate from them. Each of the broad categories has many subdivisions according to the specific cell type, the location in the body, and the structure of the tumor; many of the names used are fixed by tradition and have no modern rational basis. In parallel with the set of names for malignant tumors, there is a related set of names for benign tumors: an *adenoma,* for example, is a benign epithelial tumor with a glandular organization, the corresponding type of malignant tumor being an *adenocarcinoma* (Figure 24-2); a *chondroma* and a *chondrosarcoma* are, respectively, benign and malignant tumors of cartilage. About 90% of human cancers are carcinomas, perhaps because most of the cell proliferation in the body occurs in epithelia or perhaps because epithelial tissues are most frequently exposed to the various forms of physical and chemical damage that favor the development of cancer.

Each cancer has characteristics that reflect its origin. Thus, for example, the cells of an epidermal *basal-cell carcinoma,* derived from a keratinocyte stem cell in the skin, will generally continue to synthesize cytokeratin intermediate filaments, whereas the cells of a *melanoma,* derived from a pigment cell in the skin, will often (but not always) continue to make pigment granules. Cancers originating from different cell types are, in general, very different diseases. The basal-cell carcinoma, for example, is only locally invasive and rarely forms metastases, whereas the melanoma is much more malignant and rapidly gives rise to many metastases (behavior that recalls the migratory tendencies of the normal pigment-cell precursors during development, discussed in Chapter 21). The basal-cell carcinoma is usually easy to remove by surgery, leading to complete cure; but the malignant melanoma, once it has metastasized, is often impossible to extirpate and consequently fatal.

Most Cancers Derive from a Single Abnormal Cell 3

Even when a cancer has metastasized, its origins can usually be traced to a single primary tumor, arising in an identified organ and presumed to be derived by cell division from a single cell that has undergone some heritable change that enables it to outgrow its neighbors. By the time it is first detected, however, a typical tumor already contains about a billion cells or more (Figure 24-3), often including many normal cells - fibroblasts, for example, in the supporting connective tissue that is associated with a carcinoma. What evidence do we have that the cancer cells are indeed a clone descended from a single abnormal cell?

One type of demonstration comes from analysis of the cells' DNA. In almost all patients with *chronic myelogenous leukemia,* for example, the leukemic white blood cells are distinguished from the normal cells by a specific chromosomal abnormality (the so-called Philadelphia chromosome, created by a translocation between the long arms of chromosomes 9 and 22, as shown in Figure 24-4). When the DNA at the site of translocation is cloned and sequenced, it is found that the site of breakage and rejoining of the translocated fragments is identical in all the leukemic cells in any given patient but differs slightly (by a few hundred or thousand base pairs) from one patient to another, as expected if each case of the leukemia arises from a unique accident occurring in a single cell. We see later how Philadelphia translocations lead to leukemia by inappropriately activating a specific gene.

Another way to show that a cancer has a monoclonal origin is by exploiting the phenomenon of X-chromosome inactivation. A normal woman is a random mixture, or mosaic, of two classes of cells - those in which the paternal X chromosome is inactivated and those in which the maternal X chromosome is inactivated (as discussed in Chapter 9). The inactivation of one or the other of the X chromosomes occurs at random in each cell early in embryonic development, but once the choice has been made it is irreversible, so that when a cell divides it passes on its own state of X-inactivation to its daughters. Consequently, the state of X-chromosome inactivation - maternal or paternal - can be used as a heritable marker to trace the lineage of cells in the body. In the great majority of tumors that have been analyzed - both benign and malignant - all the tumor cells have been found to have the same X chromosome inactivated, strongly suggesting that they are derived from a single deranged cell (Figure24-5).

Most Cancers Are Probably Initiated by a Change in the Cell's DNA Sequence 4

If a single abnormal cell is to give rise to a tumor, it must pass on its abnormality to its progeny: the aberration has to be heritable. A first problem in understanding a cancer is to discover whether the heritable aberration is due to a genetic change - that is, an alteration in the cell's DNA sequence - or to an *epigenetic* change - that is, a change in the pattern of gene expression without a change in the DNA sequence. Heritable epigenetic changes, reflecting cell memory, are a familiar feature of normal development, as manifest in the stability of the differentiated state and in such phenomena as X-chromosome inactivation; and there is no obvious a priori reason why they should not be involved in cancer. For one rare and extraordinary type of cancer - the teratocarcinoma (see Chapter 21) - the evidence does favor an epigenetic origin. There are, however, good reasons to think that

most cancers are initiated by genetic change. Thus cells of a given cancer can often be shown to have a shared abnormality in their DNA sequence, as we have just seen for chronic myelogenous leukemia; many other examples are discussed in the second half of this chapter. Further evidence that genetic change can be a *cause* of cancer comes from a study of agents known to give rise to the disease. A correlation between carcinogenesis (the generation of cancer) and *mutagenesis* (the production of a change in the DNA sequence) is clear for three classes of agents: chemical carcinogens (which typically cause simple local changes in the nucleotide sequence), ionizing radiation such as x-rays (which typically cause chromosome breaks and translocations), and viruses (which introduce foreign DNA into the cell). The role of viruses in cancer is discussed later; we pause here to discuss chemical carcinogens.

In general, a given cancer cannot be blamed entirely on a single event or a single cause: as we shall see, cancers as a rule result from the chance occurrence in one cell of several independent accidents, with cumulative effects. There are, however, some unusually carcinogenic agents that increase the likelihood of the critical events to the point where it becomes virtually certain, given a high enough dosage, that at least one cell in the body will turn cancerous. The compound 2-naphthylamine, used in the chemical industry in the early part of this century, is one notorious example: in one British factory, all of the men who had been employed in distilling it (and were thereby subjected to prolonged exposure) eventually developed bladder cancer.

Many quite disparate chemicals have been shown to be likewise carcinogenic when they are fed to experimental animals or painted repeatedly on their skin. Some of these carcinogens act directly on the target cells; many others take effect only after they have been changed to a more reactive form by metabolic processes - notably by a set of intracellular enzymes known as the cytochrome P-450 oxidases. These enzymes normally help to convert ingested toxins and foreign lipid-soluble materials into harmless and easily excreted compounds, but they fail in this task with certain substances, converting them instead into direct carcinogens (Figure 24-6). Although the known chemical carcinogens are very diverse, most of them have at least one property in common - they cause mutations. In one popular test for mutagenicity, the carcinogen is mixed with an activating extract prepared from rat liver cells (to mimic the biochemical processing that occurs in an intact animal) and is added to a culture of specially designed test bacteria; the resulting mutation rate of the bacteria is then measured (Figure 24-7). Most of the compounds scored as mutagenic by this rapid and convenient bacterial assay also cause mutations and/or chromosome aberrations when tested on mammalian cells. When mutagenicity data from various sources are analyzed, one finds that the majority of carcinogens are mutagens.

There is, nevertheless, a significant minority of carcinogens that do not appear to be mutagenic. We shall discuss below how nonmutagenic substances may promote the development of cancer by affecting the behavior of preexisting mutant cells. But first we must consider how frequently such mutant cells are likely to arise in the normal course of events.

A Single Mutation Is Not Enough to Cause Cancer 1, 5

Something on the order of 10^{16} cell divisions take place in a human body in the course of a lifetime; in a mouse, with its smaller number of cells and its shorter life-span, the number is about 10^{12}. Even in an environment that is free of mutagens, mutations will occur spontaneously at an estimated rate of about 10^{-6} mutations per gene per cell division - a value set by fundamental limitations on the accuracy of DNA replication and repair. Thus, in a lifetime, every single gene is likely to have undergone mutation on about 10^{10} separate occasions in any individual human being, or about 10^6 occasions in a mouse. Among the resulting mutant cells one might expect that there would be many that have disturbances in genes involved in the regulation of cell division and that consequently disobey the normal restrictions on cell proliferation. From this point of view, the problem of cancer seems to be not why it occurs but why it occurs so infrequently.

Evidently, a single mutation is not enough to convert a typical healthy cell into a cancer cell that proliferates without restraint, or we would not be viable organisms. Many lines of evidence indicate that the genesis of a cancer as a rule requires that several independent rare accidents occur together in one cell. One such indication comes from epidemiological studies of the incidence of cancer as a function of age. If a single mutation were responsible, occurring with a fixed probability per year, the chance of developing cancer in any given year should be independent of age. In fact, for most types of cancer the chance goes up very steeply with age - typically as the third, fourth, or fifth power (Figure 24-8). From such statistics it has been estimated that somewhere between three and seven independent random events, each of low probability, are typically required to turn a normal cell into a cancer cell; the smaller numbers apply to leukemias, the larger to carcinomas.

Now that specific mutations responsible for the development of cancer have been identified, it has become possible to test the effects of the mutant genes in transgenic mice; as we see later, the results give additional and more direct evidence for the hypothesis that a single mutation is insufficient to cause cancer. The hypothesis is also supported by many older studies of the

phenomenon of tumor progression, whereby an initial mild disorder of cell behavior evolves gradually into a full-blown cancer. These observations of how tumors develop, moreover, provide insight into the nature of the multiple changes that must occur for a normal cell to become a cancer cell and into the factors that control their occurrence.

Cancers Develop in Slow Stages from Mildly Aberrant Cells [1], [5], [6]

For those cancers that have a discernible external cause, there is almost always a long delay between the causal event(s) and the onset of the disease: the incidence of lung cancer does not begin to rise steeply until after 10 or 20 years of heavy smoking; the incidence of leukemias in Hiroshima and Nagasaki did not show a marked rise until about 5 years after the explosion of the atomic bombs, and it did not reach its peak until 8 years had elapsed; industrial workers exposed for a limited period to chemical carcinogens do not usually develop the cancers characteristic of their occupation until 10, 20, or even more years after the exposure (Figure 24-9); and so on. During this long incubation period, the prospective cancer cells undergo a succession of changes. Chronic myelogenous leukemia, mentioned earlier, provides a clear and simple example. This disease begins as a disorder characterized by a nonlethal overproduction of white blood cells and continues as such for several years before changing into a much more rapidly progressing illness that usually ends in death within a few months. In the chronic early phase the leukemic cells in the body are distinguished simply by their possession of the chromosomal translocation mentioned previously. In the subsequent acute phase of the illness, the hemopoietic system is overrun by cells that show not only this chromosomal abnormality but also several others. It appears as though members of the initial mutant clone have undergone further mutations that make them proliferate more rapidly (or divide more times before they die or terminally differentiate), so that they come to outnumber both the normal hemopoietic cells and their cousins that have only the primary disorder.

Carcinomas and other solid tumors are thought to evolve in a similar way. Although most such cancers in humans are not diagnosed until a relatively late stage, in a few cases it is possible to observe the early steps in the development of the disease. We shall discuss one example - colorectal cancer - at the end of this chapter. Another example is provided by cancers of the *uterine cervix* (the neck of the womb). These cancers derive from the multilayered cervical epithelium, which has an organization similar to that of the epidermis of the skin (discussed in Chapter 22). Normally, proliferation occurs only in the basal layer, generating cells that then move outward toward the surface, differentiating into flattened, keratin-rich, nondividing cells as they go, and finally being sloughed off from the surface (Figure 24-10A and E). When many specimens of this epithelium from different women are examined, however, it is not unusual to find patches of dysplasia, where dividing cells are no longer confined to the basal layer and there is some disorder in the process of differentiation (Figure 24-10B). Cells are sloughed from the surface in abnormally early stages of differentiation, and the presence of the dysplasia can be detected by scraping a sample of cells from the surface and viewing it under the microscope (the "Pap smear" technique - Figure 24-11). Left alone, the dysplastic patches will often remain harmless or even regress spontaneously; more rarely, however, they may progress, over a period of several years, to give rise to patches of so-called *carcinoma in situ*(Figure 24-10C). In these more serious lesions (somewhat misleadingly named, since they are not yet fully malignant), the usual pattern of cell division and differentiation is much more severely disrupted, and all the layers of the epithelium consist of undifferentiated proliferating cells, which are often highly variable in size and karyotype; the abnormal cells are still confined, however, to the epithelial side of the basal lamina. At this stage it is still easy to achieve a complete cure by destroying or removing the abnormal tissue surgically. Without such treatment the abnormal patch may still remain harmless or regress; but in an estimated 20-30% of cases it will develop, again over a period of several years, to give rise to a truly malignant cervical carcinoma (Figure 24-10D and F), whose cells break out of the epithelium by crossing the basal lamina and begin to invade the underlying connective tissue. Surgical cure becomes progressively more difficult as the invasive growth spreads.

Tumor Progression Involves Successive Rounds of Mutation and Natural Selection [6], [7]

As illustrated by the examples just discussed, cancers in general seem to arise by a process in which an initial population of slightly abnormal cells, descendants of a single mutant ancestor, evolves from bad to worse through successive cycles of mutation and natural selection. This evolution involves a large element of chance and usually takes many years; most of us die of other ailments before cancer has had time to develop. To understand the causation of cancer, it is essential to understand the factors that may speed up the process.

In general, the rate of evolution, whether in a population of cells exploiting the opportunities for cancerous behavior in the body or in a population of organisms adapting to a new environment on the surface of the earth, would be expected to depend on four main parameters: (1) the *mutation rate,* that is, the probability per gene per unit time that any given member of the population will undergo genetic change; (2) the *number of individuals in the population;* (3) the *rate of reproduction,* that is, the average number of generations of progeny produced per unit time; and (4) the *selective advantage* enjoyed by successful mutant

individuals, that is, the ratio of the number of surviving fertile progeny they produce per unit time to the number of surviving fertile progeny produced by nonmutant individuals. Experimental studies on the induction of cancer in animals illustrate these evolutionary principles.

The Development of a Cancer Can Be Promoted by Factors That Do Not Alter the Cell's DNA Sequence [6], [8]

The stages by which an initial mild lesion progresses to become a cancer can be most easily observed in the skin. Skin cancers can be elicited in mice, for example, by repeatedly painting the skin with a mutagenic chemical carcinogen such as benzo[a] pyrene (a constituent of coal tar and tobacco smoke) or the related compound dimethylbenz[a]anthracene (DMBA). A single application of the carcinogen, however, usually does not by itself give rise to a tumor or any other obvious lasting abnormality. Yet it does cause latent genetic damage, and this can be detected through a greatly increased incidence of cancer when the cells are exposed either to further treatments with the same substance or to certain other, quite different, insults. A carcinogen that sows the seeds of cancer in this way is said to act as a tumor initiator. Simply wounding skin that has been exposed once to such an initiator can cause cancers to develop from some of the cells at the edge of the wound. Alternatively, repeated exposure over a period of months to certain substances known as tumor promoters, which are not themselves mutagenic, can cause cancer selectively in skin previously exposed to a tumor initiator. The most widely studied tumor promoters are *phorbol esters,* such as tetradecanoylphorbol acetate (TPA), which we have already encountered in another context as artificial activators of protein kinase C (and hence as agents that activate part of the phosphatidylinositol intracellular signaling pathway, discussed in Chapter 15). These substances cause cancers at high frequency only if they are applied *after* a treatment with a mutagenic initiator (Figure 24-12).

As one might expect for genetic damage, the hidden changes caused by a tumor initiator are irreversible: thus they can be uncovered by treatment with a tumor promoter even after a long delay. The immediate effect of the promoter is apparently to stimulate cell division (or to cause cells that would normally undergo terminal differentiation to continue dividing instead), and in the region that had previously been exposed to the initiator, this results in the growth of many small, benign, wartlike tumors called *papillomas.* The greater the prior dose of initiator, the larger the number of papillomas induced; it is thought that each papilloma (at least for low doses of the initiator) consists of a single clone of cells descended from a mutant cell that the initiator has engendered. Both wounding and the application of the promoter probably act by inducing the expression of some of the genes that directly or indirectly affect cell proliferation. Such genes may remain quiescent in the resting epithelium, so that any mutations they have undergone in response to the initiator go undetected; by inducing expression of the mutated genes, the promoter or the stimulus of wounding may enable them to begin influencing cell proliferation (Figure 24-13).

A typical papilloma might contain about 10^5 cells. If exposure to the tumor promoter is stopped, almost all the papillomas regress, and the skin regains a largely normal appearance - as expected from the hypothesis illustrated in Figure 24-13. In a few of the papillomas, however, further changes occur that enable growth to continue in an uncontrolled way, even after the promoter has been withdrawn. These changes seem to originate in occasional single papilloma cells, at about the frequency expected for spontaneous mutations. In this way a small proportion of the papillomas progress to become cancers. Thus the tumor promoter apparently favors the development of cancer, in this system at least, by expanding the population of cells that carry an initial mutation: the more such cells there are and the more times they divide, the greater the chance that at least one of them will undergo another mutation carrying it one more step along the road to malignancy. Although naturally occurring cancers do not necessarily arise through the specific sequence of distinct initiation and promotion steps just described, their evolution must be governed by similar principles. They too will evolve at a rate that depends both on the frequency of mutations and on influences affecting the survival, proliferation, and spread of certain types of mutant cells once they have been created.

Most Cancers Result from Avoidable Combinations of Environmental Causes [9]

The development of a cancer generally involves many steps, each governed by multiple factors, some dependent on the genetic constitution of the individual, others dependent on his or her environment and way of life. By changing our surroundings or our habits, therefore, we should, in principle, be able to reduce drastically our chance of developing almost any given type of cancer. This is demonstrated most clearly by a comparison of cancer incidence in different countries: for almost every cancer that is common in one country, there is another country where the incidence is several times lower (Table 24-2); and migrant populations tend to take on the pattern of cancer incidence typical of the host country, implying that the differences are due to environmental, not genetic, factors. From such data it is estimated that 80-90% of cancers should be avoidable. Unfortunately, different cancers have different environmental risk factors, and a country that happens to escape one such danger is no more likely than other countries to escape the rest; thus the incidence of all cancers combined (among individuals of a given age) is similar from country to country. There are, however, some subgroups whose abstinent way of life does seem to reduce the total

cancer death rate: the incidence of cancer among strict Mormons in Utah, for example, is only about half that among Americans in general.

While such epidemiological observations indicate that cancer can be avoided, it remains difficult to identify the specific environmental risk factors or to establish how they act. Some certainly operate as mutagenic tumor initiators, directly provoking genetic change; others presumably serve as tumor promoters that help to enlarge the population of cells liable to progress, through further mutation, to full-blown cancer. The carcinogens in tobacco smoke, like the aflatoxin on tropical peanuts (see Figure 24-6), probably belong mostly in the first category, while the reproductive hormones that circulate in a woman's body at different stages of her life may belong in the second category. The importance of these hormones is indicated by the striking correlations that exist between a woman's reproductive history and her risk of developing breast cancer; the hormones presumably affect cancer incidence through their influence on cell proliferation in the breast (Figure 24-14). It is possible that some factors act in still other ways - for example, by causing heritable epigenetic changes. Of course, it is not necessary to understand how cancer-causing agents act in order to identify them and show how to avoid them. In this task cancer epidemiology has had some notable successes and promises more to come. Simply by revealing the role of smoking, it has shown a way to reduce the total cancer death rate in North America and Europe by as much as 30%. The prevention of cancer is not only better than cure but seems also, given our present state of knowledge, to be much more readily attainable.

The Search for Cancer Cures Is Hard but Not Hopeless 10

The difficulty of curing a cancer is like the difficulty of getting rid of weeds. Cancer cells can be removed surgically or destroyed with toxic chemicals or radiation; but it is hard to eradicate every single one of them. Surgery can rarely ferret out every metastasis, and treatments that kill cancer cells are generally toxic to normal cells as well. If even a few cancerous cells remain, they can proliferate to produce a resurgence of the disease; and unlike the normal cells they may evolve resistance to the poisons used against them. Yet the outlook is not hopeless. In spite of the difficulties, effective cures using anticancer drugs (alone or in combination with other treatments) have been devised for some formerly highly lethal cancers (notably Hodgkin's lymphoma, testicular cancer, choriocarcinoma, and some leukemias and other cancers of childhood). For several of the more common cancers, moreover, appropriate surgery or local radiotherapy enables a large proportion of patients to recover if the illness is diagnosed at a reasonably early stage. Effective treatments can sometimes be based on an understanding of the causes of a specific type of cancer. Estrogens, for example, appear to act as natural tumor promoters in cancer of the breast (see Figure 24-14), and treatment with an estrogen antagonist, such as the drug *tamoxifen,* is effective in many breast cancer patients in preventing or delaying recurrence of the disease. Even for types of cancer where a cure at present seems beyond our reach, there are treatments that will prolong life or at least relieve distress.

A great deal of clinical cancer research centers on the problem of how to kill cancer cells selectively. For the most part, current methods exploit relatively subtle differences between normal and neoplastic cells with respect to proliferation rate, metabolism, and radiosensitivity, and they have unpleasant toxic side effects. A few types of cancer cells are especially vulnerable to selective attack because they depend on specific hormones or because their surfaces have unusual chemical features that can be recognized by antibodies. In general, however, progress with the vexing problem of anticancer selectivity has been slow - a matter of trial and error and guesswork as much as rational calculation.

In the search for better ways of curbing the survival, proliferation, and spread of cancer cells, it is important to examine more closely the strategies by which they thrive and multiply.

Cancerous Growth Often Depends on Deranged Control of Cell Differentiation or Cell Death 11

We have so far emphasized that cancer cells defy the normal controls on cell division: this is their central property. But there are other requirements too, if a tumor is to grow without limit. The tumor cells must, for example, stimulate the development of blood vessels to bring the nutrients and oxygen they require for growth, as discussed in Chapter 22. Moreover, many tissues are organized in such a way that even an uncontrolled increase in the frequency of cell division will not by itself produce a steadily growing tumor. The example of the uterine cervix, discussed above, illustrates this point. Like the epidermis of the skin and many other epithelia, the epithelium of the uterine cervix normally renews itself continually by shedding terminally differentiated cells from its outer surface and generating replacements from stem cells in the basal layer. On average, each normal stem cell division generates one daughter stem cell and one cell that is condemned to terminal differentiation and a cessation of cell division. If the stem cell simply divides more rapidly, terminally differentiated cells will be produced and shed more rapidly, and a balance of genesis and destruction will still be maintained. Thus if a transformed stem cell is to generate a steadily growing clone of progeny, the basic rules must be upset: either more than 50% of the daughter cells must remain as

stem cells or the process of differentiation must be deranged so that daughter cells embarked on this route retain an ability to carry on dividing indefinitely and avoid dying or being discarded at the end of the production line (Figure 24-15).

Presumably, the development of such properties underlies the progression from a mild dysplasia of the uterine cervix to carcinoma *in situ* and malignant cancer (see Figure 24-10). Similar considerations apply to the development of cancer in other tissues that rely on stem cells, such as the skin, the lining of the gut, and the hemopoietic system. Several forms of leukemia, for example, seem to arise from a disruption of the normal program of differentiation, such that a committed progenitor of a particular type of blood cell continues to divide indefinitely, instead of differentiating terminally in the normal way and dying after a strictly limited number of division cycles (as discussed in Chapter 22). In general, changes that block the normal maturation of cells toward a nondividing, terminally differentiated state or prevent normal programmed cell death must play an essential part in many cancers. In the treatment of cancer, therefore, there is some prospect that drugs that promote cell differentiation may turn out to be a useful alternative to drugs that simply kill dividing cells.

To Metastasize, Cancer Cells Must Be Able to Cross Basal Laminae 12

It is the ability to metastasize that makes cancers hard to eradicate surgically or by localized irradiation. To disseminate widely in the body, the cells of a typical solid tumor must be able to loosen their adhesion to their original neighbors, escape from the tissue of origin, burrow through other tissues until they reach a blood vessel or a lymphatic vessel, cross the basal lamina and endothelial lining of the vessel so as to enter the circulation, make an exit from the circulation elsewhere in the body, and survive and proliferate in the new environment in which they find themselves (Figure 24-16). Each of these steps requires different properties. For example, in a variety of carcinomas that have been studied, loss of adhesion to neighboring cells in an epithelium depends on loss of expression of the epithelial cell-cell adhesion molecule *E-cadherin,* but the ability to burrow through tissues seems to depend on the production of proteolytic enzymes that can break down extracellular matrix. The final steps in metastasis are probably the most difficult: many tumors release large numbers of cells into the circulation, but only a tiny proportion of these cells succeed in founding metastatic colonies.

A few types of normal cells - notably white blood cells - already have some or all of the properties needed to disseminate through the body, but for most cancers the ability to metastasize probably requires additional mutations or epigenetic changes. Such transformations, like the others involved in the development of cancer, are thought to occur at random in the initial tumor population: only those few cells that acquire the properties needed for metastasis and that happen to land in a suitable environment will be able to produce secondary tumors. In accordance with this concept of evolution through random variation and natural selection, one finds that the cells of a single tumor are heterogeneous in metastatic capacity (Figure 24-17).

An understanding of the molecular mechanisms of metastasis should eventually allow the design of treatments to block it. Some progress is being made along these lines. It has been shown, for example, that for tumor cells to cross a basal lamina they must have appropriate integrins to act as laminin receptors, which enable the cells to adhere to the lamina, and they must carry on their surface type-IV collagenase, which helps them digest the lamina (Figure 24-18). Antibodies or other reagents that block either laminin attachment or the activity of type-IV collagenase have been found to block metastasis in experimental animals. It remains to be seen whether human cancer patients can be helped by similar treatments.

Mutations That Increase the Mutation Rate Accelerate the Development of Cancer 1, 13

As we have emphasized, the incidence of tumors and their rate of progression toward malignancy depends on the frequency of mutations. The mutation rate may be high because of mutagens in the environment or because of intracellular defects in the machinery governing replication, recombination, and repair of DNA. People with the rare genetic disorder *xeroderma pigmentosum,* for example, have a defect in the system of enzymes required to repair the type of damage done to DNA by ultraviolet irradiation; as a result, the slightest exposure of the skin to sunlight is liable to provoke skin cancers. A more general predisposition to cancer due to faults in DNA repair and replication occurs in the relatively common *HNPCC syndrome,* as we shall see on page 1290, and in *Bloom's syndrome, Fanconi's anemia,* and *ataxia-telangiectasia*. In all these rare genetic disorders the abnormality is inherited through the germ line and is therefore present in all the cells of the body. Similar genetic defects in DNA metabolism can also arise, however, through mutations originating in somatic cells. In fact, mutations that increase the mutation rate appear to be an important factor in the development of many cancers. Some of these mutations facilitate small local changes of DNA sequence. Others, especially common, facilitate gross disturbances of the genome.

Cancer cells often display an abnormal variability in the size and shape of their nuclei and in the number and structure of their chromosomes; indeed, abnormal nuclear morphology is one of the key features used by pathologists to diagnose cancer (Figure

24-19). When cancer cells are grown in culture, they are often found to have an extraordinarily unstable karyotype: genes become amplified or deleted and chromosomes become lost, duplicated, or translocated with a far higher frequency than in normal cells in culture. Such chromosomal variability suggests that the cells have some heritable fault in the machinery or control of chromosome replication, repair, recombination, or segregation. Such a fault, arising by somatic mutation, would be liable to increase the likelihood of subsequent mutations in other classes of genes and so to provide a short cut to the accumulation of the multiple mutations required for cancerous behavior. Molecular genetic studies have revealed one mechanism for this destabilization of the karyotype in cancer cells, as we see in the last part of the chapter when we discuss the role of a protein known as the *p53 protein.*

The Enhanced Mutability of Cancer Cells Helps Them Evade Destruction by Anticancer Drugs <u>10</u>, <u>14</u>

Because of the abnormally high mutability of many cancer cells, most malignant tumor cell populations are heterogeneous in many respects and capable of evolving at an alarming rate when subjected to new selection pressures. This aggravates the difficulties of cancer therapy. Repeated treatments with drugs that are selectively toxic to dividing cells can be used to kill the majority of neoplastic cells in a cancer patient, but it is rarely possible to kill them all. Usually some small proportion are drug-resistant, and the effect of the treatment is to favor the spread and evolution of cells with this trait.

To make matters worse, cells that are exposed to one drug often develop a resistance not only to that drug, but also to other drugs to which they have never been exposed. This phenomenon of multidrug resistance is frequently correlated with a curious change in the karyotype: the cell is seen to contain additional pairs of miniature chromosomes - so-called *double minute chromosomes* - or to have a *homogeneously staining region* interpolated in the normal banding pattern of one of its regular chromosomes. Both these aberrations consist of massively amplified numbers of copies of a small segment of the genome. The amplified DNA often contains a specific gene, known as the *multidrug resistance (mdr1)* gene, which codes for a plasma-membrane-bound transport ATPase (belonging to the ABC transporter superfamily discussed in <u>Chapter 11</u>) that is thought to prevent the intracellular accumulation of certain classes of lipophilic drugs by pumping them out of the cell. The amplification of other types of genes can also give the cancer cell a selective advantage: thus the gene for the enzyme dihydrofolate reductase (DHFR) often becomes amplified in response to cancer chemotherapy with the folic-acid antagonist methotrexate, and *myc* proto-oncogenes (to be discussed later), whose products stimulate cell proliferation, are similarly amplified in some cancers (<u>Figure 24-20</u>).

While defects in DNA replication, recombination, or repair may help cancer cells to evolve by increasing their mutability, they may also make the cells more vulnerable to certain types of attack. This may explain the observation - exploited in therapy - that the cells of many tumors are killed more easily than normal cells by irradiation or by exposure to specific drugs that interfere with DNA metabolism. As we learn more about the molecular mechanisms regulating DNA replication, recombination, and repair, it is beginning to be possible to pinpoint defects in these functions in individual cases of cancer, as the final section of this chapter will show. By using such information, we may be better able to kill the delinquent cells by designing drugs that exploit their particular weaknesses.

Summary

Cancer cells, by definition, proliferate in defiance of normal controls (that is, they are neoplastic) and are able to invade and colonize surrounding tissues (that is, they are malignant). By giving rise to secondary tumors, or metastases, they become hard to eradicate surgically. Most cancers are thought to originate from a single cell that has undergone a somatic mutation, but the progeny of this cell must undergo further changes, probably requiring several additional mutations, before they become cancerous. This phenomenon of tumor progression, which usually takes many years, reflects the operation of evolution by mutation and natural selection among somatic cells; the rate of the process is accelerated both by mutagenic agents (tumor initiators) and by certain nonmutagenic agents (tumor promoters) that affect gene expression, stimulate cell proliferation, and alter the ecological balance of mutant and nonmutant cells. Thus many factors contribute to the development of a given cancer, and since some of these factors are avoidable features of the environment, a large proportion of cancers are in principle preventable.

Much effort in cancer research has been devoted to the search for ways to cure the disease by exterminating cancer cells while sparing their normal neighbors. A rational approach to this problem requires an understanding of the special properties of cancer cells that enable them to evolve, multiply, and spread. Neoplastic cell proliferation often seems to be associated, for example, with a block in differentiation whereby the progeny of a stem cell are enabled to continue dividing instead of entering a terminal nondividing state or dying; in principle, the proliferation could be curbed by promoting cell differentiation. To become

malignant, tumor cells must be able to cross basal laminae; antibodies can be designed that interfere with this ability, thereby hindering metastasis. Cancer cells are often found to be abnormally mutable. This hastens evolution of the complex set of properties required for neoplasia and malignancy and helps the cancer cells develop resistance to anticancer drugs. At the same time, however, defects of DNA metabolism underlying such mutability may make the cancer cells uniquely vulnerable to a suitably designed therapeutic attack.

Figure 24-1. Metastasis. Malignant tumors typically give rise to metastases, making the cancer hard to eradicate. The drawing shows common sites in the bone marrow for metastases from carcinoma of the prostate gland. (From Union Internationale Contre le Cancer, TNM Atlas: Illustrated Guide to the Classification of Malignant Tumors, 2nd ed. Berlin: Springer-Verlag, 1986.)
Figure 24-2. The contrast between a benign glandular tumor (an adenoma) and a malignant glandular tumor (an adenocarcinoma). There are many forms that such tumors may take; the diagram illustrates types that might be found in the breast.

Table 24-1. Cancer Incidence and Cancer Mortality in the United States, 1993

Type of Cancer	New Cases per Year	Deaths per Year
Total cancers	1,170,000	528,300
Cancers of epithelia: carcinomas	992,700 (85%)	417,175 (79%)
Oral cavity and pharynx	29,800 (3%)	7,700 (1%)
Digestive organs (total)	236,900 (20%)	120,325 (23%)
Colon and rectum	152,000 (13%)	57,000 (11%)
Pancreas	27,700 (2%)	25,000 (5%)
Stomach	24,000 (2%)	13,600 (3%)
Liver and biliary system	15,800 (1%)	12,600 (2%)
Respiratory system (total)	187,100 (16%)	154,200 (29%)
Lung	170,000 (15%)	149,000 (28%)
Breast	183,000 (16%)	46,300 (9%)
Skin (total)	(>700,000) [*]	9,100 (2%)
Malignant melanoma	32,000 (3%)	6,800 (1%)
Reproductive tract (total)	244,400 (21%)	59,950 (11%)
Prostate gland	165,000 (14%)	35,000 (7%)
Ovary	22,000 (2%)	13,300 (3%)
Uterine cervix	13,500 (1%)	4,400 (1%)
Uterus (endometruim)	31,000 (3%)	5,700 (1%)
Uterine organs (total)	79,500 (7%)	20,800 (4%)
Bladder	52,300 (4%)	9,900 (2%)
Cancers of the hemopoietic and immune system: leukemias and lymphomas	93,000 (8%)	50,000 (9%)
Cancers of central nervous system and eye: gliomas, retinoblastoma, etc.	18,250 (2%)	12,350 (2%)
Cancers of connective tissues, muscles, and vasculature: sarcomas	8,000 (1%)	4,150 (1%)
All other cancers + unspecified sites	57,050 (5%)	43,425 (8%)

*. Nonmelanoma skin cancers are not included in total of all cancers, since almost all are cured easily and many go unrecorded. In the world as a whole, the five most common cancers are those of the lung, stomach, breast, colon/rectum, and uterine cervix, and the total number of new cancer cases per year is just over 6 million. Note that only about half the number of people who develop cancer die of it. (Data for USA from American Cancer Society, Cancer Facts and Figures, 1993.)
Figure 24-3. The growth of a typical human tumor such as a tumor of the breast. The diameter of the tumor is plotted on a logarithmic scale. Years may elapse before the tumor becomes noticeable.

(Ph^1)

Figure 24-4. The translocation between chromosomes 9 and 22 responsible for chronic myelogenous leukemia. The

smaller of the two resulting abnormal chromosomes is called the Philadelphia chromosome, after the city where the abnormality was first recorded.

Figure 24-5. Evidence from X-inactivation mosaics demonstrates the monoclonal origin of cancers. As a result of a random process that occurs in the early embryo, practically every normal tissue in a woman's body is a mixture of cells with different X chromosomes heritably inactivated (indicated here by the mixture of *red* cells and *gray* cells in the normal tissue). When the cells of a cancer are tested for their expression of an X-linked marker gene, however, they are usually all found to have the same X chromosome inactivated. This implies that they are all derived from a single cancerous founder cell.

AFLATOXIN　　　　　AFLATOXIN-2,3-EPOXIDE　　　　　CARCINOGEN BOUND TO GUANINE IN DNA

Figure 24-6. Metabolic activation of a carcinogen. Many chemical carcinogens have to be activated by a metabolic transformation before they will cause mutations by reacting with DNA. The compound illustrated here is *aflatoxin B1,* a toxin from a mold (*Aspergillus flavus oryzae*) that grows on grain and peanuts when they are stored under humid tropical conditions. It is thought to be a contributory cause of liver cancer in the tropics and is associated with specific mutations of the *p53* gene (discussed later in this chapter).
Figure 24-7. The Ames test for mutagenicity. The test uses a strain of *Salmonella* bacteria that require histidine in the medium because of a defect in a gene necessary for histidine synthesis. Mutagens can cause a further change in this gene that reverses the defect, creating revertant bacteria that do not require histidine. To increase the sensitivity of the test, the bacteria also have a defect in their DNA repair machinery that makes them especially susceptible to agents that damage DNA. A majority of compounds that are mutagenic by tests such as this are also carcinogenic and vice versa.

(B)

Figure 24-8. Cancer incidence as a function of age. The number of newly diagnosed cases of cancer of the colon in women in England and Wales in one year is plotted as a function of age at diagnosis and expressed relative to the total number of individuals in each age group; the same data are shown on an ordinary linear scale (A) and on a logarithmic scale (B). The incidence of cancer rises steeply as a function of age - roughly as the fifth power, in this example (that is, the slope of the log-log plot in (B) is about 5). If only a single mutation were required to trigger the cancer and this mutation had an equal chance of occurring at any time, the incidence would be independent of age (that is, the slope of the graph would be 0). The data suggest that a cell must accumulate the disruptive effects of about six independent rare accidents before it will give rise to a cancer of this type; the frequency of each of these events is a rate-limiting factor in the incidence of the cancer. (Data from C. Muir et al., Cancer Incidence in Five Continents, Vol. V. Lyon: International Agency for Research on Cancer, 1987.)

Figure 24-9. Delayed onset of cancer following exposure to a carcinogen. The graph shows the length of the delay before

onset of bladder cancer in a set of 78 men who had been exposed to the carcinogen 2-naph-thylamine, grouped according to the duration of their exposure. (Modified from J. Cairns, Cancer: Science and Society. San Francisco: W.H. Freeman, 1978. After M.H.C. Williams, in Cancer, Vol. III (R.W. Raven, ed.). London: Butterfield, 1958.)

Figure 24-10. The stages of progression in the development of cancer of the epithelium of the uterine cervix. (A-D) Schematic diagrams. In dysplasia the most superficial cells still show some signs of differentiation, but this is incomplete, and proliferating cells are seen abnormally far above the basal layer. In carcinoma *in situ* the cells in all the layers are proliferating and apparently undifferentiated. True malignancy begins when the cells cross the basal lamina and begin to invade the underlying connective tissue. Several years may elapse from the first signs of dysplasia to the onset of full-blown malignant cancer. (E) Photograph of a section of normal cervical epithelium. (F) Photograph of a section of a cervical carcinoma that is just beginning to be invasive; the *arrow* points to cells that are in the process of escaping from the epithelium into the connective tissue below. (E and F, courtesy of Andrew Hanby.)
Figure 24-11. Photographs of cells collected by scraping the surface of the uterine cervix (the Papanicolaou or "Pap smear" technique). (A) Normal: the cells are large and well differentiated, with highly condensed nuclei. (B) Dysplasia: the cells are in a variety of stages of differentiation, some quite immature. (C) Invasive carcinoma: the cells all appear undifferentiated, with scanty cytoplasm and a relatively large nucleus. Debris in the background includes some white blood cells. (Courtesy of Winifred Gray.)

Figure 24-12. Some possible schedules of exposure to a tumor initiator (mutagenic) and a tumor promoter (nonmutagenic) and their outcomes. Cancer ensues only if the exposure to the promoter follows exposure to the initiator and only if the intensity of exposure to the promoter exceeds a certain threshold. Cancer can also occur as a result of repeated exposure to the initiator alone.
Figure 24-13. One hypothesis proposed to explain the observed effect of tumor promoters on the development of tumors. An initiator causes a mutation in a gene that is not normally expressed in resting cells. The promoter activates the mutant gene and, by causing cell division, increases the number of cells containing the mutation. Alternatively, the mutant gene might be constitutively expressed but have no effect until the promoter activates other genes required for cell proliferation.

Table 24-2. Variation Between Countries in the Incidence of Some Common Cancers

Site of Origin of Cancer	High-Incidence Population		Low-Incidence Population	
	Location	Incidence*	Location	Incidence*
Lung	USA (New Orleans, blacks)	110	India (Madras)	5.8
Breast	Hawaii (Hawaiians)	94	Israel (non-Jews)	14.0
Prostate	USA (Atlanta, blacks)	91	China (Tianjin)	1.3
Uterine cervix	Brazil (Recife)	83	Israel (non-Jews)	3.0
Stomach	Japan (Nagasaki)	82	Kuwait (Kuwaitis)	3.7
Liver	China (Shanghai)	34	Canada (Nova Scotia)	0.7
Colon	USA (Connecticut, whites)	34	India (Madras)	1.8
Melanoma	Australia (Queensland)	31	Japan (Osaka)	0.2
Nasopharynx	Hong Kong	30	UK (southwestern)	0.3
Esophagus	France (Calvados)	30	Romania (urban Cluj)	1.1
Bladder	Switzerland (Basel)	28	India (Nagpur)	1.7
Uterus	USA (San Francisco Bay Area, whites)	26	India (Nagpur)	1.2
Ovary	New Zealand (Polynesian Islanders)	26	Kuwait (Kuwaitis)	3.3
Rectum	Israel (European and USA born)	23	Kuwait (Kuwaitis)	3.0
Larynx	Brazil (Sao Paulo)	18	Japan (rural Miyagi)	2.1
Pancreas	USA (Los Angeles, Koreans)	16	India (Poona)	1.5
Lip	Canada (Newfoundland)	15	Japan (Osaka)	0.1
Kidney	Canada (NWT and Yukon)	15	India (Poona)	0.7
Oral cavity	France (Bas-Rhin)	14	India (Poona)	0.4
Leukemia	Canada (Ontario)	12	India (Nagpur)	2.2
Testis	Switzerland (urban Vaud)	10	China (Tianjin)	0.6

*. Incidence = number of new cases per year per 100,000 population, adjusted for a standardized population age distribution (so as to eliminate effects due merely to differences of population age distribution). Figures for cancers of breast, uterine cervix, uterus, and ovary are for women; other figures are for men. Adapted from V.T. DeVita, S. Hellman, and S.A. Rosenberg (eds.), Cancer: Principles and Practice of Oncology, 4th ed. Philadelphia: Lippincott, 1993; based on data from C. Muir et al., Cancer Incidence in Five Continents, Vol. 5. Lyon: International Agency for Research on Cancer, 1987.
Figure 24-14. Effects of childbearing on the risk of breast cancer. The relative probability of breast cancer developing at some time in a woman's life is plotted as a function of the age at which she gives birth to her first child. The graph shows the value of the probability relative to that for a childless woman. The longer the delay before bearing the first child, the higher the probability of breast cancer, suggesting that exposure to certain combinations of reproductive hormones, especially estrogen, may promote development of the cancer. There is some evidence from laboratory studies that the first full-term pregnancy may result in a permanent epigenetic change in the cells of the breast, altering their subsequent responses to hormones. Other environmental factors may also be correlated with breast cancer, and some women carry genes that increase the risk of the disease. (From J. Cairns, Cancer: Science and Society. San Francisco: W.H. Freeman, 1978. After B. MacMahon, P. Cole, and J. Brown, *J. Natl. Cancer Inst.* 50:21-42, 1973.)

**Figure 24-15. Normal and deranged control of cell production from stem cells.** (A) The normal strategy for producing new differentiated cells. (B and C) Two types of derangement that can give rise to the unbridled proliferation characteristic of cancer. Note that an excessive cell-division rate for the stem cells will not by itself have this effect, as long as each cell division produces only one daughter that is a stem cell.
Figure 24-16. Steps in the process of metastasis. This example illustrates the spread of a tumor from an organ such as the lung or bladder to the liver. Tumor cells may enter the bloodstream directly by crossing the wall of a blood vessel, as diagrammed here, or, more commonly perhaps, by crossing the wall of a lymphatic vessel that ultimately discharges its contents (lymph) into the bloodstream. Tumor cells that have entered a lymphatic vessel often become trapped in lymph nodes along the way, giving rise to lymph-node metastases. Studies in animals show that typically less than one in every thousand malignant tumor cells that enter the blood-stream will survive to produce a tumor at a new site.
Figure 24-17. Experiment showing that there are clonally heritable differences between the cells of a single tumor with respect to the ability to metastasize. Cells derived from a single cancer cell line are subcloned, and standard aliquots of each subclone are tested by injection into the bloodstream of host mice. The subclones differ markedly in the number of resulting metastases per mouse.
Figure 24-18. Three steps in crossing a basal lamina - a task that invasive tumor cells must be able to perform. Some of the experimental evidence for this mechanism is presented in Figure 19-59.
Figure 24-19. Abnormal size and variability of cancer cell nuclei. The photograph shows a section through the epidermis of the breast of a patient with *Paget's carcinoma,* in which the epidermis is invaded by cancer cells originating within the breast. The cancer cells can be distinguished from the ordinary epidermal cells by their abnormally large and variable nuclei and by the rim of clear space that appears to surround each of them. (Courtesy of Andrew Hanby.)
Figure 24-20. Chromosomal changes in cancer cells reflecting gene amplification. In these examples the numbers of copies of a *myc* proto-oncogene have been amplified. The chromosomes are stained with a *red* fluorescent dye, while the multiple copies of the *myc* gene are detected by *in situ* hybridization with a *yellow* fluorescent probe. (A) Karyotype of a cell in which the *myc* gene copies are present as double minute chromosomes (paired *yellow specks*). (B) Karyotype of a cell in which the multiple *myc* gene copies appear as a homogeneously staining region (*yellow*) interpolated in one of the regular chromosomes. (Ordinary single-copy *myc* genes can be just seen as tiny *yellow dots* elsewhere in the genome.) Similar structures are seen in cancer cells that have other genes amplified. (Courtesy of Denise Sheer.)

The Molecular Genetics of Cancer <u>15</u>

Introduction

Because cancer is the outcome of a series of random genetic accidents subject to natural selection, no two cases even of the same variety of the disease are likely to be genetically identical. Nevertheless, all cancers can be expected to involve a disruption of the normal restraints on cell proliferation, and for each cell type there is a finite number of ways in which such disruption can occur. In fact, changes in a relatively small set of genes appear to be responsible for much of the derangement of cell behavior in cancer. The identification and characterization of many of these genes has been one of the great triumphs of molecular biology.

Cell proliferation can be regulated directly or indirectly - directly through the mechanism that determines whether a cell passes the restriction point, or "Start," of the cell-division cycle, as discussed in <u>Chapter 17</u>; or indirectly, for example, through regulation of the commitment to terminal differentiation or programmed cell death. In either case the normal regulatory genes can be loosely classified into those whose products help stimulate an increase in cell numbers and those whose products help inhibit it. Correspondingly, there are two mutational routes toward the uncontrolled cell proliferation and invasiveness that are characteristic of cancer. The first is to make a stimulatory gene hyperactive: this type of mutation has a dominant effect - only one of the cell's two gene copies need undergo the change - and the altered gene is called an oncogene (the normal allele being a proto-oncogene; from Greek *onkos,* a tumor). The second is to make an inhibitory gene inactive: this type of mutation usually has a recessive effect - both the cell's gene copies must be inactivated or deleted to free the cell of the inhibition - and the lost gene is called, for want of a better term, a tumor suppressor gene.

The mutant genes with a dominant effect - that is, the oncogenes - can be identified directly by taking DNA from the tumor cells and searching for fragments of it that, when introduced into normal cells, will cause these cells to behave like tumor cells. Techniques for achieving this feat were first devised in the late 1970s; their development followed earlier studies of a very similar process that occurs naturally, when viruses move their genetic material from cell to cell. This work paved the way for an explosion of discoveries of oncogenes and proto-oncogenes. More recently, progress has been made in the more difficult task of identifying and cloning tumor suppressor genes.

In this section we discuss oncogenes and tumor suppressor genes in turn. We conclude by presenting a case study of one common variety of cancer, where the steps of tumor progression can be related to a series of identified mutations.

Retroviruses Can Act as Vectors for Oncogenes That Transform Cell Behavior [16], [17], [18]

Viruses have played a remarkable part in the search for the genetic causes of human cancer. Although viruses have no role in the majority of common human cancers, they are more prominent as causes of cancer in some animal species, and analysis of animal tumor viruses has provided a key to the mechanisms of cancer in general.

The first animal tumor virus was discovered more than 80 years ago in chickens, which are subject to infections that cause connective-tissue tumors, or *sarcomas.* The infectious agent was characterized as a virus - the *Rous sarcoma virus,* which we now know to be an RNA virus. Like all the other RNA tumor viruses discovered since, it is a retrovirus. When it infects a cell, its RNA is copied into DNA by reverse transcription and the DNA is inserted into the host genome, where it can persist and be inherited by subsequent generations of cells. Figure 6-82 outlines the life cycle of a retrovirus and shows how its genome undergoes reverse transcription, integration into host DNA, and exit from and entry into host cells.

But how does the viral infection cause tumors? The solution to this problem, as to so many others in cell biology, depended on the development of a convenient assay by which different strains of virus could be rapidly tested for their tumor-causing capacity. The assay system, still widely used, consists simply of fibroblast cells proliferating in a culture dish. If active tumor virus is added to the culture medium, small colonies of abnormally proliferating transformed cells appear within a few days. Each such colony is a clone derived from a single cell that has been infected with the virus and has stably incorporated the viral genetic material. Released from the social controls on cell division, the transformed cells outgrow normal ones in the culture dish just as in the body and are therefore usually easy to select. The transformed cells commonly show a complex syndrome of abnormalities (summarized in Table 24-3). They tend not to be constrained by density-dependent inhibition of cell division (see Figure 17-39), for example, but pile up in layer upon layer as they proliferate (Figure 24-21). In addition, they often do not depend on anchorage for growth and are capable of dividing even when held in suspension; they have an altered shape and adhere poorly to the substratum and to other cells, maintaining a rounded appearance reminiscent of a normal cell in mitosis; they may be able to proliferate even in the absence of growth factors; they are immortal and do not undergo senescence in culture; and when they are injected back into a suitable host animal, they can give rise to tumors.

The misbehavior of the transformed cells can be traced to an oncogene that is carried by the virus but is not necessary for the virus's own survival or reproduction. This was first demonstrated by the discovery of mutant Rous sarcoma viruses that multiply normally but no longer transform their host cells. The loss of transforming ability could be shown to correspond to loss or inactivation of a particular gene, which was given the name *src* (Figure 24-22). This specific gene in the Rous sarcoma virus is responsible for cell transformation *in vitro* and for tumor formation *in vivo,* but it is unnecessary baggage from the point of view of the virus's own propagation.

Retroviruses Pick Up Oncogenes by Accident [16], [17], [19]

If the viral *src* gene is bad for the animal and unnecessary to the virus, why is it present and where does it come from? When a radioactive DNA copy of the viral *src* gene sequence was used as a probe to search for related sequences by DNA-DNA hybridization, it was found that the genomes of normal vertebrate cells contain a sequence that is closely similar, but not identical, to the *src* gene of the Rous sarcoma virus. This normal cellular counterpart of the viral *src* gene (v- *src*) is called c- *src* (or just *src*). It is the proto-oncogene corresponding to the oncogene v- *src.* Evidently, the gene has been picked up accidentally by the retrovirus from the genome of a previous host cell but has undergone mutation in the process (Figure 24-23). The result is a perturbed gene function that leads to cancer and so brings the gene, and the virus that carries it, to the scientist's attention. The retrovirus has, in effect, cloned the gene for us. A large number of other oncogenes have been identified in other retroviruses and analyzed in similar ways (Table 24-4). Each has led to the discovery of a corresponding proto-oncogene that is present in every normal cell.

A Retrovirus Can Transform a Host Cell by Inserting Its DNA Next to a Proto-oncogene of the Host [20]

There are two ways in which a proto-oncogene can be converted into an oncogene upon incorporation into a retrovirus: the gene sequence may be altered or truncated so that it codes for a protein with abnormal activity, or the gene may be brought under the control of powerful promoters and enhancers in the viral genome that cause its product to be made in excess or in inappropriate circumstances. Retroviruses can also exert similar oncogenic effects in a different way: DNA copies of the viral RNA may simply be inserted into the host cell genome at sites close to, or even within, proto-oncogenes. The resulting genetic disruption is called an insertional mutation, and the altered genome is inherited by all the progeny of the original host cell. More-or-less random insertion of DNA copies of the viral RNA into the host DNA occurs as part of the normal retroviral life cycle, and in at

least one well-documented case, insertion anywhere within about 10,000 nucleotide pairs from a proto-oncogene can cause abnormal activation of that gene.

Insertional mutagenesis provides an important means of identifying proto-oncogenes, which can be tracked down by their proximity to the inserted viral DNA. Proto-oncogenes identified in this way often turn out to be the same as those discovered in the other way, as counterparts to oncogenes that retroviruses carry from cell to cell, but some new ones have been discovered as well (Table 24-5). An example is the *Wnt*-1 gene, activated by insertional mutagenesis in breast cancers in mice infected with the mouse mammary tumor virus (Figure 24-24). This gene turns out to be closely homologous to the *Drosophila* gene *wingless,* which is involved in cell-cell communications that regulate details of the body pattern of the fly, as discussed in Chapter 21.

Different Searches for the Genetic Basis of Cancer Converge on Disturbances in the Same Proto-oncogenes 17, 21

While some researchers pursued the line of investigation leading from retroviruses to oncogenes, others took a more direct approach and searched for DNA sequences in human cancer cells that would provoke uncontrolled proliferation when introduced into noncancerous cells. The assay was again done in cell culture, using an established line of mouse-derived fibroblast cells - NIH 3T3 cells - as the noncancerous hosts and transfecting them with DNA taken from human tumor cells. The findings were dramatic. Oncogenes were detected in many lines of human cancer cells, and in several cases these oncogenes turned out to be mutant alleles of some of the same proto-oncogenes that had been identified by the retroviral approach or of genes very closely related to them. About one in four human tumors, for example, was found to contain a mutated member of the *ras* gene family, first discovered as oncogenes carried by retroviruses that cause sarcomas in rats. Thus two independent lines of inquiry converged on the same genes.

Yet another approach that led to some of the same proto-oncogenes was based on the karyotyping of tumor cells. As mentioned earlier, in almost all patients with chronic myelogenous leukemia, the leukemic cells show the same chromosomal translocation, between chromosomes 9 and 22; likewise, in Burkitt's lymphoma there is regularly a translocation between chromosome 8 and one of the three chromosomes containing the genes that encode antibody molecules. In both these types of cancer the translocation breakpoint, where part of one chromosome is joined to another, was found to coincide exactly with the location of a proto-oncogene already known from retroviral studies - *abl* in chronic myelogenous leukemia, *myc* in Burkitt's lymphoma. Analogous chromosome translocations are similarly associated with some other types of cancer. From DNA sequencing studies it seems that in some cases the translocation turns a proto-oncogene into an oncogene by fusing the proto-oncogene to another gene in such a way that an altered protein is produced (Figure 24-25); in other cases the translocation moves a proto-oncogene into an inappropriate chromosomal environment that activates its transcription so that the normal protein is produced in excess.

A Proto-oncogene Can Be Made Oncogenic in Many Ways 17, 22

So far, about 60 proto-oncogenes have been discovered (Tables 24-4 and 24-5 show a small selection); each of these can be converted into an oncogene that plays a dominant part in cancers of one sort or another. Most such genes have been encountered repeatedly, in a variety of mutant forms and in several kinds of cancer, suggesting that the majority of mammalian proto-oncogenes may already have been identified.

But what functions do these genes have in a normal healthy cell, that mutations in them should be so dangerous? Most proto-oncogenes code for components of the mechanisms that regulate the social behavior of cells in the body - in particular, the mechanisms by which signals from a cell's neighbors can impel it to divide, differentiate, or die. In fact, many of the components of cell-signaling pathways were first identified through searches for oncogenes, and a full list of proto-oncogene products includes examples of practically every type of molecule involved in cell signaling - secreted proteins, transmembrane receptors, GTP-binding proteins, protein kinases, gene regulatory proteins, and so on, as summarized in Figure 24-26 and discussed in detail in Chapter 15. All these molecules normally serve in complex relay chains to deliver signals for the production of more cells when more cells are needed. But mutations can alter them so that they deliver the signals even when more cells are not needed. The proto-oncogene *erbB,* for example, codes for the receptor for epidermal growth factor (EGF); when EGF binds to the receptor's extracellular domain, the intracellular domain generates a stimulatory signal inside the cell. A mutation in c-*erbB* can turn it into an oncogene by deleting the extracellular EGF-binding domain in such a way that the intracellular stimulatory signal is produced constantly, even if no EGF is present. In a similar way a point mutation at an appropriate site in a *ras* gene can create a Ras protein that fails to hydrolyze its bound GTP and so persists abnormally in its active state, transmitting an intracellular signal for cell proliferation even when it should not. Innumerable other examples can be given.

The basic types of genetic accident that can convert a proto-oncogene into an oncogene are summarized in Figure 24-27. The gene may be altered by a point mutation, by a deletion, through a chromosomal translocation, or by insertion of a mobile genetic element such as retroviral DNA. The change can occur in the protein-coding region so as to yield a hyperactive product, or it can occur in adjacent control regions so that the gene is simply overexpressed. Alternatively, the gene may be overexpressed because it has been amplified to a high copy number through errors in the process of chromosome replication. (The mechanism is discussed later - see Figure 24-34.) Specific types of abnormality are characteristic of particular genes and of the responses to particular carcinogens. For example, 90% of the skin tumors evoked in mice by the tumor initiator dimethylbenz[a]anthracene (DMBA) have an A-to-T alteration at exactly the same site in a mutant *ras* gene; presumably, of the mutations caused by DMBA, it is only the ones at this site that efficiently activate skin cells to form a tumor. Members of the *myc* gene family, on the other hand, are frequently overexpressed or amplified. The Myc protein normally acts in the nucleus as a signal for cell proliferation, as discussed in Chapter 17; excessive quantities of Myc cause the cell to embark on the cell-division cycle in circumstances where a normal cell would halt.

The Actions of Oncogenes Can Be Assayed Singly and in Combination in Transgenic Mice 23

The concept of an oncogene is paradoxical. As we have argued at length in the first part of this chapter, a single mutation is not enough to cause a cancer. Yet an oncogene is defined as a dominantly acting gene and is typically assayed by its ability to cause neoplastic transformation of cultured cells on its own. This apparent contradiction reflects the gulf between the simplified models of cancer most widely studied by molecular biologists and the complexity of the actual human disease. The standard assay for identification of oncogenes does not test their effects on normal human somatic cells but on a mouse-derived fibroblast cell line, and the cells of this line, through establishment in culture, have already undergone mutations that make them abnormally easy to transform by a single further genetic change. Moreover, as we noted earlier, mice, with their shorter life-spans and smaller cell numbers, run an intrinsically smaller risk of cancer than do human beings, so that their cells may be less securely protected against the consequences of carcinogenic mutations than are human cells.

Even in a mouse, however, a single oncogene is not usually sufficient to turn a normal cell into a cancer cell. This can be strikingly demonstrated by studies of transgenic mice. An oncogene in the form of a DNA fragment, derived from either a virus or a tumor cell, can be linked to a suitable promoter DNA sequence and then injected into a mouse egg nucleus. Often this recombinant DNA molecule will become integrated into a mouse chromosome, leading to the generation of a strain of transgenic mice that carry the oncogene in all their cells. The oncogene introduced in this way may be expressed in many tissues or in only a select few, according to the tissue specificity of the associated promoter. Typically, in mice that are thus endowed with a *myc* or *ras* oncogene, some of the tissues that express the oncogene grow to an exaggerated size, and occasional cells with the passage of time undergo further changes and give rise to cancers. The vast majority of the cells in the transgenic mouse that express the *myc* or *ras* oncogene, however, do not give rise to cancers, showing that the single oncogene is not enough to cause neoplastic transformation. From the point of view of the whole animal, the inherited oncogene, nevertheless, is a serious menace because it increases the risk of developing cancer. Inherited oncogenes can act similarly in humans, although the phenomenon is rare. In the one well-documented example a mutant form of the *ret* proto-oncogene confers a hereditary predisposition to certain tumors of the thyroid and adrenal glands (a syndrome known as multiple endocrine neoplasia type 2A [MEN2A]).

The experimental analysis of oncogene action has been taken a step further by mating a pair of transgenic mice - one carrying a *myc* oncogene, the other carrying a *ras* oncogene - so as to obtain progeny that carry both oncogenes together. These offspring develop cancers at a much higher rate than either parental strain (Figure 24-28), but again the cancers originate as scattered isolated tumors among noncancerous cells. Thus, even with these two expressed oncogenes, the cells must undergo further, randomly generated changes to become cancerous.

The synergistic action of two or more specific oncogenes to make cells cancerous is known as *oncogene collaboration,* and it can be demonstrated *in vitro* as well as *in vivo*. If normal rat embryo fibroblasts are transfected with a *ras* oncogene alone or with a *myc* oncogene alone, they continue to behave normally. If they are transfected with both oncogenes together, they are transformed. In different cell types, different combinations of oncogenes are required for transformation. The lymphocyte-derived cancer known as B-cell lymphoma, for example, appears to depend on a collaboration between *myc* and the *bcl*-2 gene (which we encountered in Chapter 21, in connection with programmed cell death). If *myc* alone is overexpressed, cells are driven round the division cycle inappropriately, but no cancer results because the progeny of such abnormally forced divisions are programmed to die. If *bcl*-2 is overexpressed at the same time, however, the excess progeny cells survive and proliferate: *bcl*-2 acts as an oncogene because the Bcl-2 protein inhibits programmed cell death.

These phenomena reflect the fail-safe character of the complex network of controls that regulate cell proliferation and survival. It seems that multiple control mechanisms operate in parallel, so that a single faulty component is not enough to cause a disaster. In this control system, however, proto-oncogenes are only half the story. No less important are the tumor suppressor genes that act as counterbalance to them. As we see next, deletions and disturbances of tumor suppressor genes play as large a part in human cancer as do mutations of proto-oncogenes into oncogenes.

Loss of One Copy of a Tumor Suppressor Gene Can Create a Hereditary Predisposition to Cancer 24, 25

Given a cancer cell, it is harder to pinpoint a normal gene that it lacks than it is to discover an abnormal gene that it possesses: one cannot take the DNA and use a cell transformation assay to identify something that simply is not there. Knowledge of tumor suppressor genes has thus been harder to obtain than knowledge of proto-oncogenes.

The difficulty is compounded because loss of a single tumor suppressor gene - even loss of both copies of the gene - usually is not sufficient by itself to cause a cancer; this makes it hard to incriminate specific mutations. We have seen that the same problem arises in tracking down oncogenes and can be resolved by assays using cultured cell lines that are unusually easy to transform with a single mutant gene. In the study of tumor suppressor genes the key insight came instead from a rare type of human cancer, retinoblastoma, that arises from cells in the body that are transformed by an unusually small number of mutations.

Retinoblastoma occurs in childhood; tumors develop from neural precursor cells in the immature retina. About one child in 20,000 is afflicted. There are two forms of the disease, one hereditary, the other not. In the hereditary form multiple tumors usually arise independently, affecting both eyes; in the non-hereditary form only one eye is affected and by only one tumor. Some hereditary sufferers from retinoblastoma are found to have a visibly abnormal karyotype, with a deletion of a specific band on chromosome 13, and deletions of this same locus are also encountered in tumor cells from patients with the nonhereditary disease. This suggests that the cancer may be caused by loss of a tumor suppressor gene rather than acquisition of an oncogene. Specifically, if all of the cells of patients with the hereditary disease lack one of the two normal copies of a tumor suppressor gene, then those cells will be predisposed to become cancerous: a single somatic mutation that eliminates the remaining good copy of the gene in one of the million or more cells in the growing retina will suffice to initiate a cancer. The gene whose loss thus appears to be critical for development of the cancer is called the retinoblastoma, or *Rb,* gene. In children without the hereditary predisposition retinoblastomas are very rare because they require the coincidence of two somatic mutations in a single retinal cell to destroy both copies of the *Rb* gene (Figure 24-29).

Using the known location of the chromosomal deletion associated with retinoblastoma, it was possible to clone and sequence the *Rb* gene and hence to analyze the genetic defects in detail in individual patients. Just as predicted, in those who suffer from the hereditary form of the disease, a deletion or loss-of-function mutation of the *Rb* gene is found in every cell of the body. The cells that are not cancerous are defective in only one of their two copies of the gene, while the cancerous cells are defective in both. In patients with the nonhereditary form of the disease, by contrast, the noncancerous cells show no defect in either copy of *Rb,* while the cancerous cells are again defective in both copies.

Many different combinations of genetic mishaps can eliminate or cripple both copies of a gene. The first copy may, for example, be lost by a large-scale chromosomal deletion or inactivated by a point mutation; the second copy may be lost in a similar way or by mitotic recombination (explained in Figure 21-73) or by gene conversion (see Figure 6-66). The range of possibilities is summarized in Figure 24-30. It can be seen that most of these mechanisms are such that the second copy of the gene, and usually flanking regions of its chromosome as well, are either totally deleted or replaced by a copy of the corresponding region of the first defective chromosome; in other words, the usual heterozygous combination of maternal and paternal alleles of genes in that chromosomal region is lost. In fact, when tumor cells from many different retinoblastoma patients are analyzed, a loss of heterozygosity in the region of the *Rb* gene is observed in about 70% of cases. As we see below, loss of heterozygosity in the cells of a tumor provides the basis for a general method by which tumor suppressor genes can be identified and cloned.

Loss of the Retinoblastoma Tumor Suppressor Gene Plays a Part in Many Different Cancers 25, 26

Given the *Rb* gene sequence, it is possible to test for its presence in cells of tumors other than retinoblastoma. The gene turns out to be frequently missing in several common types of cancer, including carcinomas of lung, breast, and bladder. These more common cancers arise by a more complex series of genetic changes than does retinoblastoma, and they make their appearance later in life and in other tissues of the body. But in all of them, it seems, loss of *Rb* is a major step in the progression toward malignancy. Thus although retinoblastoma is rare, cancers involving the *Rb* gene are not.

As discussed in Chapter 17, *Rb* is normally expressed in almost all the cells of the body, and its product appears to act as one of the main brakes on progress around the cell-division cycle. The braking action is normally regulated by phosphorylation. The Rb protein alternates between a phosphorylated and an unphosphorylated state in every cycle, and in cells that have withdrawn from cycling it is kept unphosphorylated. As long as it is unphosphorylated, Rb binds strongly to certain gene regulatory proteins and in this way prevents them from acting in the nucleus to promote DNA replication. Loss of the gene sets the cell free from this restraint.

The molecular interpretation of how Rb acts takes us a step further still in the understanding of cancer, for it throws light on yet another way in which cancer can be triggered - by DNA viruses. Before explaining how, we must pause to examine the role that viruses in general play in the causation of human cancer.

DNA Tumor Viruses Activate the Cell's DNA Replication Machinery as Part of Their Strategy for Survival 16

About 15% of human cancers, in the world as a whole, are thought to arise by mechanisms that involve viruses. As shown in Table 24-6, the main culprits in humans are not retroviruses but DNA viruses. Evidence for their involvement comes partly from the detection of viruses in cancer patients and partly from epidemiology. Liver cancer, for example, is common in parts of the world (Africa and Southeast Asia) where hepatitis-B viral infections are common, and in those regions the cancer occurs almost exclusively in people who show signs of chronic hepatitis-B infection.

The precise role of a cancer-associated virus is often hard to decipher because there is a delay of many years from the initial viral infection to the development of the cancer. Moreover, the virus is responsible for only one of a series of steps in the progression to cancer, and other environmental factors and genetic accidents are also involved. In some cancers viruses seem to have indirect promoting actions; the hepatitis-B virus may, for example, favor the development of liver cancer by doing damage that provokes cell division in the liver. In some other human cancers, however, viruses help directly to cause neoplastic transformation of the cells they infect. Studies with cultured cells *in vitro* show how this can occur.

If a cell is to be stably transformed by a virus, a stable parasitic association must be established: the virus must not kill the cell, and the cell must retain the viral genes from one cell generation to the next - usually by integrating those genes into one or more of its own chromosomes, occasionally by retaining them as an extrachromosomal plasmid that replicates in step with the chromosomes. This applies equally to DNA viruses and retroviruses, but the two classes of virus differ fundamentally in the nature of the viral genes that cause neoplastic transformation.

As explained in Chapter 6, a DNA tumor virus normally propagates in the wild by a process that does not depend on the production of cancer. An SV40 virus (Figure 24-31), for example, produces a viral protein that rapidly activates the host cell's machinery for DNA replication. The virus then uses host proteins to replicate and transcribe its own genome; the infection continues until the host is killed, releasing a horde of new infectious virus particles. Much more rarely, however, the viral DNA fails to replicate and instead becomes stably incorporated into a host cell chromosome. If the viral gene that activates the host's machinery for DNA replication is transcribed, this gene can act as an oncogene, causing a cancerous transformation. Unlike the retroviral oncogenes discussed earlier, however, this oncogene is an essential part of the viral genome, and it has no counterpart in the normal host cell.

DNA Tumor Viruses Activate the Cell's Replication Machinery by Blocking the Action of Key Tumor Suppressor Genes 16, 27

DNA viruses are a diverse group, but the general principles just described apply to most of those that are involved in cancer. The *papillomaviruses,* for example, are the cause of human warts and are also implicated in carcinomas of the uterine cervix. They are distantly related to the *polyomavirus* family that includes SV40, and the cancer that they cause in humans requires the integration of specific viral replication genes into a host chromosome, as illustrated in Figure 24-32.

Like SV40, papillomaviruses have to be able to commandeer the host cell's DNA synthesis machinery, and the viral genes that have this function can act as oncogenes. They are called the *E6* and *E7* genes of the papillomavirus, and their protein products are functionally equivalent to a single large dual-purpose protein called *large T antigen,* encoded by a corresponding viral oncogene in the SV40 genome. The mechanism of action is apparently simple: these viral proteins bind to the protein products of two key tumor suppressor genes of the host cell, putting them out of action and so permitting the cell to replicate its DNA and divide (Figure 24-33). One of these host proteins is Rb: by binding to it, the viral protein (E7 or large T) prevents it from binding to its normal associates in the cell.

The other tumor suppressor gene product that the viral proteins serve to inactivate is called p53 (from its molecular mass of 53 kilodaltons). Like Rb, it plays a part in the development of many types of cancer, not only those dependent on viruses.

Mutations of the *p53* Gene Disable an Emergency Brake on Cell Proliferation and Lead to Genetic Instability [13], [14], [28]

People who inherit from their parents only one functional copy of the *p53* gene, like those who inherit only one functional copy of *Rb,* are predisposed to cancer. They are liable to develop several independent tumors in any of a wide variety of tissues at a relatively early age - typically as young adults. This propensity, running in families, is called *Li-Fraumeni* syndrome; like hereditary retino-blastoma, it is very rare. Tumor cells in the Li-Fraumeni patient have defects in both copies of *p53,* while the nontumor cells have a defect in only one.

These findings are typical of a tumor suppressor gene, and, in confirmation of this role for p53, it is found that artificially raised levels of normal p53 protein in an ordinary cultured cell will stop it from proliferating. The p53 protein binds to DNA and exerts its effect, in part at least, by inducing the transcription of another regulatory gene, whose product, a 21-kilodalton protein, binds to the complexes of G_1 cyclin with Cdk2 protein that normally serve to drive the cell past the G_1 checkpoint in the cell cycle, as discussed in Chapter 17. By blocking the kinase activity of these complexes, the 21-kilodalton protein prevents the cell from progressing into S phase and replicating its DNA.

In contrast with Rb, very little p53 protein is found in most of the cells of the body under normal conditions. In fact, p53 is not required for normal development: transgenic mice in which both copies of the gene have been knocked out appear normal in all respects except one - they usually develop cancer by the age of 3 months. These observations suggest that *p53* may serve a function that is required only occasionally or in special circumstances. Further evidence supports this idea. When normal cells are exposed to ultraviolet light or to gamma rays, they react by raising their concentration of p53 protein (by reducing the normally rapid rate of degradation of the molecule). The resulting high level of p53 protein blocks cell proliferation: the cells are barred from progressing into the S phase of the cell cycle, and either delay in the G_1 phase or die by apoptosis. Cells lacking the *p53* gene fail to show this response: they carry on dividing, plunging into DNA replication without pausing to repair the breaks and other DNA lesions caused by the damaging radiation. As a result, they either die or, worse, survive and proliferate but with a corrupted genome. A common consequence is that chromosomes become fragmented and rejoined, creating a highly unstable karyotype. This can lead to gene duplications and, through further rounds of cell division, to gene amplifications such as we described earlier for *mdr*1 and for *myc* in tumor cells (Figure 24-34).

It seems, therefore, that the normal function - or at least a normal function - of p53 is to enable cells to cope safely with DNA damage. It is possible that p53 may also act as a check on cell proliferation in other stressful circumstances. In fact, many cancer cells contain large quantities of p53 (of the mutant, ineffectual type), suggesting that the other genetic accidents that occur on the way to cancer are sufficient to call p53 into play. Loss or inactivation of p53 may thus be doubly dangerous in relation to cancer - first, by removing a block to the proliferation of cells that have suffered carcinogenic mutations and, second, by allowing further carcinogenic mutations to be generated when these cells divide. Mutations of the *p53* gene are the most common genetic lesion in human cancer, present in more than 50% of all cases of the disease.

Colorectal Cancers Develop Slowly Via a Succession of Visible Structural Changes [29], [30]

In the first part of this chapter we saw that most cancers develop gradually from a single aberrant cell, progressing from benign to malignant tumors by the accumulation of a half-dozen independent genetic accidents. In the second part of the chapter we have discussed what some of these accidents are in molecular terms. We must now consider how the general principles and the fragments of molecular genetic explanation fit together to give a coherent account of the development of one of the common human cancers. We take colorectal cancer as our example, because in this case the steps of tumor progression have been followed *in vivo* as a series of visible structural changes that can be related to specific molecular events.

Colorectal cancers arise from the epithelium lining the colon and rectum (the lower end of the gut). They are common, currently causing over 50,000 deaths a year in the United States, or about 11% of total deaths from cancer. Like most cancers, they are not usually diagnosed until late in life (90% after the age of 55). However, routine examination of normal adults with a colonoscope (a fiber-optic device for viewing the interior of the colon and rectum) often reveals a small benign tumor, or *adenoma,* of the gut epithelium forming a protruding mass of tissue called a *polyp* (Figure 24-35). These adenomatous polyps are believed to be the precursors of a large proportion of colorectal cancers. Because progression of the disease is usually very slow, there is typically

a period of 10-35 years in which the slowly growing tumor is detectable but has not yet turned malignant. Thus, when people are screened by colonoscopy in their fifties and the polyps are removed - a quick and easy surgical procedure - the subsequent incidence of colorectal cancer is very low - according to some studies, less than a quarter of what it would be otherwise.

Colon cancer provides a clear example of the phenomenon of tumor progression discussed previously. In polyps smaller than 1 cm in diameter, the cells individually and the local details of their arrangement in the epithelium usually appear almost normal. The larger the polyp, the more likely it is to contain cells that look abnormally undifferentiated and form abnormally organized structures. Sometimes, two or more sectors can be distinguished within a single polyp, the cells in one sector appearing relatively normal, those in the other appearing frankly cancerous, as though they have arisen as a mutant subclone within the original clone of adenomatous cells. At later stages in the disease the tumor cells become invasive, first breaking through the epithelial basal lamina, then spreading through the layer of muscle that surrounds the gut, and finally metastasizing to lymph nodes, liver, lung, and other tissues.

Mutations Leading to Colorectal Cancer Can Be Identified by Scanning the Cancer Cells and by Studying Families Prone to the Cancer [29], [31]

What are the mutations that accumulate with time to produce this type of cancer? One approach to answering this question is to use DNA probes for known proto-oncogenes and tumor suppressor genes to test whether any of these have undergone mutation in the colorectal cancer cells. In this way it has been shown that about 75% of colorectal cancers have inactivating mutations in the p53 tumor suppressor gene; about 50% have a point mutation in a *ras* proto-oncogene (usually a specific activating mutation, in codon 12 of the *K-ras* gene); a few percent have an amplified number of copies of a *myc* proto-oncogene; and another few percent have mutations in various other known proto-oncogenes (see Table 24-7).

Another approach is to track down the genetic defect in those rare families that show a hereditary predisposition to colorectal cancer. Chief among these hereditary cancer syndromes is a condition known as *familial adenomatous polyposis coli (APC),* in which hundreds or thousands of polyps develop along the length of the colon. These make their appearance in early adult life, and if they are not removed, it is almost inevitable that one or more of them will progress to become malignant; on average, 12 years elapse from the first detection of polyps to the diagnosis of cancer. The disease can be traced to deletion or inactivating mutation of a specific gene - the *APC* gene on the long arm of chromosome 5. Individuals with the APC syndrome have inactivating mutations or deletions of the *APC* gene in all the cells of the body. Of the patients with colorectal cancer who do not have the APC syndrome, more than 65% have similar mutations in the cells of the cancer but not in their other tissues. Thus, by a route similar to that which we have discussed for retinoblastoma, mutation of *APC* has been identified as one of the central ingredients of colorectal cancer. The normal function of the APC protein is not known, but it has been found to bind to beta-catenin (see Chapter 19), suggesting that it may be involved in some control mechanism based on the sites of anchorage of the cytoskeleton at cell-cell junctions.

Genetic Deletions in Colorectal Cancer Cells Reveal Sites of Loss of Tumor Suppressor Genes [29], [32]

Yet another approach has led to the discovery of further tumor suppressor genes. As explained earlier, the loss of both copies of a tumor suppressor gene often involves a loss of heterozygosity in the chromosomal region where the gene lies: in place of distinct maternal and paternal variants there is only one version of the chromosome sequence or sometimes none at all. Because there is a lot of genetic variability in human populations, it is possible in most individuals to find many differences of sequence between the maternal and the paternal copies of any given chromosome and to design genetic probes that will detect these differences. Using such probes, one can systematically scan the genome of the cells of a tumor looking for loss of a heterozygosity that is detectable in the normal cells of the individual. If a loss of heterozygosity is detected repeatedly at the same chromosomal site in many independently derived tumors, there is a strong presumption that that site normally harbors a tumor suppressor gene whose loss is instrumental in causing the tumors.

A systematic scan of a large number of colorectal cancers in this way reveals several distinct sites where loss of heterozygosity is so common as to suggest the presence of a tumor suppressor gene. The site of the *APC* gene is among them, as is the site of the *p53* gene; another site, showing loss of heterozygosity in more than 70% of the tumors, is occupied by a gene called *DCC* (*deleted in colon carcinoma*). This gene, which was discovered through this method of analysis, codes for what appears to be a transmembrane protein whose extracellular domain has similarities to that of the cell-adhesion molecule N-CAM, suggesting that it may be involved in cell-cell or cell-matrix adhesion or in the reception of signals from the cell's environment. Table 24-7 gives a summary of the main proto-oncogenes and tumor suppressor genes that have been implicated in colorectal cancer.

The Steps of Tumor Progression Can Be Correlated with Specific Mutations [29], [33]

In what sequence do these mutations occur, and what contribution does each of them make to the eventual unruly behavior of the cancer cell? Mutations inactivating the *APC* gene appear to be the first, or at least a very early, step. They can be detected already in small benign polyps at the same high frequency as in large malignant tumors. Their effect seems to be simply to increase the rate of cell proliferation relative to the rate of cell loss, without affecting the way the cells differentiate or the details of the histological pattern they form. Mutations activating the *ras* oncogene come a little later; they are rare in small polyps but common in larger ones that show disturbances of cell differentiation and histological pattern. When malignant colorectal carcinoma cells containing such *ras* mutations are grown in culture, they show typical features of transformed cells, such as the ability to proliferate without anchorage to a substratum; and the cells revert to a nontransformed character and reduce their rate of proliferation if their activated *ras* gene is eliminated.

Mutations in *DCC* and in *p53* come later still. They are rare in polyps but common in the malignant tumors that develop from them. Loss of *p53* seems to relieve the mutant cells of their last inhibitions, and if normal *p53* is transfected back into colorectal carcinoma cells, their proliferation is suppressed. According to one theory, oncogenic mutations of *ras*, like radiation-induced genetic damage, activate an emergency brake on proliferation that depends on p53 protein; only when this brake is disabled by mutation of *p53* can the cells finally give rise to a full-blown cancer. Loss of p53 function is thought to allow the cells not only to divide but also to accumulate further mutations at a rapid rate by progressing through the cell cycle when they are in no fit state to do so. Because these further mutations occur readily, they are probably not rate-limiting events in the incidence of the cancer (see Figure 24-8), but they may have important functional consequences. In this way one arrives at the final malignant tumor, with its many and varied genetic aberrations and its distressing ability to survive by evolving in the face of therapeutic attack (Figure 24-36).

Although mutations in *APC, ras, DCC,* and *p53* may be crucial rate-limiting steps in a large proportion of colorectal cancers, these mutations do not always occur in the same sequence, nor are they the only route to the disease. In about 15% of cases, for example, it seems that the development of colorectal cancer is speeded from the outset by another type of mutation, which increases cell mutability by decreasing the fidelity of replication of specific classes of repetitive DNA sequences (such as dinucleotide repeats of the form CACACA . . .) that are scattered throughout the genome. Individuals who inherit this mutation that promotes mutations tend to develop colorectal (and some other) cancers at an early age; their condition is known as *hereditary non-polyposis colorectal cancer,* or *HNPCC.* The *HNPCC* gene is one with an ancient evolutionary history: it is a human homologue of a gene called *mutS* that is found in bacteria and yeast and is required for repair of regions in the DNA where there is a mismatch in the nucleotide sequences of the two strands of the double helix (see Figure 6-50). Such repair mechanisms are clearly of fundamental importance in all living organisms. Tumor cells with the *HNPCC* mutations usually do not show the gross chromosomal instability associated with *p53* mutations: they have found another and more subtle route toward rapid accumulation of the mutations required for cancer.

Other types of cancers that have been analyzed genetically often show an even larger variety of genetic lesions and even greater variation from one case of the disease to another. In the form of lung cancer known as small-cell lung cancer, for example, one finds mutations not only in *ras, p53,* and *APC* but also in *Rb,* in members of the *myc* gene family (in the form of amplification of the number of *myc* gene copies), and in at least five other known proto-oncogenes and tumor suppressor genes. Different combinations of mutations are encountered in different patients and correspond to cancers that react differently to treatment.

Each Case of Cancer Is Characterized by Its Own Array of Genetic Lesions

All medical progress depends on accurate diagnosis. If one cannot identify a disease correctly, one cannot discover its causes, predict its outcome, select the appropriate treatment for a given patient, or make trials on a population of patients to judge whether a proposed treatment is effective. As we have just seen, the traditional classification of cancers is simplistic: a single one of the conventional categories turns out on close scrutiny to be a heterogeneous collection of disorders, with some features in common but each characterized by its own array of genetic lesions (Figure 24-37). Molecular biology is beginning to provide tools to find out precisely which genes are amplified, which are deleted, and which are mutated in the tumor cells of any given patient. Such information may prove to be as important for the management and prevention of cancer as is the identification of microorganisms in patients with infectious diseases.

The discovery of oncogenes and, more recently, of tumor suppressor genes has marked the end of an era of groping in the dark for clues to the biochemical basis of cancer. It has been encouraging to find that there are, after all, some general principles and that some key genetic abnormalities are shared by many forms of the disease. But we are still far from fully understanding the

common human cancers. We know the DNA sequences of many oncogenes and proto-oncogenes and of several crucial tumor suppressor genes but the precise physiological functions of only a few. In order to devise effective rational treatments, we need better understanding of how these and other molecules interact to govern the behavior of the individual cell, better understanding of the sociology of cells in tissues, and better understanding of the cell population genetics that govern the genesis of cancer cells through mutation and natural selection.

Looking back on the history of cell biology, we can be hopeful. The desire to understand that drives basic research will surely reveal new ways toward our humanitarian goals, not only in relation to cancer but also in wider areas that we can as yet scarcely foresee.

Summary

Two classes of genes are critical in the causation of cancer - tumor suppressor genes and proto-oncogenes. Loss-of-function mutations of tumor suppressor genes relieve cells of inhibitions that normally hold their numbers in check; gain-of-function mutations of proto-oncogenes stimulate cells to increase their numbers when they should not. These latter mutations have a dominant effect, and the mutant genes, known as oncogenes, can be identified by their ability to transform the behavior of cells into which they are introduced. Many oncogenes have been tracked down by their presence in transforming retroviruses, which can pick up such dangerously corrupted versions of host cell genes and carry them into other host cells. A large proportion of proto-oncogenes code for components of the pathways by which external signals stimulate cells to divide.

Mutations in tumor suppressor genes are usually recessive in their effects on the individual cell: there is no loss of control until both gene copies are put out of action. People who inherit one defective and one functional gene copy, however, are often strongly predisposed to cancer, since a single somatic mutation is enough, with the inherited mutation, to create a cell that totally lacks the tumor suppressor gene function. Cancers that run in families in this way are rare, but they provide one means to identify tumor suppressor genes whose loss turns out to be a feature of many common cancers. DNA viruses such as papillomaviruses and SV40 can promote the development of cancer by sequestering the products of tumor suppressor genesin particular, the Retinoblastoma protein, which regulates progress through the cell division cycle in normal circumstances, and the p53 protein, which is thought to act as an emergency brake on cell division in cells that have suffered genetic damage.

The steps of tumor progression can be correlated with mutations that activate specific oncogenes and inactivate specific tumor suppressor genes. A loss of p53 function, for example, is a common late event and may be responsible for the genetic instability of many full-blown metastasizing cancers. Different combinations of mutations are found in different forms of cancer and even in patients that nominally have the same form of the disease, reflecting the random way in which mutations occur. Nevertheless, many of the same types of genetic lesions are encountered repeatedly, suggesting that there is only a limited number of ways in which our defenses against cancer can be breached.
Figure 24-21. Loss of contact inhibition. Cancer cells, unlike most normal cells, usually continue to grow and pile up on top of one another after they have formed a confluent monolayer.

Table 24-3. Some Changes Commonly Observed When a Normal Tissue-Culture Cell Is Transformed by a Tumor Virus

1. Plasma-membrane-related abnormalities

    A. Enhanced transport of metabolites

    B. Excessive blebbing of plasma membrane

    C. Increased mobility of plasma membrane proteins

2. Adherence abnormalities

    A. Diminished adhesion to surfaces; therefore able to maintain a rounded morphology

    B. Failure of actin filaments to organize into stress fibers

    C. Reduced external coat of fibronectin

    D. High production of plasminogen activator, causing increased

3. Growth and division abnormalities

    A. Growth to an unusually high cell density

    B. Lowered requirement for growth factors

    C. Less anchorage dependence (can grow even without attachment to rigid surface)

    D. 'Immortal' (can continue proliferating indefinitely)

    E. Can cause tumors when injected into susceptible animals
Figure 24-22. Cell transformation by the Rous sarcoma virus. The scanning electron micrographs show cells in culture infected with a form of the Rous sarcoma virus that carries a temperature-sensitive mutation in the gene responsible for transformation (the v-*src* oncogene). (A) The cells are transformed and have an abnormal rounded shape at low temperature (34°C), where the oncogene product is functional. (B) The same cells adhere strongly to the culture dish and thereby regain their normal flattened appearance when the oncogene product is inactivated by a shift to higher temperature (39°C). (Courtesy of G. Steven Martin.)
Figure 24-23. The structure of the Rous sarcoma virus. (A) The organization of the viral genome as compared with that of a more typical retrovirus (murine leukemia virus). Rous sarcoma virus is unusual among the retroviruses that carry oncogenes in that it has retained all the three viral genes required for the ordinary viral life cycle: *gag* (which produces a polyprotein that is cleaved to generate the capsid proteins), *pol* (which produces reverse transcriptase and an enzyme involved in integrating the viral chromosome into the host genome), and *env* (which produces the envelope glycoprotein). In other oncogenic retroviruses one or more of these viral genes are wholly or partly lost in exchange for the acquisition of the transforming oncogene, and therefore infectious particles of the transforming virus can be generated only in a cell that is simultaneously infected with a nondefective, nontransforming *helper virus,* which supplies the missing functions. (Often the transforming oncogene is fused to a residual fragment of *gag,* leading to production of a hybrid oncogenic protein that includes part of the Gag sequence.) (B) The relationship between the v- *src* oncogene and the cellular *src* proto-oncogene from which it has been derived. The introns present in cellular *src* have been spliced out of v- *src;* in addition, v- *src* contains mutations that alter the amino acid sequence of the protein, making it hyperactive and unregulated as a tyrosine-specific protein kinase. Rous sarcoma virus has been highly selected (by cancer research workers) for its ability to transform cells to neoplasia, and it does this with unusual speed and efficiency.

Table 24-4. Some Oncogenes Originally Identified Through Their Presence in Transforming Retroviruses

| Oncogene	Proto-oncogene Function	Source of Virus	Virus-induced Tumor
abl	protein kinase (tyrosine)	mouse cat	pre-B-cell leukemia sarcoma
erb-B	protein kinase (tyrosine): epidermal growth factor (EGF) receptor	chicken	erythroleukemia, fibrosarcoma
fes	protein kinase (tyrosine)	cat/chicken	sarcoma
fms	protein kinase (tyrosine): macrophage colony-stimulating factor (M-CSF) receptor	cat	sarcoma
fos jun	products associate to form AP-1 gene regulatory protein	mouse chicken	osteosarcoma fibrosarcoma
kit	protein kinase (tyrosine): Steel factor receptor	cat	sarcoma
raf	protein kinase (serine/threonine) activated by Ras	chicken/ mouse	sarcoma
myc	gene regulatory protein of the HLH family	chicken	sarcoma; myelocytoma, carcinoma
H-ras	GTP-binding protein	rat	sarcoma; erythroleukemia
K-ras	GTP-binding protein	rat	sarcoma; erythroleukemia
rel	gene regulatory protein related to NFκB	turkey	reticuloendotheliosis
sis	platelet-derived growth factor, B chain	monkey	sarcoma
src	protein kinase (tyrosine)	chicken	sarcoma
Figure 24-24. Insertional mutagenesis. In this example the process activates a gene called *Wnt*-1 (formerly called *int*-1) and produces breast cancer in mice infected with the mouse mammary tumor virus (MMTV). The sites of MMTV integration observed in 19 different tumor isolates are indicated by *arrows*. Note that the insertions can activate transcription of the *Wnt*-1 gene from distances of more than 10,000 nucleotide pairs away and from either side of the gene. This effect is attributed to a powerful enhancer DNA sequence present in the terminal repeats of the MMTV genome.

Table 24-5. Some Oncogenes Originally Identified by Means Other Than Their Presence in Transforming Retroviruses

| Means of Detection	Oncogenes
Insertional mutation	*Wnt*-1 (*int*-1), *fgf*-3 (*int*-2), *Notch*-1 (*int*-3), *lck*
Amplification	L- *myc*, N- *myc*
Transfection	*neu*, N- *ras*, *trk, ret*
Translocation	*bcl*-2, *RARa*

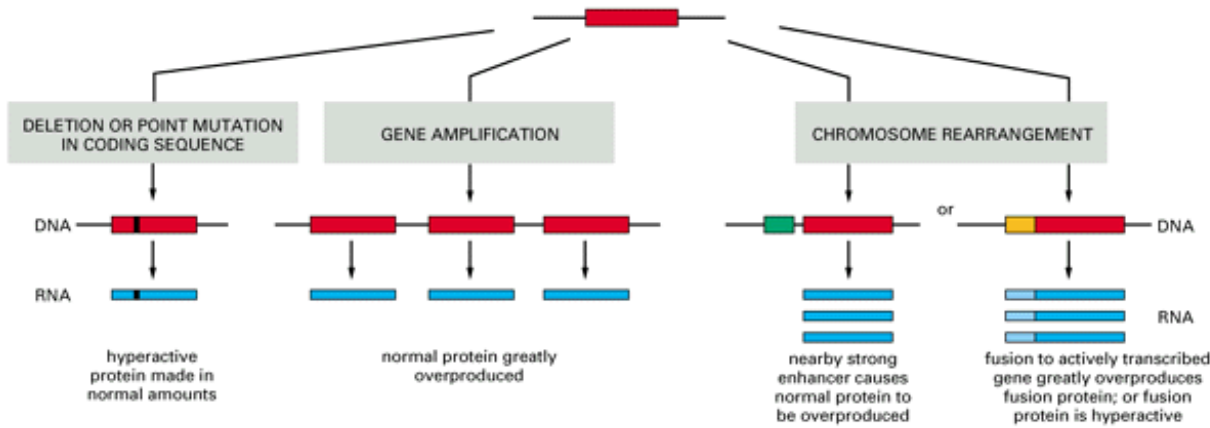
Figure 24-25. The conversion of the *abl* proto-oncogene into an oncogene in patients with chronic myelogenous leukemia. The chromosome translocation responsible joins the *bcr* gene on chromosome 22 to the *abl* gene from chromosome 9, thereby generating a Philadelphia chromosome (see Figure 24-4). The resulting fusion protein has the amino terminus of the Bcr protein joined to the carboxyl terminus of the Abl tyrosine protein kinase. In consequence, the Abl kinase domain presumably becomes inappropriately active, driving excessive proliferation of a clone of hemopoietic cells in the bone marrow.
Figure 24-26. The activities and cellular locations of the products of the main classes of known proto-oncogenes. Some representative proto-oncogenes in each class are indicated in brackets.


Figure 24-27. Three ways in which a proto-oncogene can be converted into an oncogene. A fourth mechanism (not shown) involves recombination between retroviral DNA and a proto-oncogene (see Figure 24-24). This has effects similar to those of chromosome rearrangement, bringing the proto-oncogene under the control of a viral enhancer and/or fusing it to a viral gene that is actively transcribed.

Figure 24-34. How replication of damaged DNA can lead to chromosome abnormalities and gene amplification. The diagram shows one of several possible mechanisms. The process begins with accidental DNA damage in a cell that lacks functional p53 protein. Instead of halting at the p53-dependent checkpoint in the G_1 phase of the division cycle, where a normal cell with damaged DNA would halt until the damage was repaired, the p53-defective cell enters S phase, with the consequences shown. Once a chromosome carrying a duplication and lacking a telomere has been generated, repeated rounds of replication, chromatid fusion, and unequal breakage can increase the number of copies of the duplicated region still further. Selection in favor of cells with increased numbers of copies of a gene in the affected chromosomal region will thus lead to mutants in which the gene is amplified to a high copy number. The multiple copies may eventually become visible as a homogeneously staining region in the chromosome, or they may - either through a recombination event or through unrepaired DNA strand breakage - become excised from their original locus and so appear as independent double minute chromosomes (see Figure 24-2020).
Figure 24-28. Oncogene collaboration in transgenic mice. The graphs show the incidence of tumors in three types of transgenic mice, one carrying a *myc* oncogene, one carrying a *ras* oncogene, and one carrying both oncogenes. For these experiments two lines of transgenic mice were first constructed. One carries an inserted copy of an oncogene created by fusing the proto-oncogene *myc* with the mouse mammary tumor virus promoter/enhancer (which then drives *myc* overexpression in specific tissues such as the mammary gland). The other line carries an inserted copy of the oncogene v-H- *ras* under control of the same promoter/enhancer. Both strains of mice develop tumors much more frequently than normal, most often in the mammary or salivary glands. Mice that carry both oncogenes together were obtained by crossing the two strains. These hybrids develop tumors at a far higher rate still, much greater than the sum of the rates for the two oncogenes separately. Nevertheless, the tumors arise only after a delay and only from a small proportion of the cells in the tissues where the two genes are expressed. Some further accidental change, in addition to the two oncogenes, is apparently required for the development of cancer. (After E. Sinn et al., *Cell* 49:465-475, 1987. © Cell Press.)

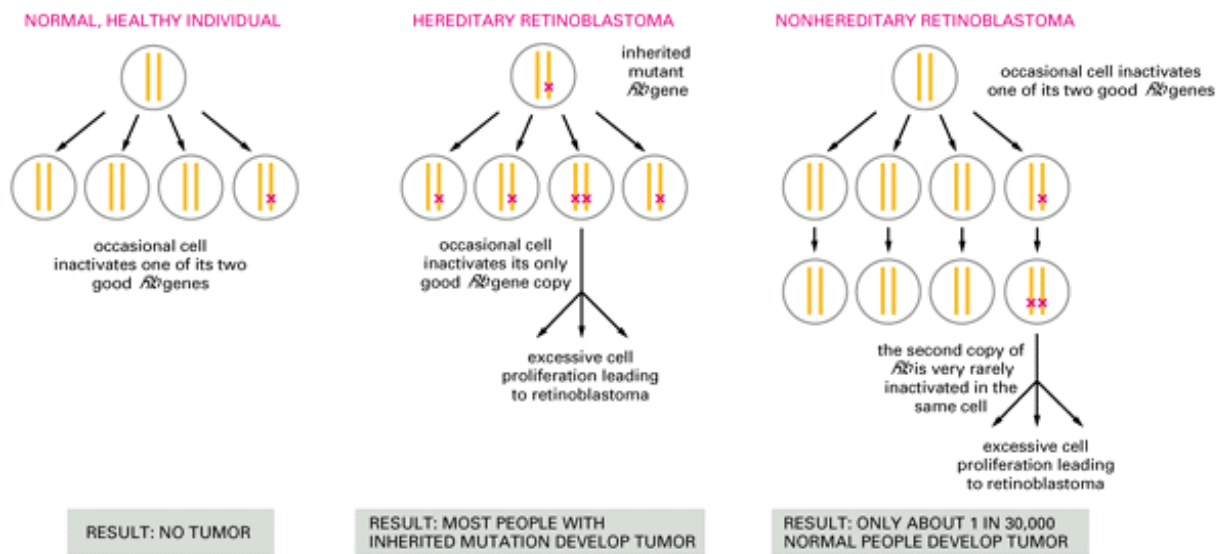

Figure 24-29. The genetic mechanisms underlying retinoblastoma. In the hereditary form all cells in the body lack one of the normal two functional copies of a tumor suppressor gene, and tumors occur where the remaining copy is lost or inactivated by a somatic mutation. In the nonhereditary form all cells initially contain two functional copies of the gene, and the tumor arises because both copies are lost or inactivated through the coincidence of two somatic mutations in one cell.
Figure 24-30. Six ways of losing the remaining good copy of a tumor suppressor gene. A cell that is defective in only one of its two copies of a tumor suppressor gene usually behaves as a normal, healthy cell; the diagrams show how it may come to lose the function of the other gene copy as well and thereby progress toward cancer. Cloned DNA probes can be used in conjunction with restriction-fragment length polymorphisms (see Chapter 7) to analyze the tumor DNA and so to discover which type of event has occurred in a given patient. Note that most of the mechanisms result in a cell that totally lacks either the maternal or the paternal copy of the tumor suppressor gene, along with adjacent chromosomal regions. This is reflected in a *loss of heterozygosity* in the neighborhood of the genetic defect. Loss of heterozygosity at a specific site in the genome is a hallmark of a cancer dependent on loss of the function of a tumor suppressor gene. (After W.K. Cavenee et al., *Nature* 305:779-784, 1983. © 1983 Macmillan Magazines Ltd.)

Table 24-6. Viruses Associated with Human Cancers

Virus	Associated Tumors	Areas of High Incidence
DNA viruses		
Papovavirus family		
Papillomavirus (many distinct strains)	warts (benign)	worldwide
carcinoma of uterine cervix	worldwide	
Hepadnavirus family		
Hepatitis-B virus	liver cancer (hepatocellular carcinoma)	Southeast Asia, tropical Africa
Herpesvirus family		
Epstein-Barr virus	Burkitt's lymphoma (cancer of B lymphocytes)	West Africa, Papua New Guinea
nasopharyngeal carcinoma	Southern China, Greenland (Inuit)	
RNA viruses		
Retrovirus family		
Human T-cell leukemia virus type I (HTLV-I)	adult T-cell leukemia/lymphoma	Japan (Kyushu), West Indies
Human immunodeficiency virus (HIV-1, the AIDS virus)	Kaposi's sarcoma [cancer of endothelial cells of blood vessels or lymphatics (?)]	Central Africa

For all the above viruses, the number of people infected is much larger than the number who develop cancer: the viruses must act in conjunction with other factors. Moreover, some of the viruses probably contribute to cancer only indirectly; for example, HIV-1, by obliterating cell-mediated immune defenses, may allow endothelial cells transformed by some other agent to thrive as a tumor instead of being destroyed by the immune system.

Figure 24-31. The SV40 virus. The structure of the capsid of this widely studied DNA virus that infects monkeys has been determined by x-ray diffraction. (Courtesy of Robert Grant, Stephen Crainic, and James M. Hogle.)

Figure 24-32. How certain papillomaviruses are thought to give rise to cancer of the uterine cervix. Papillomaviruses have double-stranded circular DNA chromosomes of about 8000 nucleotide pairs. In a wart or other benign infection these chromosomes are stably maintained in the basal cells of the epithelium as plasmids whose replication is regulated so as to keep step with the chromosomes of the host (*left*). Rare accidents can cause the integration of a fragment of such a plasmid into a chromosome of the host, altering the environment of the viral genes and disrupting the control of their expression. The consequent unregulated production of viral replication proteins - in particular, the products of the viral E6 and E7 genes - tends to drive the host cell into S phase, thereby helping to generate a cancer (*right*).
Figure 24-33. Activation of cell proliferation by the SV40 DNA tumor virus. SV40 uses a single dual-purpose viral protein, called large T antigen, to sequester both Rb and p53; other related DNA tumor viruses use two separate viral proteins (E6 and E7 in the case of papillomavirus) for the same purpose.

Figure 24-35. Cross-section of an adenomatous polyp from the colon. The polyp protrudes into the lumen of the colon. The rest of the wall of the colon is covered with normal colonic epithelium, forming typical short glands; the epithelium on the polyp appears mildly abnormal, forming longer glands. (Courtesy of Anne Campbell.)

Table 24-7. Permission to reproduce this table in this web version of *Molecular Biology of the Cell* is either pending or has not been granted.
Figure 24-36. Typical sequence of genetic changes underlying the development of a colorectal carcinoma. Note that the loss of *APC, DCC,* or *p53* generally requires two mutations, to eliminate both copies of the gene. Thus the changes shown here correspond to a total of seven mutations. (After E.R. Fearon and B. Vogelstein, *Cell* 61:759-767, 1990.)

Figure 24-37. Each tumor will generally contain a different set of genetic lesions. In this schematic diagram, W, X, Y, and Z denote alterations in as yet undiscovered tumor suppressor genes or oncogenes. Tumors that arise from different tissues are generally more different in their genetic abnormalities than tumors of similar origin.
